However, by using Fig. 6-9 and Fig. 10-13 as guides, there should now be no confusion in recognizing damage cracks in abraded and etched surfaces, particularly when the damaged layer had been almost completely removed; Figure 12 illustrates how clearly the last traces of the damage cracks can be distinguished. A simple yet reliable method of estimating the depth of damage can be based on this technique, the approximate depth removed when the last traces of the damage cracks disappear being estimated by the weight-loss method. The results obtained by this technique have been compared in a number of instances with those obtained by the original taper-sectioning technique (1), and in all cases the agreement was good. For example, the series illustrated in Fig. 10-13 for abrasion with 220-grade silicon carbide slurry indicated a depth of damage of 88μ. the value determined by taper sectioning was 85μ (1).

Cellular structure.—The cellular structure developed in the areas between the cracks; the cell diameter increased with increased etching (Fig. 6-9 and

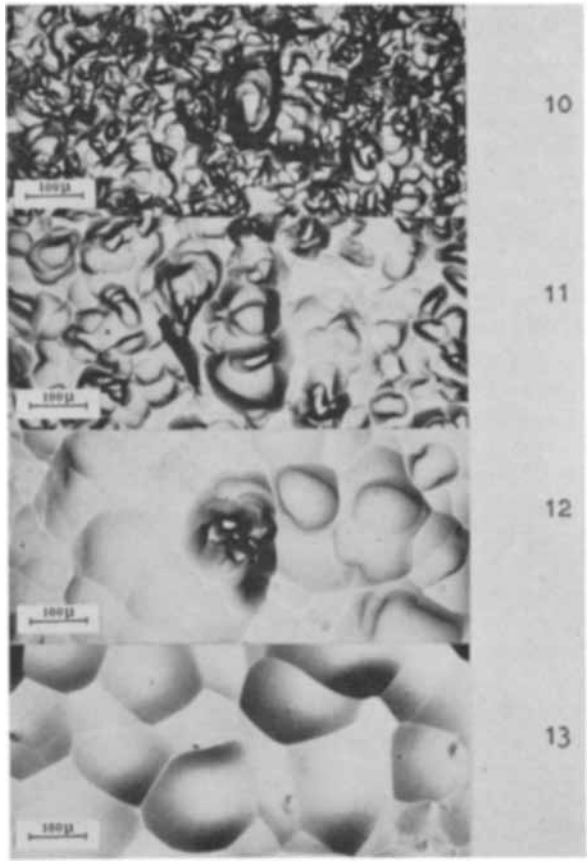

Fig. 10-13. Germanium surface abraded with 220-grade silicon carbide slurry and etched with CP-4 reagent.

10-13) and was still prominent when the damaged layer had been removed completely (Fig. 9 and 13). Under otherwise comparable conditions, the cell diameter was smaller the finer the abraded finish; indeed, it did not develop at all if the surfaces were initially quite flat, as after complete metallographic polishing. Correlation with the taper sections (*e.g.*, Fig. 5) indicated that each "cell" consisted of a dish-shaped depression bounded by a comparatively sharp rim.

This structure is the so-called "first-order" network reported by Chang (4). The present observations confirm the findings of Noggle and Stiegler (5) that it results not from any substructure in the crystal itself but rather from the mechanical preparation of the surface. The cleavage pits in the original abraded surface are smoothed out into a series of dish-shaped depressions during etching. Some depressions then grow at the expense of the others, at the same time becoming progressively shallower. The pattern is no longer detectable when a layer some five times deeper than the damaged layer has been removed. Noggle and Stiegler (5) used the disappearance of the cellular pattern as a criterion for the complete removal of the damage, but the present observations indicate that there is no real relationship between the two.

Some confusion has resulted from the fact that Bonfiglioli *et al.* (6) have also used the term first-order network to describe a similar but much less pronounced cellular pattern produced by the etching of grown-in dislocations, which is considered in the following section. Both patterns result from the mechanism by which the CP-4 reagent smooths out depressions in the surface, but clearly different terms should be used for the two cases.

Dislocation etch pits.—During the formation of the cellular structure, classical dislocation etch pits of the type described by Pfann and Vogel (7) were also observed (several are present in the field shown in Fig. 9). The type of cellular pattern described by Bonfiglioli (6) developed when these dislocation etch pits were suitably grouped, but this pattern could always be distinguished from that due to the cleavage pits.

The density of the dislocation etch pits was about $10^8/cm^2$, which is of the order to be expected for grown-in dislocations. Faust (3) has reported observing dislocation etch pit densities as high as $10^6/cm^2$ in the damaged layer in a similar type of experiment. It is possible that Faust mistook an early development of the first-order network for dislocation etch pits, but this cannot be confirmed from his published micrograph.

Comparison between the Metallographic and Other Methods of Estimating the Depth of Damage

The earlier work (1) showed a considerable discrepancy between the results of the metallographic taper-sectioning method of estimating the depth of damage and the method based on the photomagnetoelectric (PME) effect developed by Buck and McKim (2). The metallographic method gave consistently higher results. The principle of the PME and most earlier methods of estimating the depth of damage is to remove successive layers from the damaged surface by etching and to determine some relevant property of the surface at each stage. The damaged layer is assumed to have been removed completely when this property reaches a constant base level, and the depth removed at that stage is estimated from the weight lost from a known area of surface.

The first possibility in accounting for the discrepancies between the two general methods is that the weight-loss method of depth measurement is unreliable because of the irregular topography of these surfaces. It was to check this point that the weight-loss method was compared with the metallographic method described above. The latter method indicated that the etched surfaces were irregular on a macro scale when the damaged layer was almost completely removed and frequently were not exactly parallel to the original surface. These irregularities develop mainly as a result of the general unevenness in the depth of the damaged layer itself and from the penetration of the etchant along the damage cracks. Consequently, this metallographic method of measuring the depth removed during etching, which measures a local depth, yielded a range of values which lay on both sides of the value given by the weight-loss method. This suggests that the latter is reliable in estimating the average value of the depth removed, although the exact significance of this figure is debatable. The early stages of etching, when the etchant penetrated along the cracks, are exceptional. The weight-loss method then grossly overestimates the depth removed, but this is not significant in the present context.

The original taper-section method of estimating the depth of damage (1) measures the maximum local depth from the crests of the surface irregularities to the extremities of the deepest cracks. This is necessarily greater than the average value determined by any of the methods depending on weight-loss measurements. It is doubtful, however, whether this would account for more than a small portion of the discrepancy between the two methods. The explanation must be sought in the characteristics of the methods used to detect the damage, and the present work does throw some light on two of the more important of these, namely, the PME method (2) and the etching rate method (8, 9).

The PME method determines the balance between the production of carrier pairs by the illumination of the surface and the recombination of these pairs in the damaged layer. The surfaces of the cracks now known to be present in the damaged layer provide extensive surfaces on which recombination can occur, and the forest of cracks must be a very efficient trap for the drifting carriers. The PME voltage consequently is initially very low. When the surface layers are removed by etching, the area of the recombination surface is reduced as also is the depth of the trap, so the PME voltage rises. However, the cracks are also opened out and, at some stage, the illumination may become incident on their sides and bases, in which event these surfaces now become

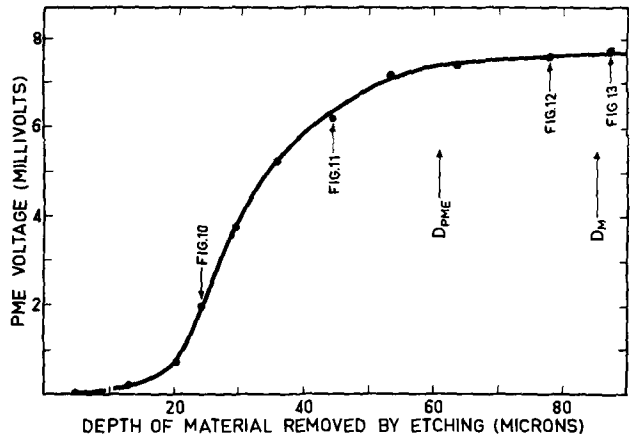

Fig. 14. Change of open-circuit PME voltage with etching, after abrasion on 220-grade silicon carbide slurry. D_{PME} and D_M indicate the depth of damage estimated from this curve and by the metallographic taper-sectioning technique (1), respectively. The arrows labelled Fig. 10-13 indicate the surfaces for which the micrographs shown in Fig. 10-13, respectively, are representative.

sources of carrier pairs. It seemed probable, therefore, that the PME voltage would reach a constant value before the original damaged layer had been removed completely.

To confirm this, a specimen used for the determination of the depth of damage by the PME method was examined microscopically at each successive stage in the etching process. The resulting PME curve is shown in Fig. 14, and representative fields of the surface at various stages are illustrated in Fig. 10-13. It can be seen that cracks are still visible in Fig. 12 although the PME curve indicated that all the damage had been removed at this stage. The stage at which all the cracks had actually been removed, as shown by microscopic examination (Fig. 13), is indicated in Fig. 14. It can be concluded that the original metallographic method (1) is more reliable in measuring the full extent of the crack-containing layer. However, it may be argued that the value determined by the PME method is adequate for practical purposes, since the residual crevices would not be expected to affect the electrical properties of the material significantly.

The etching rate method of measuring the depth of damage depends on the fact that the dissolution rate of abraded surfaces is initially very high and decreases as material is progressively removed until a constant rate is reached; the depth removed at the latter stage is taken as the depth of damage. Camp (8) attributed the increased etching rate merely to increased surface area, but Faust (10) has suggested that a high dislocation density in the damaged layer also contributes. It is now apparent that the damaged layer does not contain high densities of dislocations (1), so that the increase in etching rate must be attributed entirely to increase in surface area; the results described above leave little doubt that this factor can adequately account for an initially high dissolution rate of an abraded surface. On this basis, the etching rate should reach an approximately constant value when the surface area reaches an approximately constant value. Although a quantitative assessment has not been made of this factor, the observations made in the course of the present work clearly suggest that this stage would be reached before the original damaged layer had been removed completely.

Summary

The CP-4 reagent penetrates the damage cracks in abraded surfaces, opening them into deep crevices. At the same time, cleavage pits in the regions between the cracks are smoothed into dish-shaped depressions which, on further etching, result in the formation of a cellular structure. This structure persists for etching times considerably longer than those required to remove the damage cracks. The reagent also produces dislocation etch pits in the surface, but these are solely due to dislocations produced during growth of the crystal.

The complex manner in which the crack-containing layer is removed by CP-4 reagent introduces uncertainties into the measurement of its depth by methods involving changes in some surface property as the damaged layer is removed by etching. It is suggested that metallographic methods of measuring the depth of damage are the more reliable. The metallographic taper-sectioning technique is probably the most precise method, but a simpler approximate method adequate for many purposes would be to examine the surface microscopically after removal of successive layers by etching with the CP-4 reagent. The damage cracks can be recognized in the etched surface and the stage at which they have been completely removed can be determined, the approximate average depth removed by etching then being estimated by the weight-loss method. This microscopic method of examining etched surfaces to determine whether damage cracks have been removed could also be used in production control.

The Electrochemistry of V_2O_5 in LiCl-KCl Eutectic Melt

H. A. Laitinen and D. R. Rhodes[1]

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

The electrochemistry of V_2O_5 in an LiCl-KCl eutectic melt has been investigated with the aid of several electroanalytical techniques. Independent measurements with voltammetry, chronopotentiometry, and constant current electrolysis indicate that V_2O_5 is reduced to a mixed lithium vanadium oxide (lithium vanadium bronze) on the electrode surface at a potential which is a function of V_2O_5 concentration. Lithium vanadates of limited solubility are also formed during the reduction. Lithium vanadium bronzes which were obtained by the thermal decomposition of Li_2CO_3 and V_2O_5 do not agree in chemical and x-ray analysis with those obtained by the electrochemical reduction of V_2O_5.

Although numerous papers have been published concerning the electrochemistry of metal chlorides in molten alkali metal chloride systems, relatively few investigations have been made of the electrochemistry of complex metal oxide systems in these solvents. In general, the electrochemical techniques which have been developed for simple metal ions should be useful for the study of complex metal oxide systems.

Vanadium (V) oxide in LiCl-KCl eutectic melt represents a complex system in which electrochemical and acid-base properties are interrelated. This system is of practical interest because of its use as a cathode in high-temperature batteries (1). Because V_2O_5 should act as a relatively strong acid in this solvent, the oxidizing strength of vanadium (V) will be a function of the basicity of the melt. The addition of electrons to V_2O_5 might be expected to cause the release of oxide ions which will react with V_2O_5 to form anionic species of vanadium (V).

The chemistry and electrochemistry of vanadium in molten salt systems has been partially studied by several groups. The standard potentials of V(II)/V(O) and V(III)/V(II) in an LiCl-KCl eutectic melt have been determined (2). Molina (3) has described the absorption spectra of V(II), V(III), VO^{+2}, and V_2O_5 and gave a detailed discussion of the effect of adding oxide ion and acidic species to a V_2O_5 solution in an LiCl-KCl eutectic melt. Van Norman and Osteryoung (4) found that metavanadate in an LiCl-KCl eutectic melt reacted with an excess Na_2CO_3 to form orthovanadate as determined from the evolution of CO_2.

Massive electrolysis of V_2O_5 in molten magnesium or lithium borates gave spinels of the formula, $MgO:V_2O_3$ or $Li_2O:2V_2O_3$ (5). Electrolysis of V_2O_5 in molten $AlBr_3$-KBr (6) yielded a deposit of VO_2 on the cathode, but electrolysis of V_2O_5 in $AlCl_3$-KCl gave no deposit. The electrolytic reduction of V_2O_5 in alkali phosphate melts gave, in general, VP in weakly alkaline melts, V_2O_3 in strongly alkaline melts in the presence of chloride, and VO in strongly alkaline melts in the absence of chloride (7, 8).

[1] Present address: California Research Corporation, Richmond, California.

Voltammetry, chronopotentiometry, potentiometry, and coulometry were used in this investigation to study the electrochemistry of V_2O_5 in an LiCl-KCl eutectic melt solution. These methods have been shown to be useful techniques to study molten salt systems (9).

Experimental

A eutectic mixture of 41 mole % KCl and 59 mole % LiCl (melting point 352°C) at a temperature of 450°C was used as the solvent system for these investigations. The method employed in the preparation of the solvent has been described in detail elsewhere (10). The purity of the melt was tested by taking residual current-voltage curves of the melt with a platinum microelectrode (0.8 mm^2 in area). Up to a potential of −2.0v *vs.* Pt(II) (1M)/Pt reference the residual current was of the order of 1μa.

The fused salt cell and related equipment was similar to that described previously (10). All electrodes and solutions were separated into compartments by means of fritted glass sealing tubes.

The reference electrode for this system was a platinum foil in contact with a Pt(II)-melt solution. This electrode is stable, reproducible, and nonpolarizable in the eutectic melt at 450°C (11). Unless otherwise noted, all potentials are given with reference to a Pt(II) (1M)/Pt electrode, which is defined as an arbitrary reference point of zero. The IUPAC sign convention (polarity refers to charge of metal phase for reduction half-reaction) is used.

Several types of indicator electrodes were used in this investigation. Platinum microelectrodes were prepared by sealing the appropriate gauge wire into a glass bead of Corning 010 G-164-EC glass and by sealing this glass bead to a 5 mm tube of lead glass (Corning 0120). The tip of the bead was ground to a flat surface with emery paper to expose a cross section of platinum wire and was then polished to a smooth surface with 4/0 emery paper.

Gold-plated microelectrodes were prepared by electrolyzing the appropriate gauge platinum microelectrode as a cathode in an aqueous gold-cyanide bath buffered with Na_2HPO_4 (12). A smooth gold plate, which was stable in the eutectic melt, could

be obtained by using a current density of 1-5 ma/cm² in a bath at 70°C. Residual current curves with gold microelectrodes in LiCl-KCl eutectic melt were similar to those obtained with platinum microelectrodes except for a positive shift of the anodic limit of about 0.1v.

Because platinum and, to a lesser extent, gold are oxidized by V_2O_5-melt solutions, a nonporous indicator electrode which was stable in a V_2O_5-eutectic melt solution was needed. Spectroscopic graphite rods gave ill-defined potentials because of their porosity. Recently, a special form of graphite called Pyrographite (13) or Pyrolytic Carbon (14) has been developed. This is a polycrystalline form of graphitic carbon, impervious to gases and liquids (13), which has been deposited from a carbonaceous vapor on a graphite substrate at temperatures above 2000°C.

The Pyrographite electrode (15) used as an indicator electrode consisted of a Pyrographite coating, 6-11 mils thick, on a ¼-in. graphite rod. The rod was threaded and attached to a ⅜-in. by 12-in. graphite rod. The surface of the electrode under 80 times magnification with a Leitz microscope had the appearance of a "blistered paint surface."

Where necessary, a ⅛-in. spectroscopic graphite rod, which had been previously cleaned in HCl and dried with heat under vacuum, was used as a counter or working electrode.

Potential measurements were made with several types of instruments. An adapted L&N student potentiometer with a sensitivity of 13 μv was used for high sensitivity and accuracy. For measurement of potential as a function of time, a MR Sargent Recorder or Tektronix, Type 502, oscilloscope was used. According to the instruction manual, the recorder is accurate to 0.1% or 20 μv, whichever is greater. The oscilloscope voltage scale and sweep rate are accurate to within 3% of full-scale deflection.

Current-voltage curves were obtained with either a L&N Electrochemograph, Type E, or a Sargent, Model XV, polarograph.

For chronopotentiometric measurements, an apparatus was constructed which was similar to that used by Laitinen and Gaur (15, 16). The potential of the indicator electrode during the transition time *vs.* a platinum reference electrode was followed with an oscilloscope and recorded on 35-mm Kodak Plus-X film. The measurements were made from 4-in. by 5-in. enlargements. A large Pyrographite electrode (1.2 cm²), a ⅛-in. spectroscopic graphite rod, and a Pt(II)/Pt electrode were used as the indicator, counter, and reference electrodes, respectively.

Constant current for coulometry was obtained from two sources. A Sargent coulometric current source, Model IV, provided an accurate and constant supply of current. When this was not available, current was obtained from a constant current-voltage source through a high resistance in the usual manner. The procedure for coulometry was to pass a constant current between the indicator electrode and a counter electrode in separate compartments and to measure the potential of the indicator electrode *vs.* a reference electrode as a function of time with a Sargent MR recorder. During electrolysis, the solution was stirred with a long glass rod connected to a stirring motor above the melt.

The solubility of V_2O_5 in an LiCl-KCl eutectic melt is unlimited. At higher concentrations, however, V_2O_5 reacts with the melt to form Cl_2 and some type of insoluble reduced vanadium compound (17). Since large additions of V_2O_5 to the melt would result in large localized concentrations, only small additions of V_2O_5 were made, and the solution was vigorously stirred to prevent any reactions.

Results and Discussion

Synthetic lithium vanadium oxides.—There exists some confusion in the literature concerning anionic species of vanadium oxides and their solubilities in LiCl-KCl eutectic melt. Molina (3) concluded that metavanadate ion is soluble and that orthovanadate is insoluble. Van Norman and Osteryoung (4) did not report the formation of any insoluble vanadates when they added Li_2CO_3 to metavanadate-eutectic melt solutions. Observations made in this laboratory indicate that several lithium vanadate species have limited solubilities. Attempts were made to measure their solubilities, but only qualitative results could be obtained.

Because the electrochemical reduction of V_2O_5 involves the formation of a mixed lithium vanadium oxide (lithium vanadium bronze), several attempts were made to prepare bronzes by thermal decomposition of Li_2CO_3 and V_2O_5 mixtures.

In a typical preparation, these substances in molar ratio of one were heated to the molten state in a platinum crucible. The molten mixture was left open to air for several hours and then slowly cooled. While the melt was cooling, dark blue-black crystals formed; but when the frozen mass was ground up for analysis, a brown phase was also observed to be present. The brown phase was removed by boiling the mixture in aqueous ammonia solution. The remaining blue-green precipitate was filtered, dried, and analyzed. Chemical analysis of two mixtures gave a stoichiometry of 2.6 ± 0.2 Li_2O:V_2O_4:4.8 ± 0.4 V_2O_5. The similarity between the x-ray powder diffraction patterns for the two mixtures is shown in Table I.

Chemical analysis of the thermally prepared bronzes does not fit the results of other authors. Flood and co-workers (18) prepared a number of

bronzes by heating various ratios of Li_2CO_3 and V_2O_5. Ozerov (19) obtained a different bronze, 1.1 $Li_2O:V_2O_4:2.6$ V_2O_5, noting that the stoichiometry varied significantly with the experimental technique.

Voltammetry of $NaVO_3$ *and* V_2O_5.—In order to examine the course of the reaction involved in the reduction of V_2O_5, current-voltage curves of $NaVO_3$ and V_2O_5 solutions were obtained. A typical C-V curve of Na_2VO_3 taken with a Pt microelectrode in the forward or negative direction of polarization is shown in Fig. 1. The reproducibility of these curves was not good.

A definite reduction wave can be observed at —0.9v. The reverse C-V curve indicates the oxidation of a deposit on the electrode surface at a potential corresponding to the first reduction wave.

Above a concentration of about 10 mM $NaVO_3$, a light-tan colored precipitate was formed. However, the cathodic current still increased with each addition of $NaVO_3$. This would indicate that metavanadate equilibrates in solution to form orthovanadate and polyvanadate(s), some of which are insoluble in the melt.

The same general shape of current-voltage curves was obtained for V_2O_5 with a gold microelectrode except for the presence of a wave at more positive potential (—0.4v) for V_2O_5 (Fig. 2). This wave had poor shape and a rather diffuse limiting current region. This could have been caused by the slow oxidation of the gold microelectrode by V_2O_5. Current was roughly proportional to concentration, but meaningful measurements of current were difficult because of the formation of insoluble products with rapid changing surface area on the electrode surface.

Chronopotentiometry of V_2O_5.—In recent years much attention has been given to chronopotentiometry as a tool in elucidating reaction mechanisms for electrochemical reactions. Using a variety of boundary conditions, mathematic expressions have been derived for various reaction mechanisms (20). These have been recently summarized and extended by Reinmuth and co-workers (21-24).

Potential-time curves for chronopotentiometry of V_2O_5 melt solutions were obtained by applying a constant current between an indicator electrode and a counter electrode and by measuring the potential of the indicator electrode *vs.* a reference electrode as a function of time.

"Blank" chronopotentiograms of the melt with a large Pyrographite indicator electrode (1.2 cm^2) at a current of 500 μa indicated a short residual transition time of approximately 0.5 sec at —1.4v. Since these experiments involve transition times at more positive potentials, the results were not affected.

A typical chronopotentiogram of V_2O_5 with an applied current of 500 μa is shown in Fig. 3 with cathodic current and then with reversal of current at —0.7v for observation of the reverse process. A chronopotentiogram at higher current (800 μa) is shown in Fig. 4. No transition time was observed for the reduction at —0.94v even with a current of 1000 μa and over a period of 20 sec. The transition waves occur at about the same potential as the polarographic waves obtained from the voltammetry of V_2O_5.

Anodic chronopotentiometric curves are also shown in Fig. 3 and 4. For the ideal case of a reversible reduction to a soluble species followed by a reversible reoxidation, the ratio of the transition time for the cathodic wave to the transition time for the anodic wave is 3:1. If an insoluble species is formed, the ratio should be 1:1. If the reduction is reversible and the solution resistance is small, the $E_{1/4}$ for the cathodic wave should equal the $E_{1/4}$ for the anodic wave for either an insoluble or soluble species.

For the trace in Fig. 3, the current was reversed at what seemed to be the inflection point after the first transition time (about —0.7v). In Fig. 4, the cur-

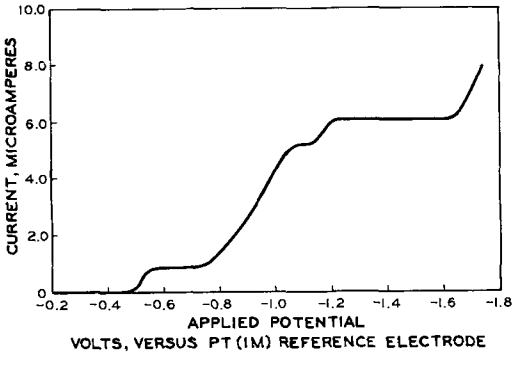

Fig. 2. Current-voltage curve of 8 mM V_2O_5 in LiCl-KCl eutectic melt at 450°C with a gold-plated Pt microelectrode, 0.8 mm^2 in area.

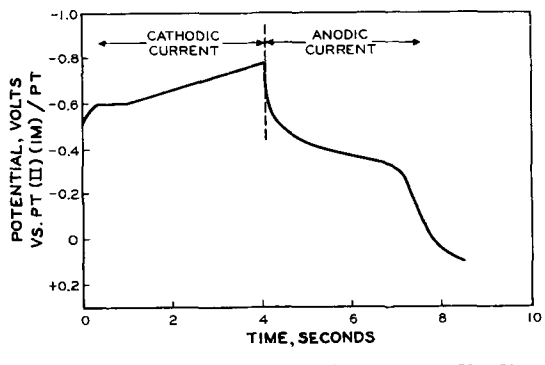

Fig. 3. Chronopotentiogram of 2.1 mM V_2O_5 in LiCl-KCl eutectic melt at 450°C with a Pyrographite indicator electrode. Area = 1.2 cm^2, current = 500 μa.

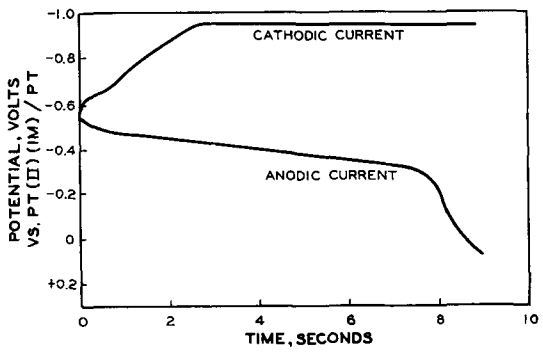

Fig. 4. Chronopotentiogram of 2.1 mM V_2O_5 in LiCl-KCl eutectic melt at 450°C with a Pyrographite indicator electrode. Area = 1.2 cm^2, current = 800 μa.

rent was reversed after the trace had reached the side of the oscilloscope (about —0.95v). In each case, the total time required for reduction and the transition time of reoxidation were about equal. These facts indicate the formation of one or more insoluble products for the reduction at —0.64v and at —0.94v. The reoxidation potential is the same for the reduction at —0.64v and —0.94v.

The results for different concentrations of V_2O_5 and currents are given in Table II. Because of the poorly defined character of the transition time curve, there was an error of measurement of ±5%.

For a semi-infinite linear diffusion controlled process, the following equation may be given:

$$\frac{\tau^{1/2} i}{C} = \frac{n \mathbf{F} A D^{1/2} \pi^{1/2}}{2} \qquad [1]$$

where i is the current (amp) applied to an electrode of area, A (cm^2), τ is the transition time (sec), C is the concentration of V_2O_5 (moles cm^{-3}), D is the diffusion coefficient (cm^2 sec^{-1}), and n, $\mathbf{F}$, and π have their usual significance. The left hand term in this equation, the transition time constant, should be independent of current or concentration for a simple reversible, linear diffusion controlled process. This constant has been calculated and is given in Table II. It seems to increase slightly with an increase in current or concentration, but the measurement error is too large for any definite conclusions.

Because a solid product is formed on the electrode during the first transition, the $E_{1/4}$ of the wave will be a function of the logarithm of V_2O_5 concentration.

$$\frac{dE_{1/4}}{d \ln C} = \frac{RT}{n\mathbf{F}} \qquad [2]$$

This equation can be used to calculate n without having to assume an electrode area and a diffusion coefficient for V_2O_5.

Table II. Chronopotentiometry of V_2O_5 Pyrographite indicator electrode, apparent geometric area = 1.24 cm^2

$[V_2O_5]$, moles/liter	I, $\mu a/cm^2$	$\tau^{1/2}$, $sec^{1/2}$	$\tau^{1/2}I/[V_2O_5]$, amp $sec^{1/2}$ / mole/cm	$E_{1/4}$, v
2.12×10^{-3}	403	0.73 ± 0.05	0.14 ± 0.01	—0.64
2.12×10^{-3}	323	0.79 ± 0.08	0.12 ± 0.01	—0.62
5.16×10^{-3}	968	0.87	0.16	—0.54
5.16×10^{-3}	1210	0.63 ± 0.04	0.16 ± 0.01	—0.52

For concentrations of 2×10^{-3}M V_2O_5 and 5×10^{-3}M V_2O_5, the observed $E_{1/4}$ potentials were —0.63 ± 0.01 and —0.54 ± 0.01v, respectively. By substitution into Eq. [2], n was calculated to be 0.6. Because there was a measurement error of about 20 mv, n fell within the range 0.5-0.7.

From this value of n and assuming that the electrode area was the apparent geometric area (1.2 cm^2), the diffusion coefficient for V_2O_5 was estimated to be 0.8×10^{-5} cm^2/sec.

For more precise chronopotentiometric results, a greater range of current and concentration should be used. However, several factors severely limit the range that can be investigated. Most important is the large area of the Pyrographite electrode; relatively large currents must be used for small concentrations of V_2O_5. Because of convection effects at these high temperatures, the transition time must be kept below 2 sec (16). These and other factors limited the concentration range of V_2O_5 to about 1×10^{-3}M to 6×10^{-3}M V_2O_5.

The following conclusions can be made from the above chronopotentiometric data: two steps, which are similar to those obtained with voltammetry, occur in the reduction of V_2O_5. Although rather poor in definition, the transition time of the first step may be determined. An insoluble product is reversibly formed on the electrode surface. The number of electrons per V_2O_5 is 0.6 ± 0.1. Therefore, the ratio of V_2O_4:V_2O_5 in the insoluble reduction product which forms on the electrode surface is probably within the limits of 1:2 to 1:3.

Coulometry of V_2O_5.—The most satisfactory method to substantiate the results obtained with voltammetry and chronopotentiometry is the coulometric reduction of V_2O_5 in LiCl-KCl. A constant current was applied between a Pyrographite cathode and a working anode which were in separate compartments. The potential of the cathode *vs.* a Pt(II)/Pt reference electrode was followed during the period of electrolysis. Because the current density was kept small and the solution was stirred, the only reduction process taking place should have been that with the most positive reduction potential. Since the potentials of the first and second reduction processes of V_2O_5 were known from chronopotentiometry and voltammetry, it was possible to follow the potential during electrolysis and to determine when the first process was completed. An estimation of the number of coulombs to the first potential break gave the number of electrons involved in the reduction. Analysis of the product formed on the electrode helped to characterize it.

At a current density of 10 ma/cm^2, two types of insoluble products formed in the V_2O_5 solution. Dark blue-green needles adhered to the surface of the electrode; a light tan precipitate, which was qualitatively identified as a lithium polyvanadate, was present in the bulk of the solution.

After 20% of the total number of coulombs needed to reduce V(V) to V(IV) had been passed, the electrolysis of the V_2O_5 solution was stopped, and the electrode and product were removed from the melt. The potential, which at the beginning of the elec-

Table III. X-ray diffraction data of $Li_2O \cdot 2V_2O_5 \cdot 4V_2O_5$ CuKα Source

2.79	25	1.52	10

trolysis was +0.27v *vs.* Pt(II) (1M)/Pt reference, slowly decreased to +0.18v at the end.

The dark blue-green product was boiled in water to remove all chlorides and water-soluble vanadates. After the sample had been dried, an x-ray powder diffraction pattern was obtained. The product was then boiled in 0.1M K_2CO_3 solution to remove V_2O_5 and less soluble vanadates and another x-ray pattern obtained (Table III). There was no significant difference between the two patterns.

The x-ray powder diffraction patterns did not resemble those of any known compound or compounds. The d-spacings did not compare with those obtained from the product of thermal decomposition of Li_2CO_3 and V_2O_5. The electrolysis experiment using the Pyrographite electrode was repeated; the x-ray patterns which were obtained were reproducible.

The product after being weighed was dissolved in 1M H_2SO_4 to analyze for Li^+, V(V), and V(IV). Lithium was determined by flame photometry, and V(V) and V(IV) were determined by addition of an excess of Ce(IV) and back-titrating with Fe(II) using a potentiometric end point determination.

Chemical analysis of the product gave a stoichiometry of $0.5Li_2O \cdot V_2O_4 \cdot 1.9V_2O_5$ suggesting the compound $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$. This does not agree with a stoichiometry of $2.6Li_2O \cdot V_2O_4 \cdot 4.8V_2O_5$ obtained for the thermally prepared product.

A similar type of experiment was repeated, except in this case the electrolysis was continued until after a large change in potential of the Pyrographite electrode had taken place. The potential of the Pyrographite electrode *vs.* a Pt(II)/Pt reference electrode was followed with a Sargent MR recorder. At periodic intervals the electrolysis was stopped, and the steady-state potential was measured.

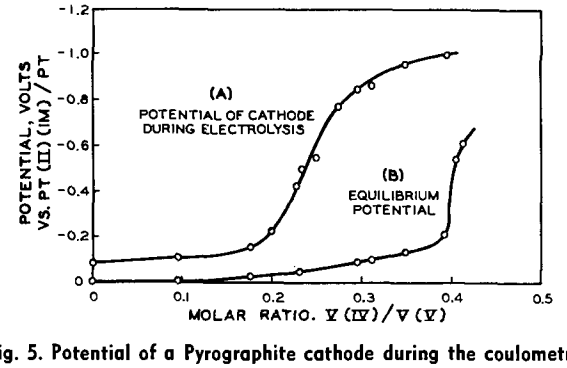

Fig. 5. Potential of a Pyrographite cathode during the coulometric reduction of V_2O_5 in LiCl-KCl eutectic melt at 450°C with a constant current density of 10 ma cm^{-2}.

The results are shown in Fig. 5. The potential of the Pyrographite electrode has been plotted as a function of the molar ratio of vanadium (IV) formed to vanadium (V) originally present in solution. These values were calculated on the basis of 100% current efficiency. The potential for curve A was obtained during electrolysis. If stirring of the V_2O_5-melt solution was sufficiently rapid to make the diffusion layer very thin, the rapid rise to more negative potentials may be taken as the point where V_2O_5 approaches extremely small concentrations. The inflection point of this curve occurs at about 0.25, corresponding to 25% of the total number of coulombs necessary to reduce vanadium (V) to (IV). The number, 0.25, corresponds to a value of 0.50 for the number of electrons needed for the reduction of a molecule of V_2O_5 in agreement with the chronopotentiometric value of 0.6 ± 0.1. Since the stoichiometry of the product which is formed on the electrode is $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$ corresponding to 0.67 electrons per V_2O_5 molecule, the indication is that $2V_2O_5$ are involved in acid-base reactions.

Curve B in Fig. 5 was obtained by stopping the electrolysis at periodic intervals and allowing the potential to come to a steady-state value. After stopping or starting electrolysis, the potential would rapidly reach steady-state conditions in 1-5 min. This equilibrium potential showed a break at 0.4 V(IV)/V(V).

Potentiometry of V_2O_5.—The number of electrons needed per V_2O_5 (n) in the most positive reduction step of V_2O_5 in molten LiCl-KCl eutectic was determined, as discussed above, with chronopotentiometry using a form of the Nernst equation. This value was obtained in a dynamic situation with an electrode of rapidly changing surface area and with a diffusion layer of uncertain composition. In this section the determination of n from the Nernst equation using equilibrium conditions is discussed.

From the results in the preceding sections, the reduction of V_2O_5 at a potential of about −0.4v *vs.* a Pt(II) (1M)/Pt reference electrode may be written as follows:

$$6V_2O_5 + 2Li^+ + 4e \longrightarrow \underline{Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5} + O^{-2}$$

The Nernst equation for this reaction may be given as

$$E = E^\circ + \frac{RT}{4F} \ln \frac{[V_2O_5]^6\,[Li^+]^2}{[O^{-2}]\ (\text{Solid})}$$

Because Li^+ has a constant activity in the solvent, the $[Li^+]$ term can be considered a constant and can be included in the E° term. Oxide ion will combine with V_2O_5 in acid-base reactions to form some type of vanadate ion. The particular species formed will depend on the relative concentrations of V_2O_5 and O^{-2}. If a sufficient amount of vanadate ion is present, lithium vanadate will precipitate out of solution. Because little is known at present concerning the complex equilibria between V_2O_5 and oxide ion in a LiCl-KCl eutectic melt, a complete solution of the Nernst equation is impossible at this time.

The solid lithium vanadate bronze in the Nernst equation is a semiconductor. Little is known about electromotive force properties of such a film in this

type of solvent. In this study, the solid has been assumed to act as a pure solid with an invariant thermodynamic activity. However, it is possible that the activity of this product is not constant and that its thermodynamic properties are a function of the concentration of V_2O_5 or base.

Several types of experiments were used to investigate the potentiometry of V_2O_5. In all cases, a coating of lithium vanadium bronze was formed on the electrode by partial reduction of a V_2O_5-melt solution. V_2O_5 was added to the melt in small known amounts, and the potential of the lithium vanadate bronze covered electrode *vs.* a Pt(II)/Pt reference electrode was determined with a potentiometer or Sargent MR recorder. Normally, stable potentials were obtained in 5 min.

Both gold and Pyrographite were used as a support for the bronze. In one type of experiment, potential measurements were made as a function of V_2O_5 concentration in the same compartment in which the bronze was prepared (Fig. 6, curve A). This meant that a small amount of vanadate ion existed in the solution. Curve B in Fig. 6 is a representative curve of potential as a function of log $[V_2O_5]$ for an electrode which had been covered with bronze in a separate compartment.

With a Nernst constant equal to 0.143 at 450°C, the slope of both of these curves gave a value of n equal to 0.85. The difference between the two curves on the potential axis is 0.02v.

The potential of a lithium vanadium bronze electrode was also measured as a function of the amount of K_2CO_3 added to a V_2O_5-melt solution. The procedure was to add K_2CO_3 in small amounts to a V_2O_5 solution and to measure the potential of the indicator electrode after attainment of steady-state potentials.

With each addition of K_2CO_3, CO_2 was given off and the solution became less intense in color. A light-tan precipitate formed in the solution throughout most of the titration. In Fig. 7 is shown a plot of potential of the bronze-covered electrode *vs.* the molar ratio of K_2CO_3 added to V_2O_5 originally present in solution. This plot has the general shape of a potentiometric titration curve with the inflection point occurring at a molar ratio of about one. However, the slope of the curve at the inflection

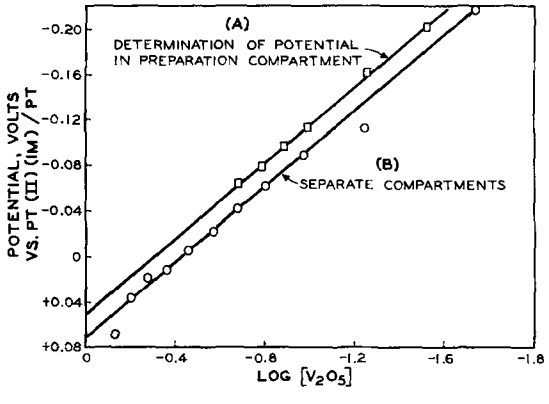

Fig. 6. Potential of $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$ covered Pyrographite electrode as a function of V_2O_5 concentration in LiCl-KCl eutectic melt at 450°C.

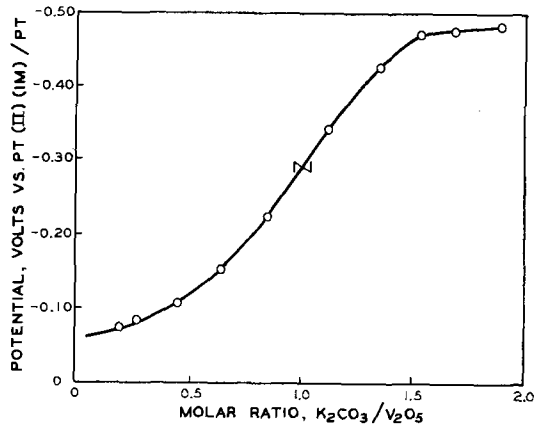

Fig. 7. Potentiometric titration of V_2O_5 with K_2CO_3 in LiCl-KCl eutectic melt at 450°C with a $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$ on gold indicator electrode.

point is relatively small, and the inflection point would be difficult to determine for an unknown amount of V_2O_5 oxide concentration.

Because the inflection point occurs at one for the molar ratio, K_2CO_3/V_2O_5, it may be assumed that the following reaction occurs

$$V_2O_5 + CO_3^{=} \rightleftarrows 2VO_3^{-} + CO_2$$

The small slope of the curve at the inflection point indicates a relatively small equilibrium constant for this reaction. Also, this equilibrium was affected by the formation of a lithium vanadate precipitate.

Conclusions

In a LiCl-KCl eutectic melt at 450°C, V_2O_5 is reduced to an insoluble mixed lithium vanadium oxide at a potential which is a function of V_2O_5 concentration. Chemical analysis of the lithium vanadate bronze which was formed in the potential region 0.00-0.20v *vs.* Pt(II) (1M)/Pt reference electrode gave a compound with a stoichiometry of $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$. With dynamic nonequilibrium conditions, electrochemical measurements indicated that the equivalent of 0.5-0.7 electrons (n) were required to reduce one V_2O_5 molecule, whereas n values of 0.85 and 0.8 were obtained from equilibrium electrochemical measurements.

For the Nernst equation which can be derived for the solid, $Li_2O \cdot 2V_2O_4 \cdot 4V_2O_5$, n cannot be larger than 0.67 electron per V_2O_5 regardless of the various possible equilibria between V_2O_5 and $O^{=}$ which can be considered.

One factor which could cause the discrepancy between dynamic and equilibrium values of n is the adsorption of V_2O_5 or vanadate ions into the surface of lithium vanadate crystals to change the surface composition. These crystals are composed of mixed metal oxides which could present active sites for the adsorption of acidic or basic species. Another factor, which was neglected because of the lack of necessary supporting information, was the electrochemical behavior of semiconductors.

Improved Electrolytic Processes for the Production of Iodic Acid, Periodic Acid, and Their Salts Using a Special Lead Dioxide Anode

ABSTRACT

A special type of lead dioxide anode was found to be the most suitable anode material to produce iodate from iodide, periodic acid from iodine, and also to regenerate periodic acid (periodate) from iodic acid (iodate). This anode could be used in the absence of sulfate with a very slight loss. The yields of the products were almost quantitative with good current efficiency. Improved processes for the production of periodic acid from iodine and iodate from iodide using this anode and also those concerning the regeneration of periodic acid (periodate) from iodic acid (iodate) are covered in this paper.

The increasing importance of periodic acid and its salt in the chemical industry prompted a study of the electrolytic process for the production of these compounds using a special lead dioxide anode[1] which was described previously (1).

It is known that lead dioxide is the best anode material for the oxidation of iodate to periodate. However, the so-called lead dioxide anode is truly a lead anode coated with lead dioxide. Preliminary experiments showed that this anode can be used in the oxidation of iodine to iodic and periodic acid only when the anolyte contains sulfate ion. But, even in this case, a certain amount of mud forms which shortens the electrode life and contaminates the product. Moreover, the presence of sulfuric acid or sulfate in the electrolyte seems to make the separation of the pure product difficult. These disadvantages led us to make this investigation using an anode consisting entirely of lead dioxide.

The electrolytic oxidation of iodine to periodic acid (periodate) or of iodic acid (iodate) to periodic acid (periodate) had been carried out by several investigators in both acid and alkali solution at anodes of platinum (2), nickel (2), lead dioxde on platinum (3), lead dioxide on lead (4), and lead dioxide (5). Among these, the following three processes are of practical interest: Willard and Ralston's (3) in which iodine in hydrochloric acid is converted to iodic acid at platinum and then to periodic acid at an electrodeposited lead dioxide layer on platinum; Mehltretter's (4) in which iodine in sodium hydroxide is oxidized directly to periodate at lead dioxide coated lead in the presence

[1] Manufactured by Sanwa Pure Chemicals Ltd.

of sulfate or borax; Torigai and Ishii's (5) for the direct production of periodic acid using a special lead dioxide anode of the same type as used in this study. They used hydrochloric acid as anolyte and reported conversion to periodic acid of 95% or more with about 70% current efficiency.

We conducted a series of experiments with the special lead dioxide anode for iodic acid, iodate, and periodic acid (periodate) production in both acidic and alkaline medium using various kinds of electrolytes. These results confirm that this electrode was the most suitable as an anode material for this purpose from the viewpoint of its effectiveness and its insolubility.

Experimental Results

Direct Production of Periodic Acid from Iodine

Dilute bromine water was used instead of hydrochloric acid as in (5).

The anolyte consisted of a suspension of iodine in 0.1-0.4*N* aqueous bromine solution. Iodine was dissolved gradually in the anolyte during electrolysis. All electrolyses were conducted until the formation of periodic acid was complete, as indicated by the disappearance of iodic acid.

The apparatus consisted of the simple cells shown in Fig. 1a, a', and b. A 6000 cc (Fig. 1a' 700 cc) and a 300 cc vessel served as the cell, respectively. In cell a, a porous cylindrical pot (unglazed earthenware) separated the anode chamber from the surrounding cathode space. In cell b, two porous pots encircled two cathodes and thus separated the cathode space from the anode chamber. The anode was a lead dioxide sheet of rectangular shape. Cell a was 50 mm wide, 7 mm thick, and 350 mm long, and cell a', b was 25 mm wide, 7 mm thick, and 150 mm long. It stood in the porous pot (cell a, a') or was placed in the center of the cell (cell b). A thermometer was inserted within the anode space. The anolyte was agitated by a glass or a magnetic stirrer.

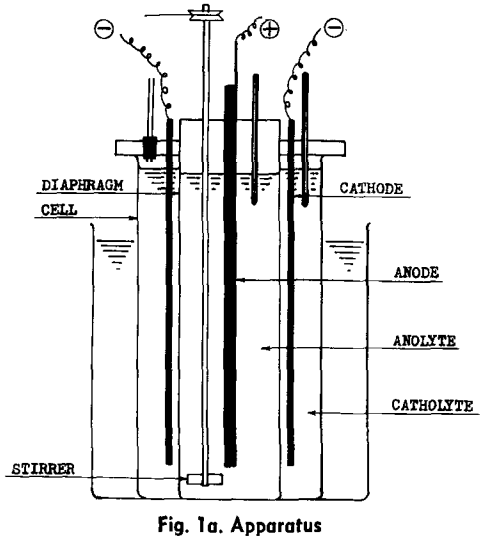

Fig. 1a. Apparatus

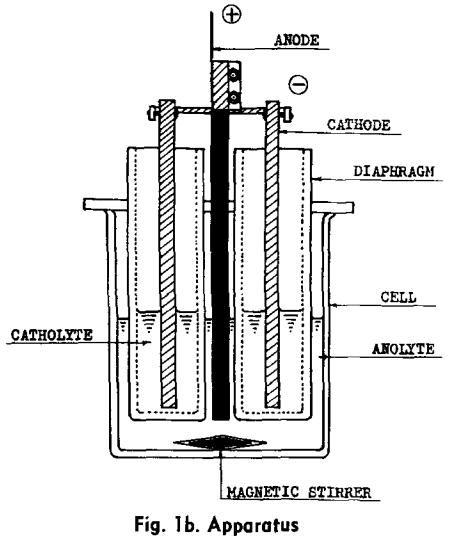

Fig. 1b. Apparatus

Operating conditions and results are shown in Table I.

Periodic acid and combined periodic acid and iodic acid were determined in the anolyte. The accuracy of the analysis was checked by direct recovery of periodic acid as crystals from 100 cc of the resulting anolyte and by the determination of its purity.

The yield of periodic acid was almost quantitative with 70-75% current efficiency. Except in run 1, a slight decrease of the yield resulted from the migration of anolyte to the cathode space and also the sublimation of iodine.

After electrolysis, the anolyte of two or three runs was combined, filtered to remove the small amount of mud, and concentrated at diminished pressure. Periodic acid crystallized out on cooling this solution. After removal of the crystals, the mother liquor was concentrated to a small bulk *in vacuo* and cooled. Almost all crude periodic acid was recovered by this procedure. It was purified by recrystallization from dilute nitric acid. About 70-80% of periodic acid produced could be obtained as pure crystals (purity 99%). When sulfuric acid was used as catholyte, it went into the anolyte making the crystallization of periodic acid difficult.

Anode losses averaged 0.07-0.15 g/100 amp-hr and indicated that the loss would amount to 15% of the original weight after the anode had been used for a year.

The results of separate runs using hydrochloric acid instead of bromine water also are shown in Table I. A slight decrease in yield and in current efficiency was observed in this case. The anode loss increased to 0.20-0.30 g/100 amp-hr, that is about twice the amount in bromine water. In addition, when electrolytically oxidizing iodine in hydrochloric acid, fine iodine powder should be used since it is only slightly soluble in dilute hydrochloric acid. Accordingly, here 0.4*N* solution is better from the viewpoint of iodine solubility even though anode loss increases with increasing concentration. However, according to the bromine water process, the above disadvantages can be eliminated due to high solubility of iodine in bromine water.

Production of iodic acid from iodine.—In this case, all electrolyses were stopped when the formation of iodic acid was complete. Results are shown in Table II.

5	157	88	63	0.20
6	164	91	69	0.28

Runs 10 and 11 in which hydrochloric acid was used as anolyte also are shown for comparison.

Analytical procedure was the same as in the previous experiments. Total iodic acid present indicates the amount of iodic acid after conversion of periodic acid to iodic acid by the procedure described below.

The following processes ($I_2 \rightarrow HIO_3$, $HIO_3 \rightarrow HIO_4$) seemed to take place successively; the resulting anolyte contained mostly iodic acid with a small amount of periodic acid. After electrolysis, the electrolyte was evaporated to desired concentration at ordinary pressure. Periodic acid was decomposed to iodic acid by the action of remaining hydrobromic acid or hydrochloric acid, so that crystals of iodic acid were obtained by procedures described in the recovery of periodic acid.

When 0.2*N* hydrochloric acid was used as anolyte (run 10), the formation of iodic and periodic acid occurred at the same time due to low iodine concentration.

Experiments with other anode materials.—The results at various anode materials are shown in Table III. All electrolyses were conducted within the stage of iodic acid formation because practically no periodic acid was formed at platinum or graphite as described later.

For the production of iodic acid from iodine, the special lead dioxide and lead, platinum, and graphite, each lead dioxide coated, proved effective. Some differences were seen in their current efficiencies, with the loss greatest at graphite. For the production of periodate, graphite and platinum showed their inefficiency as described later. It is obvious, therefore, that lead dioxide and lead dioxide coated lead are the best anode materials for periodic acid production from iodine. However, it should be pointed out that lead dioxide coated lead could be used only in the presence of sulfate ion. Even in this case, the loss amounted to about 2.5 g/100 amp-hr which is ten times larger than that at the special lead dioxide anode. Moreover, as mentioned above, the use of sulfuric acid as catholyte makes the separation of pure periodic acid from anolyte very difficult. On these bases, it is concluded that the special lead dioxide anode is the best material for both the production of iodic acid and periodic acid from iodine.

Production of Iodate from Iodine

In this process, sodium iodide solution was electrolyzed without diaphragm in the presence of 2 g/l sodium bichromate.

This process also can be useful in the production of periodate by combining it with the process described later. In regard to this electrolysis, no literature was found except Mehltretter's which used diaphragm to prevent cathodic reduction of iodate.

Apparatus.—A 700 cc beaker served as the cell. The anode was the lead dioxide of rectangular shape and was 25 mm wide, 7 mm thick, and 150 mm long. Two stainless steel cathodes were placed on either side of the anode.

A 500 cc aqueous solution containing 100g iodine, 40g sodium hydroxide (purity 94%), or 55g potassium hydroxide (purity 85%) and 1g $Na_2Cr_2O_7$ or $K_2Cr_2O_7$ was used as starting electrolyte. The *p*H of the electrolyte was adjusted within the range of 8.0-9.5. All electrolyses were conducted with 95% of the theoretical amount of current.

The results are shown in Table IV.

In this case, sodium iodate was recovered as crystals, and the amount of iodate in crude crystals and in solution was determined by analysis.

The current efficiency was almost 100% with 85-95% conversion. Lead dioxide losses were seen to be about the same order as in the electrolytic production of bromate from bromide at this electrode. That was about 50 mg/1000 amp-hr.

After electrolysis, the electrolyte was cooled to room temperature, and the crystals of sodium iodate were separated out by filtration. About 75% of sodium iodate produced was recovered as crystals. The mother liquor could be used for a new run by adding a suitable amount of iodine and alkali hydroxide to make up to the original concentration.

Following are the chemical specifications of the final product currently being produced: colorless crystal, $NaIO_3$ or KIO_3 assay, 99.9%, chloride, bromide 0.02% max., chlorate, bromate 0.02% max., sulfate 0.02% max., heavy metal (as Pb) 0.003% max., iron 0.002% max., iodide 0.03% max.

As reference, the results at various anode materials are shown in Table V.

In the case of lead dioxide coated lead or graphite, the current efficiency was almost quantitative with 80% conversion. However, losses averaged 1.9 g/100 amp-hr and 0.16 g/100 amp-hr, respectively. Moreover, lead dioxide coated lead must be used in the presence of sulfate. In the absence of sulfate, it could not serve as an insoluble anode. The presence of sulfate complicates the separation of pure iodate from the resulting solution. At graphite, the final product became slightly yellow and could not be decolorized easily. Therefore, these electrodes were considered inferior to the special lead dioxide anode.

Oxidation of Iodic Acid or Iodate to Periodic Acid

Electrolytic oxidation of iodic acid to periodic acid or iodate to periodate was studied with regard to the production of periodate from iodate obtained

by the above process and also the regeneration of periodic acid solution from spent oxidant solution containing iodic acid and its salt.

At a special lead dioxide anode several experiments were carried out varying the composition of both anolyte and catholyte. Material yields and current efficiencies in each experiment are shown in Table VI.

Analytical procedure was almost the same as in the previous experiments.

At the lead dioxide coated lead anode the same experiments were carried out by using the usual lead dioxide coated lead anode for comparison. Results are shown in Table VII.

At the graphite or platinum anode practically no periodic acid was obtained. Results are shown in Table VIII.

The lead dioxide and lead dioxide coated lead are the only practical anode materials for the oxidation of iodate to periodate. At these anodes, iodic acid or iodate was converted to periodic acid or periodate almost quantitatively. However, the special lead dioxide anode proved its superiority over ordinary lead dioxide coated lead as follows.

First, no loss was observed when a special lead dioxide anode was used for the oxidation of metal iodate. Even when used in iodic acid, the loss amounted to about one-tenth of that at lead dioxide coated lead.

Second, a current density as high as 5-15 amp/dm² could be used. At lead dioxide coated lead, a current density less than 2.5 amp/dm² had to be met to hold reasonable current efficiency.

As for the regeneration of periodic acid solution from the spent oxidant solution containing iodic acid and its salts, a process using metal iodate (containing some free acid) as anolyte and sodium hydroxide as catholyte (run No. 3-6) was seen to be the most advantageous. This produces periodic acid solution containing some periodate which is directly useful to the oxidation of organic substances.

Work on the mechanism of electrolytic oxidation of iodic acid (iodate) to periodic acid (periodate) at lead dioxide anode continues using polarographic method and techniques of constant potential electrolysis.

Reduction Mechanism of Chemisorbed Oxygen on Platinum Electrodes by Molecular Hydrogen

M. W. Breiter

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Chemisorbed oxygen on platinum electrodes is reduced at open circuit in electrolytes in the presence of molecular hydrogen. It is shown that the rate of the chemical reaction between molecular hydrogen and the oxygen layer is small. The reduction occurs mainly by an electrochemical mechanism. The electrode is the seat of an anodic and a cathodic reaction. The anodic current of hydrogen dissolution on free sites is equal to the cathodic reduction current on the layer.

It is known that chemisorbed layers of oxygen or thin oxide layers on platinum, iridium, rhodium, and palladium are reduced at open circuit in electrolytes saturated with molecular hydrogen. The potential of a platinum electrode which was held potentiostatically at a value between +0.8v and +2.0v *vs.* a hydrogen electrode in the same solution decreases with time and tends toward the value zero after opening the circuit. The potential time curves at open circuit have arrests similar to those of cathodic charging curves at constant current which are taken from the same initial potential (1). The reduction of the oxygen layer occurs during the transition time of the first arrest after interruption. The transition time increases with increasing potential of interruption (1).

The net reaction of the reduction is

$$M - O + H_2 \rightarrow M + H_2O \qquad [1]$$

Here $M - O$ stands for the chemisorbed oxygen or an oxide. Two reduction mechanisms of different nature are conceivable. The hydrogen may interact chemically with the oxygen layer and reduce it. Many metal oxides are reduced in this way in the gaseous phase. A transfer of charges across the interphase platinum metal/solution is not involved in this case. The single steps of net reaction [1] in the gaseous phase are not yet known. As the knowledge of the single steps is not required here a detailed model of the chemical mechanism will not be given because of its tentative nature.

The second mechanism is electrochemical. After some free sites have been formed initially due to the chemical mechanism or due to a self-decomposition of the oxygen layer, the oxidation of molecular hydrogen occurs on these sites as an anodic electrochemical reaction. This reaction involves a splitting of the H_2 molecules in hydrogen atoms and the subsequent ionization of the adsorbed hydrogen atoms whose surface concentration is very small in the considered potential range. The anodic current of hydrogen oxidation is equal to the cathodic current of the electrochemical reduction of the oxygen layer. A mechanism for the electrochemical reduction was suggested and discussed recently (2). Then

on free sites: $$H_2 \xrightarrow{i_a} 2H^+ + 2e^- \qquad [2]$$

on layer: $$M + H_2O \xleftarrow{i_c} M - O + 2H^+ + 2e^- \qquad [3]$$

$$|i_a| = |i_c| \qquad [4]$$

The electrode is a bi-electrode (3) in this case. The purpose of this paper is to distinguish between the two mechanisms of reduction on the basis of experimental results. The experimental evidence presented so far in literature is not sufficient for the decision.

Experimental Results

The following technique was used to determine how the reduction proceeds with time. A potential of 1.25v or 1.5v, respectively, was applied potentiostatically from $U = 0$ (stationary open-circuit potential of the platinum electrode) and held there for 60 sec. Then the circuit was opened. This procedure gave fairly reproducible potential time curves (U-t-curves) at open circuit. When the decaying potential had reached a certain value, a cathodic current of 20 ma/cm² was impressed to the electrode by closing an auxiliary circuit (voltage supply and high resistor in series) with the aid of the Western Electric 275C Relay. Figure 1a shows the U-t-curves from +1.25v and +1.5v at open circuit. Some cathodic charging curves, obtained from different potentials during the decay of the upper curve in Fig. 1a, are represented in Fig. 1b. The charging curves are drawn only to $U = 0$. The continuation at negative potentials is not shown in Fig 1b. The smooth plati-

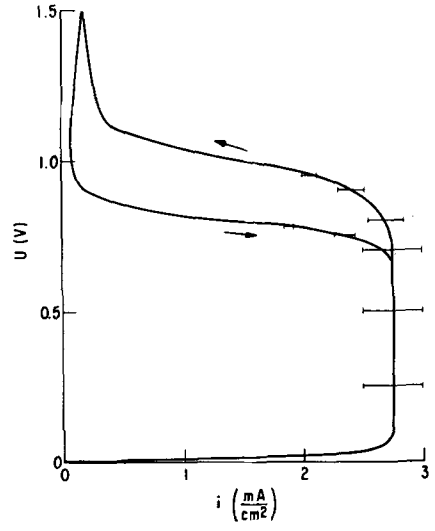

Fig. 3. Potentiostatic current potential curve, measured at 30 mv/sec in 1N $HClO_4$ with hydrogen stirring.

num wire electrode was in 1N $HClO_4$ at 30°C. The electrolyte was stirred with molecular hydrogen vigorously. The cathodic charging curves in Fig. 1b consist of the well-known three parts (oxygen region, double layer region, hydrogen region). The reduction of the oxygen layer occurs after a fast initial potential decay. In a first approximation, the transition time for reduction is equal to the time in which the potential decays from its original value to +0.4v. The electricity required for the double layer charging does not exceed 7% of Q_o under the experimental conditions here (1). Q_o is the number of coulomb/cm² necessary for the reduction of the oxygen layer. A layer of hydrogen atoms is formed during the potential decay between +0.4v and 0. The number Q_H of coulomb/cm² for the formation of the hydrogen coverage was 0.38 millicoulomb/cm² here. The double layer region which separates the hydrogen and oxygen region of anodic charging curves clearly overlaps with the oxygen region in the case of cathodic charging curves (1, 4). A thorough discussion of charging curves on platinum is given in the fundamental papers by Slygin and Frumkin (5).

Figure 2 shows Q_o as a function of U during the decay at open circuit. The upper curve is related to a starting potential of +1.5v, the lower curve to +1.25v. The oxygen coverage changes only slightly with potential between +1.5v and +1.0v. The main part of the reduction takes place between 1.0v and +0.6v.

Figure 3 represents a current potential curve which was measured potentiostatically. The potential was changed linearily with time between 0 and +1.5v with a voltage speed v = 30 mv/sec. The platinum electrode was in 1N $HClO_4$ at 30°C. The current fluctuations, due to irregular stirring with hydrogen, are marked. The limiting diffusion current of reaction 2 is observed between +0.1v and +0.7v. The current decreases gradually between +0.8v and +1.5v during the anodic sweep when the oxygen coverage is formed in this potential range (1). The inhibition of reaction [2] by adsorbed oxygen will be discussed in a subsequent paper. A very small current flows between +1.5v and +1.0v during the cathodic sweep. The time in which the potential changes from +1.5v to +1.0v is 16.6 sec. Below +1.0v the current reaches the limiting diffusion current in a relatively small potential range. A similar current potential curve was obtained with v = 3 mv/sec. Again the current was very small between +1.5v and +1.0v during the cathodic sweep.

Discussion

Although the potential decay between +1.25v and +1.0v or between +1.5v and +1.0v takes more than half the time of the potential decay from +1.25v to 0 or from +1.5v to 0 (see Fig. 1), only a small fraction of the oxygen coverage is reduced there (see Fig. 2). The average rate of reduction between +1.25v and +1.0v is 24 $\mu a/cm^2$. It is 15 $\mu a/cm^2$ between +1.5v and +1.0v. Probably these initial values represent the rate of the chemical mechanism. The rate of reduction i_r increases considerably with decreasing potential below +1.0v. It was determined according to

$$i_r = \frac{\Delta Q}{\Delta U} \cdot \frac{\Delta U}{\Delta t} \qquad [5]$$

for different potentials. A potential decay curve was taken with higher resolution to obtain $\Delta U/\Delta t$ between +1.0v and +0.6v. $\Delta Q/\Delta U$ is computed from the curves in Fig 2. Table I gives i_r at some potentials

Table I. Rate of reduction as a function of potential

U(v)	+1.0	+0.9	+0.8	+0.7	
$i_r \left(\frac{ma}{cm^2}\right)$	0.07	0.37	1.38	3.70	run +1.25v to 0
$i_r \left(\frac{ma}{cm^2}\right)$	0.02	0.045	0.30	1.64	run +1.5v to 0

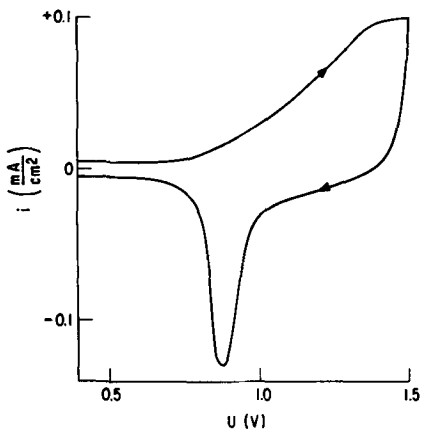

Fig. 4. Potentiostatic current potential curve, measured at 30 mv/sec in 1N $HClO_4$ with argon stirring.

below +1.0v. It follows from Table I that the rate of reduction grows considerably between +0.9v and +0.7v. This is the potential range where potentiostatic current potential curves in acidic solutions with nitrogen stirring show the electrochemical reduction of the oxygen layer during the cathodic sweep (4). Figure 4 represents part of such a current potential curve on platinum in 1N $HClO_4$ at 30°C with vigorous argon stirring. The voltage changed linearily with time with v = 30 mv/sec between 0 and +1.5v. The hydrogen region is omitted in Fig. 4. The cathodic current is counted negative, the anodic current is positive.

It can be concluded on the basis of the results in Fig. 2, Table I, and Fig. 4 that the reduction of the oxygen layer occurs according to electrochemical mechanism (Eq. [2], [3], and [4]). This conclusion is confirmed by the experimental result of Fig. 3 that the anodic current is relatively small between +1.2v and +1.5v during the anodic sweep and between +1.5v and +1.0v during the cathodic sweep. The oxygen coverage increases (1) from about 0.5 to 1 during the anodic sweep in the said potential range and remains practically equal to 1 between +1.5v and +1.0v during the cathodic sweep.[1] The above conclusion is in agreement with the results of a recent paper by Aikasyan (6) on the passivity of the platinum electrode.

It is suggested that the above conclusion can be transferred to smooth electrodes of iridium, rhodium, and palladium as these electrodes have a behavior similar to platinum. The potentiostatic current potential curves (4) have the same shape in the region of the oxygen coverage during the anodic and cathodic sweep and the oxygen coverage (2, 4) depends in a similar way on the potential. A similar situation exists for the reduction of an oxygen layer on platinum in the presence of some oxidizable organic substances like alcohols, aldehydes, or acids. There is no appreciable current during the cathodic sweep in the presence of CH_3OH, CH_2O, and CHOOH on platinum (6) as long as the surface remains partially covered with oxygen. An increase of the anodic current always is observed during the cathodic sweep in the potential range where the reduction of the oxygen layer takes place in the electrolyte without fuel.

[1] Unpublished measurements show that the oxygen coverage on platinum decreases with potential during the cathodic sweep in 1N $HClO_4$ at 30°C in practically the same way whether the electrolyte is stirred with hydrogen or argon.

Continuous Coulometric Analysis of Chlorine Bleach Solutions

Edgar L. Eckfeldt and Eugene R. Kuczynski

Research and Development Center, Leeds & Northrup Company, North Wales, Pennsylvania

ABSTRACT

An experimental coulometric system was devised for continuously and automatically titrating chlorine bleach solutions ranging in concentration from 20 ppm up to about 3%. The titrating reagent was produced cathodically, and the coulometric cell current at equivalence was a measure of concentration. The special cell construction provided about ±1% measurement accuracy throughout the concentration range. Difficulties in holding the titration solution at the required condition of equivalence were met by means of a function-generating circuit in the automatic control system.

A number of years ago a coulometric instrument was developed for continuously measuring low-level free chlorine concentrations (1-3). That instrument was intended primarily for water treatment applications and provided measurement ranges from 0 to 1 up to 0 to 20 ppm chlorine. Although the cell reactions used in that instrument appeared suitable for making measurements at high chlorine concentrations, the form of the equipment did not permit such measurements to be made. The continu-

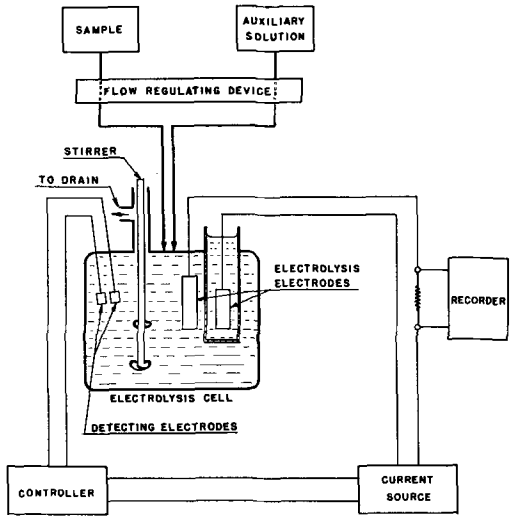

Fig. 1. Schematic diagram of continuous coulometric analysis system.

ous coulometric measurement of concentrated solutions poses certain basic problems. These problems have been surmounted in a newly devised system which is capable of making measurements throughout the concentration range from 20 ppm up to approximately 3% chlorine. It is a purpose of the present paper to describe this new measuring system. Although the equipment was of experimental character and was not tested in field applications, it is believed that potential applications for a measurement of this kind exist in the chlor-alkali industry and in industries that need to monitor and control chlorine in process solutions.

Principle of Operation

The measurement system is schematically shown in Fig. 1. The chlorine solution to be analyzed is metered into an electrolysis cell where it quantitatively reacts with ferrous ions that have been generated electrolytically from ferric ions. To provide a source of ferric ions, an auxiliary solution containing ferric iron and sulfuric acid is introduced into the cell. Detecting electrodes monitor the redox potential of the reacting solution and furnish a control signal to an electric control unit. The control unit automatically adjusts the electrolyzing current to the proper value to maintain a condition of equivalence in the cell solution. The chlorine concentration is given by the equation

$$N = I/96{,}500F \qquad [1]$$

where N is the chlorine concentration in equivalents per liter (normality), I is the generation rate in amperes, F is the flow rate of sample in 1/sec, and 96,500 amp-sec per equivalent is the Faraday constant.

The high chlorine concentrations in the present work made it difficult to maintain automatic control. Conditions in the cell changed rapidly, and large swings in potential were produced by slight deviations from exact chemical equivalence. It thus was necessary to have a control system with special response characteristics. Also, the large current levels placed severe demands on the cell, the electrode assembly, and the output current amplifier.

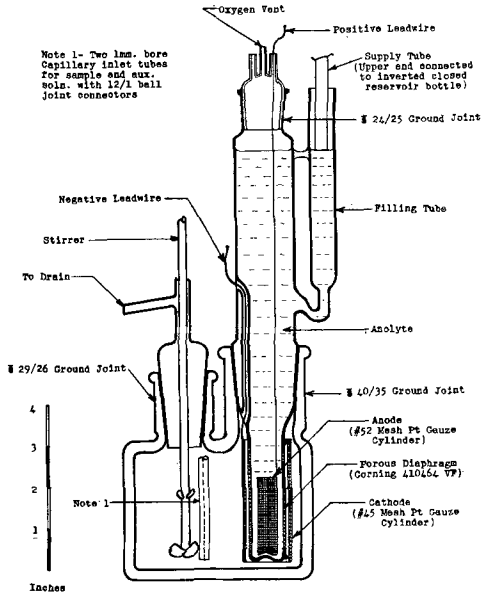

Fig. 2. Electrolysis cell

Equipment

Cell construction.—The cell chamber, shown in Fig. 2, was a short cylindrical vessel of 560-ml capacity and of all-glass construction to provide chemical inertness. A cell of this large a volume was needed for the more concentrated sample solutions. When the cell was in use the outward flow of discharge solution around the propeller shaft prevented the atmosphere from making contact with the interior solution and thus minimized possible loss of chlorine. The speed of stirring was kept as rapid as possible without allowing cavitation to occur.

The electrolyzing electrodes were part of a subassembly that could be removed from the cell as a unit. Sixteen louver-like openings were formed in the outer, titrating electrode to promote circulation of solution in the region between the electrode and the diaphragm. Provisions were made in the subassembly construction to prevent the two electrodes, one on either side of the diaphragm, from actually touching the diaphragm.

The interior of the subassembly was kept filled with a 20% sulfuric acid anolyte. The hydrostatic pressure inside resulted in a slow outward flow of about 20 ml/hr. This leakage of anolyte into the analytical reaction zone caused no harm. The inner solution level was maintained by a reservoir that operated on the chicken-feeder principle.

The detecting electrode system (not shown) consisted of a platinum oxidation-reduction electrode operating in conjunction with a saturated calomel reference electrode. The redox electrode comprised a 2-in. strip of flattened No. 22 platinum wire, wrapped in three turns around the lower, 6-mm diameter end of the calomel tube, and terminated in a loop placed at the bottom of the tube, adjacent to the liquid junction construction (4). This detecting system was placed in the upper region of the cell, not far from the outlet ground joint. False potentials from the field of the electrolysis current were minimized by the arrangement described.

Solution flow metering.—The chlorine sample solution was introduced into the cell by means of a positive displacement metering pump of piston type which had been developed for a previous application (2). The fluorocarbon plastic construction of the pump provided good chemical resistance, but in the present application the pulsating nature of the solution flow was objectionable, because of the large variations in signal voltage caused by influx surges of chlorine solution. The sample flow to the cell therefore was rendered relatively smooth by interposing a small chamber in the line to the cell, followed by a flow-restricting capillary tube. All solution lines were of glass or polyethylene plastic. Frequently the sample flow rate was checked precisely and during the course of the work remained at approximately 6 ml/min.

Auxiliary solution.—The auxiliary solution was a mixture of 17% sulfuric acid and 17% ferric sulfate in water. Because of the impure nature of commercially available ferric sulfate it was found desirable to prepare the solution from ferrous sulfate which salt is available commercially in suitably pure form. Potassium permanganate was preferred for the oxidation of ferrous to ferric sulfate. Two-gallon batches of solution were made using ingredients as follows: $FeSO_4 \cdot 7H_2O$, U.S.P. or C.P., 2.39 kg; H_2SO_4, assay 97%, S.G. 1.84, C.P., 1.35 l; $KMnO_4$, C.P., 0.271 kg; water (good grade), 4.92 l. With the aid of mechanical agitation, the ferrous sulfate was added to the water, and then the sulfuric acid, to the mixture. The potassium permanganate then was added until it was in very slight excess. At this stage the solution redox potential somewhat exceeded + 1.00v, referred to SCE. After the solution had stood for a half hour or so in the oxidizing condition it was passed through a fritted glass filter and then adjusted to equivalence potential of + 0.80v, referred to a SCE, by making appropriate additions of ferrous sulfate or potassium permanganate as saturated solution. If the auxiliary solution was to be used for making measurements on dilute chlorine solutions, moderate care was exercised in adjusting the potential to + 0.80v. If concentrated bleach solutions were to be measured, correspondingly less care was needed in adjusting the final solution potential. A properly prepared solution was stable with time and was not affected adversely by temperature changes.

The auxiliary solution was added to the cell through a separate section of the sample metering pump. The flow rate was adjusted to maintain the concentration of the ferric sulfate in the cell at about 0.1*N*, although this figure was not critical.

Cell resistance.—The cell resistance was obtained by measuring the voltage drop across the generating electrodes under typical operating conditions at several current levels. Figure 3 is a plot of the data. Assuming a constant electrode polarization voltage of 2.1v, the electrical resistance of the cell was calculated to be 0.13 ohm. A current of 7 amp in this magnitude of resistance produces only about 6.4w of heat. In actual operation the temperature of the cell solution never exceeded about 50°C.

Control system.—The automatic control system

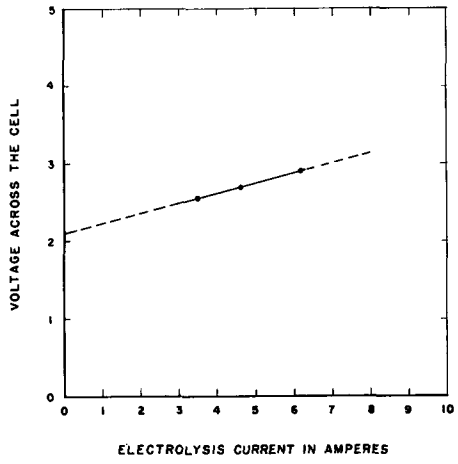

Fig. 3. Electrical characteristics of electrolysis cell

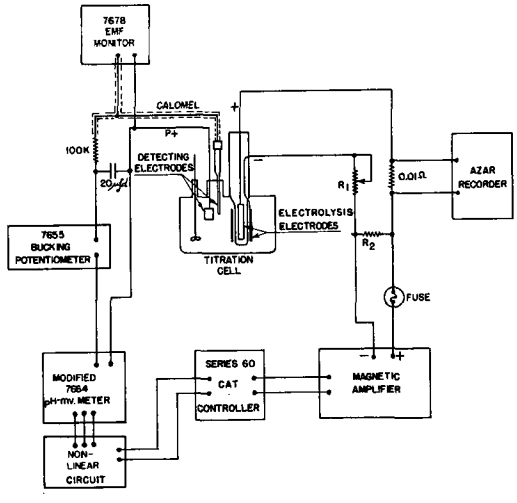

Fig. 4. Block diagram of control system

comprised a combination of essentially stock instruments as shown diagrammatically in Fig. 4. The L&N 7655 potentiometer was set at 800 mv, thereby establishing the intended equivalence potential of the cell solution. The L&N 7678 instrument (a *p*H meter) served only as a monitor to reveal the actual redox condition of the cell solution. The modified L&N 7664 *p*H meter and associated function-generating circuit introduced an important signal-transforming effect. The L&N series 60 current-adjusting controller was connected in a manner to produce full output response from small input voltage swings. The magnetic amplifier which produced the electrolysis current was obtained from Fidelity Instrument Corporation (model No. 1150) and had a maximum rated output of 12 amp d.c. at 25v.

All components requiring 115v a-c power were connected to the 60 cycle power line through a Raytheon voltage stabilizing transformer of 500w rating. This unit improved the stability and performance of the system. Additionally, the magnetic amplifier was powered through a 300 VA isolating transformer to eliminate possible interferences between the electrolysis and detection electrodes, as might otherwise have occurred through common connections to the power line.

The electrolysis current was measured by determining the voltage drop across a calibrated resistor

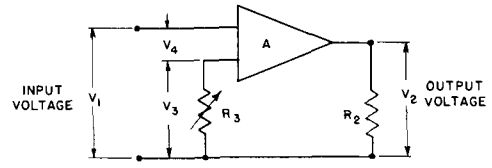

Fig. 5. Schematic representation of modified 7664 pH meter

in the circuit and was displayed on an L&N AZAR recorder.

Function-generating circuit.—The redox electrode produced a typical S-shaped titration curve. Ordinary process controllers, such as the one used in the present study, do not work well with such error signals, because they are designed to operate from a signal that varies linearly with respect to process deviations.

The modifications introduced in the 7664 instrument were intended to linearize the response signal. As schematically represented in Fig. 5, the modified circuit comprised a zero-stabilized d-c amplifier, A, provided with a feed-back loop including a resistor R_2 and a varistor R_3. The amplifier of high gain caused the *Ir*-drop voltage V_3 across the varistor virtually to equal the input voltage V_1. The varistor R_3 exhibited high resistance when the current through it was of small magnitude, but as the current increased its resistance decreased significantly. A situation of variable gain thus existed in the overall circuit. A small input voltage V_1 produced a small output voltage V_2, while a larger input voltage produced a proportionately much larger output voltage.

The actual modifications in the circuit are shown in Fig. 6. The variable resistance element in the feedback loop was composed of two rectifier-type varistors (International Resistance Co., type 28PA1-V) placed in opposing-conductance orientation and in parallel with each other. The potentiometer R_1 of relatively high resistance provided adjustment of the width of the "dead-band." By moving the setting towards 0, the dead band was widened. The magnitude of the output signal was made adjustable by using an adjustable resistor at R_2.

The characteristics of the modified 7664 instrument are shown in Fig. 7 which is a graphical plot of error signal *vs.* output voltage, at several arbitrary settings of R_1 and R_2. The response at the particular settings employed in the present work is shown as curve 4. The difference in the shape of these curves in the first and third quadrants was caused by the use of unmatched varistors in the network. This lack of symmetry was used advantageously to compensate for lack of symmetry in the titration curve. The modifications made in the 7664 instrument appreciably straightened out the S-shaped titration curve and significantly improved the automatic control action.

Testing Procedure

Samples.—The chlorine sample solutions were prepared by diluting ordinary Clorox bleach solution with water. A number of solutions were prepared to cover the wide concentration range of interest.

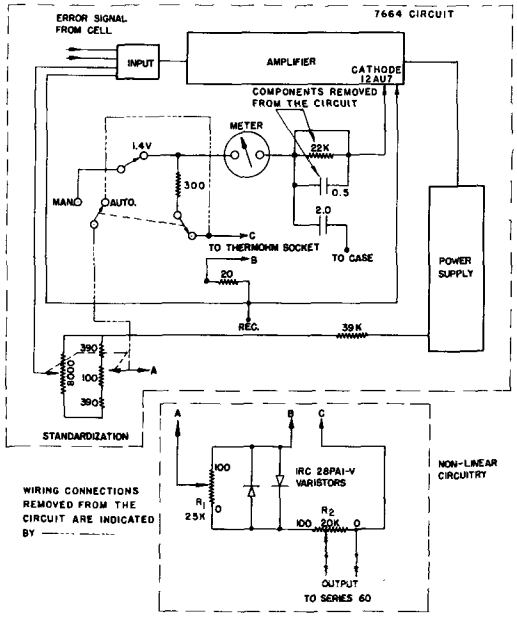

Fig. 6. Circuit diagram of modified 7664 pH meter

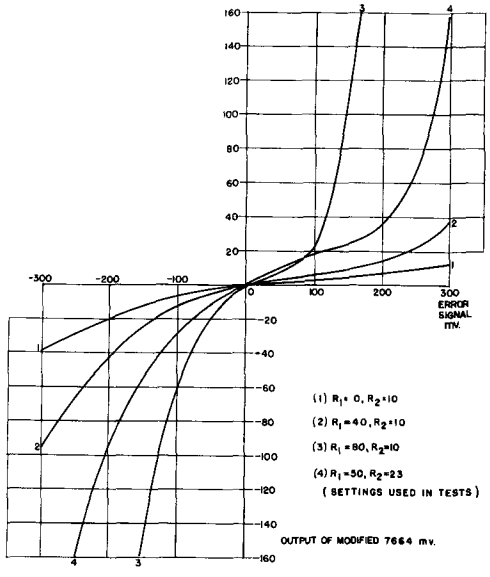

Fig. 7. Response characteristics of modified 7664 pH meter

Operating the Equipment.—At the beginning of the work the optimum settings of the various adjustments were determined by experimenting with the equipment. The proportional band setting of the series 60 unit was the principal sensitivity adjustment for the entire system. This unit also provided an appropriate amount of reset action. Rate action did not help the control action and accordingly was not used. Although the equipment was quite capable of automatically commencing operation, the time taken for start up was reduced by initially producing a condition of approximate equivalence in the cell. This was done by manually adjusting the current and sample addition. The system then was turned over to automatic operation.

The 7678 emf monitor was helpful in revealing the condition of the cell solution. Not only did this instrument serve in the start up procedure but also gave clear evidence of satisfactory operation when the equipment was running. Under operating

0.10	50	20	20	1.0	160	2

conditions the cell voltage stayed close to 800 mv. The slight swings on either side of this voltage indicated that the reaction was under control.

Response studies.—The response characteristics of the control system were studied in a number of runs in which the chlorine concentration was changed abruptly from one value to another. Adjustments were made in the control settings to obtain both a rapid response to concentration change, with a minimum of overshoot, and a narrow current trace under steady conditions. These objectives conflicted somewhat and compromises were necessary. The settings were somewhat dependent on the chlorine concentration level and once established were left alone for experimental work in a particular concentration range. The preferred control settings at various current levels are summarized in Table I.

The response to a slowly changing solution concentration also was determined. While the instrument was running, a chlorine solution was added slowly to and mixed with a more dilute solution contained in a vessel connected to the instrument inlet. The operation required about 3 hr, and the final concentration was almost double that at the start.

To test the long-term stability of the entire system, a 28-hr continuous run was made with the equipment left unattended. In addition, tests also were made to determine the upper limit of electrolysis current for this cell and control system.

Determining analytical accuracy.—The analytical accuracy of the continuous coulometric method was studied by comparing the coulometric results with independent results obtained by a standard chemical method (5). In that method iodide first was added to the sample to convert the chlorine to an equivalent amount of iodine, and the liberated iodine then was titrated with standardized thiosulfate solution. The coulometric concentration was computed from the measured values of current and solution flow rate, using Eq. [1]. In most cases the current trace had an appreciable width caused by hunting of the automatic control, and in such cases it was necessary to estimate the average current for the analytical calculation.

Results and Discussion

Response characteristics.—The performance of the system and its response to changes in concentration are shown in Fig. 8 and 9. These figures were constructed by tracing over the pen line of the original chart record. Although a sample in actual practice would probably never undergo abrupt step changes in concentration, as in Fig. 8, such changes nevertheless demonstrate the performance of the equipment under extreme conditions of reaction upset. As Fig. 8 and 9 show, the equipment quite satisfactorily followed abrupt and gradual concentration changes. In the case of the gradual change, the solution voltage stayed very close to 800 mv during the entire transition.

The 28-hr continuous run was accomplished quite satisfactorily without any difficulties occurring. Al-

6.95	0.771	0.771	0
Average difference (disregarding sign)			0.6%
Average difference (taking sign into account)			−0.3%

though representing only meager experience, this run nevertheless suggests that the continuous coulometric technique is suitable for extended and unassisted measurement of concentrated chlorine solutions.

The maximum electrolysis current for practical operation with the present cell was found to be about 7 amp. At currents above about 8 amp hydrogen evolution was noted at the cathode, and the system gave poor analytical results. The evolution of hydrogen gas was obviously a sign of poor efficiency of the coulometric reaction. When this occurred, the cathode interestingly enough became ineffective and required an hour or so of operation at a considerably lower current level to recover its normal high efficiency.

Chlorine-measuring accuracy.—The effectiveness of the coulometric system in measuring chlorine is shown in Table II, which presents analyses by the electrical and chemical methods. A comparison of the two methods is given by the percentage difference figures.

These comparisons show that the cell system operated at very close to 100% efficiency throughout the entire range of concentration studied, up to a current level of almost 7 amp. The average of the electrical values was 0.3% lower than the average of the chemical values. While the cause of this minor difference was not ascertained, it might have resulted from a slight loss of chlorine accompanying the discharge of the cell solution.

The upper limit of measurable concentration attained in the present work (0.77*N* or approximately 3%) does not represent necessarily a maximum chlorine concentration that is analyzable by the continuous coulometric technique. To push this figure upward, the sample solution flow rate might have been reduced somewhat, or the critical components of the cell might have been made suitably larger to enable the cell to tolerate currents of greater magnitude.

In contrast with existing methods of measuring chlorine, the present technique would appear to offer a continuous, rapid, and automatic measurement of an accuracy that heretofore was attainable only by conventional titrimetric methods.

Technical Notes

An Electrolytic Polish and Etch for Lead Telluride

Marriner K. Norr

United States Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland

Chemical etches for detecting dislocations (1, 2) and an electrolytic polish (3) have been published for lead telluride. With two of these (2, 3) the crystals are sometimes cracked by thermal shock because the procedures must be carried out at temperatures near 100°C. The etch of ref. (1), however, is used at room temperature and therefore avoids this difficulty.

This note describes a method for electropolishing lead telluride at room temperature, where the danger of thermal cracking is avoided. Also, a closely related, room temperature electrolytic etch for detecting dislocations is described. When used under the conditions given below, it is simpler and faster than the procedure of ref. (1).

Procedure

The surface to be electropolished is ground on 600 grit silicon carbide paper lubricated with water, after which it is washed with water and thoroughly wiped with lens paper. The electrolyte is prepared by dissolving 20g of potassium hydroxide pellets in 45 ml of distilled water. To this are added, with stirring, 35 ml of glycerol and 20 ml of ethanol. The chemicals are reagent grade; the cell container is a 250 ml beaker. The cathode is a piece of platinum foil, 2-20 cm^2, and the anode is the lead telluride to be electropolished, with its ground surface oriented horizontally. The electrolyte is stirred with a magnetic stirrer at the rate of 75-200 rpm and the anode is slowly rotated around its vertical axis, at about 4 rpm, to prevent the formation of flow lines on its surface. The voltage drop across the cell during electropolishing is 6v, and the current density is about 0.2 amp/cm^2. (Since the surface area to be polished has generally varied with different samples, the cell voltage, rather than the current density, has proven to be the more convenient parameter to control.) The temperature of the electrolyte is about 25°C. The anode is electropolished until the surface is smooth and free from scratches (generally 5-15 min). It is then rinsed with water, immersed a few seconds in 1:10 nitric acid, rinsed with distilled water, and carefully dried on lens paper.

When lead telluride is to be etched, either a fresh cleavage or an electropolished surface may be used. In the latter case, a surface parallel to a cleavage plane is prepared and electropolished as described in the preceding paragraph. Then (without removing it from the cell) it is etched by reducing the cell voltage to 1v for 15 sec. Rinsing and drying are carried out in the manner previously described. If the surface to be etched is a freshly cleaved one, it is etched in the manner described above, except that the electropolishing step is omitted.

The pits can be erased by electropolishing for about 5 min.

Results and Discussions

The surface produced by the electropolishing procedure has proven satisfactory for reflectivity measurements used for the calculation of the carrier effective mass (4). The procedure was successful on both single-crystalline and polycrystalline p-type lead telluride. Under a magnification of 9X, a few tiny raised specks of lead telluride could be seen occasionally on the surface. With material that contained more than one phase, the surface was shiny but not smooth.

A graph of "current density *vs.* cell voltage" did not show the pronounced plateau frequently observed with successful electropolishing solutions. During electropolishing, a thin film was sometimes visible, but it disappeared when the cell was disconnected or when the anode was withdrawn from the solution. Consistent with the presence of the film were the facts that (i) the vertical and horizontal surfaces of the anode were polished equally well, (ii) the cell current did not vary significantly when the cathode area was increased from 2 to 20 cm^2, and (iii) the cell current did not vary significantly when the anode-cathode distance was increased by a factor of 7. A possible explanation of these observations is that an anode film, rather than the electrolyte, was the current-limiting unit within the cell during electropolishing.

The electroetching procedure produced pits on p-type lead telluride, but only on planes approximately parallel to the cleavage planes. The pits were generally square and pyramidal and were 3-13μ across. As the surfaces departed from the {100} planes, the pits became distorted and finally disappeared. The diagonals of the pits were parallel to the <110> directions. Pits occurred along small-

angle grain boundaries, traces of active slip planes, and at random points on the surface. Crystals deformed plastically and etched before and immediately after the deformation showed new pits which appeared to be due to dislocations introduced by the deformation.

The Dissolution Reaction and Attack of Beryllium by HF, HCl, and H_2SO_4

M. E. Straumanis and D. L. Mathis

Department of Metallurgy, University of Missouri School of Mines and Metallurgy, Rolla, Missouri

The kinetics of dissolution of Be in various acids can be studied easily, if the rate of reaction is followed by measuring the volume of hydrogen evolved. However, there is a complete absence of quantitative data in this respect. Inorganic chemistry literature sources state that Be metal dissolves vigorously in dilute acids, except dilute HNO_3, where the reaction ceases soon in the cold (1-4). The stoichiometry of these reactions is not revealed.

Since Be exhibits a stable valency of two, it may be expected to react with the three acids as follows

$$Be + 2HF \rightarrow BeF_2 + H_2 \quad [1]$$

$$Be + 2HCl \rightarrow BeCl_2 + H_2 \quad [2]$$

and

$$Be + H_2SO_4 \rightarrow BeSO_4 + H_2 \quad [3]$$

The respective salts are soluble in water; no residue should appear therefore. By dissolving a weighed amount of the metal in the acids and measuring the volume of hydrogen evolved the reactions can be checked.

Experimental

The Be was obtained from the Brush Beryllium Company as premium grade vacuum cast metal lump and contained about 99.0% Be, the rest mainly oxygen. Iron, aluminum, silicon, magnesium, and carbon were present in still smaller amounts. As the other metals also develop hydrogen while dissolving in acids, it was calculated that the Be sample was approximately equivalent to a metal containing 99.5% Be.

The apparatus used for the dissolution of the Be samples and the collection of hydrogen consisted of a constant temperature reaction vessel sealed to a gas burette (5, 6). The reaction temperature was 36.0° ± 0.2°; the gas burette was at room temperature, but protected with an outer glass tube from sudden temperature changes.

Because of the low atomic weight of Be, the samples were weighed with an accuracy of ± 0.00001g on a gold balance. The concentration of the acids was so chosen that the dissolution of the samples was complete in about 30 min. The air in the reaction vessel was not replaced by an inert gas as no oxidation of the Be ions was expected.

Results

The results obtained with the Be samples are summarized in Table I.

Despite the not very accurate knowledge of the composition of the Be samples, the agreement, as shown by Table I, between the H_2 volume developed by the samples and the volume calculated from Eq. [1], [2], and [3] is sufficient to prove the correctness of these reactions. The H_2 volume evolved can therefore be used for the determination and monitoring of reaction rates of Be with H_2-developing acids. No residue was left after dissolution of the samples.

Although the quantitative reactions [1], [2], and [3] are quite similar, the attack of the metallic surface by HCl differed from that by the two other acids. A polished surface of Be, subjected to the action of HF or H_2SO_4 remained smooth, as if polished, even after a longer etching time. How-

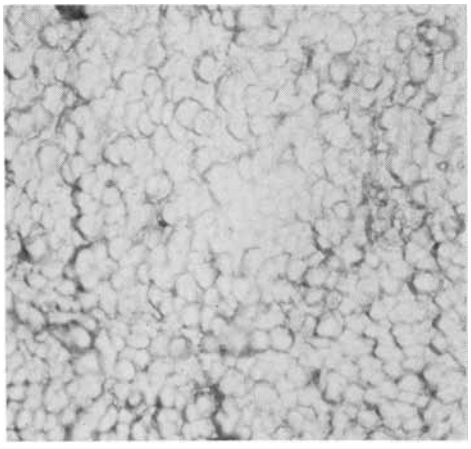

Fig. 1. Attack of a smooth Be plate by 0.5*N* H_2SO_4. Magnification 1300X.

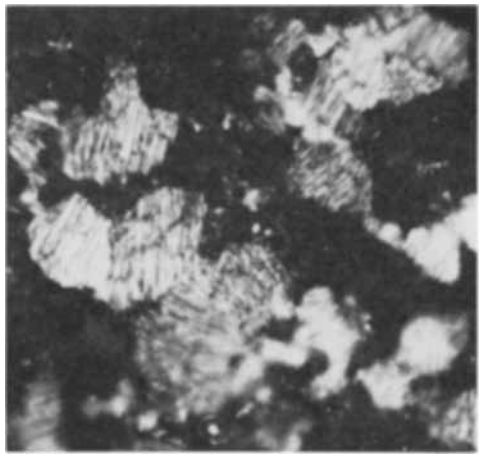

Fig. 2. Plate of Be (powder metallurgy) after etching it deeply with concentrated HCl. Magnification 300X.

ever, high magnifications revealed some structure (Fig. 1). Contrary to this, the reaction with HCl (about 0.5*N*) was strongly localized since the structure of the metal appeared clearly with striations across the grains (Fig. 2).

Another observation was made while Be dissolved in HCl at concentrations lower than 0.5*N*: a black deposit covered the metal which then separated from the latter and turned the whole solution black. It could be shown that the deposit consisted mainly of very fine Be needles which separated from the compact metal during the dissolution process (7). The formation of the needles on the edge of Be pieces is shown in Fig. 3 and 4.

The blackening of the Be surface while dissolving in HCl was previously observed by Bockris (8). Later the phenomenon also was described by Laughlin *et al.* (9) and by Heusler (10), who observed it while dissolving Be anodically in a NaCl solution. However, they did not recognize the blackening of the solution as a result of a partial disintegration of the anode, although such phenomena are known and are mentioned by Evans (11). Nevertheless, since the black deposit was found to consist of metallic Be, the mentioned authors (9) explained the formation of it by the following disproportionation reaction

$$2\,Be^{+} = Be^{2+} + Be \qquad [4]$$

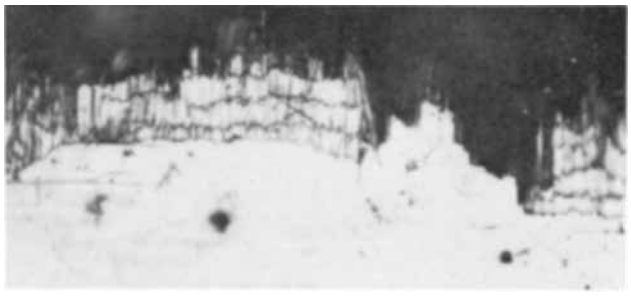

Fig. 3. Initial attack of vacuum cast Be by HCl. Magnification 750X.

Fig. 4. Crystal needles formed on vacuum cast Be corroding in HCl. Magnification 1300X.

Consequently it was assumed that Be was expelled by the anode in form of monovalent Be^{+} ions which then in a very short spread of time react with each other according to [4]. There are three main objections to this explanation:

1. It could be observed during the present investigation that Be needles (Fig. 3 and 4) and particles separated from the compact metal while dissolving in HCl; they also were formed anodically in neutral NaCl solutions.

2. Particles which are observable microscopically must grow, if reaction [4] is correct, from a nucleus; however, nobody could deposit metallic Be in a process of growth from aqueous solutions.

3. To form visible metallic Be particles according to [4] a great number of Be^{+} must travel against the forces of repulsion to collide with each other so that the second valence electron of one Be^{+} could leap to another Be^{+} to give metallic Be. This is quite impossible.

The deviation from Faraday's law therefore is not by formation of Be^{+}, but simply by partial disintegration of the Be anode as observed, while the current was flowing. This phenomenon also was investigated by Marsh and Schaschl (12). The Be disintegration is one of the possible explanations of the negative difference effect (13).

No formation of a black deposit was observed in concentrations higher than 0.5*N* HCl. This is one of the reasons why a stronger concentration of HCl was chosen for the measurements of Table I. No blackening of the acids could be observed in any concentration of HF and H_2SO_4.

However, formation of a black deposit and hence, disintegration of Be was observed in $HClO_4$. Quali-

tative experiments showed that chunk formation started while Be was dissolving in about 0.3*N* $HClO_4$. In stronger concentrations of the acid the amount of the deposit increased, but it dissolved after some time. The same phenomenon also was observed in HBr, only the concentration of the acid at which the black deposit started to appear was about 1*N*. In higher concentrations the formation of the deposit was abundant, but it dissolved soon afterward.

Electron Microscopic Investigations on the Structure and Topography of Electrodeposited Nickel

B. C. Banerjee and P. L. Walker, Jr.

Mineral Technology Division, The Pennsylvania State University, University Park, Pennsylvania

As a result of successful application of electron waves in revealing many structural details of electrodeposited metal surfaces (1-6), the mechanism of growth of cathodic deposits is becoming better understood. It has become evident that a detailed knowledge of surface conditions of the initial cathode surface (based on chemical, electrochemical, and metallurgical studies) is necessary before one can arrive at a valid conclusion as to the factors determining not only the cathodic growth processes but also many of the physical and mechanical properties of the electrodeposits (2, 3, 7, 8). Experimental evidences in favor of the dislocation theory of crystal growth processes are overwhelming, but very few attempts have been made, to the authors' knowledge, to explain many structural details that develop on the surfaces of electrodeposited metals on the basis of this theory. In our electron microscopic investigations of the topography of such surfaces, we have observed not only the formation of substructures but also striations or steps and dendritic type of growth during initial stages of deposition and microcavities resembling etch pits at an advanced stage of deposition. These finer structures formed on a growing cathode surface, stress the importance of the various structural imperfections and the thermal energies involved in the growth of electrodeposited metals (2, 7, 8).

Experimental

Our experiments mainly consist of an electron microscopic study of the structures and topography of Ni at various stages of electrodeposition on reagent grade Cu, Ag, Au, Ni, and Pt cathode surfaces. Results for Ni, electrodeposited on two types of Cu cathodes are presented in particular detail. Carbon replicas of surfaces preshadowed with Pt at angles varying from 15° to 25° generally were used for electron microscopic investigations. The Ni was electrodeposited at a current density of 10 ma/cm^2 and at a bath temperature of 25°C from a purified sulfate-chloride bath adjusted to different *p*H conditions (2.1, 3.2, 5.1). Deposition times generally ranged from about 1 min to about 120 min. The procedures involved in the preparation, purification, and *p*H adjustments of the reagent grade plating solutions have been given elsewhere (1, 2). The thickness of the Cu and Ag foils was adjusted to about one mil by etching them slowly in dilute acid solutions, followed by washing in distilled water. Slow etching generally helps in revealing grain boundaries in greater detail. The Au foils, originally of 0.4 mil thickness, were further thinned to reveal grain boundaries by slow etching in dilute aqua regia. Figure 1 is a typical electron micrograph revealing the small grained structures of the Ag foil. Foils of Au, Cu, Ni, and Pt possess similar structure. Details of the preparation of the carbon replicas and the method of their separation from the metal surfaces have been published previously (2). Two types of Cu surfaces were used as the cathodes for electrodeposition: (A) Two mil thick copper foils were etched in moderately dilute HNO_3 to adjust the ultimate thickness to about one mil followed by a dip in concentrated HCl and a rinse in distilled water (2). (B) This surface was prepared by electrodepositing Cu for 15 min on a type (A) surface of Cu

foil from a complex Cu-glycine bath of *p*H 2.5 maintained at 25°C and a current density of 10ma/cm². The deposits mostly consist of grains with well-developed boundaries and $(10\bar{1}0)$ + (211) preferred orientations (2).

Results and Discussion

Nickel was deposited on Cu surface (A) for 1 min from baths having a *p*H of either 2.1 or 5.1. An electron micrograph of this Ni surface (Fig. 2) shows that the Ni deposits reproduced the particle size and texture of the Cu substrate. Similar results also were found for Ni deposits formed from the same bath on substrates of Ag, Au, Ni, or Pt.

On the other hand, if electrodeposition of Ni is conducted for 1 min from a bath having a *p*H of 3.2, different results are obtained. When deposition occurs on Cu substrate (A), an elongated type of subgrain structure develops [Fig. 3a to 3c]. These sub-

Fig. 2. Electron micrograph of the surface of Ni obtained by electrodepositing Ni from a sulphate-chloride bath at 25°C and at a current density of 10ma/cm² on Cu cathode (A) for 1 min at a *p*H of either 2.1 or 5.1. (2400X).

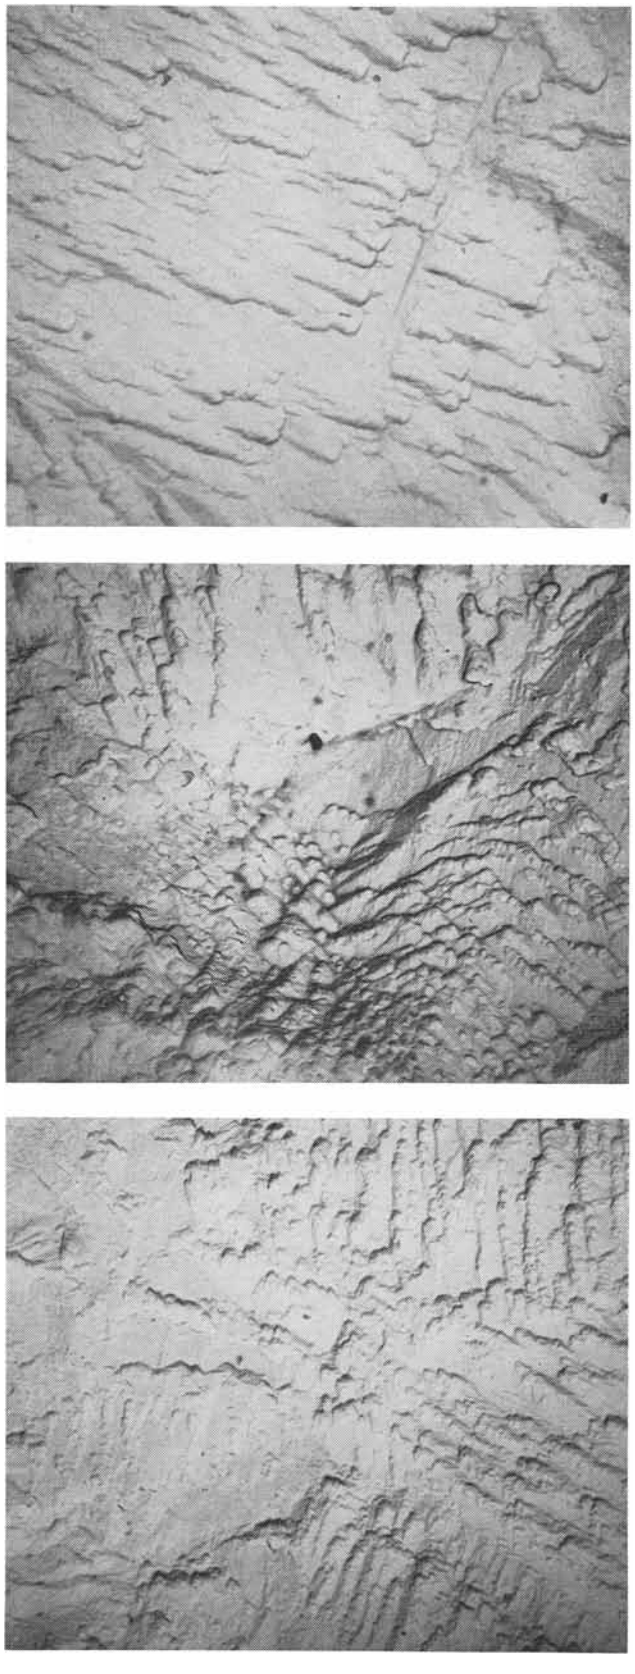

Fig. 3a-c. Electron micrographs of subgrain structures formed on Cu cathode (A) when Ni is electrodeposited from a sulphate-chloride bath of *p*H 3.2, at 25°C and at a current density of 10ma/cm² for a deposition time of 1 min. (2400X).

structures are oriented parallel to each other within a grain, but considerable difference in grain orientation is noted. When deposition occurs on the Ag or Au substrates, a similar type of substructure also is

observed. Analogous substructures were obtained by Deslisle (9) who heated a polycrystalline Cu foil near its melting point for more than 1 hr and then etched the surface of the annealed copper in a suitable reagent. When deposition occurs on Cu substrate (B), large (111) facets containing a dendritic type of structure (Fig. 4) and striations or steps (Fig. 5) are observed. Figure 4 is very similar to the photomicrograph of the surface dendrites obtained by Laukonis and Coleman (10) in the case of γ-phase Fe formed on Fe whisker surfaces that were annealed in H_2 for 2 hr at 1200°C.

No such substructures, dendritic type of growth, and striations or steps were found for Ni electrodeposited on the surface of Pt or Ni at any of the above *p*H conditions.

The development of subgrains on metal surfaces generally is thought to be a thermally activated process. Subgrains have been obtained by various workers (11-13) by annealing a slightly deformed high-purity metal near its melting point, followed by an etch in a suitable solution. Dislocations require sufficient mobility in order to arrange themselves in dislocation walls to produce this effect. There is evidence, such as that put forward by Lambot (14), that deformation itself is able to produce subgrains without the requirement of substantial thermal energy. In this connection, it has been found that electrodeposits develop large amounts of internal stresses (7, 8, 15) which vary in magnitude with deposition conditions.

Electrodeposited Ni generally develops (210), (100), and $(10\bar{1}0)$ + (211) preferred orientations at the deposition conditions used in these experiments at *p*H conditions of 2.1, 3.2, and 5.1, respectively (1, 2). Another interesting feature of our results, then, is the development of microcavities, which resemble etch pits, on parts of the (210) and (100) surfaces of Ni, when the deposit thickness exceeds

Fig. 4. Electron micrograph showing the tendency of Ni deposits to form a dendritic type of growth on a (111) facet of Ni when Ni is electrodeposited on Cu cathode (B) from a sulphate-chloride bath, of *p*H 3.2, at 25°C, and at a current density of 10ma/cm² for 1 min. (7100X).

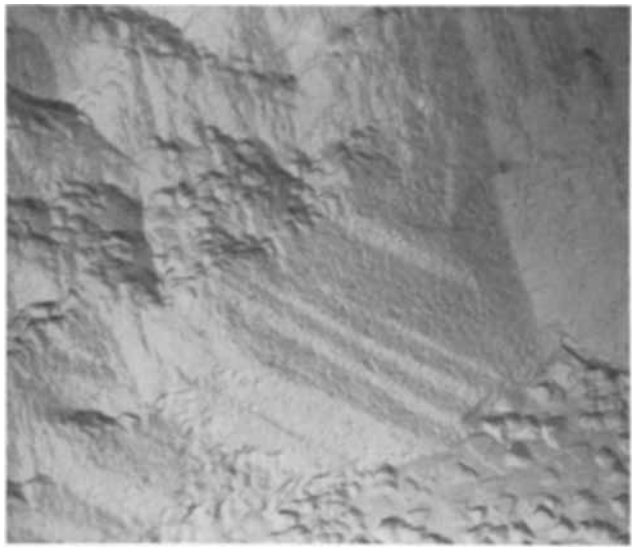

Fig. 5. Electron micrograph showing striations or steps formed on parts of the Ni surface under deposition conditions similar to those in Fig. 4. (7100X).

20μ. The development of these microcavities is found to be independent of the original cathode material used. They are often found to be either square or rectangular in cross section, the shape depending on the crystal symmetry of the surface on which they are formed. Figures 6 and 7 show microcavities formed on (210) and (100) Ni surfaces, respectively. No cavities were found on surfaces at thicknesses below 20μ. For example, Fig. 8 is an electron micrograph for either the (210) or (100) nickel surface at a deposit thickness of about 12μ.

Many structural features of our results at the advanced stages of deposition can probably be explained on the basis of a "Bunching Mechanism" of cathodic crystal growth, proposed recently by the Birmingham School (3, 4). They suggest that kinks or structural inhomogeneities present on the surface of the original cathode may become extended and

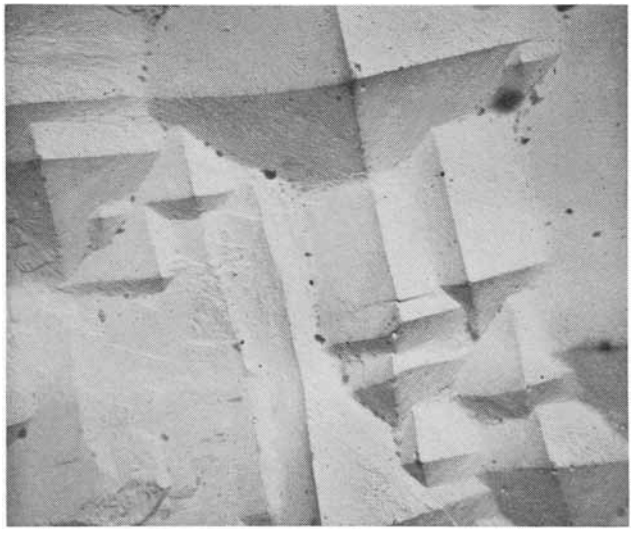

Fig. 6. Electron micrograph showing microcavities formed on the (210) surface of Ni electrodeposited for 120 min on cathode surfaces from the sulphate-chloride bath of *p*H 2.1, at 25°C, and at a current density of 10ma/cm². (2400X).

Fig. 7. Electron micrograph showing microcavities formed on the (100) surfaces of Ni at 25°C from the bath of pH 3.2, at a current density of 10ma/cm^2 when the deposit thickness is about 20μ. (2400X).

Fig. 8. Electron micrograph of (210) surface of Ni, obtained by electrodeposition of Ni from the bath of pH 2.1, at 25°C and at a current density of 10ma/cm^2 with a time deposition which favors a thickness of about 12μ. (1300X).

hence magnified on a macroscopic scale as the deposit grows thicker (3). But the development of substructures, the formation of dendritic-type of structures, and steps or striations during the early stages of deposition cannot be understood on the basis of any one of the existing mechanisms for the cathodic crystal growth processes. The importance of considering some of the parameters involved in the solid-state reactions operative in cathodic crystal growth processes at the various stages of deposition might be helpful in the understanding of this complex phenomena, rather than restricting our ideas wholly to classical mechanisms of crystal growth processes (5, 6). Consideration of the porosity of thinner electrodeposits, the properties of line imperfections in acting as scattering centers for conduction electrons (16), the exothermic nature of the electrodeposition processes (7, 8), and the large deformations of cathode surface layers during various stages of deposition resulting from high magnitudes of internal stresses (7, 8, 15) in the deposits might be particularly helpful in explaining many of the structural anomalies which are often encountered on the surface of a growing deposit during cathodic growth processes.

Controlled Electrode Potential Deposition of Nickel-Iron Films

F. H. Edelman

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

The relationship of the decrease in iron content of a nickel-iron film with increasing thickness when electrodeposited from a constant current source has been reported (1, 2). It is a fairly common practice in the field of analytical chemistry, since the introduction of the commercially available potentiostats, to use the controlled electrode potential (CEP) method to permit the deposition of one cation from a solution containing more than one species whose electrode potentials are close (3). The procedure used in this note was not to separate nickel from iron, but to deposit them in a fixed ratio by the CEP method.

The electroplating bath was a conventional sulfate-chloride type similar to those reported elsewhere (1, 4). The substrates were 1.8 cm square cover glasses that were made conducting by evaporating about 350Å of chromium followed by 2000Å of gold. The anode was a 1½ in. platinum gauze cylinder which encircled the cathode. The cathode was rotated at 200 rpm, and a calomel reference electrode was used. Similar data can be obtained without using a rotating cathode, or stirring, and by using other plating-cell geometries. The substrates were cleaned in a caustic-peroxide solution, followed by a distilled water rinse and activation by a stannous chloride dip. No separation of the anolyte and catholyte or a nitrogen flush of the solution were found necessary

A commercial potentiostat and current integrator were used (5). The potentiostat worked by continuously comparing an accurately known selected voltage to the potential difference between the controlled and reference electrode. The difference voltage was used to drive a motor which rapidly adjusted the voltage between the working electrode and the reference electrode until it became zero.

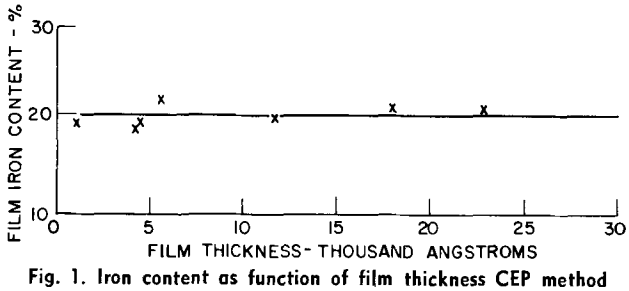

Fig. 1. Iron content as function of film thickness CEP method

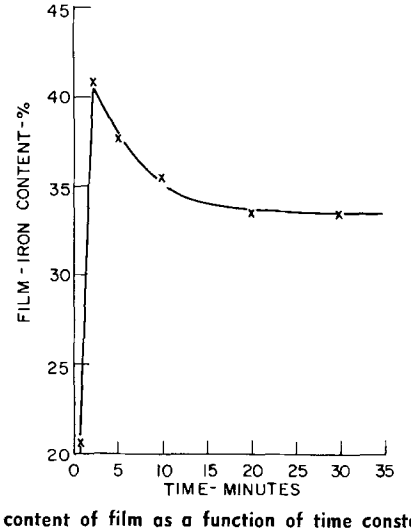

Fig. 2. Iron content of film as a function of time constant current

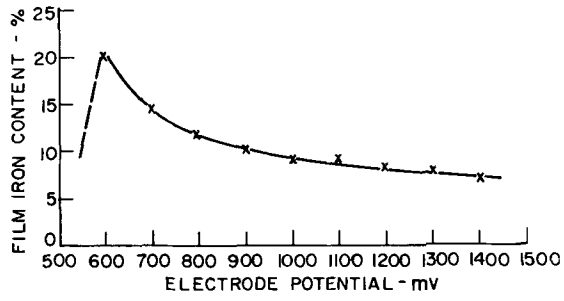

Fig. 3. Iron content as a function of electrode potential

The polarization curves were obtained by adjusting the potentiostat for a given potential and reading the current after stabilization. A separate metallized glass substrate was used for each run. The duration of the electrodeposition was controlled by the integrator. The film composition and thickness were measured by x-ray fluorescence (6). This procedure had an accuracy of ± 5%.

The relative invariance of the iron content of a permalloy film with thickness when prepared by the CEP method is shown in Fig. 1. For comparison Fig. 2 shows the variation in iron content with time of deposition of a film electrodeposited using a constant-current source. For reference purposes, the film composition as a function of electrode potential is presented in Fig. 3.

It may be therefore concluded that the CEP method can be used to prepare alloy films whose composition remains relatively constant with deposition time.

Thermodynamic Properties of the Tantalum and Tungsten Borides

James M. Leitnaker and Melvin G. Bowman

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

and Paul W. Gilles

The Department of Chemistry, University of Kansas, Lawrence, Kansas

During the course of extensive experiments on the thermodynamic and vaporization properties of ZrB_2, information relating to the thermodynamic properties of the tantalum and tungsten borides has been obtained. The purpose of this paper is to present the results of these experiments.

Brewer and Haraldsen (1) have studied the thermodynamic properties of various refractory borides by studying three component systems. The three components were either two metals and boron, or a metal, boron and carbon, or a metal, boron and nitrogen. They have presented their results in phase diagrams and in limits on the heats of formation of the boride phases.

Some of our experiments also were of this type. The experiments involved high-vacuum heating of samples of the tantalum borides, or tantalum and ZrB_2, or tungsten and ZrB_2. The identification of the resulting phases by x-ray diffraction procedures served to indicate what chemical reactions occurred and what products can exist together at the test temperature. The results are used to obtain limiting values for the heats of formation of the various phases.

Experimental

Four types of experiments were performed in our previous work: (*A*) vaporization experiments with the tantalum borides, (*B*) phase diagram studies of the tantalum borides, (*C*) investigation of the ternary system Ta-Zr-B, and (*D*) investigation of the ternary system W-Zr-B.

(*A*) It was demonstrated in recent work on the phase diagram of the tantalum borides between tantalum and TaB (2) that tantalum metal appeared on the surfaces of tantalum boride samples that had been subjected to high-temperature vaporization. Thus, gaseous boron is lost preferentially from all the tantalum borides at high temperature.

(*B*) In the same work, it was shown by a large number of experiments that "Ta_2B" disproportionates at temperatures below 2040° ± 30°C into tantalum and "Ta_3B_2" and that "Ta_3B_2" disproportionates at temperatures above 2180° ±20°C into "Ta_2B" and TaB. This unusual behavior is fortunate for our purposes; it indicates the closeness of thermodynamic stability of these three phases. The work furthermore showed that Ta_2B has the chemical composition $Ta_{2.420.2}B$ and that the composition of Ta_3B_2 is really $Ta_{1.60\pm0.05}B$. Simple experiments revealed that boron reacts with TaB to produce TaB_2 and that TaB_2 reacts with tantalum to produce TaB.

(*C*) During the course of the work on the vaporization properties of ZrB_2 (3), tantalum metal was considered as a possible crucible material to use in effusion experiments. Samples of tantalum metal and ZrB_2 were heated together in high vacuum to temperatures of 1650° to 2200°C. The results indicated that tantalum liberates zirconium, forming Ta_2B, Ta_3B_2, or TaB depending on the temperature and the initial proportions of reactants. No reaction occurs, however, between TaB and ZrB_2.

(*D*) In the same investigation of the vaporization properties of ZrB_2 (3), possible reactions of the diboride with tungsten also were investigated. Samples of tungsten metal and ZrB_2 were heated together in high vacuum between 2075° and 2140°C for several days. The only result was the sharpening of x-ray lines of the two phases in the diffraction pattern of the quenched sample and the eliminating of faint impurity lines in the pattern. Hence, no reaction occurred.

Results

(*A*) Consider the two reactions by which Ta_2B might evaporate

$$Ta_{2.4}B(s) = 2.4\,Ta(g) + B(g) \qquad [1]$$

and

$$Ta_{2.4}B(s) = 2.4\,Ta(s) + B(g) \qquad [2]$$

Experimental observations showed that reaction [2] instead of reaction [1] occurred; hence the rate of loss of B(g) must be greater than 2.4 times the rate of loss of Ta(g) from Ta(s). The limiting standard free energy for reaction [2] can be computed by assuming the rate of loss of B(g) equals 2.4 times the rate of loss of Ta(g) from Ta(s). This assumption is equivalent to assuming the pressure of B(g) equals 1/9.82 times the pressure of Ta(g) over Ta(s). The limiting heat of formation for Ta_2B was computed from the free energy. The actual heat of formation of Ta_2B will be less negative than this.

For this calculation we selected a vapor pressure of tantalum of 8.69×10^{-14} atm at 2000°K from Stull and Sinke (4), Robson's (5) value of 135.0 kcal/mole for the heat of sublimation of boron, free energy functions for tantalum solid and boron gas from Stull and Sinke (4), and free energy functions for Ta_2B by summing free energy functions for the elements (4). The result is $\Delta H_{Ta_{2.4}B} > -64.9$ kcal/mole.

(*B*) The equilibria mentioned among Ta, Ta_2B, Ta_3B_2, and TaB lead to the conclusion that the heats

of formation of the three borides are nearly the same per boron. We have taken $\Delta S = 0$ for all reactions involving only crystalline phases. Thus

$$\Delta H_{Ta_{2.4}B} = \Delta H_{Ta_{1.6}B} = \Delta H_{TaB} > -64.9 \text{ kcal/mole} \quad [3]$$

(*C*) The results of the experiments involving ZrB_2 and Ta metal can be described in terms of the equation

$$ZrB_2(s) + 2Ta(s) = 2TaB(s) + Zr(s) \quad [4]$$

The failure of TaB to reduce ZrB_2 implies that the reaction

$$2TaB_2(s) + Zr(s) = 2TaB(s) + ZrB_2(s) \quad [5]$$

will take place as written. Since Huber, Head, and Holley (6) have given the ΔH of formation of ZrB_2 as -76.7 ± 1.5 kcal/mole, one can deduce that the ΔH of formation of TaB is more negative than -38.4 kcal/mole.

A lower limit for the ΔH of formation of TaB_2 can be imposed by considering the results of Brewer and Haraldsen (1) who have shown that the reaction

$$2TaC(s) + B_4C(s) = 2TaB_2(s) + 3C(s) \quad [6]$$

proceeds as written. The ΔH of formation of TaB_2 can be calculated to be more negative than -45.5 kcal/mole by using Kelley's data [quoted by ref. (1)] on TaC of -38.5 kcal/mole and the data of Smith, Dworkin, and Van Artsdalen (7) on B_4C of -13.8 kcal/mole.

Results for the tantalum borides are summarized in Table I.

(*D*) The stability of W_2B can be estimated in a fashion quite similar to that used for Ta_2B. Since the experimental evidence indicates that the reaction

$$ZrB_2(s) + 4W(s) = 2W_2B(s) + Zr(g) \quad [7]$$

does not proceed as written, one concludes that the partial pressure of boron in equilibrium with ZrB_2 is less than that in equilibrium with tungsten and W_2B. Taking the partial pressure of boron arising from the evaporation of ZrB_2 as 1.6×10^{-10} at 2000°K (3), the ΔH of formation of W_2B is computed to be less negative than -26.0 kcal/mole.

A lower limit of stability has been derived for W B by Brewer and Haraldsen (1) who have shown that the heat of formation is more negative than -20 kcal/mole. Hence, the limits of stability of W_2B are set as

$$-26.0 < \Delta H_{W_2B} < -20 \text{ kcal/mole} \quad [8]$$

Brewer and Haraldsen also have shown that the heat of formation of WB is less negative than that for W_2B by no more than 8 kcal/mole.

The ternary phase diagrams in Fig. 1 and 2 summarize the results of this work. The possible existence of ternary compounds and regions of homogeneity have been ignored since the purpose is to provide an easy-to-visualize thermodynamic relationship among the respective binary compounds of the system.

Table I. Limits on heats of formation
(Based on -76.7 for ZrB_2)

	kcal/mole
$Ta_{2.4}B$, $Ta_{1.6}B$, TaB	-64.9 to -38.4
$\frac{1}{2}TaB_2$	-51.7 to -22.7
W_2B	-26.0 to -20.

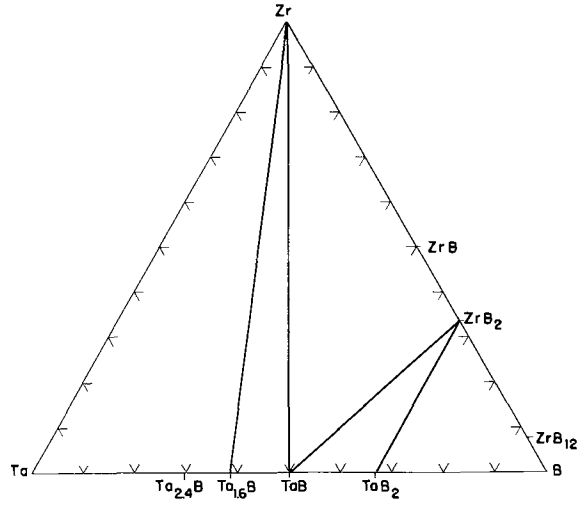

Fig. 1. Schematic phase diagram for the Ta-Zr-B system for a temperature of 1500°C.

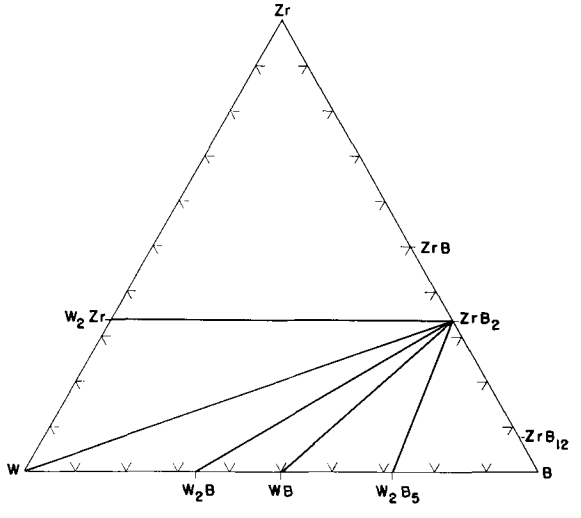

Fig. 2. Schematic phase diagram for the W-Zr-B system for a temperature of 1500°C.

Discussion

Results reported here reveal the kind of data and information that can be obtained from relatively simple experiments. Great accuracy is not claimed for the results, yet they are meaningful and worthwhile.

The results are not in disagreement with those of Brewer and Haraldsen, but they do indicate greater stability for the tantalum borides than were reported previously and, furthermore, have set bounding limits on the stability of lower borides of both tantalum and tungsten.

The solid solubility that is present in these systems has been ignored, but relatively little error results.

Manuscript received July 31, 1961; revised manuscript Jan. 26, 1962. This work was done under the auspices of the Atomic Energy Commission and abstracted in part from the doctoral thesis presented by James M. Leitnaker to the University of Kansas.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Experimental Study of the Anode Effect When Electrolyzing Mixtures of Fused Sodium Chloride and Zirconium Tetrafluoride

C. Decroly and R. Winand

Department of Metallurgy and Electrochemistry, University of Brussels, Brussels, Belgium

Work done in our laboratory (1, 2) on the electrolytic production of zirconium metal by electrolysis of fused mixtures of sodium chloride and zirconium tetrafluoride showed that under certain conditions it was possible to observe the apparition of the anode effect with all its setbacks. We thought it worthwhile to study the several factors which could have an influence on this phenomenon and to determine the best conditions of electrolysis to avoid its occurrence.

The anode effect is well known and was mentioned by Bunsen. It is particularly well known by the aluminum metallurgists, and it is specially for this case that researches have been conducted to elucidate this complex phenomenon. Work on the subject by Arndt and Probst (3), by von Wartenberg (4), and by Schischkin (5) may be cited. More recently, Drossbach (6) and his pupil Ostrowski (7), as well as Piontelli and coworkers (8), have published the results of their investigations on this problem.

Arndt and Probst appear to have been the first to have spoken of a critical anodic current density above which the anode effect is always observable. From the results of recent researches it can be said that the anode effect has several causes. Piontelli (8) and Drossbach (6) have shown that such factors as time, temperature, bath viscosity, and nature of the anodic gases can influence the anode processes. Taylor (9) has shown that addition of oxides to the melt also had an action on the anode effect. Since all of these factors can act together, it is rather difficult to determine separately the role of each of them. In the present work we have tried to find out what could be the importance of each of these causes on the anode effect in the special case of the electrolysis of zirconium tetrafluoride dissolved in molten sodium chloride. As is well known, in this case chlorine is evolved at the anode.

Experimental

Apparatus.—The main features of the apparatus used have been described elsewhere (1, 2, 10). However, in the present work the anode was the central electrode and was made of graphite. The crucible, also of graphite, was the cathode.

Experimental procedure.—All measurements were recorded photographically. Mirror galvanometers were used to measure the several electrical variables and the difference of potentials between silver wire electrodes and the anode. The reproducibility of the results is not perfect, but it is possible to observe a general trend of the phenomena as a function of the several variables which can be changed independently. The duration of the electrolysis must be taken into account and the "induction period," already observed by Piontelli, must be determined to fix the critical current density under which the anode effect is not observed.

The sequences of the experimental procedure were as follows.

(*A*) Measurements begin with a fresh anode, either new or not having been submitted to the anode effect for at least 15 min. Current is first set at a low value, then the cell voltage is progressively and continuously increased up to the moment the anode effect is observed. The value of the corresponding current is noted and immediately afterwards the cell is shut off. The related current density is called D_i.

(*B*) After 10 sec, the same voltage is applied to the cell. The induction time is observed, the cell is again shut off when the anode effect is observed. This procedure is repeated several times but with small increases of the voltage after each current interruption. After a certain number of these operations the anode effect is observed as soon as the voltage is applied to the cell. Such measurements allow plotting of the observed induction time against the anodic current density. Figure 1 shows the curve obtained, which has the shape of an hyperbola. The asymptote parallel to the ordinate axis gives the critical current density $D_{i_{crit}}$. In this particular case the value of $D_{i_{crit}}$ is 120 amp/dm^2.

(*C*) When the anode has been submitted several times to the anode effect, it behaves as if it has a certain memory, and it is no longer possible to avoid the anode effect even when shutting off or applying

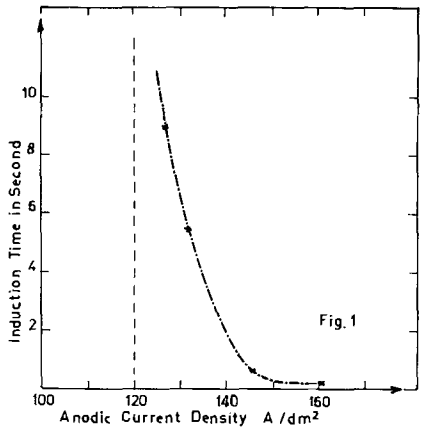

Fig. 1. Induction time vs. anodic current density. Composition of the bath: 25 w/o ZrF_4 and 75 w/o NaCl; temperature, 850°C. The position of the vertical asymptote to the curve gives the critical anodic current density.

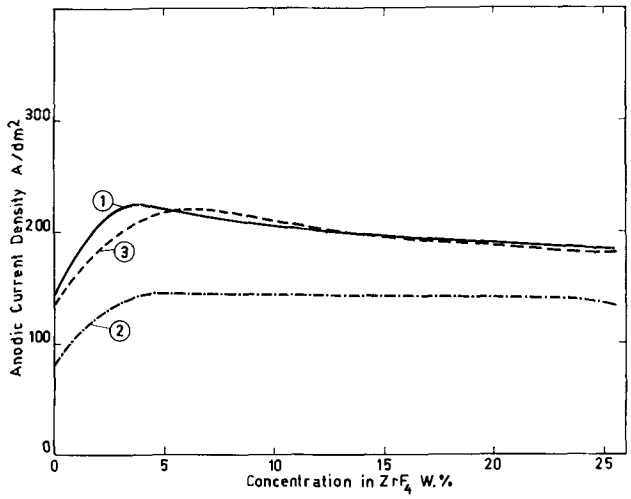

Fig. 2. Influence of the composition of the molten electrolyte on the critical current density; temperature, 850°C; anode diameter: curve 1: 16 mm, curve 2: 32 mm, curve 3: 64 mm.

the voltage to the cell. The surface of the anode is in a sort of excited state which gives it peculiar properties. It is possible to get the anode in this particular state by the following technique: one applies the voltage with such a value as to observe immediately the anode effect, and this state is maintained for 5 sec. Then the current is shut off for 10 sec. Afterwards the voltage is applied again for 5 sec and the current is shut off for 10 sec. These operations are repeated 20 times.

(*D*) After the last interruption of the current the procedure described in (*A*) and (*B*) is repeated, and it is possible to observe a new value of the anodic current density which produces the anode effect and a new value of the critical anodic current density. They are called respectively D_2 and D_{2crit}.

The four values of the anodic current density found when using the procedure described above are considered as defining the behavior of a given anode when all other factors are known.

Raw materials.—Commercial chemically pure sodium chloride was used. Zirconium tetrafluoride was prepared in our laboratory by a procedure described elsewhere (11). Before use it was purified by sublimation under vacuum and kept dry under argon atmosphere.

Experimental program.—Influence of the following factors has been studied: (*a*) electrolyte composition: concentrations of zirconium tetrafluoride in sodium chloride varied from 0 to 25 w/o. A bath obtained after electrolysis with 300 amp-hr of a mixture of 1800g sodium chloride and 600g zirconium fluoride was also studied. This bath is called "bath of end of electrolysis"; (*b*) diameter of the cylindrical central anode; (c) temperature; (*d*) rotation of the anode; and (*e*) addition of zirconium dioxide.

Results and Discussion

Influence of Bath Composition

Figure 2 shows how the critical current density is dependent on the bath composition for anode diameters of 16, 32, and 64 mm. Rather large discrepancies appear between the results of experiments made under similar conditions, and a mean curve has been drawn which shows the trend of the phenomena.

For pure sodium chloride the critical current density is rather small. When adding zirconium tetrafluoride it begins to increase, has a maximum for about 5 w/o of zirconium tetrafluoride, then decreases slowly with increasing concentration of zirconium tetrafluoride.

The shape of these curves might be explained when considering the influence of the interfacial tension. Although we did not make measurements of interfacial tension, we have been able to observe empirically that additions of zirconium tetrafluoride to molten sodium chloride could change the adherence of the mixture to the graphite crucible after solidification. When pure sodium chloride is molten in a graphite crucible and then allowed to solidify and cool off, it is very easy to get the solid salt out of the crucible. On the contrary, solidified mixtures of sodium chloride and zirconium tetrafluoride stick to the graphite crucible. This shows that the interfacial tension of the mixtures of salts is probably lower than that of pure sodium chloride and this might have an influence on the anode effect.

Measurements made with the "bath at end of electrolysis" have shown that the critical current density was of the same order of magnitude as that of the pure sodium chloride for the same electrode diameter. This mixture after solidification did not stick to the crucible.

An explanation of the decrease of the critical current density when the concentration of zirconium tetrafluoride is higher than 5 w/o might be that when the proportion of zirconium fluoride increases the vapor pressure of the salt increases also, a phenomenon which could have an influence on the anodic processes.

Influence of Anode Diameter

Some preliminary experiments had shown that, for a given current density, the area of the anode might have an influence on the anode effect. On the other hand our measurements of the critical current density gave results which were much lower

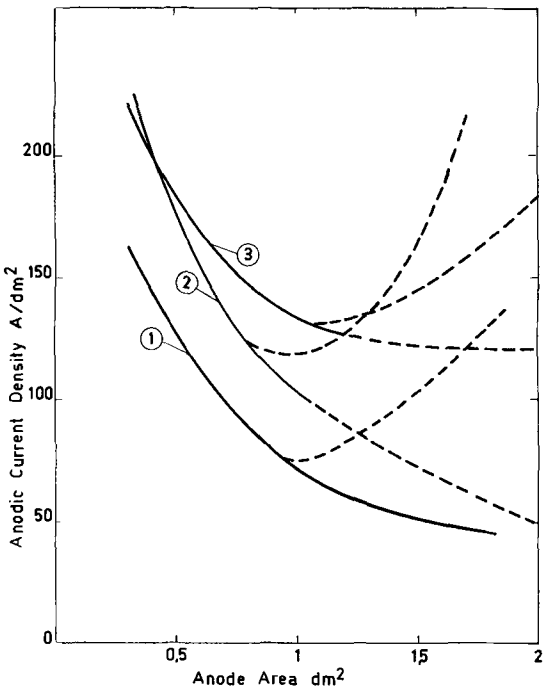

Fig. 3. Influence of the anode area on the critical current density; temperature; 850°C; electrolyte: curve 1: pure sodium chloride, curve 2: 7.7 w/o ZrF_4 + 92.3 w/o NaCl, curve 3: 25 w/o ZrF_4 + 75 w/o NaCl.

than those obtained by Piontelli and his coworkers when electrolyzing pure chlorides with a small hemispherical anode. As our electrolytic cell had a cylindrical symmetry and as the anode was always in the same position with regard to the level of the molten salt, we choose to define the geometrical characteristics of the anode with only one number: its diameter in mm. Five values of the diameter were chosen: 16, 22.6, 32, 45.2, and 64 mm. The ratio between each diameter is $\sqrt{2}$, so that the anode area increases by a factor of 2 when passing from one anode to the next and when using the same bath level.

Figure 3 shows the curves obtained when plotting the critical anode current density against the anode area for a given bath and a given temperature of 850°C. Curve 1 is obtained with pure sodium chloride; curves 2 and 3 are obtained with mixtures of sodium chloride and zirconium tetrafluoride containing, respectively, 7.7 and 25 w/o of this last salt.

The three curves show that, up to an anode area of about 1 dm^2, the critical current density decreases rather sharply, but for anode areas above 1 dm^2 the anode effect appears to obey two different laws. In some cases there is a minimum in the curve and the critical current density increases again; but in some other cases the critical current density becomes continually smaller when the anode area is increased. The minimum in the curves might be explained if it were supposed that, for areas above 1 dm^2, under certain conditions, there are parts of the anode which are working without anode effect, the remainder being submitted to this effect. Everything is going on as if the true anode area were smaller than the measured one. When the minimum does not appear in the curve it might be supposed that all of the anode area bears the anode effect. We have already said that Piontelli and his co-workers have found critical current densities higher than ours. This is probably due to the fact that Piontelli used much smaller anodes.

All these experimental facts show that anodic phenomena are rather intricate and it is not easy to give a theoretical explanation. Thermal considerations do not support the observed facts, namely, the high value of critical current density when anode diameter is small. At first sight, the local production of heat by joule effect and the small area of the electrode should not be in favor of a high critical current density. Other causes may prevail, and the hydrodynamics of the processes occurring at the anode surface should be studied to get a reasonable explanation.

Influence of Temperature

Between 780° and 950°C with a salt mixture containing 25 w/o of zirconium tetrafluoride no noticeable change of the critical current density could be observed. This shows that the thermal effect in our special case had not a predominant influence and that, as already mentioned, a simple thermal theory does not fit with the facts.

Influence of the Rotation of the Anode

Some experiments have been performed with a rotating anode. Between 0 and 100 rpm no significant change in the value of the critical anodic current density could be observed when using a bath containing 25 w/o zirconium tetrafluoride and with anode diameter of 32 mm. Further research should be carried out modifying the anode diameter and with greater speed of rotation to see if the hydrodynamic viewpoint has actually some importance.

Influence of Addition of Zirconium Dioxide

For a bath containing 25 w/o zirconium tetrafluoride as well as for baths of end of electrolysis, additions of zirconium dioxide up to saturation did not influence appreciably the critical current density. This may be due to the fact that additions of zirconium dioxide has no influence on the anodic reaction and that the wettability of the anode is not influenced either.

Conclusions

Factors which appear to play an important part in the processes involved in the anode effect are: (*a*) the wettability of the electrode by the bath, (*b*) nature of the gas evolved by the normal anodic reaction, and (c) the hydrodynamics of the gas evolution.

To get a clearer idea of the anode effect mechanism, it is necessary to carry out viscosity and interfacial tension measurements and to study the hydrodynamics of the gas evolution on a working anode.

From a practical viewpoint our work has shown that when electrolyzing baths containing sodium chloride and zirconium tetrafluoride it is possible to work with fairly high current densities, provided the anodes are of sufficiently great area.

Copper Corrosion

I. Thermodynamic Aspects

D. J. G. Ives

ABSTRACT

Thermodynamic data for reactions concerned in the corrosion of copper in waters containing dissolved oxygen and carbon dioxide are assembled and are used to demonstrate certain features of the corrosion processes. These include the extreme vulnerability of copper to attack, the critical effects of oxygen, and the inadequately protective properties of films of solid corrosion products. Confirmation and extension of these conclusions are obtained by experimental studies of systems derived from copper, cuprous oxide, cupric oxide, malachite, and azurite in water kept in equilibrium with gaseous atmospheres containing known partial pressures of oxygen and carbon dioxide. It is shown, *inter alia*, that cuprous oxide is highly susceptible to dissolution, both by disproportionation and oxidation, and that metallic copper dissolves in such media at a constant rate, despite the accompanying film growth, accumulation of cupric bicarbonate in solution, and rise of pH. The maximum rate of dissolution is attained at a molar ratio of $O_2/CO_2 = 7/3$ in the gas phase, when a substantial oxide film is formed on the metal.

The general (nonpitting) corrosion of copper by waters containing oxygen and carbon dioxide produces cupric bicarbonate in solution and an inadequately protective film of cuprous oxide on the metal. This action, which may be indefinitely prolonged, is an insidious industrial hazard, because the copper in solution may initiate acute corrosion elsewhere by setting up local cell action. Yet little effort has been made to study it systematically, even to discover whether the reactions producing soluble and insoluble corrosion products are functionally inter-related. There is thus a need for thermodynamic and kinetic studies of the Cu, H_2O, O_2, CO_2 system (both without and with saline additions), which the present series of papers is intended to initiate.

In attempting to correlate laboratory experiments with practical corrosion problems, a difficulty arises in the disparity of time scales; some adjustment of conditions must be made to hasten the experiments, with unavoidable introduction of an element of artificiality. In the present work, this adjustment has been confined to an increase above normal of the partial pressures of oxygen and of carbon dioxide with which the experimental systems have been kept in equilibrium. It is believed that this is a better compromise than some others which have been adopted.

Application of Thermodynamic Data

The thermodynamic data in Table I were derived from entries in the N.B.S. Circular 500 (1), except for the case of reactions involving the basic carbonates. For these substances, only heats of formation could be found (2), and an attempt to obtain the required Gibbs free energies of formation on the basis of entropy estimates [using approximate figures quoted by Latimer (3) for carbonate and hydroxide] was unsuccessful, giving results widely at variance with experiment. The entries in Table I for reactions involving malachite (5) and azurite (6) are therefore derived from our own experimental work and are of correspondingly limited accuracy.

Each reaction in Table I produces one mole of cupric bicarbonate in solution, so that subtraction of one equation from another (with the appropriate free energy changes) provides information about a third reaction in which cupric bicarbonate is not involved. The table thus summarizes data for 28 re-

Table I. Standard free energies, $\Delta G°$, and equilibrium ionic products, $K' = (Cu^{2+})(HCO_3^-)^2$, for copper corrosion reactions at 25°C

[7] $Cu_2O - Cu + H_2O + 2CO_2 = Cu(HCO_3)_2$	15.10	$-11.07 + 2 \log P_{CO_2}$

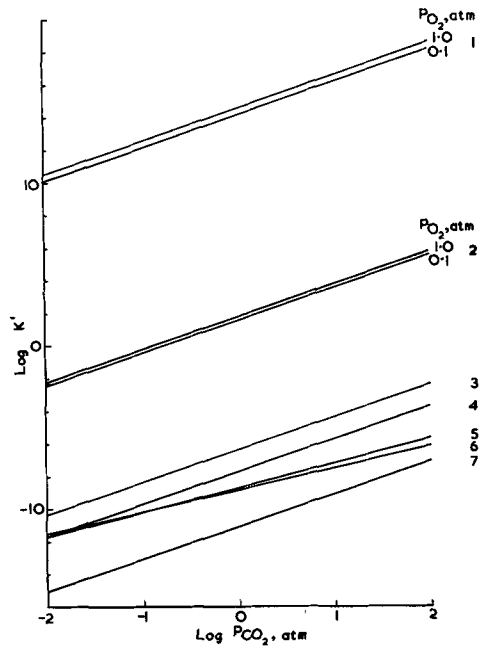

Fig. 1. Log K' = log $(Cu^{2+})(HCO_3^-)^2$ as function of log P_{CO_2} at 25°C for reactions [1] to [7] of Table 1. Plots relating to P_{O_2} = 1.0 atm and 0.1 atm are shown for reactions [1] and [2].

actions which may be concerned in the corrosion of copper in the Cu, H_2O, O_2, CO_2 system. The last column contains values of log K', where $K' = (Cu^{2+})(HCO_3^-)^2$, the ionic activity product, which would be attained in solution if each reaction proceeded to equilibrium. Figure 1 shows the dependence of the log K' values on appropriate gas pressures.

Certain inferences may be drawn from this thermodynamic survey.

Reaction [1] is accompanied by a free energy loss of nearly 20 kcal, indicating that copper has a considerable tendency to dissolve in water containing oxygen and carbon dioxide. Since it is this dissolution which constitutes the main problem, it is reasonable to regard this quantity as an over-all "corrosion potential" of copper in this connection. It is, however, unlikely to be fully effective because the system can decrease its free energy still further by undergoing any of the reactions [3] to [7] in reverse. All of these produce solid compounds, which are likely to deposit on the metal and exert some protective action.

The same inference may be drawn by inspection of Fig. 1. Thus, it can be seen that for $P_{O_2} = P_{CO_2} = 0.1$ atm, log K' for reaction [1] has a value of around 12. This corresponds with cupric bicarbonate in solution at molality ~6000 mole kg^{-1}. This striking result is absurd only because it expresses the corrosion potential of copper on an unsuitable scale. It correctly indicates that copper, far from being noble, is extremely vulnerable and is protected from rapid destruction only by the solid films which form on it. Thermodynamic information about these secondary film forming processes can be obtained from Fig. 1. Thus, a concentration of cupric bicarbonate defined by a point on this diagram will exceed the equilibrium concentration for a reaction represented by a line passing below the point. Such a concentration of cupric bicarbonate will therefore have a thermodynamic tendency to drive this reaction backwards. It is emphasized that these thermodynamic arguments are unlikely to be related to mechanisms of reaction and certainly carry no implication that all solid corrosion products arise from consecutive dissolution and deposition steps. Such arguments should, on the other hand, give the true sequence of stabilities of the solid corrosion products under defined P_{O_2} and P_{CO_2} conditions.

Reaction [7] is a disproportionation reaction occurring anaerobically. The data indicate that, by this reaction, cuprous oxide in presence of metallic copper can send appreciable concentrations of cupric ion into solution. Thus, for $P_{CO_2} = 1$ atm, the equilibrium concentration of cupric ion is 8 ppm,[1] indicating that cuprous oxide is unlikely to form a protective film of any permanence unless it is constantly regenerated; such regeneration, however, implies continued attack on the copper substrate.

The waters in which copper corrosion normally occurs contain oxygen as well as carbon dioxide; this greatly worsens the situation because reaction [2], which is much more favored thermodynamically, comes into play. Even if the effects of this should be largely nullified by deposition of hydroxide, oxide, or basic carbonate (reactions [3] to [6] in reverse), the damage is not entirely repaired, for all these substances provide far from negligible concentrations of cupric ions in solution. This provides an additional reason why it is unlikely that copper will, in course of time, provide its own adequately protective film.

The critical effects of oxygen are well illustrated by calculating equilibrium molalities of cupric bicarbonate in solution for reactions [1] and [2] over a complete range of oxygen-carbon dioxide mixtures at a total pressure of 1 atm. The results are shown in Fig. 2. The very steep rise of the curves as the oxygen partial pressure increases from zero is obvious; the tendency of copper to dissolve increases rapidly, and the protective action of a cuprous oxide film decreases even more rapidly.

Exploratory Experiments and Results

Although not all the equilibria of interest could be accessible, experiments were carried out to check the inferences made from the available thermodynamic data and to serve as a guide for further work. Pow-

[1] The convenient notation of parts per million (mg l^{-1}) is used for very low concentrations of solutes.

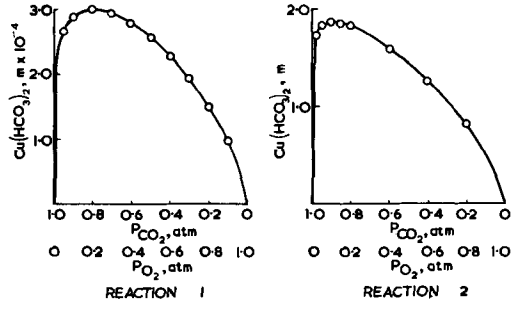

Fig. 2. Calculated molalities of $Cu(HCO_3)_2$ for reaction [1], $Cu + H_2O + 2CO_2 + \frac{1}{2}O_2 = Cu(HCO_3)_2$ and reaction [2], $\frac{1}{2}Cu_2O + H_2O + 2CO_2 + \frac{1}{4}O_2 = Cu(HCO_3)_2$ for systems in equilibrium with mixtures of O_2 and CO_2 at a total pressure of 1 atm.

dered (100 mesh) solid phases, carefully freed from electrolytic impurities, were maintained in contact with circulating water continuously equilibrated with known gas mixtures (O_2, CO_2, N_2) at a total pressure slightly greater than barometric. Samples of aqueous phase were periodically withdrawn for estimation of copper content, and records were kept of conductance and *p*H. Accuracy in these experiments, conducted in a thermostatically controlled room at 24° ±1°C, was not better than ±5%, but the following useful indications were obtained.

Dissolution of cupric compounds, or of cuprous oxide, or copper in oxygenated media, led to increase in *p*H and (sometimes after an initial decrease) conductance. In conjunction with copper analyses and P_{CO_2} values, such results were invariably consistent with the existence of copper in solution solely as fully dissociated cupric bicarbonate, and with *p*H determined by the bicarbonate/carbonic acid buffer ratio. To establish this, use was made of the electroneutrality requirement, of data for the solubility of carbon dioxide in water (4) and its dependence on partial pressure (5), of the ionic product of water (6), the dissociation constants of carbonic acid (6), and ion conductances of hydrogen (7), cupric (8) and bicarbonate (9) ions.

Cupric oxide, prepared from cuprous oxide (see below) by heating in oxygen at 400°C, was used in studies of equilibria in CuO, H_2O, N_2, CO_2 and CuO, H_2O, O_2, CO_2 systems. The results, shown in Fig. 3(a), agreed reasonably well with some earlier determinations (10) and with those calculated thermodynamically for reaction [4], from which the curve in Fig. 3(a) was constructed.

The thermodynamic data indicate, however, that cupric oxide is not the most stable solid phase except at very low partial pressures of carbon dioxide. This

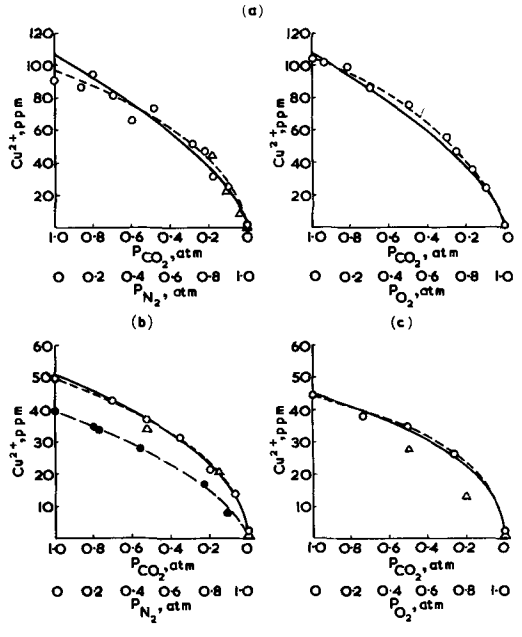

Fig. 3. Experimental concentrations of Cu^{2+}, ppm, for (a) CuO, (b) malachite, and (c) azurite equilibrated with water and with N_2 and CO_2 mixtures (left-hand diagrams) or with O_2 and CO_2 mixtures (right-hand diagrams) at a total pressure of 1 atm. ——— Thermodynamic curve; - - - ○ - - - experimental, present work; △ Tronstad and Veimo; —— ● —— free.

was confirmed by the occasional appearance of green-blue solids at $P_{CO_2} \sim 1$ atm. In two cases these were identified by x-rays as malachite, or a mixture of malachite and azurite.

Malachite (Burra Burra, Australia) and azurite (MacAlder Mine, Kenya), hand-picked, ground, and extracted with water to constant conductance of the aqueous phase, were used in similar equilibrium studies. The results are shown in Fig. 3(b) and 3(c), in which the curves represent the requirements of the data in Table I for reactions [5] and [6]; these data were, however, derived from these same experiments, so the agreement is not significant. Agreement with some earlier data (10, 11) is not good, but it is believed that the present results slightly improve an unsatisfactory situation, even though they are derived from rough, exploratory experiments quite inadequate for setting up new standards (thus, the experimental values, for reactions [4], [5], and [6], respectively, of $\partial \log K'/\partial \log P_{CO_2}$ were 1.84, 1.40, and 1.20).

There is some subsidiary evidence relating to the placing of the lines in Fig. 1. If, by some means (possibly reaction [1]), a concentration of cupric bicarbonate has been set up in solution, then, in the presence of metallic copper, reaction [7] in reverse is thermodynamically preferred, and there is no doubt that cuprous oxide is the first solid corrosion product to appear under these circumstances. In long-term experiments in which copper strips were allowed to corrode for many months in aerated solutions the second product was malachite. Azurite, cupric oxide, or hydroxide were not found. This is in agreement with expectations from Fig. 1. On the other hand, in experiments in which cuprous oxide has been subjected to prolonged treatment with water in equilibrium with $P_{CO_2} = 0.3$ atm, malachite, not azurite, has been identified by x-rays as the final product. This suggests that the malachite line in Fig. 1 should be slightly dropped relative to the azurite line. Such adjustments, however, must await the provision of more satisfactory data. It must also be remarked that purely thermodynamic arguments of this kind cannot be taken as an infallible guide to the sequence in which corrosion products may appear and can certainly not be taken as evidence on the mechanisms of their formation.

Cuprous oxide, prepared by glucose reduction of cupric acetate solution, was extracted with water in absence of air to constant conductance of the aqueous phase, dried, graded (100 mesh), and used in studies of Cu_2O, H_2O, N_2, CO_2 and Cu_2O, H_2O, O_2, CO_2 systems. The results for the first of these are shown in Fig. 4(a) and are seen to be erratic, corresponding with observations of instability and deposition of green-blue solid phases. Copper in solution was undoubtedly predominantly, if not exclusively, in the form of cupric bicarbonate (basic cupric carbonate was recovered on displacement of dissolved carbon dioxide by nitrogen), which must have been formed by the disproportionation reaction [7]. Yet at $P_{CO_2} =$ 1 atm, the concentration of cupric ion in solution, 83 ppm, was ten times that expected from the thermodynamic data. This result could not have been due to imperfect deoxygenation of the system (residual

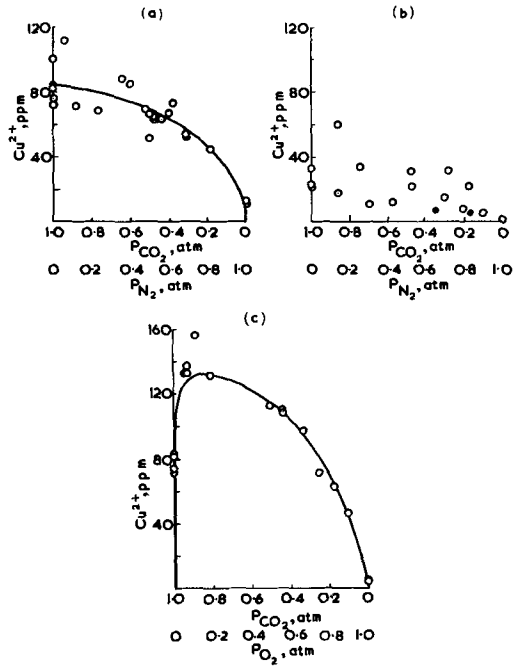

Fig. 4. Experimental studies of systems (a) Cu_2O, H_2O, N_2, CO_2, (b) Cu, Cu_2O, H_2O, N_2, CO_2, and (c) Cu_2O, H_2O, O_2, CO_2 for binary gaseous mixtures to a total pressure of 1 atm. ○ Present work; • Tronstad and Veimo.

oxygen 0.0 — 0.7 ppm) and must be attributed to nonstoichiometry of the oxide and to the absence of metallic copper, except for that produced in the reaction itself, from the system. Such copper could, perhaps, be accommodated in lattice defects and certainly fell short of attaining the standard state for the metal. This point was checked by carrying out a set of experiments in which copper powder was included with the cuprous oxide. The results, shown in Fig. 4(b), were even more erratic, but appreciably lower. Instability was very marked, and some of the copper in solution must have been in the cuprous valency state.

Although these results have no absolute, quantitative significance, they underline the extreme vulnerability of cuprous oxide to dissolution, both by disproportionation and oxidation, and indicate the necessity of giving separate consideration to Cu_2O and Cu, Cu_2O systems. In the latter case it seems that the copper may have some difficulty in controlling its somewhat thermodynamically undisciplined lower oxide. This general point seems to have escaped Tronstad and Veimo (10), who set out to determine the solubility of cuprite in water containing dissolved carbon dioxide. Their results (in presence of added copper) are included in Fig. 4(b) and fall within the scatter of the present determinations, but their conclusion that cuprous oxide is only 1/5 to 1/10 as "soluble" as cupric oxide in water containing carbon dioxide is untenable; their subsequent discussion of copper corrosion, hinging on this conclusion, consequently loses significance.

Inspection of Fig. 1 indicates that there could be no hope of realizing equilibria in the Cu_2O, H_2O, O_2, CO_2 system, for molalities of cupric bicarbonate up to nearly 2 mole kg^{-1} would have to be attained. In spite of this, an attempt was made to study this system. Instability was encountered, but the highest attainable concentrations of copper in solution were recorded and appear as functions of gas composition in Fig. 4(c). Surprisingly enough, a curve can be placed through the somewhat scattered results (orders of magnitude lower than those corresponding with equilibrium) identical in shape with the thermodynamic curve of Fig. 2. Coincidental though this may be, the extreme vulnerability of cuprous oxide in such systems, containing even traces of oxygen, is demonstrated.

Since the limit of thermodynamic studies had been reached, and since in practical problems kinetic and thermodynamic factors are often not easily disentangled, experiments were made in order to follow the course of all the solid phase dissolution reactions over an initial period of 3 hr. In general, the results served only to confirm conclusions already reached, with the following exceptions.

For the cupric compounds, a fast initial reaction decreased smoothly in rate, giving a copper concentration curve concave to the time axis, a form not unexpected and easily explained. In the case of cuprous oxide, however, these features were accentuated; thus for the conditions $P_{O_2} = 0.2$ atm and $P_{CO_2} = 0.8$ atm, the aqueous phase contained 15 ppm of dissolved copper within 5 min, but required 3 hr to attain 30 ppm. This behavior could be due to a change in that part of the solid phase accessible to the aqueous medium, impoverishment in oxygen, or enrichment in copper of nonstoichiometric surface layers. But perhaps the most important aspect is again the high reactivity of cuprous oxide, now demonstrated kinetically as well as thermodynamically, when not under the restraining control of metallic copper in its standard state. Again, remarkably, the extent of copper uptake after 1, 2, or 3 hr of dissolution reproduced approximately the shape of the thermodynamic curve.

Copper powder, formed by reduction in hydrogen at 200°C of the same cuprous oxide (in the hope of preserving some correspondence of specific surface areas), was used to study the Cu, H_2O, O_2, CO_2 system. Attention was necessarily confined in this case to kinetic aspects, which were later studied in more detail by modified methods, but the following preliminary results of some significance were obtained.

The dissolution of metallic copper, often delayed by an induction period, took place at a constant rate. This is illustrated in Fig. 5(a) and stands in marked contrast to the behavior found for the four copper compounds examined in this way. This remarkable constancy of rate, later shown to be preserved for prolonged periods, suggested some sort of automatic self-regulation, the nature of which was not clear at this stage.

The extent of dissolution in a fixed time, as a function of gas composition, did not reproduce the shape of the thermodynamic curve in Fig. 2. The maximum copper uptake was found in the range 20-30 mole % of carbon dioxide, 80-70 mole % of oxygen. For gas mixtures containing less than 20 mole % of oxygen, the copper retained its pristine pink color, but for mixtures richer in oxygen, it rapidly became brown or black. This may be related to the peak in the solu-

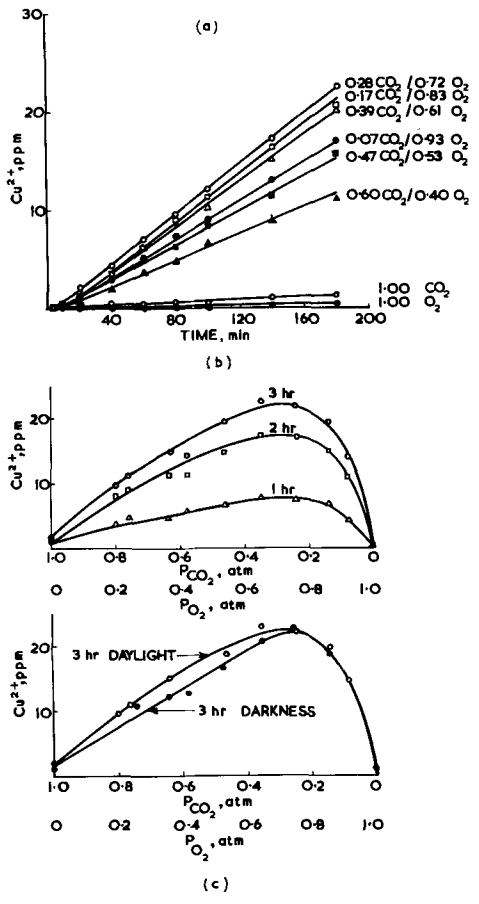

Fig. 5. Dissolution of Cu powder in water equilibrated with mixtures of O_2 and CO_2 to a total pressure of 1 atm (a) as a function of time for various gas mixtures, (b) as a function of gas composition for various times, and (c) as a function of gas composition for constant time, in daylight and in darkness.

bility of cuprous oxide at around 10 mole % of oxygen (Fig. 2 and 4(c)), which perhaps gives a film little chance to thicken. It was certainly the case that the maximum rate of dissolution was attained when the copper powder, as indicated by its color, was covered with a substantial oxide film. Although it was clear from the present and previous (12, 13) work that neither cuprous oxide nor cupric oxide can be very protective in an aqueous medium, this conclusion does not imply an accelerated rate of dissolution as a consequence of progressive oxide formation. The idea that a film, far from giving increased protection with increasing thickness, might be active in promoting dissolution was novel.

In these experiments, previous observations (12, 14-16) that light accelerates chemical attack on copper was confirmed; steps were subsequently taken to eliminate this photo effect. Features of these experiments are illustrated in Fig. 5(b) and 5(c) and confirm that neither carbon dioxide nor oxygen is particularly aggressive toward copper in the absence of the other.

ABSTRACT

Experimental methods are described for studying rates of formation of soluble and insoluble corrosion products of copper exposed to water containing dissolved oxygen and carbon dioxide. Coulometric reduction indicates that the films formed on copper under these conditions are predominantly of cuprous oxide. Generation of cupric bicarbonate in solution and film growth are constant in rate over long periods, and both are kinetically of first order with respect to dissolved oxygen. Dependence of these rates on the concentration of dissolved carbon dioxide follows no obvious kinetic law, but is such as to suggest that the initial pH of solution is a major factor. Experiments in which either solution or metallic phase is replaced during kinetic measurements demonstrate that a cuprous oxide film on copper may have either an activating or a passivating effect, depending on its mode of generation. The evidence indicates the existence of an electrochemical mechanism for general corrosion of copper by which dissolution and film growth are kinetically linked processes.

Preliminary work (Part I; preceding paper) indicated the need for concurrent measurements of rates of formation of soluble and insoluble corrosion products in the Cu, H_2O, O_2, CO_2 system. The technique developed for this purpose was designed to break a wide area of new ground, rather than to obtain precise kinetic data.

Experimental Methods

Corrosion Apparatus

Units of the kind illustrated in Fig. 1, which is largely self-explanatory, were used to circulate glass-distilled water (initial $\kappa \sim 3$ μmho cm^{-1}, free $NH_3 < 0.1$ ppm) at a constant rate of 4-5 l hr^{-1} through vessels containing copper electrodes, each of 15 cm^2 apparent surface area. The water was kept in equilibrium with gas mixtures of known composition (Orsat) by means of a diaphragm pump, which continuously circulated the gas through the main water reservoir. The apparatus, of silicone-treated Pyrex, was assembled with glass-to-glass junctions inside PVC sleeves, and neoprene stoppers were used for mounting electrodes and a dipping conductance cell. The electrodes were screened from light by shields round the electrode vessels.

Before use, the apparatus was repeatedly flushed out with batches of water to remove residual traces of copper and until the conductance of the water fell to about 3 μmho cm^{-1} (residual CO_2; glass-derived solutes). It was then charged with a standard volume (3.1 l) of water, which was brought into equilibrium with a prepared gas mixture; conductance and pH determinations were made and showed reasonably good correlation with the CO_2 contents of the mixtures concerned. The electrodes, prepared as described below, were then inserted and the run commenced.

The electrodes were made from electrolytic copper foil, 0.01 cm thick, initially degreased with acetone and polished to a mirror finish by use successively of "3/50 slow cutting Microid" alumina and "γ-Microid" alumina. The foil was then cut into strips 2 cm wide and annealed in hydrogen (~700°C). Shortly before use, these strips were cut to form electrodes, each provided with a tang which was gripped by a claw formed at the end of a heavy copper wire (1.6 mm diameter), sealed into a glass mounting tube with vacuum wax. Uncovered portions of the wire and tang were coated with beeswax, applied to leave only the desired area of foil exposed. The electrodes were stored in hydrogen and, immediately before use, were immersed for 1 min, with gentle agitation,

in 10% ammonium persulfate solution (1), washed rapidly in air-free water and inserted directly into the corrosion apparatus. This procedure removed any coulometrically measurable oxide film and gave a lightly etched surface hoped to be of reasonably reproducible properties. Details of electrode mounting and of part of the water-circulating system are shown in Fig. 2.

The progress of the kinetic runs, normally conducted for 100 hr at 21° ±2°C was followed by conductance measurements, determinations of dissolved copper, and coulometric analyses of solid films formed on the electrodes.

Solution Analysis

Copper in solution (as cupric bicarbonate; cf. Part I) was determined colorimetrically (Hilger "Spekker"), using sodium diethyldithiocarbamate, *bis*-cyclohexanone oxalyldihydrazone, or rubeanic acid (preferred), against reference standards prepared from "Specpure" copper. Sampling reduced the volume of water in the corrosion apparatus progressively to 2.9 l, but a mean volume of 3.0 l was assumed, without appreciable error.

Electrodes were removed at intervals for examination, and correction was applied to the observed rates of change of cupric ion concentration (and of conductance) for the step-wise reduction of total area of metal-solution interface; all the results reported relate to a total apparent surface area of exposed copper of 90 cm^2. At the conclusion of each run, *pH was redetermined. Checks on gas composition* by analysis indicated a maximum variation of about 0.01 atm in partial pressures.

Examination of Solid Films

Solid films on the electrodes were estimated coulometrically by galvanostatic cathodization in nitrogen-saturated, 0.2*N* ammonium chloride solution. The apparatus was designed to secure reasonable uniformity of current density over the whole surface of an electrode undergoing cathodic reduction and was provided with Luggin capillaries leading to a saturated calomel electrode. The ammonium chloride electrolyte was recommended by Miley (2), but, because of its appreciable film-stripping action under open-circuit conditions (3), it has been replaced in some later work of this kind (1, 3-5) by 0.1*N* or 1.0*N* potassium chloride solutions. We have found, however, that ammonium chloride is preferable because it tends to reduce electrode polarization (reduction potentials less negative) and gives more sharply defined arrests on the potential-time curves. No serious discrepancies were found in estimates of film thickness due to this variation in the electrolyte, and 1.0*N* or 0.1*N* potassium chloride solution was frequently employed in confirmatory or duplicated measurements.

Although this coulometric method is unique in its suitability for a long series of routine measurements, it is, unfortunately, limited in accuracy and unsatisfactory in its powers of discrimination between alternative reducible copper compounds. Observed reduction potentials are not related to reversible potentials calculated for various copper-copper compound couples and vary considerably according to the current density within a practicable range. They also vary quite widely according to the physical nature and distribution of a given film substance, *i.e.*, with the "topography" of the film (5). It is not surprising that films deposited in various ways, many of them conferring appreciable passivity, do not conform to the conditions required for electrode reversibility, nor that properties such as film conductance, permeability, and solubility should control irreversible reduction potentials, which are consequently thermodynamically unpredictable. In any case, no electrode carrying a composite deposit can be at equilibrium, and no reversible basic copper carbonate electrode exists.

The method therefore had to be used empirically, with calibration using films of known constitution. For this purpose, electrodes were subjected to the following treatments: (*a*) anodization for 15 min at 4.0 ma cm^{-2} in 4*N* NaOH solution. Halliday (6) has shown that this provides a composite film, in which he identified $Cu(OH)_2$, CuO, and Cu_2O by electron diffraction; (*b*) exposure to moist oxygen at room temperature for 22 hr to produce a film consisting mainly of Cu_2O; (*c*) ignition (~300°C) for 1 min in air, then for 1 min in oxygen, to ensure the presence of CuO; (*d*) long-term spontaneous corrosion in very dilute salt solutions [~200 ppm of NaCl, Na_2SO_4, $NaNO_3$, $Ca(HCO_3)_2$] in equilibrium with air, to produce basic salts. In all cases the films consisted of cuprous oxide overlaid with malachite, identified by x-rays.

Coulometric reduction curves of these electrodes are shown in Fig. 3. It is seen that cupric hydroxide and oxide, and cuprous oxide, are reduced at well-separated potentials, which differ from reversible potentials appropriate to the experimental conditions [$Cu(OH)_2 \rightarrow Cu_2O$, 0.268v; $CuO \rightarrow Cu_2O$, 0.190v; $Cu(OH)_2 \rightarrow Cu$, 0.130v; $CuO \rightarrow Cu$, 0.091v; $Cu_2O \rightarrow Cu$,

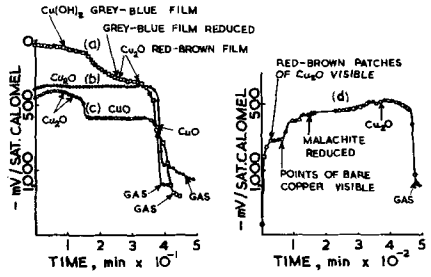

Fig. 3. Coulometric reduction of films on copper; control experiments, (a) to (d), details as in text [c.d.: (a) 0.2 ma/cm²; (b) 0.3 ma/cm²; (c) 0.5 ma/cm²; (d) 1.0 ma/cm²].

−0.008v).[1] Even the sequence of the reduction potentials is not the same, but is identical with that found by Halliday (6), although his cathodizations were performed in 4*N* NaOH solutions. The latter fact suggests that the irreversible reduction potentials are determined largely by the properties of the solid phases.

It is also seen that the malachite-bearing film initially was very resistant to cathodic reduction, and that no characteristic reduction potential could be identified. This was the case for all the electrodes of this kind. Fortunately malachite seems invariably to be a very long-term corrosion product which appears as an easily distinguishable, bright green phase. Neither malachite nor gray-blue cupric hydroxide has appeared in any of the kinetic corrosion experiments, so that attention may be confined to cuprous and cupric oxides.

The calibration experiments lead to typical reduction potentials for Cu_2O and CuO of −390 ±30 mv and −660 ±60 mv, in 0.2*N* NH_4Cl solution, with respect to the saturated calomel electrode. This agrees tolerably with Miley's (2) results of about −360 to −390 mv and −670 to −710 mv for these two oxides, and with −370 mv for Cu_2O obtained by Price and Thomas (7). Although Lambert and Trevoy (5) were unable to confirm that CuO is reduced at a potential some 300 mv more negative than is Cu_2O, this fact is now substantiated and is supported by Halliday's findings (6). In the present work, it was expedient to arrange for all the corrosion films to be cathodically reduced in a period not exceeding 40 min, and current densities were adjusted accordingly within the range 0.1-1.0 ma cm^{-2}. Under these conditions, the films were generally reduced at potentials between −350 and −450 mv with respect to the saturated calomel electrode. Occasionally it was necessary to use higher current densities, with a corresponding negative displacement of potential. It was concluded that all the films were composed of cuprous oxide, and mean film thicknesses were calculated throughout on this assumption. At first sight somewhat questionable, this conclusion is strongly supported by the fact that, apart from initial eccentricities assigned to elimination of tendencies to passivity, or gentle gradients attributed to variation in physical nature, all the potential-time curves at constant current showed but a single plateau. Since it is undoubted that in all cases cuprous oxide was a major film constituent, the inference may be drawn

[1] The Stockholm sign convention, 1953, is used throughout.

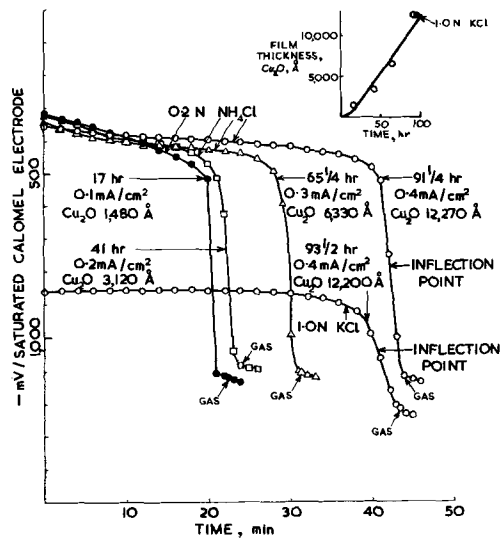

Fig. 4. Typical set of coulometric reduction curves used to follow growth of cuprous oxide film (inset).

that it was essentially the only constituent. It must be mentioned, however, that in a few isolated cases a second, ill-defined arrest occurred at −500 to −550 mv, the source of which was not identified. A typical set of coulometric reduction curves, illustrating the course of film growth on electrodes successively removed from the corrosion apparatus during a kinetic run, is shown in Fig. 4.

Results

Since a complete survey of the effects on corrosion rates of two independent variables (*i.e.* partial pressures of oxygen and of carbon dioxide) was impracticable, one of these pressures was fixed in turn at 0.30 atm while the effect of variation in the other was studied. This choice was made in the light of the results of the preliminary experiments with copper powder described in the preceding paper, and led to the following sets of results.

Experiments at constant pressure of carbon dioxide: $P_{CO_2} = 0.30$ atm; $P_{O_2} = 0.10 - 0.70$ atm.—In these experiments, rates of copper dissolution and of film growth were measured as a function of the partial pressure of oxygen, total gas pressure being maintained slightly in excess of atmospheric by the required addition of nitrogen.

Difficulty was experienced in obtaining reproducible results, only partly due to the occurrence of an induction period in the dissolution reaction. This trouble, which appears to be common in this field of work, is no doubt to be associated with difficulty in reproducing the surface states of polycrystalline metal specimens and was reflected in the uneven early stages of film growth, particularly at low P_{O_2} values. As corrosion proceeded, however, the films became more uniform and were light brown or red-brown in color, except that blue, green, or purple patches were sometimes formed. Even in these cases subsequent coulometric reduction gave rise only to the single plateau assumed to be characteristic of cuprous oxide.

Considerable scatter had therefore to be tolerated in the results, a typical selection of which is pre-

sented graphically in Fig. 5(a) and 5(b), and establish beyond reasonable doubt that there is a constant rate of copper dissolution for each value of P_{O_2}, confirming the results of the earlier experiments with copper powder. It is also shown, with somewhat less certainty, that there is a constant rate of film growth which is a function of P_{O_2}. It is noteworthy that a film of cuprous oxide about 25,000Å thick seems to confer no additional protection to the metal, for dissolution continues at the same constant rate when such a film has been formed.

The erraticity of these results has been countered to some extent by replication of experiments. In later studies of the effects of saline additions (Part IV), each experiment was accompanied by a control, identical in all respects except that no salt was added. Many such control experimental results were combined by interpolation and averaging and gave rise to the plots shown in Fig. 6(a) and 6(b). These give the average concentrations of dissolved copper and the average thicknesses of cuprous oxide films, attained at 20, 50, and 100 hr of corrosion time, as a function of P_{O_2} at constant P_{CO_2} (0.30 atm).

In these plots, the lines are those predicted by the equations $d[Cu^{2+}]/dt = 0.00645\ P_{O_2}$ ppm hr^{-1} for dissolution and $d(Å)/dt = 390\ P_{O_2}$ Å hr^{-1} for film growth. It is justifiable to conclude that, after an induction period, both of these processes follow first order kinetics with respect to oxygen; at least, first order kinetics fit the results better than any other. It is perhaps more important to observe that dissolution and film growth may be linked together kinetically, or both may be controlled by the same rate-limiting process. This seems all the more probable in the light of the fact that, in this set of experiments, the ratio of film thickness to cupric ion concentration in solution was constant to ±7% over the range of P_{O_2} = 0.25 to 0.70 atm for 60 determinations. It

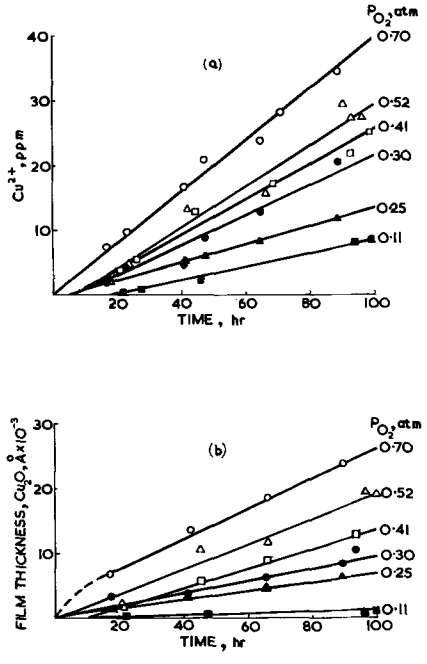

Fig. 5. Typical selection of corrosion experiments; P_{CO_2} = 0.30 atm (const.), P_{O_2} = 0.11 to 0.70 atm, P_{N_2} = (1.00 − P_{O_2} − P_{CO_2}) atm; (a) Cu^{2+}, ppm, as function of time, (b) Cu_2O, film thickness, Å x 10^{-5}, as function of time.

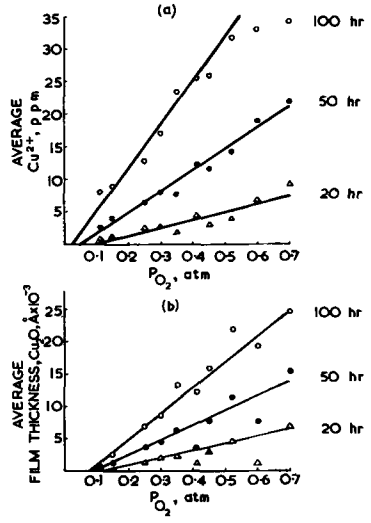

Fig. 6. Average results of corrosion experiments; P_{CO_2} = 0.30 atm (const.), P_{O_2} = 0.10 to 0.70 atm, P_{N_2} = (1.00 − P_{O_2} − P_{CO_2}) atm; (a) dissolution, (b) film growth, for periods of 20, 50, and 100 hr.

was shown that diffusion of oxygen in solution (P_{O_2} = 0.70 atm; C ~ 9 x 10^{-4} mole l^{-1}; D ~ 2 x 10^{-5} cm^2 sec^{-1}; δ ~ 0.05 cm) could cope with a dissolution rate more than tenfold that observed and could be excluded from rate control. Some confirmation of this point came from two corrosion runs (P_{O_2} = 0.20 and 0.40 atm) with 250 ppm of EDTA (sodium salt) added to the aqueous phase, with the idea of suppressing back reaction (disproportionation of Cu_2O in reverse). Dissolution rates were increased by factors of about 3 and 2, respectively, and were independent of P_{O_2}. Film growth was largely inhibited.

Experiments at constant pressure of oxygen: P_{O_2} = *0.30 atm*; P_{CO_2} = *0.10-0.70 atm*. Reproducibility was even less satisfactory, but was adequate, within each kinetic run, to establish that rates of dissolution and film growth were constant for periods up to 100 hr. Averaged results are displayed in Fig. 7(a) and 7(b), which are to be compared with Fig. 6(a) and 6(b). The dependence of the corrosion rates on P_{CO_2} at constant P_{O_2} is seen to be quite different from the dependence on P_{O_2} at constant P_{CO_2}. Nevertheless, although some imagination was required in drawing the representative curves, similarity of shape is retained between those relating to dissolution and those relating to film growth. This adds a little weight to the idea that these two processes may be functionally related.

The two sets of experiments differ in an important respect. In the first set (P_{CO_2} constant) the initial pH was the same for all the kinetic runs, but in the second (P_{CO_2} variable), this was not the case. Attention must therefore be given to the variation of pH with P_{CO_2}, and this is shown in Fig. 7(c), for the initial waters (calculated values) and for the solutions produced after 100 hr corrosion time (observed values). In the latter case, the expected flattening of the curve due to the accumulation of bicarbonate ion in solution is discernible. If the corrosion rates increase with falling pH, and it can hardly be otherwise, it therefore seems that the dependences of pH on P_{CO_2} and on concentration of

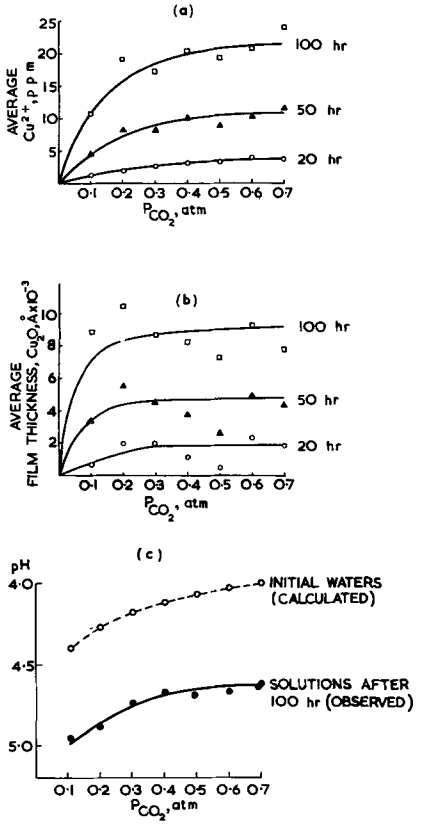

Fig. 7. Average results of corrosion experiments; $P_{O_2} = 0.30$ atm (const.), $P_{CO_2} = 0.10$ to 0.70 atm, $P_{N_2} = (1.00 - P_{O_2} - P_{CO_2})$ atm; (a) dissolution, (b) film growth, for periods of 20, 50, and 100 hr, and (c) pH values at 0 and 100 hr.

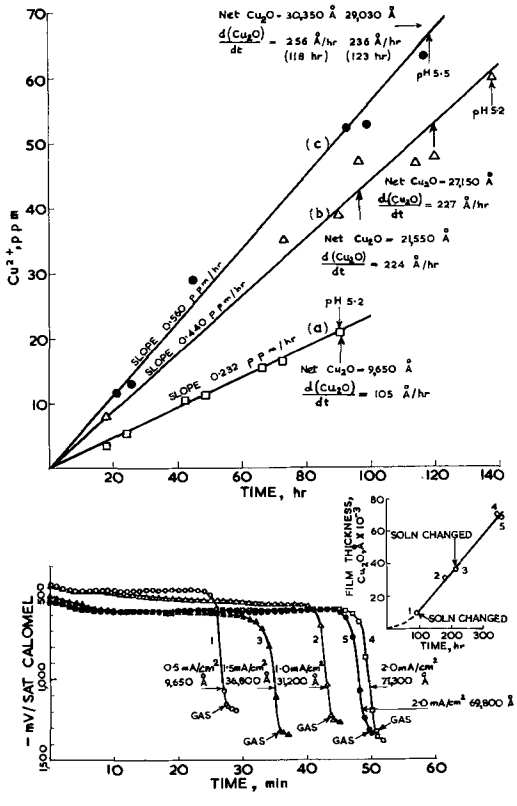

Fig. 8. Solution replacement experiments

cupric bicarbonate in solution might be the factors principally concerned in determining the shapes of the curves in Fig. 7(a) and 7(b). This assumption, however, leads to a paradox, for during a kinetic run pH continuously rises and this should cause the corrosion rates to fall, which they do not. On any grounds, the constancy of these rates is remarkable; there is no indication of a falling away by reason of an approach to an equilibrium state and no sign of the increasing incidence of a back reaction, which might favor the production of cuprous oxide at the expense of cupric ion in solution.

This paradox can be resolved by assuming that the thickening film of cuprous oxide progressively promotes both dissolution and its own continued growth, so compensating the increasing effects of factors adverse to these processes. It was recollected that, in the preliminary experiments (Part I), the maximum rate of dissolution of copper powder was attained when the latter was discolored by the presence of a substantial oxide film.

The possible functional properties of oxide films were investigated accordingly by means of two kinds of "replacement experiments," as follows.

Replacement Experiments

Solution replacement.—The course of an experiment of this kind is recorded in detail in Fig. 8. A normal kinetic run was carried out, with $P_{O_2} = P_{CO_2} = 0.30$ atm, for 92 hr; the increasing concentration of cupric ion in solution is shown in curve (a) of Fig. 8. One electrode was then removed for coulometric estimation of film thickness (these estimations are represented in the lower part of Fig. 8). The entire solution in the apparatus was then removed and replaced by a fresh charge of water, already equilibrated with the same gaseous mixture. A similar run was at once started with the remaining five electrodes, carrying the films deposited on them in the first run. It is seen from curve (b) of Fig. 8 that dissolution proceeded at about twice the original rate and continued constantly at this higher rate for a further 140 hr. This increase in dissolution rate did not occur at the expense of the existing oxide film on the copper, for tests on two of the electrodes showed that the rate of film growth had also been approximately doubled. A further replacement of the solution led to another increment in dissolution rate, curve (c) in Fig. 8, but not in rate of film growth.

Copper replacement.—Under the same standard conditions of $P_{O_2} = P_{CO_2} = 0.30$ atm, a kinetic run was followed for 110 hr. Dissolution and film growth are represented by the rectilinear curves (a) in Fig. 9. The remaining electrodes were discarded and six new ones, prepared by the standard method, were introduced. The kinetic run was then continued, with the solution unchanged. It is understandable that the dissolution reaction was temporarily reversed, and that a film grew rapidly upon the fresh copper surfaces, as shown by curves (b) in Fig. 9. But it can be seen that, after the initial spurt, film growth practically ceased and a normal rate of dissolution was reached only after a delay of 60-80 hr. A second replacement of the same kind produced even more marked effects on dissolution and film growth, curves (c) in Fig. 9.

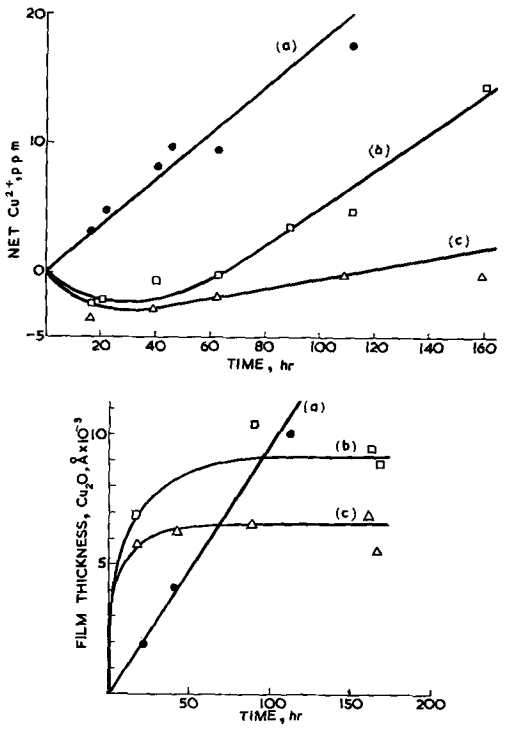

Fig. 9. Copper replacement experiments

Conclusions from Replacement Experiments

At first sight, the results of these experiments seem to be explicable in terms of a back reaction

$$Cu + Cu(HCO_3)_2 = Cu_2O + H_2O + 2CO_2$$

eliminated when the solution is changed, and facilitated when oxide coated copper is replaced by fresh metal. Although such a reaction must play its part in the latter case, it is inadequate to explain all the facts. This can be seen from the data collected in Table I, which shows the state of affairs toward the end of experiments lasting approximately two weeks, in each of which two replacements had been made.

If, for a given total rate of corrosion, the much lower concentration of cupric ion attained in solution were due to the back reaction, the deficit should appear as an excess of cuprous oxide. This is not the case, and it is obvious that the total corrosion rates are quite different after the two kinds of replacement. It is quite remarkable that in one case copper bearing a film about 73,000Å thick should be growing more film and dissolving (at a less favorable pH) enormously faster than in the other case, where the copper is carrying a film less than one tenth as thick. The conclusion is inescapable

Table I

	Replacement of Solution	Copper
Cu converted to Cu^{2+}, g	0.35	0.09
Cu converted to Cu_2O, g	0.13	0.12
Total Cu metal lost by corrosion, g	0.48	0.21
Total area of Cu exposed for corrosion, cm^2	90	270
Total area of Cu × period of exposure, cm^2 hr × 10^{-3}	21	39
Final concentration of Cu^{2+} in solution, ppm	60	21
attained in hr	117	440
Final rate of dissolution, ppm hr^{-1} (per 90 cm^2)	0.56	~0
Final film thickness, Å	73,000	6,500
attained in, hr	350	160
Final rate of film growth, Å hr^{-1}	236	~0
Final pH of solution	5.5	5.2

that the "naturally grown" film, generated in the course of corrosion, is catalytically active for dissolution and autocatalytic for film growth. On the other hand, the "unnaturally deposited" film is appreciably protective.

These results have some bearing on practical corrosion problems. The effects of the intermittent flow of water in copper pipes and over other types of copper surfaces are likely to be similar to those observed in the solution-replacement experiments. It is seen that these are adverse, and films with activating rather than passivating properties are likely to be formed. Perhaps the copper replacement experiments give a pointer to one method by which this undesirable effect could be countered. It is, however, clear that a rather complex electrochemical mechanism for the linked corrosion processes remains to be identified; one possible mechanism is presented in the following paper.

Manuscript received Oct. 2, 1961; revised manuscript received Jan. 23, 1962. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

ABSTRACT

The oxidative dissolution of copper in acidic, aqueous media is limited in rate by the presence at the metal-solution interface of a growing film of cuprous oxide. A brief survey of what is known about the nature and modes of growth of such films provides the basis for a "duplex film" model of the corroding copper system. This leads to an interpretation of some features of the observed kinetics of the corrosion reactions reported in the preceding paper, including the constancy of rates of dissolution and film growth following induction periods, the kinetic link between them, the absence of effects due to concentration polarization of dissolved oxygen, and the results of "replacement experiments." The interpretation is made in terms of the operation of a hypothetical double electrochemical cell, corresponding with the duplex film model, and leaves unresolved problems associated with possible special functions of carbon dioxide and the mechanism of oxygen reduction.

The oxidative dissolution of copper in an acidic, aqueous medium, $Cu + 2H^+ + \frac{1}{2}O_2 = Cu^{2+} + H_2O$, has a standard free energy change of −41.16 kcal, comparable with that of the reaction of sodium with water, but does not in practice occur as a vigorous, exothermic reaction because of the restraining influence of, *inter alia,* the cuprous oxide film which forms on the metal, at least at pH values greater than 3.5. In the absence of control by diffusion of hydrogen ions or dissolved oxygen, it is clear that this film, itself undergoing growth, must determine reaction rate, and this certainly seems to be the case for the corrosion experiments reported in the preceding paper. The kinetics of corrosion must therefore be intimately related to the nature and mode of growth of cuprous oxide films on copper, which accordingly require consideration.

Oxidation of Copper in Gaseous Media

Attention has hitherto been largely confined to the oxidation of copper in gaseous media, and the reaction has been discussed in terms of the properties of cuprous oxide as a metal-deficient, p-type semiconductor containing vacant cation sites and positive holes. At high temperatures, thick films of cuprous oxide grow at a rate inversely proportional to their thickness (1-4), following the so-called parabolic law first interpreted by Wagner (5) in terms of rate limitation by transport of ions across the film. Discussions of parabolic film growth by Hoar and Price (6) and, more recently, by Grimley (7) provide the following representation of reaction mechanism.

For the Cu, Cu_2O, O_2 system at equilibrium, with P_{O_2} equal to the oxygen dissociation pressure of the Cu, Cu_2O couple, vacant cation sites and positive holes are distributed uniformly throughout the oxide film. For greater oxygen pressures, however, a gradient of these defects is established in the film. They are generated at the oxide-oxygen interface, where reduction of oxygen and generation of cuprous oxide occur, and are destroyed at the copper-oxide interface, where oxidation of copper takes place, with provision of cuprous ions and electrons. The system is analogous to a nearly reversible, working galvanic cell in which the outer surface of the film is the cathode and the inner surface the anode. The film itself serves both as electrolyte, transporting cuprous ions by diffusion *via* vacant cation sites, and as "external" resistive circuit, conducting electrons. The rate of film growth can be expressed in terms of a current conforming to Ohm's law, a function of appropriate film resistivities and a potential difference calculable from the free energy of the net oxidation process.

This model serves as a satisfactory basis for the more comprehensive theory of Mott (8), which deals with lower temperature, thin film oxidations which follow different kinetic growth laws, such as cubic (9, 10) or logarithmic (11). It is envisaged that electrons can penetrate an oxide layer by thermionic emission from the metal into conduction levels of the oxide or, for thin films, by quantum mechanical tunnelling, and cooperate in dissociative adsorption of oxygen at the oxide-gas interface. There is evidence (12) that singly charged oxygen ions and oxygen atoms are formed in this process, but the essential result is the establishment of a layer of negative charge, which gives rise to an electrical field in the oxide layer. This field may be strong enough to enforce an outward movement of cations at temperatures too low for normal diffusional mobility to sustain an adequate supply of them. In the general case, various kinetic consequences follow the dependence of cationic drift velocity on field strength. On scales of decreasing temperature and film thickness, there is a change from zero, through linear, to exponential

dependence, and this sequence corresponds with observed growth laws.

At low temperatures, many metals show asymptotic film growth, leading to the formation of very thin, limiting films which increase in thickness as the temperature is raised to a critical value, when continuous growth supervenes. This behavior, possibly due to rate limitation by release of cations from the metal to the film (13), is familiar in the case of self-passivating metals such as aluminum and is also shown by copper (14, 15). Such protective films must clearly be coherent and adherent, and this is no doubt associated with the tendency of the first formed layers of the oxide film to adopt the lattice parameters of the parent metal on which they are growing. This can occur if the dimensions of the cation lattice in the oxide do not exceed 109-114% of those in the metal lattice (16); this condition is satisfied for cuprous oxide on copper. It is to be expected, and is found, that rates of growth and limiting thicknesses should vary widely from one crystallographic plane of the metal to another (14, 17) so that some irregularity of behavior must be anticipated for polycrystalline metal samples. Films formed in this way must become increasingly metastable as they thicken because of lateral compressional strains, which ultimately will lead to breaking up. Lattice distortion in very thin films and absence of preferred orientation in thicker films of cuprous oxide on copper have been observed (18), but it has also been reported that cuprous oxide formed on a polished surface of polycrystalline copper has a unique orientation (19), no doubt through operation of other factors.

The stages through which oxygen must pass as it is transformed into its final "lattice ion" state are interesting and complex. It seems that p-type semiconductors are able to chemisorb oxygen "externally to the lattice" and can provide electrons for the process $\frac{1}{2}O_2 + e^- \rightarrow O^-_{ads}$ at room temperature (20). The participation of the singly charged ion-radical O^- is supported by magnetic measurements (21) and has important implications, discussion of which is reserved. It has already been indicated that the initial uptake of oxygen by copper is extremely rapid, and the initial heat of reaction, 109 kcal mole^{-1}, is so great that hydrogen cannot completely reduce the surface oxide so formed (22). This super-normal stability of "elementary" cuprous oxide films, no doubt due to strong adhesive forces, is supported by electrochemical evidence (23). After the formation of 3-4 layers of oxide, however, heat of reaction has fallen to about 55 kcal mole^{-1} and remains sensibly constant for film thicknesses up to at least 170Å (22). Although the dissociation of oxygen molecules normally requires 117 kcal mole^{-1}, dissociative adsorption at a cuprous oxide surface proceeds by a first order reaction (24) to provide oxygen atoms in two situations (25). One of these atoms is incorporated into the cuprous oxide film, generating vacant cation sites and positive holes (associated with cupric ions), and the other remains in a mobile adsorbed state until trapped at a surface discontinuity. In this state, it retains an exceptional chemical reactivity (as in the oxidation of carbon monoxide at room temperature) which decays with time (21). Discussions of the oxidation of copper, however, are not always conducted in terms of a mechanism involving the O^- radical ion.

This introductory survey provides the minimum background for the theory of copper corrosion in aqueous media which follows.

Oxidation of Copper in Aqueous Media

It is assumed that copper, immersed in an oxygenated aqueous medium, almost instantaneously forms a very thin film of cuprous oxide with a compressed structure fitted to that of the metal. Adherent, self-healing, and complete, it cannot grow in thickness beyond perhaps 20Å before mechanical strains break up its outer regions, and this is thought to occur before an asymptotic stage of growth can be reached. The film therefore never becomes fully protective and oxidation continues, leading at quite an early stage to a porous film of disorganized structure, somewhat loosely adherent to the compact, underlying layer, which is imagined to be constantly regenerated. It is further assumed that film growth is based primarily on dissociative adsorption of dissolved oxygen and passage outward through the film of cuprous ions and electrons. Without any implications as to detailed mechanism, and purely for the sake of simplicity, this may be represented

$\frac{1}{4}O_2 + e^- = \frac{1}{2}O^{2-}$ occurring at the outer surface of the film

$Cu = Cu^+ + e^-$ at the inner surface, followed by outward migration of cuprous ions and electrons

$Cu^+ + \frac{1}{2}O_2^- = Cu_2O$ at the outer surface

Thermodynamic Treatment

Taking a thermodynamic view of the corroding system, it is seen that between the extremes of the fully reduced substrate, metallic copper, and the fully-oxidized, aggressive reactant, oxygen, there is the possibility of various redox systems, one or another of which may be close to equilibrium. The least oxidized of these is the Cu, Cu_2O couple, which, in aqueous solution free from dissolved copper, would confer on the metal phase a potential of

$$E_{Cu,Cu_2O,H^+} = 0.471 - 0.0592\ pH \quad \text{abs. V}$$

at 25°C. The most oxidized is the oxygen electrode equilibrium which, for a gaseous mixture typically used in the corrosion experiments described in the preceding paper (0.30, 0.30, and 0.40 atm, respectively, of O_2, CO_2, and N_2), has a potential of

$$E_{O_2(0.30\ atm),H^+} = 1.222 - 0.0592\ pH \quad \text{abs. V}$$

This is much more positive than any potential encountered in the Cu, H_2O, O_2 system within the relevant pH range, corresponding with the fact that completion of corrosion would oxidize all the copper to the cupric state. There must therefore be a considerable oxidation gradient within the corroding system, no doubt mainly, if not exclusively, confined to a number of oxidation jumps, at the biggest of which rate limitation is likely to occur.

Oxidation beyond the cuprous state probably begins in the film itself, in virtue of the capacity of cuprous oxide to take up excess of oxygen. This is

unlikely to proceed far, as long as electrical contact with the copper substrate is preserved and, because the conductance of the oxide increases with its departure from stoichiometry, there may be a kind of automatic regulation of the state of oxidation of the film; the more it becomes oxidized, the better able is the copper substrate to keep it reduced. But the electrical resistance of the film is bound to increase as it grows, particularly when it begins to break up. This may allow the potential of the copper to deviate somewhat toward that of the Cu, CuO couple, namely

$$E_{Cu,CuO,H^+} = 0.570 - 0.0592\ pH \qquad \text{abs. V}$$

Certainly, oxidation of the film is thermodynamically favored, since

$$\tfrac{1}{2}Cu_2O + \tfrac{1}{4}O_2 = CuO; \qquad \Delta G^\circ = -12.9 \text{ kcal}$$

and so is subsequent dissolution

$$CuO + 2H^+ = Cu^{2+} + H_2O; \qquad \Delta G^\circ = -10.8 \text{ kcal}$$

There is no reason why cupric oxide should be formed as an intermediate between these reactions occurring consecutively. Combined, they give

$$\tfrac{1}{2}Cu_2O + \tfrac{1}{4}O_2 + 2H^+ = Cu^{2+} + H_2O; \qquad \Delta G^\circ = -23.7 \text{ kcal}$$

This is regarded as the primary dissolution reaction, which could occur reversibly in the cell

$$Pt \mid Cu_2O, Cu^{2+}, H^+ \mid\mid H^+ \mid O_2$$

The potential of the left-hand electrode would be

$$E_{Cu_2O,Cu^{2+},H^+} = 0.203 + 0.0592\ pH + 0.0592 \log (Cu^{2+}) \qquad \text{abs. V}$$

For relevance to the Cu, H_2O, O_2, CO_2 system, the last two reactions should be combined with

$$2CO_2 + 2H_2O = 2H^+ + 2HCO_3^-; \qquad \Delta G^\circ = 21.3 \text{ kcal}$$

to give the corrosion reactions, with their much less negative standard free energy changes, previously discussed (Part I).

These electrochemical considerations may be applied to the model of the corroding system, illustrated in Fig. 1, arising out of the preceding discussion.

Duplex Film Corrosion Model

The copper substrate is covered by a compact, adherent film of cuprous oxide, in good electrical contact with it. Superimposed on this is a porous film, formed in the corrosion process by the disruption of the growing film underneath it. This disruption must be accompanied by a large increase in the resistance

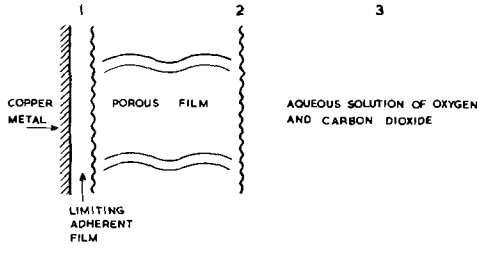

Fig. 1. "Duplex film" model of the copper corrosion system

of the electrical path between the metal and the partially broken away oxide. It is unlikely, however, that this resistance will become infinite, for any oxide which became insulated from the metal would either fall off, or dissolve quite rapidly, as free cuprous oxide has been shown to do (Part I). Thus, even the porous film remains to some extent under the influence of the copper substrate because of a significant electrical conductance of the film, over and above that of the aqueous phase which permeates it.

Attention is directed to the potentials at the three "zones," or locations, indicated in Fig. 1. The first of these is to be identified with that of the copper phase, acting as part of a copper-cuprous oxide couple. The second and third may be regarded as the potentials which would be recorded by hypothetical redox probes, appropriately situated. In so far as it is electronically conducting, the substance of the porous oxide film can assume a potential related to electrochemical reactions which may occur at its surface. The "probes" and the separation of zones 2 and 3 in space are devices introduced in the interests of clarity.

Ideally, these potentials would be

$$\left.\begin{aligned} E_1 &= 0.471 - 0.0592\ pH \text{ at zone 1} \\ E_2 &= 0.203 + 0.0592\ pH \\ &\quad + 0.0592 \log (Cu^{2+}) \text{ at zone 2} \\ E_3 &= 1.222 - 0.0592\ pH \text{ at zone 3} \end{aligned}\right\} \text{abs. V at } 25^\circ\text{C}$$

as previously enumerated. In the very early stages of corrosion when only the thin, compact film has been formed, zone 2 coincides with zone 1, and E_2 must be identical with E_1. Under these conditions, it can be shown that at $pH = 4$, the equilibrium concentration of cupric ions in solution is 21 ppm, but is diminished by a factor of two powers of ten for each unit rise of pH. This indicates that there will be little tendency for dissolution to occur, except at quite low pH values. The development of an appreciable rate of dissolution must wait upon the growth of sufficient resistance between the copper and the surface of the dissolving film. This provides an interpretation of the induction periods reported in both preceding papers, and the behavior of "new" electrodes placed in "old" solution in the second kind of replacement experiment described in Part II.

Consideration may next be given to the case in which extensive corrosion has proceeded, with formation of cupric ions in solution and establishment of the suggested "duplex film." If it is supposed, by way of example, that the solution is at $pH = 5$ and contains 20 ppm of cupric ions, the potentials at the three zones will be

$$E_1 = 0.175; \quad E_2 = 0.292; \quad E_3 = 0.926 \text{ abs V at } 25^\circ\text{C}$$

except that E_2 may be somewhat depressed toward E_1.

The primary dissolution process, which is imagined to occur at the hypothetical electrode at zone 2, is

$$\tfrac{1}{2}Cu_2O + H^+ = Cu^{2+} + \tfrac{1}{2}H_2O + e^-$$

while

$$\tfrac{1}{4}O_2 + H^+ + e^- = \tfrac{1}{2}H_2O$$

occurs at the imaginary oxygen electrode at zone 3.

These two, added together, give the complete dissolution reaction

$$\tfrac{1}{2}Cu_2O + \tfrac{1}{4}O_2 + 2H^+ = Cu^{2+} + H_2O$$

But zones 1 and 2 together constitute a cell which is, moreover, a working cell because the electronic conductance of the film is equivalent to an external, resistive connection between the electrodes. At 1 an anodic reaction proceeds

$$Cu + \tfrac{1}{2}H_2O = \tfrac{1}{2}Cu_2O + H^+ + e^-$$

which will supply electrons to 2 and bring about the reverse of the dissolution reaction, *i.e.*, the cathodic process

$$Cu^{2+} + \tfrac{1}{2}H_2O + e^- = \tfrac{1}{2}Cu_2O + H^+$$

The electrode process at zone 1 may be regarded as the normal, primary film growth mechanism as it occurs in an aqueous medium, for, added to the cathodic process at zone 3, it gives

$$Cu + \tfrac{1}{4}O_2 = \tfrac{1}{2}Cu_2O$$

It is, however, no longer directly depolarized by elementary oxygen, but by cupric ion acting as an intermediary. This is no doubt why no sign of concentration polarization of dissolved oxygen has been found in any of the corrosion experiments, even when thick, porous films have been formed.

The cathodic reaction at zone 2 has the effect merely of diminishing the net anodic dissolution which occurs there, for electrode 2 is the anode with respect to 3 as cathode. At the same time, however, it provides more cuprous oxide at the expense of cupric ion and thus ensures that dissolution and film growth reactions remain in step with each other. It may also be regarded as a secondary film forming reaction, which generates cuprous oxide elsewhere than at the outer boundary of the compact film. Such a process is required to explain why even the thickest films are essentially composed of nothing but cuprous oxide. It may also be important that the rise in pH which accompanies the net anodic dissolution at zone 2 will facilitate the generation of cuprous oxide at zone 1 in the close vicinity. This reaction scheme may be clarified by the formal illustration of the hypothetical double cell given in Fig. 2.

The rise in pH and cupric ion concentration, which accompanies corrosion, might be expected to cause a decrease in dissolution rate with time, but this is observed not to be the case. This is because film growth proceeds in step with dissolution, and film thickening allows the potential at zone 2 to become more positive, thus counteracting any tendency for the rate to fall away. When, however, the film becomes very thick, its worsening electrical conductance favors dissolution rather than film growth; this trend was observed in the first kind of "replacement experiment" described in the preceding paper. Ultimately, with a runaway dissolution reaction, the pH may rise so high close to the outer surface of a thick film that basic carbonate is formed. If the corroding medium is a natural water containing calcium bicarbonate in solution, calcium carbonate may be deposited. It is to be noted, however, that this is likely to occur only on a cuprous oxide film that is already thick, porous, and rather loosely attached to its substrate; a calcium carbonate film laid down on such a foundation is unlikely to have the adhesion and cohesion necessary to confer good protection. This may be associated with the fact that copper pipes, even when conveying such hard waters, often continue for years to send copper into solution; nevertheless calcium carbonate films, consolidated by traces of organic material, can afford a marked degree of protection, even if not complete protection.

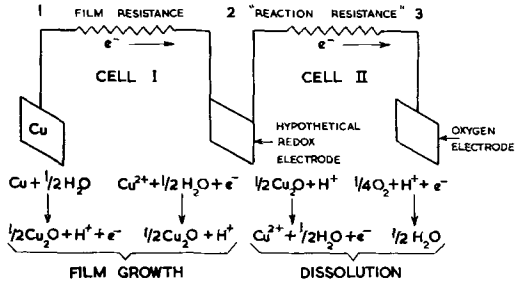

Fig. 2. Hypothetical double cell involved in copper corrosion

Rate Limitation of the Corrosion Reaction

The final contribution to this theory of copper corrosion is concerned with over-all rate limitation. It has already been shown that this does not reside in oxygen diffusion, even through the pores of a thick film. The suggestion is made that it is due to hindrance of the oxygen electrode reaction, which must occur at some solid-solution interface at a rate proportional to the exponential factor familiar in electrode kinetics, $\exp -(\omega - \alpha VF)/RT$, where ω is an activation energy, α is a transfer coefficient probably much less than 0.5, and V is a potential difference effective in promoting reaction. If V can be identified with the difference between the oxygen and copper-cuprous oxide potentials

$$E_{O_2,H^+} - E_{Cu,Cu_2O,H^+} = 0.759 + 0.0148 \log P_{O_2}$$

abs. V at 25°C

a possible basis is obtained for the observed first order kinetics with respect to oxygen, although this is likely to be a gross oversimplification.

Even if the theory of general corrosion of copper which has been proposed is along the right lines and uniquely explains some otherwise puzzling features, it cannot at present be extended without unwarrantable speculation, because it is obviously incomplete. Two outstanding defects may be mentioned.

Carbon dioxide has been treated merely as a component of a buffer system controlling pH, whereas it is quite strongly adsorbed from aqueous solution by cuprous oxide (cf. Part IV) and may play a far more intimate part. This is all the more likely in view of the observation (26) that cuprous oxide adsorbs carbon dioxide from the gas phase only if oxygen is simultaneously, or has been previously, adsorbed. This cooperative process leads to the formation of a reactive CO_3 complex.

It is highly probable that the reduction of oxygen proceeds *via* the formation of hydrogen peroxide or its derivatives, for this is almost invariably the case (27) and is a tolerable certainty if the radical

ion O^- is involved. Delahay (28) has shown that hydrogen peroxide is almost always formed when oxygen is cathodically reduced, even at copper electrodes; the yield is small in this case because of catalytic decomposition, but this might in itself indicate functional participation in oxidation mechanism. The Russell effect (29) has been re-investigated and has been shown to be due to the formation of hydrogen peroxide by the action of moist air on abraded metals (30, 31); it is attributed to the abnormal availability of electrons trapped in anion vacancies in freshly formed or disrupted oxide films (32). It is claimed that hydrogen peroxide has been detected in the vicinity of, *inter alia*, atmospherically corroding copper (33). The case for the formation and probable participation of hydrogen peroxide in the corrosion of copper is therefore quite strong, and there is also evidence (34) that it could cooperate with carbonic acid in a special way. The possible significance of this to corrosion problems has been noted (35).

Manuscript received Oct. 2, 1961; revised manuscript received Jan. 23, 1962. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Copper Corrosion

IV. The Effects of Saline Additions

D. J. G. Ives

Department of Chemistry, Birkbeck College, London, England

and A. E. Rawson

Colne Valley Water Company, Watford, Hertfordshire, England

ABSTRACT

The effects on the corrosion of copper, under the influence of dissolved oxygen and carbon dioxide, of trace additions of salts have been studied. In the case of chloride ion, radical changes in the kinetics of dissolution and film growth processes have been observed and have been interpreted in terms of a transition from general to local action corrosion. The effects of sulfate, nitrate, and bicarbonate ions are also reported. The influence of calcium bicarbonate, under conditions which preclude the deposition of calcium carbonate, in retarding corrosion is particularly noteworthy.

A study has been made of the effects on corrosion reactions in the Cu, H_2O, O_2, CO_2 system of the ions Cl^-, SO_4^{2-}, NO_3^-, and HCO_3^- (as the sodium salts) and of HCO_3^- (as the calcium salt) at concentrations in which they may occur in natural waters. The "powder method" of Part I was first used to explore the influence of these ions on rates of dissolution of cuprous oxide and of copper. This was followed by

kinetic studies of concurrent dissolution and film growth reactions by the method of Part II. In all cases, experiments were accompanied by salt-free controls in which all other conditions were identical.

Results

Preliminary Powder Experiments

Dissolution was followed in each case for 3 hr in solutions (or water in the controls), at 24° ±2°C, kept in equilibrium with analyzed mixtures of oxygen and carbon dioxide at a total pressure slightly in excess of atmospheric.

Cuprous oxide dissolution.—For cuprous oxide, a qualitative report is adequate. Sodium chloride (100 ppm of Cl^-) produced a marked acceleration of dissolution; the rate was approximately doubled near the mid-point of the gas composition range. Even 50 ppm of chloride ion produced about 30% increase in rate under these conditions. That this remarkable effect was specific to chloride ion was shown by the complete lack of influence of 100 ppm of sulfate or nitrate ion on dissolution rate. Both sodium and calcium bicarbonates depressed the rate of dissolution markedly, but to an extent commensurate with the rise in pH which they produced. Although in no case was equilibrium approached, it may be recollected that the equilibrium concentration of cupric ion is decreased by two powers of ten for each unit rise of pH (cf. Part III). It may be noted that, for the case of calcium bicarbonate, the Langelier (1) saturation index varied between −1.6 and −2.0, which ostensibly precluded the deposition of calcium carbonate.

Metallic copper dissolution.—The results of the copper powder experiments are summarized in Fig. 1, in which each small-scale plot of the course of a dissolution run is disposed along a gas-composition axis to define the conditions under which it was carried out. The broken curves, which are all approximately rectilinear, represent the parallel control runs. Each curve was characterized by a minimum of seven analytical determinations of dissolved copper.

It is evident that these very low concentrations of salts (~0.001 — 0.002 g equiv l^{-1}) have surprisingly marked and variable effects on the dissolution of copper under the influence of dissolved oxygen and carbon dioxide. Perhaps the most outstanding effect is that of chloride ion in destroying constancy of dissolution rate; comparison with the appropriate controls indicates an initial acceleration of attack on the metal (particularly in darkness), followed by retardation, the latter making its appearance at an earlier stage in the more oxygenated systems. Conversely, the acceleration effect tends to be more prolonged, and perhaps more marked, in the least oxygenated systems. The other additions seem generally to depress dissolution rate (except that nitrate ion increases it at low P_{O_2} values) while usually maintaining its constancy. A very marked degree of passivation is attained in the presence of calcium bicarbonate in the least oxygenated solutions, but again a negative Langelier index suggests that this cannot be due to calcium carbonate deposition. The effects of illumination have not been systematically studied, but are in some cases seen to be considerable. It is suggested that the powder technique by which these results were assembled may be valuable for the rapid assessment of the corrosive or inhibitory properties of aqueous solutions on metals, for the indications obtained were generally confirmed subsequently. Nevertheless, significant color changes of the copper

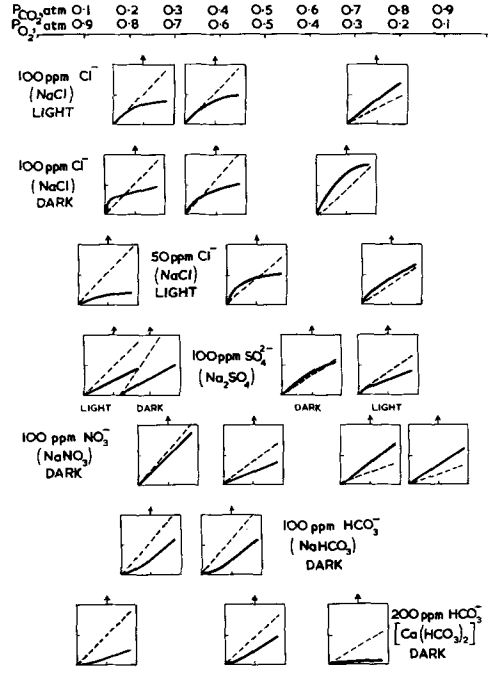

Fig. 1. Dissolution of Cu powder in water containing added salts, approximately at the concentration (ppm) indicated, equilibrated with mixtures of O_2 and CO_2 to a total pressure of 1 atm. Each plot is appropriately placed along the common gas composition axis, and has the same scales of abscissas (0-200 min) and ordinates (0-20 ppm of Cu^{2+}). Broken lines indicate salt-free control experiments.

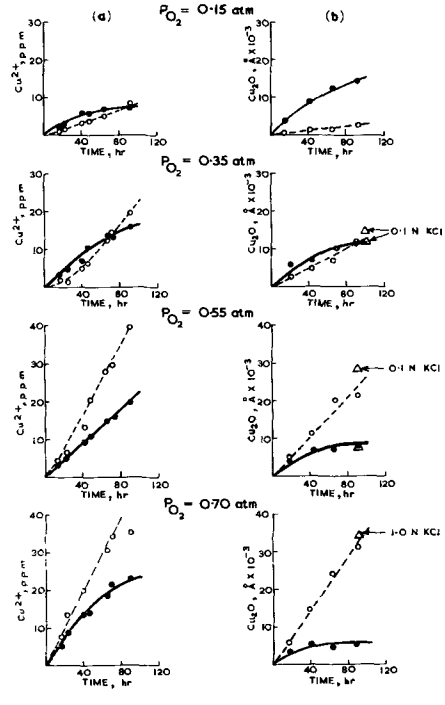

Fig. 2. Corrosion experiments showing influence of approximately 100 ppm Cl^- (NaCl); P_{CO_2} = 0.30 atm (const.), P_{O_2} = 0.15-0.70 atm, P_{N_2} = (1.00 — P_{O_2} — P_{CO_2}) atm, (a) dissolution, (b) film growth. Broken lines indicate salt-free control experiments.

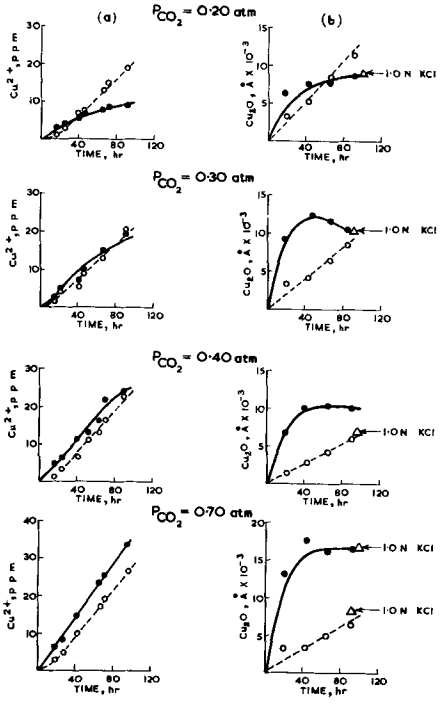

Fig. 3. Corrosion experiments showing influence of approximately 100 ppm Cl^- (NaCl); P_{O_2} = 0.30 atm (const.), P_{CO_2} = 0.20-0.70 atm, P_{N_2} = (1.00 — P_{O_2} — P_{CO_2}) atm, (a) dissolution, (b) film growth. Broken lines indicate salt-free control experiments.

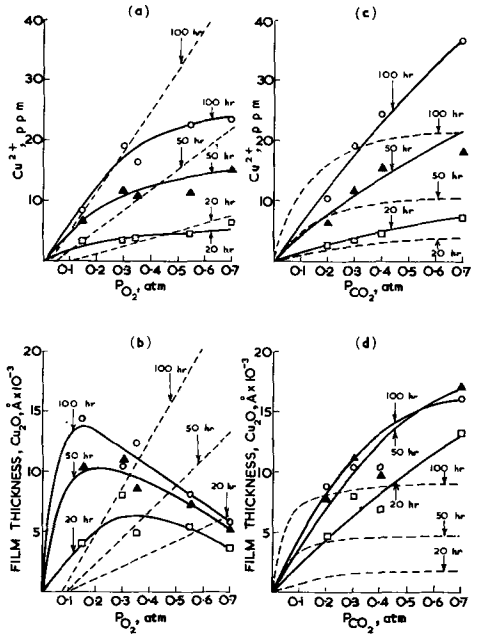

Fig. 4. Collected results of corrosion experiments involving the presence of approximately 100 ppm Cl^- (NaCl); (a) and (b) dissolution and film growth, respectively, for P_{CO_2} = 0.30 atm (const.); (c) and (d), the same for P_{O_2} = 0.30 atm (const.). Broken lines indicate salt-free control experiments.

powder during the course of dissolution indicated the need for film formation studies.

Rates of Dissolution and Film Growth

The same two sets of conditions were used as in the studies of salt-free systems described in Part II; P_{CO_2} then P_{O_2} were successively fixed at a value of 0.30 atm while the other was varied, the total pressure being made up to 1 atm with nitrogen when necessary. Each kinetic run was continued for 100 hr at 21° ±2°C.

Sodium chloride additions.—The results for systems containing 100 ppm of chloride ion as sodium chloride are shown in Fig. 2 and 3, the simultaneous controls being represented by broken lines. Three observations can be made immediately. Chloride ion does not always promote corrosion; on the contrary, it sometimes retards it. Rates of dissolution and film growth are no longer constant, but show a tendency to decrease with time, so that sometimes an initial activation of corrosion passes sooner or later to inhibition. There is obviously no longer a general relation between the kinetics of dissolution and film growth, except the tenuous one that the highest rate of dissolution was observed for the system in which the thickest film was developed. The main features of the results are summarized in Fig. 4, which contains plots of the copper concentrations in solution and the film thicknesses attained after 20, 50, and 100 hr of corrosion time, together with similar data for the controls, shown by broken lines. Although, even in these averaged data, the scatter is very large, it is clear that the almost dramatic effects of only 100 ppm of chloride ion are not obscured; the kinetics of the corrosion reactions are greatly changed, and the only regularity previously observed (first order kinetics with respect to P_{O_2}) has gone.

Comparison of Fig. 4(a) and 4(c) suggests a reversal of the kinetic roles of oxygen and carbon dioxide, *i.e.*, that in presence of 100 ppm of chloride ion, first order kinetics of dissolution with respect to oxygen has been replaced by first order kinetics with respect to carbon dioxide. A similar trend is less convincingly shown by comparison of Fig. 4(b) and 4(d) relating to film growth. It is not known if anything can be made of this, promising as it may appear in elucidating the role of carbon dioxide. The case for giving significance to this observation is weakened by the lack of relation between rates of dissolution and film growth, by the evidence which follows for a transition of corrosion mechanism, and by the great deterioration in reproducibility of physical conformation of the corroding system. It is felt that very careful and detailed studies would be needed to arrive at a decision on this point.

The main effects of chloride ion can perhaps best be seen by a formal tabulation, where acceleration or retardation of dissolution and film growth are indicated by + and — signs.

Acceleration (+) or retardation (—) of dissolution (D) and film growth (F) produced by 100 ppm of Cl^-

		D	F
P_{CO_2} const.	low P_{O_2}	+	+ +
	high P_{O_2}	—	— —
P_{O_2} const.	low P_{CO_2}	—	—
	high P_{CO_2}	+	+

Still more generally, increase of P_{O_2} has a relatively depressing effect on both dissolution and film formation; increase of P_{CO_2} has a relatively stim-

ulating effect. Perhaps the most significant observation of all is the complete breakdown of the kinetic relationship between dissolution and film growth.

Other diagnostic observations which were made may be enumerated.

The films, mainly red or red-brown in color, with sometimes greenish or purple areas, were less uniformly deposited. They were flocculent and loosely adherent, suggesting an enhanced degree of structural disorder. In some cases loss of film substance unavoidably occurred before coulombic estimation could be effected, and this is thought to be the reason for the apparent decrease in film thickness with time which was sometimes observed for the thickest films (cf. Fig. 3). This effect may be associated with the enhanced rate of dissolution of cuprous oxide in presence of chloride ion (already noted), with the effect of this ion upon a bed of cuprous oxide (reported below), and with the peptizing action reported by Gatty and Spooner (2) and the general facility of chloride ions in penetrating oxide films noted by Evans (3).

The coulometric film analysis method was insensitive to cuprous chloride in a film consisting essentially of cuprous oxide, but chemical analysis indicated the presence in the film substance of 0.7-1.5% of chloride. Although it has been shown (4) that atacamite may be present in films formed on copper in chloride solutions, it is unlikely that this was the case in films formed from solutions so dilute in chloride ion as ours. This basic cupric chloride would almost certainly have to appear as a discernible, separate phase, and the evidence is that when this does occur under our experimental conditions it is malachite which appears, not atacamite. These conditions were also outside the range of those required for stability of cuprous chloride as a solid phase (5), and it is therefore regarded as justified to regard the films as consisting of cuprous oxide, perhaps somewhat contaminated.

"Chromatographic" experiments with cuprous oxide columns, using solutions kept in equilibrium with standard pressures of oxygen and carbon dioxide ($P_{O_2} = P_{CO_2} = 0.30$ atm) indicated strong chloride ion adsorption, which also considerably reduced the adsorption of carbon dioxide, observed to take place from salt-free aqueous solution. Further, the chloride ion had a marked effect on the cuprous oxide column, causing a lightening of color, with a loosening and disruption of the bed, which led to channelling. In long-term experiments of this kind, the upper regions of the column were converted to malachite, identified by x-rays. Chloride ion caused this conversion to extend to a much lower level in the column.

Films formed on copper in chloride-containing solutions were punctured by tiny holes, revealing bright spots of apparently bare metal. This was not observed in any salt-free control experiment.

These results, taken as a whole, seem to justify the following tentative interpretation of the influence of chloride ion on copper corrosion.

It is suggested that chloride ion is incorporated to a limited extent into the growing cuprous oxide film. If Cl^- is substituted for O^{2-}, the deficiency of negative charge is likely to promote the formation of a vacant cation site. This may initially increase the ionic conductance of the film and accelerate the general corrosion reactions, both dissolution and film growth. It is also likely to lead to a more disrupted and porous film in which cracks and fissures may more readily develop, exposing the lower layers to easy access of the solution phase. This opening up process may have several consequences, as follows.

There may be a switch from general to local action corrosion and, perhaps, eventually to pitting corrosion. Local anodic dissolution, $Cu \rightarrow Cu^{2+} + 2e^-$ supervenes, at exposed bare sites, from the anodic process which previously could only occur at the metal-oxide interface. The existing film in the vicinity has a much higher electronic than ionic conductance (all the more if the cuprous oxide has acquired n-type characteristics), and assumes a predominately cathodic function, $\frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2\ OH^-$ occurring at its outer surface. This short-circuits the normal film growth mechanism, so that film growth practically stops. At the same time, the considerable increase in pH which now takes place at areas of film surrounding the anodic cavities, which are exuding cupric ions, favors the deposition of basic carbonate. This view is supported by the behavior of copper strips left corroding in very dilute, aerated salt solutions for many months. A uniform and often very beautiful red layer of cu-

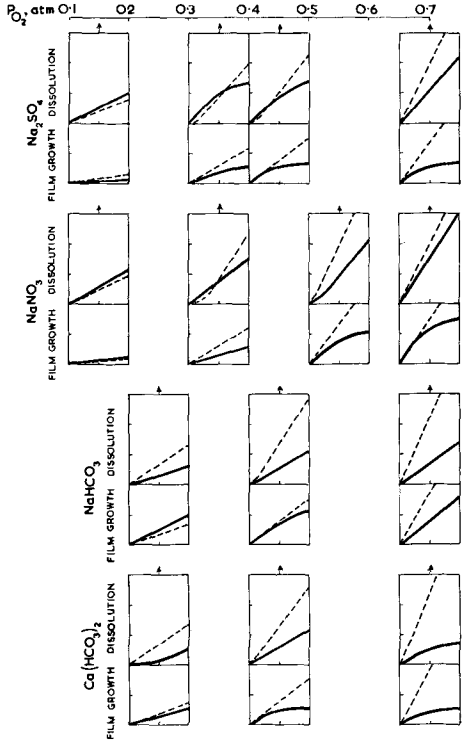

Fig. 5. Graphical summary of corrosion experiments involving the presence of approximately 100 ppm of SO_4^{2-}, NO_3^-, HCO_3^- as Na^+ salts and of approximately 200 ppm of HCO_3^- as Ca^{2+} salt, $P_{CO_2} = 0.30$ atm (const.), $P_{O_2} = 0.15$-0.70 atm, etc. The pairs of plots (upper, dissolution; lower, film growth) are appropriately placed along the common gas composition axis and have the same scales of abscissas (0-100 hr) and of ordinates (0-30 ppm of Cu^{2+} or 0-20Å x 10^{-3} thickness of Cu_2O film). Broken lines indicate salt-free control experiments.

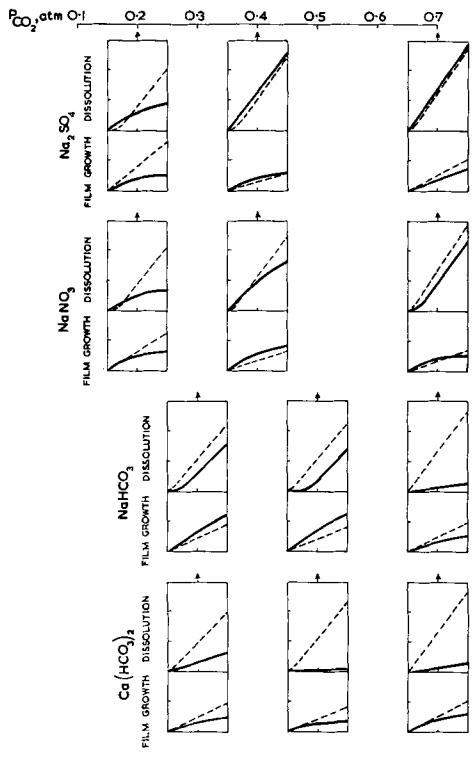

Fig. 6. As for Fig. 5 except that P_{O_2} = 0.30 atm (const.), P_{CO_2} = 0.20-0.70 atm, etc.

prite is overlaid by brilliant green islands of malachite. These have the appearance of having grown outward, over the cuprous oxide, from centers at which anodic pits may well have been located.

The effect of penetration of the aqueous phase into the porous film may be critically dependent on their respective conductances; if the solution is well-conducting, this will again have a short-circuiting effect and promote the switch to local action. On the other hand, if the solution is highly oxygenated, this may lead to a recrudescence of the primary film-forming process, with a corresponding tendency toward passivation by the sealing up of cracks and pores. Examples of the promotion of passivity by a sufficiently high concentration of dissolved oxygen are available (6). This is no doubt why a generally depressing effect of increasing oxygen partial pressure on corrosion is found in these particular systems.

In review, it is suggested that the main effects which have been observed are intelligible in terms of a rather delicate balance between general and local action corrosion, the latter taking over from the former sooner or later under the influence of added chloride with, however, a tendency to reversion in the more highly oxygenated systems.

Other saline solutions.—The effects of the addition of salts other than sodium chloride are summarized in Fig. 5 and 6, which are arranged similarly to Fig. 1. The information they contain may be supplemented by the observations that sulfate ion is strongly adsorbed from solution by cuprous oxide, but that nitrate and bicarbonate ions are not. Surprisingly, however, calcium bicarbonate shows strong adsorption. It may also be relevant to note that copper corrosion in the presence of 100 ppm of nitrate ion as sodium nitrate is accompanied by formation of traces of nitrite (Griess-Ilosvay reaction; 0.006-0.024 ppm).

Detailed interpretation of these results is not practicable at the present stage, and the main purpose must be to place them on record, for they demonstrate further the very large effects which trace concentrations of added salts may have on corrosion processes. The very remarkable passivating effect of calcium bicarbonate under certain conditions is worthy of special attention. Only partly due to a pH effect (largely shared by sodium bicarbonate), it cannot be due to deposition of calcium carbonate. Attention is also drawn to the possibility of establishing a criterion for the existence of general corrosion, as opposed to local action corrosion, of copper. It is the retention of constancy of rates of dissolution and of film growth.

Electrochemical Dissolution of Single Crystalline Copper

Leslie H. Jenkins and James O. Stiegler

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[1]

ABSTRACT

Galvanostatic studies of single crystal copper anodes in oxygen-free, 0.2M copper sulfate solutions revealed discontinuities in the curves resulting from a plot of electrode overpotentials *vs.* current density. Using observations of changes in electrode surface topography as supporting evidence, the discontinuities were explained on the basis of dissolution processes which were related to the defect structure of the electrode.

Since the early work of Glauner and Glocker (1) on the difference in chemical dissolution rates of the different crystallographic faces of copper crystals, similar effects have been noted for electrochemical dissolution. Early in his studies of anodic polishing of metals, Jacquet (2) established that, under certain conditions of current density and voltage, a difference in the reactivity of grain boundaries and other surfaces of copper polycrystals undergoing anodic dissolution in phosphoric acid could be demonstrated, and Bakish and Robertson (3) observed a potential difference between grains and grain boundaries in polycrystalline copper.

An orientation dependence of electrochemical dissolution of single crystalline copper in acidic copper sulfate was demonstrated by Leidheiser and Gwathmey (4), who also determined that the potential differences between different crystalline faces in their systems were changed by the presence of dissolved oxygen in the solution. The variation of equilibrium potential with crystallographic orientation of single crystalline copper in acidic copper sulfate was studied by Tragert and Robertson (5). They concluded that the (111) was the only truly stable surface in the system investigated. Faizullin and co-workers (6) observed a difference in the current density-potential relationships of anodes containing oriented and nonoriented copper deposits. More recently Piontelli's group has collected current-potential data for the low index faces of copper anodes (7) as well as hydrogen overvoltages on the same orientations (8).

The use of single crystals to study dissolution processes generally has two advantages: (i) the effect, if any, of crystallographic orientation of the reacting surface can be observed; (ii) if the defect structure of the metal affects the dissolution process, the effect is often more easily observed on single crystalline surfaces. It is generally assumed that anodic processes involving the dissolution of an ion from a metallic single crystal into a solution containing the metal ions of interest is most difficult at a theoretical, atomically smooth, close-packed surface. The most reactive site is assumed to be at a kink in a step on the surface, and the next most reactive site is at the straight step edge. Screw dislocations intersecting the surface may be considered sources of steps, but since it is very rare that a difference in reactivity between edge and screw dislocations can be observed on metal surfaces (9), it is reasonable to consider the points where all line defects intersect the surface as reaction sites which are less active than step edges but more active than the idealized flat surface. This paper demonstrates that under certain conditions these assumptions are reasonable for (100) oriented surfaces of copper single crystals undergoing galvanostatic dissolution in acidic solutions of copper sulfate.

Experimental

Materials.—Copper single crystals, 0.1 x 1 x 7 cm, of (100) orientation on the 7 x 1 cm area were grown from 99.999% metal, supplied by American Smelting and Refining Company, by seeding from the melt in graphite crucibles. From these crystals two samples, 0.1 x 1 x 3 cm, were carefully cut with a jeweler's saw and a 1/16 in. diameter hole drilled in one end of the crystal. The specimens were then chemically polished on a polishing wheel with a $CuCl_2$-HCl solution. Details of this operation have been discussed by Young and Wilson (10). Finally, the crystals were electropolished (usually ~ 40 min) to a smooth, bright finish in a phosphoric acid bath. Then in the manner recommended by Young and Gwathmey (11), they were rinsed in dilute H_3PO_4, washed in running distilled water, and dried in a jet of oxygen. Chemical polishing was necessary only to remove minor grown-in topographic irregularities (due to the graphite molds) in the surface of interest or to obtain a flatter surface over the entire crystal after the edges of the sample had become excessively rounded from repeated electropolishing. Usually, a crystal could be electropolished and used to obtain data about three times before another chemical polish was judged to be necessary.

With the one exception noted below, all the water used in these studies, both for preparation of solutions and for washing crystals, was prepared by distilling demineralized water through a tin-lined still. The storage reservoir for water was of seasoned polyethylene.

Hydrogen was purified by passing commercial tank gas over hot copper, then through magnesium perchlorate drying towers. Oxygen-free hydrogen saturated with water vapor was obtained by bypassing the drying towers and bubbling the gas through a series of three fritted glass disks in gas washing bottles.

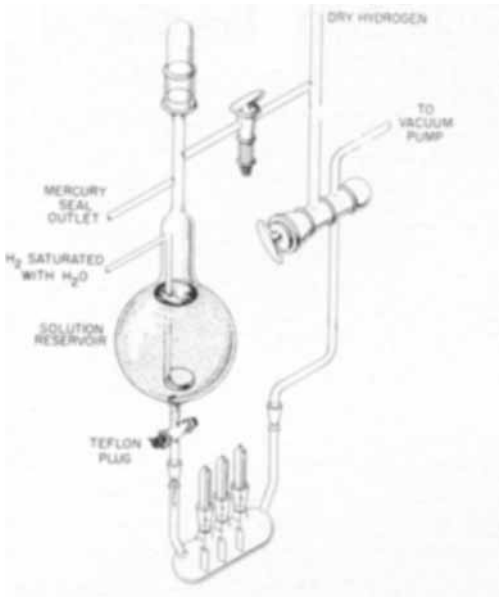

Fig. 1. Portion of filling rack with reaction cell

Two types of copper sulfate solutions were prepared. One was made from material obtained by dissolving a weighed sample of 99.999% copper in excess reagent grade nitric acid. The resulting mixture was then evaporated in excess reagent grade sulfuric acid until free of nitric acid. Water for these solutions was prepared by triply distilling water from the polyethylene reservoir in an all-quartz apparatus. One distillation was from alkaline permanganate solution. Other solutions were prepared from reagent grade $CuSO_4 \cdot 5H_2O$. All the solutions used in this study were 0.2M in $CuSO_4$ with *p*H adjusted to 1.0 with H_2SO_4. Approximately half the data presented here were obtained from solutions of the first type. However, identical results were obtained both for surface effects and current-potential relationships regardless of which solutions were used.

After introducing the solutions into the 2-liter storage reservoir shown in Fig. 1 they were freed of dissolved oxygen in the following manner: After about 20 ft^3 of water saturated hydrogen had been bubbled through a fritted disk in the solution, the reservoir cover cap was momentarily removed, and a polycrystalline bar of ASR copper which had been cleaned in nitric acid and washed for 2 min in running distilled water was quickly immersed in the solution. The cover cap was replaced and about 80 ft^3 of moist hydrogen was passed through the solution at a rate of 10 ft^3 day^{-1}. In this manner, not only was the resulting oxygen-free solution at equilibrium with a hydrogen atmosphere, but also the presence of metallic copper (surface area $\sim$ 15 cm^2) allowed the equilibrium requirements of the following reaction to be satisfied

$$Cu^{++} + Cu^{\circ} \leftrightharpoons 2Cu^{+} \qquad [1]$$

The previous precautions were taken to prevent changes in surface topography of the electrodes resulting from the oxidation and dissolution of the metal by oxygen and/or ions in solution.

Experimental procedure.—The reaction cell was attached to the filling rack as shown in Fig. 1. Three

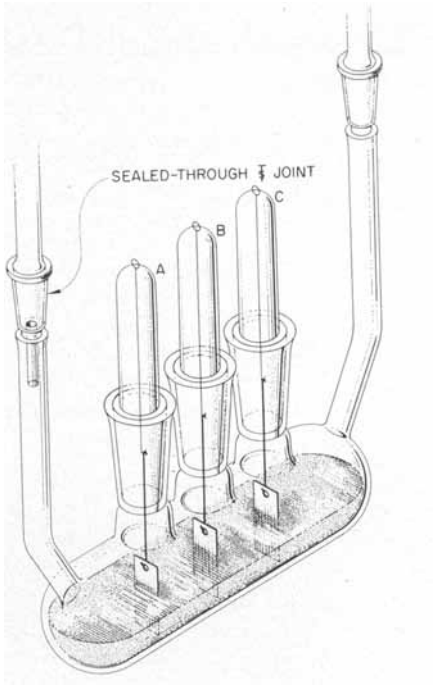

Fig. 2. Reaction cell with electrodes

polished samples of (100) orientation were then suspended from copper hooks which were fabricated from ASR metal. Prior to use, the hooks were cleaned in nitric acid, washed in running distilled water for 2 min, and then air dried. The hooks were attached to platinum wires sealed through the male standard taper joints which were then positioned in the cell as shown in Fig. 2. All joints on the cell were mechanically clamped to help guard against leaks in the system. The cell was alternately evacuated and filled with hydrogen for about 20 cycles, and then the samples were annealed in the dry hydrogen atmosphere overnight at 450°C. During annealing, jets of cooling air were blown over the sample port joints so that their outside temperature never exceeded 50°C. After the 16-20 hr anneal the furnace was removed and the system cooled to room temperature under positive hydrogen pressure. Solution from the rack reservoir was then admitted to the reaction cell until the copper crystals were immersed to a depth of 2 cm. The bottoms of the holes which had been drilled in the crystal were about 5 mm above the solution level. A portable constant temperature bath was then placed about the cell. This procedure permitted data to be gathered from oxide-free, electropolished metal surfaces in chemical equilibrium with oxygen-free, hydrogen-saturated solutions.

All the data reported here were gathered at 25° ±0.1°C under galvanostatic conditions using a 6v dry cell with in-line, fixed resistors as a source of constant current. One copper crystal served as the anode, another as the cathode, and the third as a reference electrode. Potential differences of the working electrodes were measured *vs.* that of the third crystal in the system with a "master-slave" matched pair of vibrating reed electrometers,[2] outputs of which were coupled to Brown recorders so that potential-

[2] The model 31-31 VMS electrometers manufactured by the Applied Physics Corporation of Monrovia, California, permits synchronous reed drive in the two units by the oscillator in the "master" unit.

time relationships were recorded. The small currents used were measured with Weston model 301 DC microammeters which were accurate within 2%. Currents were constant within the accuracy of the meters under all experimental conditions. Although both anodic and cathodic overpotentials were measured, only anodic data are discussed here.

All the tapered joints on the cell were greased with silicone vacuum stopcock grease. The male through joint attaching the solution arm of the filling rack to the cell, as well as the joint on the vacuum side, was lightly greased prior to attaching the cell to the rack. Also, the male joints serving as sample holders were greased near the top just before the samples and joints were inserted in the female entry ports. At the completion of an experiment the apparatus was cleaned of grease by repeated scrubbings with benzene, then acetone. Next the apparatus was scrubbed with alcoholic potassium hydroxide, rinsed with alcohol, and then water. Finally, after soaking in hot nitric acid it was thoroughly rinsed with distilled water. Frequently the alcoholic potassium hydroxide treatment was eliminated without observable effect on the ensuing determinations.

Experimental Results

Anodic current-potential relationships.—The sample ports of the reaction cell were approximately on 3 cm centers making it possible to vary the separation between working electrodes. Data were taken with the electrode surfaces parallel to each other, but at right angles to the long axis of the cell, and with the crystals at ports A and B (Fig. 2) serving as working electrodes. The polarity of the samples at each port was varied each time new assemblies were used. At other times the crystals at ports A and C, again at right angles to the long axis of the cell, served as working electrodes. In the latter series the reference electrode at port B was parallel to the long axis of the cell. Also, other cells of different design which allowed working electrode separations of 1 and 2 cm were used. These cells are discussed more fully below. No differences in potential-current (η *vs.* i) relationships or surface effects due to changes in cell geometry could be found.

At equilibrium, the potential differences of the three electrodes were almost always zero. Occasionally, immediately after exposure to the solution, a difference which never exceeded 0.1 mv and which rapidly decayed to zero was observed. To demonstrate that these systems were at chemical equilibrium and that, therefore, there were no changes in electrode surface topography due to reaction [1], and also to determine if there were similar effects resulting from the reasonably large exchange current densities reported for systems such as these (12), several different assemblies were allowed to stand for various periods up to 8 days. During these times, in which no current was passed through the system, no potential differences were observed, nor were any changes in surface topography such as faceting, etc., detected when the samples were removed from the solutions and surface replicas observed with the electron microscope. It was concluded that, from the standpoint of surface topography, the system was in a state of at least metastable equilibrium.

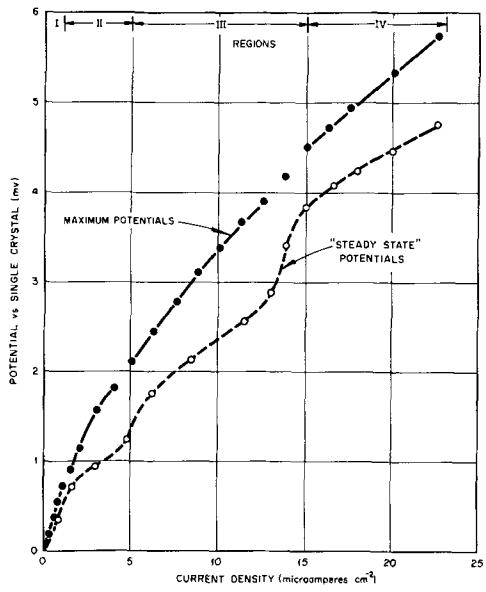

Fig. 3. Experimental current-potential data at 25°C in 0.2M $CuSO_4$, pH adjusted to 1.0 with H_2SO_4.

Anodic overvoltages, resulting from the passage of current through the system, were characterized by initial maxima, the build-up times of which were functions of the current densities applied. At the lower current densities studied, ~ 0.5 μa cm^{-2}, the build-up times were 2-3 min while at the relatively high current density of ~ 20 μa cm^{-2} the time was 6-8 sec. After the maxima were established, anodic potentials rapidly decayed to about 70-80% of the peak values. They then decreased very slowly with time as long as current was passed through the system. A typical plot of these quasi-steady-state, post-maxima potentials are shown as a function of applied current density in Fig. 3. The inflections in the curves always occurred at the same current densities, but the values of the corresponding potentials varied widely from one assembly to another.

In most assemblies the applied current was interrupted as soon as possible after the maxima had been established so as to minimize surface changes due to pitting and faceting. The anodic potentials then decayed slowly to the initial zero value. At current densities of approximately 7 μa cm^{-2} this usually required 15-20 min. At higher current densities, and correspondingly higher potentials, the decay, in addition to being slower, was characterized by a minimum value which was more negative than the reference crystal. The minima were never observed to be more than —0.7 mv and may have been present, although too small to be observed, at lower current densities. This behavior led to decay times of as much as 2 hr at the highest current densities studied before the anode regained equilibrium potential.

In any one assembly the maximum anodic potential values were reproducible within 3% if the current was quickly interrupted after the maxima were attained, and if true equilibrium had been es-

tablished before current was again applied. However, at a given current density, maximum potential values varied as much as 20% from system to system, but in all cases discontinuities in the η_{max} *vs.* i curves occurred at the same current densities. The maximum potentials shown in Fig. 3 as a function of anodic current density are experimental values obtained from one assembly. Coincidentally, they are near the average values obtained from determinations in more than thirty different assemblies. Smoother curves could have been drawn, but it was desired to emphasize the incoherent nature of the data. Inflections in the η_{max} *vs.* i curves ordinarily could be attributed to experimental error. However, the reproducibility of the shapes of the curves from one assembly to another as well as their obvious relationship to the post maxima potentials *vs.* current curves and the topographic changes of electrode surfaces, which are discussed later, suggest that the discontinuities were real and significant.

By normalizing the maximum potentials observed at 15 and 20 μa cm^{-2} to values arbitrarily selected as standard for these current densities, conversion factors were obtained which permitted all η_{max} *vs.* i curves to be fitted to each other very well indeed. This fact suggested that the discontinuities in the curves were a function of the apparent current densities rather than the anodic overvoltages.

Surface effects.—In the presentation of the data below and in the discussions which follow, it is assumed *ipse dixit* that dissolution occurs from monatomic steps on the metal surface. Since, in systems such as these, it is possible to observe only the net effect of many single atom processes, the arguments advanced can in a sense be regarded as speculative at best. However, the data presented are capable of explanation and understanding on the self-consistent atomistic basis adopted.

The inflected nature of the anodic η *vs.* i curves suggested that possibly four different dissolution phenomena, each associated with a definite range of current densities as shown in Fig. 3, were occurring on the metal surfaces. Galvanostatic studies in which currents were passed for long periods of time were, therefore, conducted. After attaining the initial maxima, anodic potentials rapidly fell to about 80% of the maximum values. Thereafter, they decreased monotonically with time, although at a very slow rate, as long as current was passed through the system. Since the topography and area of an anode surface changed with time and rate of dissolution, and since the post-maxima potentials were reproducible only to $\sim \pm$ 10-15%, their utility was limited. However, they were useful in determining which areas of current density should be investigated for electrode surface effects as well as lending credence to the much less pronounced inflections in the η_{max} *vs.* i curves. Although the times required to establish the potential maxima were longer than would be expected to be required to charge the double layer, the reproducibility of any one series of such potentials, as well as the coincidence of different η_{max} *vs.* i curves when normalized to an arbitrary standard, suggest that these potentials reflect a real property of the system. Their true significance is not clear at this time.

After interrupting the current, the anode was removed from the cell, washed in distilled water, and dried in a jet of oxygen. Crystal surfaces were then examined by optical and/or electron microscopy. Surface replicas for the electron microscope were platinum preshadowed carbon replicas which were chemically stripped from the metal (13). The results discussed below, obtained from observations on more than twenty anodic surfaces, strengthened the belief that different removal processes were operative at certain current densities. Changes in surface topography were the net result of both deposition and dissolution processes at the anode. To facilitate presentation, the surface effects are discussed solely in terms of the dissolution process. This problem is explored more completely in the discussion section.

Region I (0-1 μa cm^{-2}).—Figure 4 illustrates that, in this region of current density, removal of material from the anode apparently occurred at atomic steps[3] on the crystal surface. The movement of steps across the surface was restricted in some manner for with time, facets, which must have resulted from the coincidence of steps, were developed. The electron micrograph seen in Fig. 5 shows the facets in detail. Large areas which protruded above the remainder of the surface, and which were therefore less reactive than steps, were also seen (Fig. 4). These areas, which seemed to serve as obstacles to restrict step motion, produced surface patterns of the type usually associated with subgrain bound-

[3] In this presentation the term "step" is used in the monatomic sense. Steps higher than ~50A (approximately the limit of resolution of the carbon replica technique used) are arbitrarily termed facets. Step facet signifies a facet formed by growth of steps, as opposed to facets developed from pits.

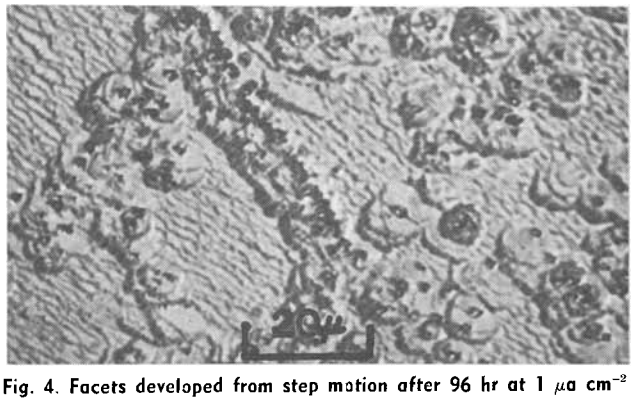

Fig. 4. Facets developed from step motion after 96 hr at 1 μa cm^{-2}

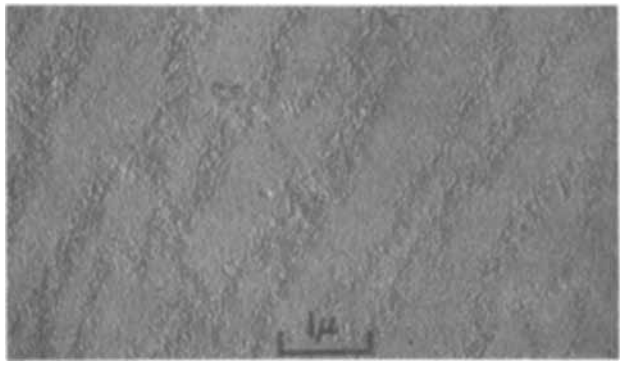

Fig. 5. Electron micrograph of facets on same surface seen in Fig. 4

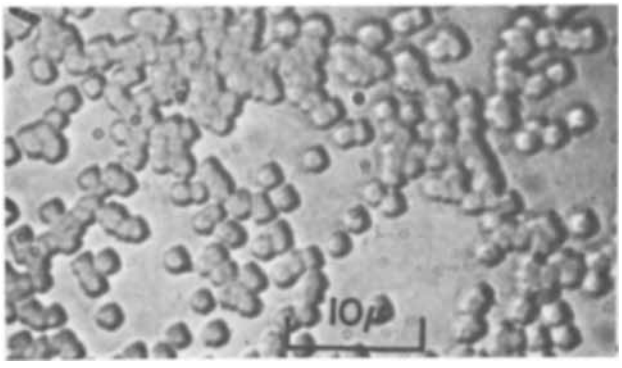

Fig. 6. Pits developed after 5 hr at 10 μa cm^{-2}

aries and points where line defects intersect crystal surfaces. It has previously been observed that crystals of (100) surface orientation undergoing chemical dissolution were less reactive at subgrain boundaries (14).

Region II (1-5 μa cm^{-2}).—The inactive areas of Region I became active in this region. At current densities $\sim$ 2 μa cm^{-2} some tendency to form step facets was still observed, but no large, protruding unreacted areas were seen. As the current density approached $\sim$ 5 μa cm^{-2} no tendency to facet was observed nor were any differences in reactivity observed at areas corresponding to subgrain boundaries. Rather, surface replicas revealed a smooth surface much like that of the unpitted area shown in Fig. 9 and only slightly more roughened than the original surface.

Region III (5-15 μa cm^{-2}).—A further increase in dissolution rates resulted in pit formation as shown in Fig. 6. In the lower portions of Region III the less stringent removal demands resulted in pits which were very shallow, broad, and difficult to detect. The pits grew into each other and, in one experiment conducted at 5 μa cm^{-2}, formed a surface completely covered with very shallow facets after four days of such treatment. As the current density increased the area:depth ratio of pits decreased, and the pits were more easily discerned. However, the increased rate of removal also increased the rate at which pits grew together and consequently shortened the time before pits disappeared as facets developed from them.

Figure 6 shows pits in the earlier stages of development. After prolonged reaction at the same current density, the pits grew into each other and started facet formation as shown in Fig. 7. Even

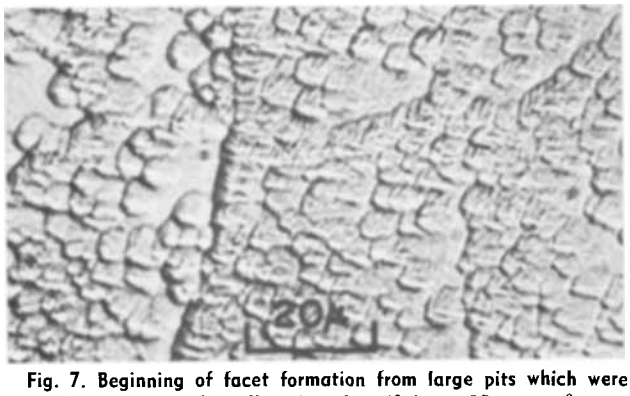

Fig. 7. Beginning of facet formation from large pits which were formed from union of smaller pits after 40 hr at 10 μa cm^{-2}.

Fig. 8. Surface just before pits obscured by facet development after 72 hr at 9 μa cm^{-2}.

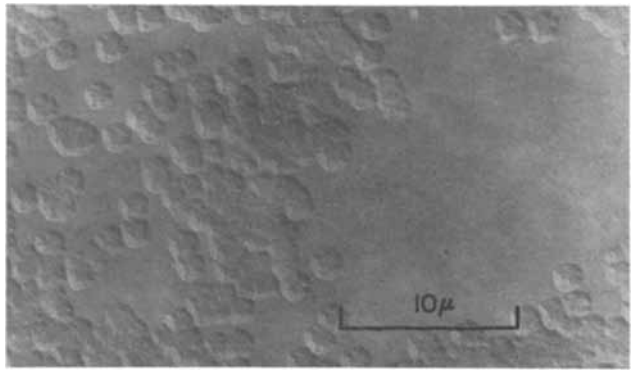

Fig. 9. Electron micrograph showing detail of pits developed after 5 hr at 10 μa cm^{-2}.

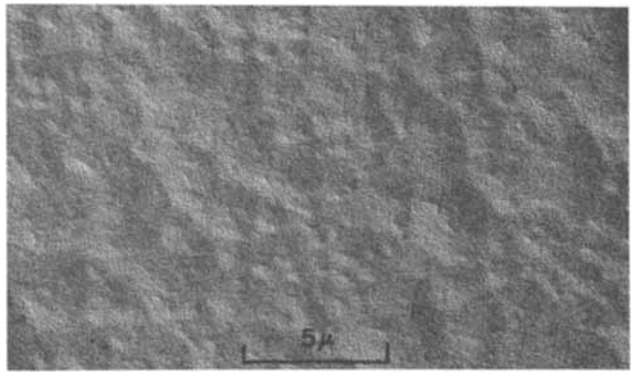

Fig. 10. Initial stages of facets developed from growth of pits after 40 hr at 10 μa cm^{-2}.

more material could be removed at slightly lower current densities, as is illustrated in Fig. 8, before the pits completely lost their identity. An electron micrograph of the same surface seen in Fig. 6 is shown in Fig. 9. The relative smoothness (lack of faceting) of the area between pits was typical of all surfaces in this region, as well as the nonpitted surfaces obtained at higher current densities in Region II. The electron micrograph of Fig. 10 illustrates the initial stages of facet development from pit growth. The faceted structure seen in Fig. 11 was initially developed by pit growth, for in the early stages of reaction this surface was pitted like that shown in Fig. 9. These facets are completely developed while the surface of Fig. 8 still shows distinguishable pits, even though approximately the same amount of material had been removed from each surface.

Region IV (15-20 μa cm^{-2}).—In this region the rates of dissolution were such that facet formation did

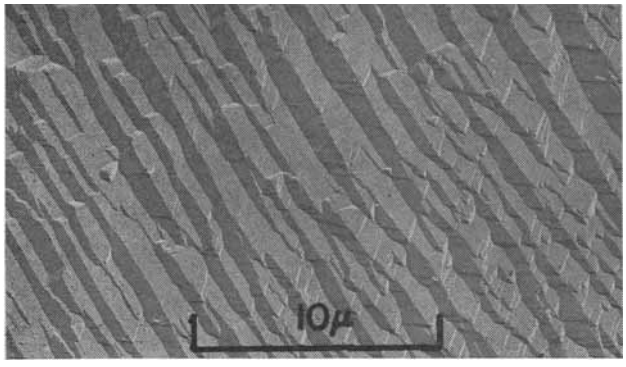

Fig. 11. Facets developed from pits after 47 hr at 14 μa cm^{-2}

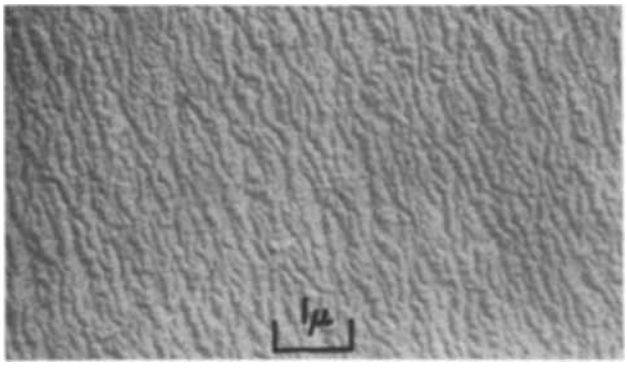

Fig. 12. Initial development of facets not resulting from pit growth after 2 hr at 20 μa cm^{-2}.

not result from the growth of pits, but rather small facets immediately developed as material was removed. Figure 12 shows a surface with facet development well started even though less material has been removed than from the pitted surface of Region III shown in Fig. 9. With time the small facets grew together to form a surface indistinguishable from the surface with pit-developed facets shown in Fig. 11.

The preceding data and comments do not refer to observations made at equivalent microcoulomb values, but rather to the values indicated on the relevant figures. The values were chosen to best represent the cumulative changes in surface topography occurring at typical current densities within the various regions.

Discussion

Experimental method.—Initially data were gathered using an adaptation of a previously described cell (14) designed for chemical dissolution studies. All stopcocks in this apparatus, which allowed anode-cathode separation of 1-2 cm, were of Teflon. Unfortunately, the mechanical pressure required to make the stopcocks vacuum tight resulted in a high rate of failure of the Teflon plugs, with the subsequent loss of samples and contamination of solutions in the reservoir by air. For this reason the cell design was changed to that shown in Fig. 2. Some weeks later the reservoir Teflon stopcock failed and was replaced with a glass stopcock lightly greased with silicone vacuum grease. Fortunately, no differences in η *vs.* i characteristics or surface effects resulted from these changes. It would, of course, have been ideal had no grease been used. However, the final experimental conditions seemed to be the best available choice between compromises involving vacuum requirements, annealing conditions, etc. Apparently the cleaning method used was effective, and the major source of contamination was probably from the stopcock at the solution reservoir.

Surface effects and current-potential data.—Additional experiments were conducted to test further the hypothesis that discontinuities in the current *vs.* potential curves were governed by applied current densities rather than the corresponding overvoltages exhibited by the anode. Since the sides and ends of the electrodes were not of the desired orientation they were obviously a source of error. Therefore, data were gathered from crystals 0.2 cm thick so that the misoriented area of the electrode was increased to about 20%. Also, 0.1 cm thick crystals were electropolished for long periods so that the edges of the area of desired orientation were rounded. In both cases the current-potential data produced curves with less pronounced discontinuities, but with wide variations in potential values. However, the entire surface of proper orientation of the thick crystals, as well as the center of the corresponding area of the thin, rounded-edge crystals, did pit and/or facet at the same current densities previously observed. These observations—when considered with the previously discussed variations of potentials in different assemblies at a given current density, as well as the reproducibility of the shape of the η *vs.* i curves from one assembly to another, and the fact that the observed potentials in any one assembly could be normalized to an arbitrary standard—certainly indicate that the hypothesis is not an untenable one. Furthermore, the surface effects observed on typical crystals, as well as those crystals with a higher percentage of misoriented areas, were almost certainly a function of current densities. It was not unusual to observe pit development on a crystal which exhibited, at a low Region III current density, both a maximum and a "steady-state" potential lower than the corresponding potentials developed by another nonpitting anode at a high Region II current density in another assembly. Therefore, it is reasonable to assume that changes in current densities, rather than overvoltage changes, were responsible not only for discontinuities in η *vs.* i. curves, but also for the different surface structures developed in the current density Regions defined by these discontinuities.

The following discussions of the different methods of facet formation in Regions I, III, and IV, as well as the lack of facet development in Region II and the development of pits in Region III, are based on the previous hypothesis.

Region I.—The development of step facets on anodic surfaces in Region I and the presence of less reactive areas which were compatible with a typical line defect structure suggested that material was removed by the motion of steps across the surface. Decreased reactivity at sites similar to subgrain boundaries and points where line defects intersect the surface could have been due to a "Cottrell atmosphere" of impurities at such imperfections. These sites could have served as pinning points to retard step motion and eventually would result in facets developed from the pile-ups of steps. The total number of steps present

on a surface before the passage of any current was surely not a reproducible number. Also, the pile-up of steps to form facets must have decreased the number of steps available. Therefore, it is not unreasonable to conclude that new steps were being nucleated, and that it was the maximum rate at which such steps could be nucleated which determined where this region ended. When the apparent current density reached 1 μa cm^{-2} this rate was apparently at a maximum. If the areas where line defects intersected the surface did not act as step sources, then crystal edges and point defects must have served as nucleation sites for steps.

Region II.—The faster rate of removal in Region II apparently required nucleation of reaction sites more numerous than could be supplied by the sources active in Region I. The tendency to produce only step facets in lower portions of the region and the lack of faceting or pitting observed near the top of the region indicate that removal of material was still proceeding *via* a step motion mechanism. The smooth surfaces obtained at the higher current densities in the Region suggest that both line and point defects were acting as sources for step formation, and that at these current densities, steps were being removed at a rate at least equal to the rate at which they were created. Furthermore, it would appear that just before the onset of pitting at current densities greater than 5 μa cm^{-2}, steps were being generated at the maximum rate possible. It seems that, as in Region I, it was the maximum rate at which steps could be nucleated which determined the end of this region.

Region III.—Having reached a maximum rate at which dissolution could proceed *via* step motion, pitting began to occur at current densities greater than 5 μa cm^{-2}. The pits shown in Fig. 6, 7, and 8 reveal patterns which are typically associated with the defect structure of crystals such as these. Also, it was determined that the number of pits (5×10^6 cm^{-2}) agreed with the measured number of dislocations in these crystals.[4] Pits then are believed to have formed at subgrain boundaries and at areas surrounding points where line defects intersected the surface of the crystals. It is probable that these areas were active as step sources in Region II, but the lower removal rates did not require more material than could be supplied by the immediate surface. When dissolution rates increased, the additional material was more easily removed at these defect areas.

Region IV.—If removal rates exceeded the maximum amounts of material which could be supplied both by steps nucleated at areas surrounding defects and by pitting, nucleation of reaction sites apparently occurred at random on the crystal surface. This change marked the boundary between Regions III and IV. It is a reasonable assumption that in Region IV removal was by step motion. If so, the large number of steps nucleated and their rapid interaction resulted in such rapid development of facets (Fig. 12) that the mechanism of their early formation and growth could not be determined.

Exchange current.—By evaluating the slope of the overvoltage *vs.* current density curve at the lowest current densities the exchange current density for the system was estimated to be $\sim 5 \times 10^{-5}$ amp cm^{-2}. This value agrees well enough with that anticipated from results on similar systems (12). Therefore, even the measurements obtained at the highest current densities studied represented relatively minor deviations from the equilibrium state. It is then reasonable to assume that deposition at the anode, as well as dissolution, contributed to changes in surface topography. However, it should be recalled that: (*A*) After eight days at equilibrium, surface replicas showed there had been no changes in electrode surface topography. (*B*) At higher current densities in Region II the anode surface remained relatively smooth after prolonged dissolution. (C) Even after pitting had been well developed in Region III the nonpitted area of the surface remained smooth.

Pitting in Region III obviously did not result directly from deposition, but it can be argued that the maintenance of smooth surfaces in non-pitted areas was aided by the simultaneous deposition reaction. The latter argument could also be applied to the upper portions of Region II. Thus it would be expected that as equilibrium was approached in the lower portions of Region II and in Region I, the deposition reaction became more important and contributed greatly to the development of facets. Finally, it should follow that at equilibrium, topographic changes, much like those seen in Region I, would be expected to occur. Such was not the case. Therefore, it is not unreasonable to conclude that the observed anodic topographic changes were due primarily to the dissolution reaction.

Structural aspects.—Assuming previously postulated processes of dissolution to be correct, some interesting calculations can be made. For the Region III surface illustrated in Fig. 9 only 5 μa cm^{-2} of the total of 10 μa cm^{-2} contributed to the formation of pits since half the material was being removed by the step mechanisms postulated for Region I and II. Using the measured dislocation density value of 5×10^6 cm^{-2} and the coulombs of material removed by 5 μa cm^{-2} after 5 hr, it was possible to calculate the average volume of material removed from each pit. Surface replicas showed the pits to be approximately 2×10^{-4} cm^3. To accommodate the volume of material calculated to have been removed at each pit, the pits should have been an order of magnitude wider than they were deep. This was approximately the value observed, and since there was some slope to the sides of the pits, the agreement between calculated and observed results was considered good.

The operation of two sources of dissolution in Region III is illustrated by the surfaces shown in Fig. 6 and 7. Although almost an order of magnitude more material had been removed from the latter surface, faceting was not well developed since half the total material removed was supplied by steps which had also been active in Region II. This point is augmented by the surfaces seen in Fig. 8 and 11. Although approximately the same amount of material had been removed from both surfaces, the latter was well faceted due to the growth of pits since about 65% of the total material removed had been supplied by pitted areas, the remainder of the metal

[4] Dislocation densities were determined by the persulfate etch method [see ref. (9) for details].

dissolving by step motion. Only 45% of all metal removed from the surface shown in Fig. 8 came from pits.

Just before the onset of pitting at 5 μa cm^{-2} it has been postulated that 1 μa cm^{-2} was removing material at sites which had been active in Region I and which were not related to line defects. The remaining 4 μa cm^{-2} were associated with a dislocation density of 5 x 10^{6} cm^{-2}. Therefore, assuming the maximum rate of step removal to be constant regardless of the origin of the step, there would have been ~10^{6} sites cm^{-2} in Region I which acted as sources for nucleation of steps. The maximum dissolution rate in both Region I and II would then be ~3 x 10^{6} atoms site^{-1} sec^{-1}. The maximum rate of removal at a pit would be about twice as great.

It should be pointed out that an alternative explanation exists for the mechanism of removal in Region I. The approximately 10^{6} cm^{-2} sources of step sites calculated above may have been associated with screw dislocations. Even if the presence of impurities prohibited dissolution near the core of the dislocation, a permanent step on the surface would emerge from the screw dislocation. The calculated number of step sources is probably of the proper magnitude for a correspondence to screw dislocations, and since all crystals were grown and handled in a similar manner, this number should have been reasonably constant from crystal to crystal. Therefore, if removal in Region I occurred at steps resulting from screw dislocations, it would be reasonable to expect the surface effects observed in this Region, as well as the reproducible ending of the Region, when removal rates exceeded those allowed at screw dislocation steps. However, it can be shown that for every ½° variation from the (100) orientation, ~5 x 10^{5} monatomic steps cm^{-1} result on a copper surface. It is difficult to believe that the electropolishing techniques used in this study produced exact (100) surfaces, or that the degree of variation from the desired orientation, and consequently the total number of steps resulting from orientation changes and screw dislocations, was reproduced on every crystal. Also, the results obtained with rounded-edge, thin crystals, which must have contained more steps per unit area than crystals with flatter surfaces, cannot be ignored. Therefore, the argument that the end of Region I was determined by the rate at which new steps could be nucleated, regardless of their origin, seems preferable to the authors.

Overpotential and kinetics.—In all assemblies an interesting relationship was observed between the potential maxima at current densities corresponding to discontinuities in the η *vs.* i curves. In any one system the ratio of the potential at the Region II—Region III boundary to that at Region I—Region II was always ~3, and that of the Region III—Region IV discontinuity to the Region I—Region II value was always ~5. These potential ratios were reasonably constant even though, as previously noted, the measured potential maxima varied as much as 20% from one assembly to another. Perhaps if ϵ was the energy required to nucleate steps at dislocations, then 3ϵ was required to remove material at points where dislocations with a "Cottrell atmosphere" of impurities intersected the surface, and 5ϵ was necessary for removal from smooth surfaces of (100) orientation.

Since different anodic sites were reactive at distinct current densities, a distribution of reaction rates must have occurred over the surface. It would be a difficult, and not a particularly rewarding, task to adapt electrode kinetics, as well as to approximate the time dependence of surface structure and η *vs.* i data, in order to interpret the observed data kinetically. In systems of the type studied it is possible that the simpler equations of electrode kinetics should apply only at current densities as large as, or greater than, those of Region IV where nucleation of reactive sites apparently occurred in a random manner; that is, the metal surface acted homogeneously. For these reasons, and also since their solutions were more concentrated in both copper sulfate and sulfuric acid, these results could not be compared with those of Piontelli *et al.* (7) whose lowest current densities correspond to those of Region IV reported here.

Conclusions

It should be emphasized that the discussions and interpretations of the data presented here were based on the reasonable assumption that dissolution occurred from monatomic steps on the anode surface. Obviously it is impossible to prove absolutely the validity of this assumption in a system of the type investigated. The following conclusions should be regarded solely as deductions arising from a self consistent explanation of experimental observations:

1. It is believed that galvanostatic dissolution from (100) oriented surfaces of copper single crystals occurred initially at steps on the surface. These steps were not nucleated at areas where line defects intersected the crystal surface. The rate at which new steps could be nucleated determined the rate at which material could be removed in this manner.

2. An increase in dissolution rates demanded the formation of additional reaction sites. These sites were supplied by the nucleation of additional steps at areas where line defects intersected the crystal surface. The subsequent motion of steps across the surface provided a means of removing the metal from the anode.

3. After the maximum rate of step formation was reached, further increases in the rate of dissolution resulted in pit formation at points where line defects intersected the surface and at subgrain boundaries. As dissolution continued the pits grew together to form facets.

4. When removal demands exceeded the rate at which material could be supplied by the previous sources, reaction sites were apparently nucleated at random on the metal surface. A faceted structure, which was not formed by the growth of pits, developed rapidly.

5. The nucleation of reaction sites was probably governed by the rate of anodic dissolution, *i.e.*, impressed current density, rather than by the overpotential exhibited by the electrode.

6. The relative energies required to nucleate steps at dislocations, remove material from points where line defects intersected the surface and from the

idealized flat surface were apparently in the ratios of 1:3:5.

7. The applicability of simple kinetic electrode theory to the system studied could not be demonstrated. This was thought to be due to the heterogeneous nature of the anodic surface.

Acknowledgment

Dr. F. A. Posey made many helpful suggestions both while the work was in progress and during the preparation of this manuscript. The authors also acknowledge helpful discussions with Drs. F. W. Young, Jr. and D. K. Holmes.

Manuscript received Aug. 24, 1961; revised manuscript received Jan. 30, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Oxidation of Sputtered Tantalum Films

Harold Basseches

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

ABSTRACT

The oxidation of sputtered tantalum films has been studied over a temperature range of 100°-600°C in oxygen at a gas pressure of 7.6 cm of Hg. The results obtained by means of a vacuum microbalance are compared with data on bulk tantalum, and it is found the rate of oxidation and amount of oxidation is considerably smaller than the bulk. A logarithmic relation was found to represent the data best in the range 400°-600°C. The factors which may give rise to the differences found between the film and the bulk are discussed.

In the course of an investigation of the stability of the electrical resistance of thin sputtered tantalum films (1), the oxidation of these films has been studied as a function of temperature.

The oxidation of sputtered tantalum films was carried out using a vacuum microbalance to obtain weight gain over a range of temperatures from 100° to 600°C in pure oxygen at a pressure of 7.6 cm of Hg. A logarithmic relation of the form $y = a \ln (1 + bt)$ was found to give a slightly better fit of the data over the range of temperatures 400°-600°C than a parabolic one. y is the weight gain of tantalum in $\mu g/cm^2$, t is the time in minutes, a and b are constants at any given temperature and have the dimensions $\mu g/cm^2$ and min^{-1}, respectively. The results indicate that the amount and rate of oxidation of the film are considerably smaller (by about an order of magnitude) than that reported for bulk tantalum. Vermilyea's (2) results are in somewhat closer agreement.

Although quantitative correlations are not yet possible, the factors which may affect the weight gain measurements and may explain the differences in oxidation between film and bulk tantalum are discussed.

Experimental Procedure and Results

The details of the sputtering technique and the sample preparation have been described elsewhere (1). The samples consisted of tantalum films (600-2500Å in thickness) sputtered on quartz substrates ½ in. x 2 in. x 30 mils in thickness. The oxidation was performed in a vacuum microbalance (3-5) by Gulbransen. The oxidation was carried out over a range of temperatures from 100° to 600°C in a pure oxygen atmosphere at a pressure of 7.6 cm of mercury. The total oxidation time was 2 hr. The graphs of the results are shown in Fig. 1 and 2 in which the weight gain per unit area is plotted as a function of time. The sensitivity of the apparatus is between 0.1-0.2 $\mu g/cm^2$ and indicates that films of the order of 7-15Å of tantalum oxide could be detected (69 Å/$\mu g/cm^2$ based on Ta_2O_5) (6).

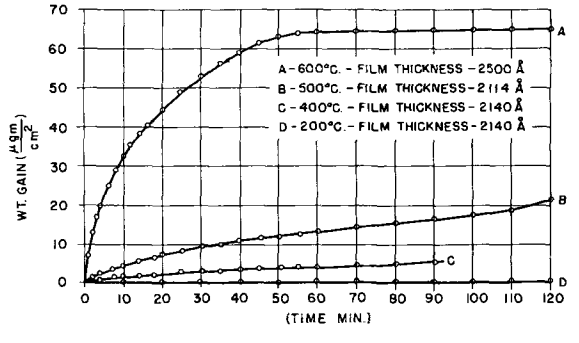

Fig. 1. Effect of temperature on oxidation of sputtered tantalum films (O_2 pressure, 7.6 cm of Hg).

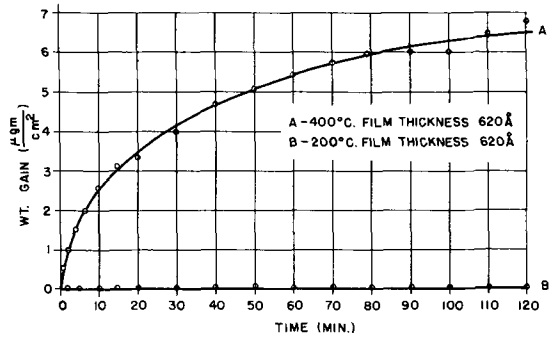

Fig. 2. Effect of temperature on oxidation of sputtered tantalum film (O_2 pressure 7.6 cm of Hg).

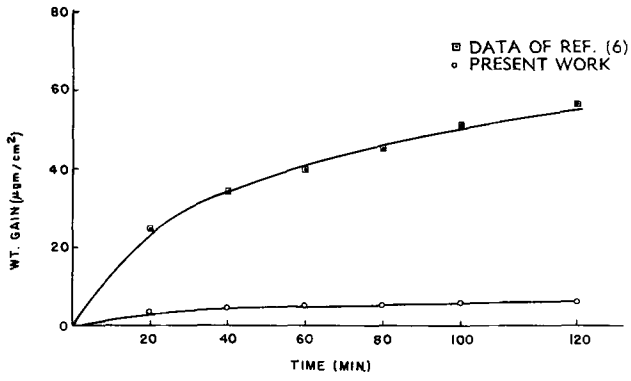

Fig. 3. Comparison of weight gain of sputtered tantalum film and bulk tantalum (400°C, O_2 pressure, 7.6 cm of Hg).

There are several points that can be noted on these curves. The flat portion of curve A on Fig. 2 after the 60-min mark may result from the consumption of all the tantalum. Oxidation at a temperature of 200°C produced no measurable change, nor was there a visible color change. This is confirmed on two samples of different thicknesses, namely, curve D of Fig. 1 and curve B of Fig. 2. There appears to be no thickness effect in the oxidation since the value at 90 min for the total weight gain of curve C, Fig. 1 and curve A, Fig. 2 agree quite well.

It should be noted that the same samples were used for the 400°C tests as in the 200°C tests. Electron diffraction studies were made on the oxidized deposits on the quartz by Gulbransen. The results of this work are reported in Table I. In only one case does there seem to be an indication of the tantalum oxide structure. The patterns in the other cases were very diffuse and difficult to interpret.

Comparison of Oxidation Data on Thin Tantalum Films with That of Bulk Tantalum

In Fig. 3 the data of the present work are compared to earlier work of Gulbransen and Andrew (6). The data for both bulk and sputtered tantalum were obtained in the same apparatus. The total amount of oxidation, as well as the rate of oxidation, is much less on the sputtered film than on the bulk material. Further comparisons are also available in Table II. The difference between Vermilyea's work and others may be related to differences in surface preparation; however, his

comes closest to agreeing with the data of the present work.

It will be helpful to get some idea of what kind of reproducibility one can expect in oxidation studies of the type reported by Gulbransen. Although data are not available on tantalum, Gulbransen has worked on two other materials, columbium and zirconium, at several different times. In the case of columbium (6, 7) and zirconium (6, 8, 9) differences of a factor of from 2 to 4 have been observed among samples studied at different times. The comparisons have been made at similar temperatures, but other conditions such as surface preparation and pressure of oxygen have not necessarily been the same. There is some risk in trying to compare sputtered films with bulk material since purity of samples, differences in surface treatment prior to oxidation, etc., could have strong influences on the result. It might have been expected that the conditions existent in films would tend to increase the rate over that of bulk rather than decrease it, as has been found.

It is also possible to make a comparison with bulk results and the present study as far as rate of oxide formation is concerned. From Gulbransen and Andrew's data (6) at 300°C for tantalum, an estimate can be made of the rate of oxide formation over the time interval of 1-2 hr to be of the order of 0.04 Å/sec. On the basis of Vermilyea's work (2), assuming that an oxide film of the order of 600Å has built up after oxidation of between 1 and 2 hr, one can estimate that at 300°C the rate of oxide formation would be of the order of 0.0001 Å/sec. This value is obtained from Fig. 4 which is a plot made from calculations of McLean (10) who used Vermilyea's data. However, this graph extends the calculations up to higher temperatures.

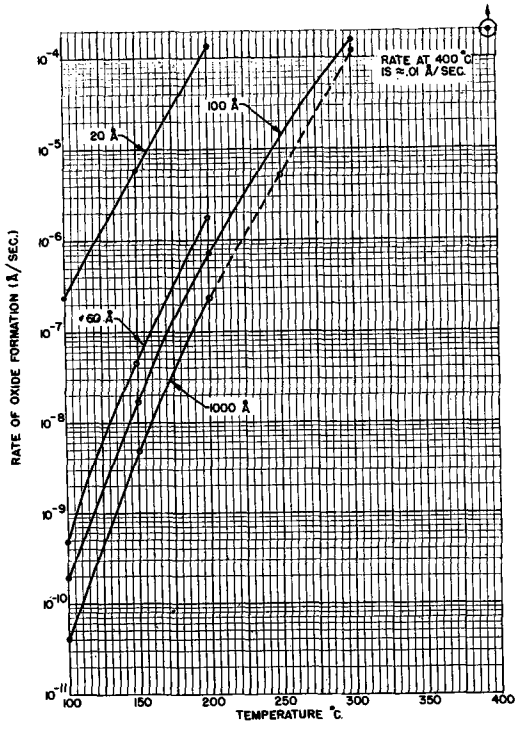

Fig. 4. Rate of oxidation of tantalum as a function of temperature and oxide thickness [data from Vermilyea (2)].

Table III. Constants for logarithmic rate law

Temp, °C	a	b
600	20.985	0.3820
500	7.029	0.0901
400 (2140Å)	2.399	0.0836
400 (620Å)	1.828	0.293

Unit of a is $\mu g/cm^2$; unit of b is min^{-1}.

In an effort to make some comparisons with the present work, Vermilyea's data (2) have been extrapolated to 400°. Assuming a thickness of oxide of somewhere between 100-1000Å, extrapolation gives an oxidation rate of 0.01 Å/sec. as noted in Fig. 4. The data in the present study which can be used to best advantage to make a comparison are that of Fig. 2 at 400°C. The tangent to the 2-hr point gives the rate of 0.015 Å/sec. The rate calculated from a logarithmic relation deduced from the present study, as given below, is $(dy/dt) = ab/(1 + bt)$. Utilizing the values of a and b derived at 400°C for the 620Å film (see Table III) the rate is 0.017 Å/sec. Although it is dangerous to carry out the extrapolation of Vermilyea's data, the agreement may be noted.

A number of different equations has been proposed to account for the observed oxidation behavior of metals (11, 12). In comparing parabolic with logarithmic behavior, on the basis of a least squares criterion, a logarithmic equation of the form $y = a \ln (1 + bt)$ was found to fit the data slightly better than a parabolic one in the temperature range 400°-600°C. The various values of a and b are listed in Table III for data in the range of 400°-600°C. The units for t are in minutes. No theoretical significance is attached to this logarithmic behavior at the present time.

It appears that the amount of oxidation of sputtered tantalum is less, by about an order of magnitude, than that of bulk tantalum. Variations obtained over periods of time using the same apparatus suggest factors of somewhere between two and four could arise. Therefore, the factor of nearly ten obtained as the difference between the bulk material and the present thin film material does indeed suggest it to be a significant difference. A consideration of those factors which could affect this variability all tend to substantiate that differences exist between the bulk material and the sputtered film.

Discussion

Previous studies of the oxidation of tantalum over various temperature and pressure ranges have characterized the behavior in various ways either as parabolic (6) logarithmic (2, 13), cubic (14), and linear (15, 16). In most of these studies the products of reaction were not completely identified so detailed discussion of the mechanism is not possible. In most cases the formation of tantalum pentoxide has been assumed. Recent studies of Kofstad *et al.* (17), however, give considerable detail on the products in the temperature range 500°-700°C.

X-ray diffraction and electron diffraction studies indicate that in the early stages, described as an incubation period, (for example, extending to 150-250 min at 500°C) oxygen dissolution occurs along with the formation of Ta_4O and a compound characterized by TaO_z. During the transition from the incubation period to the linear oxidation region, Ta_9O_5 is formed as traces on the surface, and in the linear region there is heavy formation of β-Ta_2O_5. The present electron diffraction studies have not characterized the products adequately. There was some suggestion that Ta_2O_5 formed. However, if it is assumed from curve A in Fig. 1 that all of the tantalum is consumed at the point where the curve flattens out, then from the weight gain data it is shown that 65 $\mu g/cm^2$ of oxygen react with 415 $\mu g/cm^2$ of tantalum. On an atom basis this corresponds to a compound $TaO_{1.76}$ which is one of the types of product indicated by Kofstad.

Although the evidence found in the present study indicates only a slight preference for a logarithmic over a parabolic behavior over the time periods studied, there seems to be no indication of linear behavior. This region may well correspond to the incubation period described by Kofstad (17). This incubation period, before the linear region, varied with the temperature and became shorter as the temperature and pressure increased. At 600°C and above it became too short to observe experimentally. The data of Albrecht *et al.* (16) still show an incubation period at 600°C. Kofstad (17) concluded that the oxidation during the incubation period was difficult to interpret in terms of any definite rate law although it was most closely approximated by a parabolic function.

Kofstad found oxygen dissolution to be an important step in the initial oxidation of tantalum. At 500°C the weight gain due to oxygen dissolution could amount to more than 75% of the weight gain found experimentally. Computations of the time necessary for oxygen to diffuse through a 2500Å thick tantalum film (18) using diffusion data of Gebhardt (19) were made. At 600°C this is 0.1 sec, at 400°C it is 10 sec, but at 300°C it is 6 min. It would appear therefore that in range of 400°-600°C oxygen dissolution is of minor importance in the rate measurements, although at lower temperatures it could become a major factor. Thus as far as measurements with thin films are concerned the relative importance of oxygen dissolution could change with temperature. The diffusion data used are those available for bulk tantalum, and it is conceivable that they are not strictly applicable to thin films.

The reasons for the difference between the behavior of the thin film and the bulk are not obvious. It may be due to differences in the oxides formed on the bulk as compared to that on the film. There is some evidence from studies on the anodization of sputtered tantalum films (20) made in connection with work on sputtered tantalum capacitors (21) that the oxide is different and does not crystallize as readily as on bulk tantalum. A strip of bulk tantalum was anodized in the same solution with a film of tantalum sputtered on a microscope slide. The solutions used were those reported to promote crystallization (22). The strips were pulled out after a given time and examined microscopically. The bulk piece showed crystals, the sputtered film did not. The sputtered film was reimmersed for a period ten times longer and removed and examined. There were still no signs of crystallization.

The electron diffraction obtained on the present study suggests an amorphous structure at the elevated temperature. Vermilyea (2) showed on bulk tantalum, however, that at 350°C oxide films began to crystallize. His other work on tantalum (22) has shown that where crystalline oxide exists the rate of oxidation is more rapid than where the oxide film is amorphous. This may be the basis for the differerences observed between the present study and bulk material.

The difference may arise because the surfaces of the films are in some way very different from most of the bulk samples studied. The oxidation data of Kofstad showed a profound effect of surface treatment on the oxidation behavior during the incubation period. Although no careful studies were made, chemical etching and high-vacuum annealing increased the incubation period. Albrecht's data at 600°C using vacuum annealed tantalum did indicate an incubation period (16). The structural results of Cathcart (23) on tantalum indicated a relationship between the state of perfection of the metal surface and its oxidation characteristics.

One perhaps may view the present work as giving a picture of what happens at the surface of the tantalum by greatly enhancing the surface to bulk relationship and hence the surface effects. Further kinetic and structural work using longer time periods, more intermediate temperatures, and a variety of thicknesses is necessary to get further understanding of the factors which appear to cause a difference between the oxidation results with thin film and bulk tantalum.

Acknowledgment

The author is indebted to Mr. E. A. Gulbransen of the Westinghouse Electric Corporation for carrying out the oxidation studies with his microbalance. Mr. S. S. Gupta and Miss Phyllis Groll contributed to the statistical analyses and data testing. He wishes to thank Mr. U. B. Thomas and Mr. N. Schwartz for helpful comments and discussion and Mr. P. Kofstad for detailed comments on the manuscript and the opportunity to discuss his work prior to publication.

Manuscript received May 8, 1961; revised manuscript received Jan. 30, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Influence of Residual Stress on the Magnetic Characteristics of Electrodeposited Nickel and Cobalt

Robert D. Fisher

Physical Research Department, The National Cash Register Company, Dayton, Ohio

ABSTRACT

Cobalt and nickel were electrodeposited from aqueous solutions at a current density of 16 ma/cm^2. The influence of the metal chloride salt and saccharin concentrations on the residual stress and microstructure of the cobalt and nickel electrodeposits was investigated in conjunction with measurements of their magnetic characteristics. In all cases the residual stress in the deposits as measured with a stressometer was found to be tensile in nature, *i.e.*, the deposits tend to contract. The coercive force of the cobalt and nickel deposits was determined as a function of the residual or internal stress at a thickness of approximately 7μ. This coercive force was compared with a theoretical coercive force obtained from the relation $Hc = \sigma\lambda/Is$ as proposed by Kersten where σ is the experimentally determined internal stress, λ is the magnetostriction value, and Is is the saturation magnetization. It is shown that the coercive force of nickel deposits is directly proportional to the internal stress. However, the coercive force of cobalt deposits appears to be dependent on the crystal structure as well as the internal stress. Heat treatment of the cobalt deposits for 2 hr at 440°C in nitrogen results in a decrease in the squareness and an increase in the coercive force while nickel deposits increased in squareness and decreased in coercive force. The former results are explained on a crystal structure basis while the latter results can be explained on a stress relief basis.

The magnetic characteristics of most ferromagnetic materials change with the application of stress. For example, the effect of a macroscopic unidirectional stress on the remanence and permeability of positive and negative magnetostrictive materials is well known (1). Electrolytic and vacuum deposited ferromagnetic materials possess an inherent residual or internal stress. Numerous investigators have determined this stress in both electro and vacuum deposited metals, but very little attention has been given to the effects of the internal stress on the magnetic characteristics of electrodeposits. In this investigation the internal stress and surface characteristics of electrodeposited cobalt and nickel were determined in conjunction with measurements of their magnetic properties at the same thickness. Deposits were prepared at a thickness of 7μ in order to: (*a*) minimize any effect of the substrate on the magnetic properties through epitaxial growth, and (*b*) obviate any changes in the coercive force of the deposit due to thickness. Cobalt and nickel were electrodeposited from aqueous solution containing primarily their metal salts. The influence of the metal salt concentration and small additions of saccharin to the solution was investigated as to their effects on the magnetic properties, internal stress, orientation, and surface characteristics of the deposited cobalt and/or nickel.

Experimental

Deposit preparation and stress measurements.— Deposits for magnetic studies and stress measurements were made using a stressometer developed by J. B. Kushner. Its use and operation are described in detail elsewhere (2) and consequently will not be

discussed in this paper. The cathodes used in the stressometer were brass disks, 9 cm in diameter and 0.052 cm in thickness. All cathodes were cleaned in an identical manner and cut from the same sheet. The cleaning procedure was as follows: (*a*) alkaline cathodic cleaning, (*b*) distilled water rinse, (*c*) acid dip in 6*N* hydrochloric acid, and (*d*) distilled water rinse. The cathodes were then dried, weighed, and placed directly into the stressometer. The anode used with the stressometer was a platinum disk with the same diameter and area as the cathode, but the thickness was 0.21 cm. The stressometer was then calibrated and placed in the metal salt solution. Reagent grade metal salts of nickel chloride and cobalt chloride hexahydrate were dissolved in distilled water, and the single metals were independently deposited on the cathode of the stressometer at a current density of 16 ma/cm². The total volume of solution in which the stressometer was immersed was approximately 7 liters. Agitation was not used in any of the solutions. Temperature of all solutions was 25°C, and the pH was adjusted with hydrochloric acid to a value of 2.0 ±0.1.

Magnetic measurements.—B-H loops of the deposits were obtained from a low frequency (60 cycle) hysteresis loop tracer. The drive field was supplied by a pair of Helmholtz coils in series consisting of 400 turns each which permitted drive fields up to 400 oersteds without overheating. A Type 53/54B Tektronix preamplifier was used on the horizontal drive oscilloscope input. The sensing circuit consisted of a 5000-turn sense coil, a corresponding canceling coil wound in opposition, an R-C integrator and a Type 53/54E Tektronix preamplifier on the vertical oscilloscope input. The oscilloscope was a Tektronix 536.

Thickness measurements.—The thickness of all the deposits was determined by weight-density calculations. The thickness was then checked utilizing an x-ray diffraction technique. The integrated intensity of a diffraction peak of the brass substrate and the integrated intensity of the same peak with the magnetic coating over the substrate were obtained and related to the thickness. Agreement between the two methods was ±5%.

Electron microscopy and x-ray diffraction.—Samples examined with the electron microscope were replicated by applying a collodion-platinum replica followed by shadowing with carbon. The magnification in all instances was 20,000 diameters. The x-ray diffraction patterns were obtained using a Norelco x-ray diffractometer. Copper Kα radiation and iron Kα radiation were used on the nickel and cobalt deposits, respectively.

Errors and reproducibility.—The standard deviation of the stress measurements for electrodeposited cobalt was calculated as 140 kg/cm². A value of 14 kg/cm² was determined for nickel electrodeposits. The average stress value of nickel deposits was 780 kg/cm², and for cobalt deposits the average value was 1,660 kg/cm². The stress measurements in each given system were reproducible within twice the standard deviation. Magnetic measurements were reproducible within the error of reading the oscilloscope which was ±3%.

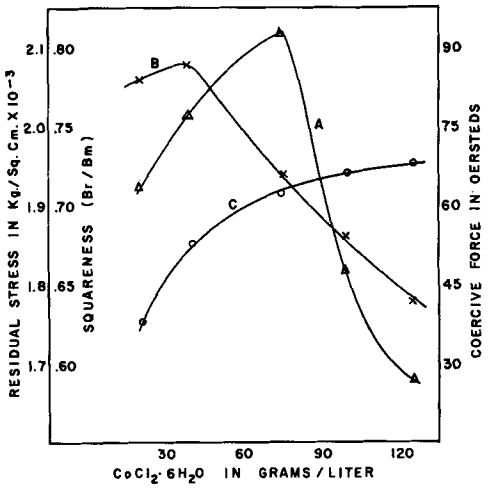

Fig. 1. Effect of cobalt chloride concentration on the residual stress and magnetic properties of electrodeposited cobalt; (A) residual stress; (B) squareness (Br/Bm); and (C) coercive force *vs.* $CoCl_2 \cdot 6H_2O$ concentration.

Experimental Results

Cobalt deposits.—The internal stress was determined in cobalt deposits from solutions containing 0.084M (20 g/l), 0.168M (40 g/l), 0.315M (75 g/l), 0.42M (100 g/l) and 0.525M (125 g/l) cobalt chloride hexahydrate. The current density was 16 ma/cm². The internal stress gradually increases as the cobalt chloride concentration increases up to 75 g/l. Further increase in the cobalt chloride concentration (100-125 g/l) decreases the residual stress. Thus a maximum stress occurs at 75 g/l cobalt chloride hexahydrate (see Fig. 1A).

The magnetic characteristics of the deposits were obtained by observation of the hysteresis loop of the deposits. The squareness (Br/Bm) of the cobalt deposits tends to decrease (0.78-0.64) with increasing salt concentration (Fig. 1B). The coercive force varies from 38 to 68 oersteds and increases as the salt concentration increases. The coercive force increases rapidly with a small increase in metal salt concentration, but further additions results in smaller changes of the coercive force (Fig. 1C). The coercive force as a function of the internal stress is shown in Fig. 2A. The coercive force appears to be directly

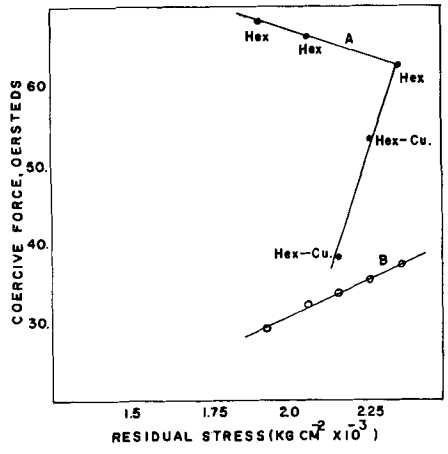

Fig. 2. Experimental and theoretical coercive force of cobalt as a function of the residual stress produced by varying salt concentration: (A) experimental coercive force vs. residual stress; (B) theoretical coercive force ($Hc = \sigma\lambda/Is$) vs. residual stress.

proportional to the internal stress up to 75 g/l cobalt chloride and then increases with a decrease in the internal stress. The increase in coercive force with a decrease in stress is similar to the results of Polukarov (3).

X-ray diffraction patterns of the deposits prepared from the low salt (20 and 40 g/l) concentrations have a hexagonal-cubic structure, but the other deposits at high salt concentrations have only a hexagonal structure with no discernible cubic peaks. Deposits which are hexagonal have the $(11\bar{2}0)$ plane parallel to the substrate while deposits with the mixtured structure have the $(11\bar{2}0)$ and in addition the (220) cubic plane parallel to the substrate. There appears to be more cubic phase in the 20 g/l deposit than in the 40 g/l deposit based on the relative diffraction peak areas.

Electron micrographs (20,000X) of the cobalt deposits obtained at 20, 75, and 125 g/l of cobalt chloride hexahydrate were examined to determine the surface characteristics. A series (12 areas) of micrographs was obtained to assure a representative picture of the surface of each deposit. The 20 g/l deposit is relatively smooth with a fine texture in the range of 50-100 mμ. Approximately 15-20% of the surface shows a grain or crystallite development in the size range of 0.3μ. The 75 g/l deposit displays the same fine texture as the 20 g/l deposit but the surface has become very rough (on the 1μ scale) with little evidence of a characteristic grain structure. The 125 g/l deposit is also extremely rough, but there is better evidence of the development of grains similar to those observed in the 20 g/l deposit.

Heat treatment of these deposits at 440°C in nitrogen for 2 hr resulted in a decrease in the squareness and an increase in the coercive force of the deposits (Table I). X-ray diffraction patterns indicate that the percentage cubic phase present in the deposits prepared at 20 and 40 g/l cobalt chloride hexahydrate has decreased, especially in the case of the 40 g/l deposit. Also the diffraction peak heights increase and are sharper in nature, indicating an increased particle size and/or stress relief. No cobalt oxide phase was discernible from the diffraction peaks prior to or after the heat treatment. The deposit prepared at 20 g/l cobalt chloride showed the least increase in the coercive force after heat treatment and the 40 g/l cobalt chloride deposit showed the greatest increase in the coercive force after heat treatment. The other deposits increased in coercive force by approximately the same amount after heat treatment.

The influence of saccharin (Na salt O-benzoic sulfimide) on the internal stress of cobalt deposits was

Table I. Cobalt deposits

g/l $CoCl_2$	Magnetic properties after heat treatment, 440°C: Coercive force	Squareness Br/Bm	Magnetic properties prior to heat treatment: Coercive force, oersteds	Squareness Br/Bm
20	46.5	0.54	38.0	0.78
40	76.5	0.68	53.0	0.79
75	80.5	0.64	62.5	0.72
100	84.5	0.64	66.0	0.68
125	80.5	0.66	68.0	0.64

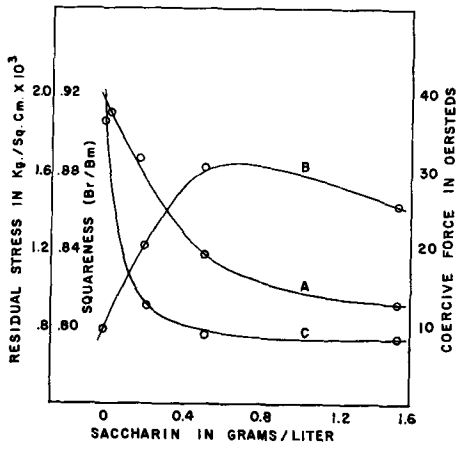

Fig. 3. Effect of saccharin on the residual stress and magnetic properties of electrodeposited cobalt: (A) residual stress; (B) squareness (Br/Bm); and (C) coercive force vs. saccharin concentration.

determined by depositing cobalt from a 20 g/l cobalt chloride hexahydrate solution containing 0.2 g/l (0.83×10^{-3}M), 0.5 g/l (2.07×10^{-3}M), and 1.5 g/l (6.22×10^{-3}M) of saccharin. The current density was 16 ma/cm². The internal stress decreases with increasing saccharin concentration. Initial concentrations of saccharin (0 g/l, 0.2 g/l, and 0.5 g/l) decrease the stress linearily, but the 1.5 g/l addition decreases the stress less rapidly, *i.e.*, it is less effective in reducing the stress (Fig. 3A)

The magnetic characteristics of the deposits were obtained as before by observation of the hysteresis loop of the deposits. The squareness of the deposits tends to increase slightly from approximately 0.8 Br/Bm to approximately 0.9 Br/Bm (Fig. 3B). Since the magnetostriction of the cobalt deposits is negative the increase in squareness may be partially attributed to a tensile stress relief. The coercive force of the deposits decreases with increasing saccharin concentration but not in a linear manner (Fig. 3C). Additions of small amounts of saccharin (0.2 and 0.5 g/l) decreases the coercive force from 38 oersteds to 8.5 oersteds at 0.5 g/l of saccharin. However, the coercive force remains constant with further additions of saccharin up to 1.5 g/l, although the internal stress continues to decrease. Deposits at high saccharin concentrations (0.5 and 1.5 g/l) have a coercive force which is the same as normal bulk deposits, namely, 8 oersteds (4). The coercive force of the deposits as a function of the internal stress is shown in Fig. 4A.

X-ray diffraction patterns of the deposits indicate a mixed hexagonal-cubic structure. Saccharin alters the orientation of the deposits from a hexagonal $(11\bar{2}0)$, cubic (220) planes parallel to the substrate to a hexagonal $(10\bar{1}0)$, cubic (111). In addition saccharin increases the amount of cubic phase in the deposit as based on the relative peak heights.

Electron micrographs of the surface characteristics of each deposit were obtained at a magnification of 20,000 diameters (Fig. 5A-D). The surface characteristics of the 0.5 and 1.5 g/l saccharin deposits are nearly identical as far as can be estimated from the electron micrographs (Fig. 5C and D). Both

possess rounded surface projections which appear to be polycrystalline aggregates in the range of 3-5μ. The remainder of the surface (background) has an extremely fine texture in the range of 10-50 mμ. Similar projections or aggregates in the 0.2 g/l saccharin deposit have dimensions in the range of 0.3-1.0μ region. The background appears fine grained, but is more coarse than in the case of the 0.5 and 1.5 g/l saccharin deposits (Fig. 5B). The deposit without saccharin (20 g/l $CoCl_2 \cdot 6H_2O$) is relatively smooth with a fine texture in the range of 50-100 mμ (Fig. 5A). A few projections or grains in the size range of 0.3μ appear over approximately 15-20% of the surface but are not shown in Fig. 5A.

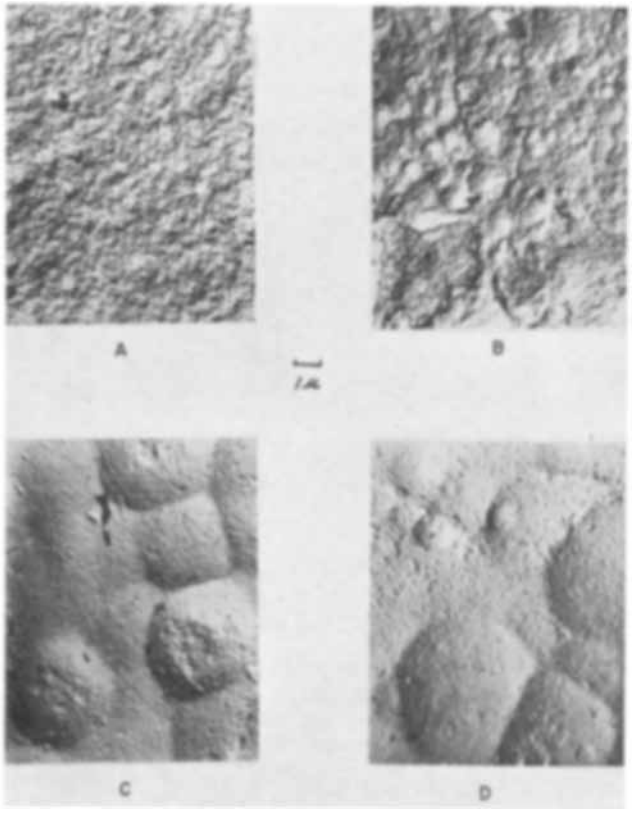

Fig. 5. Electron micrograph (magnification approximately 10,000 X) of the surface of cobalt deposits prepared in the presence of: (A) 0 g/l; (B) 0.2 g/l; (C) 0.5 g/l; and (D) 1.5 g/l of saccharin and 20 g/l of $CoCl_2 \cdot 6H_2O$.

Nickel deposits.—The internal stress was determined in nickel deposits from solutions containing the following amounts of nickel chloride hexahydrate: 0.084M (20 g/l), 0.168M (40 g/l), 0.294M (70 g/l), 0.526M (125 g/l), and 0.702M (167 g/l). The current density was 16 ma/cm^2. The internal stress increases as the nickel chloride concentration increases. In fact the increase is linear and is approximately 2.7 kg/cm^2/gram/liter addition of nickel chloride hexahydrate (Fig. 6A).

The magnetic characteristics of the deposits were obtained by observation of the hysteresis loop of the deposits. The squareness of the deposits decreases with increasing nickel chloride concentration from approximately 0.9 Br/Bm to 0.57 Br/Bm (Fig. 6B). Thus the remanent magnetization decreases with increasing metal salt concentration. The coercive force of the deposits increases from 48 oersteds at the lowest salt concentration to 76 oersteds at highest salt

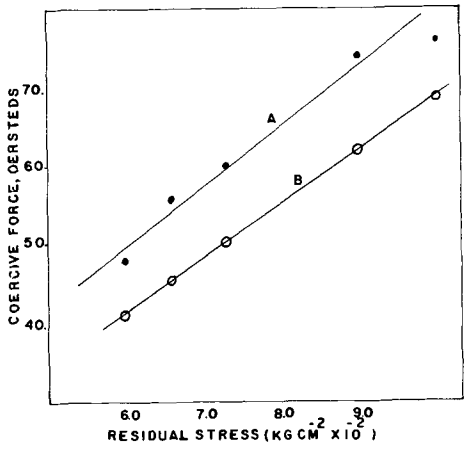

Fig. 7. Experimental and theoretical coercive force of nickel as a function of the residual stress: (A) experimental coercive force *vs.* stress; (B) theoretical coercive force ($Hc = \sigma\lambda/Is$) vs. residual stress.

concentration (Fig. 6C). Thus the coercive force increases with increasing internal stress. This has also been pointed out by Polukarov (5). The coercive force as a function of the internal stress is shown in Fig. 7A.

X-ray diffraction patterns of the deposits indicate a face-centered cubic structure typical of nickel with a decreasing (220) orientation of the deposit as the nickel chloride concentration increases from 20 to 125 g/l. The deposit at 167 g/l nickel chloride concentration appears to be random in orientation.

Electron micrographs of the deposits were obtained at a magnification of 20,000 diameters. The grain size distribution is very broad in the 20 and 40 g/l deposits making an estimate of the grain size difficult. The texture or background of the deposit is finely crystalline in nature and smooth. It would appear that the 20 g/l deposit has a larger grain size than the 40 g/l deposit. The 70 g/l deposit includes large continuous masses which are probably single crystals or grains with dimensions in the neighborhood of 10μ. These large flat crystals are connected by smaller crystals or grains in the neighborhood of 1μ (Fig. 8A). The 125 g/l deposit displays these large grain masses, but in much smaller proportions. These are occasionally joined to each other, but in most intances they are separated by areas containing crystals in the range of 1.0μ (Fig. 8B). The 167 g/l deposit does not contain any large crystal or grain masses, but consists of a relatively uniform crystallite size of 0.5-1.0μ (Fig. 8C).

Annealing of the deposits at 440°C in nitrogen for 2 hr results in a general increase in squareness and a decrease in the coercive force (Table II). This is in direct contrast with those results obtained with the cobalt deposits under a similar heat treatment (Table I). X-ray diffraction patterns of heat treated deposits indicate slight changes in the orientation of the deposits. The deposit which was initially random in orientation (167 g/l) showed the largest decrease in the coercive force. It should be pointed out that the results from the heat treatment could have been predicted qualitatively from the coercive force *vs.* internal stress curves if a stress relief should occur (Fig. 7A).

Discussion

A source of internal stress may be imperfections in the crystal structure of the electrodeposited material. A tensile stress can be attributed to the existence of a certain proportion of vacant sites in each lattice layer. A compressive stress occurs with an interstitial occupancy of a foreign material in the crystal structure. The measured stress may be determined by a preponderance of one type of imperfection over the other. The stressometer used in this investigation measures the average stress. Consequently, there could be highly localized stresses of both a tensile and compressive nature in the deposit which are not detected by simply measuring the average stress. However, it can be assumed that generally the average stress is a result of localized stress gradients in the deposit. The higher the stress gradients in the deposit, the higher will be the value of the average stress. This assumption is obviously invalid if the stress gradients in the deposit are highly nonuniform in nature. Under the conditions investigated, all of the deposits exhibited a tensile stress.

No extensive effort was made in this investigation to eliminate impurities other than the use of reagent grade chemicals, and therefore the effect of impurities cannot be disassociated from those of stress. Thus, even though in certain instances the stress can be correlated directly with the coercive force, it does not necessarily mean that the stress is the cause of the coercive force. However, it is likely that whatever influences the internal stress subsequently causes the same effect on the coercive force.

Heat treatment of the cobalt deposits at 440°C in nitrogen for 2 hr resulted in a decrease in squareness (Br/Bm) and an increase in the coercive force of all deposits. The increase in coercive force after heat treatment may be attributed to a decrease in the internal stress of the deposits prepared from solutions containing 75, 100, and 125 g/l cobalt chloride according to the coercive force *vs.* internal stress relation as shown in Fig. 2A. However deposits prepared from the low concentration of salt (20 and 40

g/l) cannot be explained on a stress relief basis since the coercive force should have decreased with a stress relief rather than increased (see Fig. 2A). This anomalous behavior may be explained by the decrease in the cubic crystal structure of these deposits on heat treatment as shown by x-ray diffraction. Consequently, the cubic structure of cobalt decreases the coercive force over that of the hexagonal cobalt structure, and as the cubic phase decreases due to heat treatment the coercive force increases. These data substantiate results shown in Fig. 2 which indicate that the cubic phase decreases the coercive force of hexagonal cobalt deposit under the same stress conditions.

Heat treatment of the nickel deposits at 440°C in nitrogen for 2 hr decreased the coercive force and increased the squareness (Br/Bm). The decrease in coercive force could have been predicted qualitatively from the coercive force *vs.* internal stress curve in Fig. 7A. The increase in squareness can be explained on a stress relief basis since it is well known that a tensile stress relief on a negative magnetostrictive material will increase the remanence (1). Thus the magnetic properties of nickel deposits before and after heat treatment can be explained on a stress relief basis rather than on a crystal structure-stress basis as in the case of the cobalt deposits.

The coercive force of nickel deposits is directly related to the internal stress. This suggests a model proposed by Kersten relating the coercive force to stress in the material. Kersten (6) (neglecting the energy associated with magnetic pole effects) relates the coercive force to the stress as follows: $Hc = \sigma\lambda/Is$, where λ is the magnetostriction, σ the internal stress, and Is the saturation magnetization. Thus the coercive force at a given composition and orientation (constant λ and Is) is directly proportional to the residual stress. Calculations of the coercive force of nickel deposits prepared at various salt concentrations by substituting the experimental value of the internal stress, a magnetostrictive value of 34×10^{-6}, and a saturation magnetization of 484 gauss results in coercive force values of 41-68 oersteds. A plot of the calculated and experimental coercive force *vs.* the internal stress is shown in Fig. 7A and B. The agreement between the calculated and experimental results is quite good.

Calculating the coercive force of cobalt deposits on the same basis at varying salt concentrations by substituting the experimental stress values, a saturation magnetization value of 1422 gauss, and a magnetostrictive value of 25×10^{-6} results in coercive force values of 29-37 oersteds. The internal stress *vs.* the calculated coercive force is shown in Fig. 2B. Experimentally the coercive force ranges from 38 to 68 oersteds. Agreement between the calculated and experimental coercive force *vs.* internal stress is obviously poor due to the fact that the experimental results are not linear with stress. In the case of cobalt deposits in the presence of various amounts of saccharin similar calculations of the coercive force range from 15 to 34 oersteds, and a plot of the coercive force *vs.* residual stress is shown in Fig. 4B. Again agreement with the calculated results is poor since the experimental coercive force *vs.* residual stress is not linear. Although the initial and final values of the calculated coercive force agrees well with the experimental values, intermediate values are generally too high. Thus the coercive force of cobalt deposits is dependent on other factors in addition to the residual stress, *e.g.*, Cu-Hex structure. In fact the coercive force of the hexagonal cobalt deposits (high salt concentration) is inversely proportional to the residual stress, *i.e.*, the coercive force increases with decreasing residual stress.

The surface characteristics of the deposited cobalt is dependent on the salt concentration and on the saccharin concentration. Increasing cobalt salt concentration increases the surface roughness of the deposited cobalt. Additions of saccharin result in a finer background texture of the cobalt deposit with the formation of large polycrystalline aggregates on the surface. Thus a stress relief can be associated with a grain refinement or a finer background texture. In the case of nickel deposits increasing salt concentration results in the formation of small crystallites at high salt concentration, but large flat crystals are formed at low salt concentrations. The internal stress increases with increasing salt concentration, and a decrease in stress can be associated with the formation of large flat crystals.

Summary

It has been shown that a mixed cubic-hexagonal structure of cobalt occurs at a low cobalt chloride concentration. The cubic phase results in a lower coercive force since at the same internal stress value the cubic-hexagonal structure has a lower coercive force than the hexagonal structure. The effect of the cubic phase may be attributable to a lowering of the high crystalline anisotropy of the deposit which results in lower coercive force values. It should also be noted that a stress relief of a hexagonal cobalt deposit increases the coercive force. Saccharin increases the cubic phase of the cobalt with respect to the hexagonal phase and reduces the coercive force. It also reduces the residual stress considerably, but the reduction of the coercive force is more likely due to an increase in the cubic phase rather than a stress relief. The residual stress *vs.* the coercive force of cobalt deposits is not linear, and it would appear that the coercive force is primarily determined by the crystalline anisotropy. In contrast to the cobalt deposits the magnetic properties of nickel deposits appear to be directly related to the residual stress. This is shown by the linear relation of the coercive force *vs.* stress curve. In addition the coercive force calculated as proposed by Kersten ($Hc = \sigma\lambda/Is$) agrees quite well with the experimental coercive force. A low stress appears to be associated with a grain refinement in the case of cobalt deposits and with the formation of large flat crystals in the case of nickel deposits.

Preparation and Magnetic Characteristics of Chemically Deposited Cobalt for High-Density Storage

R. D. Fisher and W. H. Chilton

Physical Research Department, The National Cash Register Company, Dayton, Ohio

ABSTRACT

Chemically reduced cobalt coatings on a nonconductive substrate (Mylar) have been prepared which are suitable for high-density data storage applications. The influence of deposition parameters such as temperature, total solution concentration of cobalt plus hypophosphite ion, and *p*H on the hysteresis properties and surface characteristics of chemically reduced cobalt was investigated. The deposits are isotropic in nature so that no preferred direction of magnetization exists in the plane of the film. The coercive force of the deposits is an inverse function of the thickness, and the squareness (Br/Bm) is primarily dependent on the thickness. The saturation magnetization may vary from 8,000 to 14,000 gauss depending on the impurity content of the deposit. A typical deposit has a coercive force of 360 oersteds at a thickness of 13,000Å. The deposits are crystalline as evidenced by x-ray diffraction patterns and electron microscopy in contrast to chemically reduced nickel deposits which are reported to be amorphous. Recording characteristics of the deposits are similar to those of commercial oxide recording tapes.

Electrodeposited cobalt-nickel films and iron oxide (Fe_2O_3) coatings have been used as high-density data storage materials on drums, disks, and tapes. Requirements for high-density data storage are well known and have been discussed by many investigators (1). In general, the requirements are: (*a*) a magnetic coating with a nearly rectangular B-H loop, (b) a high coercive force generally greater than 200 oersteds, and (c) a relatively low ratio of remanent magnetization to coercive force. The work reported here was undertaken to ascertain whether chemically reduced films of cobalt could be obtained with suitable magnetic properties for high-density storage applications. Subsequently, the hysteresis properties of chemically reduced cobalt were evaluated with respect to thickness, deposition parameters, and microstructure. Chemical reduction is essentially a controlled autocatalytic reduction of cobalt and/or nickel on an active metal (Pd, Al, Ni, Co, and Fe) in the presence of hypophosphite ion. The method is attributed to Brenner (2).

Experimental Procedure

Film preparation.—In this investigation Mylar was used as a substrate material. The Mylar film (7.16 cm x 10^{-3} cm thick) was cleaned by: (*a*) dipping into a solution of 3*N* NaOH, (*b*) rinsing in distilled water, (*c*) dipping into a solution of 3N HCl, and (*d*) rinsing in distilled water followed by rinsing in acetone. Direct deposition of cobalt onto the Mylar resulted in a deposit which did not adhere. To enhance the adhesion an intermediate organic coating (an adhesive) was placed between the Mylar and the cobalt deposit. The adhesive was applied by immersing the Mylar into a 1:3 mixture of adhesive[1] with methyl ethyl ketone and withdrawing at a rate of 0.84 cm/sec. The adhesive coated Mylar was then air dried for 30 min and cured for 10 hr at 80°C. To activate the Mylar-adhesive surface, stannous chloride and palladium chloride were used. The stannous chloride solution (sensitizing solution) contained 20 g/l of stannous chloride, 10 ml of concentrated HCl acid/liter, and 0.0166 g/l of sodium lauryl sulfate. The solution will not wet the Mylar-adhesive surface satisfactorily unless 2-3 hr has elapsed before immersion of the sample. The solution is used in a precipitated condition, *i.e.*, a yellow coloration due to the formation of stannous oxychloride. The palladium chloride solution (activating solution) contained 0.5 g/l of palladium chloride and 5 ml of concentrated HCl acid/liter. The temperature of the sensitizing and activating

[1] Adhesive No. 200 TF supplied by the Shipley Company, Wellesley, Massachusetts.

solutions was 25°C. A standard cobalt-hypophosphite solution was prepared and contained the following unless otherwise specified: 7.5 g/l (0.031M) cobalt chloride hexahydrate, 3.52 g/l (0.033M) sodium hypophosphite monohydrate, 12.5 g/l (0.23M) ammonium chloride, 17.9 g/l (0.093M) citric acid, 0.0145 g/l sodium lauryl sulfate, and sufficient sodium hydroxide to adjust the *p*H to 8.2. The temperature of the cobalt-hypophosphite solution was 80°C and was controlled to ±0.5°C by means of a heating mantle. The total volume of the solution was 27.6 liters. All solutions were prepared by dissolving reagent grade chemicals in distilled water and were used without further treatment or purification.

Magnetic measurements.—B-H loop measurements were made with a low-frequency (60 cycle) hysteresis loop tracer similar to that described by Howling (3). The maximum drive field without overheating was 1,030 oersteds. A Tektronix 536 oscilloscope was used with a type 53/54E preamplifier on the vertical input (B) and a 53/54B preamplifier on the horizontal input (H). The maximum vertical sensitivity was 0.29 maxwells/cm deflection.

Electron microscopy and x-ray diffraction.—Samples examined with the electron microscope were replicated by applying a collodion-platinum replica followed by shadowing with carbon. The magnification in all instances was 20,000 diameters. The x-ray diffraction patterns were obtained using a Norelco x-ray diffractometer. Chromium K α radiation was used on the cobalt deposits.

Errors and reproducibility.—Coating thicknesses were calculated from the coating weight and the theoretical density of cobalt corrected for the phosphorous content (approximately 4%). The phosphorous content was determined using a standard colorimetric procedure (4). Any appreciable porosity of the coating will result in thickness values that are smaller than the actual thickness. However, microscopic examination of the coatings indicated that the porosity error was small since the volume of the pores was approximately 1-4% of the total volume of the deposit.

For fixed preparation conditions the values of the coercive force of the deposits are reproducible within ±10% and the flux density values (Br and Bm) within ±5%. The calculated flux densities are not necessarily absolute as the applied field was only two to three times the coercive force of the deposited cobalt.

Experimental Results

Total concentration of cobalt plus hypophosphite.—Initially, cobalt solutions were prepared according to Brenner (2). These solutions produced deposits with a coercive force of 20-50 oersteds depending on the experimental conditions. The deposits were unsatisfactory since the coercive force was much too low for high-density data storage applications. It was determined early in this investigation that a high concentration of cobalt and hypophosphite ions (typical of solutions described by Brenner) generally produced deposits with a low coercive force. After considerable investigation a standard solution was formulated which produced deposits with values of coercive force greater than 200 oersteds at thicknesses less than 2μ. The solution constituents are similar to those described by Brenner, the essential difference being that the solution was very dilute (see Experimental).

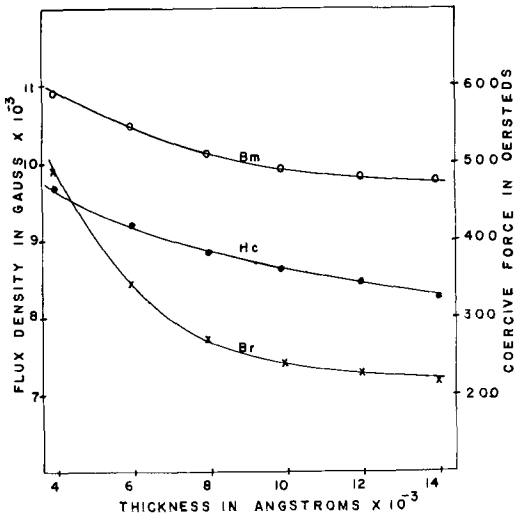

Fig. 1. Coercive force, remanent and maximum flux densities of cobalt deposits as a function of thickness.

The magnetic properties of cobalt deposits prepared from the standard solution are a function of the thickness. The coercive force, remanent (Br) and maximum (Bm) flux density of deposits as a function of thickness are shown in Fig. 1. Both the remanent and maximum flux density appear to decrease with increasing thickness from 4,000 to 13,000Å.[2] The squareness (Br/Bm) of the deposits decreases with increasing thickness from 90% at approximately 4,000Å to 74% at approximately 10,000Å. The average (4,000-14,000Å) flux density of cobalt deposits was 10,500 gauss in comparison to 18,000 gauss for pure cobalt. Analysis of the deposits indicates an average phosphorous content of 4% with a trace quantity (less than 0.5%) of copper and nickel. The phosphorous content undoubtedly is primarily responsible for the loss in maximum flux density of the deposited cobalt in comparison to pure cobalt. The coercive force decreases with increasing thickness from 470 oersteds at 4,000Å to 360 oersteds at 10,000Å. In extremely thin films (<2,500Å) the coercive force may be greater than 650 oersteds (Table I). Under the conditions investigated the coercive force was determined to be an inverse function of the thickness to the one third power. By plotting the logarithm of the coercive force *vs.* the logarithm of the thickness a

[2] In the case of Bm the decrease in flux density may be fortuitous since any error in thickness will result in relatively large errors of Bm in the thin film region. However, $\phi r/\phi m$ as well as Br/Bm definitely decreases as evidenced by hysteresis loops.

Table I. Grain size and coercive force of thin films of chemically reduced cobalt

Thickness, Å	Grain size, μ	Coercive force, oersteds
700	0.1	>650
1,200	0.2	>600
2,300	0.45	500

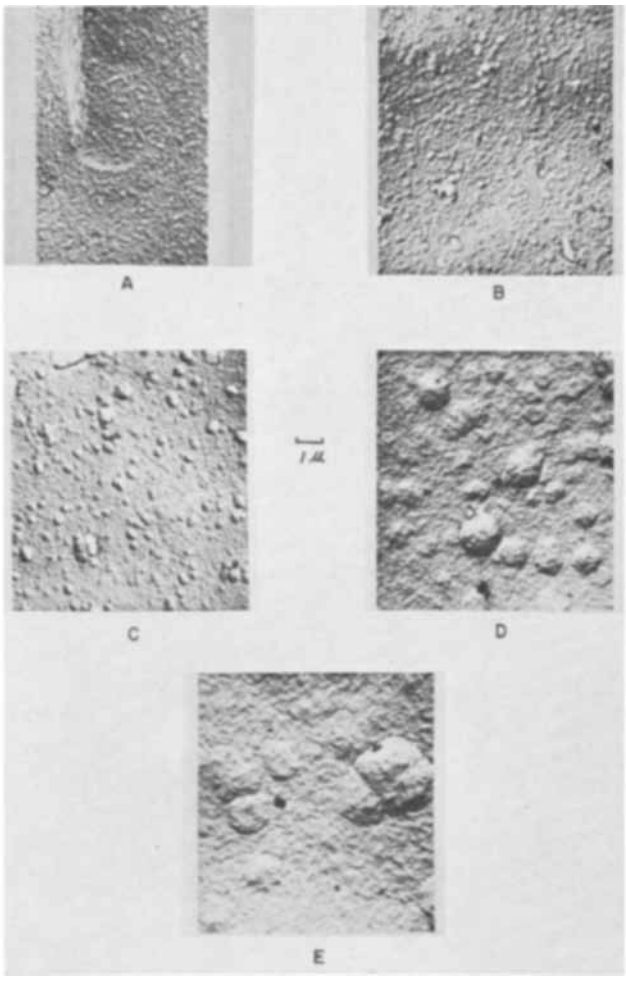

Fig. 2. Electron micrographs (magnification approximately 10,000X) of cobalt deposits at thicknesses of (A) 700Å, (B) 1200Å, (C) 2,300Å, (D) 7,000Å and (E) 14,000Å.

linear plot was obtained whose slope is one third. Thus the coercive force may be expressed as $Hc = KT^{-1/3}$.

Electron micrographs (20,000X) of the surface of deposits prepared at 700Å (3 min), 1,200Å (5 min), 2,300Å (10 min), 7,000Å (30 min) and at 14,000Å (60 min) were obtained to study the effect of thickness on the surface characteristics. The electron micrographs are shown in Fig. 2 A,B,C,D, and E. Examination of the micrographs indicated that initially (Fig. 2A) the deposit consists entirely of crystallites in the size range of 0.08-0.15μ projecting above the surface; as the deposit becomes thicker these crystallites become larger (colonies, aggregates, or single crystals) but fewer in number. For example, at 10 min these crystallites have a size of approximately 0.40-0.50μ (Fig. 2C) and at 60 min (Fig. 2E) the size (diameter) increased to 1.5μ to 2.0μ. The height of these crystallites above the surface (estimated from shadow) apppears to decrease slightly with increasing thickness, but the number per unit area decreases rapidly. Therefore, the average smoothness increases as the deposit becomes thicker, but locally the surface may be quite rough. The surface texture or background of the deposit becomes apparent at a thickness of approximately 2,300Å (Fig. 2C). The background growth becomes more well-defined as the thickness increases, *i.e.*, edges and facets are apparent in the thicker deposits (Fig. 2E).

X-ray diffraction data indicate that the deposits are crystalline, finely grained, and have a hexagonal structure typical of cobalt. The crystallinity is in contrast to chemically deposited nickel which is reported to be amorphous (5). The diffraction patterns indicate a $(10\bar{1}0)$ preferred orientation parallel to the substrate. The relative peak broadening increases as the thickness decreases indicating a finer grain size and/or increasing stress with a decrease in thickness.

The deposition rate increases directly with an increase in solution concentration of cobalt plus hypophosphite ion. Therefore, to determine the effect of total concentration on the magnetic properties, deposits were compared at equal thicknesses. Solutions were prepared at 1.8, 4.0 (standard solution), 7.3, and 14.5 g/l of cobalt plus hypophosphite concentration at a fixed cobalt to hypophosphite ratio of 0.86. The magnetic properties as a function of thickness were determined at each concentration of cobalt plus hypophosphite ion. The coercive force vs. thickness for deposits prepared at 1.8, 4.0, and 7.3 g/l concentration is shown in Fig. 3 while the results for 14.5 g/l are shown in Fig. 4. Increasing the total concentration of cobalt and hypophosphite ion at a fixed ratio of cobalt to hypophosphite (0.86) increases the coercive force from 315 oersteds (10,000Å) to 390 oersteds (10,000Å) at a concentration of 1.8-7.3, but at 14.5 g/l the coercive force decreases to 47 oersteds (10,000Å). Thus a high concentration of cobalt plus hypophosphite ion, *i.e.*, between 7.3 and 14.5 g/l at a cobalt to hypophosphite ratio of 0.86, produces deposits with a low coercive force. The remanent flux density decreases as the thickness increases in all cases (1.8, 4.0, 7.3, and 14.5 g/l Co^{++} plus $H_2PO_2^-$). The desposits prepared at the low concentration (1.8) have the highest

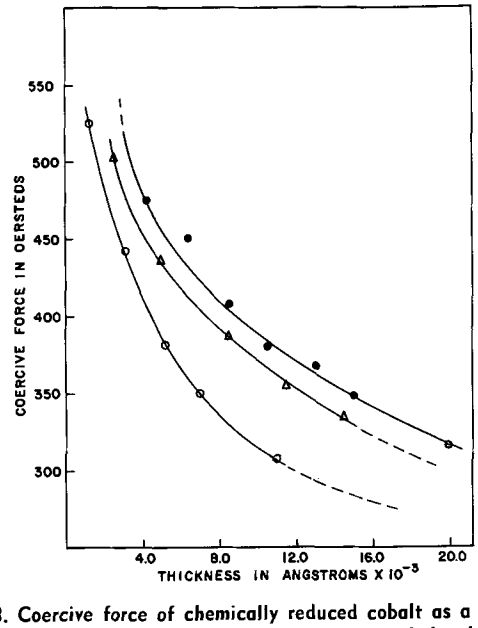

Fig. 3. Coercive force of chemically reduced cobalt as a function of thickness at various total concentrations of cobalt plus hypophosphite ion: • Co^{++} plus $H_2PO_2^-$ = 7.3 g/l; △ Co^{++} plus $H_2PO_2^-$ = 4.0 g/l; ○ Co^{++} plus $H_2PO_2^-$ = 1.8 g/l; cobalt ion to hypophosphite ion ratio = 0.86.

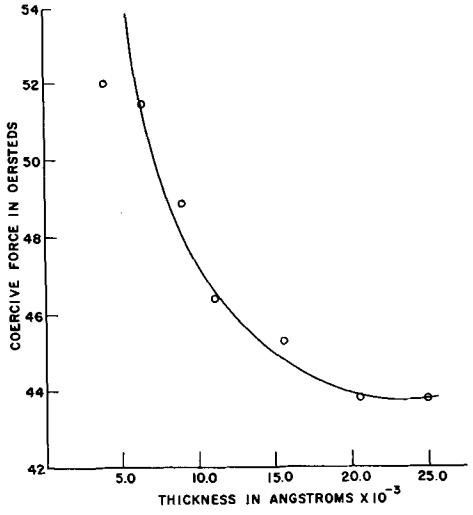

Fig. 4. Coercive force of chemically reduced cobalt as a function of thickness from a solution containing 14.5 g/l of Co^{++} plus $H_2PO_2^-$ ion; ratio of cobalt ion to hypophosphite ion = 0.86.

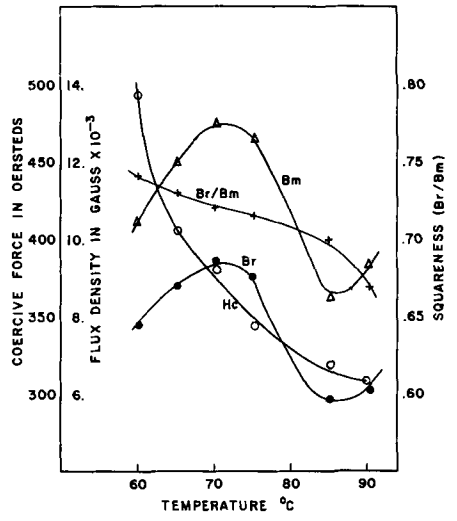

Fig. 5. Magnetic properties of chemically deposited cobalt at various temperatures but at constant time (60 min). • Remanent flux density; △ maximum flux density; ○ coercive force; and X squareness (Br/Bm).

remanent and maximum flux densities. The squareness (Br/Bm) of the deposits generally decreases with increasing thickness, but deposits from the dilute solutions tend to have a slightly higher squareness in comparison with deposits prepared at the higher (14.5 g/l) concentration of cobalt plus hypophosphite ion.

Influence of pH.—The influence of pH on the coercive force of chemically deposited cobalt was determined at pH values from 7.0 to 9.0 at intervals of 0.2 pH unit. The coercive force as a function of thickness was determined at each individual pH value. The coercive force decreases with increasing thickness at all pH values. The magnitude of the coercive force at a given thickness is nearly constant at pH values between 7.4 and 8.2. However, an increase in coercive force at a given thickness occurs at pH values from 8.2 to 8.6, *e.g.*, 389 oersteds (8.2) to 406 oersteds (8.6). Between a pH of 8.6 to 9.0 a drastic decrease in coercive force occurs from 406 oersteds (8.6) to 50 oersteds. This drastic decrease in coercive force with pH is similar to that which occurs with an increase in cobalt plus hypophosphite ion concentration. Below a pH of 7.4 cobalt will not deposit readily, and at a pH of 7.0 deposition ceases.

Volume to area ratio.—A few experiments were performed to determine if the magnetic properties of the deposits from the standard solution were dependent on the ratio of volume of plating solution to sample surface area. The volume to area ratio was varied by a factor of 100 by varying the sample area (cm^2) and solution volume (ml). The coercive force, remanent, and saturation flux densities were then determined as a function of thickness (time) at volume to area ratios of 8.0, 55.0 and 800. The coercive force does not appear to be appreciably dependent on the volume to area ratio. However, the lowest maximum flux density occurs at the highest volume to area ratio. The rate of deposition increases slightly with increasing volume to area ratio, *e.g.*, approximately 330 Å/min at a volume/area ratio of 800 and approximately 240 Å/min at a volume/area ratio of 8.0. The decrease in flux density may be associated with greater occlusion of impurities with increasing rate of deposition. However, the squareness of the deposits does not appear to be significantly different at various volume to area ratios. Consequently, all the magnetic properties remain similar with volume/area changes with the exception of the maximum flux density.

Influence of temperature.—The effect of temperature on cobalt deposits prepared from the standard solution was investigated by depositing for a constant time (60 min) at solution temperatures varying from 60° to 90°C at intervals of 5°C. The effect of solution temperature on the magnetic properties of the deposits is shown in Fig. 5. The coercive force decreases with increasing temperature. The saturation and remanent flux densities increase to a maximum at approximately 75°C and then decrease with further increases in temperature. The thickness (or deposition rate) increases directly with solution temperature for the 60-min deposition time. The squareness of the deposits decreases with increasing temperature. Thus the decrease in coercive force and squareness can be attributed primarily to an increase in the thickness. However, the variation of flux density with temperature cannot be explained by the change in thickness since the flux density decreases from the standard solution (80°C) without going through a maximum.

Electron micrographs (20,000X) of the surface of these deposits were examined. It can be seen from these micrographs that the deposits contain a fine textured background crystal growth with relatively large aggregates or colonies of crystallites growing perpendicular to the background. These aggregates or colonies increase in size as the solution temperature increases (increasing thickness), but the number per unit area decreases with increasing temperature. The surface roughness of the deposit is determined primarily by the height of these projections above the surface. The micrographs appear similar to those shown in Fig. 2 depending on

Table II. Recording Characteristics

Tape	Thickness, mils	Coercive force, oersteds	Pulse width, mils	Packing density, bits/in.	Signal amplitude, Mv	Saturation current, ma
Cobalt	0.03	400	1.0	800	700	60
Cobalt	0.055	330	1.5	550	925	70
3M #189	>0.3	278	1.3	665	1,200	80
3M #198	>0.3	282	1.2	770	1,100	80
Ampex 832	>0.3	278	1.2	770	1,100	65

the temperature and indicate that the primary effect of temperature on the magnetic properties is to vary the thickness. For further verification some measurements of the effect of solution temperature were made at (various deposition times) constant thickness. The coercive force was nearly constant as the temperature increased from 65° to 90°C.

Heat treatment.—A cobalt deposit from the standard solution was heat treated at low temperature (40°-175°C) for 24 hr in air to determine the effect of a stress relief on the magnetic properties of the cobalt deposit. Increasing temperature increases the coercive force of the deposit from 320 oersteds at 40°C to 354 oersteds at 175°C. The squareness (Br/Bm) remains nearly constant although a slight decrease is noted from 0.80 to 0.78 Br/Bm prior to and after heat treatment. Therefore a stress relief results in an increase in the coercive force of chemically reduced cobalt since at such a low-temperature grain growth, diffusion or orientation changes can hardly occur. This result is in agreement with previous results (6) showing that a stress relief of hexagonal cobalt electrodeposits results in an increase in coercive force.

Recording characteristics.—Preliminary recording tests of chemically deposited cobalt samples were made to determine their recording characteristics such as pulse width, packing density, signal amplitude, and saturation current. Nonreturn to zero saturation recording was used. The tests were made on a conventional closed-loop tape transport mechanism utilizing an Ampex head for recording and reading. The tape speed was 100 ips. The saturation current was determined at 20 kc as the value beyond which output and/or uniformity no longer increased. The maximum packing density in bits/in. was determined by the pulse interval at the value of recording frequency which reduced the output signal by 20%. The recording characteristics of several cobalt deposits were compared with three commercial oxide recording tapes, namely, Minnesota Mining and Manufacturing Tapes #189 and #198 and Ampex Tape #832. The tests were made under identical conditions of recording and reading. Results are shown in Table II. It is obvious that the cobalt deposits may have a slightly higher or equivalent packing density to that of oxide tapes. In addition the pulse width may be slightly higher or less than that of the tapes. However, the signal amplitudes were generally less. The saturation current is lower despite the higher coercive force of the cobalt deposits since the coating is much thinner than the oxide coatings.

Discussion

It is apparent from the experimental data that, in order to define the magnetic properties of chemically deposited cobalt, the concentration of cobalt plus hypophosphite ion, the pH, the solution volume to sample area ratio and temperature must be specified. The effect of these parameters on the magnetic properties can be explained by their subsequent effect on the thickness, crystal growth, and impurity content of the deposit. However, there does not appear to be any single factor which determines the magnetic properties.

The coercive force of the deposits is a function of the thickness. It would appear that the grain size in thin films (Fig. 2A) is approximately the same size as the background texture in thick films (Fig. 2E), *i.e.*, if one assumes that no subdivisions of the background texture or grains in the thin films occur. Also the grains would appear to be more isolated in the thin films. In addition, thick films contain aggregates, colonies, or large crystals. These large crystals, colonies, or aggregates may be responsible for the lowering of the coercive force as the deposit becomes thicker.

Generally, a high coercive force (Hc>300 oersteds) may be attributed to a rotational mechanism either coherent or some mode (fanning, curling) of incoherent rotation of the magnetization against the anisotropy (magnetocrystalline, magnetoelastic, magnetostatic) (7). In such cases the particle size determines the coercive force, and the coercive force is independent of the thickness. In the case of these deposits, the coercive force is dependent on the thickness, but it is not entirely clear from the electron micrographs whether the grain size is dependent on the thickness. Thus it cannot be determined whether a rotational model is applicable.

It is interesting to note that Neel (8) has proposed a relationship between grain size of a multidomain grain and the coercive force as $Hc = \gamma_o^{2/3} K^{1/6} Is^{-2/3} D^{-2/3}$ where γ_o is the wall energy, K is the anisotropy constant, Is the saturation magnetization, and D is the grain size of the film. Substituting the following values of $\gamma_o = 1$ erg/cm^2, $K = 4.0 \times 10^6$ ergs/cm^3, $Is =$ 1422 gauss for cobalt, and $D = 0.2\mu$, the average background grain size in thick films estimated from the electron micrographs (neglecting the clumps or aggregates), a coercive force of 350 oersteds is obtained. This agrees with the experimental coercive force of 360 oersteds at a thickness of 13,000Å. However, this model fails to explain the high coercivity in thin films which appear to have approximately the same grain size as thick films.

Thus, the source of the relatively high coercive force and the mechanism of reversal such as wall motion or rotation is unknown.

Manuscript received Dec. 8, 1961; revised manuscript Feb. 20, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Effect of Binary Alloy Plating on Delayed Brittle Failure of Ultrahigh Strength Steel

Walter Beck and E. J. Jankowsky

Aeronautical Materials Laboratory, Naval Air Material Center, Philadelphia, Pennsylvania

ABSTRACT

In a number of applications, involving high strength steel, tin-cadmium alloy plating has been substituted for cadmium plating. In this study, notched specimens of high strength steel were plated with tin-cadmium alloys, produced by codeposition of the components from a fluoborate bath. The steel was also plated separately with tin from the stannate bath and cadmium from the cyanide bath and the two layer system subjected to a thermal treatment. The marked differences in delayed cracking of specimens plated from baths with different compositions were discussed in the light of the coverage of the steel surface with adsorbed atomic hydrogen in conjunction with a recently advanced theory of the kinetics of crack propagation in delayed failure.

Some years ago the corrosion protection afforded a steel substrate by cadmium, zinc-cadmium, and tin-cadmium alloy coatings was evaluated at the Naval Air Material Center (1, 2). The protection offered by tin-cadmium systems was found to be most promising, and they have been used extensively on aircraft engine components since that time.

Recently, failures of tin-cadmium plated, carburized, and nitrided engine parts were reported, and hydrogen embrittlement was considered to be a possible cause. No information was available regarding embrittlement characteristics of the process, and inasmuch as hydrogen embrittlement could seriously curtail its use and extension to other high strength steel parts, it was deemed necessary to investigate the problem thoroughly.

Binary alloy coatings are formed by direct plating from an alloy bath and also may be formed by thermal treatment of separately plated layers of the constituent metals.

In either case, the embrittlement problem is probably more complex than it is for single metal deposition, as may be expected, particularly for the two-layer system. A study of this problem, therefore, appears of general interest.

The baths used in this investigation for tin and cadmium plating in producing the two layer system were different from each other and from that employed for plating the alloy directly, because they were patterned after industrial and governmental practice now extensively used for plating internal steel components of aircraft engines. The same is true for the coating thicknesses and alloy compositions selected for this study.

The principal objective of this study was the determination of the differences in embrittlement resulting from the plating of tin-cadmium coatings on a high strength steel by two different processes, and if differences resulted, to determine to what extent the component parts of each process contributed to the total embrittlement.

A secondary objective was to apply an existing theory of the kinetics of delayed brittle failure to the results and to interrelate hydrogen coverage with this theory.

The embrittlement was determined by sustained loading delayed failure measurements on notched specimens of ultrahigh strength AISI SAE 4340 steel. Some delayed fracture studies were also conducted on a type H-11 hot work die steel plated with cyanide cadmium and a diffused, heat resistant nickel-cadmium alloy, respectively.

Experimental Procedures and Results

Specimens and testing.—Most of the work was done with specimens fabricated from 4340 steel heat treated to a strength level of 260-280 (R_c 51-52) ksi. Some studies were made on a type H-11 hot work die steel heat treated to the same strength level as the 4340 steel. Cylindrical, notched tension specimens were selected for the experiments because they are known to be very sensitive to hydrogen embrittlement. Notches were ground after heat treatment, to the dimensions shown in Fig. 1. Notches were lightly polished, gauge sections highly polished. Static tension tests were performed in a universal testing machine, at a constant cross head speed of 0.05 in./min. Times to fracture under sustained loading were determined in constant load lever arm stress rupture machines at room temperature. The loading devices used were designed to insure concentricity of load application.

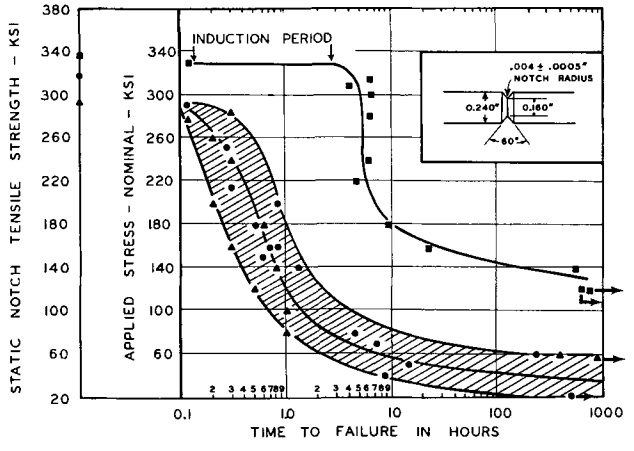

Fig. 1. Hydrogen embrittlement by plating of 4340 steel with tin, cadmium, and tin followed by cadmium and a thermal treatment. ■, Cyanide cadmium plating; ▲, stannate tin plating; ●, stannate tin, followed by cyanide-cadmium plating. All plated specimens treated for 30 min at 340°F. The tin-cadmium double coating consisted of approximately 50% tin and remainder cadmium. UTS unplated steel 260-280 ksi; NTS unplated steel 360-380 ksi; $K_T = 4.2$.

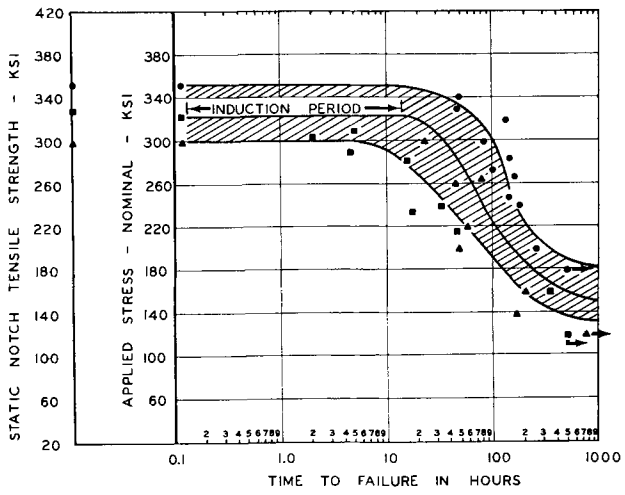

Fig. 2. Hydrogen embrittlement by plating of 4340 steel with tin-cadmium alloy and its components. ■, Fluoborate cadmium plating; ▲, fluoborate tin plating; ●, tin-cadmium alloy formed by codeposition of the metals from fluoborate bath; approximate composition of alloy 30% tin, remainder cadmium.

When no thermal treatment was to be applied, specimens were stressed 5 min after plating. Thermally treated specimens were stressed immediately after cooling down to room temperature. Threads were carefully masked before immersion in the plating bath to avoid thread breaks during load application.

Two-layer tin-cadmium plating followed by a thermal treatment.—Prior to plating, the specimens were anodically cleaned in a hot alkaline solution and dipped in 50% HCl solution for 50 sec at room temperature. This pretreatment insured good adhesion of the plating without affecting the notch dimensions. The acid dipped specimens, stressed immediately after dipping to 95% of the notch tensile strength of the untreated steel (4340 steel average 370 ksi, type H-11 steel average 385 ksi), did not fail when kept underload for the maximum time of 1000 hr.

Tin was plated from a stannate bath to an approximate thickness of 0.00008 in. measured on the gauge section. Immediately following tin plating and rinsing, cadmium was plated to the same thickness from a cyanide bath.

To alloy the tin with the cadmium, a recommended thermal treatment (1) at 340°F, for a period of 30 min, was used. Nominal composition of the alloy was 50% tin, 50% cadmium.

Specimens were also plated singly with tin or cadmium under the same conditions as those used for plating each of the two layers, and the same thermal treatment was applied.

Delayed failure curves are presented in Fig. 1 for tin, cadmium, and tin-cadmium plated specimens. Failure times determined for tin-cadmium plated steel and for those plated only with tin were close enough to be covered by a scatter band, typical of delayed brittle failure measurements under sustained loading.

Tin-cadmium alloy formation by codeposition of its components.—After alkaline cleaning and acid dipping, the alloy was directly plated from a complex fluoborate bath (1, 3, 4) recommended in the literature. The approximate thickness of the plating, measured on the gauge section, was 0.0005 in. and its composition, as determined by chemical analysis, was approximately 30% tin, remainder cadmium. Tin and cadmium were also plated separately from fluoborate baths to thicknesses of approximately 0.00015 in. and 0.00035 in., respectively, corresponding to their ratio in the alloy.

Figure 2 is a plot of the failure curves recorded with specimens plated from fluoborate baths. Again, the values for the failure times are randomly distributed in the field of a comparatively wide scatter band.

Plating of nickel followed by cadmium and a diffusion heat treatment.—The nickel-cadmium coating system was applied on hot work die steel specimens pretreated in the same manner as the 4340 specimens. Nickel was plated to an approximate thickness of 0.0002 in. from a Watt-type bath without brightener, and cadmium to an approximate thickness of 0.0001 in. from a cyanide bath, according to ref. (5). The coating system, with a nominal composition of 65% nickel, remainder cadmium, was diffusion heat treated in a circulating air furnace at 630°F for 40 min (5).

The comparatively high diffusion temperature did not have a detrimental effect on the strength of the substrate which was an air hardening steel tempered at a temperature of 1050°F. This type of steel is used at elevated temperatures and, therefore, not plated with tin-cadmium but heat and oxidation resistant nickel-cadmium alloy. The delayed failure behavior of this steel, coated with diffused nickel cadmium or plated with 0.0005 in. cyanide cadmium[1] is depicted in Fig. 3. Cyanide cadmium was plated on this steel to allow comparison with 4340 steel.

Metallographic and electrochemical evaluation.—The work on tin-cadmium alloy plating was considered incomplete without some information about the metallurgical structure of the system obtained by thermal treatment of the separately plated layers.

The opinions concerning the question of whether or not alloy formation takes place under the thermal

[1] Fed. Spec. QQ-P-416a (1956).

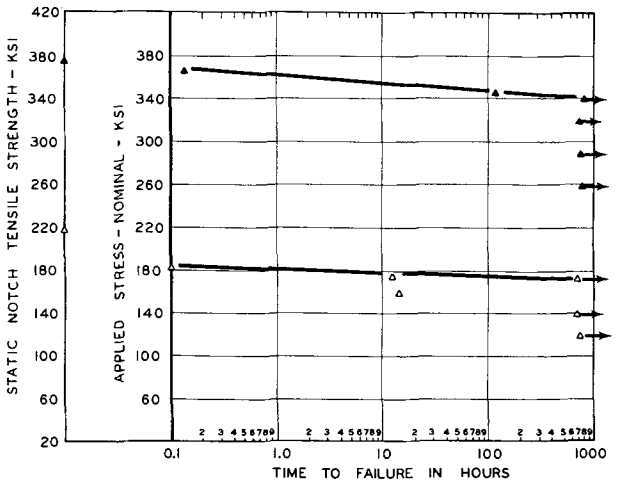

Fig. 3. Hydrogen embrittlement by plating of a hot work die steel with nickel followed by cadmium and a diffusion heat treatment, and by cyanide cadmium plating. Inverted solid triangle, Watts-type nickel plating followed by cyanide cadmium plating, diffusion heat treated for 40 min at 630°F; inverted open triangle, cyanide cadmium plating; the nickel cadmium system consisted of approximately 65% nickel and remainder cadmium; UTS unplated steel 260-280 ksi, NTS unplated steel 380-390 ksi, $K_T = 4.2$.

treatment conditions used in this investigation are divided. According to Britton and de Verre Stacpoole (6), the coating remains in layers; however, Scott and Gray show evidence that tin diffuses through the cadmium matrix (7).

In the studies made at this laboratory, steel panels were plated first with 0.002 in. of tin, and then with 0.002 in. of cadmium. After plating, the panels were thermally treated at 340°F for 1, 2, and 24 hr, respectively. The specimens were then sectioned at a low angle, mounted in cold hardening epoxy, rough polished with emery paper of increasingly finer grades up to 000, final polished with diamond dust of 3 and 0.5μ, and etched for 2 min in 30% aqueous NaOH solution at room temperature.

According to the phase diagram, at 340°F, under conditions near or approaching equilibrium, the only phases that can be present are α, ranging in composition from pure tin to 1% cadmium in solid solution, in contact with β, with from 4.0 to 5.5% cadmium in solid solution, and γ, ranging from pure cadmium to 0.25% tin in solid solution, in contact with β. The α solid solution can be in equilibrium only with the β (4.0% tin); likewise, γ may only be in equilibrium with β (5.5% tin). Since no evidence of a eutectoid structure resulting from the decomposition of a β phase was observed metallographically, even after 24 hr at 340° ± 3°F, it must be concluded that little or no diffusion of either tin or cadmium in other than the terminal solid solutions took place.

The metallographic findings were in excellent agreement with the electrochemical behavior of the coatings. Average steady-state potentials of two layer, thermally treated coating systems containing from 10 to 75% cadmium, measured in 0.1*N* NaCl solution at room temperature, were found to be —800 mv on the saturated calomel scale. Similar values were obtained on steel panels plated only with cyanide cadmium. The average potential of tin plated panels was —500 mv.

These results are in good agreement with the statements by Britton and de Verre Stacpoole (6), but do not concur with the results obtained by Scott and Gray (7). There are indications that the diffusion of tin into cadmium, demonstrated microscopically by the latter investigators, may be due to overheating, because the alloy appears homogeneous from the edge to the base, even though the time of thermal treatment (30 min at 350°F) appears much too short to ensure complete diffusion.

Because alloy formation could not be detected, the tin-cadmium system will now be designated a two-layer plating.

With respect to alloy formation by codeposition of the tin and cadmium components, attention is directed to a very recent paper by Smart *et al.* (8) who studied alloys formed by codeposition of the two metals from a complex sodium stannate-cyanide cadmium bath. According to these investigators, the plated tin-cadmium alloy is a simple eutectic system which consists of a mixture of the two high-purity components.

No metallographic investigations were made of the nickel-cadmium system. Therefore, diffusion of cadmium into nickel was only assumed to take place because it was implied in the aeronautical specification (5).

Discussion of Results

The discussion of the curves presented in Fig. 1-3 will be based partially on a recently advanced theory of the kinetics of crack initiation and propagation in delayed failure (9, 10). According to this theory, delayed brittle cracking can be aptly described by various parameters such as the incubation period, failure time, and the static fatigue limit.

The incubation time is the period required for initiation of the first crack, and the failure time is a measure of the crack propagation rate subsequent to crack initiation. The stress below which delayed failure cannot take place for an indefinite period and above which it must occur is called the static fatigue limit.

The incubation period represents the time which is needed for the hydrogen atoms to accumulate in the region of maximal triaxial stress state until a critical concentration, required for crack initiation, has been attained. Following crack initiation, there is a period of crack propagation, and finally, failure takes place. The parameter called "induction period" in the following discussion, includes both the incubation period and the crack propagation period at the highest stress at which delayed failure occurs (see Fig. 1).

It has been shown that immediately after cadmium plating (9) or cathodic charging (10) the hydrogen atoms remain concentrated in a thin layer underneath the steel surface, and from there, they diffuse into the interior of the specimen. With decreasing surface concentration of hydrogen, incubation, fracture time, and static fatigue limit increase, progressively.

Based on the work of Troiano and his co-workers (11, 12), it is inferred that a long induction time results, at least in part, from a long incubation period.

Induction time.—To simplify the analysis of the results of determinations of the induction times, they

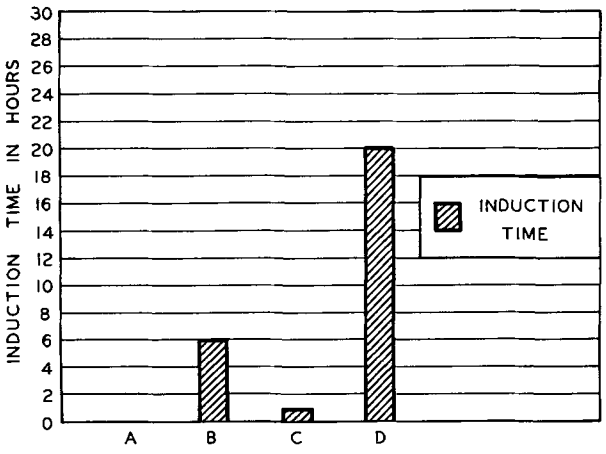

Fig. 4. Effect of plating on induction time of various steels. A, plating of stannate tin (sodium stannate bath operated at 160°F) followed by thermal treatment, plating of stannate tin followed by cyanide cadmium and a thermal treatment; B, plating of cyanide cadmium layer to approximately 0.00008 in. followed by a thermal treatment; C, plating of cyanide cadmium layer to approximately 0.0005 in.; D, platings from the fluoborate baths. A-D — 4340 steel.

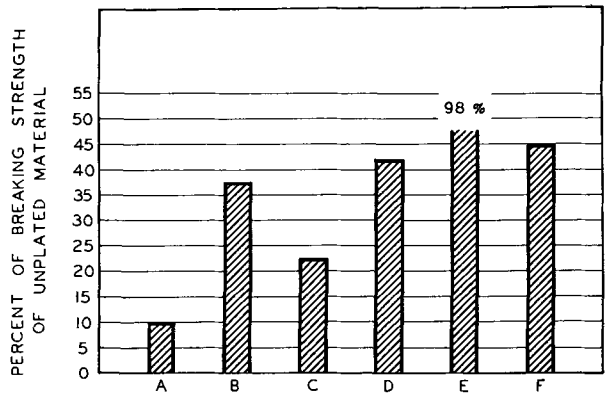

Fig. 5. Effect of plating on breaking strength of various steels, A,B,C,D as in Fig. 4. E, Plating of nickel followed by cadmium and a diffusion heat treatment; F, plating of cyanide cadmium to approximately 0.0005 in; E-F, hot work die steel.

are presented as bars in Fig. 4. Two interesting features of the results obtained with plated 4340 steel specimens are revealed in this figure: 1. The induction time is increased about twentyfold by plating the steel from the fluoborate bath (bar D) instead of the cyanide bath (bar C). 2. On specimens thermally treated after plating, that is, stannate tin plated specimens, and specimens plated with stannate tin and cyanide cadmium, respectively, the induction time is zero (bar A), and in the case of cyanide cadmium plated specimens, it was observed that the induction time was comparatively short (bar B).

In accordance with the theory discussed above and the results summarized under 1, it is concluded that the rate of crack initiation and propagation in specimens plated from the cyanide bath exceeds that in fluoborate plated specimens very appreciably. It is more difficult to explain the nonexistence of an induction period for the stannate tin or the stannate tin-cyanide cadmium plated specimens subjected to the same thermal treatment. It may be the result of homogenization (11) of the hydrogen distribution in the steel produced by the thermal treatment. It may also be speculated that the tin coating is a better hydrogen diffusion barrier than the thin cadmium coating (13) and that it therefore more effectively prevents outgassing of the embrittling hydrogen during thermal treatment, which would explain the short but finite induction time of the cyanide cadmium plated specimens. In any case, it is difficult to make predictions, based on induction time, about crack propagation in specimens coated with different metals and subjected to a thermal treatment.

Static fatigue limit.—The static fatigue limit should provide a more direct and more easily interpreted measure of embrittlement damage than the induction period. Figure 5 is a bar diagram of the static fatigue limits expressed in terms of percent of the breaking strength of the untreated notched specimens.

The differences in the static fatigue limits determined for fluoborate and cyanide cadmium plated specimens without thermal treatment, respectively, (bars D and C), confirm qualitatively the conclusions drawn from the induction times.

The low relative breaking strength (bar A) indicates that despite a comparatively short plating time (3.5 min for stannate tin, 2 min for cyanide cadmium) and the subsequent thermal treatment, the susceptibility of the steel to brittle cracking is very high as a result of stannate tin plating.

Hydrogen surface coverage.—The foregoing discussion clearly illustrates the usefulness of the theory of the kinetics of crack initiation and propagation, and particularly of the static fatigue limit, in accessing hydrogen embrittlement damage. However, the theory does not suggest a mechanism which determines the accumulation of hydrogen atoms in the metal surface.

For a number of years, extensive efforts have been made in the Aeronautical Materials Laboratory to obtain more information about this mechanism during cathodic polarization or plating. These efforts have been based on electrochemical and radioactive tracer studies on ultrahigh strength 4340 steel charged cathodically in sodium hydroxide solutions with and without sodium cyanide added, as well as electrochemical studies on steel plated with cadmium from cyanide and fluoborate baths. A comprehensive report of the results will be presented in a forthcoming paper (14). A few that relate to this paper are summarized below.

By radioactive measurements on steel surfaces after cathodic polarization in a 0.1M NaOH solution containing $NaC^{14}N$ in low concentrations, cyanide compounds were detected which tenaciously adhered to the metal. A positive heat of adsorption, in conjunction with increasing concentration of these cyanide compounds with temperature of radioactive charging solution, clearly indicated the mechanism of layer formation to be controlled by chemisorption. Hydrogen overvoltage measurements on steel electrodes with chemisorbed cyanide indicated a retardation of the hydrogen recombination reaction and hence a rise in the coverage of the surface with hydrogen. By means of the hydrogen permeation current method of Bockris and Devanathan (15) important information has been secured about this hydrogen coverage.

Addition of 0.02M sodium cyanide to a 0.1M sodium hydroxide solution raised the steady-state coverage of the steel surface with adsorbed atomic hydrogen during cathodic hydrogen evolution about 4.5 times above that in the pure sodium hydroxide solution.

In the case of cadmium plating from the cyanide bath, the coverage was only 3 times greater than that in the pure sodium hydroxide solution. It dropped further when cadmium was plated from the fluoborate bath, which was ascribed to the absence of a highly capillary active anion such as cyanide.

The extraordinarily high susceptibility of the stannate tin plated specimens to delayed failure is believed to be related to chemisorption accelerated by the comparatively high temperature of the plating bath. The rate of diffusion of the hydrogen atoms into the steel depends on the coverage of the surface with hydrogen (16). A high coverage will ensure that the hydrogen atoms diffusing from the thin layer underneath the specimen surface into its interior will be replenished at a high rate.

It is suggested that the differences in delayed brittle failure behavior of the specimens plated with tin followed by cadmium and those plated directly from an alloy bath be explained by combining the concept of hydrogen surface coverage with the theory of the kinetics of crack propagation.

In the case of the tin-cadmium coating applied by plating the constituent metals separately, the short stress rupture life is intimately related to a high hydrogen surface coverage, and it follows that the lower embrittlement imparted to the alloy plated specimens is the result of a comparatively low surface coverage with adsorbed hydrogen atoms, surface coverage being determined by the electrochemical action of the different bath anions.

Finally, the effect of plating on delayed failure of the hot work die steel will be discussed briefly.

As shown in Fig. 3, the embrittlement response of this type of steel is somewhat different from that of the 4340 steel. As can be seen from the diagram, the static notch tensile strength of the nickel-cadmium plated steel and its static fatigue limit are very close to the notch tensile strength (380 to 390 ksi) of the untreated specimen. The cyanide cadmium plated specimens again showed severe embrittlement (bar F in Fig. 5) but they were not as badly embrittled as the 4340 specimens (bar C in Fig. 5).

The almost complete absence of embrittling hydrogen in the steel (bar E in Fig. 5) may be the result of the high-temperature diffusion treatment or the proven effectiveness (17) of the low embrittling Watts nickel plating as a hydrogen diffusion barrier.

It is hoped that the studies now being conducted in this laboratory will give more information about the response to delayed brittle fracturing of H-11 and similar high strength hot die steels.

Summary

Delayed brittle cracking of ultrahigh strength 4340 steel, plated with stannate tin, followed by cyanide cadmium and a thermal treatment, is controlled by the tin phase of the plating process.

Embrittlement induced by plating the metals in two separate layers from the above baths appreciably exceeds that by codeposition of tin and cadmium from a complex fluoborate bath.

Delayed brittle failure in an ultrahigh strength hot work die steel plated with nickel from Watts type bath, followed by cyanide cadmium and a thermal treatment at a comparatively high temperature, was only of a negligible order.

The relative breaking strength derived from the static fatigue limit is representative of the embrittlement damage imparted to the steel. The marked differences in the stress rupture behavior of the plated specimens were related to differences in the surface coverage with adsorbed atomic hydrogen and discussed in the light of a recently advanced theory of the kinetics of crack propagation in delayed failure.

Rotating Disk Electrode Techniques for the Study of Addition Agents

I. Preliminary Studies with Cupric Sulfate Solutions

Seward E. Beacom and Robert N. Hollyer, Jr.

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

The rotating disk electrode is being used as a tool to study the influence of organic addition agents on the electrodeposition of metals; the initial phases of the study are reported in this paper. Rotating disk electrode theory has been verified for deposition of copper from cupric sulfate solutions in the presence of certain ratios of inert electrolyte ions. The experimental conditions required to proceed with a study of the role of organic additives have been established. It is found that current density is distributed uniformly across the surface of the disk electrode.

Many details of the influence of organic addition agents on the electrodeposition of metals are still unresolved. To attack certain phases of this problem, it is desirable to study the electrodeposition process under the most elementary conditions, *i.e.*, with the number of uncontrolled variables at a minimum. Because of its simplicity, an electrode system consisting of a stationary anode and a rotating disk cathode was chosen for the present investigation. This system has been successfully employed by a number of investigators to study redox reactions (1-7), but its use for the examination of the electrodeposition of a metal ion is relatively recent; the few reports in the literature indicate only limited success (4, 8, 9).

The rotating disk cathode is attractive because of the large volume of readily available literature concerning its flow pattern and the related mathematical analyses (1, 2, 5, 10-14). Examination of the equations shows that deposition must be carried out at the limiting current plateau and that migration due to electrical fields must be made negligible; the latter is accomplished by the use of a large excess of indifferent electrolyte.

The primary aim of the experimental program is to establish the conditions for which the mathematical description can be applied to the deposition of copper from an aqueous cupric sulfate solution. This is a necessary step in a program to employ the rotating disk electrode for examination of the influence of organic addition agents on the electrodeposition of metals.

Experimental

Description of apparatus.—Figure 1 is a block diagram of the apparatus which permits the rotation of a disk electrode at accurately controlled angular velocities. The shaft is driven by a variable speed motor. The frequency of rotation, recorded as revolutions per minute, is counted electronically by a scaler. Electrical contact to the shaft is made through a torroidal mercury cup. The glass vessel which holds the electrolyte is equipped with a side arm to permit the introduction of the 5 x 5 cm copper anode without disturbing the solution flow symmetry. The vessel, 12.7 cm in diameter, is sufficiently large to prevent the walls from interfering with the solution flow about the disk. A tight-fitting Lucite cover permits the maintenance of a nitrogen atmosphere above the electrolyte.

The potential, which is supplied by 1.5v dry cells and varied by means of a potentiometer, is measured with a vacuum tube voltmeter while current is measured with a milliammeter.

Electrodes.—The cathodes are stainless steel or solid copper disks, 6 mm thick and 1.27, 1.91, and 2.54 cm in diameter, respectively, mounted normal to the drive shaft. The sides and backs of the disks, as well as the drive shaft, are insulated from contact with the electrolyte. Very careful polishing and cleaning procedures are required. When the stainless steel disks are used they must be flash plated, first with a Wood's nickel strike, and then with cyanide copper. Experience has shown that the disks must be polished between runs and, if any roughness or staining develops, the complete plating preparation must be repeated. Because trouble was experienced with porosity in the cyanide copper deposit, the more recent work has been done with electrodes machined from high-purity copper.

Composition of electrolytes.—The electrolyte used in the majority of the work done thus far is an aqueous solution of cupric sulfate containing potassium sulfate as inert electrolyte. The cupric sulfate concentrations range from 0.001 to 0.020M and the po-

4D	0.004	0.05

tassium sulfate concentrations from 0.05 to 0.3M. The pH of all solutions was adjusted to 3.0 by the addition of sulfuric acid. The composition of the solutions is recorded in Table I.

Removal of oxygen.—To provide an oxygen-free environment, the nitrogen used for gassing is purified by passage through a solution containing vanadyl sulfate over amalgamated zinc as recommended by Meites (15). Gassing is carried out for 30 min before the start of each experiment, and a nitrogen atmosphere is maintained above the electrolyte during the run.

Procedure and Results

The plateau voltage, that is, the cell voltage required for the deposition of cupric ions at the limiting current, is determined from the current-potential curve obtained at a constant frequency of rotation. The plateau for the $CuSO_4$ solutions extends over a range of 0.35-0.45v; the value 0.4v was used for all experiments. The same general shape of the curve and the same plateau voltage is obtained regardless of disk size or of the frequency of rotation. As expected, the magnitude of the current varies with disk size and the frequency of rotation used.

Under the experimental conditions being employed, the mathematical description predicts that a plot of current density *vs.* the square root of the frequency of rotation will yield a straight line passing through the origin. A further consequence of the theory, which holds that the distribution of current will be uniform across the surface of the disks irrespective of size, was checked by using three disks of different diameters. As shown in Fig. 2, both of these requirements are met. The fact that the average current density is the same for all three disk sizes can be assumed to indicate that the local current density is everywhere the same. An additional check of this point was made by measuring the thickness of copper deposits along the radii of the 1.91- and 2.54-cm disks using the interference microscope. Within the limit of experimental error (±5%) the deposit thicknesses are uniform over the disk surfaces.

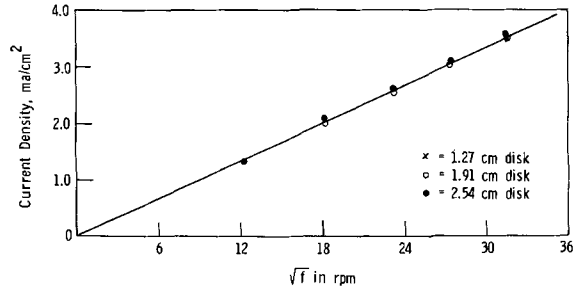

Fig. 2. Current density *vs.* root frequency for various sized disks

Since the general objective of this investigation is to use the controllable deposition conditions at the rotating disk electrode to examine the role of addition agents in the electrodeposition of metals, it is important to determine a range of cupric ion and potassium sulfate concentrations over which the requirements of the rotating disk theory may be met. When this range is once established, it then becomes possible to investigate the influence of organic addition agents.

Using the electrolytes listed in Table I, the current density *vs.* root frequency relationship is determined over a range of solution compositions. A plot, typical of the results obtained, is given in Fig. 3. It will be noticed that the plots, which are straight lines passing through the origin, meet the predictions of rotating disk theory. A plot of the slope $i/\sqrt{f}$, *vs.* the cupric sulfate concentration should be a straight line intersecting the origin. Figure 4 is a plot of this expression for the A, B, and C solutions. The agreement with theory is apparent.

Inspection of Fig. 5 shows that the plots of solutions 12B and 20B deviate from a straight line. The

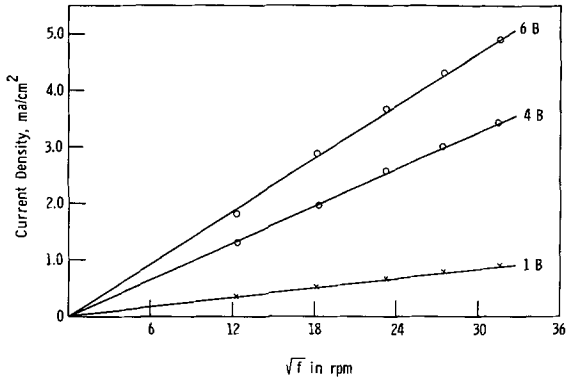

Fig. 3. Current density *vs.* root frequency for a series typical of electrolytes used.

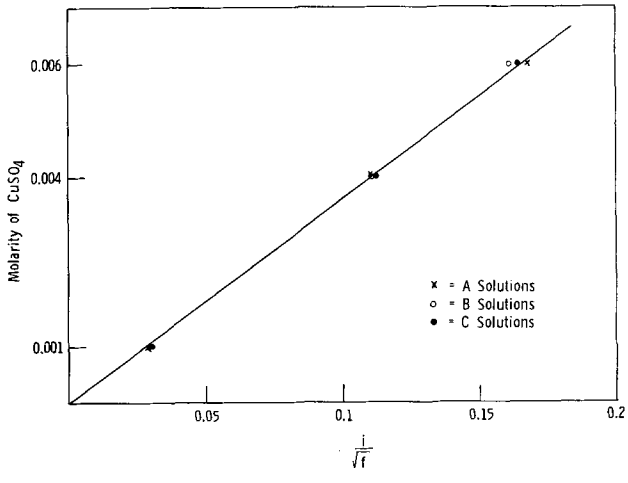

Fig. 4. Plot of slope, $i/\sqrt{f}$, *vs.* molarity of cupric sulfate solutions

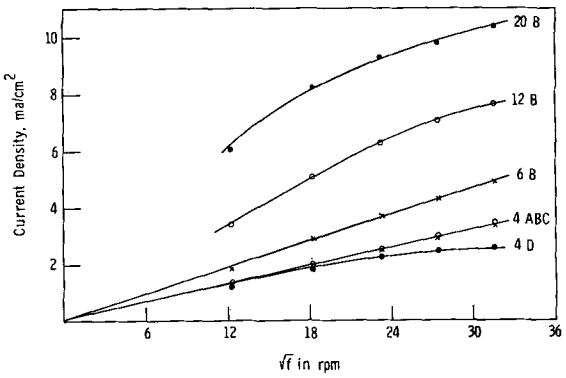

Fig. 5. Current density vs. root frequency for some extreme values of electrolyte composition.

plot for solution 6B is included for comparison. A similar deviation is observed for the plot of solution 4D which is compared with solutions 4A, B, and C. Apparently the compositions of solutions 12B, 20B, and 4D do not provide the electrolyte characteristics required to meet the predictions of rotating disk electrode theory.

Discussion

It is apparent that the predictions of rotating disk electrode theory may be met under certain very carefully controlled conditions. Analysis of the results shows that plots of current density *vs.* root frequency are straight lines passing through the origin when the ionic ratio of potassium ions to cupric ions is fifty or larger. Solutions with a ratio of fifty and up show straight lines; solutions 12B, 20B, and 4D, having ionic ratios of 33.3, 20, and 25, respectively, deviate from a straight line. Apparently an electrical transport factor is introduced, and transfer of metal ions to the electrode is no longer diffusion and convection controlled. It appears safe to assume that ionic ratios above fifty provide electrolyte conditions which are suitable for investigating the influence of organic additives on the electrodeposition of copper.

A Flow Synthesis of Gallium Phosphide and Some Properties of Gallium Phosphide Powder Layers

Lewis J. Bodi[1]

General Telephone & Electronics Laboratories, Incorporated, Bayside, New York

ABSTRACT

A simplified synthesis of gallium phosphide powder in an open flow-system is described. Phosphorus vapor is carried over gallium(III) oxide by a stream of hydrogen. The oxide undergoes complete conversion to phosphide at about 1000°C. A thermal treatment enhances average particle size, and electroded GaP powder layers are fabricated. Electrical properties and electroluminescence characteristics of these layers are reported.

The projected utilizations of the unique properties of gallium phosphide have effectively dictated approaches to its synthesis which are directed at yields of single crystals. The simplest synthesis from a chemical standpoint is the most complicated in terms of implementation. Gallium is generally induction heated in a graphite container which is part of a two or three thermal-zone, sealed-quartz system. A phosphorus atmosphere is maintained by one of the heated zones which acts as a phosphorous reservoir. The attainment of sound polycrystalline ingots in such a system requires the maintenance of the equilibrium phosphorous pressure (~ 20 atm) at the melting point of the stoichiometric material (~1500°C) to facilitate zone refining. These conditions of pressure and temperature are stringent impositions on such systems, and the system of Frosch and Derick (1) aptly illustrates the degree of sophistication necessary to idealize the experi-

[1] On leave from Department of Chemistry, Brooklyn College, Brooklyn, New York.

mental conditions. Other syntheses have been published, however, in which the synthesis' reaction is not a direct combination of elements. Notable among these are the efforts of Antell and Effer (2, 3) which, in addition to providing a variety of approaches utilizing sealed systems, also include an open-flow-system procedure. Recently, Gershenzon and Mikulyak (4) described a preparation in which a mixture of gallium and gallium (III) oxide reacted to form the suboxide which in turn reacted with phosphorus vapor in a sealed two-thermal-zone system. An interesting variety of single crystal morphologies resulted, but the reaction failed to go to completion.

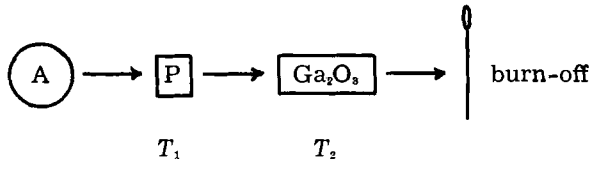
Among the properties of gallium phosphide which suggest device application the electroluminescent character is of particular interest in these Laboratories. The possibility of employing this material in the preparation of a broad area light source is especially intriguing because of its fast ($\sim 10^{-8}$ sec) response to stimulating fields (5). One broad area electroluminescent source of simple conception but of considerably more challenging execution is the single crystal containing a p-n junction which has been effected by impurity in-diffusion. The difficulty of attaining this end begins with the aforementioned, nontrivial problem of producing uniform-cross section, single-crystal ingots of GaP. It is evident that a broad area light source consisting of gallium phosphide powder should have the double advantages of simplified fabrication of the light producing layer and of an easing of the stringent pressure-temperature conditions attending synthesis. It was this interest in a powder technology of gallium phosphide, promoted to some extent by occasional calamitous experiences with sealed system syntheses of GaP, which provoked a search for a chemically reliable powder preparation which presents no explosion hazard.

Synthesis

Previous to the development of an open-flow synthesis of gallium phosphide, sealed tube syntheses were successfully carried out which established the method which would eventually be employed. Phosphorus and gallium (III) oxide were sealed into a quartz ampoule. The ampoule was sufficiently long to permit heating in a two-zone furnace. The vapor pressure controlling end was heated to about 400°C, the reaction end containing the oxide to about 1000°C. A brownish granular product resulted which gave a clean, GaP x-ray diffraction pattern. All of the oxide underwent conversion. The reaction is presumed to be the reduction of the oxide to the phosphide accompanied by the formation of oxides of phosphorus.

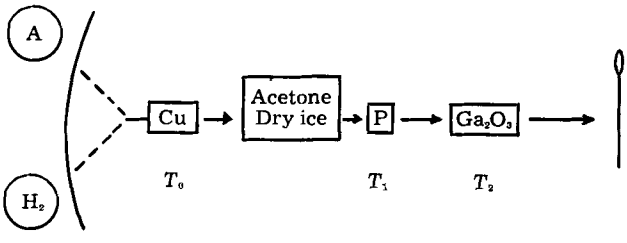
The GaP produced consisted of powder, of about the fine state of subdivision of the starting oxide, and a surface mat of needles. It would seem that the latter is a recrystallization of the initially formed powder by a vapor phase transport mechanism.

Although the approach described was successful chemically, it did not provide the stability guarantees which were desired; several such tubes achieved self-destruction while undergoing post-reaction cooling. Examination of the tube fragments in those cases revealed the existence of an inner surface layer of a gallium silicate (indicated by x-ray diffraction analysis) suggesting that the synthesis runs were terminated by differential thermal contraction between the quartz envelope and the adhering silicate. Although surface silicate formation could have been prevented by appropriate modification of the oxide position within the tube, it was decided to attempt the same synthesis in an open system. An inert carrier gas was to be used to transport phosphorus vapor over the gallium oxide. To that end, the following system was set up employing argon as the carrier



$T_1 \sim 400°C$ $T_2 \sim 1000°C$ $t \sim 1$ hr

The product was an orange-pink material which, under the microscope, was seen to consist of a mixture of separate orange and white granules. X-ray diffraction analysis indicated the presence of GaP and $GaPO_4$ as major phases. The incompleteness of the reaction (or re-oxidation of product) was attributed to the presence of oxygen and/or moisture in the system. To reduce these the system was modified to include a copper trap for oxygen which was maintained at 500°C and a dry-ice, acetone moisture trap. The product which resulted from the modified system was not an improvement over the initial flow-system material. The copper turnings exhibited no darkening indicating the low oxygen content of the argon. The acetone-dry ice trap did, however, pick up observable moisture. At this point it seemed evident that an additional source of oxidizing impurity must be the phosphorus itself (Fisher P. 99). It is known that this grade of phosphorus contains moisture, phosphoric acid, oxides of phosphorus, and water soluble salts. Because of the oxidizing nature of the impurities a reducing carrier was utilized to resolve the difficulty. (Although purer phosphorus was available the necessity for break seals for such phosphorus detracted from the over-all objective of operating simplicity.) A consequent system modification resulted in:



Conditions of time and temperature were those of the preceding synthesis attempt. Argon was used to flush the system prior to and following the hydrogen flow which was maintained during heating of the gallium oxide. The effect of the reducing atmosphere was decisive. The product was a granular orange-brown material covered with a mat of needles (Fig. 1 and 2). A well-defined x-ray diffraction pattern verified the presence of a single

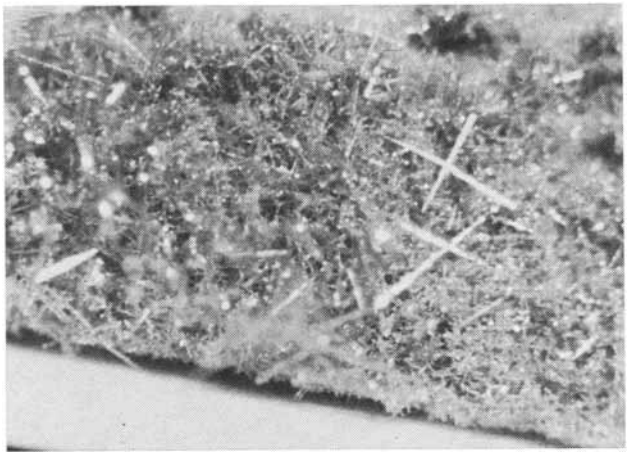


Fig. 1. Mat of GaP needles covering crucible resulting from reaction of phosphorus with gallium (III) oxide. Magnification about 30X.

Fig. 2. Fine grained GaP underlying the surface mat of GaP needles. Magnification about 30X.

cubic phase consisting of gallium phosphide. Spectroscopic examination of the starting Ga_2O_3 (prepared in our laboratories by high-temperature oxidation of 9[5] gallium in a vitreosil vessel) revealed the presence of traces of Al, Cu, Fe, and Mg as well as Si at higher levels ($\sim$ 200 ppm). The resulting GaP contained the preceding plus additional traces of Ni, Mn, and Cr which had evidently been introduced when the Ga_2O_3 was milled. The red phosphorus seems not to have been a source of additional impurities.

Recrystallization and Layer Preparation

The product obtained in the described synthesis was of approximately the same grain size as the parent gallium oxide, namely submicron to micron. In the applications for which the powder was intended, particle size is important and growth from the micron range was necessary. Because of the relatively high volatility of gallium phosphide, the appreciation of particle size posed no real difficulty. That vapor transport is the probable grain growth mechanism is indicated by our experiments in which appreciable crystal growth was observed on the upper walls of crucibles in which GaP powder was heated at as low as 900°C. The small grained gallium phosphide was sealed into an evacuated quartz ampoule which was rotated in a furnace

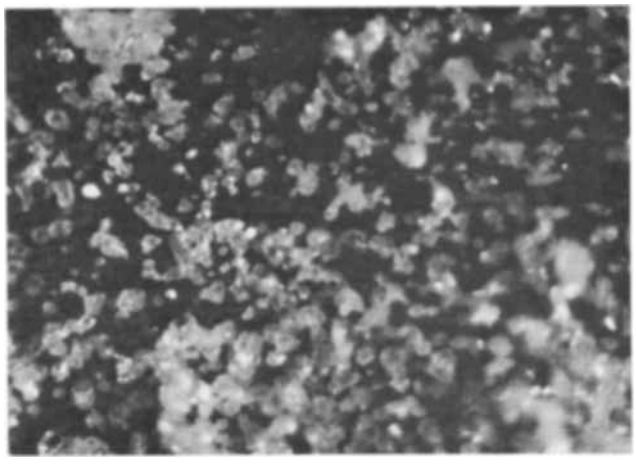

Fig. 3. Material of Fig. 2 after recrystallization. Magnification about 30X.

at 1050°C for several hours. The appreciation in particle size can be readily observed by reference to Fig. 2 and 3. Although it would have been possible to conduct experiments which would relate time and temperature of heating to particle growth, granules in the desired size range were obtained by conventional milling and sieving of the recrystallized material. The usual techniques of layer preparation were utilized. The properties of such layers do, not unexpectedly, exhibit some dependence on the mode of construction. In these laboratories powder layers of gallium phosphide have been prepared by spraying, settling, and blade spreading. Each method involves the use of a binder. Various organics and low-melting inorganics have fulfilled that function. Phosphor particle size is limited to a narrow range to eliminate the problems attending layer preparation when an undiscriminated milling mix is employed. The foremost of these problems is that of obtaining a continuous evaporated aluminum electrode on the exposed side of the powder layer. The other and transparent electrode is tin oxide coated glass.

Current-Voltage Characteristics of GaP Powder Layers

The presence of p-n junctions in gallium phosphide is indicated by the light emission observed in excited crystallites at intergranular boundaries (6). In addition there seem to be point-like regions in the crystalline material with p-n junction character judging by the roles of these sites as well-defined light sources in electric field (7-9). That preferred junction sequences seem to exist in crystallites of GaP is indicated by the rectifying properties they exhibit when identical electrodes are used as anode and cathode. Because of the randomness of grain orientation in a powder layer it would not be expected that the layer exhibit rectification except as the possible result of differences between the contacts, in this case SnO_x to GaP and Al to GaP. Such differences are mitigated in the present consideration by the intervening binder. It cannot be stated with certainty, however, that all of the grains are completely encapsulated. A voltage-current plot for a gallium phosphide powder layer with a plastic binder is represented in Fig. 4. It can

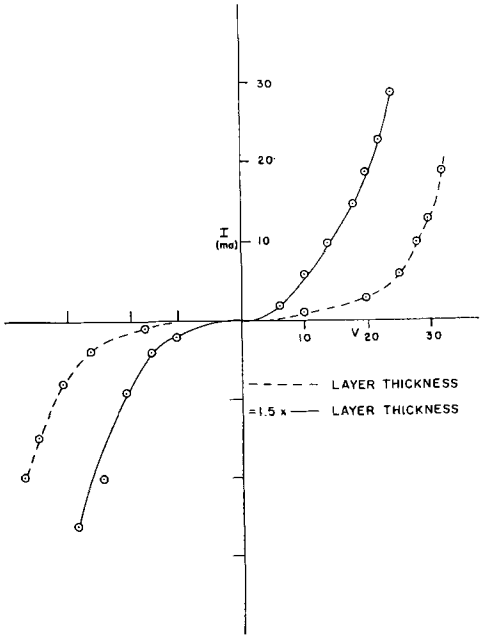

Fig. 4. Current-voltage plot for a gallium phosphide powder layer with a plastic binder. The contacts are SnO_x and evaporated aluminum.

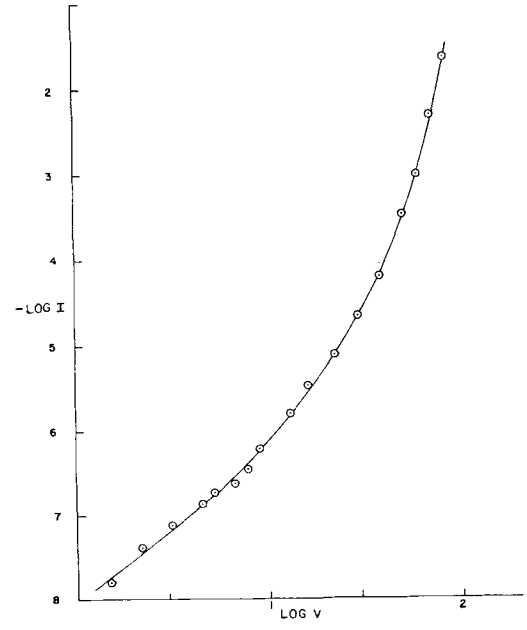

Fig. 5. General current-voltage relationship for a layer as in Fig. 4 on a log-log plot.

be readily appreciated that significant rectification does not take place. (However, below the milliampere level there is frequently an order of magnitude or so difference between the conductivities corresponding to the two polarities). Figure 5 depicts a log-log plot of current *vs.* voltage. No simple relationship of the type $I = KV^n$ fits the data. The nonlinear character of current as a function of voltage is reflected in the slopes of the plot. At low voltages, the current increases as roughly the square of the voltage, whereas at high voltages for some layers an extrapolated n value of 13 has been observed. Plotting the log of I *vs.* V yields connected linear segments. Each segment obeys the diode equation: $I = I' \exp(V/V' - 1)$, Fig. 6. The discontinuities represent abrupt changes of the parameters I' and V' as a function of the applied voltage. Individual crystallites exhibit a similar I-V relationship.

Electroluminescent Characteristics

Figure 7 shows a gallium phosphide powder layer as it appears under d.c. excitation and viewed through the transparent contact. Brightness measurements were made as functions of voltage and current. The photo measurements were made employing a Wratten No. 106 eye response compensated filter and a 1P21 photomultiplier feeding a Photovolt Model 520-M photometer. Brightness measurements were limited in voltage range by the sensitivity of the measuring system on the low voltage side and by excessive heating of the cell on the high voltage side.

A plot of brightness *vs.* power is presented in Fig. 8. The linearity observed for powder layers has also been observed for the emission from sintered pressed-pellets of gallium phosphide powder. A plot of the log of the brightness against $V^{-1/2}$ also yields a linear plot. The functional relationship between brightness and voltage for the two cases is vastly different and the simultaneous linearities must be

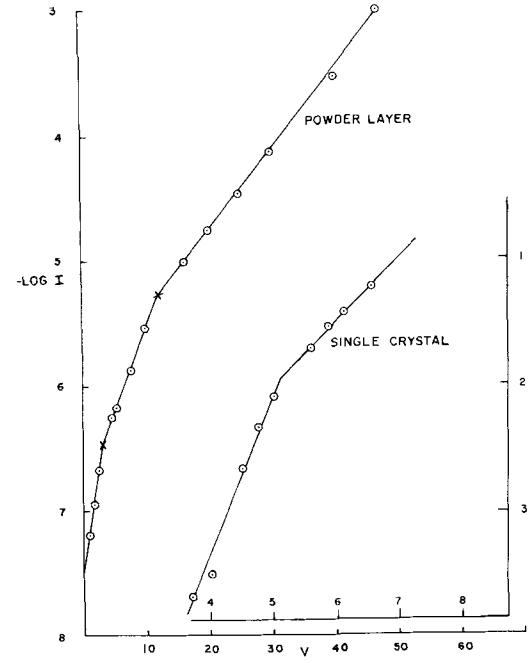

Fig. 6. Log I *vs.* V plot for a GaP powder layer and for a small single crystal illustrating adherence to the diode equation.

an accident of the narrowness of the voltage range encountered in these measurements. Wolff, Hebert, and Broder (10) have previously reported the linear character of a log B *vs.* $V^{-1/2}$ plot over a range of voltages somewhat broader than those of the author's measurements.

Microscopically the layer looks identical for reversed polarities. Light is seen to originate in point-like regions within the granules (not all of the granules by any means). The light emitted at these sites appears to be of considerably different spectral distribution than that which seems to characterize the layer as a whole. The latter is somewhat orange while the former is yellow-green. The difference between the two is due to optical filtering by the

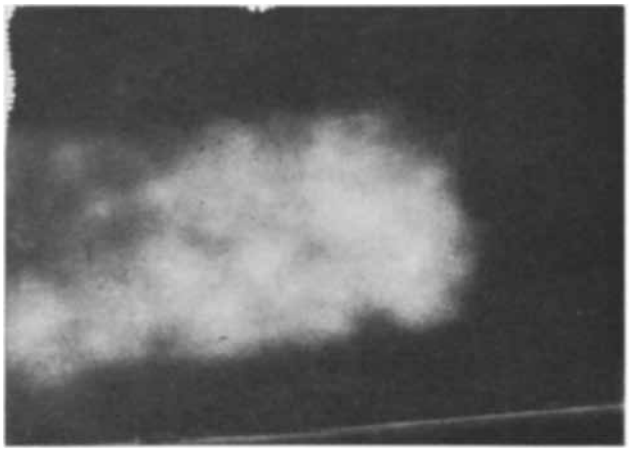

Fig. 7. GaP powder layer photographed under its own emission while d.c. excited.

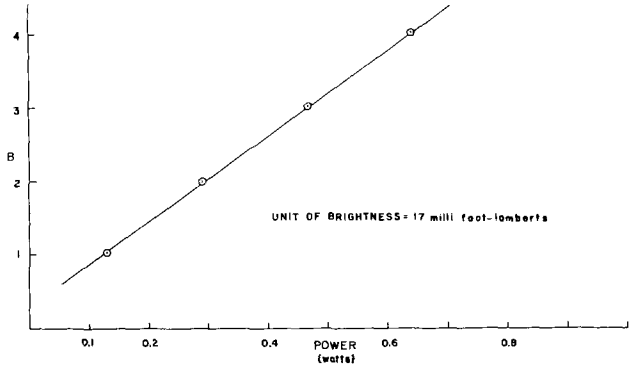

Fig. 8. Brightness *vs.* power for a gallium phosphide powder layer

granules. The efficiency of the powder layer as a light source has been calculated to be of the order of 10^{-4} lumens per watt. After the eye response character of the measured brightnesses has been taken into account, as well as internal absorption, the efficiency is of the order of 10^{-7} photons per electron.

Summary

Gallium phosphide can be synthesized by flowing phosphorus vapor in a hydrogen carrier gas over gallium (III) oxide. The oxide should be maintained at about 1000°C; the phosphorous reservoir at about 400°C. Moisture and oxygen traps in the flow train reduce the oxidant content of the carrier gases. The product can undergo a subsequent heating in a sealed-evacuated ampoule to effect particle size appreciation. The recrystallized material, after mechanical sizing has been carried out, may be used to make powder layers of gallium phosphide. Such layers have been fabricated and exhibit minimal rectification. Light emission from the layers is simultaneously linear in I x V and in exp $(aV^{-1/2})$. This seems to be a consequence of the limited range in V over which brightness measurements were made. As light sources, the layers have efficiencies of approximately 10^{-4} lumens per watt which correspond to about 10^{-7} photons per electron.

Acknowledgments

The technical assistance provided by Mr. James Yee, Jr. and Mr. Robert Fuller was of great value in the course of this investigation. Also contributing significantly to this research effort was Dr. Rubin Summergrad who initiated the powder layer studies. Special thanks are the due of Dr. Albert K. Levine for the encouragement which led to the author's researches in semiconductors. Dr. Paul Goldberg and Dr. Donald Baird made helpful suggestions pertaining to the manuscript.

Manuscript received Jan. 4, 1962; revised manuscript received Feb. 26, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Preparation and Properties of ZnO Phosphors

Arnold Pfahnl

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

ZnO phosphors were prepared at a variety of firing temperatures according to the reaction $2ZnO + ZnS \rightarrow 3Zn$ (excess) $+ SO_2$. The absolute values of the cathodoluminescent intensity, I, and the decay time, τ, were determined for the green emission band of these phosphors at 5 ma/cm² and 10 kv excitation. The temperature dependence of I and τ, the form of the decay, the dependence of τ on exciting current density, the aging characteristics, and the spectral distribution were also measured.

It was found that, at liquid nitrogen temperature, I and τ are nearly constant for all samples regardless of the firing temperature used during the phosphor preparation. As the sample temperature is raised above that of liquid nitrogen, I and τ both become temperature dependent, which is attributed to nonradiative quenching processes that compete with the luminescent transitions. At room temperature a nearly linear relationship exists between I and τ. This behavior is independent of sample preparation methods or commercial source of the phosphor. It was also observed that the decay was nonexponential and that τ is dependent on the exciting current density, which shows that the green luminescence is the result of a second-order recombination process. The influence of the firing temperature on the structure of the luminescent center is also evident from the increased aging rate of those samples which were prepared at higher temperatures.

Many different conditions and methods of preparation are reported in the literature for luminescent ZnO (Table I). The present work describes some of the properties of phosphors obtained according to the reaction $2ZnO + ZnS \rightarrow 3Zn$ (excess) $+ SO_2$.

Emphasis in this study has been placed on the relationship between emission intensity and decay time of the green emission, and no attempt was made to investigate the relationship between the green and the u.v. emission. High emission intensities and decay times $\leqq$250 nanosec were desired, in view of the intended use of a phosphor of this type in a special purpose flying-spot scanner cathode-ray tube (1,41).

Results also were sought which may contribute to a better understanding of the basic processes involved in the green luminescence of ZnO.

Experimental

For the preparation of the phosphors, 5 or 10g of ZnO (r.p.) + X weight % ZnS (X = 0,1,5,10,15) were fired for 1 hr at various temperatures in covered quartz crucibles and in an atmosphere of nitrogen. The samples were cooled rapidly after firing.

All samples used in the present experiments were prepared from the same batches of ZnO and ZnS, as some variations in the emission intensity were found among batches from different producers. It was necessary that the luminescent pure (l.p.) grade of ZnS be used, since the use of reagent pure (r.p.) grade resulted in a considerable reduction of the emission intensity (Table II).

For the cathode-ray tube screen preparation, the phosphor was suspended in a solution of potassium silicate using ultrasonic agitation and was then settled on microscope slides with barium nitrate as the coagulant. A series of tests on several selected samples showed that the ultrasonic treatment did not change the intensity or the decay time. For each phosphor sample, the optimum screen weight was determined by measuring the emission intensity as a function of the screen weight.

Table II. Emission Intensity of ZnO + 5% ZnS Samples prepared with combinations of base materials from various producers

Firing time: 1 hr; firing temperature: 850°C; excitation: mercury lamp with blue glass filter

ZnO batches (all r.p.)	ZnS batches (all l.p. except c)	Intensity
A	a	29
A	b	30
B	a	30
B	b	31
A	c (r.p.)	10

The particle size of the phosphors increases with the firing temperature and reaches an average of about 30-40μ for the samples fired at the highest temperatures. This is well within the limits of the particle size of commercial samples. On the other hand it was found that it is possible to change the particle size distribution considerably without reducing the maximum intensity if careful mechanical treatment (grinding) is applied. The grain of the screens obtained with the present powders is comparable to that of screens prepared with commercial samples of ZnO (Zn).

A demountable cathode-ray tube was used to measure the emission intensity and decay time. All data (except aging data) were taken under identical excitation conditions (anode voltage 10 kv; current density 5 ma/cm^2; pulse length 5 μsec; repetition frequency 1000 pulses/sec). These are the operation conditions under which the cathode-ray tube would be finally used (1), but they are milder than those of other flying-spot scanner operations where the product of excitation time for a screen element and the current density may be increased by a factor of ten.

The green emission from the side opposite from that of excitation was detected by a photomultiplier with S11 response. The u.v. emission band was filtered out (Corning filter CS3-72, 2.9 mm thick). The photocurrent was displayed on an oscilloscope. The time constant of the circuit was small enough to permit measurement of decay times down to 50 nanosec.

The aging data, needed in practical phosphor applications for the determination of the useful screen life, were obtained with sealed-off cathode-ray tubes having aluminized screens (seal-off pressure 10^{-7} mm Hg). Clean vacuum conditions were required during aging measurements, since burn from positive ions or contamination from back-streaming pump fluid vapors might otherwise have introduced major errors (29). To reduce the aging time, a stationary beam was used with the beam focused to a power density of 0.5 w/cm^2 at the phosphor screen. This is low enough to avoid thermal damage.

The spectral distribution of the fluorescent emission was determined with a Bausch and Lomb "Model 250 mm" monochromator and a photomultiplier tube. An absolute calibration of the ensemble was made.

Results

Emission intensity and decay time.—At and above room temperature, the emission intensity and the decay time (measured at the 1/e point) depend strongly on the firing temperature (Fig. 1). The intensity increases with the firing temperature up to about 1100°C and then decreases monotonically. The decay time goes through a similar maximum, which is about 100°C lower than that of the intensity. Samples fired at higher temperatures have, consequently, shorter decay times for equal emission intensities. Similar curves are obtained for preparation with 1%, 10%, and 15% ZnS content.

The data for the 20°C curve of Fig. 1 are replotted in Fig. 2 showing the decay time τ as a function of

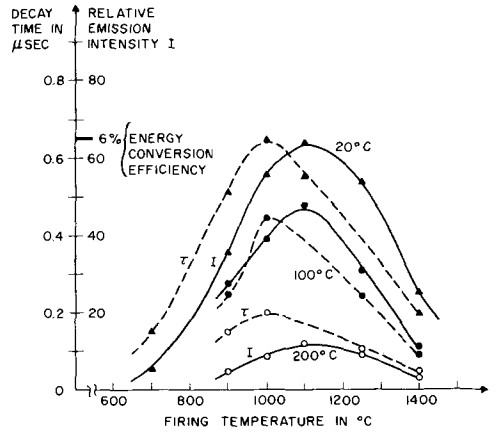

Fig. 1. Relative emission intensity *I* and decay time τ of ZnO(Zn) phosphors as a function of the firing temperature. Base material: ZnO + 5% ZnS; atmosphere: nitrogen; firing time: 1 hr. Phosphor temperature varied from 20° to 200°C.

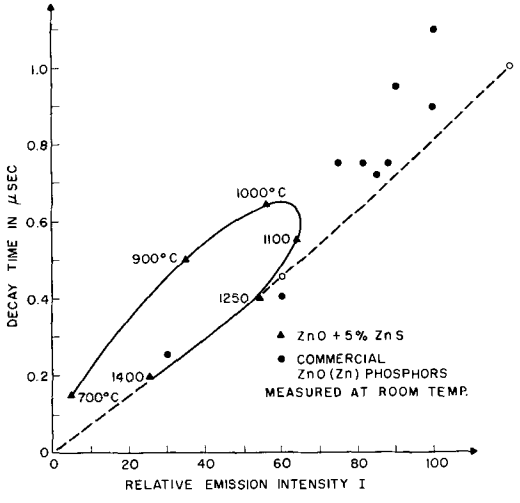

Fig. 2. Decay time τ vs. emission intensity *I* for ZnO(Zn) phosphors prepared at various firing temperatures, as well as for several industrial samples.

the emission intensity *I*. This is a convenient method of determining the quality of a phosphor sample when the shortest decay time at a given intensity is sought. The lower part of this curve, corresponding to the higher firing temperatures, can be continued through the points representing the best ZnO phosphor samples obtained from various industrial sources. This shows that, at the present state of the art, most of the industrially produced ZnO phosphors possess nearly the optimum combination of decay time and intensity, but it does not mean that this curve necessarily represents a physical limit. Improvements in the quality (purity) of the base materials may lead to improved quality of the phosphors (see Table II).

A comparison between the commerical samples and those prepared in the present experiments shows that most of the former have higher intensities than the latter (Fig. 2). The method used for the preparation has certainly a strong influence on the maximum intensity as can be seen in Fig. 3 where the results of various preparation methods and commercial samples are compared. The highest intensity in the present experiments was obtained by the oxidation of luminescent pure ZnS, but this

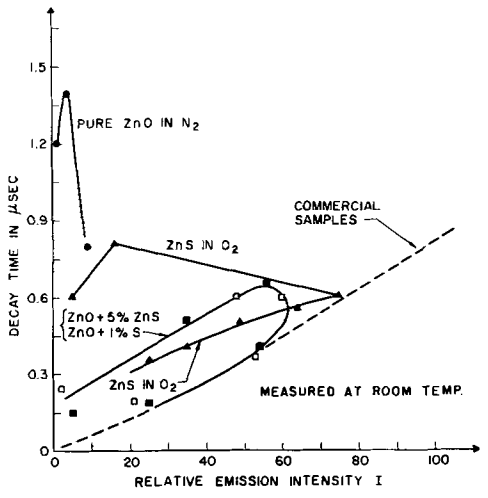

Fig. 3. Relative emission intensity *I* vs. decay time τ for ZnO(Zn) phosphors prepared by various methods.

is still about 20% below the maximum found for commercial samples. Another possible method to achieve higher intensities would be doping [ref. (17), Table I]. Further investigation would be necessary to elucidate this point.

It is interesting to note that ZnO phosphors prepared according to various other methods have quite similar properties. This is shown in Fig. 3, where the emission intensities and the decay times of ZnO + 5% ZnS are compared with the values measured on ZnS oxidized in pure O_2 for 20 min, ZnO + 1% S fired in N_2, and reagent-pure ZnO fired in N_2. ZnS oxidized at a temperature greater than 1000°C rapidly loses its green luminescence and acquires properties similar to calcined pure ZnO.

Data for a fixed firing temperature of 1000°C and varying ZnS concentrations are given in Fig. 4. ZnO without a special addition of ZnS exhibits very low intensities but long decay times of the order of 1 μsec when fired at 1000°C. Addition of 1% ZnS causes an increase of the intensity and a decrease of the decay time. Greater concentrations of ZnS have relatively little effect.

The presence of larger quantities of sulfur in the samples fired below 1000°C (see section on Analysis of samples) indicated that, at these firing temperatures, a firing time of 1 hr may not suffice to complete the reaction. A few experiments with various

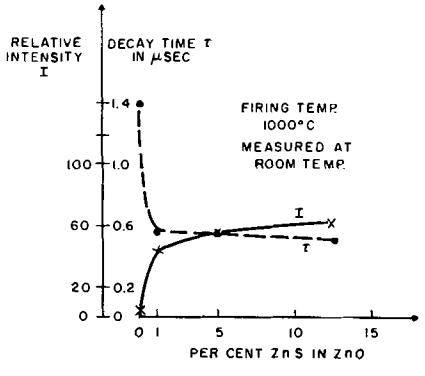

Fig. 4. Emission intensity *I* and decay time τ as a function of increasing ZnS content in the ZnO + ZnS preparation. Firing time, 1 hr.

firing times, up to 6 hr, at a firing temperature of 850°C showed a continuous increase of *I* with firing time, in which *I* was proportional to the logarithm of the firing time. To reach the full intensity of 65 rel. units measured at room temperature, a firing time of over 12 hr would be necessary as shown by an extrapolation. At 910°C, the intensity reaches 90% of its saturation value after 1 hr. At 1100°C, less than 7 min are necessary. For the purpose of practical ZnO phosphor preparation, firing temperatures at or above 1000°C therefore seem advisable.

If the temperature of the sample is lowered, the intensity, *I*, increases monotonically, the rate of increase being a function of the firing temperature. If the temperature is lowered from 20 to −180°C the intensity increases 1.8 times if the sample was fired at or below 1000°C, 2.0 times for a firing temperature of 1250°C, and 4.3 times for a firing temperature of 1400°C. In the vicinity of −180°C the slopes level off, and a common value of the intensity is reached for all samples except those fired below 1000°C for which the firing time of 1 hr was not long enough to give the maximum possible intensity (Fig. 5). The decay times measured at the 37 and 5% points are also practically constant and independent of the firing temperature if measured at −180°C (Fig. 5).

Figure 6 shows the decay time, τ, as a function of the sample temperature. For the samples fired up

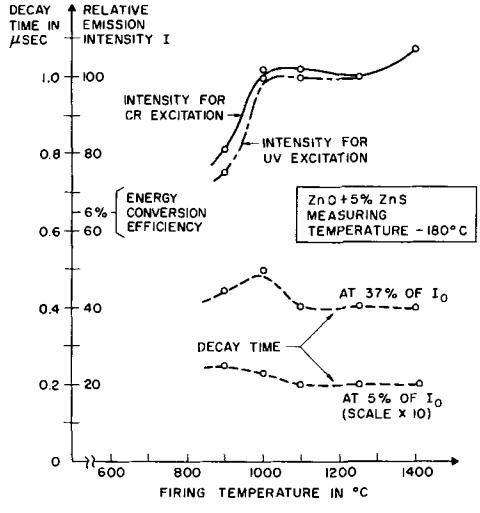

Fig. 5. Emission intensity *I* and decay time τ of ZnO(Zn) phosphors prepared from ZnO + 5% ZnS as a function of the firing temperature (measured at −180°C). Firing time, 1 hr.

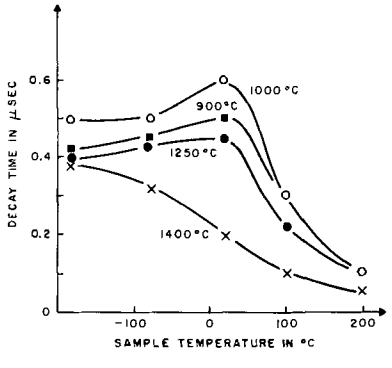

Fig. 6. Variation of the decay time as a function of temperatures. ZnO + 5% ZnS. Firing time, 1 hr.

to 1250°C there is a slight increase of τ up to room temperature and then a rather sharp decrease. The sample fired at 1400°C exhibits a steady decrease of τ with increasing temperature.

The absolute value of the energy conversion efficiency, which depends on the experimental conditions, was determined by comparison with optical measurement standards developed at this laboratory (30). It was found that the value of 65 rel. units of the intensity scale as used in Fig. 1-5 corresponds to an energy conversion efficiency of 6% for the excitation conditions mentioned in the experimental section above. This is in good agreement with other published data (31) taken at 1-10 μa/cm^2 at 6-8 kv, which indicate an efficiency of 7.5% for a ZnO (Zn) phosphor having approximately 1 μsec decay time.

Other parameters.—The form of the decay is nonexponential regardless of the firing temperature of the samples (Fig. 7) or the temperature at which the measurement is taken (Fig. 8).

The decay time is also a function of the current density, as shown in Fig. 9. It decreases by approximately 30% if the current density is increased by a factor 10. This has been found to hold over a range of 1 μa/cm^2 to 50 ma/cm^2, with either pulse or raster excitation.

Figure 10 shows the relative aging characteristics of four ZnO phosphors fired at different temperatures. The decrease in intensity due to electron bombardment has been observed to be most sensitive to the accumulated charge per unit area deposited by the beam and is relatively independent of accelerating voltage; hence coulombs/cm^2 is used as the abscissa of the aging curve. The samples fired at a higher temperature (1400°C) age slightly more rapidly at the beginning than those fired at a lower temperature (1000°C). This is in agreement with observations of the sensitivity of the luminescence to mechanical damage (*e.g.*, grinding) recorded by other authors (32). The curves coincide after a deposited charge of about 100 coulombs/cm^2 has been reached. Some aging data obtained under raster excitation were also available but only for a total deposited charge up to 10 coulombs/cm^2. No difference in the results was found.

The green emission spectrum of six representative samples fired between 900° and 1400°C was determined at various temperatures ranging from −180° or + 130°C. The spectra were found to be identical, each having its maximum at 500 mμ regardless of the firing temperature, the measurement temperature, or the amount of ZnS in the base material before firing. This is in good agreement with data published in the literature (40).

Analysis of samples.—A mass-spectrometric analysis of the gases liberated from three representative fired samples by reheating at 650°C under high vacuum showed that sulfur is still present in quantities up to about 0.01% of the initial content (Table III). The quantities of SO and SO_2 liberated decrease exponentially for a linear increase of the firing temperature. The remaining sulfur is present in the form of ZnS which was shown by the

detection (by means of x-ray diffraction) of α-ZnS crystals in the green luminescent samples fired at 1000° and 1400°C. At 1400°C the crystallites have grown large enough to give a relatively strong diffraction pattern. The analysis of an industrial sample with similar luminescent properties revealed no sulfur.

Discussion

ZnO is typically an n-type semiconductor, with donor levels at 0.04 to 0.05 ev. They result from an interstitial excess of Zn in concentrations ranging from 10^{15} to 10^{18} atoms/cm^3, depending on the mode of preparation of the material (33). Green luminescence appears if ZnO is prepared under reducing conditions (see Table I), which produces a further excess of Zn. The oxygen vacancies corresponding to the deviation from stoichiometry must be produced during the formation of the crystal and cannot be obtained by a reducing agent acting solely on the surface (7).

Based on these and other considerations, it has been proposed by various authors that the green luminescence corresponds to a transition from $Zn^{\cdot}$ to $Zn^{\cdot\cdot}$ in the excess Zn ions (23) or to a transition in an oxygen vacancy (7, 42b).

As an alternative explanation, it has been advanced that the green band could be the result of a small amount of ZnS (0.1% or less) present in solid solution in the ZnO (26).

On the basis of the experiments previously reported, it is not possible to decide between these two interpretations, even though the mass spectrometric analysis of the green luminescent industrial sample did not reveal any sulfur content (see the Experimental section above). Therefore high-purity Zn 99.9998% was oxidized, and it was found, in agreement with other authors (22), that a green luminescent ZnO was formed. The reducing agent (ZnS, S, etc.,) consequently would serve only to create oxygen vacancies in the ZnO lattice. Considering the high sensitivity of the luminescent materials to small amounts of impurities further investigations would be necessary to ascertain the absence of sulfur in these experiments.

At a given firing temperature certainly only a limited number of excess Zn ions and oxygen vacancies can be incorporated in the crystal. This explains the leveling-off of the intensity even when increasing quantities of reducing agent are added to the base material (Fig. 4). (The form of the curves is similar for firing temperatures up to 1400°C where the reaction is completed before one hour of firing time.)

At low concentrations of the reducing agent (*e.g.*, in the r.p. ZnO containing less than 0.001% S used in the present sample preparation) only a few luminescent centers are formed and the intensity is low. It is also possible in this case that a small amount of oxygen leaves the lattice without requiring the action of a reducer. This also agrees with the observation of the appearance of a new band of dipolar Debye absorption above 1000°C, corresponding to an activation energy of 0.25 ev (35).

From the data shown in Fig. 5 and from the experiments relating the intensity to the firing time it can be concluded that, for the present preparation method, the number of luminescent centers produced in the crystal is independent of the firing temperature. For firing temperatures below 1000°C longer firing times than 1 hr are necessary to incorporate the maximum possible number of luminescent centers, but an increase of the firing temperature from 1000° to 1400°C increases only the number of quenching processes which may be associated with some lattice defects.

The number of these quenching processes is strongly temperature dependent and seems to disappear completely below —180°C. Other limitations on the maximum attainable efficiency must nevertheless still be present, due probably to the basic absorption processes of cathode rays in the phosphor, as the best efficiency at —180°C is only 10% (Fig. 5).

The form of the I *vs.* T curves can be represented by the equation: $\eta = L/(L+N)$ where η is the luminescent efficiency, L the number of radiative, and N the number of radiationless transitions. It is generally assumed, that L is nearly independent of T and that N increases rapidly with the ambient temperature of the phosphor. Further measurements extending the range to liquid helium temperature would here be valuable.

The nonexponential decay (Fig. 7, 8) indicates a second-order recombination process between holes and electrons. As green luminescent ZnO has a high dark conductivity (23, 42) there should not be a great change of the electron concentration in the conduction band during the excitation. It could therefore be assumed that the rate-determining process is the trapping of holes in the center. The green emission then takes place immediately after the hole has been trapped. This would be in agreement with the different temperature dependence of decay time as compared to that of intensity, the latter being determined by the action of the quenching process on the luminescent transition, the former by the thermal action on the hole-capture process.

The increase of the decay time at low excess Zn concentrations (Fig. 4) could be explained by the sensitivity of the lifetime of the holes to lattice imperfections (43), which probably increase with increasing amounts of excess Zn. Possibly no impurity conduction band has yet been formed, and the luminescent centers are independent of one another.

At high excitation densities and low center concentration, two effects should consequently be observed: (*a*) a relative increase of the intensity of the u.v. emission as a consequence of the reduced possibility for recombination via activator centers, and (*b*) an exponential form of the decay of the green band due to the fact that the number of holes is much greater than the number of centers (at least at the beginning of the decay). Unfortunately the decay form of these samples could not be measured, but an increase in u.v. emission was observed in the present experiments. The hypothesis could also explain that exponential decay forms have repeatedly been indicated in the literature (8, 42).

The decrease of the luminescent efficiency with electron bombardment may result from damage to the luminescent centers (37) or from an increase in the number of radiationless transitions by formation of lattice defects (38). If the luminescent process takes place in a center formed by one or several ions and the electron does not leave this center during the excitation, destruction of a center decreases only the intensity and the decay time remains practically constant. This is the case, for example, with $CaWO_4$ (29). Measurements on several samples of ZnO showed (29) that the decay time decreases about 30% after a bombardment with 100 coulombs/cm^3. This would indicate an increase of the possibility for radiationless transitions. The different aging behavior of crystals prepared at various temperatures indicates also that the aging process is sensitive to structural differences in the lattice.

Acknowledgments

This project was under the general direction of R. W. Sears, whose encouragement throughout the study has been most valuable. Mr. R. S. Ehle performed many of the measurements, and his help is greatly appreciated. Mrs. M. H. Read did the x-ray analysis, and E. J. Becker provided the mass spectrometric data.

Manuscript received Nov. 6, 1961; revised manuscript received Feb. 20, 1962. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Dissolution of Germanium in Aqueous Hydrogen Peroxide Solution

N. Cerniglia and P. Wang

Semiconductor Division, Sylvania Electric Products Inc., Woburn, Massachusetts

ABSTRACT

The dissolution of germanium in aqueous hydrogen peroxide of from 3 to 90% H_2O_2 and *p*H from 1 to 9 has been studied at temperatures varying from 25° to 90°C. It has been found that dissolution rate remains constant in solutions of 3-30% by weight of H_2O_2 at low *p*H, then decreases with increasing H_2O_2 content. The reaction is highly *p*H dependent above *p*H 4, and this *p*H dependence varies as a function of H_2O_2 concentration. This indicates that the rate-controlling step in low and high H_2O_2 concentration solutions at *p*H 5 and above may be different. Reaction mechanism to explain this situation is proposed.

The use of hydrogen peroxide solution as a final clean-up etch for germanium is an established practice in the semiconductor industry. The use of dilute aqueous hydrogen peroxide solutions as an etch for germanium was first suggested by Camp (1). Miller (2) determined the dissolution rate of germanium at various temperatures in 3.4% by volume hydrogen peroxide solutions of *p*H 5. The present study has been carried out in order to obtain a better understanding of the mechanism of the dissolution reaction and to determine its dependence on the hydrogen peroxide concentration, temperature, and *p*H of solution. The effects of the resistivity, resistivity type, and crystalline perfection of the germanium on the dissolution rate also have been studied.

Experimental

The samples used were 1 x 1.5 x 0.010 in. single crystal n- and p-type germanium of 2 to 6 ohm-cm resistivity.[1] Samples were oriented with the major surfaces in the <111> plane within one degree and were prepared with an aluminum oxide lapped finish. Random area measurements on the slices showed less than 2% variation in apparent surface area. Resistivity measurements on individual samples showed variations less than 5%. Prior to etching, each sample was degreased in trichloroethylene, chloroform, and methanol, dried, cleaned in hydrofluoric acid, and rinsed in distilled, deionized water of better than 15 megohm resistivity. After drying, samples were weighed to the nearest hundredth of a milligram and thickness was measured with a dial micrometer to the nearest tenth of a mil.

Samples were placed in small passivated stainless steel wire baskets and were etched individually in separate beakers containing 150 ml of solution, each maintained within ±1°C of temperature. No agitation of the etchant was used. The heat of reaction was low and quickly dissipated through the beaker so that the reaction was effectively carried out at constant temperature in all cases. At the end of each etch period, the germanium samples were quickly removed and quenched in a large volume of deionized water. After rinsing and drying, the samples were measured and weighed again.

Samples were etched a number of times in the same solution in order to establish a constant etch rate. The assumption was made that the constant etch rate reached after the work damaged layer had been removed was close to the true etch rate. Since the decrease in thickness per etch period was below the sensitivity of the dial micrometer for the slow etching in very high concentration hydrogen peroxide, the majority of data for etch rate is presented in units of milligrams per square centimeter-hour, in order to be consistent from low to high hydrogen peroxide concentrations.

The etching solutions were prepared by diluting Becco reagent grade 90% hydrogen peroxide (in some cases, electronic grade 30% hydrogen peroxide from Solvay was used to prepare the solutions). Dilutions were volumetrically measured from a burette to the nearest 0.1 ml. Control of the composition for any etch run was established by analyzing for hydrogen peroxide composition using potassium permanganate titration. For dilute solutions in the neutral and alkaline *p*H regions, the peroxide solutions were neutralized with 10% reagent grade NH_4OH. Stability of high *p*H solutions at elevated temperatures was accomplished by addition of a small amount of hydrated sodium stannate. The higher *p*H samples taken for analysis were acidified with dilute sulfuric acid immediately after quenching in order to minimize hydrogen peroxide decomposition. Precautions to maintain hydrogen peroxide stability during etching made it possible to control the H_2O_2 composition to ±0.5%. This variation in hydrogen peroxide concentration was less at lower *p*H and temperatures. During the etching period *p*H measurements were taken periodically and adjustment was made whenever necessary to control variations within ±0.1 *p*H unit.

Results

Dependence of germanium dissolution rate on H_2O_2 concentration.—A plot of dissolution rate of nondegenerate germanium with respect to H_2O_2 con-

[1] Specific experiments were carried out with germanium specimens of other resistivity ranges.

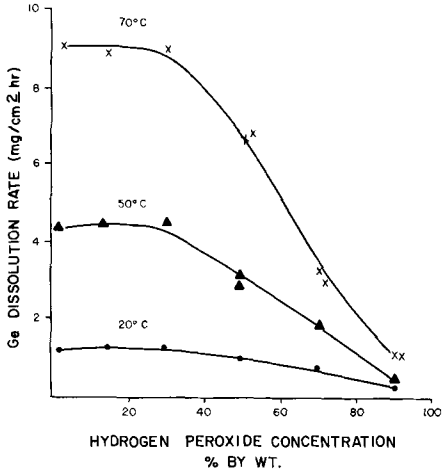

Fig. 1. Germanium dissolution rate as a function of H_2O_2 concentration.

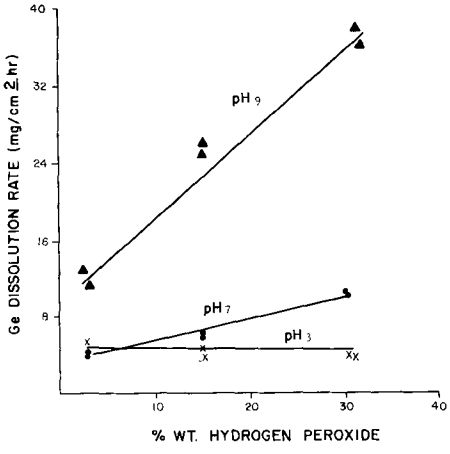

Fig. 2. Dependence of etch rate on H_2O_2 concentration, pH 3, 7, 9

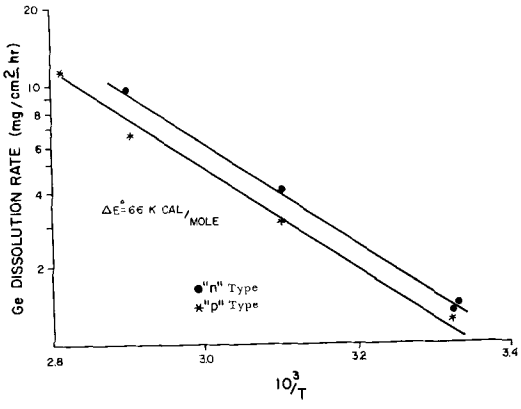

Fig. 3. Dissolution vs. temperature for n and p type germanium in 30% H_2O_2 aqueous solutions pH 4.

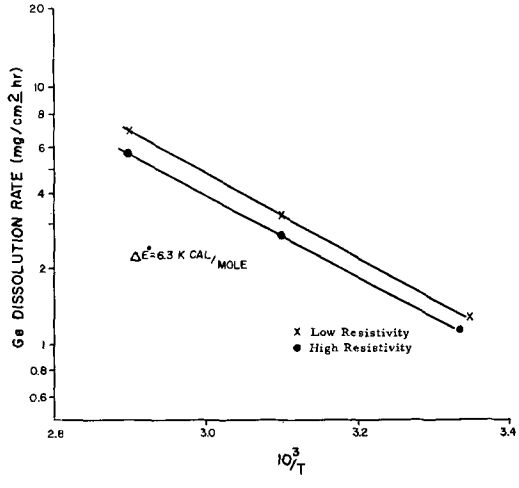

Fig. 4. Dissolution rate vs. temperature for high and low resistivity n type germanium in 30% H_2O_2 aqueous solutions at pH 4.

centration is given in Fig. 1. In H_2O_2 solutions of 3-30% H_2O_2 by weight, the dissolution rates at each temperature are essentially constant. Above 30% concentration, they decrease linearly with increasing H_2O_2 concentration. All the solutions were prepared by diluting 90% H_2O_2 with water, and no attempt was made to control the pH.

In Fig. 2, germanium dissolution rate is plotted as a function of H_2O_2 concentration at three pH values. At pH 3 the rate is independent of H_2O_2 concentration in the range 3-30%. At pH values of 7 and 9, there is a linear relationship between dissolution rate and H_2O_2 concentration.

Dependence of dissolution rate on solution temperature.—The relation between germanium dissolution rate and solution temperature was studied for n-type and p-type nondegenerate germanium and for degenerate n-type germanium. Etching experiments were performed at several H_2O_2 concentrations ranging from 15 to 90% H_2O_2 by weight, at several pH values ranging from 1.0 to 9.0, and at four temperatures, 25°, 50°, 70°, and 90°C. In general a 50% increase in dissolution rate is obtained with each 10°C temperature rise. Figure 3 is a plot of dissolution rate as a function of $1/T \times 10^3$ for n- and p-type germanium of 10^{15} atom/cm³ impurity level etched in 30% H_2O_2 solution at pH 4.0. The activation energy $\mathring{E}$ is estimated at 6.6 kcal/mole by application of the Arrhenius equation.

Figure 4 plots dissolution rate as a function of temperature for n-type germanium samples of 10^{15} and 10^{19} atom/cm³ impurity levels in 30% H_2O_2 solutions at pH 4.0. The activation energy is estimated at 6.3 kcal/mole.

Table I gives values of estimated activation energy for the dissolution of n-type germanium in aqueous H_2O_2 solutions determined by these investigations at various solution pH and % composition by weight. Values determined for p-type germanium are quite similar. From these data it is seen that at pH 5 and above the activation energy is about 10.5 kcal/mole and at pH 4 and below the value

Table I. Activation energy for various H_2O_2 etching compositions using n-type germanium (2-6) ohm-cm

Composition, % by weight H_2O_2	pH	Activation energy, kcal/mole
90	1.0	6.4
70	2.1	6.8
50	3.0	7.9
30	4.0	6.6
30	5.1	11.0
30	7.1	11.0
15	4.9	10.0
15	7.0	10.5
15	9.1	10.3

is approximately 6.5 kcal/mole. The activation energy is the same for germanium of both n-type and p-type conductivity and for low and high impurity levels up to 10^{19} atom/cm^3.

Dependence of dissolution rate on pH of solution.—In Fig. 5, germanium dissolution rates are plotted against *pH* of solution for etching experiments carried out with n-type nondegenerate germanium in 15, 30, and 50% H_2O_2 solutions at 50°C. At each H_2O_2 concentration the dissolution rate stays relatively constant until a critical *pH* is reached and increases rapidly thereafter. The critical *pH* is a function of H_2O_2 concentration. At 50% H_2O_2 it is 4.5, at 30% H_2O_2 it is 5.5, and at 15% H_2O_2 it is 6.0. In Fig. 6 and 7, similar plots are given for dissolution rates in 15 and 30% H_2O_2 solutions at 25°, 50°, and 70°C. The dependence of dissolution rate on *pH* increases at higher temperatures.

Effect of impurity concentration and crystal perfection on germanium dissolution rate.—Etching experiments were carried out using n-type germanium specimens with resistivities from about 30 down to 0.007 ohm-cm, corresponding to an impurity concentration range from 10^{13} to 10^{19} atom/cm^3. The high impurity germanium has a dissolution rate about 30% higher than near intrinsic germanium. Typical results are given in Table II.

Dislocation density variation in the 1 x 10^3 to 1 x 10^4/cm^2 range does not change the dissolution rate appreciably, although macroscopic crystal imperfections such as lineage appear to increase the dissolution rate.

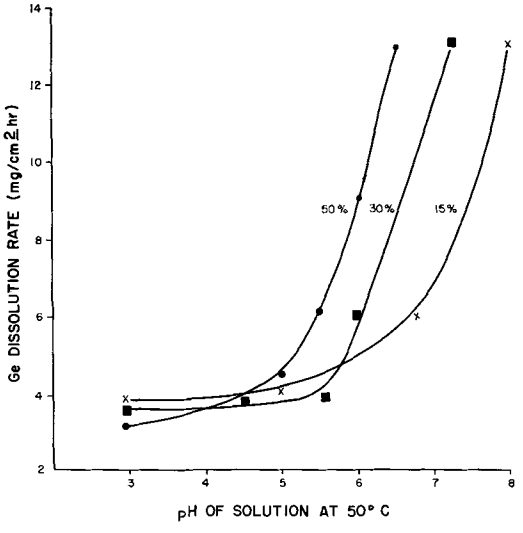

Fig. 5. Dependence of germanium dissolution rate on *pH* of solution for three H_2O_2 concentrations.

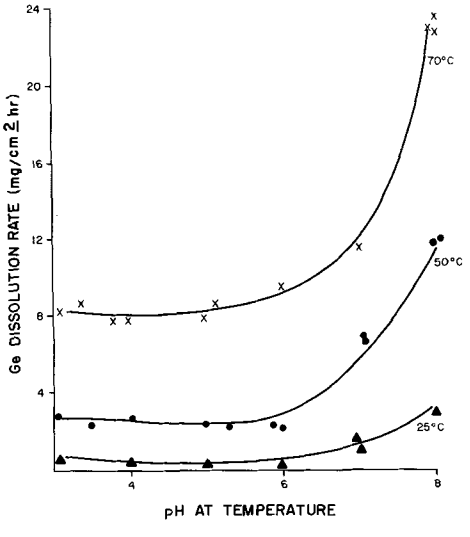

Fig. 6. Variation in dissolution rate as function of *pH* in 30% H_2O_2.

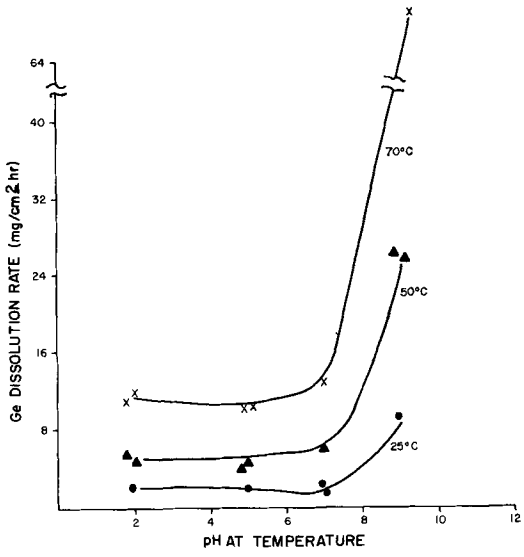

Fig. 7. Dependence of dissolution rate on *pH* in 15% H_2O_2 aqueous solution.

Discussion

From the experimental results it is clear that: (*a*) the germanium dissolution rate remains essentially constant in aqueous H_2O_2 solutions of from 3 to 30% by weight H_2O_2 in the *pH* 1 to 5 range, even at elevated temperatures; (*b*) in the concentration range above 30% H_2O_2 and at low *pH* the rate decreases linearly with increasing H_2O_2 content; (*c*) in *pH* range above 5, there is a certain critical *pH* value above which the rate increases linearly with increasing *pH* as seen in Fig. 2. This critical *pH* varies with H_2O_2 concentration, as seen in Fig. 5 and 6; (*d*) in solutions of *pH* 4 and below the activation energy of the reaction is approximately 6.5 kcal/mole and at *pH* 5 and above it is approximately 10.5 kcal/mole. Activation energy given by Miller

Impurity level, atom/cm^3	H_2O_2 weight percentage	*pH* at 70°C	Dissolution rate, mg/cm^2-hr
10^{13}	30	4.0 ± 0.1	6.60
10^{15}	30	4.0 ± 0.1	7.38
10^{19}	30	4.0 ± 0.1	8.64
10^{13}	32-33	3.9 ± 0.1	7.50
10^{19}	32-33	3.9 ± 0.1	8.82
10^{16}*	32-33	3.9 ± 0.1	10.68
10^{19}**	32-33	3.9 ± 0.1	10.14
10^{13}	33-35	7.0 ± 0.1	25.2
10^{15}	33-35	7.0 ± 0.1	25.8
10^{19}	33-35	7.0 ± 0.1	27.6

* Heavy lineage.
** Lineage.

(2) is 11 kcal/mole in a solution of 3% H_2O_2 of *p*H 5; (*e*) p-type germanium etches at a slightly faster rate than n-type germanium; (*f*) germanium with gross imperfections and high impurity concentration has a higher dissolution rate than nondegenerate germanium of better crystalline perfection.

On the basis of the above experimental results, the following two-step mechanism for germanium dissolution in H_2O_2 is proposed.

In aqueous solutions of H_2O_2, as suggested by Schumb *et al.* (3), the dissociation of H_2O_2 occurs as in reaction Eq. [1]

$$2H_2O_2 \longrightarrow H_3O_2^+ + O_2H^- \qquad [1]$$

When the O_2H^- ions diffuse to the germanium surface, they attach instantly to surface germanium atoms forming surface complex $> Ge(OH)_2$, or $Ge(OH)_2^{++}$, by reaction shown in Eq. [2]

$$Ge + O_2H^- + H_2O + 2e^+ \longrightarrow \underset{\text{surface}}{Ge(OH)_2^{++}} + OH^- \qquad [2]$$

The chemical bonds between the surface germanium atom and underlying atoms remain unbroken. The rate of this reaction is determined by the supply of O_2H^- ions and supply of holes, and the number of available surface germanium atoms. If the supply of holes is more abundant than O_2H^- ions at the interface, the reaction rate will be limited by the diffusion of O_2H^- ions to the interface. In this aqueous system it is proposed that holes are supplied by the reaction between H^+ ions and H_2O_2, as shown in Eq. [3]

$$H_2O_2 + 2H^+ \longrightarrow 2H_2O + 2e^+ \qquad [3]$$

The supply of holes is abundant and not rate determining. In p-type Ge, the availability of holes in the germanium bulk may aid this supply, resulting in slightly faster dissolution rates in p-type Ge under similar experimental conditions.

The formation of the final dissolution products, metagermanate ions or metagermanic acid, can proceed by one of the following two reactions, Eq. [4] and [5]

$$\underset{\text{surface}}{Ge(OH)_2^{++}} + H_2O \longrightarrow H_2GeO_3(aq) + 2H^+ \qquad [4]$$

$$\underset{\text{surface}}{Ge(OH)_2^{++}} + 2OH^- \longrightarrow H_2GeO_3(aq) + H_2O \qquad [5]$$

Either reaction will occur instantly as soon as the reactants are brought together. In solutions of low *p*H, the final dissolution reaction is believed to proceed primarily according to Eq. [4]. In the *p*H range of 1 to 5 where the dissolution rate remains essentially constant, the O_2H^- ion availability at the interface is probably quite constant. This occurs because the variation in H_2O_2 concentration and *p*H does not change the (O_2H^-) gradient in the diffusion layer and the layer thickness. At higher temperatures, the availability of O_2H^- ion will improve and give faster dissolution rates.

In Fig. 1 it is seen that at 30% hydrogen peroxide the dissolution rate begins to decrease linearly with increasing H_2O_2 concentration or decreasing H_2O concentration. The formation of metagermanic acid involves a $Ge(OH)_2^{++}$ ion and a H_2O molecule as evidenced by the linear relation indicating that under these conditions reaction [4] becomes rate limiting. The rate for a certain $Ge(OH)_2^{++}$ surface concentration is limited primarily by the availability of H_2O molecules at the interface, *i.e.*, a diffusion mechanism. The activation energy for all these cases is approximately 6.5 kcal/mole.

According to Greischer (4) germanium reacts preferentially with hydroxyl ions in aqueous solutions. When OH^- ions are consumed as fast as they reach the surface by Eq. [5], dissolution takes place with H_2O molecules as shown in Eq. [4]. With increasing *p*H, the reaction with OH ions becomes more important. Since OH^- ions react much faster than H_2O molecules in the formation of H_2GeO_3, the dissolution steps become very fast in neutral and basic solutions where reaction [5] predominates. In a basic solution, the situation is further complicated by another mechanism in forming the $Ge(OH)_2^{++}$ surface complex, as shown in Eq. [6]

$$Ge + 2\,OH^- + 4e^+ \longrightarrow Ge(OH)_2^{++} \qquad [6]$$

This reaction may become competitive with Eq. [2], involving a different activation energy. The experimental value here is 10.5 kcal/mole. Since each germanium surface atom requires two OH^- ions to form the surface complex $Ge(OH)_2^{++}$ and requires two additional OH^- ions for the final dissolution product, the dependence of the rate on OH^- ion concentration is very strong. Because the reaction can proceed by Eq. [2] and [4] just as well, there is no simple relationship established between rate and *p*H. It is interesting to note in Fig. 5 that after reaching the critical *p*H, the germanium dissolution rates in 50, 30, and 15% H_2O_2 solutions increase in the same fashion with increasing *p*H, indicating the same mechanism where OH^- ion availability plays an important role. Since reactions [2] and [6] proceed simultaneously in the more concentrated H_2O_2 solutions the effect of increasing OH^- ion concentration becomes more noticeable at lower *p*H.

For very impure germanium (*i.e.*, 10^{19} atoms/cm^3) and germanium with macroscopic imperfections such as gross lineage, the dissolution rates are higher. This may be due to the electric field built-in with these imperfections or by postulating that the chemical bond between Ge surface atoms and the bulk can be broken more readily by H_2O_2 when the presence of these defects weakens the bond. At the present time we have no quantitative explanation of the dependence of the dissolution rate on the degree of crystal perfection in germanium.

This proposed mechanism can only explain the experimental facts qualitatively. Experimental difficulties limit the conditions where controlled dissolution can be obtained. For instance, experiments in a 30% H_2O_2 solution of *p*H greater than 9 at high temperatures or in a 90% H_2O_2 concentration solution of *p*H greater than 9 cannot be carried out. Extreme instability of the H_2O_2 solution makes it impossible to maintain constant temperature and com-

position. However, it is feasible to carry out experiments at temperatures below 25°C. For more quantitative results, further experimental work at lower temperature is required.

Acknowledgment

The authors wish to thank Mrs. A. R. Waters for her assistance in the experimental work, and to Mr. S. Crytzer and Mrs. B. Zaffina for their help in the chemical analyses of the hydrogen peroxide solutions. They would also like to acknowledge the assistance of Mr. F. Bower in preparation of the manuscript.

Manuscript received Oct. 16, 1961; revised manuscript received Feb. 14, 1962. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Batch Evaporation or Crystallization at Constant Composition by a Two-Container Method

W. G. Pfann, J. R. Patel, and H. C. Theuerer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A two-container method is described for producing a vapor or pulling a crystal of constant composition from a binary or multicomponent liquid solution. As the liquid level falls in the first container due to evaporation or crystal growth, liquid enters from the second container. The cross section and liquid composition of the second container are selected in a manner such that the composition in the first container remains constant.

In a companion paper (1) a method is described for evaporating essentially all of a batch of liquid solution at constant vapor composition. In this paper we describe a different method of achieving the same result, which is also applicable to crystallization. Our method is less generally useful, as it requires a knowledge of the volatilities of the components of solution and vapor and is less flexible in other respects. Nevertheless, it appears to be a useful alternative.

The basis of the method is as follows. Because the vapor differs in composition from the liquid, continued evaporation changes the composition of the remaining liquid. This change is automatically nullified by introducing feed liquid of appropriate composition.

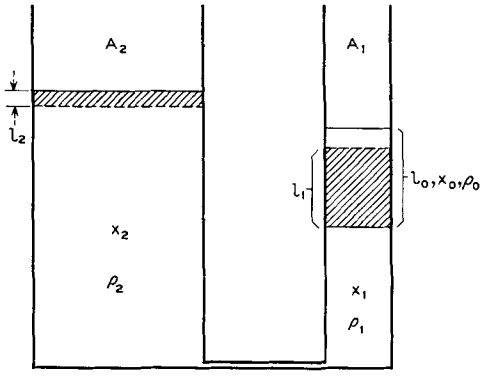

Fig. 1. Schematic illustrating quantities involved in the two-container method.

The apparatus consists essentially of two columns or reservoirs of liquid connected by a one-way passage that permits flow only from the second to the first, as shown in Fig. 1. The liquid heads are the same in the two columns, both being maintained at the same atmospheric pressure. As liquid is removed from column 1 by evaporation (either by heating it or by a hydrogen bubbler, for example), the level falls and liquid flows into column 1 from column 2 so as to equalize the heads.

If the cross-sectional area, A_2, of column 2 is chosen correctly with respect to the area, A_1, of column 1, the vapor leaving 1 will be of constant composition. (We assume rapid mixing in 1, which a bubbler would provide.)

The required area ratio, (A_1/A_2) is given by:

$$\frac{A_1}{A_2} = \frac{M_0(1 - x_2/x_1)}{M_2(1 - x_0/x_1)} - 1 \qquad [1]$$

where subscripts 0, 1, and 2 refer to the product vapor, the liquid in 1, and in 2, respectively, M denotes average molecular weight of the solution, and x denotes mole-fraction of heavy (less volatile) component. Equation [1] is derived in the Appendix. The ratio (x_0/x_1) may be called a distribution coefficient, k.

In terms of M_H and M_L, the molecular weights of heavy and light components, respectively, [1] may be written:

$$\frac{A_1}{A_2} = \frac{[x_0 M_H + (1 - x_0)M_L](1 - x_2/x_1)}{[x_2 M_H + (1 - x_2)M_L](1 - k)} - 1 \qquad [2]$$

In general, it will be preferable to have pure light component in column 2, *i.e.*, $x_2 = 0$, in which case 2 reduces to

$$\frac{A_1}{A_2} = \frac{k + x_0\left(\frac{M_H}{M_L} - 1\right)}{1 - k} \qquad [3]$$

If the liquids in 1 and 2 differ in density, they will be at different levels. But if they do not (as when x_0 is very small), they will be at the same level. Equation [3] shows that the ratio (A_1/A_2) depends only on k at small x_0, but on x_0 as well, at larger x_0, because of the density difference which large x_0 introduces.

The apparatus can be adapted for solutions of different k-values by designing for small k (that is, A_1/A_2 small), and either providing inert glass rods to reduce A_2 to the proper value, or adjusting the composition of column 2 as described in the next section.

Extension to Ternary or Higher Order Solutions

The method can be generalized to accommodate a higher-order system having solutes, a, b, c . . . $(n-1)$, and "solvent," n. It is merely necessary to choose the proper mole fraction, x_{2a}, x_{2b}, etc., of these solutes in column 2. This is done by selecting (A_1/A_2) to match the solute of lowest k (call it solute "a"), with $x_{2a} = 0$. It is then possible to choose values of x_{2b}, x_{2c}, etc., for which this same area ratio will be correct.

Let R designate (x_2/x_1), then, in accord with Eq. [1], and since M_2 and M_0 pertain to the solutions as a whole, we may write

$$\left(1 + \frac{A_1}{A_2}\right)\left(\frac{M_2}{M_0}\right) = \frac{1 - R_a}{1 - k_a} = \frac{1 - R_b}{1 - k_b} = \cdots\cdots \frac{1 - R_{n-1}}{1 - k_{n-1}} \qquad [4]$$

It is evident from [4] that as k increases (from component to component), R must also increase.

The generalized expression for M_0 is

$$M_0 = x_{0a}M_a + x_{0b}M_b + x_{0c}M_c \ldots + x_{0(n-1)}M_{n-1} + (1 - x_{0a} - x_{0b} - x_{0c} \ldots - x_{0(n-1)})M_n \qquad [5]$$

An analogous expression holds for M_2.

The value of (A_1/A_2) for $R_a = 0$ is

$$\frac{A_1}{A_2} = \frac{M_0}{M_2} \cdot \frac{1}{1 - k_a} - 1 \qquad [6]$$

The value of x_{2b}, for $R_a = 0$, is

$$x_{2b} = x_{0b} \cdot \frac{1 - k_a/k_b}{1 - k_a} \qquad [7]$$

The value of x_{1b} is

$$x_{1b} = x_{0b}/k_b \qquad [8]$$

Equations analogous to [7] and [8] hold for each of the other solutes.

Relationship to Crystallization

These considerations apply to the withdrawal of a solid, rather than a vapor, from column 1, as by crystal pulling. In fact, Patel and Mullen (2) have described the application of the two-container technique to the pulling of germanium crystals lightly doped with gallium. The equations derived in the present paper represent a generalization which accounts for density differences and for the presence of two or more solutes.

There is a zone leveling technique (3) which accomplishes for solids the same result described here. This is the method in which a zone containing solute advances into a charge of pure solid solvent, and in which the zone-length, l, decreases linearly with distance, s, at a rate, dl/ds, given by

$$\frac{dl}{ds} = -k \qquad [9]$$

where k now refers to the solid rather than the vapor. The zone length falls to zero at $s = l_0/k$, where l_0 is the initial length. As described, the method was restricted to values of k less than unity. By analogy with the two-container technique, it can be seen that this zone leveling technique can be extended to k's greater than unity by having a uniform concentration x_2 in the charge, in which case the required rate of change of zone length is:

$$\frac{dl}{dx} = -k \cdot \frac{1 - x_2/x_0}{1 - k} \qquad [10]$$

For k's > 1, Eq. [10] permits operation at increasing zone length (for $x_2/x_0 > k$). However, this leaves one at the end of the operation with a large zone of concentration x_0/k.

Manuscript received Jan. 4, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

APPENDIX

Derivation of Eq. [1]

Assume the liquid heads in columns 1 and 2 of Fig. 1 to be initially equal. Imagine a length l_0 of the liquid in 1 to be made to have composition $x_0 < x_1$ (where x denotes mole fraction of heavy component) by a segregation process occurring within column 1, where x_0 is the desired vapor composition. Remove length l_0 of this liquid whose composition is x_0 and density is ρ_0.

Then allow the pressure heads to equalize by flow of volume l_2A_2 of liquid from 2 into 1. The net changes in head as a result of these two operations must be equal. Therefore:

$$-l_2\rho_2 = -l_0\rho_0 + l_1\rho_2 = -l_0\rho_0 + l_2\left(\frac{A_2}{A_1}\right)\rho_2 \qquad [A\text{-}1]$$

From which:

$$\frac{l_2}{l_0} = \frac{\rho_0}{\rho_2} \cdot \frac{A_1}{A_1 + A_2} \qquad [A\text{-}2]$$

If the composition of the liquid in column 1 is to be unchanged by these operations (and we assume complete mixing in 1), then the composition of the net material leaving 1 must equal x_1. We therefore obtain an expression for the mole fraction of heavy component, H, leaving 1, using the relation:

$$\text{mole } H = \text{mole fraction } H \times \frac{\text{total moles}}{\text{unit volume}} \times \text{volume} \qquad [A\text{-}3]$$

Let B denote total moles per unit volume of solution. Then:

Moles H leaving in vapor $= x_0 B_0 l_0 A_1$
Moles L leaving in vapor $= (1 - x_0)\ B_0 l_0 A_1$
Moles H entering from 2 $= x_2 B_2 l_2 A_2$
Moles L entering from 2 $= (1 - x_2)\ B_2 l_2 A_2$

$$x_1 = \frac{x_0 B_0 l_0 A_1 - x_2 B_2 l_2 A_2}{x_0 B_0 l_0 A_1 - x_2 B_2 l_2 A_2 + (1-x_0) B_0 l_0 A_1 - (1-x_2) B_2 l_2 A_2} \quad [A\text{-}4]$$

which reduces to

$$\frac{A_1}{A_2} = \frac{l_2 B_2 (x_1 - x_2)}{l_0 B_0 (x_1 - x_0)} \quad [A\text{-}5]$$

Substituting for (l_2/l_0) from [A-2], we obtain

$$1 + \frac{A_1}{A_2} = \frac{B_2 \rho_0 (x_1 - x_2)}{B_0 \rho_2 (x_1 - x_0)} \quad [A\text{-}6]$$

which can be used to solve for area ratio (A_1/A_2). However, a more useful form of [A-6] can be obtained using the relation

$$B = \rho/M \quad [A\text{-}7]$$

where M denotes average molecular weight of the solution, and for solutions 2 and 0 is given by

$$M_2 = x_2 M_H + (1 - x_2)\ M_L$$
$$M_0 = x_0 M_H + (1 - x_0)\ M_L \quad [A\text{-}8]$$

where subscripts H and L refer to heavy and light components. Equation [A-6] then reduces to

$$1 + \frac{A_1}{A_2} = \frac{M_0 (x_1 - x_2)}{M_2 (x_1 - x_0)}$$
$$1 + \frac{A_1}{A_2} = \frac{M_0 (1 - x_2/x_1)}{M_2 (1 - k)} \quad [A\text{-}9]$$

Epitaxial Deposition of Silicon in a Hot-Tube Furnace

Bruce E. Deal

Raytheon Company, Mountain View, California

ABSTRACT

A method has been developed for depositing single crystal silicon epitaxially in a conventional hot-tube furnace. Silicon is deposited on a silicon substrate by the reduction of a silicon halide at temperatures in excess of 1200°C. A modification of the gas inlet system prevents decomposition of the silicon halide before contacting the silicon substrate. Several silicon slices can be treated simultaneously with good reproducibility of deposit thicknesses and resistivities.

The announcement of the successful fabrication of an epitaxial transistor was made a little over a year ago (1). There has been much interest in the subject since then, as is demonstrated by the large number of papers concerning epitaxial deposition presented at technical societies and in the literature (2-8). There appear to be many possibilities for improved semiconductor devices using epitaxial material. At the same time, many problems exist regarding the actual deposition of an epitaxial layer suitable for a particular device. Reported here are the results of a particular program in which it was demonstrated that single crystal silicon can be successfully deposited using a conventional diffusion furnace. The program was undertaken to determine if the more expensive, less common types of apparatus using resistance heated or induction heated substrates are necessary for silicon epitaxial deposition. These methods involve the use of a relatively cool reaction tube or chamber, as contrasted to a diffusion apparatus where the tube is as hot as the specimen being treated.

Apparatus and Materials

The furnace used in our experiments was a Hevi-Duty Globar furnace, 26 in. long, with three heat zones. All three zones were controlled to ±1°C with a L&N Speedomax H recorder with C.A.T. controller. Reaction tubes, 45 mm ID, constructed of either Mullite or quartz were used in the experiments. The silicon used for the substrate material was single crystal, (111) oriented, n-type, antimony-doped with resistivities ranging from 0.01 to 0.05 ohm-cm. The slices were prepared similarly to those used for conventional transistors. After being sliced and coarse-lapped to 9-mils thickness, they were polished with Linde A on one side to 8 mils. They were given a hot acetone rinse, two rinses in hot trichloroethylene, one rinse in warm isopropyl alcohol (with the appropriate deionized water rinses), and dried. They were then oxidized 1 hr in steam at 1250°C and the oxide removed by a standard oxide etch solution. The purpose of the oxidation procedure was to remove any lapping damage as well as to provide a cleaner surface.

The method of silicon deposition chosen for this program was that of hydrogen reduction of silicon tetrachloride

$$SiCl_4 + 2H_2 \leftrightharpoons Si + 4HCl$$

Various sources of silicon tetrachloride were used in this program, including some prepared in our own laboratory. For most of the experiments described here, however, ultrapure $SiCl_4$ was obtained from Matheson Coleman and Bell Co. with boron specified as being less than 10 ppb and phosphorus less than 50 ppb.

Experimental—Single Slice Deposition

Initially, hydrogen gas was passed through a bubbler of $SiCl_4$ maintained at −25°C and directly into the reaction tube as in a diffusion process. The silicon substrate was placed flat on a quartz slab at about 1200°C. Some slices were first subjected to a hydrogen treatment, others were not. However, results were all unsatisfactory. Reduction of the silicon tetrachloride was occurring well ahead of the silicon substrate or at too low a temperature. Numerous

reaction products were being carried to the substrate, tube wall, and elsewhere. No suitable deposits were obtained.

These results suggested that reduction of the silicon tetrachloride should be prevented until it reached the substrate. This would have to be accomplished by cooling the reacting gas mixture of hydrogen and silicon tetrachloride as it flowed into the furnace. Therefore, the system shown in Fig. 1 was designed and constructed. A 4 mm ID quartz insert tube, surrounded by a cooling jacket, extended into the furnace tube. Nitrogen gas was found to be the most efficient coolant. The optimum rate of nitrogen flow, determined experimentally, was 25 liters/min. The furnace temperature profile with and without a flow of cooling gas is shown in Fig. 2. It is evident from this profile that the reacting gases are maintained below 1000°C until contacting the silicon substrate. The use of a cooled insert tube resulted in smooth silicon deposits, later shown to be single crystal. As is shown in Fig. 1, the reaction gases were directed vertically and perpendicular to the substrate through a nozzle. The latter had an opening diameter of approximately 15 mm. The silicon substrate was about 10 mm beneath the nozzle opening. By varying the flow rate and the deposition time, optimum process conditions were determined for uniform deposit formation. A silicon deposit about 10-20μ thick could be produced in from 5 to 15 min. Flow rates of between 1 and 2 liters/min were found to be the most satisfactory. Resistivities were in the neighborhood of 2 ohm-cm, n-type. The deposits appeared uniform across the surface except for a slight

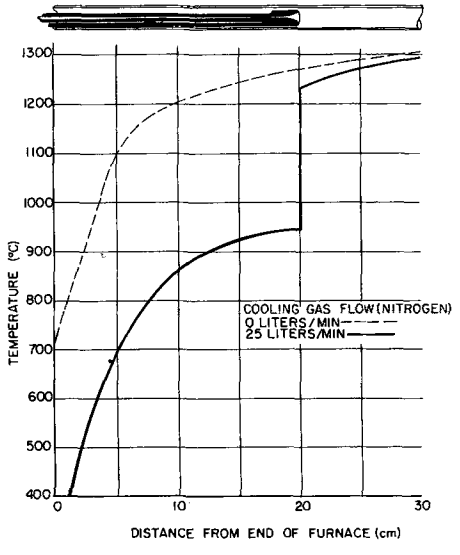

Fig. 2. Temperature profile of epitaxial reaction chamber

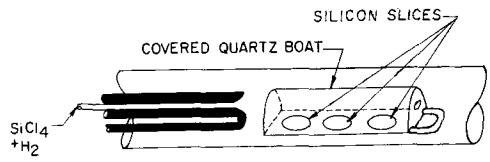

Fig. 3. Modified apparatus for epitaxial deposition on more than one silicon slice.

tapering at the edges. No deposit was observed on the underside of the substrate.

For a typical run, silicon tetrachloride was maintained at −25°C, providing a mole fraction of about 0.025 in hydrogen. The system was first purged with argon. The substrate was placed in position on a flat quartz boat and was exposed to hydrogen for 15 min at 1250°C. Deposition was then carried out under conditions necessary to obtain a desired deposit thickness. For instance, if the flow rate was 1.5 liters/min, a deposit thickness of about 18μ could be obtained in 6 min. After purging again with argon, the slice was removed from the furnace and evaluated. The total time that the slice remained in the furnace was about 30 min.

It was demonstrated that the process is extremely sensitive to any water vapor or air admitted to the system through leaks in the apparatus. Thus a very tight system is required.

Deposition of Several Slices

After successful deposition on a single slice, three slices were treated simultaneously using the modification of the system shown in Fig. 3. As can be observed, the stream of reacting gases was directed straight out from the insert tube into a covered quartz boat. The latter was referred to as a "covered wagon." It was approximately 10 cm long, 2.8 cm high, and 2.5 cm wide at the bottom. The distance between the covered boat and the nozzle opening was about 5 cm. The nozzle opening was 10 mm in diameter. The covered boat was used originally to prevent reaction products from dropping from the top of the furnace tube onto the substrates. In addition, deposited silicon could be removed from the sides of the boat between runs. But it was soon found that by selecting the correct size of hole in the end of the boat and the correct flow rate, the covered boat would permit better control of the reacting gas mixture. A hole diameter of 10 mm and flow rates of 2-4 liters/min provided satisfactory results. As was the case for the single slice system, the mole fraction of $SiCl_4$ in hydrogen was 0.025, and the substrate temperature was maintained in the range of 1230°-1270°C. The 15-min hydrogen pretreatment was also used for the multislice depositions. Deposition times were longer than for the single slice depositions, about 10-15 min.

By using this system, uniform deposits could be produced on several slices. Deposit thicknesses were equal among the slices and from run to run for a given set of operating conditions. Resistivities were also reproducible among runs, provided the same source of $SiCl_4$ was used. No tapering at the edges of the deposits was observed as was the case in the previous one-slice system. This was undoubtedly due to the more uniform gas concentration above the substrates in the covered boat system.

Table I. Thickness and resistivity profile of silicon epitaxial deposits produced in hot-tube furnace

To better understand the deposition process, a smoke chamber was assembled which duplicated the geometry of the multislice system. Nitrogen flowing through hydrochloric acid and ammonium hydroxide represented the hydrogen-silicon tetrachloride flow pattern. By observing these patterns, process variables could be optimized for uniform deposition on several slices. The smoke chamber experiments also indicated where certain beneficial changes in the geometry of the system could be made. One proposed modification was the formation of a grid of quartz fibers across the opening of the covered boat, thus providing better dispersion of the gas mixture. The smoke chamber also permitted the evaluation of other sizes and shapes of boats, including some with more than one shelf.

During continuing deposition experiments, it was found the quartz insert tube would last several weeks if used under proper conditions. If the outlet of the tube became plugged or broken, the entire insert assembly was removed from the furnace and the tube end replaced by the glassblower. Thus, the main portion of the insert assembly had a relatively long life.

Evaluation of Deposits

Deposits were evaluated in the following manner. All slices were weighed before and after deposition. In addition, deposit thickness values were obtained by angle lapping and staining. As mentioned above, deposit thicknesses across a sample prepared in the multislice system were quite uniform. Profiles of thicknesses for two typical, deposited slices are listed in Table I. These values were obtained at various locations on the slice. It was soon found that a definite relationship existed between deposit weight per unit area and thickness, approximating the density of silicon. A plot of weight-thickness data is presented in Fig. 4. Weights are expressed as weight gain per total slice, the slices being 20.6 mm in diameter and 0.2 mm thick. We were able, therefore, to estimate the thickness values to ±10% from the weight measurements. This would not have been possible if deposition occurred to any extent on the underside of the substrate.

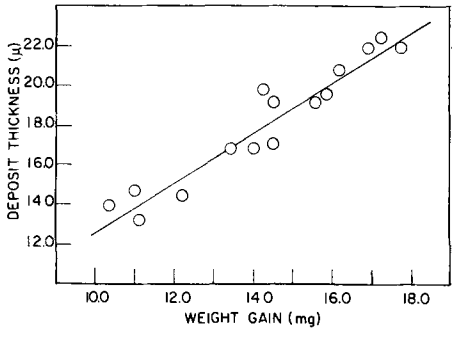

Fig. 4. Relationship of weight gain to deposit thickness for hot-tube, epitaxial deposition of silicon.

Resistivities were determined from capacitance-voltage measurements (9) and were generally found to be quite uniform across the deposit and through the deposit. An example of a resistivity profile is given in Table I. Early in our experiments it was obvious that the resistivity of the deposits was dependent on the specific supply of silicon tetrachloride. Later, it was observed that the hydrogen source is also a factor. For a given source of these reactants, we could obtain good reproducibility of resistivities. Special experiments were conducted in which boron tribromide was added to the silicon tetrachloride. Predicted increases in deposit n-type resistivities were obtained initially. However, if the doped silicon tetrachloride was allowed to stand for 24 hr, resistivities dropped back down to close to the original value. It was concluded, therefore, that boron tribromide was probably unstable in silicon tetrachloride and that doping should be carried out at the time of deposition.

A series of runs was made using the single slice system. The same supply of silicon tetrachloride was used for all runs of this series. Deposition conditions were as follows: $SiCl_4$ was maintained at −24°C, substrate temperature was 1200°C, flow rate was 1.5 liters/min, and deposition time was 6 min. Deposit weight and resistivity results as well as calculated thickness values are tabulated in Table II. All deposits were n-type. These results indicate reasonable reproducibility of deposit characteristics.

Similar data are listed in Tables III and IV for the multislice system. The reproducibility among

slices in each of four runs is indicated in Table III. Runs 88 and 91 are both for depositions using a flow rate of 3 liters/min but for different times. A slightly higher flow rate was used for runs 89 and 97. The deposit weights are reasonably reproducible among the three slices of each run, as are resistivities.

Table IV demonstrates reproducibility of deposit weights, thicknesses, and resistivities for a series of runs in the multislice system. Only two slices were deposited per run. Substrate temperature was 1270°C, flow rate was 4 liters/min, deposition time was 12 min, and $SiCl_4$ was maintained at —25°C for this series of runs. It should be noted that the silicon tetrachloride was changed between runs 141 and 142. This change affected the resistivity values, as is indicated in the table. With one or two exceptions, all values are fairly consistent.

Various deposited slices were turned over to our development pilot line for fabrication of transistors. A number of mesa switching transistors were completed and tested for electrical properties. As expected, collector-emitter saturation voltages as well as storage times were considerably lower than those of similar nonepitaxial transistors.

Conclusions

The results of this program have demonstrated that silicon can be deposited epitaxially on a silicon substrate in a conventional hot-tube diffusion furnace. Several slices can be treated simultaneously. Deposits produced are uniform in thickness and resistivity and have very few surface irregularities. For a given source of silicon tetrachloride and hydrogen, results are reproducible from run to run. As is the case with any silicon vapor deposition process, the process is highly sensitive to the presence of water vapor or air. Resistivities of deposit can be controlled by doping the reacting materials at the time of deposition. It is probable that this system can be used for the vapor deposition of other materials, both elements and compounds, required in the various phases of electronic device fabrications.

Acknowledgments

The author wishes to thank W. Peterson for his help in the experimental portion of this program. Also, W. R. Lamb and E. A. Swanson of these laboratories provided valuable assistance in evaluating the deposits.

Polarography of Mercaptoalkyl Compounds and Their Disulfides

Walter Stricks, J. K. Frischmann, and R. G. Mueller

Department of Chemistry, Marquette University, Milwaukee, Wisconsin

ABSTRACT

The polarography of 2-mercaptoethylguanidine (RSH), 2-mercaptopropylguanidine (R_ISH), 2-mercaptoethylamine ($R_{II}SH$), and 2-mercaptoethanol ($R_{III}SH$) and their disulfides (RSSR, R_ISSR_I, $R_{II}SSR_{II}$ and $R_{III}SSR_{III}$) has been studied. The mercaptans behave in the same way as other mercaptans described previously in the literature. RSSR gives well-defined reduction waves. The characteristics of the RSSR waves in the absence and presence of RSH are the same as those of oxidized glutathione and can be accounted for by the sequence of the two reactions: $RSSR + e + H^+ \rightleftarrows RS^\cdot + RSH$, $RS^\cdot + e + H^+ \rightarrow RSH$ in which the first reaction is the rate and potential determining step. R_ISSR_I, $R_{II}SSR_{II}$, and $R_{III}SSR_{III}$ are reduced irreversibly at the dropping mercury electrode.

In recent years a large number of mercaptoalkyl compounds have been studied with regard to their properties as radiation protective drugs for animals. In the course of systematic investigations of reactions of these compounds with metal ions and proteins it appeared to be useful to study the polarographic behavior of a few typical mercaptoalkyl compounds under various experimental conditions.

This paper deals with a polarographic study of 2-mercaptoethylguanidine (denoted as RSH), 2-mercaptopropylguanidine (R_ISH), 2-mercaptoethylamine ($R_{II}SH$), and 2-mercaptoethanol ($R_{III}SH$) and their disulfides which for the sake of brevity will be referred to as RSSR, R_ISSR_I, $R_{II}SSR_{II}$, and $R_{III}SSR_{III}$, respectively. The results obtained for these compounds are compared with each other and with those obtained for other mercaptans and disulfides described in the literature (1-3).

Experimental

Materials.—Solutions of mercaptoalkyl guanidine were prepared from S,2-aminoalkylisothiouronium bromide hydrobromide which undergoes rearrangement in neutral solution to form mercaptoalkylguanidine (4). Stock solutions of 10^{-2}M mercaptan were prepared by weighing an appropriate amount of the isothiouronium compound in a glass cap which together with the compound was introduced into a bottle provided with metal screw cap into which a few holes were bored. In order to obtain an airtight seal the cap was fitted with a self sealing Buna N rubber gasket. Now a given volume of air free sodium hydroxide solution containing an amount of sodium hydroxide exactly equimolar to the isothiouronium salt was added in order to neutralize the liberated hydrobromic acid. The bottle was sealed immediately and after dissolution of the sample the solution was purged thoroughly with nitrogen introduced by means of a hypodermic needle which pierced the cap of the bottle. Samples were withdrawn from the bottle by means of a 2 ml calibrated syringe. When not in use the solution was stored in a refrigerator. The mercaptan solutions were found to be stable for a week. Stock solutions of mercaptoethylamine and mercaptoethanol were prepared in the same way as described for RSH and R_ISH except that no sodium hydroxide was added to the solution.

The isothiouronium compounds were obtained from Dr. D. G. Doherty of the Biology Division, Oak Ridge National Laboratory. The mercaptoethylamine hydrochloride was obtained from the Walter Reed Army Medical Center, and the mercaptoethanol was an Eastman Kodak white label product. The mercaptan solutions were analyzed by amperometric titration with ethylmercury chloride at the rotated dropping mercury indicator electrode (5).

The disulfide solutions were obtained by air oxidation of the mercaptans. A slow stream of carbon dioxide and dust free air was passed through 50 ml of 0.01M mercaptan solution. The progress of the oxidation was followed polarographically. The air bubbling was continued until the anodic wave of the mercaptan had disappeared. The oxidation of RSH and R_ISH was performed in neutral medium and found to be complete after 15-20 hr. The oxidation of $R_{II}SH$ and $R_{III}SH$ was sluggish in neutral medium and faster in alkaline solutions. The solutions of these compounds were therefore made 0.1M in ammonia which was driven out from the solution with air toward the end of the reaction. The oxidation of $R_{III}SH$ was slow even in alkaline medium and a trace of copper (10^{-5}M) was added as a catalyst in order to accelerate the oxidation. The resulting stock solutions were 5×10^{-3}M in disulfide.

All the other chemicals used were commercial C.P. reagent grade products.

Methods.—Current-voltage curves were obtained at 25.0° ± 0.1° with a Fisher Electropode, Model 65, the manual apparatus and circuit described by Lingane and Kolthoff (6) and with a self-recording Sargent Polarograph, Model XXI. All potentials were measured against the saturated calomel electrode (S.C.E.). Oxygen was removed from the solution with a stream of nitrogen (Linde nitrogen, 99.996% pure). During an experiment an atmosphere of nitrogen was maintained over the solution. Corrections were made for the residual current.

Two capillaries were used: capillary I: $m = 1.76$ mg sec^{-1}; $t = 4.4$ sec (in 0.10N KCl, open circuit); $h = 75.5$ cm; capillary II: $m = 1.98$ mg sec^{-1}; $t = 4.1$ sec (open circuit); $h = 67.4$ cm.

The pH of the solutions was measured with a Beckman zeromatic pH meter. A Beckman "General Purpose" glass electrode was used.

The ionic strength of the supporting electrolyte was adjusted by the addition of appropriate quantities of potassium chloride or sodium nitrate.

Results and Discussion

Mercaptans

Some 100 polarograms were taken with solutions of various concentrations in mercaptan in buffers at pH 1-12.1. The polarographic behavior of the mercaptans is similar to those of other mercaptans such as cysteine (1), glutathione (3), and thioglycolic acid (7) described previously in the literature and the equations for the electrode reactions are therefore not derived in this paper. In contrast to cysteine the mercaptans investigated in this work give a well defined anodic wave, the shape and the height of the wave being somewhat affected by the pH of the solution. RSH gives steep waves at pH higher than 4.6 (curve B of Fig. 1) while at pH equal to or smaller than 4.6 the wave becomes drawn out (curve A, Fig. 1). The diffusion current is markedly smaller at the lower pH. $R_{II}SH$ and $R_{III}SH$ give drawn out waves in solutions of pH smaller than 2. In contrast with glutathione no specific buffer effect was observed with the mercaptans investigated and reversible waves were obtained in acetate, phosphate, and ammonia buffers and in dilute sodium hydroxide.

Surface active substances like gelatin (0.01%) or polyacrylamide (0.01%) have no effect on the shape of the anodic wave. The mercaptans markedly reduce the surface tension of mercury as is evident from the electrocapillary curves which are similar in shape to those obtained with glutathione (3).

The waves obtained with solutions at pH 5.4-11.6 at ionic strength one and 0.1 were analyzed as described previously (3) and found to correspond to the reversible formation of mercurous mercaptide (RSHg).

The half-wave potential can be expressed by

$$E_{1/2} = E' + 0.059 \log \{[H^+] + K\} \qquad [1]$$

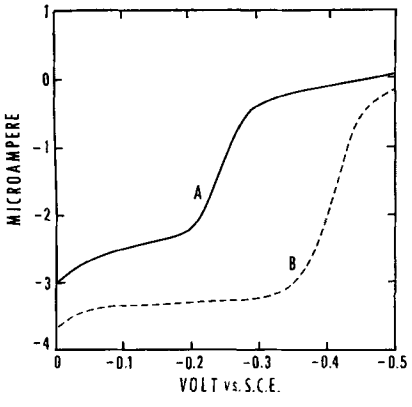

Fig. 1. Polarograms of 10^{-3}M RSH in various buffers ($\mu = 1$). A, acetate, pH 4.67; B, phosphate, pH 7.4.

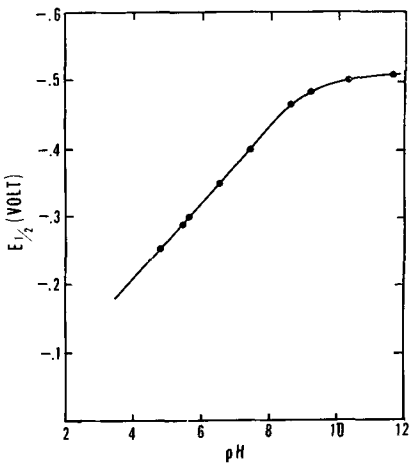

Fig. 2. Half-wave potential of RSH vs. pH ($\mu = 1$).

where the constant E' is $E^\circ + 0.059 \log k_1/k_2$ at 25°C, K is the dissociation constant of the sulfhydryl group, k_1 and k_2 are constants which are proportional to the square roots of the diffusion coefficients of RSH and RSHg, respectively, and E° is the standard potential of the electrode reaction.

The half-wave potentials of RSH which were taken from the plots log $(i_d - i)/i$ *vs.* the potential are plotted in Fig. 2. By extrapolation of the curve of Fig. 2 the value of E' which corresponds to the half-wave potential at a pH of zero is obtained. Values of E', the half-wave potentials at pH 11.5 corresponding to the horizontal portion of the $E_{1/2}$ — pH plot, and the apparent dissociation constants of the sulfhydryl group of the mercaptans are listed in Table I. The apparent dissociation constants K of the sulfhydryl group were obtained from titrations of the mercaptans with sodium hydroxide, using a glass electrode. With the exception of cysteine which forms a film at the electrode (1) the half-wave potentials in acid medium are approximately of the same order of magnitude, while the

half-wave potentials in the alkaline pH region vary according to the variation of the pK values of the sulfhydryl group as required by Eq. [1].

Diffusion currents of the anodic wave of the mercaptans were measured in the concentration range between 2.6 x 10^{-4} to 1.4 x 10^{-3}M. The diffusion current is independent of the pH in the pH region from 5 to 12. At pH smaller than 5 the diffusion current decreases. Thus the diffusion current of a 10^{-3}M RSH solution was found to be 3.30 and 2.36 μa at pH 11.6 and 4.7, respectively. Polarographic diffusion coefficients of the various mercaptans and disulfides are compared in Table I.

Disulfides

Guanidinoethyldisulfide (RSSR) gives a single reduction wave over the entire pH range investigated. In 2.5 x 10^{-4}M RSSR solutions a pronounced maximum occurs at pH 2.8 (curve A of Fig. 3). As the pH of the solution is increased the maximum becomes considerably flatter. At pH equal to or higher than 7 the maximum disappears (curve C of Fig. 3). Gelatin at concentrations of 0.001-0.003% suppresses the maximum at low pH and has hardly any effect on the half-wave potential and on the diffusion current. Increasing amounts of gelatin give rise to waves which are drawn out, the effect becoming more pronounced with decreasing pH (curve B, Fig. 3).

Electrocapillary curves taken with RSSR solutions have exactly the same shape as those obtained with RSH.

Analysis of current voltage curves obtained with RSSR solutions of various concentrations (1 to 3.8 x 10^{-4}M) at pH 11.6 to 5.82 at ionic strength 1 and 0.1 in the absence and presence of 1.23 to 6.17 x 10^{-4}M RSH revealed that the characteristics of the wave is exactly the same as that of oxidized glutathione (3). The equation of the wave at 25°C is therefore given by

$$E = E' + 0.059 \log \{[H^+] + K\} + 0.059 \log (i_d - i)/i^2 \quad [2]$$

where E' is a constant. The reaction mechanism suggested for the reduction of oxidized glutathione also explains the experimental results obtained with RSSR (RSSR + e + $H^+ \rightleftharpoons$ RS· + RSH, RS· + e + $H^+ \rightarrow$ RSH, the first reaction being the rate and potential determining step).

The diffusion current of RSSR hardly changes with pH in solutions at pH lower than 10 (i_d/c=6.0) but is higher at pH above 10 (i_d/c=6.8). At a concentration range between 6.7 x 10^{-5} to 3.2 x 10^{-4}M the diffusion current was found to be proportional to the concentration.

The experiments performed with guanidino propyldisulfide (R_ISSR_I), aminoethyldisulfide ($R_{II}SSR_{II}$), and hydroxyethyldisulfide ($R_{III}SSR_{III}$) were essentially of the same kind as those mentioned for RSSR.

The current voltage curves of R_ISSR_I and $R_{II}SSR_{II}$ have the appearance of reversible waves. However, the analysis of the R_ISSR_I-wave gave a plot log $(i_d-i)/i^2$ *vs.* potential which was a curved line. In the presence of an excess of R_ISH (2.5 x 10^{-4}M R_ISSR_I, 5 x 10^{-4} to 4 x 10^{-2}M R_ISH) the plots log $(i_d-i)/i$ gave straight lines of slopes 0.052 to 0.062 as required by Eq. 2. The plot log C_{RSH} (C_{RSH} is molar concentration of RSH) *vs.* $E_{1/2}$ gave a straight line of slope 0.071 instead of the theoretical value of 0.059. The wave of $R_{II}SSR_{II}$ analyzed to give a plot log $(i_d-i)/i^2$ *vs.* E which was a straight line of the theoretical slope of 0.059. The plot log $i_d/2$ *vs.* $E_{1/2}$ was a straight line of slope 0.076 instead of the theoretical value of 0.059. Mixtures of 2.5 x 10^{-4}M $R_{II}SSR_{II}$ with varying concentrations of $R_{II}SH$ (2.5 x 10^{-4} to 1.2 x 10^{-3}M) gave plots log $(i_d-i)/i$ *vs.* E which were straight lines of theoretical slopes of about 0.060 similar to the waves obtained with R_ISSR_I. The plot log $C_{R_{II}SH}$ *vs.* $E_{1/2}$ was found to be a curved line and therefore does not conform to the requirements of Eq. 2.

The observations with R_ISSR_I and $R_{II}SSR_{II}$ indicate that the reduction of these two compounds at the dropping mercury electrode is not reversible since the experimental results do neither satisfy the conditions for a two electron reduction nor do they agree with the conditions for a free radical mechanism (Eq. [2]).

Polarograms of $R_{III}SSR_{III}$ were taken with solutions at various pH (12 to 4) in the absence and presence of gelatin. All waves obtained with $R_{III}SSR_{III}$ were distorted and drawn out, indicating an irreversible electrode process. Therefore an analysis of these waves was not attempted.

It is of interest to note that, while the polarographic behavior of all mercaptans reported in the literature is essentially the same, the disulfides differ rather markedly as far as their polarography is concerned. The difference between RSSR on one hand and R_ISSR_I, $R_{II}SSR_{II}$, and $R_{III}SSR_{III}$ on the other hand is remarkable, considering that all these compounds are of a similar structure. In contrast to this it is noteworthy that compounds as different as oxidized glutathione and RSSR show the same polarographic behavior.

Equilibrium Studies in the Reduction of Thorium Oxide by Aluminum

Douglas O. Raleigh

Atomics International, Canoga Park, California

ABSTRACT

When metallothermic reductions are carried out with an excess of the reducing metal, formation of an intermetallic compound between the reactant and product metals can make reduction energetically more favorable. Thorium oxide can be reduced by an excess of aluminum despite unfavorable standard-state energetics. The intermetallic compound involved is shown to be $ThAl_3$. From equilibrium experiments, its standard free energy of formation is estimated to be —36 kcal.

Recent interest in our laboratory in alloys of thorium and their preparation led us to experimental work on the reduction of thorium oxide by metals less reactive than calcium. The reduction of thorium oxide by aluminum as a process for preparing thorium-aluminum alloys was achieved; studies on the optimum conditions for reduction are reported elsewhere (1). The occurrence of the reduction despite nominally unfavorable energetics was of interest to us. The standard-state reaction

$$ThO_2(s) + \frac{4}{3}Al(l) \rightarrow \frac{2}{3}Al_2O_3(s) + Th(s) \quad [1]$$

is associated with a positive free energy of reaction at all temperatures of interest. At 1050°C, the temperature chosen for our work, $\Delta F = +38$ kcal from the reported (2) standard free energies of formation of $ThO_2(s)$ and $Al_2O_3(s)$. In the process developed by us, however, the thoria is suspended or dissolved in a molten fluoride mix in contact with liquid aluminum and, since the product thorium is dissolved in the aluminum, the actual reaction is

$$ThO_2(\text{sol. fluoride}) + \frac{4}{3}Al(\text{sol. Al-Th}) \rightarrow \frac{2}{3}Al_2O_3(\text{sol. fluoride}) + Th(\text{sol. Al-Th}) \quad [2]$$

It was suspected that the required chemical potential for the reaction was derived primarily from the formation of one or more intermetallic Th-Al compounds and their solution in the metallic melt. The possibility, however, of strong solute-solvent interaction between the alumina and the fluoride melt could not be eliminated. To clarify the situation, the series of experiments reported here was carried out. Thorium-aluminum melts were equilibrated with a molten fluoride salt that was saturated with thoria and alumina and contained a solid excess of both. Under these conditions, the dissolved and solid oxides are in equilibrium, so that the reaction occurring may be written

$$ThO_2(s) + \frac{4}{3}Al(\text{sol. Al-Th}) \rightleftharpoons \frac{2}{3}Al_2O_3(s) + Th(\text{sol. Al-Th}) \quad [3]$$

By determining the equilibrium concentration of thorium in aluminum in this system and carrying out the necessary supplemental work, it was shown that the primary driving force for the reaction is the free energy of formation of $ThAl_3$, and an estimate of its value was made. The results indicate that intermetallic compound formation may play a useful role in promoting metallothermic reductions in a number of systems.

Experimental

Apparatus.—The experimental work required a high-temperature inert atmosphere furnace system with provision for outgassing, stirring, and withdrawing samples from the reaction mix. The apparatus is shown in Fig. 1. The chemical systems of interest were heated in cylindrical graphite crucibles set inside a Vycor tube vacuum furnace as shown. Heating was provided by an induction coil connected to a 2½ kv-amp Lepel induction unit. Temperature was measured with a nickel-sheathed chromel-alumel thermocouple set into the crucible as shown and connected, through sealed copper leads, to a type 8662 L & N Millivolt Indicator. The thermocouple sheath was carefully grounded to

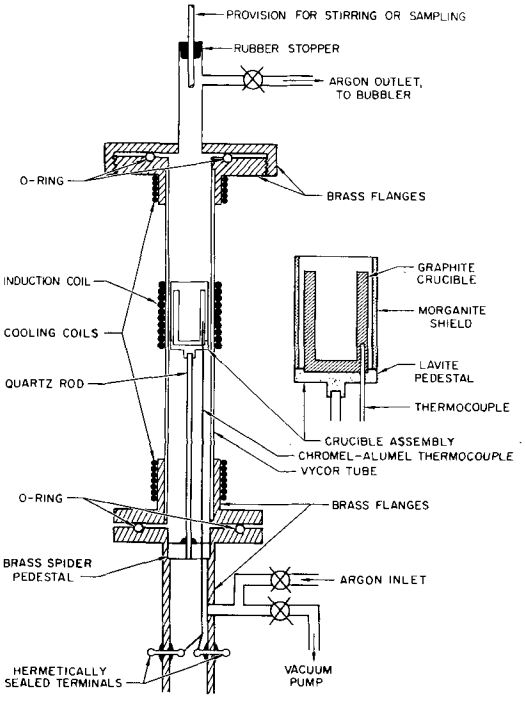

Fig. 1. Apparatus

insulate the thermocouple from induction currents. The temperature measured with this arrangement checked that of a test quantity of molten aluminum in the crucible as measured with a calibrated optical pyrometer to within several degrees at 1050°C. The temperature was controlled to ±5°C by a Wheelco Capacitrol controller.

Vacuum and argon lines allowed outgassing and provision of the required inert atmosphere. The argon used was purified by passing it over uranium turnings at 500°C. The vacuum line was connected to a Kinney KC-5 vacuum pump and the vacuum pressure measured with a standard thermocouple gauge. By use of a greased rubber stopper, the furnace top was equipped for gastight operation of either a motor-driven stirring rod or a sampling tube.

The metals used in this work were reactor grade thorium and 99.99% ingot aluminum. The chemicals employed were reagent grade lithium fluoride, aluminum oxide, and thorium oxide. No further purifications were carried out.

Selection of salt phase.—To carry out the equilibration studies between Al-Th alloy and the oxides of aluminum and thorium with favorable kinetics, a suitable molten salt flux was required. Since the salt mix was to be saturated with both oxides, the oxide solubilities in the mix needed to be moderate, but not high, to achieve saturation conveniently and avoid unfavorable increases in the viscosity of the melt. Further, no reaction or compound formation is allowable between the salt melt and either the oxides or the molten metal phase. Fluoride salts were favored because of their solubilities for metallic oxides, but cryolite mixes were found to be unsuitable because of reaction with the aluminum[1] and excessive alumina solubility. The following experiments showed lithium fluoride to be inert toward aluminum under the planned equilibration conditions.

Identical mixtures of lithium fluoride and aluminum were heated for 1 and 2 hr, respectively, at 1050°C under 1 atm of argon in the described apparatus. Analysis of both metal phases by flame photometry showed less than 0.03 w/o (weight per cent) Li present. The aluminum content in the molten LiF was found to be 2.28 w/o in both runs as determined by EDTA titration, but the absence of the corresponding amount of Li in the metal phase and the constancy of the Al content indicated that this represented the solubility of aluminum in molten LiF at 1050°C.

That no solute-solvent reactions occurred between the oxides and LiF was shown later, in the equilibrium reduction runs, where x-ray diffraction analyses on the salt phase showed patterns only for ThO_2, Al_2O_3, and LiF.

As will be seen later, solution of the thorium in aluminum reduces its activity sufficiently that it could not be expected to react with the LiF.

Solubilities of oxides.—To obtain useful background information for the equilibration studies, the solubilities of Al_2O_3 and ThO_2 in molten LiF at 1050°C were determined separately and in common solution. In several preliminary runs, limits of solubility and relative supernatant and precipitate volumes were determined by heating LiF-ThO_2 and LiF-Al_2O_3 mixtures for ½ hr at 1050°C in our apparatus and examining the frozen melts. In each case, sharp separation into precipitate and supernatant regions was evident.

To determine the solubilities, two experimental procedures were used. In the first, a mixture of 0.4g of Al_2O_3 and 7.1g LiF was placed in the furnace setup, outgassed, and heated at 1050°C under argon. After heating for ½ hr at this temperature, a quartz tube in the apparatus was lowered into the crucible to just above the melt surface. After several minutes to allow the tube end to come to the melt temperature, the tube was lowered into the supernatant zone and a melt sample withdrawn by means of a suction gun. The tube was then removed from the furnace, the sample recovered, and the tube replaced. Acceleration of the argon flow during tube removal minimized entry of air into the system. Following replacement of the tube, the crucible temperature was raised to 1100°C, held at this temperature for ½ hr to hasten saturation, lowered to 1050°C, held at 1050°C for ½ hr, and the next sample taken. This procedure was then repeated twice more for a total of four samplings. Samples were analyzed for Al by EDTA titration. The procedure was repeated in a second run with a mixture of ThO_2, Al_2O_3, and LiF to determine the solubilities of the oxides in common solution.

In the second procedure, used as a partial check, the apparatus was equipped with a motor-driven, graphite-tipped stirring rod. A ThO_2-LiF mixture was outgassed, heated to 1050°C, and held at this temperature. Three cycles were then carried out in which the mixture was stirred for 3 min, allowed to settle for 25 min, and sampled as before. The furnace was then shut down, a portion of Al_2O_3 added atop the cooled mix, the crucible reheated to 1050°C, and

[1] $Na_3AlF_6 + Al \rightarrow 3Na\uparrow + 2AlF_3$.

Table I. Solubilities of Al_2O_3 and ThO_2 in LiF at 1050°C

Run	Procedure	Solute	w/o Solute in sample 1	2	3	4	Assumed solubility
1	1st	Al_2O_3	0.26	0.26	0.28	0.32	0.30 (?)
2	1st	Al_2O_3	0.28	0.32	0.38	0.38	0.38
		ThO_2	0.05	0.05	0.08	0.06	0.06

		ThO_2	0.05	0.09	0.06	—	0.07

three more cycles of stirring, settling, and sampling carried out.

The results of all solubility determinations appear in Table I. Accuracies of individual sample analyses were about 0.01 w/o for the ThO_2 contents and 0.02 w/o for the Al_2O_3 analyses. Of primary interest in our work were the solubilities of the oxides in common solution, which agree well in the two procedures, despite the nearness to the limits of analysis for the thoria content. In interpreting sample analyses from the runs carried out by the temperature cycling (first) procedure, constant solute contents in the last few samples are taken to indicate saturation. Thus, the choice of 0.38 w/o as the alumina solubility in run 2 seems reasonable, and the absence of any significant progression in the ThO_2 content in this run allows us to take a simple average. Results, however, are not as clear-cut in run 1. One believes that the runs with stirring (second procedure) are more reliable in that the constancy of alumina contents in the samples indicate a rapid attainment of saturation. The thoria solubility in run 3 is seen to be below the limit of analysis, but the general picture indicates somewhat of an increase of the solubilities of both ThO_2 and Al_2O_3 when present in common solution in LiF.

Equilibration experiments.—Several preliminary runs, in which LiF-ThO_2-Al_2O_3 mixes were heated in contact with Th-Al alloy melts for several hours at 1050°C, indicated that great care was needed to achieve equilibrium. Continuous stirring was required, so the motor-driven graphite-tipped stirring rod was installed in the apparatus. The arrangement, however, led to poor phase separation and extensive aluminum carbide formation from the metallic aluminum, so the graphite crucible was fitted with a liner of recrystallized alumina and a stirring rod tip of the same material was used. Partial solution or disintegration of the stirring rod tip occurred during runs, despite the presence of more than the saturation limit of Al_2O_3 in the initial salt mix. However, since the runs were to be carried out at any rate with the salt flux saturated with both oxides, this constituted no problem.

The series of equilibration runs was carried out as follows. Preliminary runs showed an achievable thorium build-up of at least 10 w/o in the metal phase, so a quantity of Al 10 w/o Th alloy was prepared by heating the alloy components for several hours at 1050°C in an argon atmosphere. A mixture of LiF and enough ThO_2 and Al_2O_3 to well exceed their solubility limits was then outgassed and heated for 15 min at 1050°C under argon to provide a suitable salt phase. The metal and salt phases were then heated together to 1050°C under argon, the motor-driven stirring rod gradually lowered into the melt, and the mixture heated for 2 hr, with continuous stirring, at 1050°C. The stirrer was then withdrawn, the mix cooled quickly, and the metal phase from the run recovered and analyzed *in toto*. The analysis showed a considerable increase in the metal phase thorium content, so a metal phase of the approximate new alloy composition was prepared and another run carried out with a salt phase of the same composition. This was repeated until the metal phase showed only a small further increase in thorium content, whereupon a metal phase with a much higher thorium content was prepared and a similar run carried out. This run showed a decrease in thorium content of the metal phase, so the procedure was repeated with initial metal phases of successively smaller thorium content.

The results of the experiments are shown in Table II. It is seen that the procedure resulted in a near-approach to equilibrium. The assumed equilibrium concentration of Th in the metal phase is 28.1 ± 0.2 w/o thorium.

Metal phase studies.—As seen later, the above equilibrium concentration can be used with the known free energy of reaction of Eq. [1] to estimate the standard free energy of formation of the intermetallic compound involved in Eq. [3]. To do this, however, requires knowing the exact identity of this compound and the solubility of thorium in aluminum at the temperature of interest. In both cases, reported work is in some disagreement. For our work, the intermetallic compound of interest was the one which is in equilibrium with a saturated solution of thorium in aluminum at 1050°C. Aluminum-thorium phase diagrams by different workers (3-5) however, variously indicate this compound to be ThAl, $ThAl_2$, and $ThAl_3$. Work by Leber (3) indicated the solubility of Th in Al at 1050°C to be 55 w/o, but other work (4) was in disagreement.

The solubility of thorium in liquid aluminum at 1050°C was determined by the first procedure used for oxide solubilities. A mixture of 10g aluminum and 26.5g thorium, the latter in small pieces, was heated to 1050°C in argon, under 0.5g LiF to serve

Table II. Weight per cent Th in equilibration run metal phases

Run	Initial	Final
1	10.0	20.3
2	18.9	26.2
3	25.0	27.9
4	40.0	35.2
5	35.0	28.3

as a flux. The mixture was heated at 1050°C for ½ hr and a sample of the melt withdrawn. Then, as in previous runs, the melt was heated at 1100°C for ½ hr, cooled and held at 1050°C for ½ hr, and the second sample taken. The process was repeated to obtain a third sample, using, as before, a quartz tube and suction gun. The thorium analyses on the three samples were 52.4, 54.6, and 54.6 w/o, respectively. Since the previous solubility data of Leber were obtained by cooling curve analysis, it was felt that an adequate check was obtained and that 55 w/o is the correct solubility of thorium in aluminum at 1050°C.

The identity of the intermetallic compound in equilibrium with a saturated solution of thorium in aluminum at 1050°C was established as follows. A mixture of Th and Al corresponding to a 55 w/o thorium alloy was heated at 1060°C for 2 hr to dissolve all of the thorium. The melt was then cooled to 925°C over a period of ½ hr, and the temperature held at 925°C for another half-hour. The bulk of the melt liquid was then removed from the crucible at 925°C by means of a quartz tube and suction gun. The material remaining in the crucible was a mat of well-defined needlelike crystals. The crucible was quickly cooled to room temperature and the crystals separated from an adhering residue of solidified melt liquid by dissolving away the latter with 10% aqueous NaOH. Chemical analysis and x-ray diffraction identified the crystals as $ThAl_3$. Since none of the phase diagrams reported showed any phase changes or thermal arrests between 1060° and 925°C, and since melt liquid was not available for reactions below 925°C, it was assumed that the crystals recovered are those of the stable aluminide at 1050°C. The result is in agreement with the work of Murray (5), which is the most recent work on this portion of the Th-Al phase diagram.

Discussion

The results of the preceding experimental work can be used to estimate the standard free energy of formation of $ThAl_3$. The reduction of thorium oxide to produce thorium-aluminum alloy can be considered in terms of the virtual formation of $ThAl_3$ and its solution in a sufficient excess of aluminum to result in the metal phase of equilibrium composition. Accordingly, Eq. [3], for the reaction at 1050°C, can be written in terms of the equivalent series

$$ThO_2(s) + \frac{4}{3}Al(l) \rightarrow \frac{2}{3}Al_2O_3(s) + Th(s) \qquad \Delta F_1 = +38 \text{ kcal}$$

$$Th(s) + 3Al(l) \rightarrow ThAl_3(s) \qquad \Delta F_2 = \Delta F_f^\circ\ (ThAl)_3$$

$$ThAl_3(s) \rightarrow Th(\text{liquidus sol.}) + 3Al(\text{liquidus sol.}) \qquad \Delta F_3 = 0$$

$$Th(\text{liquidus sol.}) \rightarrow Th(\text{sol. Al-Th}) \qquad \Delta F_4 = -RT \ln \frac{a^{sl}{}_{Th}}{a_{Th}}$$

$$3Al\ (\text{liquidus sol.}) \rightarrow 3Al(l) \qquad \Delta F_5 = -RT \ln (a^{sl}{}_{Al})^3$$

$$\frac{4}{3}Al(\text{sol. Al-Th}) \rightarrow \frac{4}{3}Al(l) \qquad \Delta F_6 = -RT \ln (a_{Al})^{4/3}$$

where $\Delta F_f^\circ\ (ThAl_3)$ is the standard free energy of formation of $ThAl_3$, a^{sl} refers to activities in the liquidus Th-Al melt (*i.e.*, saturated solution of Th in Al), and a_{Al} and a_{Th} to activities in the melt of equilibrium composition. Since the over-all reaction is an equilibrium reaction, $\Sigma \Delta F = 0$, and thus

$$-\Delta F_f^\circ\ (ThAl_3) = 38 - RT \ln (a^{sl}{}_{Al})^3 (a_{Al})^{4/3} \left(\frac{a^{sl}{}_{Th}}{a_{Th}} \right)$$

We recall that the concentrations of thorium in the equilibrium and liquidus melts at 1050°C were 28 w/o and 55 w/o, respectively. In terms of mole fractions, however, the solutions are considerably more dilute, the mole fractions being 0.043 and 0.125. Thus, there is some basis for evaluating the above activities by the use of Raoult's and Henry's laws. While the concentrations involved are admittedly marginal for this approach, no specific data on activity coefficients exist. Further, it will be seen that the activity factor term in the above expression provides only a small contribution to the calculated free energy of formation, so that even large inaccuracies in evaluating the term will have a small effect on the final result. The assumption of Raoult's and Henry's laws, then, allow the following substitutions: $a_{Al} = N_{Al}$ and $a^{sl}{}_{Th}/a_{Th} = N^{sl}{}_{Th}/N_{Th}$, and accordingly,

$$-\Delta F_f^\circ\ (ThAl_3) = 38 - RT \ln (N^{sl}{}_{Al})^3\ (N_{Al})^{4/3}\ (\frac{N^{sl}{}_{Th}}{N_{Th}})$$

Using the stated values for the indicated mole fractions, one obtains, for the standard free energy of formation of $ThAl_3$ at 1050°C, an estimate of 36 kcal.

It is seen that the predominant driving force for the nominally unfavored reduction of thorium oxide by aluminum is the free energy of formation of the intermetallic compound $ThAl_3$; associated dilution effects play an energetically small role. Even large errors in the activities, which may be involved in assuming the applicability of Raoult's and Henry's laws, will not significantly affect the calculated free energy of formation. What is more important in this respect, however, is the accuracy to which the relative free energies of formation of thoria and alumina at 1050°C are known. Estimated limits of error from Kubaschewski (2) and various original reports of these measurements indicate that the 38 kcal figure may be in error by as much as 5 kcal. Accordingly, until more accurate data become available, the −36 kcal free energy of formation of $ThAl_3$ at 1050°C must be regarded as subject to the same uncertainty. It is felt, however, that this value at least gives some indication of the stability of such compounds. It would be of interest if this quantity could be determined experimentally by an independent method.

Acknowledgments

The author wishes to thank Mr. W. D. Turner for considerable assistance in the experimental work reported. The support of the United States Atomic Energy Commission is gratefully acknowledged.

Diagrammatic Representation of the Thermodynamics of Metal-Fused Chloride Systems

R. Littlewood[1]

Tube Investments Research Laboratories, Hinxton Hall, Saffron Walden, Essex, England

ABSTRACT

Previously, diagrammatic methods of presentation have been used to study the thermodynamics of metallic corrosion in fused chlorides, and the method has now been extended to metal-winning reactions. Diagrams in which the equilibrium potential E (relative to the standard chlorine electrode) in the system is plotted against the activity of oxide ion in the chloride melt (expressed as its negative logarithm, pO^{2-}) are presented for the metals Mg, Ni, Zr, and Ti in contact with one or more of the chlorides LiCl, KCl, NaCl, and $MgCl_2$ at 800°C. As an example of the use of E-pO^{2-} diagrams, it is shown how they can be applied to metal extraction processes involving chlorides. The main advance here is that the method offers an approach to the prediction of impurity levels and is applicable equally well to electrowinning from fused chlorides and to reduction of chlorides by base metals. Levels of impurity, particularly of oxygen, in the metal product are obtainable directly from the diagrams.

The thermodynamics of metal-fused chloride systems is more complicated than appears at first sight especially when reactions involving impurities, particularly anions, are taken into consideration. The success of graphical methods of presenting thermodynamic data for aqueous systems led us to develop similar ways of presentation for fused salt systems, and we have already applied some of these to study the thermodynamics of metallic corrosion in fused chlorides (1, 2).

The presentation of thermodynamic data in a diagram has certain advantages which have not always been fully appreciated. When considering a system of a number of components, one method involves conversion of the data into linear equations linking free energy with logarithmic functions of composition. There is one such equation for each possible reaction of all the various constituents present. The relations are plotted graphically, and the resulting diagram summarizes the thermodynamic properties of the system at a given temperature. This simplicity of presentation is to be compared with the application of a similar series of equations to each particular set of conditions, from which the behavior of the system under that particular set of conditions is inferred. In this case, if the properties of the system under several different conditions are required, the whole procedure usually has to be repeated. Where a general appreciation of the effect on the system of a variety of different conditions is required, presentation of the properties of the system in a diagram has obvious advantages.

The thermodynamic diagrams of Pourbaix (3) have been particularly useful in understanding the behavior of metals in contact with aqueous solutions. Pourbaix plots equilibrium potential against pH, and the diagrams divide themselves into regions of stability of different solid phases (compounds of the metal in question).

In the fused salts also, free energies can be expressed as equilibrium potentials, and there are a number of functions of composition which might be used as the other variable. In the present paper, the composition variable chosen is the activity of oxide ion in the melt, expressed in terms of its negative logarithm, pO^{2-}. The resulting E-pO^{2-} diagrams are particularly useful when considering systems involving oxides, or oxygen, in contact with fused chlorides, and in practice this covers all conditions under which fused chlorides are normally used. As an example, the paper shows in particular how E-pO^{2-} diagrams are applicable to metal extraction processes involving chlorides.

Conventions.—In aqueous systems, the conventions used in a thermodynamic treatment are well established. With reactions in fused salts, the conventions adopted in a particular treatment need to be defined at the outset. The conventions chosen for the present paper are identical with those used previously by the author (1, 2). Free energies are converted to an emf scale using the expression

$$E^\circ = -\Delta G^\circ/n\mathbf{F} \qquad [1]$$

and the potential *zero* is taken as the potential of a chlorine electrode (1 atm pressure) in contact with a chloride melt at unit chloride activity. Activities in condensed phases are based on the pure component as the standard state, or in the case of gases, the gas at unit fugacity, approximately 1 atm pressure.

[1] Present address: The British Iron and Steel Research Association, London, England.

Principles

A fused chloride melt is stable over a range of potential, which at one atmosphere pressure extends from *zero* on the chlorine electrode scale, where the melt will be in equilibrium with chlorine at 1 atm pressure, to a negative value of potential equal to the decomposition potential of the melt. The latter is related to the free energy of formation of the chloride by Eq. [1], and the decomposition potential will be more negative the more stable the chloride. Between these two potentials, the chloride will always be partially dissociated and the activities of metal and chlorine in the melt will vary with potential, while conforming to the equilibrium constant (parentheses denote activities).

$$K = \frac{(Cl_2)^{1/2}\,(M)}{(MCl)} \qquad [2]$$

of the reaction

$$MCl = M + \tfrac{1}{2}Cl_2 \qquad [3]$$

This equilibrium constant is obtainable from the expression

$$\log K = -\Delta G^\circ_{MCl}/2.303\,RT \qquad [4]$$

where ΔG°_{MCl} is the free energy of dissociation of the chloride MCl. The activity of free metal and of free chlorine present in the melt at any given potential E can be calculated from the Nernst equations for the two half-reactions.

$$\tfrac{1}{2}Cl_2 + e^- = Cl^- \qquad [5]$$

$$M^+ + e^- = M \qquad [6]$$

Thus, when MCl is present at unit activity,

$$E = E^\circ_{Cl} + (2.303\,RT/\mathbf{F})\,\log\,(Cl_2)^{1/2} \qquad [7]$$

for half-reaction [5], and

$$E = E'_M - (2.303\,RT/\mathbf{F})\,\log\,(M) \qquad [8]$$

for half-reaction [6], where E°_M can be calculated from relation [1].

The two expressions for E (Eq. [7] and [8]) are identities, since the equilibrium potential in the system has a unique value, and in fact Eq. [7] and [8] are interrelated by Eq. [2].

To deal with a system containing oxygen and oxides, it is necessary to define a standard state for the oxide ion, and in accordance with the conventions adopted, we have chosen the pure oxide of the cation of the chloride melt under consideration as unit activity of oxide ion. For example, in the case of a KCl melt the standard state for oxide ion would be pure K_2O and the standard free energy of formation of O^{2-} ion would be calculated as follows:

$$K^+ + e^- = K;\ \mu^\circ_K = +\,78.83\text{kcal} \qquad [9]$$

$$2K + \frac{1}{2}O_2 = 2K^+ + O^{2-};\ \mu^\circ_{K_2O} = -\,53.71\ \text{kcal} \qquad [10]$$

therefore

$$2e + \frac{1}{2}O_2 = O^{2-};\ \mu^\circ_{O^{2-}} = +\,103.95\ \text{kcal} \qquad [11]$$

A standard free energy of formation of the oxide ion defined in this way will differ in value according to the particular melt chosen. In mixed chlorides, the activity of O^{2-} will be expressed in terms of one particular oxide, but provided a single definition is adhered to throughout the treatment, the final results will be the same whichever oxide is chosen, although oxides of cations other than the standard one might have either extremely large or extremely small activity coefficients.

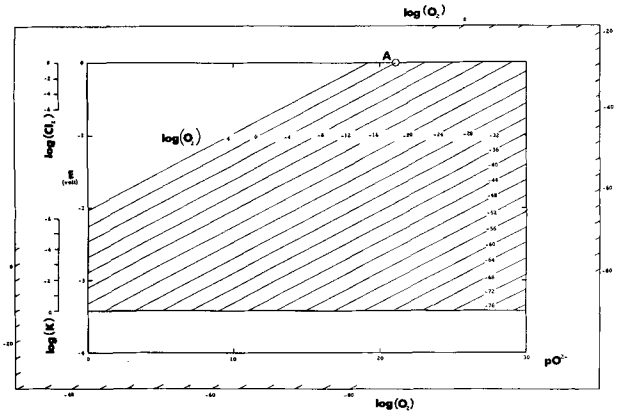

Fig. 1. Relationship between oxygen pressure, oxide activity, and potential for KCl at 800°C. E is electrode potential relative to the standard chlorine electrode. For point A, see text.

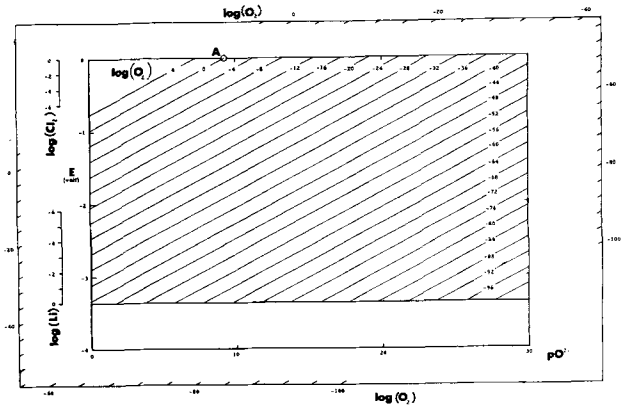

Fig. 2. Relationship between oxygen pressure, oxide activity, and potential for LiCl at 800°C.

The standard free energy of formation for the oxide ion can now be used to express the relationship between potential, oxygen pressure, and oxide activity

$$E = E^\circ_{O^{2-}} + (2.303RT/2\mathbf{F}\,\log\,[(O_2)^{1/2}/(O^{2-})] \qquad [12]$$

This relationship is shown graphically for KCl at 800°C in Fig. 1 and for LiCl at 800° in Fig. 2. For a given oxygen pressure, Eq. [12] gives rise to a straight line dependence of E on pO^{2-} and in the figures, oxygen pressures at intervals of 10^4 apart are shown, giving a grid of parallel lines. The position of these lines corresponds with the two oxygen pressure scales external to the diagrams (the line for a given oxygen pressure is found by laying a ruler on the diagram joining the appropriate points on the two scales). The upper and lower limits to the diagrams are set by the potentials at which the melt is oxidized to chlorine or reduced to metal, respectively. The other two external scales on the left-hand side give the activity of chlorine or metal present at a given potential, according to Eq. [7] and [8].

Figures 1 and 2 illustrate the marked differences in properties between melts of LiCl and KCl, which will be discussed in more detail later. Note, however, that the oxide activities in melts of LiCl and KCl prepared under atmospheres of identical composition will be very different. For example, the equilibrium conditions in melts prepared under an atmosphere of equal parts of oxygen and chlorine at a total pressure of 2 atm would be represented by the points marked A in Fig. 1 and 2. These correspond to oxide activities of $10^{-9.3}$ in LiCl and $10^{-21.1}$ in KCl, illustrating the effect of the higher affinity for oxygen of Li relative to K.

There is provision in the diagram for oxygen pressures down to extremely low values. These pressures are still meaningful and are particularly important when dealing with systems under reducing conditions, such as in the presence of metals which are strong oxygen getters, or in hydrogen atmospheres. For example, hydrogen gas at 1 atm pressure containing 1 volume per million of water vapor would be in equilibrium with an oxygen partial pressure of about 10^{-40} atm, and these conditions could therefore in principle be represented on the E--pO^{2-} diagram by the line corresponding to an oxygen pressure of 10^{-40} atm.

The solubility product of any oxide in a given chloride MCl can also be calculated, relative to the oxide M_2O. For example, the solubility product of nickel oxide in a KCl melt at 800°C is obtained as follows. When the melt is saturated with NiO, excess solid oxide will be present at unit activity, and since the system is at equilibrium, the free energy change for the dissolution reaction

$$NiO = Ni^{2+} + O^{2-} \qquad [13]$$

will be zero, so that

$$\log S = \log (Ni^{2+})\ (O^{2-}) =$$

$$(\mu^{\circ}_{NiO} - \mu^{\circ}_{Ni^{2+}} - \mu^{\circ}_{O^{2-}})/2.303RT \qquad [14]$$

Table I gives the values of activity solubility products of some oxides in melts of LiCl and in KCl calculated in this way. These illustrate the greater solubility of oxides in LiCl than in KCl, as observed experimentally (4). In addition, the relative magnitudes of solubility product of the oxides in either chloride are in the order

$$CaO > NiO \sim ZnO > MgO > ZrO_2$$

which corresponds well with experimental observations of oxide solubilities in LiCl (4), KCl (4), and LiCl-KCl eutectic (5).

Experimental data on oxide solubilities in fused chlorides are very scanty, and no attempts to determine solubility products appear to have been made. Solubility products cannot, of course, be obtained directly from simple solubility measurements of the oxide in the chloride alone, but this point will be commented on later. It will only be possible to assess fully the significance of the calculated values when experimental values of activity solubility products become available, but it appears justifiable at the moment to accept solubility products calculated in this way.

Table I. Calculated solubility products of oxides in fused chlorides at 800°C

Oxide	log S in LiCl	log S in KCl
NiO	−7.8	−19.7
CaO	−3.8	−15.8
ZnO	−8.2	−20.0
MgO	−9.9	−21.8
ZrO_2	−26.8	−50.6

The grid showing equilibria in the system KCl $-$ O_2 $-$ O^{2-} (Fig. 1) can now be used as a reference frame on which to superimpose domains of thermodynamic stability of compounds formed between components of this system and another metal, such as in Fig. 3, which is for the Mg—KCl system. For clarity, the reference grid of oxygen pressure lines has been omitted, but any line may be found simply by laying a ruler on the diagram joining the appropriate points on the two external oxygen pressure scales. Scales showing the activity of chlorine and of potassium in the melt are also given on the left as before. KCl is stable at 800°C down to a potential of −3.42v. The region of stability of KCl divides up into three domains (as shown by the heavy lines in Fig. 3) in each of which one and only one compound of Mg can be present at unit activity. In the domain marked MgO, MgO (solid, unit activity) is in equilibrium with a melt of KCl containing $MgCl_2$ and O^{2-} ions. The activity of Mg^{2+} in the melt can be found from the vertical isoactivity lines connecting with the log (Mg^{2+}) scale directly above the diagram. It can be seen that as the activity of O^{2+} ion in the melt falls, the activity of Mg^{2+} rises until at a value of pO^{2-} of 21.83 (and provided E is above −2.47v), solid MgO at unit activity can coexist with $MgCl_2$ at unit activity. At values of pO^{2-} greater than 21.83, MgO can only exist at an activity less than unity (*i.e.*, in solution) and we pass into the domain marked $MgCl_2$. At values of pO^{2-} greater than 21.83, Eq. [19], in which the activity of MgO is taken to be unity, tells us that (Mg^{2+}) must be greater than unity. This is physically meaningless, since activities can never exceed unity using the present conventions. Hence the activity of MgO must be less than unity.

In the domain $MgCl_2$, the melt may contain Mg^{2+}, O^{2-}, and Mg in solution in KCl, but the only compound of Mg which can be present at unit activity is $MgCl_2$. Its activity is not necessarily unity, and it can have any value between unity and values approaching zero. This is because the value of E defines only the value of the ratio $(Mg^{2+})/(Mg)$ and not the absolute values of (Mg^{2+}) or (Mg) which accordingly can vary over a wide range while keeping the ratio of their activities constant. The same components Mg^{2+}, O^{2-}, and Mg are present in the melt in the domain marked Mg metal, which is divided from the $MgCl_2$ domain by a horizontal line at a value of E of −2.47v, but in this domain, it is possible for Mg metal to be present at unit activity. The potential of −2.47v is simply that potential at which Mg metal at unit activity can coexist with unit activity of $MgCl_2$. The horizontal isoactivity lines, which connect with the log (Mg^{2+}) scale to the

right of the diagram, can be used to find the activity of Mg^{2+} in the melt which would be in equilibrium with Mg metal at any given potential. The boundary between the Mg metal and MgO domains is a line representing the conditions under which Mg metal and MgO can coexist, each at unit activity, and corresponds to a value of log (O_2) of −47.72, the dissociation pressure of MgO.

Figure 3 shows that solubility of an oxide in a fused chloride at a given temperature depends on several factors, an understanding of which is needed to obtain values of solubility products from solubility measurements. The solubility of MgO in KCl would be estimated by measuring the concentration of Mg^{2+} ions in the KCl melt, but this will depend on the value of pO^{2-} in the melt as in the case of an oxide in contact with an aqueous solution. For example, at a value of pO^{2-} of 21.83, the Mg^{2+} activity in the melt would be unity; at a value of pO^{2-} of 15.83, it would be 10^{-6} (Fig. 3). The results of solubility measurements will therefore depend very markedly on the value of pO^{2-} in the melt and this will need to be closely controlled. Solubility experiments described in the literature (4, 5) have not been deliberately controlled in this way, although contact with a glass or ceramic container would fix pO^{2-} at a value dependent on the nature of the oxides present in the container material (1, 6, 7) (contact with an air atmosphere would not fix the value of pO^{2-}, Fig. 1 and 2). The experimental solubilities obtained in a particular case, can in fact, be used to estimate the conditions in the melt during the experiment. Voskresenskaya and Kashcheev (4) obtained a value for the solubility of MgO in KCl at 900°C of about 0.002%: for the purpose of this example at 800°C, let us say a mole fraction of Mg^{2+} in the melt, of 10^{-5}. The measurements were made in an air atmosphere (oxygen at 0.2 atm pressure), so that writing mole fraction of Mg^{2+} as activity of Mg^{2+}, after Temkin (8), we can plot a point representing this result on Fig. 3 (point A). The conditions in the melt during these experiments must therefore have been as follows

potential −0.5v, pO^{2-} 16.83

Diagrams similar to Fig. 3 can be constructed for any metal and those for nickel in KCl and in LiCl at 800°C are shown in Fig. 4 and 5. For metals having more than one stable chloride (Figs. 6, 7, 9, 10), the situation is more complex because there is more than one way of presenting the data. For example, a set of isoactivity lines corresponding to the equilibrium of each chloride could be plotted, and at some potential the sum of the activities would become equal to unity. At potentials above this value, the only significance of the scales would be to indicate the ratios of the ion activities to that of the metal in the melt, and since the latter would be undefined, this would be a somewhat indefinite way of presenting the data. It is more convenient not to attempt to show separately the activity of every possible metal ion, but instead to express melt compositions in terms of other variables. In the diagrams presented here, the variables chosen were the sum of the activities of all ions of the metal, $(M^+) + (M^{2+}) + (M^{3+})$ + etc., and the ratios of the activities of ions with a valency difference of one, $(M^{2+})/(M^{3+})$, etc. The latter are plotted as scales external to the diagram in Fig. 6 and 7, while the sum of the metal ion activities is plotted as isoactivity lines on the diagram. Changes in redox equilibria in the melt cause these lines to curve, but nevertheless, this type of diagram is much simpler than one showing separately the activities of all possible chlorides. A diagram for Zr in contact with a KCl melt at 800°C is shown in Fig. 6. The domains are exactly analogous to the magnesium case, but are distorted in shape at potentials where changes in redox equilibria occur. The two scales at the right-hand side of the diagram indicate the position of redox equilibria of zirconium ions in the melt. These, in con-

junction with the isoactivity lines on the diagram showing the sum of the activities of Zr ions, allow the exact composition of the melt in terms of KCl, $ZrCl_4$, $ZrCl_3$, and $ZrCl_2$ to be found.

For metals with more than one oxide, there are further domains, one for each stable oxide, as in the case of titanium (Fig. 7). In addition to domains showing the conditions under which each of the oxides is thermodynamically stable, domains can also be delineated in which one of two solid substances is stable with respect to the other. For example, the dotted line shows where TiO_2 becomes stable with respect to Ti metal. (The corresponding lines for the other oxides are not shown, as they would increase the complexity of the diagram without materially increasing its usefulness). It should be clearly understood that TiO_2 is stable only in the region within the TiO_2 domain, but in view of the sluggishness of solid-state transformations, it might be kinetically favored over a wider range of conditions than indicated by the stability region of the diagram. The position of the dotted line gives an indication of this extension of the range of conditions under which TiO_2 might exist, for reactions involving metallic titanium.

In Fig. 7, a further modification has been introduced which makes the diagram applicable to titanium in LiCl, NaCl, or $MgCl_2$ as well as in KCl. The scales to the left of the diagram show the limits of stability of these melts, and the parts of the diagram extending below these limits in each particular case have, of course, no physical significance. pO^{2-} scales for each chloride are given on the lower edge of the diagram and again, parts of the diagram to the left of the zero value of pO^{2-} for each particular chloride have no meaning. The O_2 pressure scales and isoactivity lines referring to titanium ions are common to all the four chlorides, LiCl, NaCl, KCl, and $MgCl_2$.

Details of the construction of these diagrams are given in the appendix.

Applications of the Diagrams

The present diagrams have much in common with E-pH diagrams for aqueous systems, which have become well-known largely through the work of Pourbaix and his collaborators (3). It is expected that E-pO^{2-} diagrams for fused salts will prove at least as useful as these and if anything, they should be more directly applicable because at the higher temperatures common in salt melts, reactions have a greater chance of reaching equilibrium than in aqueous solutions at room temperature. In other words, predictions made about metal-fused salt systems from E-pO^{2-} diagrams are likely to be as exact as the thermodynamic data on which they are based, since most reactions in melts at high temperatures are reversible.

The condition of any system is represented on the diagrams by a point, and the equilibrium positions of all the reactions which the constituents can undergo is determined by projecting this point on to the appropriate scales, or by noting its position relative to appropriate isoactivity lines. The position of the system-point can be found if any two independent variables in the system are known. For example, if besides potential, we know either the activity of oxide ion in the melt or the partial pressure of oxygen at equilibrium, the position of the system-point is defined.

Some general conclusions regarding the possible applications of E-pO^{2-} diagrams in fused chlorides can be reached without recourse to detailed practical examples, and it is felt that the following are some of the main fields in which they might be used. The list is not considered to be exhaustive and simple cases are chosen to make the principles clear.

Aggressiveness of melts.—Consideration of the factors affecting corrosion of metals in fused chlorides has shown (1,2) that the stability of the chloride is of primary importance. Since the decomposition potentials of LiCl and KCl have similar values, it might be expected that their aggressiveness would be similar under comparable conditions. It is well known, however, that this is not so and under the same conditions of temperature, atmosphere composition, drying procedure etc. LiCl is the more aggressive towards metals. This is often loosely ascribed to the greater ease of hydrolysis of LiCl during drying or melting which leads to a greater amount of oxide or oxychloride in the LiCl melts, but it is felt that this idea is incomplete and inexact. While there will no doubt be different amounts of oxide in LiCl and KCl melts prepared by identical procedures, the greater the amount of oxide in the melt, the lower will be the redox potential of the melt at any given oxygen pressure (Fig. 1) and therefore the lower

its initial aggressiveness should be. This is the reverse of what is found in practice, and hence this effect must in practice be offset in the opposite direction by some other essential difference between melts of LiCl and KCl. Comparison of Fig. 1 and 2 shows that at any given oxygen pressure and value of pO^{2-} the redox potential of a LiCl melt is about 1.2v higher than that of a KCl melt. In other words, even if the two melts have the same oxide activity and are under atmospheres of identical composition, a LiCl melt will still be more oxidizing than a KCl melt and will thus be more aggressive. This intrinsic difference in redox potential is due to differences between the free energies of formation for oxides and chlorides of lithium and potassium and is likely to have a far-reaching effect on many chemical reactions in melts besides corrosion reactions.

It should be pointed out that the effect of water on the reactivity of chloride melts may be more complicated, since hydrolysis leads to the formation of H^+ ions as well as O^{2-} ions and the water will also dissociate to H_2 and O_2. These effects have been discussed at length elsewhere (1, 2), and the effects of water on redox potential of chloride melts are still incompletely understood experimentally (6). However, when comparing redox potential behavior in melts so different in properties as KCl and LiCl, such complications will probably be secondary to the differences due to relative oxide stability described above.

General application to corrosion in fused chlorides.—As already pointed out, the properties of E-pO^{2-} diagrams are similar in many respects to those of E-pH diagrams for aqueous solutions. For aqueous systems, Pourbaix (3) has defined domains in which the corrosion of metals is thermodynamically possible or impossible by assuming that a metal will only corrode when the substance forming its surface has a solubility in excess of an arbitrary value of 10^{-6}M. He distinguishes between two types of "domains of noncorrosion," one where the surface is actually bare metal (immunity domain) and the other where the metal is covered with a deposit of oxide or salt (passivity domain), and in the latter case, only if the substance covering the metal forms a completely perfect and nonporous screen will corrosion be prevented.

The E-pO^{2-} diagrams for fused chlorides may be divided into analogous domains, but effective passivity is less likely to occur in fused chlorides than in aqueous solution and any conclusions made from such diagrams regarding "passive" behavior should be treated with reserve. It appears safer to designate simply as "oxide-covered" the region equivalent to the passive domain, as in Fig. 8. These regions represent the conditions under which the corrosion product is insoluble in the melt, and whether these conditions do in fact lead to passivity will depend on details such as the morphology of the oxide and its tenacity to the metal surface. Figure 8 shows the nickel-KCl diagram divided into domains of corrosion and noncorrosion on the assumption that no corrosion occurs if the solubility of the metal in the melt (as ions) is less than 10^{-6} activity. Such diagrams predict whether the corrosion products of a given metal in a given fused chloride medium will be soluble metal ions or solid oxide, which may be an important consideration in some types of operation using fused chlorides.

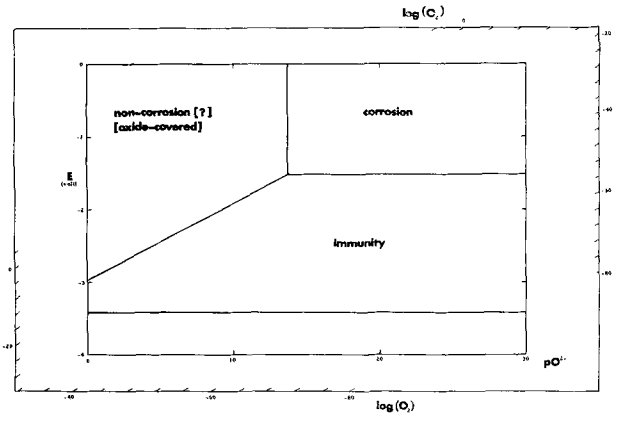

Fig. 8. Application of E-pO^{2-} diagram to corrosion of nickel in KCl melt at 800°C.

It is not proposed to consider here in detail the application of E-pO^{2-} diagrams to corrosion in fused salts, as a generalized treatment is available elsewhere (1, 2).

Electrowinning of metals from fused salts.—One of the most promising applications of E-pO^{2-} diagrams appears to be to electrowinning of metals from fused chlorides where in particular the diagrams give some guidance on the effect of variables on product purity.

Let us consider as an example the extraction of nickel by electrolysis of a bath of molten KCl containing 10^{-2} activity of Ni^{2+} ions. This is not at present a commercial process and is used only to illustrate the principles involved. Figure 4 shows that, provided the value of pO^{2-} exceeded 17.7, the Ni^{2+} ions would remain in solution as $NiCl_2$, but if the value of pO^{2-} was less than 17.7, a proportion of the Ni^{2+} ions would be precipitated as NiO. The activity of Ni^{2+} remaining in solution in the chloride melt at any pO^{2-} value less than 17.7 could be found by reference to the vertical isoactivity lines or to the scale of Ni^{2+} activities along the top of the diagram. An alternative point of view is that if the oxygen activity (partial pressure) in the system exceeded the dissociation pressure of NiO (about $10^{-13.5}$ atm), NiO would be precipitated, but if the partial pressure of oxygen were less than $10^{-13.5}$ atm, the Ni^{2+} ions would stay in solution (Fig. 4).

Deposition of nickel metal from a KCl melt containing a Ni^{2+} activity of 10^{-2}, according to Fig. 4, would not begin to occur until the potential of the cathode had fallen below −1.09v. [The potential is given by the log (Ni^{2+}) scale to the right of the diagram.] As regards the impurities in the product, the potassium content of the nickel electrodeposited at any given potential can be found from the log (K) scale on the left hand side of the diagram (extrapolation would be necessary in this particular example), and the chlorine content can be found in a similar manner. The oxygen content of the product electrodeposited at a given potential from a melt of given O^{2-} ion activity can be estimated by finding

from the external oxygen scales the value of oxygen pressure (activity) corresponding to the position of the system-point. The oxygen content of the metal product will be less, the lower the oxide ion activity in the melt and the lower the potential at which the product is deposited, but low potentials lead also to excessive contamination by potassium metal.

Besides giving quantitative guidance to the extent of product contamination in a given process under various operating conditions, E-pO^{2-} diagrams can be used as a guide to possible ways of improving product purity by altering the process itself. One possible way of obtaining a product with a lower oxygen content would be to use a solvent with a higher affinity for oxygen, *i.e.*, with a more stable oxide. For example, LiCl might be substituted for KCl. Figures 4 and 5 show that electrolysis of a melt of given $NiCl_2$ content under identical conditions of potential and pO^{2-} will lead to a product containing less oxygen if LiCl is used as solvent rather than KCl. For example, nickel metal with an oxygen activity of 10^{-10} would be obtained by electrolysis of a KCl melt with a pO^{2-} value of 20 at a potential of −1.0v, whereas the product from an LiCl melt under the same conditions would contain an oxygen activity of only 10^{-40}. In practice, of course, the preparation of a melt with a low oxide content might be more difficult for LiCl than for KCl, but these difficulties could in any case be overcome by use of an oxide "getter," which will be discussed now.

The purpose of adding a getter to the melt is to raise the pO^{2-} value and/or lower the oxygen activity in the system. For example, magnesium metal or magnesium chloride might be added to the bath to precipitate oxygen as MgO, and the values of pO^{2-} and O_2 activity obtainable in this way in KCl could be obtained from Fig. 3. For example, if Mg were gradually added so that MgO was precipitated at a constant Mg^{2+} activity of 10^{-2}, the potential of the system would fall along the vertical isoactivity line for 10^{-2} (Mg^{2+}) until a potential of −2.68v was reached, after which further additions of Mg would produce no further gettering. The addition of Mg might also lead to reduction of the $NiCl_2$ in the melt at a potential higher than −2.68v, leading to precipitation of metallic nickel, and the potentials at which precipitation would begin to occur at a given activity of $NiCl_2$ could be obtained from Fig. 4. If electrolytic separation of nickel was the requirement, the gettering process would, of course, be halted at a potential higher than that at which precipitation of metallic Ni began to occur in the body of the melt.

These simple principles are equally applicable to more complicated cases such as the winning of Ti or Zr from chloride melts, where the metal has more than one oxide or chloride. In such cases, the isoactivity lines are not always straight, and interpolation or extrapolation of activity values is sometimes less straightforward than in the simple case.

Reduction of chlorides by reactive metals.—Part of the previous section was concerned with the application of E-pO^{2-} diagrams to chloride reduction by reactive metals in the presence of a chloride solvent taking no direct part in the reaction. Many technologically important metals such as Ti or Zr are produced on a commercial scale by chloride reduction, but usually there is no "inert" chloride melt present in these processes and in its initial state the system base metal/chloride is highly reactive. However, when reduction is complete, the final products will be at, or near, equilibrium at a potential which determines the composition of all the phases then present. E-pO^{2-} diagrams can therefore be used to describe the final state of the system, the base metal chloride by-product filling the role of the "inert" chloride in previous examples, and this is particularly useful because the purity especially the oxygen content, of the product is often an important factor in determining its metallurgical properties.

As an example, the E-pO^{2-} diagram for Ni in KCl (Fig. 4) could be applied to the reduction of $NiCl_2$ to nickel by potassium metal, and to predict impurity levels in the product. If excess potassium were used, the final equilibrium potential in the system would be −3.42v and the nickel metal product would be contaminated with potassium (the extent of contamination would be determined by the solubility of K metal in Ni metal at 800°C). If less potassium were used, the equilibrium potential in the system could be measured either directly or by analysis of the KCl slag for $NiCl_2$ [which is connected with the equilibrium potential by the log (Ni^{2+}) scale to the right of the diagram]. Measurement of the oxide content of the slag would give the value of pO^{2-}. From these data, the content of oxygen and other impurities in the metallic product could be estimated as already described.

Reasoning based on these principles can give considerable guidance when a choice of process is to be made, and for example, comparison of Fig. 4 and 5 leads to the conclusion that, provided the two systems can be operated at the same levels of oxide contamination, reduction of $NiCl_2$ by Li metal is likely to lead to a metal product containing less oxygen than reduction by K metal. The extent of contamination by alkali metal would probably be roughly the same in the two cases.

As another example, let us consider the production of titanium by the reduction of $TiCl_4$. Both Mg and Na have been used as reducing agents on an industrial scale, and from Fig. 7 the relative purities of product from the two processes can be estimated for reductions at 800°C. For clarity, simplified, approximate diagrams for Ti in NaCl and Ti in $MgCl_2$ have been redrawn in Fig. 9 and 10. Comparison of these two diagrams shows immediately that for a given value of pO^{2-} the oxygen activity in the Ti metal product would be much lower for magnesium reduction than for sodium reduction. For example, let us suppose that the oxide contamination present in the two cases has been sufficient to produce a pO^{2-} value of 20 in the slag, and that in both cases excess of reductant has been used. The equilibrium potentials after reaction has gone to completion will be −3.20v in the case of sodium and −2.47v in the case of magnesium. Figure 9 shows that under these conditions, the oxygen activity in the titanium metal produced by sodium reduction would be about 10^{-62},

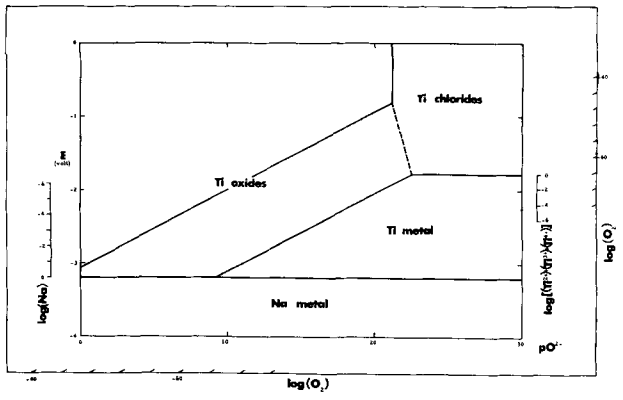

Fig. 9. E-pO^{2-} diagram for Ti-NaCl system at 800°C (approximate)

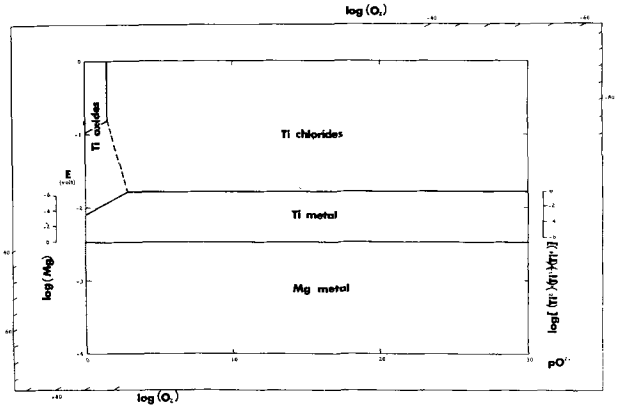

Fig. 10. E-pO^{2-} diagram for Ti-$MgCl_2$ system at 800°C (approximate).

while that in titanium produced by magnesium reduction would be about 10^{-93}. The amount of contamination by Mg or Na would depend on their solubility in titanium at 800°C, which would need to be determined experimentally. Any attempt to reduce Na or Mg contamination by carrying out reduction under conditions of a deficiency of reductant would produce titanium with a higher oxygen content, besides increasing the amount of unreacted titanium chlorides left in the $MgCl^2$ melt. The interplay of the three factors, titanium chloride content of $MgCl_2$ melt, Mg or Na content, and oxygen content of product, can be readily investigated by detailed comparison of Fig. 9 and 10. The more detailed Ti diagram (Fig. 7) would also give the actual composition of the melt in terms of $TiCl_2$, $TiCl_3$, and $TiCl_4$ if this were required.

In exactly the same way, factors affecting the purity of other metals produced by chloride reduction can be investigated, and similar trends are apparent.

Discussion

No attempt has been made to discuss in detail all possible applications of the present method, but it can be seen from the examples given that E-pO^{2-} diagrams are applicable to a wide variety of physicochemical processes in metal-fused chloride systems. The ideas presented are still at the development stage, and the approach a tentative one, but the present treatment makes an important contribution to thought in at least one major technology, the winning of metals from fused salts. The main advance here is that the method offers an approach to the prediction of impurity levels in the products of such processes. Impurity levels are calculated as activities of the impurity under equilibrium conditions and thus represent the highest product purity that could be obtained from the process under ideal conditions. Oxygen is one of the most important impurities encountered in refractory metals such as Ti or Zr, and the treatment is especially suited to deal with this impurity. It has also been shown how the levels of contamination by other metals involved in fused-salt reductions can be estimated and the treatment could easily be extended to include any impurity present in feed materials either as chloride or as metal. The treatment is applicable to electrolytic reduction processes in fused chlorides and to chloride reduction by base metals, but it obviously cannot take account of additional impurities introduced during subsequent operations, such as leaching-out of the product. In many cases, oxide contamination during leaching far exceeds the oxygen originally present in the metal product, but as nonaqueous methods become available for extracting the metal product, the purity of the original product will become more important. Unfortunately at the present time the purity of the original product cannot be maintained through the subsequent recovery operations.

Besides giving general guidance on the relative impurity levels to be expected in products from different types of processes or from a single process operated in different ways, the data may be applied to predict impurity levels in specific practical cases, when any deviation in the expected purity could be taken to indicate departure from ideal processing conditions. To make purity predictions from the E-pO^{2-} diagrams, values of only two independent variables need be known at the completion of reduction, which then fix the position of the system-point on the diagrams. It is relatively easy to measure the redox potential of a chloride melt, either directly (6, 7), or by chemical analysis for the components of any suitable redox system present. Oxide activity could also be measured by a suitable electrode, or alternatively the oxygen pressure in the system could be measured either directly or in some cases calculated from the pressures of two other suitable constituents of the atmosphere (H_2 and H_2O, for example). The measurement of redox potential and pO^{2-} in fused salts may ultimately become as routine as potential and pH measurement in aqueous systems.

Impurity levels in the products are given by the diagrams as activities and these could be translated into, say, percentages where oxygen solubilities in the product metal are available or in the case of a metallic impurity, where activity data in the appropriate alloy are available.

Besides making this contribution to an understanding of metal-winning processes, the present treatment seems also applicable to a wider field of fused-salt chemistry, and some examples involving reaction of fused chlorides with metals—the reverse of electrowinning processes—have been given. The calculation of solubility products will probably be

of particular importance. The treatment can be extended to other halides where sufficient thermodynamic data are available; the most urgent extension now is probably to fluorides because of current interest in metal winning from fluorides. It is suggested that the general features of the present method may prove of value over a wider field than fused halides; in fact, attempts have already been made to understand certain metallurgical problems by plotting thermodynamic data in a somewhat similar manner (9).

The treatment described in this paper is thermodynamic and has the limitations common to all thermodynamic treatments. The advantage of a diagrammatic method over simple consideration in terms of equations is that it allows the relative importance of all the possible reactions of the constituents of the system to be assessed at a glance.

Acknowledgment

The author wishes to thank Dr. C. Edeleanu for many stimulating discussions during the development of the ideas presented in this paper, which is published by permission of the Chairman of Tube Investments Ltd.

Manuscript received Sept. *18, 1961; revised manuscript* received Feb. 12, 1962. This paper was prepared for delivery before the 18th International Congress of Pure and Applied Chemistry, Montreal, Aug. 6-12, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

APPENDIX

Sources of thermodynamic data.—In equilibrium calculations, it is essential to use a self-consistent set of basic data. Standard free energies of formation were calculated from the equations given by Kubaschewski and Evans (10) where possible. Where no data was available in reference (10), the chloride data of Hamer *et al.* (11) and the oxide data of Glassner (12) were used. Where data from more than one reference was available for a particular compound, these invariably agreed with each other to within a few kilocalories. In a few cases (*e.g.*, $ZrCl_3$, $ZrCl_2$), extrapolation of data to 800°C was necessary.

Table II. Standard free energies of formation at 800°C

Compounds	cal/mole	Reference
LiCl	−77,580	(12)
Li_2O	−109,660	(12)
KCl	−78,830	(10)

* Extrapolated value.

The standard free energies used in all the calculations are given in Table II. The standard free energies of formation of oxide ion in LiCl, KCl, NaCl, and $MgCl_2$ at 800°C, calculated as in relations [9], [10], and [11], were as follows

in LiCl	:	+ 45,500 cal/mole
in KCl	:	+ 103,950 cal/mole
in NaCl	:	+ 82,010 cal/mole
in $MgCl_2$	:	− 3,270 cal/mole

Construction of the diagrams.—The condition for equilibrium of the electrochemical reaction

$$\Sigma\nu M + ne^- = 0 \qquad [15]$$

is given by (3)

$$-\Sigma\nu\mu + 23{,}060nE = 0 \qquad [16]$$

where the constituents M have free energies of formation of μ (cal/mole) and E is expressed in volts. Relation [16] enables equilibrium relations to be set up in terms of the two variables of interest, E and pO^{2-}. The basic equations used in constructing the diagrams are given below; Fig. 5, 8, 9, and 10 were constructed graphically from the other diagrams.

Figure 1

$\frac{1}{2}O_2 + 2e^- - O^{2-} = 0$ (in KCl)

$$E = -2.255 + 0.1065 \log (O_2)^{1/2} + 0.1065\, pO^{2-} \qquad [17]$$

Figure 2

$\frac{1}{2}O_2 + 2e^- - O^{2} = 0$ (in LiCl)

$$E = -0.9865 + 0.1065 \log (O_2)^{1/2} + 0.1065\, pO^{2-} \qquad [18]$$

Technical Notes

A Pulse Measurement of the Semiconductor-Electrolyte Space Charge Capacity

Paul T. Wrotenbery

The University of Texas and Texas Research Associates, Austin, Texas

A. W. Nolle

The University of Texas, Austin, Texas

Measurements of the space charge capacity of a semiconductor surface in contact with an electrolytic environment have been made recently by Bohnenkamp and Engell (1), Hurd and Wrotenbery (2), Efimov and Erusalimchik (3), and Zviagin and Liutovich (4). All of these measurements were made using standard bridge techniques. In these previously reported measurements the magnitude of the measured capacity at 1-10 kc measuring frequency has been at least an order of magnitude higher than values expected on the basis of theoretical space charge calculations. This deviation has been assumed to be at least partially due to the presence of surface states with time constants small relative to the period of the measuring frequency used in these bridge measurements. Hurd and Wrotenbery have utilized a radio-frequency bridge system and extended the range of measuring frequency to a megacycle in an attempt to eliminate the discrepancy between theory and experiment; however, due to the low value of the reactive component of the measured impedance, significant results could be obtained only up to about 200 kc (2). It was with this problem of obtaining a measurement of the capacity of the space charge independent of surface states that the writers conceived the idea of utilizing a current pulse method. Pulse techniques have been used previously in metal-

electrolyte capacity measurements by Hackerman and co-workers (5). In this paper the initial results of application of this method to silicon and germanium in basic environments are reported and compared to similar results obtained previously by the bridge method (2).

The method used consists of applying a constant current pulse with rise time of less than 0.2 μsec to the silicon surface through a platinum electrode in the electrolyte. The platinum electrode is also utilized to apply a controlled polarizing potential to the surface so that the space charge distribution can be altered. Changes in the electrode potential are measured relative to a saturated calomel half cell. Initially, the constant current pulse was obtained by use of a mercury switch and a constant current source. However, the results reported here were obtained by use of the pulse generator described by Riney, Schmid, and Hackerman (5). The voltage-time relationship between the platinum electrode and the bulk of the semiconductor is recorded photographically by means of an oscilloscope which is triggered as the current pulse is applied. From this recorded response, the capacity, C, of the surface at the time the pulse is applied, *i.e.*, at $t \cong 0$, can be computed. The calculation is valid even though C may be time dependent.[1] The presence of surface states would, after some finite time of the order of the response time of the state, tend to cause a deviation of the observed response from that expected without surface states. The detection of this deviation is interpreted as evidence for the presence of surface states. The experimental system used in this work is shown in Fig. 1. The inductor, L, in the d-c bias circuit is used to prevent shorting of the current pulse through the bias supply. It can be replaced by a large resistor; however, this makes necessary a much larger bias supply voltage source. In the Riney apparatus used to obtain all results reported in this paper with the exception of the results shown in Fig. 3, a resistance is used in place of L. The Riney pulse generator contains internally the bias supply and the rectification represented by the diode, D, which is necessary to prevent the pulse generator from shorting the bias supply on application of the pulse. The resistor, R_k, was used to allow measurement of the amplitude of the current pulse. Prior to electrochemical measurements, the system was checked by use of standard components of appropriate magnitude which were inserted in place of the cell. The pulse rise time was checked by use of a resistor in place of the cell. The normally assumed semiconductor surface equivalent circuit, ignoring for the moment any possible surface states, is enclosed in dotted lines. If surface states exist, additional components must be introduced into the equivalent circuit so as to make C_p effectively a time varying capacitance. In Fig. 1, C_p represents the true space charge capacity and R_p represents an effective shunting resistance, necessary since d-c current flow occurs across the interface. The resistance, R_s, is the equivalent series resistance of the semiconductor crystal, electrolyte, and contact. If the response of this circuit to a constant current pulse of magnitude, I_o, is analyzed, it is found that the capacity, C_p, is given by

$$C_p\Big|_{t=0} = I_o\left(\frac{dE}{dt}\Big|_{t=0}\right)^{-1} \qquad [1]$$

In the absence of surface states, E would be an exponential function of time, and the voltage reponse would be linear over a time $<< R_pC_p$; and under these conditions, the slope is easily and quite accurately obtained and the capacity at $t \cong 0$ consequently determined. The only effect of R_p in determination of the initial slope is in the length of time over which the response is linear. It is not necessary for C_p to be time independent (and thus the response exponential) for this equation to hold. If surface states or other possible charge transfer sites exist, the measured capacity will in effect be frequency dependent, since it will depend on the surface-state distribution. However, in a pulse measurement this frequency dependence will be observed as a time dependence. For example, if one assumes that the frequency dependence is brought about because of a set of surface states of some response time, say, 1 μsec, then the measured capacity will be frequency dependent in the vicinity of a megacycle. At frequencies with periods small compared to a microsecond, these surface states are incapable of equilibrating, while at frequencies with periods of the order of a microsecond or greater, these states will equilibrate and thus contribute to the capacity. When the constant current pulse is applied, the surface states will accept appreciable charge after a time of the order of a microsecond has elapsed; thus, the capacity, as measured by the slope of the recorded response, will initially represent the true space charge capacity and will change with the presence of new charge transfer sites. Assuming that this change occurs at $t << R_pC_p$, *i.e.*, over the linear region, the voltage response as a function of time can thus be utilized to detect the presence of surface states by observing the change of slope of the recorded response from that at times less than the time constant of the surface state to that at times greater than the time constant of the state. If it is assumed that the capacity changes from some value C_p to some value $C_p + C_{ss}$, then the second slope would allow computation of $C_p + C_{ss}$. On the basis of this simplified model, some very interesting and informative results have been obtained.

[1] Where we find that dE/dt decreases with time for $t << R_pC_p$, we shall arbitrarily describe the system as having a time varying effective capacitance.

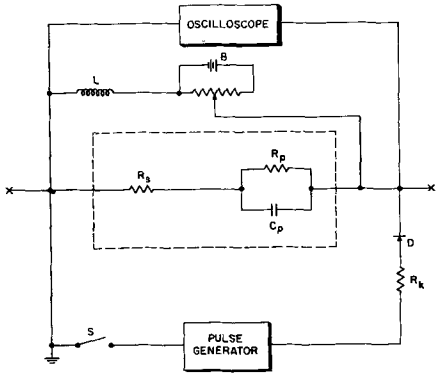

Fig. 1. Circuit diagram for pulse measurements, including semiconductor surface equivalent circuit.

The basis for estimating the effective value of R_p was the Bridge result of Bohnenkamp and Engell on germanium and Hurd and Wrotenbery on silicon (1, 2). In the vicinity of the capacity minimum, where the measurements being reported were made, and at the highest measuring frequency of 160 kc, R_p for germanium in 1*N* KOH (1) is in the range of 200-1000 ohm/cm^2. As the frequency is decreased, R_p approaches 10,000 ohm/cm^2 at 1 kc. In transforming to the time domain necessary in time dependent measurements, the approximate corresponding time dependence of R_p would be obtained by considering the R_p values associated with the reciprocal of the frequency, thus yielding from the above stated values a value of R_p at 5 μsec of 200-1000 ohm/cm^2 and increasingly larger values at greater times. The exact time dependence would have to be obtained from the Fourier Transform of the power spectrum of R_p. The results on silicon are essentially identical, with slightly higher values throughout the frequency range of 1-200 kc (2). As previously pointed out, the only effect of R_p in the linear response region is in the determination of the length of time over which the response is linear. Based on these values of R_p and theoretically computed values of C_p, the corresponding values of R_pC_p at times of the order of a microsecond and at the potentials used in this work are greater than 50 μsec in the vicinity of the minimum where good agreement with theory was obtained. At the most negative potential used in the case of germanium, *e.g.*, —0.925v relative SCE, the value of R_pC_p is in the vicinity of 20-30 μsec. For this smallest value of R_pC_p the nonlinearity at 2 μsec would be only a few per cent, and for the majority of the measurements reported, R_pC_p is sufficiently great that negligible nonlinearity would occur at 1-10 μsec.

Evidence of fast surface states with response times of the order of a few microseconds have been observed in germanium; however, in the case of silicon, no similar states were indicated. This implies that in the case of silicon, fast states, if existent, have time constants of less than a microsecond, whereas in germanium, at least some of the fast surface states have time constants greater than a microsecond. It is pointed out that the pulse rise time of 0.2 μsec sets the lower limit on observation of the voltage response.

Typical traces recorded for 10 ohm-cm n-type silicon and for 10 ohm-cm n-type germanium in 1*N* KOH are shown in Fig. 2a and 2b, respectively. The change in slope noted, in the case of germanium, during the first 2 or 3 μsec is assumed to be the result of fast surface states with time constants of the order of this time. It was found that this slope change occurs primarily on the 2-4 μsec range and that a second rather well-defined linear region follows. This rather distinct change in slope would be expected if the surface states responsible for it were of a distinct time constant of the order of 2-4 μsec. The response on silicon is linear to less than a microsecond, thus, leading to the tentative conclusion that fast states on silicon, if existent, have time constants of less than a microsecond. It is evident from the values of R_pC_p discussed previously

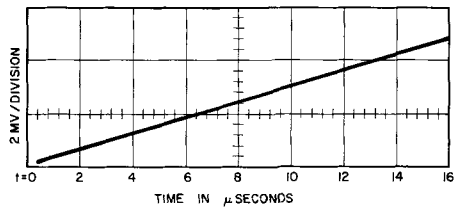

Fig. 2a. Typical voltage-time response for 10 ohm-cm n-type Si

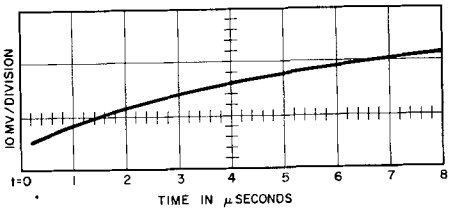

Fig. 2b. Typical voltage-time response for 10 ohm-cm n-type Ge

for germanium that this relatively large change in slope is not associated with the R_pC_p time constant.

In Fig. 3 and 4 are shown some results of capacity measurements made by this method on silicon and germanium in 1*N* KOH. In Fig. 3, a capacity measurement on silicon made by Hurd and Wrotenbery (2) by the bridge method is included for comparison. The bridge measurements were made at 10 kc, and the slope obtained from the pulse method was taken after an elapsed time of 10 μsec. It is noted that the measured capacity on silicon by the pulse method corresponds closely to the values obtained by the bridge technique at 10 kc, which would include the effect of fast surface states. The deviation between the two curves is probably due to slightly different premeasurement conditions, since the two measurements were not made on the same sample, and difference in true surface area alone can contribute significantly to this deviation. In the case of germanium (see Fig. 4), the values of capacity computed for the two slopes observed in Fig. 2b show the reduction in capacity which would be expected as the effect of equilibrating states is eliminated. It is emphasized that the difference in capacity values between the two curves in Fig. 4 is independent of direction of the current pulse, *i.e.*, whether or not it is anodic or cathodic, and also that the values are obtained

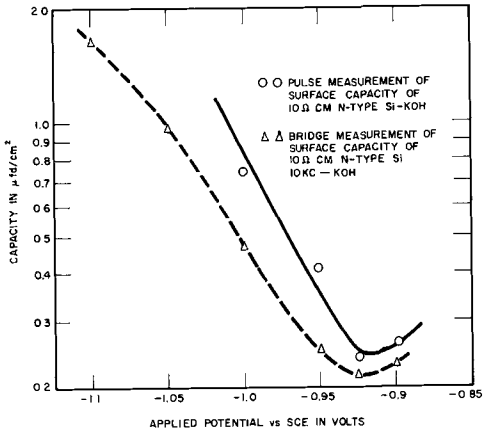

Fig. 3. Comparison of capacity of 10 ohm-cm n-type silicon measured by pulse method and by bridge method.

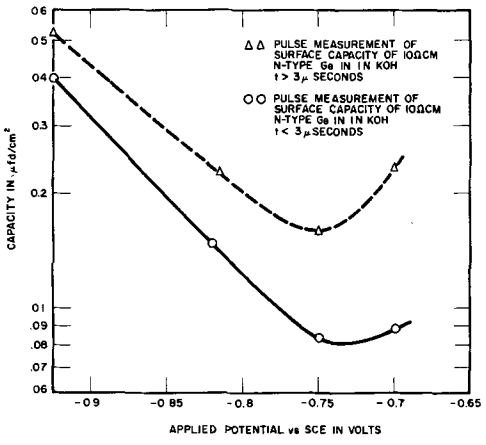

Fig. 4. Capacity of 10 ohm-cm n-type Ge, measured by pulse method showing decrease in slope obtained for times less than 3 μsec.

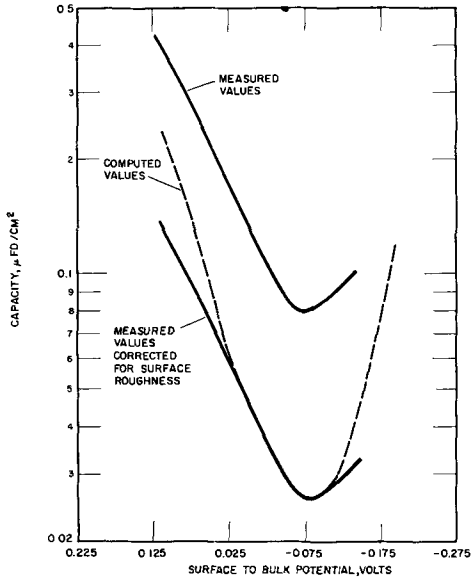

Fig. 5. Comparison of results of pulse measurement on 10 ohm-cm n-type Ge with computed values.

simultaneously in time on the same surface. The measured values on germanium at the minimum is 0.08 $\mu f/cm^2$, whereas the theoretically predicted value for the space charge of this sample is 0.027 $\mu f/cm^2$. The measured capacity of the germanium surface obtained by the above described technique is only a factor of about three greater than values predicted on the basis of previous space charge calculations (1, 2). Deviations between the true and projected surface areas could reasonably account for some or all of this difference. In Fig. 5, the measured capacity for 10 ohm-cm n-type germanium for times less than 3 μsec is compared with values theoretically calculated from the well-known Poisson-Boltzman approach.[2] The upper curve in Fig. 5 gives the measured values while the lower dotted curve gives the measured value corrected for a surface roughness factor of 3. The good agreement in the vicinity of the minimum is noted. This agreement on 10 ohm-cm germanium is somewhat better than that obtained by Bohnenkamp and Engell (1) at 160 kc bridge measurement on intrinsic germanium.

The interpretation of larger deviations from the theoretical values, obtained in all previous measurements (1-4), as being at least partially due to the fast surface states, is supported by these results. Closer agreement to theoretical space charge capacities are obtained than have previously been reported. Further application of this technique to semiconductor electrolyte systems appears a promising approach to the solution of many of the unresolved problems in these systems.

Electrolytic Etching of Germanium in Water

W. Rindner and R. C. Ellis, Jr.

Research Division, Raytheon Company, Waltham, Massachusetts

Chemical etching with water (1) has several advantages were it not for the impractically slow rate at which water attacks Ge. It is the purpose of this paper to discuss electrolytic etching with water which has been found to attack Ge at a useful rate. In addition to Ge the III-V semiconducting compounds GaAs and GaP have been etched by the same method.

Most of the work reported was done with Ge slices about 15 mils thick. These slices were held horizontally either by clip leads or metallic bases on which they were mounted by gold bonding. A positive potential was applied to the slice in actual contact with or in close proximity to a thin wire used as the negative electrode. Etching was performed by placing on the substrate a drop of water

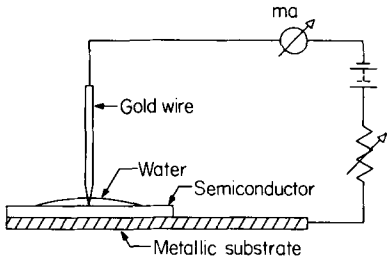

Fig. 1. Experimental arrangement for electrolytic etching in water

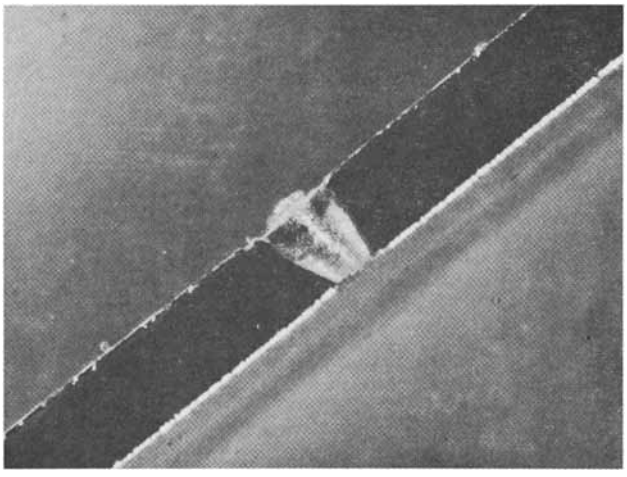

Fig. 2. Etching of a hole in Ge with a thin Au cathode. Magnification approx. 40X.

around the wire and passing currents of a few milliamperes through the system. Tap water and distilled gave the same results. Figure 1 shows the experimental arrangement and Fig. 2 a cross section of a slice etched through in the manner described.

Various materials such as Au, W, Cu, steel, and Ge were used as cathodes without very significant differences being observed among them. Similarly, Ge substrates covering the resistivity range from degenerate to near-intrinsic, both n- and p-type, were found to be equally attacked within experimental error. For good resolution the cathode had to be very close to the substrate. With high resistivity semiconductors and a sharply pointed cathode the resolution could be improved by actually making light contact between the substrate and the cathode. As the pressure was increased the resolution deteriorated and the etching rate eventually decreased by about two orders of magnitude. In the case of low resistivity material actual contact had to be avoided to allow etching to take place.

Usually current densities at the cathode were of the order of 100 amp/cm^2. With a 2 mil diameter cathode, about 5 x 10^{-7} cm^3 Ge was removed per hour. To improve resolution the current path was confined as nearly as possible to the direction of the cathode axis by immersing only the very tip in water. Alternatively, good results were obtained using a wire insulated everywhere except on the part facing the substrate.

Surrounding the point facing the cathode a concentric structure of the surface was observed as shown in Fig. 3. Around the strongly etched region

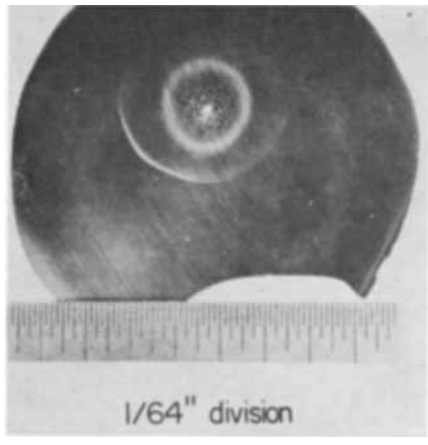

Fig. 3. Appearance of the Ge surface around the area facing the cathode.

(central white spot) there is a flat, shallow, dish-shaped depression about 3/16 in. in diameter. The entire area under the drop of water is slightly stained and is bordered by a circular white deposit. The latter was identified as hexagonal germanium oxide by its electron diffraction pattern. Removal of the oxide ring with tartaric acid solution revealed that some contact etching had taken place underneath. The dish-shaped depression is surrounded by a halo-shaped stained or etched region which corresponds in size to the extent of great turbulence during etching. The striations visible around the central spot were brought out by the etching and are due to disturbances introduced in the process of slicing the semiconductor. Etching leaves undamaged material with a smooth surface.

One experiment was performed in the following manner. A germanium slice was cut in half. The two halves were connected to a d-c power supply and brought in contact with their edges at right angles, and immersed in water. In this way the effect of current polarity on etching rate was determined under otherwise equal conditions. It was found that etching took place on both slices, but at different rates. The volume removed from the slice under positive potential was about five times larger than that removed from the other slice.

When no current was passed through the system but contact was established between cathode and substrate in the presence of water, preferential etching at the point of contact was observed after about 12 hr. This appears to be the previously described effect of contact etching (2) with water as the etchant.

Etching of GaAs and GaP was performed in a manner similar to that described for Ge.

The two conditions required for etching are met in this process: the impetus for oxidation is supplied by the potential between anode and cathode and the removal of oxidized germanium is accomplished by the slight solubility of germanium oxide in water. Excess oxide precipitates and collects in those volumes of the solution with the least turbulence.

Definition is obtained by the greatest current density being supported through the shortest distance. The greater etching rate of this region is

abetted by local heating and a subsequent increase in the solubility of GeO_2. The increased solubility facilitates the germanium removal and results in a greater conductance in the solution.

The reason for the improved resolution obtained with high resistivity substrates and light contact between the cathode and the semiconductor is probably due to the confinement of current flow being more effective than the current flow lost due to direct passage from cathode to substrate.

Hydrogen gas is formed at the cathode as expected, while little observed gas is given off at the anode. Germanium is therefore probably being oxidized to Ge^{+4} directly, unlike the case of silicon where hydrogen is found escaping from both anode and cathode in a slightly conducting solution. It has been postulated that this is due to the silicon being oxidized to Si^{+2} electrolytically with a subsequent decomposition of water by this active species (3).

Superimposed on the germanium etching is the straight electrolysis of water which in addition introduces oxygen into the water. This oxygenation by electrolysis and air solubility can account for the various contact etching phenomena observed on germanium.

Photoluminescent Effects in Contact Electroluminescence

B. Morosin and F. A. Haak (pp. 477-478, Vol. 108, No. 5)

W. Lehmann[1]: The emission of visible radiation from a mechanical mixture of an ordinarily non-electroluminescent phosphor powder and a metal (or well-conducting semiconductor) powder, suspended in castor oil and subjected to an alternating electric field, was described by Lehmann in 1957.[2] The effect was qualitatively explained as electroluminescence of the phosphor particles in the extremely high electric field strength near sharp edges of the metal particles and, because of the necessary close contact between the phosphor and the metal, was termed "Contact Electroluminescence." These experiments recently were repeated by Morosin and Haak. They explain the light emission as due to the glow of local discharges which partly can be seen directly by eye (violet in air) or which may excite adjacent phosphor particles to photoluminescent emission, which is characteristic of the particular phosphor. They supported their view by the observation that emission could even be obtained with cells containing metal powder but no phosphor.

Morosin and Haak's explanation is identical to that presented by Herwelly[3] who tried to understand the Destriau Effect, *i.e.*, the "intrinsic" electroluminescence of ZnS-type phosphors, as photoluminescence excited by the ultraviolet generated in glow discharges near the phosphor particles. It has been shown fairly convincingly by Destriau[4] that this explanation does not hold in the case of "intrinsic" electroluminescence, and it will be shown here that it does not hold either in the case of contact electroluminescence. The arguments to be used are almost identical to those used by Destriau to oppose Herwelly's view.

A glow discharge can, indeed, be observed in many cases under improper operating conditions. It may occur in air bubbles accidentally present in the cell or in bubbles caused by gaseous decomposition products of the oil and, in either case, is favored by the presence of metal or other conducting particles. Such glow can also visibly photoexcite adjacent phosphor particles. However, it is fairly easy to distinguish this photoluminescence from real electro- or contact-electroluminescence. The following facts may be mentioned.

1. Many, but not all, phosphors respond with different emission colors to photo- and electroluminescence.[5] The color of contact electroluminescence also may vary with variation of the frequency of the exciting field in the same fashion as for intrinsic electroluminescence (*e.g.*, blue at high and green at low frequencies). The color of photoluminescence is independent of the exciting frequency of the glow discharge.

2. If contact electroluminescence were actually photoluminescence, then all efficient photoluminescent phosphors should respond about equally well. This is by far not the case. As an example, green-emitting zinc silicate activated by manganese responds very well to an alternating electric field if mixed with a metal powder while red-emitting magnesium fluorogermanate, also activated by manganese, does not respond at all. One may even mix equal parts of these two phosphors with a metal powder. The germanate can well be excited by ultraviolet of wave length 2537Å or 3650Å, the silicate practically only by 2537Å. Hence, the photoluminescent emission spectrum consists of the green band of the silicate and of the red of the germanate simultaneously if excited by 2537Å, and practically only of the red germanate emission if excited by 3650Å. However, if subjected to contact electroluminescence, the spectrum of the blend shows only the green emission of the silicate phosphor while the germanate remains completely dead.

3. Morosin and Haak explain the color differences between contact electroluminescence and photoluminescence, which can sometimes be observed, by a superposition of the violet color of the glow with the emission of the phosphor excited by this glow. If so, then the color shift should be observed with all phosphors, not only with a few as actually is the case. Further, Morosin and Haak obviously do not realize that a superposition of the color of photoluminescence with the violet of the glow discharge in air does not always agree with the observed color of contact electroluminescence. As an example, the yellow photoemission of the (Zn,Cd)S:Ag phosphor mentioned in the table in Footnote 2 superimposed to the violet of a glow in air should result in a pink to reddish purple color, while yellow-green actually

[5] The table in Footnote 2 lists six examples instead of only one as stated by Morosin and Haak.

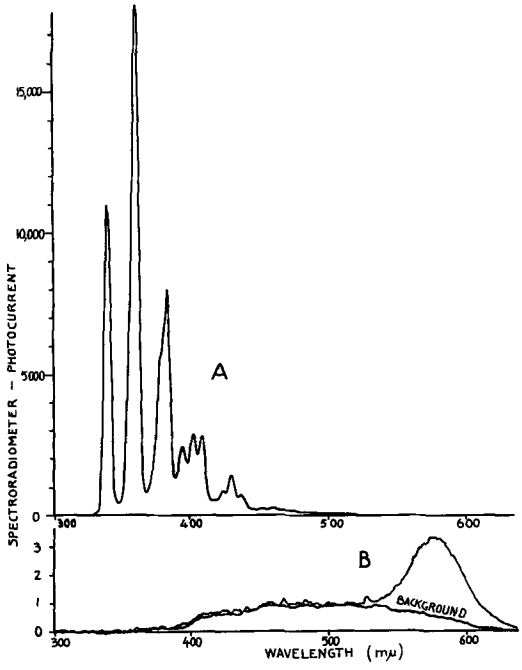

Fig. 2. A—Spectrum of a glow discharge in air (arrangement of Fig. 1A). B—Spectrum of contact electroluminescence of a ZnS:Mn phosphor and aluminum powder in castor oil (arrangement of Fig. 1B). Both spectra are uncorrected, as recorded. The background in spectrum B is due to stray light from room illumination.

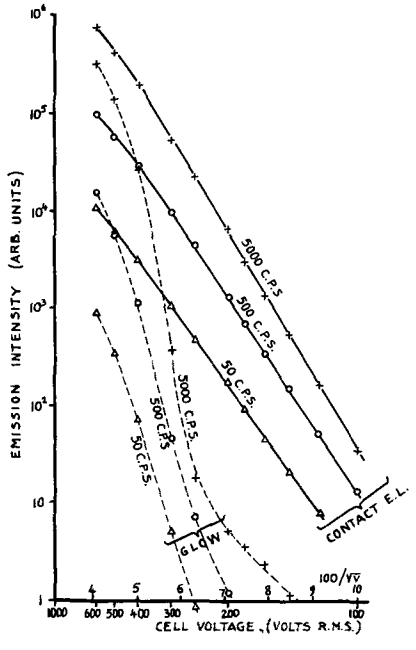

Fig. 3. Brightness-voltage dependences of a glow discharge (aluminum powder in air, arrangement of Fig. 1A) and of contact electroluminescence (green ZnS:Cu,Cl phosphor in contact with Cu_2S, arrangement of Fig. 1B.

was observed. Finally, the characteristic line spectrum of a glow discharge should be easily detectable in the spectrum of contact electroluminescence if it were present. The examples of Fig. 2 of this discussion (using the experimental arrangement of Fig. 1) show that this is not the case and that the emission of contact electroluminescence under proper conditions consists only of the spectrum emitted by the phosphor.

4. The emission of contact electroluminescence normally is confined to many small "spots" scattered over the area of the cell. If such spots were due to photoexcitation, the exciting glow discharge would also have to be concentrated in very small spots and, hence, to be very intense within each spot (otherwise, the intense but very localized emission of the phosphor could not be understood). However, microscopic examination of contact electroluminescence reveals no visible glow discharge in the vicinity of emitting spots. On the other hand, glow discharges require dimensions of many times the mean free path of the gas molecules, which in air at atmospheric pressure is about 10^{-5} cm, *i.e.*, just slightly below the limit of resolution of a good microscope (2 to 3 x 10^{-5} cm). Hence, an intense glow discharge in submicroscopically small dimensions is most unlikely.

5. The time-average of the light emittted by a phosphor excited by contact electroluminescence is fairly stable. Its dependence on the exciting voltage can well be described by the same equations which hold in the case of intrinsic electroluminescence, *e.g.*, by $L = L_o \exp [-(V_o/V)^{1/2}]$, where L_o and V_o are constants. An example of a green ZnS:Cu,Cl phosphor (originally nonelectroluminescent) in contact with Cu_2S (arrangement of Fig. 1B) is shown in Fig. 3. The emission created by a glow discharge in air (arrangement of Fig. 1A) ordinarily is much less stable and tends to strong fluctuations in intensity. The time average of its emission does not approach straight lines in Fig. 3 and, hence, cannot be described by the above equation.

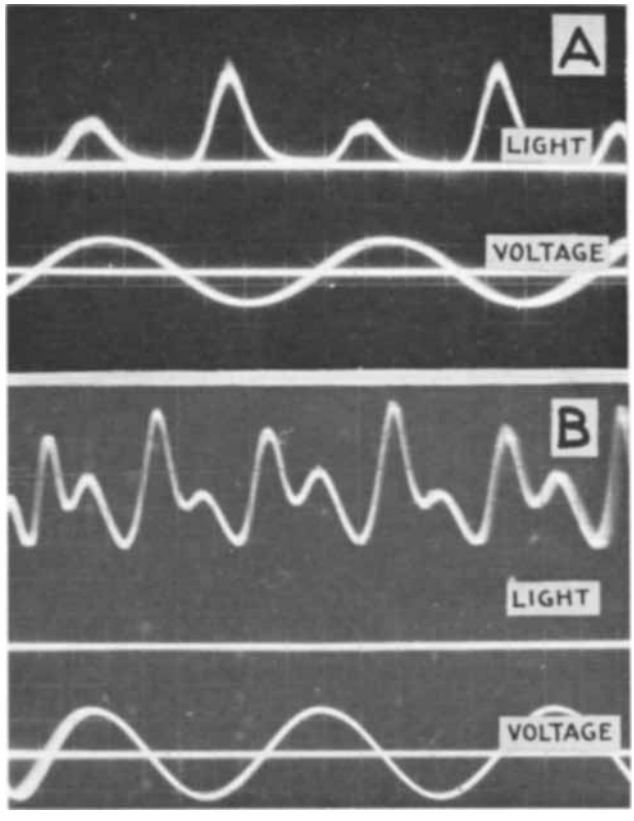

Fig. 4. Light waves of a glow discharge in air (A—arrangement of Fig. 1A, aluminum powder) and of contact electroluminescence (B—arrangement of Fig. 1B, blue-green ZnS:Cu,Cl phosphor in contact with Cu_2S), both excited by a sinusoidal voltage of 100 cps.

6. The brightness waves of contact electroluminescence excited by a sinusoidal voltage resemble those observed in "intrinsic" electroluminescence and frequently show, as do the latter, a main and a secondary peak for each half cycle of the exciting voltage. An example is shown in Fig. 4B. The brightness waves of a glow discharge in air are quite different (Fig. 4A) and never show secondary peaks.

These effects prove that contact electroluminescence can very easily be distinguished from photoluminescence excited by local glow discharges and that its mechanism in all likelihood is identical to that of intrinsic electroluminescence. In all cases, a well-conducting second phase must be present and in intimate contact with the phosphor. This may be metal particles, *etc.*, in case of contact electroluminescence, or thin coats of copper sulfide or metallic copper on the surfaces,[6] or inclusions of Cu_2S inside of the phosphor particles.[7] Inclusions of Cu_2S segregate predominantly in lattice faults, *e.g.*, in stacking faults, rather than in the otherwise undisturbed ZnS lattice. A correlation between the occurrence of electroluminescence and of stacking faults thus can readily be understood.

B. Morosin[8] and F. A. Haak[9]: Our Technical Note gave experimental evidence of the generation of ultraviolet light in these so-called contact EL cells. To state that cells in which this u.v. light is observed are operating under "improper operating conditions" is justified only if one defines what the "proper" conditions are. The occasional apparent absence of u.v. emission from certain cells may well be due to the high efficiency of absorption of short wave-length radiation by the phosphor and by the experimental cell, and is determined by the thickness and packing density of the cell. Also: the presence of only a small amount of u.v. with respect to visible light in the output of such cells does not mean that only a small amount of u.v. is internally produced. Probably it should be pointed out that we observed the u.v. bands only on photographs of several hours' exposure. Let us keep in mind the well-known wave-length dependence of intensity as far as our eye is concerned in the evaluation of comments by Lehmann regarding the addition of colors.

Conclusion: We have shown that u.v. light is generated in contact EL cells which, to the best of our knowledge, are operating properly. We obviously were aware of Herwelly's paper (our reference 3) and Destriau's response to it (Lehmann's Footnote 4); however, in our note we did not question the existence of "intrinsic" electroluminescence. The only pertinent criticism of our paper would be to show unambiguously that in certain cases no u.v. radiation is generated internally (which is not the same as emitted from the cell). Interested scientific investigators may easily quench their intellectual curiosities by performing a few simple experiments which will elucidate for them the so-called phenomenon of "contact" electroluminescence.

The Conductivity of Undehydrated Insulating Liquids

R. Guizonnier (pp. 519-522, Vol. 108, No. 6)

E. Baumann[8]: Professor Guizonnier has shown that the conductivity of insulating liquids and waxes must be due to the moisture content in these materials. We measured[9,10] the conductivity of paraffin oil with a moisture content of less than 50%. Thus we found the activation energies and the gram molecules produced per unit of volume and time of dissociated light and heavy water, respectively. The transformer insulating oil examined contained 13.3% aromatic bond parts, 22.3% naphthenic, and 64.4% paraffinic bond parts. Its mean molecular weight was 267. At 20°C the oil water-saturation content was 50 ppm[11] H_2O. The results described in this paper were obtained at a water content of 12 ppm. Consequently, at 20°C our oil had a relative humidity of 24%. The relative humidity decreases at steady water content with increasing temperature. So the measurements were carried out far from the saturation point of water solubility and there could be no disturbing minimum of the conductivity (*see* Fig. 5 of the discussed paper).

Measuring set.—First, the examined oil was moistened with distilled light water (H_2O) and then with heavy water (D_2O) having a purity of 96.7 mole %. We measured the conduction current in three oil samples of light and heavy water, respectively, at temperatures from 20° to 70°C with the applied voltage increasing and decreasing. Out of these six measuring points, the average was calculated. The voltage of the power supply was highly stable having an alternating current ripple of less than 0.01%.

Between 150v and 800v, the voltage could be adjusted to a certain value with an accuracy of ±0.25%. The average field strength during measurements could be varied from 400 v/cm to 2300 v/cm at a gap distance of 0.376 cm ±0.5% between the cylindrical measuring electrodes. We measured the current with the sensibility of 10^{-12}Å and an accuracy of about ±3% in a measuring range up to $7 \cdot 10^{-11}$Å. The testing cell had shielding electrodes and was airtight.

Measuring procedure.—As soon as the temperature balance was reached a 50-cycle a-c voltage was applied up to 9 kv and the loss factors were measured. Then we applied a continuous voltage of 400v for 6 min. The desired test d-c voltage was fixed and we waited 1.5 to 2 min until we read the current, such that it had been stable for 30 sec. Then we measured the current as a function of the voltage at different temperatures between 20° and 70°C. In all the cases, the current density first increased linearly with the applied field strength reaching a saturation point near a field strength E_s (*see* Fig. 1 of this discussion).

Evaluation of the results.—As we can see from Fig. 1, there are two components of the current density j_1 and j_3 which are proportional to the test field strength. In the case of j_1, this is only true for $E < E_s$. If the field strength is higher ($E > E_s$) j_1 turns into

[10] My thanks are due to Professor H. Lau, director of the Institute of High Tension Techniques, Technical University of Karlsruhe; under his guidance, the tests (Footnote 9) could be completed successfully
[11] ppm = parts per million and means a weight ratio.

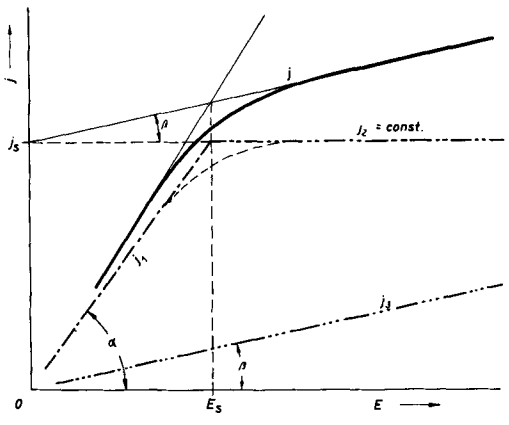

Fig. 1

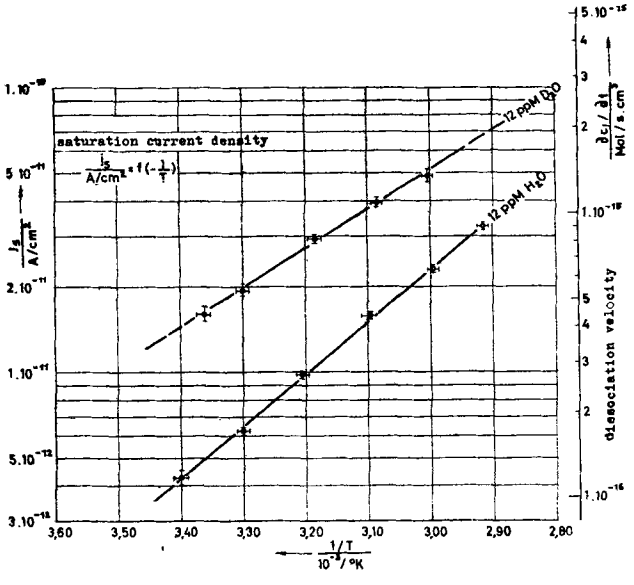

Fig. 2

the saturation current density j_2 which does not depend on the electric field.

Here we are going to treat exclusively the temperature dependence of this field-independent saturation current density $j_2 = j_s$. In our paraffin oil, we measured the saturation current and the so-called saturation field strength E_s at a humidity content of 12 ppm heavy and 12 ppm light water, respectively. While the values for E_s are very nearly independent from the temperature, the saturation current density j_s increases exponentially with the negative reciprocal value of the absolute temperature (in degrees Kelvin). Fig. 2 of this discussion shows how the saturation currents depend on the reciprocal value of the absolute temperature at a humidity content of 12 ppm H_2O and 12 ppm D_2O, respectively.

From the rise of the line

$$\ln j_s/j_o = w/k \cdot T \qquad (see\ Fig.\ 2)$$

we can calculate an activation energy w (k = Boltzmann constant, T = absolute temperature in degrees Kelvin). Above the saturation field strength E_s, we found that the viscosity variation of the oil with temperature did not influence the motion of the charge carriers.

Therefore, w represents an activation energy required to produce disintegration. The saturation field strength E_s is the same at all temperatures between 20° and 70°C. For light water (H_2O), E_s is 0.8 kv/cm, and, for heavy water (D_2O), E_s is 1.1 kv/cm.

From the field independent components of the saturation current which were measured at field strength $E > E_s$, we calculated the energies required to produce disintegration for the essentially current contributing components of light and heavy water in the insulating oil.

From Fig. 2 (12 ppm H_2O in oil) follows:

$$w_{H_2O} = 0.4\ eV \pm 3\%$$

and for 12 ppm D_2O in the paraffin oil:

$$w_{D_2O} = 0.27\ eV \pm 9\%$$

The activation energy w is approximately 1.4 times greater in oil with light water than in oil with heavy water. Thereby it is proved true that the protons and deuterons, respectively, influence the conductivity in moistened oil decisively. Our former opinions about the water influence on the dielectric qualities of insulating oils[12, 13] are herewith well confirmed.

Conclusion.—By means of many measurements, Professor Guizonnier has shown that the conductivity in insulating oils and waxes must be due to their water content. We measured and examined the saturation current of paraffin oil which was moistened with light and heavy water, respectively. We found that the activation energy is 1.4 times greater in light water than in heavy water. This pronounced isotope effect means that protons and deuterons, respectively, influence the conductivity in paraffin oil decisively.

From the characteristic of the saturation current dependent on the absolute temperature [in degrees Kelvin (*see* Fig. 2)], we see that the thermal motion of the particles causes conductivity when the field strength is smaller than 3 kv/cm. According to Eigen and De Maeyer,[14] it is possible to calculate a dissociation velocity from the field independent saturation current, at a given water concentration. The dissociation velocity is shown in the right scale of Fig. 2. At the same water concentration, more dissociation processes take place per unit of time and volume with heavy water in the oil than with light water in it.

In this thermal process, the formation of free ions may take place in several phases successively. The phase which determines the speed of the whole process needs most activation energy, and it is this energy which we measured. From the very clear isotope effect, we see that it can only be a proton transition.

The absolute values of the activation energies alone are not sufficient to design the correct model of the reaction as to where the proton transition takes place. It is necessary to examine also further test results concerning the dependence of the current on the water concentration and on the field strength. Supplementary measurements, also in other oil samples, must be made in order to investigate more ex-

actly the proton transition we found in moistened paraffin oil.

R. Guizonnier: In conditions slightly different from ours, Dr. Baumann found the relation between current and temperature that we already mentioned.

While, though approximately, we sought the initial current i_o after the application of the tension, Dr. Baumann applies, first of all, an alternating current of 50 Hertz, then 400v during 6 min, and, at last, the continuous tension V in experiment during 1.5 to 2 min, the current being read as soon as it seems to be stable for 30 sec.

Instead of considering the value thus measured, he draws the curb $i = f(V)$ and the size he thinks of is what we must call the current of saturation i_s. When the liquid is dry enough—and that is the case—the difference between i_o, that we measured, and i_s, considered by Dr. Baumann, is not very important.

Under such conditions, the value $W = 0.4$ ev that we found, is reached when the field is superior to E_s. We made evident recently[15] that, when the applied field is very low (some volts/cm), the exponential form of the relation between i_o and T is preserved, but then $W = 0.27$ ev.

It is interesting to see that this value is found by Dr. Baumann, when heavy water is added to oil. As we pointed out, that is the value obtained when using deionized water with low fields, or only distilled water.

Desensitization of Zirconium Powder, Especially Zirconium Powder Used in Primers

Peter Karlowicz, George Norwitz, and Joseph Cohen (pp. 659-663, Vol. 108, No. 7)

D. R. Zaremski[16]: This article, which appears in the July 1961 JOURNAL, has been reviewed with great interest in view of its close relationship to work performed by our laboratory in the year 1956. Specifically, the objectives of our experimental work at that time were to investigate the pyrophoric properties of potentially hazardous scrap materials, such as titanium and zirconium grindings, and to determine ways and means for our production plants to dispose of these materials safely. As an approach to the latter objective, treatment in acid solutions was one of the methods evaluated with the thought in mind that, if proven successful, it would readily lend itself to mill operations where spent nitric-hydrofluoric pickle liquors, available in large quantity, could be used as the treating medium.

Briefly, the results of our work indicated that disposition through acid treating was highly satisfactory although the type of acid medium used appeared to be an important factor. Greatest success was met in using solutions containing ½% to 1% hydrofluoric acid. Good results also were obtained in nitric-hydrofluoric acid solutions and aqua regia (3 HCl:1 HNO_3). Sulfuric acid solutions, on the other hand, were not too effective.

[15] R. Guizonnier, *Comptes rendus Académie des Sciences*, July 24, 1961.
[16] Research & Development Labs., Allegheny Ludlum Steel Corp., Brackenridge, Pa.

Our methods for evaluating the effects of a given acid treatment were not too involved and consisted simply of dispersing treated and untreated grindings over a open flame and observing the relative tendencies for the materials to ignite. In following this procedure, untreated zirconium samples and those treated in sulfuric acid solutions were found to emit a radiant white spark. In contrast, samples treated in aqua regia and in solutions containing hydrofluoric acid were found inert, exhibiting no ignition tendencies. Spent pickle liquors, as discovered in subsequent studies, also produced the desired effect provided the solutions contained at least ½% hydrofluoric acid.

In concluding this discussion, we would like to emphasize the fact that the treatments described above and used by Allegheny Ludlum were for the sole purpose of desensitizing material which was to be disposed of. In no instance were our intentions related to reclaiming material or preparing it for another application.

Anodic Polarization of Stainless Steel in Chloride Solutions

G. M. Schmid and Norman Hackerman (pp. 741-744, Vol. 108, No. 8)

U. R. Evans[17]: The authors kindly quote a very early paper by myself. This, however, concerned unalloyed iron, not stainless steel. Some later papers from my laboratory describe work on stainless steel and seem to provide evidence of the existence of a film. For instance, a detailed study carried out by Berwick[18] aimed expressly at deciding whether the resistance of stainless steel to dilute sulfuric acid should be related to adsorbed oxygen or to an oxide film; Berwick's measurements were capable of being explained on the assumption of a film thickening by the logarithmic law, but appeared incapable of explanation by assuming adsorbed oxygen. Still later, Stern,[19] using a different method, reached the conclusion that there was a film growing by the logarithmic law; as he appears to have been unaware of Berwick's work, this probably can be regarded as entirely independent evidence.

It is thought that a satisfactory theory should explain not only the new experimental data put forward in the paper propounding the theory, but also the measurements of others—providing that those measurements are regarded as experimentally accurate. It would be interesting to know how the authors of the paper under discussion are inclined to interpret the results of Stern and of Berwick.

G. M. Schmid and Norman Hackerman: We thank Dr. Evans for his remarks and the interest he has shown in this work.

We agree that the work cited by Dr. Evans provides experimental evidence for the growth of an oxide film according to a logarithmic law. We also agree that passivity of iron and stainless steel is not caused by physically adsorbed oxygen.

[17] Cambridge University, Grange Rd., Cambridge, England.
[18] I. D. G. Berwick and U. R. Evans, *J. Appl. Chem.*, 2, 576 (1952).
[19] M. Stern, *This Journal*, 106, 376 (1959).

It has to be pointed out, however, that the first step in the formation of, as well as the last step in the reduction of, an oxide film must involve a chemisorbed layer of oxygen or some oxygen-containing species. Our contention is that this layer of chemisorbed oxygen causes the rapid electrochemical changes associated with passivity, permanent passivity being effected by subsequent growth of an oxide film, the structure of which depends on the nature of the earlier step.[20] In this laboratory, stripping experiments on iron have shown that coverages of much less than one monolayer are sufficient to cause the metal to show passive characteristics.[21] Both the work of Berwick and Evans and that of Stern is entirely compatible with this point of view.

Porosity Measurements on Gold Plated Copper

M. S. Frant (pp. 774-778, Vol. 108, No. 8)

Wm. H. Fischer[22]: The use of the ammonia-ammonium persulfate solution as a test for porosity in gold plates on copper is quite interesting. About five years ago, a somewhat similar method was employed to evaluate the porosity of Inconel-clad copper.

The test solution consisted of 400g of ammonium persulfate per liter of distilled water plus 2 liters of concentrated ammonium hydroxide, thus being somewhat stronger than that used by Frant.

The test was performed by immersing a constant surface area of the Inconel-clad copper in a fixed volume of test solution in a test tube at room temperature without agitation. At ¼, ½, 1 hr, and each succeeding hour, up to 8 hours, a cuvetteful of solution was removed and its copper content determined with a Fisher Electrophotometer using a 650Å red filter, against a distilled water blank. Comparison tests employing a Beckman DK-2 Ratio Recording Spectrophotometer were in good agreement with the filter photometer tests. The solution was returned to the test tube after each reading. The data were plotted as ppm copper *vs.* time as shown in Fig. 1 of this discussion which portrays the four main types of curves obtained.

Type 1 curves are obtained from samples having large holes in the cladding. The blue color appears almost immediately upon immersion of the sample and rapidly increases in density. The test solution may get hot and evolve gas so vigorously as to appear to be boiling.

Type 2 curves are obtained from samples having one or both of two types of defects in the cladding: 1—copper on the surface or 2—small holes or thin spots in the cladding. The test solution may enlarge the small holes or perforate the thin spots. Hole enlargement may be due to gas evolution rather than to direct attack on the Inconel, although the test solution does attack Inconel slowly. Independent experiments have shown that etching accompanied by preferential removal of nickel from the alloy occurs. However, when solid Inconel is immersed in the test solution for periods up to 8 hr, a reading equivalent to less than 5 ppm copper is obtained. Emission spectrography of used solution indicated no significant amounts of any of the three main constituents of Inconel: nickel, chromium, or iron. Rough calculations showed that nickel is about 60 times less sensitive in this test than is copper. This means that if 60 ppm nickel were removed from the alloy by the test solution, it would be read as 1 ppm copper.

Type 3 curves are obtained from samples whose Inconel surface is contaminated by copper but which has no holes or thin spots.

Type 4 curves are given by cladded specimens free of all defects. The color developed is yellow in hue, not blue. It is due mainly to reagent deterioration.

Occasionally, an anomalous green color is developed. This is not due to nickel or very small amounts of copper. Its cause remains unknown. However, it does not interfere with interpretation of the results.

This test was designed as an incoming inspection method for cladded material to weed out unsuitable material. An unexpected bonus was that the shapes of the curves obtained allowed the identification of the causes of the rejections, thus aiding in preventing their reoccurrence. Thus, by using not only the amount of copper removed but also its rate of removal, additional useful information was gained.

M. S. Frant: Fischer's experience with the use of the ammonia-ammonium persulfate solution as a porosity test for Inconel-clad copper is most enlightening, particularly his comments on being able to use the test despite a very slight attack of nickel by the reagent, and his use of the test to distinguish different causes of failure.

About four years ago, we used the same reagent as a means of quantitatively measuring corrosion rates for nickel-plated copper in salt spray. The basic concept is that the observed "porosity" will measure the discontinuities produced in the plating as corrosion proceeds. The test is regarded as destructive, and the corroded samples are discarded after the porosity test. The test was run by exposing identical pieces from a sulfamate bath[23] (prepared in a single barrel load—average thickness 15μ) to varying lengths of time in salt spray, and then measuring the amount of copper dissolved by the reagent under standard conditions (the same as those described on page 775 of the discussed paper). When the log of the

amount of copper dissolved is plotted against the log of the time of salt spray exposure, an initial period is observed with a slope of *1.3* to *1.4* (*See* Fig. 1 published here.) After about 150 hr the slope becomes almost exactly proportional to the *cube* of the time of exposure. As can be seen from the graph, it is independent of the salt spray concentration.

Similar experiments on two sets of nickel samples from the Watts bath gave the following slopes: 5% NaCl—*1.85, 2.10;* 20% NaCl—*2.45, 1.99.* For Watts nickel, the amount of copper dissolved by the reagent is approximately proportional to the *square* of the exposure time.

A portion of the sulfamate nickel samples used above were chrome plated and the test repeated. Three distinct slopes were observed: a zero slope (at 0.6 ppm copper) for the first 60 hr; from 60 to 150 hr the slope was about 0.7; thereafter the slope was 2.0.

In our previous work in which this same reagent was used to follow the corrosion rate of tin-plated copper in salt spray,[24] the amount of copper dissolved was found to vary as the *square* of the time of exposure. Results from the persulfate reagent technique agree with the corrosion rate for tin measured by following the corrosion of thin tin films by light transmission.[25] The square rate was attributed to a radial (or 2-dimensional) growth of pits; while it can be visualized in terms of a single pit, the average of many pits would have the same rate of change of area.

If this line of reasoning holds for nickel and chrome plate, then a slope of *2* is believed to indicate that it is the Watts nickel or chrome which is attacked even after basis metal is exposed. The slope of *3* obtained with sulfamate nickel after a variable initial slope would indicate that, once the corrosion

process has proceeded to the exposure of copper, the copper is preferentially attacked. If attack is visualized as the growth of the segment of the sphere out from an exposed point in the nickel coating, a cubic term would be expected.

Microscopic cross sections of the corroded samples have confirmed this hypothesis. For the Watts nickel samples, no attack of the copper was observed. Fig. 2 published here shows a drawing made from a microsection of a corroded sulfamate nickel specimen which was not exposed to the persulfate reagent.

Fischer's results, like ours, indicate the range of information on coating condition and behavior which can be achieved through interpretation of results from a generally neglected technique.

Some Observations of Copper Deposits on Single Crystals of Copper

Isaac Giron and Fielding Ogburn (pp. 842-846, Vol. 108, No. 9)

S. C. Barnes[26]: I was particularly interested to note that the work reported by Giron and Ogburn completely confirmed that of the Birmingham University team. That similar structures have been obtained in two independent studies is of particular importance in view of the known susceptibility of the acid copper sulfate bath to trace impurities. It seems fairly certain that the crystallographic features formed on single crystal electrodes develop by a bunching mechansim and, in this respect, the work of Poli and Bicelli[27] is also of relevance.

It still remains to be decided, however, whether the particular growth forms evident on crystals of a par-

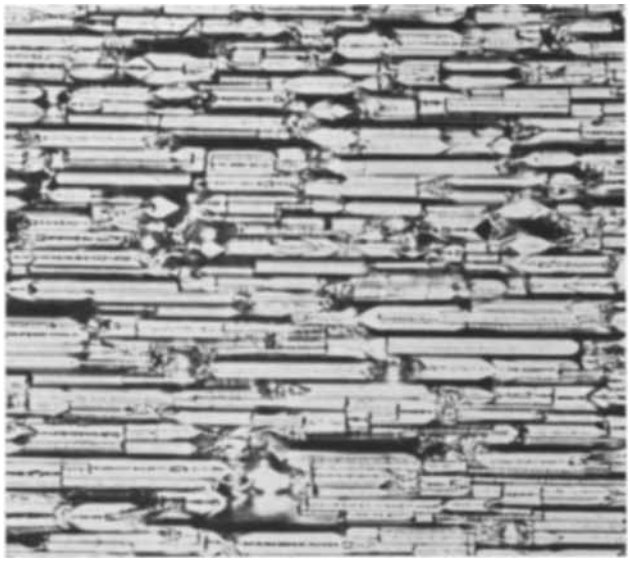

Fig. 1. Surface structure of copper deposit formed on a (110) copper single crystal cathode after plating for 20 min at 30 mA/cm² from an $N.H_2SO_4$ + N. $CuSO_4$ bath at 35°C. Magnification 575X. [110] direction parallel to long edge.

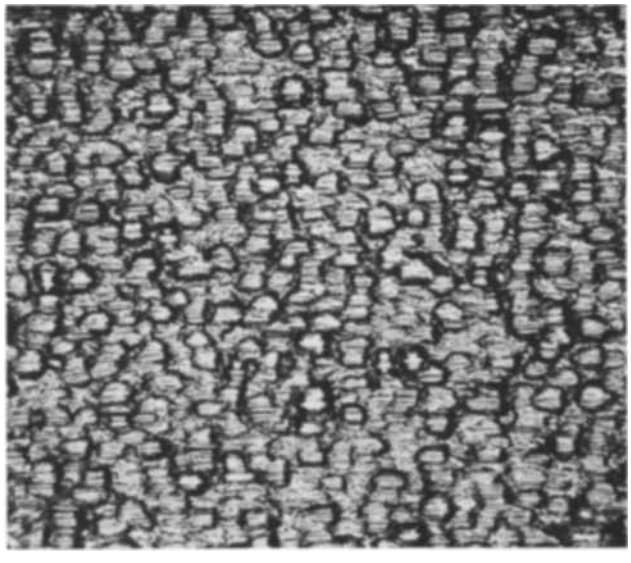

Fig. 2. Deposit obtained under the same conditions in the presence of 10^{-5} M/l thioacetamide. Magnification 575X. [100] direction parallel to long edge.

ticular orientation are rate or potential dependent. Although the information in the paper by Giron and Ogburn does not shed any light on this topic by itself, it does when considered in conjunction with observations on the effects of addition agents on the growth habit of copper deposits.

Giron and Ogburn report that at low c.d.'s the deposit surface on (110) crystals is composed of ridges aligned at right angles to a close packed [110] direction (*i.e.*, parallel to a [100] direction). At higher c.d.'s, the ridges extend parallel to the [110] direction. Previously unpublished results obtained by myself during an investigation into the effects of thio compounds on the structure of copper electrodeposits indicate that additions of thioacetamide (at a concentration of the order 10^{-5} M/l) cause the deposit form on (110) crystals to change from ridges parallel to a [110] direction to ridges at right angles to this direction (Fig. 1 and 2 of this discussion). This change is also accompanied by a large reduction in cathodic overvoltage.

It would appear, therefore, that since the habit change can be produced by either a reduction in c.d., or by the use of an addition agent which lowers polarization, the structure of the deposit is controlled by the electrode potential rather than by the applied c.d. Further work on the exact relationships between deposit structure and electrode kinetics seems warranted, and perhaps the recently developed relaxation techniques will be of use in this connection.

Cathodic Behavior of Iron Single Crystals and the Oxides Fe_3O_4, Gamma-Fe_2O_3, and Alpha-Fe_2O_3

C. D. Stockbridge, P. B. Sewell, and M. Cohen
(pp. 928-933, Vol. 108, No. 10)

An Electrometric and Electron Diffraction Study of Air-Formed Oxide Films on Iron

P. B. Sewell, C. D. Stockbridge, and M. Cohen
(pp. 933-941, Vol. 108, No. 10)

U. R. Evans[28]: The second paper ends with the words, "Stripping the film for identification, as was done by Davies and Evans, would give an erroneous result because exposure of the underlying thin magnetite layer to air would oxidize it to γ-Fe_2O_3."

These words may leave the reader with the idea that all our work is held to be invalid. It is, therefore, important to point out that, even if the three authors are right in condemning results based on film-stripping, our main conclusions remain unaffected, since the quantitative data in our two papers rest on methods independent of film-stripping. In our first paper,[29] the curves showing logarithmic growth at low temperatures, and parabolic at high temperatures (in general confirmation of Vernon and his colleagues[30]), were obtained by quite different techniques. In our second paper,[31] stripped films certainly were studied in two out of the three sections; the method was not felt to be ideal, and any attempt to fix exactly the composition of the film would have been unjustified; the conclusions, however, only claimed to show approximate values—*e.g.*, that cubic oxide contained more or less than 80% Fe_2O_3.

Despite the authors' statement at the end of their second paper, that the oxidation of magnetite is so rapid as to render measurements based on stripped films inaccurate, their own measurements recorded in Tables II and III of the first paper suggest that the oxidation is quite a slow process. This certainly accords with our experience. We generally have found that magnetite films, in absence of liquid water, are fairly stable. If it were a fact that magnetite was oxidized too rapidly for the use of the stripped-film techniques, then any film rapidly stripped, or trans-

ferred to glass, should be found to be wholly ferric oxide on testing. Throughout our work, however, we have found ferrous iron in the stripped or transferred film in cases where there was reason to think that it had been present in the film before stripping or transfer. In particular, we would recall an optical difference between duplex films (α-ferric oxide over magnetite) and simplex films (ferric oxide only) after transfer to glass; the simplex films showed the same color by transmitted light, whether the glass or the oxide was nearest to the eye, whereas the duplex film showed two different colors. If the magnetite layer oxidized so quickly as to invalidate methods based on stripping, the duplex specimen would surely acquire the optical properties of a simplex film on storage in air; this was not found to be the case. No doubt, methods based on film-stripping are less satisfactory than the more direct study of the films attached to the metal, but they need not be ruled out for all purposes.

The authors should be congratulated on much careful work. It is satisfactory that the thicknesses obtained by them agree fairly well with those of other authors but, as they point out, such estimates "do not serve to identify the film." Fresh information regarding composition is, therefore, particularly welcome, but their conclusions are somewhat contradictory. On page 940 it is stated that, "The two phase nature of the thin oxide film is clearly established," but lower down we read, "it seems unlikely that two discrete structures exist." Which represents the authors' final opinion?

M. Cohen: I would like to thank Dr. Evans for his discussion. As he points out, the thicknesses of oxide reported agree quite well with those reported by himself and others at comparable temperatures. The main disagreements between Dr. Evans' papers[32, 33] and those published from this laboratory[34–37] concern the composition of the films and the stability of Fe_3O_4 in the presence of air.

Although Dr. Evans did not observe Fe_3O_4 at any temperature below 250°C on Swedish iron and observed Fe_3O_4 at higher temperatures only after some time of oxidation, we observed Fe_3O_4 at all temperatures and from the beginning. This lack of identification of magnetite is rather surprising in view of the results obtained by annealing in vacuum by both Dr. Evans (Footnote 32, p. 454) and ourselves which show that the underlying iron reduces Fe_2O_3 to Fe_3O_4 very rapidly (<2 hr) even at 200°C. This would indicate that nucleation of Fe_3O_4 is not a problem.

I believe that the reason for the above difference lies in the methods of cathodic reduction. In a previous study from this laboratory,[38] it was shown that cathodic reduction in the ammonium chloride solution used in Reference 32 gave highly variable results such that it was not possible to correlate coulometric weight loss and iron analysis measurements. It was for this reason that the buffer solution was developed. Use of the deaerated buffer solutions allows both identification and measurement of the quantities of oxides involved. It also makes quite clear the presence of magnetite in all the cases studied. The large difference between both the immersion and reduction potentials of γ-Fe_2O_3 and Fe_3O_4 is evident in both papers.[34, 35] It should be noted that Dr. Evans observed Fe_3O_4 from the beginning with pure iron (Reference 32, pp. 455-456).

Regarding the remarks pertaining to the color of duplex films, the low temperature oxidation of magnetite to γ-Fe_2O_3 would still leave a duplex film of γ-Fe_2O_3 and α-Fe_2O_3. γ-Fe_2O_3 is a good electronic conductor in comparison to α-Fe_2O_3 and probably has quite different optical properties.

The oxidation of magnetite to γ-Fe_2O_3 by air at room temperature presents a real problem. With thick compact films, the percentage change in composition on exposure to air for short times can be quite small. However a film of Fe_3O_4, 40Å thick, exposed to air on both sides would oxidize completely to γ-Fe_2O_3 in about 30 hr and would convert over half its thickness to γ-Fe_2O_3 within 2 hr. A stripped air-formed film 25Å thick would oxidize to γ-Fe_2O_3 within ½ hr on exposure to oxygen. Although this is not rapid oxidation in the ordinary sense, it is sufficiently rapid to cause errors in analyses for ferrous-ferric ion ratios and to change electron diffraction patterns.

The points brought up in the last paragraph relate to the word thin and the two quotations refer to an 80Å film formed at 200°C and a 25Å film formed at room temperature on a (112) single crystal pure iron. In both cases, all the oxides are cubic and the cathodic reduction curves show evidence of a duplex film. With the 80Å film there is an appreciable amount of both Fe_3O_4 and γ-Fe_2O_3. At these thicknesses, it is probably permissible to write in terms of two distinct phases. With the thinner air-formed film, although the outer part of the film is γ-Fe_2O_3 and the inner part of the film is Fe_3O_4, the phase boundary probably occupies such a large portion of the thickness that it may not be permissible to insist on two discrete structures in the total thickness of 25Å. One should keep in mind that the structures of γ-Fe_2O_3 and Fe_3O_4 are very similar so that one might expect a thick phase boundary between them.

D. Gilroy and J. E. O. Mayne[39]**:** In the second paper, the authors claim that it is possible to differentiate between Fe_3O_4 and γ-Fe_2O_3 owing to different efficiencies of cathodic reduction at constant current density. In view of the similarity in structure of these two oxides, it seems very remarkable that there should be such a sharp change in reductive efficiency as suggested by the authors in their interpretation of Curve 1, Fig. 4. The air-formed film is very thin and it may not behave on reduction in a similar way to the much thicker duplex film formed at higher temperatures.

Hancock[40] examined the cathodic reduction of the air-formed film in 0.2N potassium chloride and 0.1N

sodium hydroxide. Virtually no iron passed into solution and the coulombs passed at the points of inflexion were identical. These experiments have been repeated with neutral 0.1*N* sodium sulfate and benzoate; again, virtually no iron passed into solution. However, with the borate/chloride buffer, used by the authors, ferrous ions passed into solution, but not in sufficient quantity to account for the entire film. It appears that in neutral unbuffered or alkaline solutions the cathodic process is the reduction of oxide to iron; whereas, in buffered solutions, this is accompanied by the reduction of ferric to ferrous ions, which pass into solution. A probable explanation is that upon cathodic reduction the liquid in contact with the surface of the specimen becomes alkaline; in the presence of a buffer the rise in pH will be delayed, but not indefinitely. It is suggested that in Curve 1, Fig. 4, on Section $E_{A'}$-E_B the process is essentially a one-electron reduction, whereas on Section E_B-E_C a three-electron process is involved.

If these suggestions are accepted, then it follows that the values given for the film thickness in the Tables should be recalculated, and higher values will be obtained; furthermore, the difference in the efficiency of reduction of the two oxides is not a characteristic of the oxides, but arises owing to the buffering action of the solution.

Hancock's value of 26 ± 3Å for the thickness of the air-formed film on iron, reduced in hydrogen, has been criticized because he assumed that the film was composed of γ-Fe_2O_3. Had he assumed that it was composed entirely of Fe_3O_4, the value would be greater by less than 9%. It is generally agreed that the film is of intermediate composition; the corrected value would, therefore, be within the limits of his measurements.

M. Cohen: With regard to the remarks of D. Gilroy and J. E. O. Mayne, the work in the two papers differentiates between γ-Fe_2O_3 and Fe_3O_4 by immersion potential and reduction potential as well as current efficiency of reduction. In some thousands of cathodic reduction runs made in either the borate/chloride buffer or a borate/boric acid buffer at a pH of 8.4, we always have found that the outer layer reduces to form ferrous ion in solution with high current efficiency. That the buffer appears to be quite effective for long periods of time is shown in Curves 1 and 2, Fig. 11, where the time to reach the magnetite potential obviously is dependent on the thickness of the outer γ-Fe_2O_3 layer.

I agree that with the thin films some of the magnetite is reduced to iron. This assumption was made to obtain the thicknesses shown in Table IX. As can be seen in this table, the thickness and composition of a film on polycrystalline iron will depend on the distribution of orientations of the individual grains, and probably on the oxidation characteristics of grain boundaries as well. We also have some evidence of the formation of iron from reduced magnetite by electron diffraction. From the point of view of identification and measurement of the thin films on iron, the difference in behavior of γ-Fe_2O_3 and Fe_3O_4 on cathodic treatment in the buffered solution is very useful.

The Application of an X-Y Pulsed Measuring System to Polarization Studies, I. The Hydrogen Reaction on Platinum

C. H. Presbrey, Jr., and Sigmund Schuldiner (pp. 985-995, Vol. 108, No. 10)

M. W. Breiter[41]: Presbrey and Schuldiner report experimental results which are in agreement with the results on hydrogen evolution published by the late Professor Knorr, by me, or our co-workers in recent years. However, the interpretation of the measurements by the two schools differs greatly. The results of Presbrey and Schuldiner can be explained satisfactorily by the interpretation of hydrogen overvoltage phenomena on activated platinum metals which has been given by us without drastic changes in the years since 1954:

(*A*) Mass-transport processes are rate determining for stationary current potential curves over a wide potential range.

(*B*) The exchange current densities of the two discharge reactions

$$\text{(i)} \quad H^+ + e^- \overset{i_{01}}{\rightleftharpoons} H_{ad}$$

$$\text{(ii)} \quad H^+ + H_{ad} + e^- \overset{i_{02}}{\rightleftharpoons} H_2$$

are large at $\eta = 0$ ($i_{01} \approx i_{02} \approx 0.3$ Å/cm²).

(*C*) The equilibrium of the recombination reaction

$$\text{(iii)} \quad H_{ad} + H_{ad} \overset{i_{03}}{\rightleftharpoons} H_2$$

is established for $\eta < +0.08$v. It does not exist for $\eta > +0.08$v.

The experiments which lead to the above conclusions were discussed and summarized by me recently.[42] Our interpretation is in qualitative agreement with the important contributions to the understanding of hydrogen overvoltage by Frumkin's school.

Schuldiner's interpretation ($i_{01} >> i_{03} >> i_{02}$) is based to a large extent on the occurrence of cathodic Tafel lines with $b \approx 30$ mv. These curves are measured at a high flow rate of the stirring gas. A further increase of the flow rate does not influence the current potential curves any more. So Schuldiner concludes that reaction (iii) is rate determining. However, his observation does not necessarily imply that diffusion is eliminated. It means that the thickness of the diffusion layer does not change to a measurable extent any more if the flow rate is increased above a certain value. An anodic limiting current density i_{0d} of diffusion (and convection) of molecular hydrogen of 15 ma/cm² is required to reduce the influence of the transport processes to 10% if i_{03} is 1.5 ma/cm². Such a high i_{0d}-value has not been reported in literature even under the most extreme stirring conditions (flow of electrolyte or rotating disk) at $p_{H_2} = 1$ atm.

It is felt that the Tafel relations in Fig. 7 and Fig. 8 of Schuldiner's present paper and in many of his former publications are valid for a very small range of current densities only. The range is too small to

[41] Research Lab., General Electric Co., Schenectady, N. Y.
[42] M. Breiter in "Transactions of the Symposium on Electrode Processes," Edited by E. Yeager, pp. 307-324, John Wiley & Sons, Inc., New York (1961).

draw reliable conclusions. The asumption of a slow combination step requires that the concentration of atomic hydrogen which is involved in the reaction is very small at $\eta \approx +0.06$v. Therefore it cannot be large at $\eta = 0$ either. This forces Schuldiner to postulate the formation of a second monolayer of hydrogen atoms which is completed at negative potentials. However, the a-c impedance measurements at cathodic overvoltages in $8N$ H_2SO_4 show conclusively that a second monolayer of hydrogen atoms is not formed up to cathodic current densities of 0.3 Å/cm^2. The high capacity of the platinum electrode during the cathodic pulse is due to the accumulation of molecular hydrogen in the diffusion layer, not to the formation of a second monolayer. The anodic charging curves in Fig. 10, like our charging curves, do not give evidence for a third "plateau" due to the anodic removal of a second monolayer. A better picture of the anodic oxidation of hydrogen atoms is obtained by the potentiostatic application of a sawtooth.[43, 44] The so-called plateaus of the charging curves are not well enough distinguishable to determine their length. Only part of the hydrogen associated with the surface at equilibrium is ionized near the equilibrium potential because the adsorption isotherm is very flat in the vicinity of $\eta = 0$.

The "reversible" hydrogen adsorption on platinum in the gaseous phase occurs at pressure $p_{H_2} < 1$ atm. As hydrogen adsorption in electrolytes without specifically adsorbable ions starts at about the same low pressure as in the gaseous phase, the "reversible" hydrogen adsorption was attributed by me[45] to the region of the left peak[43, 44] of the potentiostatic i-U-curves.

S. Schuldiner: Unfortunately, Dr. Breiter has misconstrued several important points in our paper. His statement that we are "forced to postulate the formation of a second monolayer of hydrogen atoms which is completed at negative potentials," is not correct. What we do postulate is that, since a double atomic layer is unfeasible, a quantity of H atoms, which coulometrically may amount to a second layer, forms Pt-H alloy on the surface layer of platinum.

Concerning the diffusion *vs.* slow combination rate-controlling mechanisms, I shall not reiterate here detailed arguments in favor of the combination mechanism since this type of redundancy is an unnecessary rehashing of the literature. A comparison of a steady-state hydrogen overvoltage curve[46] (Fig. 2) with the transient overvoltage curves shown in Fig. 8 of the paper under discussion shows a convergence at increasing current densities. If mass transport were rate controlling, then the steady-state overvoltage should diverge from the transient overvoltage curve as the current density increases.

In addition, in Fig. 2,[46] Tafel curves which extend over two and one half orders of magnitude of current density are shown. Fig. 8[46] of the same reference shows Hammett relations for three orders of magnitude of current density. These are long enough ranges of current density to be highly significant.

Since both the X-Y and sawtooth methods use measuring instruments of essentially the same precision and resolution (commercial oscilloscopes, *etc.*), neither has an advantage over the other in this respect. The disadvantage of the sawtooth method is that at fast sweep rates a displacement current, which cannot be corrected for, is included in the oscilloscope trace. The X-Y method avoids this difficulty.

Rhenium-Tungsten-Carbon Interactions

R. F. Havell and Y. Baskin (pp. 1068-1069, Vol. 108, No. 11)

Charles P. Kempter[47]: The authors state that "Interactions between rhenium and carbon are limited to absorption of about 1% carbon in the rhenium lattice producing slight changes in the lattice constants and a reduction of the c/a ratio from 1.615 to 1.600," quoting only the early work of Trzebiatowski.[48] They did not quote the recent articles by Hughes[49] ("A Survey of the Rhenium-Carbon System") or Nadler and Kempter[50] ("Some Solidus Temperatures in Several Metal-Carbon Systems"). Hughes reviewed work on the Re-C system prior to that of Trzebiatowski, and published the Re-C phase diagram above 1500°C from 0 to ~30 atomic per cent (a/o) carbon. He reported a simple eutectic system at 16.9 a/o carbon and 2480 ±50°C, with the solid solubility of carbon in rhenium varying from 11.7 a/o at the eutectic temperature to 4.2 a/o at 1800°C. In an alloy of 20 a/o carbon, the "a" parameter increased from 2.760Å to 2.792Å and the "c" parameter increased from 4.458Å to 4.471Å—thus the axial ratio decreased from 1.615 to 1.601. In agreement with Hughes, Nadler and Kempter reported the minimum solidus temperature in the rhenium-carbon system to be 2486 ±18°C. In addition, although Havell and Baskin quoted a recent reference[51] for the Re-W phase diagram, they quoted no references pertaining to the W-C system, but did state a 2600°C melting point for WC and a 2475°-2730°C range for melting points of tungsten carbides and/or eutectics in the W-C system. Nadler and Kempter[50] have reviewed work on the W-W_2C eutectic and the WC melting point, and have determined values of 2732 ±22°C and 2720 ±20°C for these, respectively. (A final pertinent reference, which appeared after the submission of the Havell and Baskin note, is a paper by Sara[52] entitled "Phase Equilibria in the System Tungsten-Carbon." Sara found the minimum solidus temperature in the W-C system to be the W-W_2C eutectic temperature and agreed well with the above N. and K. value.)

The Miller indices tabulated for the "rhenium-WC solid solution" in Table III are consistent with space group D^4_{6h}-$P6_3/mmc$, which occurs for Re (Strukturbericht type A3) and W_2C (type L'_3). Both types[53]

have two metal atoms per unit cell in set (c) at 1/3, 2/3, 1/4, and 2/3, 1/3, 3/4, and W_2C also has a carbon atom in an octahedral hole. Thus, it seems reasonable that Re would form solid solutions with W_2C, and, therefore, the use of "(Re, WC)ss" in Table I and in reference to Table III might be misleading. Although WC has a hexagonal lattice, the space group[54] is D^1_{3h}-$P\bar{6}m2$ and the assignment of Miller indices is different from the case of Re or W_2C. Even though the *initial* tungsten to carbon molar ratio was unity, this does not preclude the existence of W-C structures other than WC in the observed solid solution. Until further characterization of the solid solution is carried out, it seems appropriate to refer to it as the Re-W-C solid solution as Havell and Baskin did in Table II.

R. F. Havell and Y. Baskin: We are thankful to Mr. Kempter for citing the recent work on the binary systems Re-C and W-C which bear directly on our study. We agree that the expression (Re, WC)ss is somewhat misleading, as it implies that the structure WC exists in the solid solution. We prefer either (Re-W-C)ss or Re-W_x-C_x solid solutions. The Re-W_x-C_x solid solution is structurally similar to that of W_2C despite the fact that the W/C mole ratio is a unity. As discussed in the article, rhenium and tungsten powders with a W/C mole ratio of 2 were not reacted, since contact of these samples with the graphite plate at 2300°C would have resulted in carbon absorption, thus shifting the ratio toward unity.

We feel that Mr. Kempter's implication that the W/C mole ratio of our powders changed on firing is not justified. Accurate weighings showed negligible weight change and, consequently, no shift in this ratio. Actually, it is not necessary to alter the W/C mole ratio from unity to obtain solid solutions having a close-packed hexagonal structure. The solid solution composition (Re_2, W, C) possesses this structure and, except for a different metal constitution, has the same metal to carbon ratio as the composition (Re, W_2, C), which would be intermediate between Re and W_2C. Moreover, the lattice constants of (Re_2, W, C) (a = 2.877, c = 4.561, c/a = 1.585) are very close to those calculated for Re, W_2C on the basis of Vegard's Law (a = 2.88, c = 4.59, c/a = 1.59). The small difference in atomic radius between rhenium and tungsten might account for some of the above difference.

On the Electrodeposition of Arsenic and Its Role in Corrosion Prevention

Gösta Wranglén (pp. 1069-1070, Vol. 108, No. 11)

R. Piontelli and G. Poli[55]: According to Dr. Wranglén's opinion, the insulating properties of the amorphous arsenic layers, obtainable by plating or displacement, involve the following consequences:

(*A*) The intervening of an ohmic drop contribution in the overvoltages, concerning both arsenic and hydrogen reduction as given by the direct method,

[54] J. Leciejewicz, *Acta Cryst.*, 14, 200 (1961).
[55] Lab. of Electrochemistry, Physical Chemistry, Metallurgy, Polytechnic of Milan, Milan, Italy.

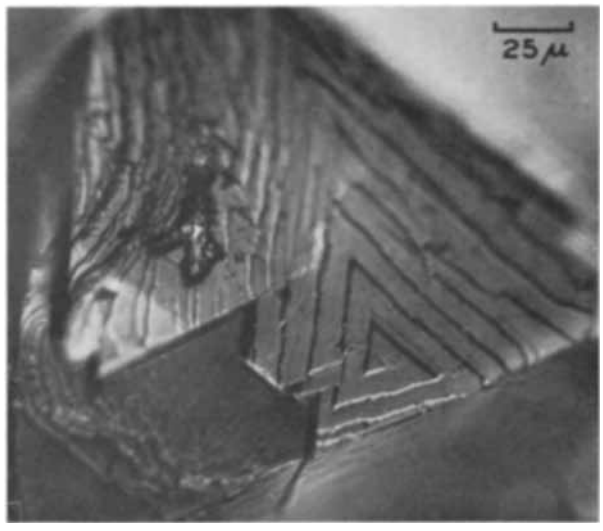

Fig. 1. Arsenic deposited in crystalline form (chloride bath); example of growth spiral. Magnification 400X.

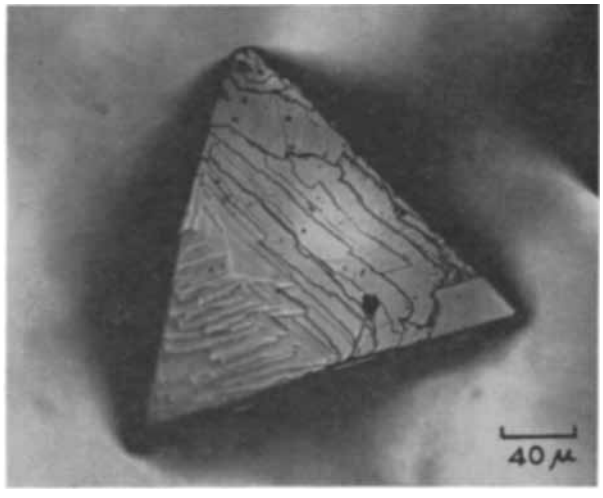

Fig. 2. Arsenic deposited in crystalline form (chloride bath). Magnification 270X.

so as to render meaningless the results thus obtainable;

(*B*) High voltages and a very poor current efficiency in the arsenic electrowinning;

(*C*) A very efficient inhibitive influence of arsenic with respect to the corrosion of iron materials, formerly explained[56] by considering the hydrogen overvoltages.

1. We agree on the point that the "cumulative overvoltages" given by the direct methods in a quasi-steady condition, although representing the item to be considered in the cell voltage-balance, are affected in this case by a quite significant ohmic contribution, which may become largely predominating for thick arsenic layers.

2. The "true overvoltages" (that is, corrected from any ohmic contribution), in the arsenic separation on arsenic layers, are definitely high (in the order of several tenths of a volt), however, also at low c.d.[57]

3. Arsenic may be plated, at least partially, also in crystalline form (*see* Fig. 1 and 2 of this discussion),

[56] O. P. Watts, *Trans. Am. Electrochem. Soc.*, 21, 339 (1912).
[57] In the succession, Bi, Sb, As, a strong increase of these "true overvoltages" corresponds to the increase of the metalloidic character (*see* R. Piontelli, *Z. Elektrochem.*, 55, 128 (1951)).

the corresponding "true overvoltage" again being quite high.[58]

4. In any case, the low and decreasing current efficiency encountered by Wranglén could not be accounted for on the basis of the assumed insulating power of the arsenic layer, which would influence both of the concurrent cathodic processes. The current efficiency in the As deposition is low, due to the high true overvoltage involved by this process, while its decrease in time, in Wranglén's experiments, is due perhaps: (*a*) to composition changes in the bath; (*b*) to the structure changes of the cathodes. As a matter of fact, we found evidence that these last, although not involving any appreciable decrease in the (true) overvoltage in the As deposition, may appreciably decrease the hydrogen overvoltage.

5. The conclusion that the strong inhibition that As may exert on the corrosion of Fe cannot be explained solely on the basis of the hydrogen overvoltage has been largely substantiated by previous experiments from this laboratory.[59]

In our opinion, however, this very efficient protection is due largely to the structure and, in particular, to the very peculiar perfection of the separated layers (which eliminate any potentially anodic area), in spite of their origin by a displacement reaction, and thanks to the very high throwing power which characterizes, under favorable conditions, arsenic deposition on some foreign metals.

The opinion that this protective influence cannot merely be attributed to the insulating power of the As layer, as Wranglén seems to consider, may be directly confirmed as follows. An iron specimen, after adequate treatment in an inhibiting arsenical solution, does not displace hydrogen from strong acids, nor copper from copper sulfate.

Let us eliminate the arsenic layer from the contour or from some other localized area, by scraping.

The specimen will now displace hydrogen, or respectively copper, but the cathodic process will then occur not only on the newly exposed area but, moreover, on a rather large fraction of the still covered one.

The very presence of the arsenic layer would be unable, therefore, to prevent the occurrence of cathodic processes complementary to the anodic ones when these last are made possible by the availability of anodic areas.

G. Wranglén: The discussion by Professors Piontelli and Poli, complementing their previous extensive work in this field, is most welcome. They have correctly interpreted and summarized the conclusions of the present writer. It seems necessary to emphasize, however, that the nonconductivity of the arsenic electrodeposited by the author was not "assumed" but experimentally established.

It is now very interesting to learn that arsenic can be deposited, "at least partially," also in crystalline form, as the micrographs 1 and 2 show. It also would have been of great interest to learn the conditions of deposition, however, since it would seem as if crystalline electrodeposits of arsenic are exceptional at low temperatures and normally to be expected only in fused salt electrolysis. Amorphous deposits (according to x-ray diffraction analysis) were obtained not only by the present writer but also by Stillwell and Audrieth[60] from solutions of $AsCl_3$ in glacial acetic acid, and by Finch, Quarrel, and Wilman[61] from aqueous cyanide baths. Deposits from the $AsCl_3$-HAc bath were used by Salzberg and Goldschmidt[62] in their studies of hydrogen overvoltage on arsenic. It is also known that arsenic precipitated chemically from aqueous solutions by reducing agents is obtained in various amorphous forms.[63] These are considered to be transition forms between the nonmetallic yellow, cubic, and the metallic gray, rhombohedral modification of elementary arsenic. They are transformed to the metallic modification on heating. According to origin, the transformation temperature varies from 100° to 377°C.[64] Their nonconductivity seems to be a direct consequence of their amorphous structure. This connection often seems to have been overlooked, however, particularly in electrochemical studies.

Piontelli and Poli maintain that the insulating properties of electrodeposited arsenic would affect the two concurrent cathodic processes equally and thus not influence the current efficiency of arsenic deposition. It must be observed, however, that the arsenic is deposited in a noncoherent condition (porous from the acid chloride bath, flaky from the alkaline arsenite bath) leaving small areas of the basis metal uncovered. On these the current density will be very high, much higher than the limiting c.d. for arsenic deposition. This is particularly true for arsenite solutions where the AsO^-_2-ions migrate away from the cathode, resulting in a low limiting c.d. Hence, copious hydrogen evolution from water will take place resulting in a low current efficiency of arsenic deposition. It seems natural that this effect is accentuated during the course of an electrolysis experiment.

The high throwing power in the electrodeposition of arsenic, referred to by Piontelli and Poli, is also a natural consequence of the low conductivity of the deposit, transferring the electrodeposition reaction to still uncovered areas. In this respect, the electrodeposition of arsenic resembles certain anodic processes, such as anodizing of aluminum.

The corrosion experiment described by Piontelli and Poli and involving the local removal of the nonconducting arsenic film very much resembles localized corrosion, such as pitting, on metals passivated by an oxide film, *e.g.*, aluminum and stainless steel. There the cathode reaction also occurs all over the passivating film or on active parts of it.

Raney Type Transition Metals as Fuel Electrode Catalysts

H. Krupp, H. Rabenhorst, G. Sandstede, and G. Walter
Battelle-Institut e.V., Frankfurt (Main), Germany

and R. McJones
Cummins Engine Company, Inc., Columbus, Indiana

ABSTRACT

Porous metal electrodes incorporating Raney catalysts are prepared by powder techniques from transition metals of the first and eighth groups. Half-cell and fuel cell measurements are taken in various aqueous electrolytes at temperatures from 20° to 100°C. At 80°C in either 5*N* KOH or 5*N* H_2SO_4 electrolyte, both hydrogen and methanol yield current densities beyond 300 ma/cm². In 5*N* K_2CO_3 electrolyte, there are limiting current densities of the order of 10 ma/cm². Neither hexane nor methylcyclohexane display appreciable electrochemical oxidation under the conditions of this report. The methanol reaction appears to approach complete oxidation; this conclusion applies in both acid (CO_2-formation) and alkaline (carbonate formation) electrolyte as well as for both half-cell and fuel cell operation.

There is so far no satisfactory low-temperature hydrocarbon fuel electrode. On the other hand, electrochemical conversion at an appreciable rate of partially oxidized hydrocarbons such as methanol and glycol seems to be possible, but only in the case of methanol was complete oxidation reported (1). At least some of the reactions involved in the stepwise oxidation at the anode must be accelerated catalytically in order to achieve a sufficient reaction rate at low temperatures (below 200°C). The electrode must, therefore, contain catalysts accelerating, above all, the acceptance of electrons from the fuel by the anode.

The activity of a catalyst seems to be related to the number of crystallographically disoriented surface atoms. Defect structures are attained by several processes which are not discussed here. In the present investigations it was decided to use Raney catalysts because, on the one hand, they can be produced at room temperature so that recrystallization enhanced by elevated temperatures is avoided, and because, on the other hand, a relatively simple method of Raney electrode preparation was described by Justi (2-4). Raney catalysts are made by alloying the catalyst material with a base metal, for instance aluminum, which is subsequently dissolved from this alloy leaving the catalyst metal in a highly active state.

Justi has used Raney nickel electrodes, especially as hydrogen electrodes, with outstanding success. He also mentioned work with Raney electrodes based on copper, tungsten, molybdenum (for carbon monoxide oxidation), and palladium (as a *p*H electrode), but he did not discuss his results with these metals in detail. The present work must be regarded as an application, and possibly an extension, of Justi's technique.

The preparation of fuel electrodes from Raney copper, cobalt, nickel, rhodium, palladium, and platinum is described in the following along with the results obtained from tests with hydrogen, methanol, and hydrocarbon fuels.

Experimental Procedure

All electrode specimens were prepared in the form of porous disks by compressing a mixture of skeleton metal powder with powdered Raney alloy and subsequent dissolution of the base metal of the Raney alloy. In all cases the skeleton material and the catalytic substance of the Raney alloy were identical. The diameter of the disks was 1.2 cm. They were glued around the circumference into an electrode support ring made of Plexiglas. The projected surface area of the active part of the disk was 0.65 cm².

The Raney alloys were prepared by alloying the catalyst metal with aluminum. In order to achieve a high alloying rate without melting the components beforehand, the two metals were mixed in the form of powders and compressed into disks. The disks contained in individual crucibles were heated in an electric furnace until the alloying reaction started with conflagration at about 700°C. Owing to the heat of reaction, the temperature increased, causing the mixture to melt and to form a homogeneous alloy. Immediately after this reaction was completed, the alloy solidified; it was then removed from the furnace. It would not be possible, at least under mild conditions, to eliminate the aluminum from, in particular, the XAl compound where the catalyst metal X is compounded with aluminum at an atomic ratio of 1:1. The percentage of the catalytically active metal in the alloy, therefore, must be lower than the stoichiometric ratio of 1:1. It must, however, be above, say, 20 at. % because the alloy becomes too ductile for powdering below this limit.

For the preparation of the electrode disks, one part by volume of a pure metal powder, the skeleton material, was mixed with one part by volume of powdered Raney alloy. The mixture was subsequently compacted by pressing it into disks. Justi's

technique to achieve homoporosity by fractionation of the powders was not applied at this research stage.

The copper, cobalt, and nickel electrodes were prepared by compacting the powders at a pressure of 3,000 kg/cm^2, and sintering them at 400°C (Cu) and 600°C (Co, Ni). The platinum, palladium, and rhodium electrodes were left unsintered in order to prevent the formation of the stable compound XAl from the Raney alloy and the skeleton metal during the heat treatment. The unsintered electrodes were compacted at a pressure of 10,000 kg/cm^2, and at the same time two platinum screens were included with a view to increase the mechanical stability.

After cementation of the disks into a Plexiglas ring, the aluminum of the Raney alloy was dissolved by treating the electrode first with a dilute and then with a concentrated KOH solution, finally at a temperature of 80°C. The aluminum is not completely eliminated by this process. Further aluminum was dissolved anodically. A KOH solution was employed irrespective of whether the disks were used in alkaline or acid electrolytes because the dissolution rate of aluminum in acids is too large.

The electrodes were tested by taking current-potential plots using the half-cell system depicted in Fig. 1.

The test electrodes (porous disk cemented into a Plexiglas ring) were fixed in a Plexiglas holder providing a gas inlet. The electrical contact with the disk was established by two spring-type platinum wires to insure good contact. A platinum wire served as counter electrode. The electrode potential was measured against a calomel electrode using a Luggin capillary placed at a distance of 5 mm from the electrode surface, which gave a maximum measuring error of 50 mv. The ohmic polarization due to the ohmic resistances in the electrode and the electrolyte was not measured and consequently is still included in the potential values as reported. The measured potentials were not corrected for the diffusion potential between the electrolyte contained in the liquid junction (5*N*) and that at the reference electrode (0.1*N*); the involved error would not exceed 30 mv. The current was adjusted by means of a galvanostat. The measured amperages were converted into current densities by taking the projected surface area of the electrode to be 0.65 cm^2.

All electrodes were tested with gaseous hydrogen and methanol and some, in addition, with methylcyclohexane and hexane. The latter three fuels were admitted to the electrodes using nitrogen as a carrier gas. The electrode gas excess pressures totalled 0.5-1 atm. Reference runs were made using pure nitrogen.

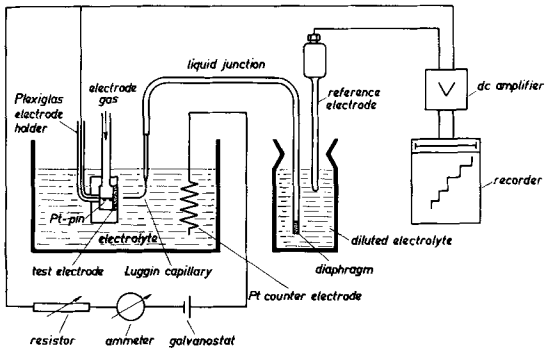

Fig. 1. Diagram of test stand for measuring current-potential plots.

In addition to the gaseous fuels, the tests included formaldehyde, formic acid, and methanol, dissolved in the electrolyte.

Alkaline, acid, and carbonate electrolytes have been employed as 5*N* solutions in water. The majority of the tests performed to date have been run at 80°C.

After the described chemical dissolution of aluminum, further aluminum was dissolved in the half-cell anodically. To this end the electrode was used as a hydrogen electrode. The electrode potential was increased stepwise to about 200 mv below the reversible oxygen potential. Although mainly hydrogen is oxidized during this process, part of the current is due to dissolving aluminum.

In the case of nickel, the electrode activity was much greater when electrochemical activation was used. For example a Raney nickel electrode using hydrogen in a half cell at −650 mv yielded current densities of 12 and 80 ma/cm^2, respectively, when the electrode was activated chemically in 5*N* KOH at 40°C for 24 hr or activated electrochemically for ½ hr in 5*N* KOH at 40°C with an electrode potential of +150 mv. Electrochemical activation was not necessary with the other metals of the eighth group tested.

The amount of hydrogen dissolved in the electrode was reduced substantially prior to tests with methanol or hexane by passing a nitrogen stream through the electrode. To accelerate this process, a potential was applied which was about 200 mv below the standard reversible oxidation potential of the corresponding electrode metal:

Current Density-Potential Plots

Most of the results are plotted in the form of current density-potential characteristics.

All reported potential values were obtained within a few minutes after adjustment of the current and remained constant during the measuring period up to several hours. Figure 2 depicts the results with hydrogen in KOH solution.

With all electrodes the open-circuit potential reached the reversible hydrogen potential. Deviations within ±30 mv are due to variations of the potential of the calomel reference electrode. The nickel electrode shows a distinct limiting current density beyond which the polarization as a function of the current deviates strongly from linearity. As the diagram shows, the platinum electrode has

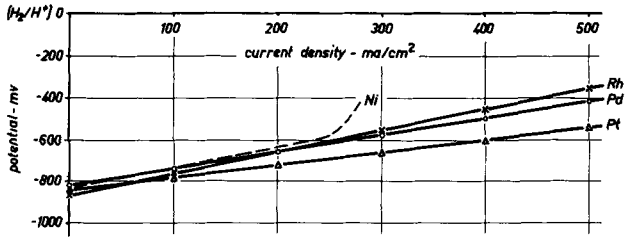

Fig. 2. Current density-potential plots of Raney electrodes with H_2 in 5*N* KOH at 80°C.

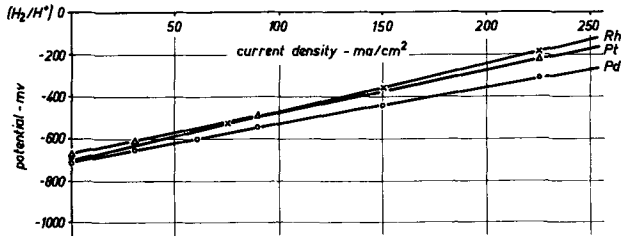

Fig. 3. Current density-potential plots of Raney electrodes with CH_3OH in 5*N* KOH at 80°C.

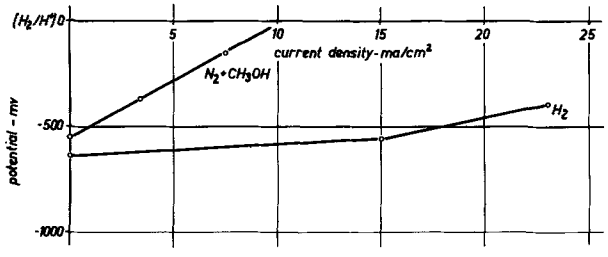

Fig. 4. Current density-potential plots of Raney palladium electrode with H_2 and CH_3OH in 5*N* K_2CO_3 at 80°C.

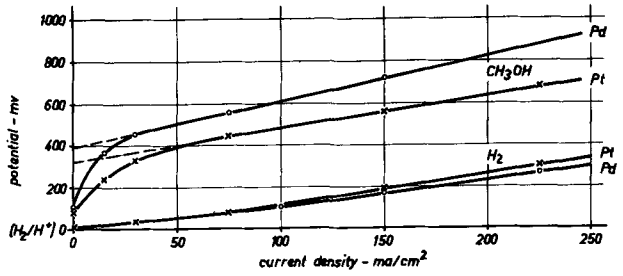

Fig. 5. Current density-potential plots of Raney electrodes in 5*N* H_2SO_4 at 100°C.

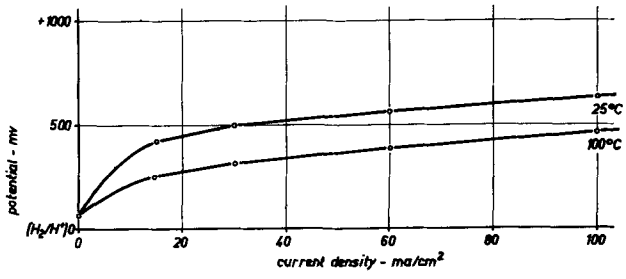

Fig. 6. Current density-potential plots of a Raney platinum electrode with CH_3OH in 5*N* H_2SO_4 as a function of temperature.

the smallest polarization. With palladium, platinum, and rhodium as hydrogen and methanol electrodes, the tests were not extended beyond current densities of about 500 ma/cm² and 300 ma/cm², respectively, so that the respective limiting current densities were not ascertained.

The results obtained with the sintered nickel electrode, using hydrogen as fuel were inferior to those reported by Justi, presumably because of the much smaller number of active pores. It is thus assumed that all electrodes investigated may be improved by employment of better techniques of powder metallurgy.

Figure 3 shows the results with methanol fuel in KOH solution.

Again the polarization increased linearly with the current. The open-circuit potential was about 100-150 mv smaller than that with hydrogen. Here palladium furnished the best results.

If the KOH electrolyte is replaced by K_2CO_3, very large polarizations are obtained both with hydrogen and methanol as fuels (see Fig. 4).

Large current densities were obtained not only in KOH solution but also in H_2SO_4 solution with hydrogen and methanol as fuel (see Fig. 5 and 6).

With methanol, the polarization shows a peculiar nonlinearity at small current densities. With methanol in an acid solution, platinum proves to be superior to palladium as a catalyst. The open-circuit potential exceeds that of hydrogen by about 100 mv.

Figure 6 shows the temperature dependence of methanol oxidation as a function of the temperature between 25° and 100°C.

The above results are summarized in Table I together with results not illustrated so far. "Specific polarization" is defined as the slope of the curve potential *vs.* current density. For methanol in acid electrolyte, the slope is taken from the linear portion of the curve at large currents; in these cases the value of the open-circuit potential is complemented by the interception of the extrapolated linear part of the polarization curve with the ordinate. Copper and cobalt turned out to be unsatisfactory catalysts for methanol or hydrogen electrodes.

Table I. Open-circuit potential, specific polarization, and limiting current density with hydrogen and methanol, respectively, at 80°C

		H_2			CH_3OH

* Basis for calculation of the specific polarization.

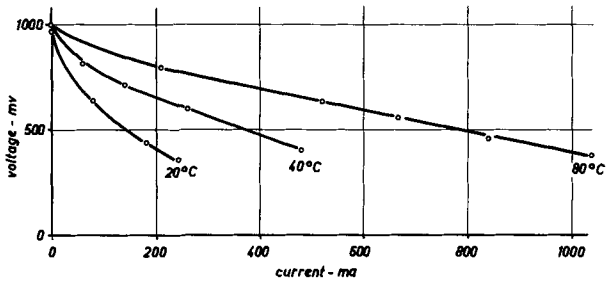

Fig. 7. Current-voltage plots of a fuel cell in 5*N* KOH as a function of temperature with methanol fuel (electrode area 12 cm²).

In addition, the following remarks may be made: (*A*) There was no appreciable electrochemical oxidation of hexane or methylcyclohexane with the described types of electrodes and under the described conditions. (*B*) Sintering of the noble metal electrodes destroys their activity with methanol and seriously affects their activity with hydrogen. (*C*) The current-potential plots with methanol are independent of whether the fuel is admitted as a vapor or dissolved in the electrolyte in excess concentrations. (*D*) In both KOH and H_2SO_4 solutions, formaldehyde and formic acid, dissolved in the electrolyte, are converted with current densities similar to those achieved with methanol.

Experiments with a Laboratory-Stage Alkaline Methanol Fuel Cell

A laboratory-stage methanol fuel cell was set up, using a palladium fuel electrode and a silver oxygen electrode of a projected surface area of 12 cm² each. The electrodes were spaced at 1 cm in an aqueous 5*N* KOH electrolyte to which methanol was added in amounts of 1 mole/l as a liquid admixture.

The current-voltage characteristic of the cell was plotted at 20°, 40°, and 80°C (Fig. 7).

It is apparent that, at the same voltage, the cell output rises about fourfold on increasing the temperature from 20° to 80°C. The characteristic does not change even after continuous operation for several weeks; the electrolyte had to be replaced several times during this period owing to the KOH consumption. The cell was used to examine the degree of conversion of, alternatively, methanol, formaldehyde, and formic acid.

Tests were run which showed that there was negligible activity of the methanol at the oxygen electrode.

A known amount of methanol was added to a cell, and the cell was operated until completely discharged. The total amount of current withdrawn was measured and compared to the calculated total current for complete oxidation to carbonate. The measured current corresponded to about 95% of the calculated current.

Methanol Oxidation Reactions

Various experimenters (1, 5-9) have found different reaction end products in methanol fuel cells. During the present program, several avenues have been followed in an attempt to investigate the course and the completeness of the methanol conversion.

In order to test their electrochemical activity, the supposed intermediates of the methanol oxidation were anodically oxidized in a half-cell arrangement. With formaldehyde as well as with formic acid large current densities were obtained at polarizations comparable to those observed with methanol. This holds for both an alkaline and an acid medium.

Another approach to the problem of the degree of oxidation is the chemical analysis of the electrolyte after extended operation. Therefore, the amounts of formaldehyde and formic acid were determined that were formed after a cell had been operated for 2 hr at, alternatively, 20° and 80°C from methanol owing to incomplete oxidation. The applied analytical procedure was based on the formation of an intensely colored complex of formaldehyde and chromotropic acid which was determined colorimetrically. Formic acid is reduced to formaldehyde by magnesium and sulfuric acid before its determination. Such a procedure was carried out for half-cells after 5000 coulombs had been withdrawn. In the case of alkaline electrolyte with a palladium electrode, the amounts of formaldehyde and formic acid totalled 5% of the converted electricity. With a rhodium electrode, they were about 10% thereof. In the case of an acid electrolyte, using a platinum electrode, the amount of formaldehyde was about 1%, and that of formic acid smaller than 0.1% of the converted electricity. There was no appreciable temperature effect.

The same analyses were conducted for the alkaline methanol fuel cell with a palladium electrode after 8000 coulombs had been withdrawn. The amounts of formaldehyde and formic acid corresponded to 1 and 3%, respectively, of the converted electricity.

Finally, at 20°C the laboratory stage alkaline fuel cell was operated on defined amounts of formaldehyde and formic acid in separate runs. Total current withdrawal was measured for each fuel and was found to be about 95% of the calculated current for complete oxidation in each case. This was in agreement with the tests run to determine fuel activity with methanol as the fuel.

These various findings lead to the conclusion that even at room temperatures methanol oxidation proceeds almost completely to carbonate or carbon dioxide on the Raney electrodes of the present study. This result appears to be independent of the electrolyte and of the half-cell *vs.* fuel cell operation.

Determination of the Internal Resistance of Leclanche Cells by Square-Wave Method

Aladar Tvarusko

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The internal resistance of Leclanché dry cells was studied on shelf and during discharge by means of a square-wave technique. A constant-current square-wave signal was passed through the cell on test, and the potential variation across the cell displayed on a high-sensitivity oscilloscope with differential input. The instantaneous voltage drop in the oscilloscope pattern, caused by the leading edge of the constant current square wave, indicated the internal resistance of the Leclanché cells. The internal resistance is independent of the amplitude and frequency of the applied square-wave current and of the momentary d-c current. The type of manganese dioxide used in the cathode mix and the composition of the electrolyte influenced the internal resistance of D-size Leclanché cells, both undischarged and during 4-ohm continuous discharge.

In the past, both steady-state and transient measuring methods using either alternating or direct current were investigated for determining the internal resistance of dry cells. Results obtained by these methods were inconsistent. One of the simplest and least accurate methods is the d-c steady-state method in which the resistance is calculated from the potential drop at a certain current drain (1-4). Several d-c transient methods were developed (5-8). Generally, the a-c steady-state methods use various types of impedance bridges to separate the resistive (real) and reactive (imaginary) part of the impedance. Various arrangements were used by the several authors (9-18). The a-c transient method is represented by Brodd's (19) current pulse method.

Impedance of an electrical circuit consists of two parts: resistive and reactive. The resistive part is frequency independent while the reactive part varies with the frequency. The reactive part can include inductance or capacitance or both. In the case of Leclanché cells with relatively short leads, the inductance is negligible, and only the capacitive reactance and the pure resistive component have a role in the impedance.

In general, the separation of the resistive and reactive components of the impedance by the a-c bridge methods is a fairly lengthy operation or complicated instrumentation is involved, *e.g.*, the use of double-servo-controlled a-c bridge (20). During the changes taking place in the discharge and storage of cells, not only the resistive part can change but also the reactive part. Brodd's pulse method (19) yielded only the resistive part of the impedance, whereas the square-wave current method gives information concerning the reactive part of the impedance as well as the resistive part. Very recently however, a pulse method was described (21) to measure parameters of the electrical double layer, namely, the reactive part of the impedance. Various square-wave techniques have been utilized previously for electrochemical studies (22-25).

In this modification of the method developed at this laboratory (25), a constant-current square-wave signal was passed through the test cell and the potential variation across the cell displayed on an oscilloscope. The instantaneous voltage drop in the oscilloscope pattern, caused by the leading edge of the constant-current square wave, represents the internal resistance of the Leclanché cell. Results concerning the reactive part of the impedance will be described in a later article.

Experimental

The block diagram of the circuit used to measure the internal resistance of Leclanché cells is shown in Fig. 1. The Leclanché cell A, was connected in series with a noninductive resistor B. This converted the constant-voltage output of the square-wave generator C, to constant current, since the value of resistor B is much larger than the sum of the impedances in the constant-current circuit loop (C-A-G-F). The voltage response of the square-wave current across the Leclanché cell was measured through oscilloscope probes (5X)D, with a high-

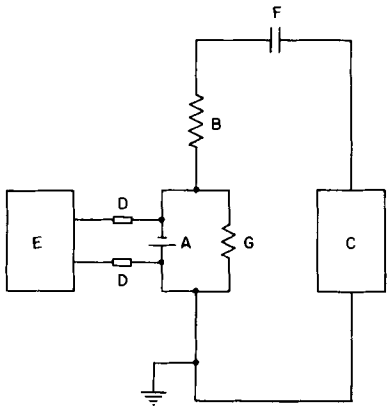

Fig. 1. Block diagram of the circuit: A, Leclanché cell; B, resistor; C, square-wave generator; D, oscilloscope probe (5X); E, oscilloscope; F, blocking capacitor; G, discharging resistor.

sensitivity differential input oscilloscope E, equipped with a Robot recorder camera. A capacitor F was used in series with the dry cell to prevent the discharge of the dry cell through the square-wave generator. Resistor G, in parallel with the cell, was used for discharging the Leclanché cell.

The use of matched oscilloscope probes and shielded cables together with the differential input of the oscilloscope minimized stray pick-up and noise. Ground loops were avoided by grounding the measuring circuitry only at one point. The shielding of the oscilloscope probes was grounded through the oscilloscope.

A Hickok Model 710 sine-square-wave generator was used with a rise time of less than 0.1 μsec for a range of 20 cycles to 1 Mc frequency. The square-wave current limiting resistor was 4200 ohm except for the study of internal resistance as a function of the square-wave current. The voltage used was 42.0v peak-to-peak. The blocking capacitor was 16 μF. The oscilloscope was a Tektronix Model 502 with a passband of d.c. to 100 kc at the most frequently used sensitivities and a rise time of 3.5 μsec.

Square waves of a certain base frequency can be represented by the Fourier series of sine waves of its fundamental and odd numbered harmonics. The leading edge of the square wave represents the high-frequency harmonics. If the inductance of the sample and leads is negligible, the instantaneous voltage drop of the signal corresponds to the resistive part of the impedance only. Knowing the square-wave current amplitude and the measured instantaneous voltage drop (times oscilloscope probes' attenuator factor 5X) the R is simply calculated from Ohm's law. When discharging the Leclanché cell, the resistor G is in parallel with the cell, and R is calculated with the help of Kirchoff's law.

All the Leclanché cells investigated were pasted-type D-size dry cells. In order to study the effect of the type of MnO_2 on the course of the internal resistance curves, MnO_2 of different origins was used. African ore (Ghana) represented the naturally occurring manganese dioxide. The African ore was also blended with a synthetic hydrous MnO_2 (4% alkali and 10% water content). The x-ray diffraction pattern of this synthetic MnO_2 had weak intensity γ-MnO_2 and very weak pyrolusite and cryptomelane peaks. The two electrolytic MnO_2 samples (sources A and B) were γ-MnO_2. The MnO_2: carbon black ratio was 8:1 for all cells. The electrolyte in the core was the same for all compositions with the exception of the African ore, synthetic MnO_2 mix which contained 20% less $ZnCl_2$ and 10% less NH_4Cl than the others. The same paste composition was used for all Leclanché cells except for the electrolytic MnO_2 from source B. The paste for this cell contained 120% more $ZnCl_2$ and 25% more NH_4Cl than the other one.

Results and Discussion

The internal resistance of the Leclanché cells was measured by a constant square-wave current. It was of interest to investigate the internal resistance as a function of the applied square-wave current amplitude. The current was varied from 1 to 20 ma peak-to-peak, and no change was observed in the internal resistance of the cell. The internal resistance is thus independent of the square-wave current amplitude, *i.e.*, it obeys Ohm's law. A current of 10 ma was subsequently chosen to obtain a convenient voltage drop.

The frequency dependence of the internal resistance was investigated in the frequency range of 20-10,000 cps. The internal resistance of Leclanché cells, R_i was thus found to be independent of the frequency as shown in Fig. 2. This frequency independence of the R_i was found for all the Leclanché cell compositions investigated.

The very slight deviation at low frequencies is due to the difficult readability of the voltage drop (where large vertical deflection factors are needed), while at high frequencies it is due to the distortion of the leading edge. The internal resistance of D-size Leclanché cells is in the range 0.1-0.4 ohm, according to the composition. These low values necessitated the use of the most sensitive range of the oscilloscope's vertical amplifier (200 μv/cm). At this range the passband of the amplifier is d.c. to 100 kc. The fifth odd harmonic component of the 10 kc square-wave signal is cut out by the amplifier, whereas the forty-ninth odd harmonic component of the 1 kc square-wave signal is carried over. The readability of the instantaneous voltage drop is good at 1 kc also. All the measurements were done at 1 kc.

Dry cells are made as uniformly as is practically possible. A certain deviation in the composition, as-

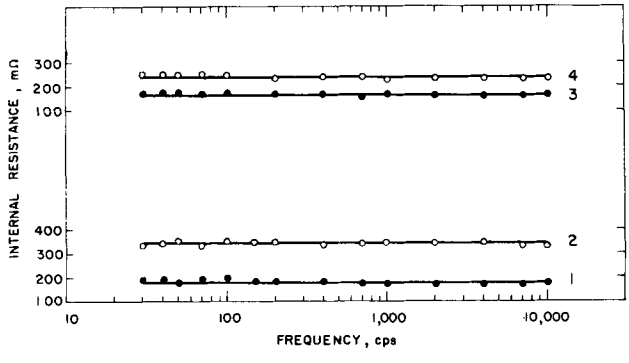

Fig. 2. Internal resistance of Leclanché cells as a function of frequency. Curve 1, African ore; curve 2, African ore, synthetic MnO_2; curve 3, electrolytic MnO_2, source B; curve 4, electrolytic MnO_2, source A.

Table I. Internal resistance of undischarged Leclanché cells (D-size) and its deviation

Type of MnO_2	Number of cells	R_{Mean}, ohm	Δ_{Max}, ohm	
African ore	15	0.18	+0.03	−0.01
Electrolytic MnO_2, source A	12	0.21	+0.06	−0.04
Electrolytic MnO_2, source B	12	0.16	+0.02	−0.01

sembly, etc., is unavoidable. This naturally shows up in the internal resistance values also. The arithmetical mean of at least 12 undischarged D-size Leclanché cells per lot, and the maximum deviation from it can be seen in Table I. The reproducibility of the internal resistance values for individual cells is good (±0.01 ohm).

On replacing part of the African ore in the core with a synthetic hydrous MnO_2, the internal resistance of the undischarged Leclanché cell was markedly increased (curve 2 *vs.* curve 1, Fig. 2). The slightly lower salt concentration in the mix electrolyte cannot be responsible alone for this marked resistance increase. Therefore, it is safe to assume that the synthetic MnO_2 in the core contributed largely to the internal resistance increase. Leclanché cells made with electrolytic MnO_2, source B, had a paste of significantly higher salt concentration which was mainly responsible for the internal resistance decrease of these cells (curve 3).

The internal resistance of Leclanché cells of various compositions was investigated also during discharge. Three cells or more were discharged for each composition to insure proper validity of results. Momentary current drains did not affect the internal resistance of cells except at very high current drains where it increased due to changes taking place which cannot be ascertained at this time. This confirms the results of Brodd (19), Fukuda *et al.* (14), and Panzer *et al.* (8) and is contrary to the studies reporting the dependence of the "internal resistance" of Leclanché cells on current drain (1, 4, 6, 14, 15). In the latter cases, the "internal resistance" includes not only the pure resistance, R_i, of Leclanché cells but also other types of polarization.

The internal resistance of Leclanché cells changes during discharge due to the current producing and secondary reactions. The internal resistance change for Leclanché cells containing African ore during 4 ohm continuous discharge can be seen in Fig. 3. The internal resistance of the cells having African ore only increased constantly, and the curve (No. 1) can be separated into two parts having slightly different slopes. Cells with synthetic hydrous MnO_2 and African ore produced a curve of an entirely different character. This curve was duplicated several times. The rapid internal resistance increase in the very beginning of the discharge and the nearly horizontal portion of the curve can be attributed to the presence of the synthetic MnO_2. In the second half of the discharge the synthetic MnO_2 had lost its influence, and the curve resembles that of cells with natural ore mixes. The voltage values on the individual

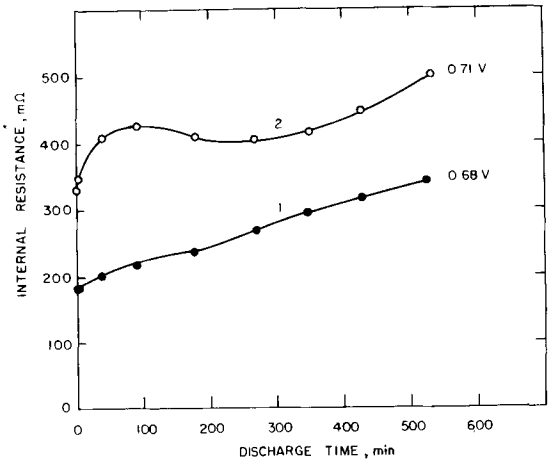

Fig. 3. Internal resistance of Leclanché cells containing natural ores discharged continuously through 4 ohm. Curve 1, African ore; curve 2, African ore, synthetic hydrous MnO_2.

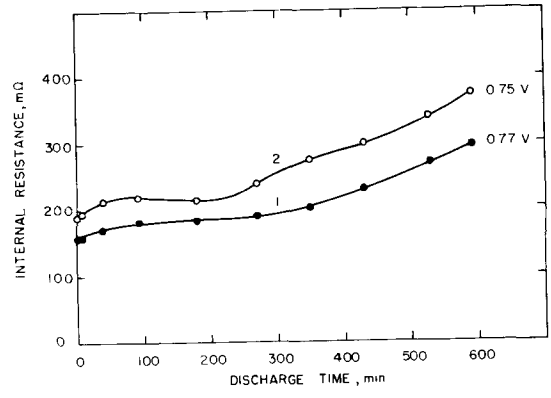

Fig. 4. Internal resistance of Leclanché cells having electrolytic MnO_2 discharged continuously through 4 ohm. Curve 1, electrolytic MnO_2, source B; curve 2, electrolytic MnO_2, source A.

curves represent the closed-circuit voltages at the cut-off time.

In the manganese dioxides of the above cells the amount of γ-MnO_2 was much less than in electrolytic MnO_2, as judged by the intensity of the γ-MnO_2 peaks in the x-ray diffraction patterns. The amount of γ-MnO_2 seems to influence the first portion of the internal resistance curve. African ore has a fair amount of γ-MnO_2, and its internal resistance curve for cells can be characterized by two slightly deviating slopes. The internal resistance curves of electrolytic MnO_2 (dominantly γ-MnO_2) can be separated into two parts with distinctly different slopes (Fig. 4). This is more evident in Leclanché cells (MnO_2, source B, curve 1) with a paste of much higher zinc chloride content (lower *p*H).

The two distinct slopes and the initial portion of the curves for the latter and other Leclanché cells represent various reactions taking place in the cells. With a paste of higher *p*H, the course of the internal resistance curve (No. 2) deviates from that previously described (No. 1) mainly in the 250-450 min range.

The previously described square-wave current method to determine the internal resistance naturally is not limited to Leclanché cells but can be applied to other electrochemical systems and their half-cells.

Oxidation Studies on 304 Stainless Steel

E. A. Gulbransen and K. F. Andrew

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The kinetics of oxidation of 304 stainless steel are studied between 500° and 1150°C at 0.1 atm for reaction times up to 6 hr. At 500°C about 2.3 $\mu g/cm^2$ of oxide are formed in a time period of 6 hr. The rate of increase after 6 hr is 0.1 $\mu g/cm^2/hr$. At 800°C a transition is observed in the rate of oxidation with the kinetics changing from the parabolic rate law to the linear rate law. This transition occurred for a weight gain of 9 $\mu g/cm^2$. At 900°C and for weight gains above 90 $\mu g/cm^2$ the parabolic rate law again was found to hold. A second transition is found in the kinetics of oxidation at 1150°C. This transition we relate to the vapor pressure of iron and chromium which acts to speed up the transfer of metal atoms through the oxide scale. A comparison of the kinetics of oxidation is made with the heat-resistant Kanthal alloys and with pure chromium.

This paper presents a systematic study of the kinetics of oxidation of 304 stainless steel between 500° and 1150°C at 0.1 atm and for reaction times up to 6 hr. Since 304 stainless steel is being used as a high-temperature material, one of the objectives of this work is to study the conditions under which the alloy fails in oxidation. Failure occurs when a rapid oxidation reaction develops in which diffusion processes are no longer rate controlling. For some metals and alloys failure is due to poor adhesion of the oxide. With other metals the oxide may volatilize. For those metals which form nonvolatile and adherent oxide films, failure may result from vaporization of the metal through the oxide film. This type of failure has been observed in the oxidation of chromium (1) and several heat resistant alloys (2-3).

From a thermodynamic point of view oxidation and corrosion are functions of the chemical potentials of the components in the environment and the chemical potentials of the metallic components in the alloy. The chemical potential of an alloying component is a function of the activity of the metal in the alloy. From a kinetic point of view the rate of oxidation or corrosion depends in part on the nature and properties of the oxide or corrosion film formed on the alloy.

Since both gaseous oxidation and corrosion in high-temperature water atmospheres depends on the same metallurgical factors in the alloy, a study of the kinetics of oxidation may help our interpretation of corrosion in water atmospheres.

Since the chemical activity of metal atoms in an alloy and the characteristics of the oxide film can be controlled by alloying additions (4), it is possible to

predict the oxidation and corrosion behavior of alloys.

Experimental

Apparatus.—The vacuum microbalance reaction system was used (5-6) for all of the measurements. The sensitivity of the microbalance was 0.83 μg per 0.001 cm. Weight changes of 0.3 μg could be estimated.

A mullite furnace tube was used to surround the specimen. This tube was sealed directly to the all-Pyrex glass vacuum system. After introducing the specimen into the reaction system and closing off, the system was evacuated for 16 hr at a pressure of 10^{-6} mm Hg or less. To avoid evaporation of metal at 1000°C and higher, the specimen and reaction tube were heated rapidly to the reaction temperature. After thermal equilibrium was established, purified oxygen was added to 0.1 atm pressure.

For the same surface treatment the reproducibility of the oxidation experiments was about 10-20%.

The furnace temperature was maintained constant to ±1.5°C by the use of a calibrated high-sensitivity recorder-controller and a calibrated Pt-Pt 10% Rh thermocouple.

Samples.—The 304, stainless steel analyzed 17.7 Cr, 8.34 Ni, 1.11 Mn, 0.02 P, 0.16 N, 0.11 C, and balance iron. Strips of 5 mil sheet were abraded through 4/0 polishing paper under purified kerosene. They were carefully cleaned before using (7). Depending on the amount of reaction, four specimen sizes and weights were used. The largest was 11.25 cm² in area and weighed 0.6831g while the smallest was 1.36 cm² in area and weighed 0.0820g.

Results

The results are presented in weight gain *vs.* time graphs. The weight gain is in micrograms per square centimeter and the time is in minutes. Although the oxide film is a mixture of oxides (8), we can estimate the thickness of the oxide by assuming the oxide to be Cr_2O_3 and by assuming a surface roughness ratio of unity. A factor of 60 is calculated to relate the weight gain to thickness in angstroms. An oxygen pressure of 0.1 atm is used for all of the experiments.

Both annealed and unannealed specimens were used. The annealed specimens were prepared by heating in a high vacuum system at a pressure of 9 x 10^{-6} mm Hg at 843°C for 2 hr and quenching. This treatment precipitates carbides and nitrides which could occur during normal oxidation at this temperature.

Oxidation at 500° and 600°C—unannealed specimens.—Figures 1 and 2 show the time courses of the experiments at 500° and 600°C. The oxide thicknesses and colors are given in Table I. No spalling of the oxide occurred on cooling the oxidized alloy to room temperature. After 6 hr of oxidation at 500°C, about 2.3 μg/cm² of oxide were formed. Since the room temperature oxide was not removed, the total oxide must include an additional 0.3-0.5 μg/cm². The reaction rate after 6 hr of reaction was of the order of 0.1 μg/cm² of oxide per hour at 500°C.

A plot of the weight gain squared against time shows a straight line between 2 and 6 hr of reaction time. A value of 1.67 x 10^{-16} $(g/cm^2)^2$/sec is calculated. No evidence was found for a transition in the kinetics of the reaction. We conclude that the reaction of 304 stainless steel with oxygen at 500°C is a slow reaction.

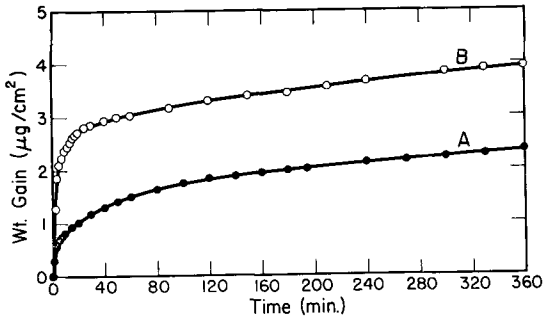

Fig. 1. Effect of temperature on oxidation of unannealed 304 stainless steel, abraded through 4/0, 7.6 cm of Hg of O_2; curve A, 500°C; curve B, 600°C.

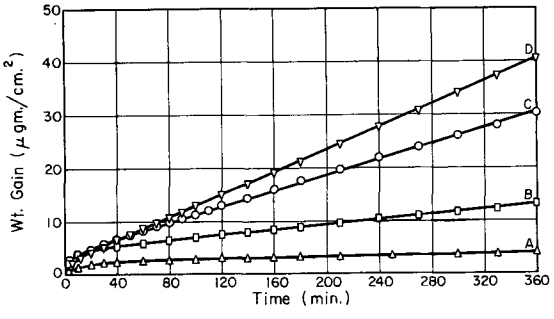

Fig. 2. Effect of temperature on oxidation of annealed stainless 304, abraded through 4/0, 7.6 cm of Hg of O_2; curve A, 700°C; curve B, 800°C; curve C, 850°C; curve D, 900°C.

Electron microscope observations on the edges of the specimens showed no evidence for oxide whiskers or platelets.

Oxidation at 700° and 1150°C.—Figures 2 and 3 show the time courses for the oxidation experiments over the temperature range of 700°-1100°C. Oxide thicknesses and colors are shown in Table I. None of the oxide films or scales spalled away from the metal on cooling to room temperature.

In this study we are particularly interested in transitions in the rate of oxidation and "breakaway" type of oxidation reactions. For this purpose we use

the parabolic rate law to interpret the rate data. This law states that the weight gain, W, depends on the time, t, by the equation $W^2 = At + C$. Here A is the parabolic rate law constant and C is a constant. The parabolic rate law based on the principles of formation and diffusion of ions or lattice defects has been the most successful rate law for explaining oxidation. Parabolic rate law plots are used to test for changes in the mechanism of reaction. Figures 4-8 show parabolic rate law plots of the 800°, 850°, 950°, 1050°, and 1150°C experiments. The first evidence for a transition in the rate of oxidation was found in the 800°C parabolic plot shown in Fig. 4. After the initial period of reaction, a good fit was obtained with the parabolic rate law for the thickness range of 5-9 $\mu g/cm^2$. An increase in slope was observed in the parabolic rate law plot above this thickness. A value of 5.83×10^{-15} $(g/cm^2)^2/sec$ was calculated for the pretransition thickness range parabolic rate law constant.

Deviations from the parabolic rate law are also observed in the 850°C plot as shown in Fig. 5. This deviation occurs after 70 min of reaction or at an oxide thickness of 9 $\mu g/cm^2$. A similar transition

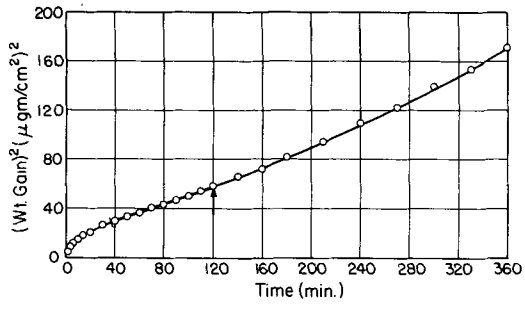

Fig. 4. Oxidation of stainless steel, 800°C, 7.6 cm of Hg of O_2; parabolic plot, abraded through 4/0; A = 5.83×10^{-15} $(g/cm^2)^2/sec$.

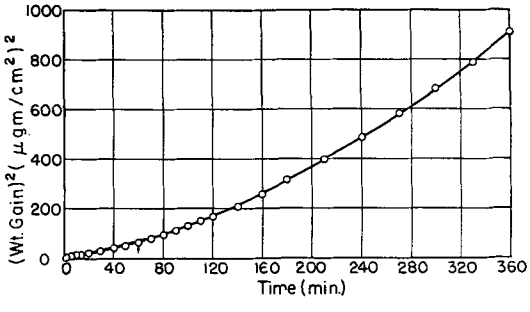

Fig. 5. Oxidation of stainless steel, 850°C, 7.6 cm of Hg of O_2; parabolic plot, abraded through 4/0; A = 1.79×10^{-14} $(g/cm^2)^2/sec$.

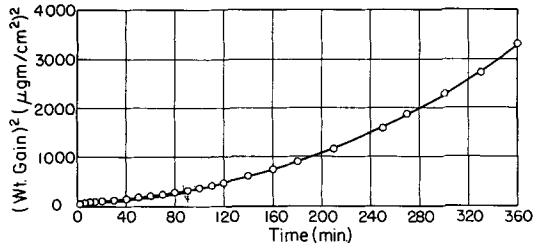

Fig. 6. Oxidation of stainless steel, 950°C, 7.6 cm of Hg of O_2; parabolic plot, abraded through 4/0; A = 2.78×10^{-13} $(g/cm^2)^2/sec$.

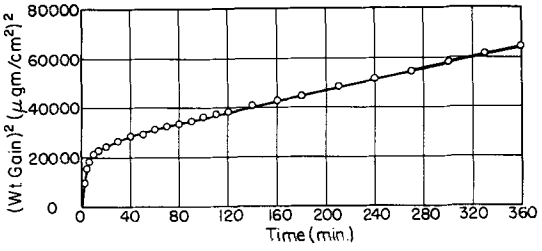

Fig. 7. Oxidation of stainless steel, 1050°C, 7.6 cm of Hg of O_2; parabolic plot, abraded through 4/0; A = 1.72×10^{-12} $(g/cm^2)^2/sec$.

thickness is found for the 900°C experiment. We conclude a transition occurs in the kinetics of the reaction for an oxide thickness of about 9 $\mu g/cm^2$. This transition thickness is the lowest we have observed for any metal or alloy. For the oxidation of chromium the first transition occurred at a thickness of 80 $\mu g/cm^2$.

Above 900°C it is not possible to observe the pretransition period of oxidation. The parabolic rate law plot of the 950°C experiment in Fig. 6 shows a continuously increasing slope. The initial value for the rate law constant is given in Fig. 6 and Table II. We interpret the changing value for the parabolic rate law constant as due to a change in oxide composition. The parabolic rate law of oxidation does not apply for the oxide composition range of 9-90 $\mu g/cm^2$. Instead the rate of oxidation follows the linear rate law.

Figure 7 shows a parabolic rate law plot for the 1050°C experiment. A straight line is found after the first hour of reaction.

A second transition is found to occur in the 1150°C parabolic rate law plot shown in Fig. 8. The rate law is observed to hold for the intermediate section of the plot. After 330 min of oxidation the rate law con-

stants increase. This increase is probably due to a vapor pressure effect which is discussed in a later section.

Temperature dependence.—To interpret the temperature dependence of the parabolic rate law constants A we use the simple form of the Arrhenius expression

$$A = Be^{-\Delta H/RT}$$

Here ΔH is the heat of activation of the rate-controlling mechanism, B is a constant, and R is the gas constant. ΔH is determined from the slope of a log A *vs.* $1/T$ plot. More elaborate equations may be used if the entropy terms are evaluated (9).

Table II shows a summary of the parabolic rate law constants for the annealed and unannealed samples. Pre- and posttransition values are given where possible. Figure 9 shows a log A *vs.* $1/T$ plot of the data.

Three straight lines are observed in Fig. 9. Curve DE gives the constants for the pretransition region. A value of 33,200 cal/mole for ΔH is calculated. The posttransition values are given by the line ABC. Line BC has about the same value for ΔH as line DE.

Point B shows a major change in the mechanism of oxidation. A heat of activation of 88,000 cal/mole is calculated.

We interpret the change in rate between line DE and line BC as due to a crystal structure transformation in the oxide system. Electron diffraction studies on a similar alloy by Hickman and Gulbransen (8) shows a crystal structure transformation occurring for this temperature range of oxidation.

Vapor pressure effect.—Figure 9 shows a drastic change occurs in the mechanism of oxidation at point B. We suggest that this change is due to the vapor pressure of the metals in the 304 stainless steel. We explained a similar change in the rate oxidation of chromium (1) at 900°C as due to the vapor pressure of chromium. At some temperature for all metals the rate of evaporation of metal into and through the oxide film acts to aid normal ion formation and transfer processes. Since all sides of the oxide crystals may be exposed in part to the metal vapor, a short circuit of the normal diffusion process is possible. However, if the oxide film is impervious to metal vapor, the metal transfer process may be limited. This occurs for oxide films on aluminum-iron alloys (4). Much smaller effects were observed for oxide films on simple chromium-iron alloys (4).

To test for the vapor pressure effect on 304 stainless steel we compare the rate of evaporation of metal from a clean surface of a 21.9 Cr-Fe alloy with the rate of oxidation calculated on the basis of chromium reacting. Due to the possibility of side reactions, such as decarburization, effecting the vapor pressure measurements, special alloys must be used. We have studied recently the vapor pressure of a clean 21.9 Cr-Fe alloy (4) both in the oxide-free condition and in the presence of an oxide film. Although this alloy differs in composition from the 8 Ni-18 Cr-74 Fe alloy, we feel that the two alloys do not differ appreciably in their vapor pressure curves since chromium is the metal vaporizing in each alloy.

Figure 10 shows a comparison of the rate of evaporation from an oxide-free surface of the 21.9 Cr-Fe alloy with the rate of oxidation of the 304 stainless steel. Below 1000°C the rate of oxidation is higher than the rate of evaporation. The two rates become equal at 1000°C, and above 1000°C the rate of oxidation is less than the rate of evaporation.

Since the oxide film is thick, the transition is not sharp. The effect of oxide films on the vapor pressure would act to lower curve A slightly.

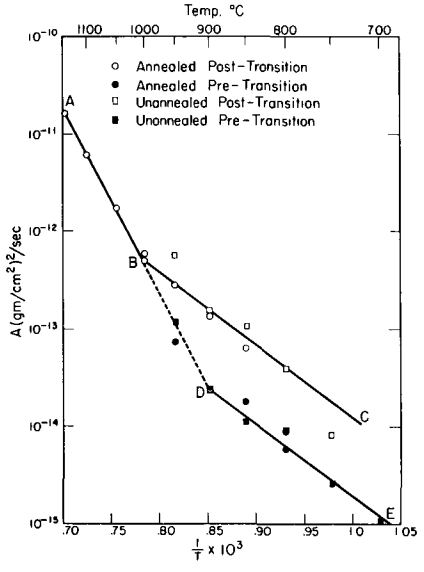

Fig. 9. Oxidation of 304 stainless steel. Log A *vs.* $1/T$. Curves A,B,C, posttransition; curves D,E, pretransition. ΔH_{AB} = 88,000 cal/mole.

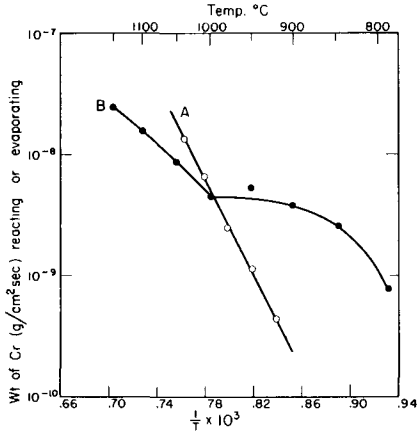

Fig. 10. Comparison rate of evaporation from clean 21.9 Cr-Fe alloy (curve A) with rate of oxidation of 304 stainless steel (curve B), log rate *vs.* $1/T$.

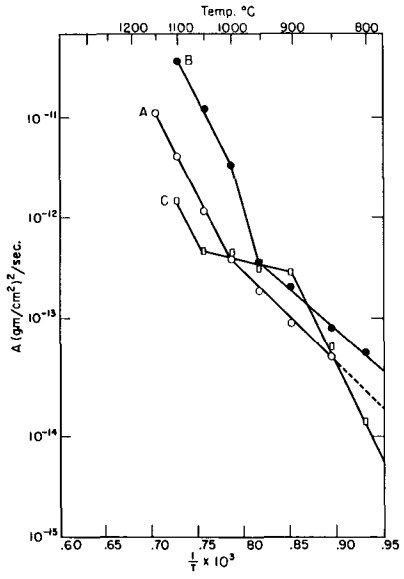

Fig. 11. Oxidation of stainless steel (A), chromium (B), Kanthal A_1 (C). Log *A* vs. 1/*T*.

Comparison with Kanthal Alloy.—Figure 11 shows a comparison of the parabolic rate law constants for Kanthal A_1 and chromium with the posttransition values for 304 stainless steel. Kanthal A_1 shows a transition in the rate of oxidation at 1050°C, 304 stainless steel at 1000°C, and chromium at 950°C. We have related all of these transitions to vapor pressure effects.

Since the aluminum oxide film is nearly impervious to the metal atoms the transition temperature is higher for Kanthal A_1. The effect of the Al_2O_3 film is shown by the nearly constant values for the parabolic rate law constants between 900° and 1050°C.

Aluminum has another favorable influence on the oxidation process. Aluminum in combination with iron and chromium forms oxides which are closely matched to the metal lattice. Thus, γ-Al_2O_3 and $FeAl_2O_4$ are both spinels which match closely the iron-iron spacings in the metal lattice.

Discussion

The effect of aluminum and nickel in chromium iron alloys can be considered from the electron configuration point of view. Aluminum can contribute one 3p electron to the unfilled 3d bands of iron and chromium with the result that aluminum is strongly bonded in the alloy. This is confirmed experimentally by the lowered chemical potential of iron and chromium in the alloy (4). Since nickel has a fraction of a 3d level unfilled, the bonding between nickel and iron and chromium is not as strong as when aluminum is added. Nickel is not expected to lower the chemical activity of iron and chromium to the same extent as aluminum.

Nickel forms a less stable oxide than aluminum. Therefore, solid phase reactions can occur in the oxide (10) which can lower the protective character of the oxide film. Although the initial rates of oxidation of stainless steel are low it would be expected that the oxide composition changes with time. Nickel oxide is also much more readily attacked by chlorides or acid vapors than aluminum oxide.

We conclude that both nickel and aluminum are good alloying elements to add in the chromium-iron series of alloys from a protection and corrosion point of view. The low permeability of the aluminum oxide film to iron and chromium atoms gives an alloy of high heat resistance. Nickel, on the other hand, gives an austenitic alloy of high strength with moderate oxidation resistance.

Growth of Halide Layers on Copper Single Crystals

A. Goswami

National Chemical Laboratory, Poona, India

ABSTRACT

Structures and orientations of cuprous halides formed on copper (111), (110), and (100) faces by reaction with halogen vapors at room temperature have been studied and the crystal growth process discussed.

Previous electron diffraction studies (1-3) on the growth of oxide or sulfide films on copper single crystals in air or sulfur vapor at various temperatures showed that these films were crystalline and had two-degree orientation with respect to substrate if the substrate temperature was high enough, but were amorphous when formed at room temperature. During the initial stage of their growth, the films consisted of cuprous compounds alone. If the growth continued for a sufficiently long time and the temperature was favorable, the top layers consisted entirely of cupric compounds either with two-degree orientation or in polycrystalline state with or without a preferred orientation. Similar reactions, however, at room temperature with halogen vapors or by anodic treatment in halide solutions, produced, on the other hand, crystalline cuprous halides even when the time of reactions was sufficiently prolonged (4-6). Since there has been little work on the growth of cuprous halide films or on their epitaxial relationship to the substrate a study has been made on single crystals of copper and the results compared with those obtained by anodic treatments.

Experimental

Samples of copper with (111), (110), and (100) faces were prepared by cutting pieces from a single crystal rod, grinding, surfacing with different grades of emery, etching in nitric acid, and finally electropolishing in phosphoric acid in a manner already described in previous papers (1, 7). The diffraction patterns (not shown) from these faces revealed that they were extremely smooth and nearly parallel to (111), (110), and (100) planes of the copper lattice. The samples were then exposed to vapors of iodine or bromine for a few seconds and immediately transferred to an electron diffraction camera (cold cathode type, 60 kv) and examined by the reflection method, in more than one azimuth. The crystals were again treated in halogen vapor and re-examined. Similar studies were also made on polycrystalline copper (spec. pure) disks.

For comparison, these crystals after etching and reelectropolishing were treated anodically (4-6) in KI or KBr solution in the presence of H_2SO_4 for a few seconds to half a minute and the surface layers examined by the diffraction technique in a similar way.

Results

Halide layers formed on copper crystals by progressive reactions with halogen vapors showed various interference colors, *viz.*, brownish orange, pink, golden yellow, etc., depending on the thickness of the layers; they finally became pale yellow accompanied by considerable roughening of the surface.

The diffraction patterns from the halide films generally consisted of spots and faint rings passing through these spots. With the rotation of the copper crystals around an axis normal to the electron beam direction, the spot patterns changed, thus indicating that the halide crystals grew epitaxially on the substrates. In other words, they developed two-degree orientations such that certain planes and axial directions of the halide crystals were parallel, respectively, to the substrate face and to an important direction lying in that face. The ring patterns were due to the formation of polycrystalline material. Arc patterns, which did not change even with the rotation of copper crystals, showed the presence of one-degree orientated halide crystallites which had a common axis parallel to one another or had a common plane, but otherwise were randomly disposed in space. Clarity or sharpness of patterns depended to a large extent on the crystal size. Hence with increase in crystal size the clarity was better. It was also noticed that sometimes with progressive reaction the spot pattern changed and ultimately became confused by the appearance of many new spots, no doubt due to the formation of new crsytals with different orientations.

Measurements of d_{hkl} values from rings as well as spots and also of their relative intensities agree with those of γ-forms of halides alone.

On Cu*(111) face.*—Cuprous iodide formed on this face yielded diffraction patterns (Fig. 1 and 2) consisting of spots and faint rings, when the electron beam was grazing along the <110> and <112> axes of the crystal, respectively. The appearance of 111

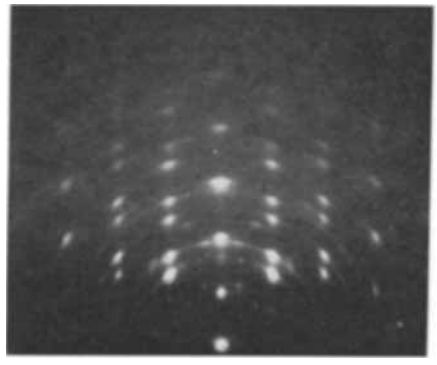

Fig. 1. 2-d {111} orientation of CuI; beam along <110>

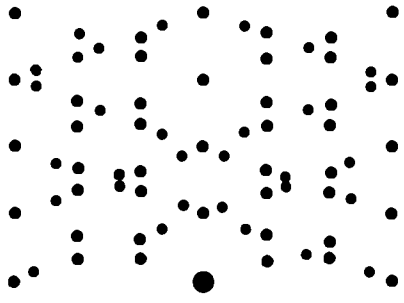

Fig. 5. Fig. 3 and 4 together

reflection and its higher orders in the plane of incidence for all azimuthal rotation of the crystal with respect to the beam, together with the fact that the spot patterns changed with the rotation of the crystal but repeated themselves after every rotation of 60°, clearly showed that the halide crystals grew epitaxially with a {111} orientation. The disposition of spots was such that <112> of cuprous iodide was parallel to <110> of Cu(111). Normally electron diffraction patterns from two-degree {111} oriented crystals would be symmetrical with the beam along <112> axis, and asymmetrical along <110>. The symmetrical nature of the diffraction patterns (Fig. 1 and 2) in both of the azimuths suggested that the deposit crystals consisted of parallel and antiparallel {111} orientations such that the electron beam was grazing along $[1\bar{1}0]$ and $[\bar{1}10]$ directions of the crystals, giving rise to symmetrical patterns. Figure 3 shows the patterns expected from such orientations.

A detailed consideration of the position of spots (Fig. 1), however, shows that a number of reflections (spots), *viz.*, 111 appearing approximately at 40°, 200 at 15°, 220 at 75°, 311 at 10° and 40°, and 422 at 52° from the plane of incidence, cannot be accounted for from Fig. 3. If, on the other hand, the halide crystals developed a two-degree {115} orientation, the positions of the spots are well explained, and also 115 spots would coincide with 333 reflection (spots) in the plane of incidence with the electron beam along <110> of the crystals (Fig. 4). Thus all these spots are well accounted for by the formation of crystals having both {111} and {115} orientations (Fig. 5).

It would seem unlikely, as pointed out before (8), that crystals would grow with an odd plane such as {115} parallel to a simple face such as (111). This orientation, however, could result from a single or multiple twinning process (8-10). Thus if an (111) orientated crystal twinned on its $(11\bar{1})$ plane, it would bring the $(\bar{1}\bar{1}\bar{5})$ plane of twinned crystals parallel to the initial (111) plane. In a similar way other orientation would result by multi-twinning process. This also explains the simultaneous presence of {111} and {115} orientated crystals. The faint spots at 1/3 or 2/3 of unit distance along a <111> direction are due to double diffraction as observed in many other cases (1, 10, 11).

Generally {111} oriented halide crystals had their <112> direction parallel to <110> of Cu(111), but sometimes they were azimuthally rotated by 30°, *i.e.*, the crystals grew with parallel orientations such that CuI <110>//Cu <110>.

Cuprous bromide also grew epitaxially in the same way as iodide, but the rate of reaction was much more rapid. The reaction with moist bromine vapor was similar to that for iodine or bromine.

On Cu(110) face.—On a Cu(110) face, dry iodine and bromine vapors formed halides which again developed a two-degree {111} orientation, but with their <110> axes parallel to <100> of Cu(110). Diffraction patterns were similar to Fig. 1 and 2.

In the presence of moist bromine vapor, however, halide crystals developed two-degree mixed {100} + {211} orientations such that $[0\bar{1}1]$ and $[01\bar{1}]$ of each were parallel to $[1\bar{1}0]$ of copper (similar to Fig. 6).

On Cu(100) face.—On a Cu(100) face, surface layers formed by reacting with iodine vapor yielded patterns consisting of spots and rings which became more distinct with increased time of reaction. The centered $\sqrt{2}$ type of rectangular patterns (Fig. 6) with 200 and higher orders of reflection in the plane of incidence, obtained when the electron beam was along the cube axis of the copper crystal, showed that the halide crystals grew epitaxially with {100}

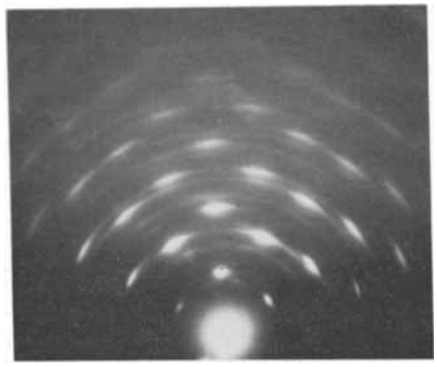

Fig. 6. 2-d {100} orientation of CuI; beam along <110> direction

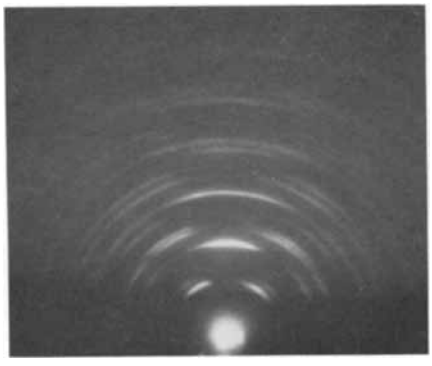

Fig. 7. 1-d {110} orientation of CuI

orientation, but with their axes azimuthally rotated by 45° with respect to the substrate crystal. The slight arcing of spots indicated that the crystals deviated from their mean position by a few degrees. There are indications that crystals had also developed a {111} twinned structure. Exposure to both dry and moist bromine vapors produced similar crystal orientations.

On polycrystalline copper.—The reaction products on polycrystalline copper were polycrystalline in nature, but they sometimes exhibited a strong one-degree {110} orientation (Fig. 7) depending on the time of reaction. The formation of polycrystalline films, even on single crystals, was facilitated with longer time of reaction, and ultimately they developed again a one-degree {110} orientation.

The texture of these crystals was also studied by the electron microscope. The technique used was to expose copper grids (≅400 mesh) to iodine vapor (very low concentration) for 10-16 hr after which time most of these grids were covered with iodide crystals. The growth was heavy and often all the holes in the grids were filled. Under a strong electron beam, the crystals melted quickly, and hence it was often difficult to photograph them in their original shape. The crystals appeared to be flaky, although sometimes needles were also observed (Fig. 8 and 9). By breaking the crystals in a Mickel microshaker it was possible to obtain good micrographs (Fig. 10).

Anodic treatment.—Copper samples treated anodically in bromide or iodide solution also formed cuprous halide crystals with similar orientations, although sometimes the halide crystals were mixed with Cu_2O crystals as reported earlier (5).

The crystal orientations obtained on different faces of copper together with the percentage lattice misfit are shown in Table I.

Discussion

The halide layers formed were always cuprous in type, and no trace of cupric halide was observed. The intensities of all reflections, spot or otherwise, were consistent with the zinc blende type of structures (T^2_d).

It is, however, known that cuprous iodide and bromide exhibit polymorphism (12). The normal γ-forms (cubic $a_o = 6.051$Å and 5.6905Å, respectively, for CuI and CuBr) change to β varieties (h.c.p. $a_o = 4.31$Å, $c_o = 7.09$Å, $c_o/a_o = 1.646$ for CuI at 369°C, and 4.06Å, 6.66Å, 1.625 for CuBr at 430°C) and finally to α modifications ($a_o = 6.15$Å f.c.c. at 407°C for CuI and 4.56Å b.c.c. at 480°C for CuBr). In the present experiments only γ phases were de-

* 1-d = one-degree orientation.

tected in the top surface layers, although their formation lower down could not be ruled out.

It is thus seen that at room temperature the halides formed on single crystals of copper were crystalline even in very thin layers, whereas cuprous oxide and sulfide were not in that state (1-3). This difference appears to be related to the high mobility of halides which facilitates the epitaxial growth even at room temperature compared to oxide or sulfide (m.p. of CuI, CuBr, Cu_2O, and Cu_2S are 605°, 500°, 1232°, and 1100°C, respectively), since mobility at a particular temperature below the melting point is greater, the lower the melting point (13).

Epitaxially grown halides often developed more than one azimuthal orientation on the same face of a copper crystal (Table I), and hence the tolerable lattice mismatch varied. It is seen that the lattice misfit, which may be defined by $100(b-a)/a$, where a and b are the corresponding lattice spacings in the substrate and deposit, respectively, could be as high as +68% without affecting the epitaxial growth. It has often been suggested in the literature that a good fit is an *a priori* condition for epitaxial growth of crystals. Our work and also that of other (14) clearly shows that crystals can grow epitaxially on the substrate even when there is a considerable misfit and even in cases where the distribution of atoms in the contact planes is very dissimilar, *viz.*, in the development of two-degree {103} and {203} orientations of Cd or {205} and {101} of Zn on Cu(110) and (100) faces (4) and {100}, {203}, etc., of Zn on (100) of NaCl (15). It may only be said that the lower the lattice misfit, the greater is the probability that the deposit will grow thicker while remaining epitaxial. It may be pointed out here that when the lattice misfit is more than 50%, the effective mismatch is much less since the spacing between 2 or 3 atoms of one is often nearly equal to that of 3 and 4 of the other. Thus a misfit of +68% of CuI on Cu(111) is nearly equal to −16% (effective) (Table I).

The change of crystals from a two-degree orientation type to polycrystalline but random, and finally to a one-degree orientated type showed that the orientation of the surface layers was gradually changing with the reaction time. This appears to be related to the migration of copper ions from inside in an outward direction to react with halogen ions (atomic radius of $Cu^{1+} = 0.96Å$, $Br^{1-} = 1.96Å$), as in the case of the growth of Cu_2O and CuO layers (1). An alternate suggestion that the halides grow by the diffusion of halogen ions inward to the copper surface may not be ruled out completely, although their ionic sizes are unfavorable. Preferential grain boundary diffusion may however facilitate a process of this kind.

Manganese-Activated Cadmium Pyrophosphate Phosphors

R. C. Ropp

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

The effects of preparation on absorption and excitation properties have demonstrated that $Cd_2P_2O_7$:Mn is a host-sensitized phosphor whose efficiency to 2537Å becomes appreciable only when a step involving refiring in a reducing atmosphere is employed. The experimental data allow an insight into the nature of the luminescent center in $Cd_2P_2O_7$:Mn.

The combination of manganese with cadmium phosphates to form luminescent systems is by no means new, and many authors have reported on such phosphors. $Cd_2P_2O_7$:Mn was described by Williams (1) as an efficient cathode-ray excitable phosphor. Fonda (2) described tribasic cadmium orthophosphate phosphors activated by manganese. Other investigators have described various modifications of the cadmium phosphate phosphors including fluorophosphate doubly activated by Pb and Mn (3, 4). Smith and Power (5), as well as Zelinskii *et al.* (6), described tribasic cadmium and zinc orthophosphates. The references to cadmium chlorophosphate phosphors are too numerous to mention. However, none of these authors recognized the effect of reduction on excitation properties, particularly for $Cd_2P_2O_7$:Mn.

The present work will describe a phenomenon whereby reduction of the matrix produces host-sensitization in $Cd_2P_2O_7$:Mn. A model will be postulated to show the nature of the luminescent center and the absorption properties as a function of preparation.

Method of Preparation and Measurement

The phosphors were easily prepared according to the following reactions:

1. $2CdNH_4PO_4 \cdot H_2O + 0.04\ MnNH_4PO_4 \cdot H_2O \xrightarrow{\Delta} Cd_2(P_2O_7)_{1.02}:Mn_{0.04} + 2.04NH_3 + 3.06\ H_2O$
2. $2CdNH_4PO_4 \cdot H_2O + CdO_2 + 0.04\ MnNH_4PO_4 \cdot H_2O \xrightarrow{\Delta} Cd_3(PO_4)_{2.04}:Mn_{0.04} + 2.04\ NH_3 + 3.06\ H_2O + 0.49\ O_2$

One could prepare $Cd_2P_2O_7$:Mn and $Cd_3(PO_4)_2$:Mn and refire with a volatile chloride to form cadmium chloroapatite:

3. $3Cd_3(PO_4)_2:Mn + CdCl_2 \xrightarrow{\Delta} 2\ Cd_5Cl(PO_4)_3:Mn$
4. $3Cd_2P_2O_7:Mn + xCdCl_2 \xrightarrow{\Delta} 2Cd_{3+0.5x}Cl(PO_4)_3:Mn + (X-1)Cl_2$

The use of HCl gas as a firing atmosphere enabled a further clarification of the gross reactions:

5. $Cd_3(PO_4)_2:Mn + 2HCl \xrightarrow{\Delta} Cd_2P_2O_7:Mn + CdCl_2 + H_2O$
6. $Cd_2P_2O_7:Mn + HCl \xrightarrow{\Delta}$ no change
7. $3CdNH_4PO_4 \cdot H_2O + 2CdO_2 + HCl \xrightarrow{\Delta} Cd_5Cl(PO_4)_3 + 3NH_3 + O_2 + 5H_2O$

Thus, $Cd_2P_2O_7$ was the stable structure once the matrix was formed in the absence of halogen. The apatite was stable otherwise.

Considerable effort was made to obtain $CdNH_4PO_4 \cdot H_2O$ and not $Cd_5H_2(PO_4)_4(H_2O)_4$ (7). The former gave a nearly stoichiometric $Cd_2P_2O_7$, whereas the latter gave $Cd_3(PO_4)_2 \cdot Cd_2P_2O_7$, a product containing 1.25 Cd atoms per 1.00 P atom. The similarity in x-ray diffraction patterns may lead to mistaken identity, particularly for mixtures containing small amounts of $Cd_5H_2(PO_4)_4(H_2O)_4$.

Manganese may be added to the phosphor mix in several forms, but was best added as $MnNH_4PO_4 \cdot H_2O$. CdO_2 (8) was preferred because of the ease in obtaining a purified material of high reactivity which gave a product of specific composition (CdO) when heated.

Measurements followed those described in a previous paper (9).

Experimental Results

Phosphors efficient to 2537Å irradiation were produced by prefiring in air to form the matrix and refiring in a reducing atmosphere. These results are shown in Table I. Note that refiring in a reducing atmosphere markedly improved the plaque response, but that refiring in air or N_2 did not. Thus, the effect could not be attributed to refiring alone, but to the combination. Prefiring in N_2-H_2 (40%) gave a black inert mass. The effect of firing atmosphere was pronounced, particularly for the pyrophosphate. If $Cd_2P_2O_7$:Mn was refired in HCl, bright phosphors were obtained, but in the case of $Cd_3(PO_4)_2$:Mn, HCl converted it to $Cd_2P_2O_7$:Mn according to reaction 5.

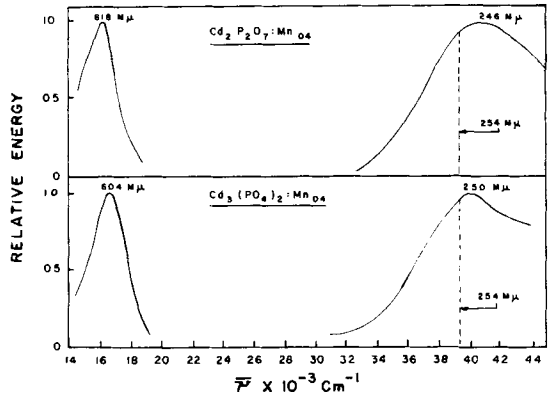

Fig. 1. Spectral properties of some cadmium phosphate phosphors

Table I. Effect of refiring

Nominal phosphor composition	Atmosphere: Prefiring	Atmosphere: Refiring	X-ray structure	Lum. color (2537Å excit.)	% Red plaque (*vs.* Cd borate std.)
$Cd_3(PO_4)_{2.10}$: $Mn_{0.04}$	Air	—	$Cd_3(PO_4)_2$	Dull pink	10
	N_2	—	$Cd_3(PO_4)_2$	Dull pink	19
	Air	Air	$Cd_3(PO_4)_2$	Dull pink	18
	HCl	—	Apatite	Bright orange	83
	Air	N_2	$Cd_3(PO_4)_2$	Dull pink	15
	Air	HCl	$Cd_2P_2O_7$	Bright red	67
	Air	N_2-H_2 (40%)	$Cd_3(PO_4)_2$	Dull pink	35
$Cd_2(P_2O_7)_{1.02}$: $Mn_{0.04}$	Air	—	$Cd_2P_2O_7$	Dull pink	15
	N_2	—	$Cd_2P_2O_7$	Dull pink	9
	HCl	—	Apatite	Orange	70
	Air	Air	$Cd_2P_2O_7$	Dull pink	20
	Air	HCl	$Cd_2P_2O_7$	Bright red	52
	Air	N_2	$Cd_2P_2O_7$	Dull pink	22
	Air	N_2-H_2 (40%)	$Cd_2P_2O_7$	Bright red	51

The emission properties of these phosphors were identical to those presented by previous authors (1, 4) for cathode-ray excitation (see Fig. 1). It was in the excitation and absorption spectra that differences were observed. Since $Cd_2P_2O_7$:Mn was by far the more efficient, the present discussion will be limited to this phosphor.

Effect of firing atmosphere.—Measurement of the excitation bands as a function of preparation is given in Fig. 2 for the $Cd_2P_2O_7$:Mn phosphors shown in Table I. (The discontinuity in the curves is the result of increasing the instrument gain at 34.0 x 10^3 cm^{-1} before proceeding to the lower energy absorption peaks.) When prefired under oxidizing or neutral conditions (air or N_2), the excitation band peaked at 2370Å and was relatively narrow, whereas on refiring under reducing conditions (N_2-20% H_2), the peak wavelength shifted to 2460Å and the 2537Å response increased markedly. The effect was not due to refiring alone since the phosphor refired in N_2 only did not change in its excitation spectrum. All spectra, and particularly the reduced phosphor spectrum, showed evidence of low level excitation spectra composed of several narrow bands in the near-ultraviolet and visible regions in addition to the broad excitation band in the higher energy region. The former have been termed edge-absorption bands (10), due to Mn^{+2}.

Figure 3 shows the spectral properties of $Ca_2P_2O_7$:Mn and $Sr_2P_2O_7$:Mn. Although these phosphors were previously said to be excited only by cathode rays (11), further reduction produced some excitation bands in the near-ultraviolet. $Zn_2P_2O_7$, $Mg_2P_2O_7$, and $Ba_2P_2O_7$, by contrast, were not found to form ultraviolet excitable phosphors even when the matrix was refired repeatedly in a reducing atmosphere. The excitation bands in $Ca_2P_2O_7$:Mn and $Sr_2P_2O_7$:Mn phosphors are due directly to energy absorption in the Mn^{+2} activator center and may be compared to the Mn^{+2} absorption bands in known phosphors such as Zn_2SiO_4:Mn^{+2} (10).

Effect of manganese.—Variation of manganese changed the relative response to 2537Å radiation, but did not shift the emission peak wavelength of $Cd_2P_2O_7$:Mn from 6180Å.

The relative plaque brightness as a function of Mn content and firing is given in Fig. 4. Note the large change in response on reduction of the preformed matrix. The plaque response to 2537Å irradiation increases to 8 mole % Mn, remains essentially constant to 20 mole % Mn and decreases beyond that

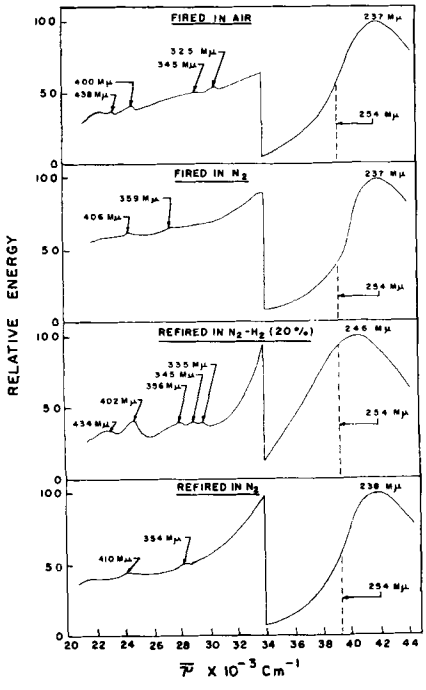

Fig. 2. Effect of firing atmosphere on excitation spectra of $Cd_2P_2O_7$:Mn_{04} phosphor.

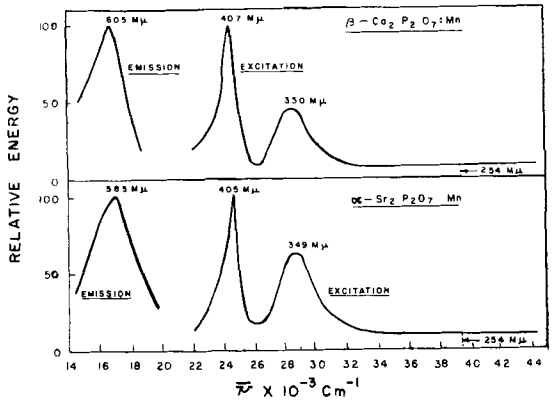

Fig. 3. Spectral properties of manganese-activated alkaline-earth pyrophosphates.

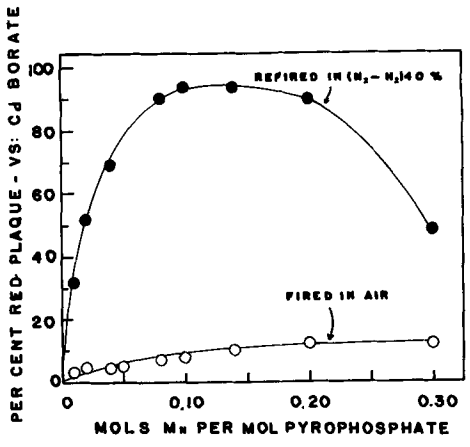

Fig. 4. Effect of manganese concentration on efficiency of $Cd_2P_2O_7$:Mn phosphor.

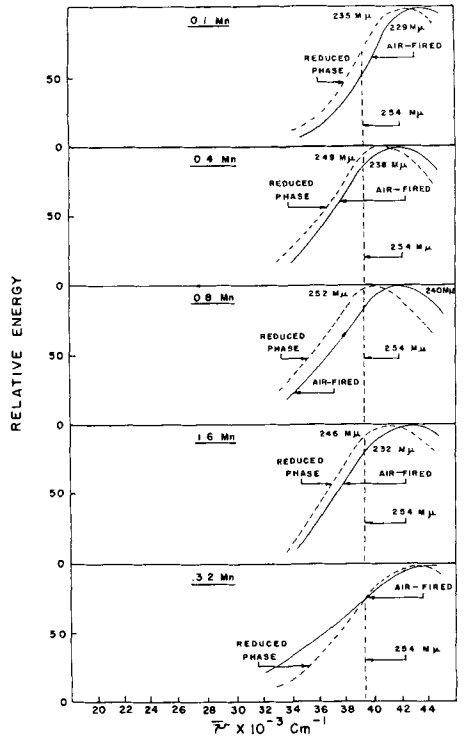

Fig. 5. Excitation spectra as a function of preparation conditions

concentration. It was further instructive to determine the effect of preparation atmosphere as a function of manganese on excitation spectra (see Fig. 5). In all cases, the excitation peaks are shifted toward lower energy by the reduction step and, in addition, these peaks shift with Mn content. However, when a concentration of 0.32 mole Mn is reached, a decided decrease in brightness was noted as reflected in the change in excitation spectra. The shift of peak wave number due to reduction was approximately constant irrespective of Mn content.

In order to establish that Mn was the primary activator, an analysis was made of the components and phosphor (see Table II). No other elements were present.

Reversibility.—The effect of reduction on response to 2537Å was reversible, and a phosphor which was efficiently excited lost brightness when reheated in air. This effect was a function of Mn content. One could heat and reheat the phosphor $Cd_2P_2O_7$:Mn alternately in an oxidizing or reducing atmosphere and change the response to 2537Å radiation providing the sintering point was not reached with consequent degradation of the structure.

Table II. Spectrographic analysis of components

	Mn	Impurities in ppm (Spec. Qual.) Ca	Mg	Cu	Fe	Ni	Sn	Sr	Al	Si
$Cd_2P_2O_7$:Mn	29,600	500	—	0.5	5	5	50	50	—	—*
$CdNH_4PO_4 \cdot H_2O$	0.5	500	50	0.5	5	—	—	—	5	5
$Cd_2P_2O_7$	0.5	500	50	0.5	5	—	—	—	5	50*

* Fired in a silica crucible.

Unactivated $Cd_2P_2O_7$.—If $Cd_2P_2O_7$ was formed from $CdNH_4PO_4 \cdot H_2O$ by prefiring at 1800°F in air and then subjected to refiring in a 40% H_2-60% N_2 atmosphere, a phosphor was produced as shown in Fig. 6. Although the brightness was low under 2537Å excitation, the phosphor responded to the higher energy wavelengths. Chemical analysis of the Mn present in this phosphor gave a value of <0.0001% or 1 ppm. Note that the absorption band is similar to the excitation band.

The matrix, $Cd_2P_2O_7$, exclusive of Mn^{+2}, possessed a high-energy excitation band. This is the fundamental absorption band for the matrix. The incorporation of Mn^{+2} into $Cd_2P_2O_7$ to form $Cd_2P_2O_7$:Mn did not change the fundamental absorption band, as shown in Fig. 7. The absorption or excitation band shifted with reduction, when Mn was present, to a greater

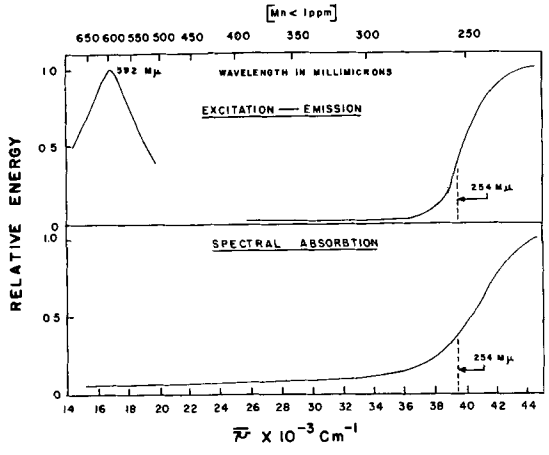

Fig. 6. Spectral properties of unactivated $Cd_2P_2O_7$

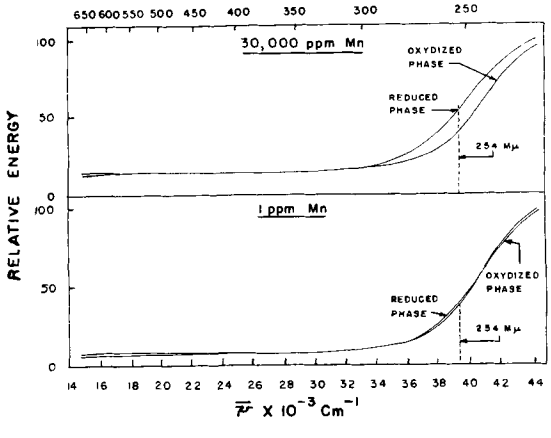

Fig. 7. Spectral absorption of $Cd_2P_2O_7$:Mn phosphor

extent than in its absence. The position of the excitation band also changed as a function of the Mn content and the shift was accentuated by reduction of the matrix (see Fig. 5). Reduction of the matrix increased the 2537Å absorption markedly in the phosphor containing 30,000 ppm Mn, but little in that containing 1 ppm Mn. In contrast, the matrices, $Ca_2P_2O_7$ and $Sr_2P_2O_7$, did not possess the broad excitation band (Fig. 3) at the higher energies (~2250Å), and therefore incorporation of Mn^{+2} did not produce 2537Å excitable phosphors.

Mn^{+2} as a luminescent center.—The spectroscopic functions of Mn^{+2} are well known. The ground state is $^6S_{5/2}$ and the four excited states are $^4G_{5/2}$, $^4D_{5/2}$, $^4P_{5/2}$, $^4F_{5/2}$, in order of ascending energy, for the free ion. In the presence of a crystal field, a d^5 ion such as Mn^{+2} has the symmetry $^6A_{1g}$ in a weak octahedral field. The configuration d^5 is exceptional in that no spin-allowed transitions are to be expected, since the ^6S ground state is not split significantly by the field (12), whereas the excited states are split, depending on the strength of the field. Weak absorptions are expected corresponding to the sextet-quartet transitions. It is generally accepted that yellow to red emission is indicative of Mn^{+2} in an octahedral site, whereas green emission is associated with Mn^{+2} in a tetrahedral site. However, in the absence of specific structure data for $Cd_2P_2O_7$, such an assumption would be illusory since the determination of the effect of crystalline field on the luminescent processes of Mn^{+2} presupposes a knowledge of site symmetry.

A long decay is characteristic of Mn^{+2} emission and probably arises from the spectroscopically forbidden transition, $^4G \rightarrow {}^6S$. Since $Cd_2P_2O_7$:Mn also possesses a long decay, it is logical to assume that the energy transition is identical since the emission is typical of Mn^{+2} as an activator. Coupled with the marked similarity in diffraction pattern between $Mn_2P_2O_7$ and $Cd_2P_2O_7$ (of which there is but one structure each), the data indicate that the luminescent center is composed of Mn^{+2} in a cationic site.

Discussion

The specific effect of reduction is difficult to assess since there are several end-results which could be attributed to reduction. Before discussing these, it would be well to summarize the observations made:

1. The matrix $Cd_2P_2O_7$, exclusive of Mn^{+2}, possessed a high-energy, stimulable excitation band. This is the fundamental absorption band for the matrix. The incorporation of Mn^{+2} into $Cd_2P_2O_7$ to form $Cd_2P_2O_7$:Mn did not change the fundamental absorption band, although a shift was observed with Mn content.

2. The equivalence between the absorption-excitation band of $Cd_2P_2O_7$ and the high-energy excitation band of $Cd_2P_2O_7$:Mn leads to the conclusion that $Cd_2P_2O_7$:Mn is a host-sensitized phosphor in which matrix absorption of radiant energy precedes fluorescence.

3. $Ca_2P_2O_7$:Mn and $Sr_2P_2O_7$:Mn are not host-sensitized. The excitation peaks are due to transitions in the Mn^{+2} activator.

4. Reduction of the matrix following formation shifts the excitation peak wave number to lower energy. Absorption bands due to Mn^{+2} are also observed.

5. The shift in peak wave number due to reduction is obtained only in the presence of manganese and is constant at each Mn^{+2} content.

6. The position of the excitation band is dependent both on Mn^{+2} content and reduction.

The logical conclusion to be drawn is that reduction simply increases the manganous ion concentration which causes a shift of the host lattice absorption edge. This explanation was first demonstrated for willemite by Kroeger (10). The data in Fig. 4 and Fig. 5 and observations 5 and 6 are thus explained. A relevant extension of this conclusion would include the role of the matrix, particularly since the host-lattice absorption edge is involved and since the experimental data indicate that host sensitization takes place. It is unlikely that the broad absorption band can be attributed to the manganese center alone.

If the effect were due entirely to the presence and number of Mn^{+2} activator centers, then one would expect the broad absorption band to be due to (*a*) the manganese center, or (*b*) the manganese center as affected by the lattice, that is, a manganese-lattice interaction. However, the broad absorption band cannot be due to transitions in the Mn^{+2} atom itself because of the edge absorption bands observed in the same spectra (Fig. 2), which are comparable to those of Mn^{+2} in $Ca_2P_2O_7$:Mn and $Sr_2P_2O_7$:Mn. Therefore, the possibility remained that the effect could be caused by an increase in the number of Mn^{+2} centers as well as an increase in the host-lattice coupling. This would give rise to a band whose width would increase or decrease with temperature.

One would then expect in the case of the comparable $Ca_2P_2O_7$:Mn and $Sr_2P_2O_7$:Mn phosphors that reduction should cause the appearance of a broad high-energy excitable band denoting that the effect of reduction was to increase the lattice-coupling of the Mn^{+2} center with its lattice surrounding. Although the position of this broad absorption peak would not be expected to be exactly at the same energy in $Ca_2P_2O_7$ or $Sr_2P_2O_7$, it should be close if the broad absorption band did arise only from the Mn^{+2} center, and not from the matrix, as in $Cd_2P_2O_7$:Mn.

Since it has been demonstrated that reduction does not result in broad absorption bands in these other phosphors, but only narrow bands directly attributable to Mn^{+2}, one can conclude that absorption is a function of both Mn content and reduction, but only in the presence of cadmium. Thus, it is probable that absorption by the matrix is involved rather than absorption in the manganese centers alone, and that host-sensitization occurs (observations 1 and 2).

One is then left with the conclusion that reduction affects both the matrix and the activator, Mn^{+2}. The effect cannot be chemical in nature since only changes in optical spectra are observed and no chemical changes were noted in the materials so treated, as determined by x-ray and infrared analysis.

Since reduction has an effect on the lattice as determined by absorption measurements, it is, perhaps, more logical to assume that the effect is electronic in

Table III. Spectroscopic levels for various ions

Atomic species	No. of Electrons	Transition	State Ground	State Excited
Mn III	23	$3d^5 \leftrightarrow 3d^4 3d^*$	$^6S_{5/2}$	$\leftrightarrow {}^4G_{5/2}$

* Excited state.

nature. Since host-sensitization requires transport of energy by other than movement of charge, a study of energy transport processes within the crystal is applicable.

The theory of impurity-sensitized luminescence as developed by Dexter (13), and independently by Botden (14), is applicable to the present case. Impurity-sensitized luminescence refers to the luminescence mechanism whereby energy is absorbed in one type of center (the sensitizer) and emission occurs in a different type of center (the activator). The mechanisms involved in the transport and transfer of excitation energy from the absorbing to the emitting center are of particular concern.

For the $Cd_2P_2O_7$:Mn system, it is interesting to compare the electronic spectroscopic transitions which may be involved. These data are given in Table III, taken from ref. (15).

The last four species in Table III represent mercury-like ions which are known sensitizers as shown by Williams (16) and Seitz (17). In regard to the Cd III species, note that the transition to the excited state is a spin forbidden transition much like that of the activator center (Mn III). The electronic $d^{10}s$ configuration of the cadmium II species is similar to that of known sensitizers and involves a spectroscopically allowed transition. Thus, the effect of reduction could be assigned to the localization of an electron in the vicinity of a Cd^{+2} atom to form the spectroscopic species, Cd II:

$$Cd^{+2} + e^- \rightarrow (Cd)^+$$

This equation is meant to imply that an electronic defect exists which utilizes the modified energy levels of the ion. Thus, the presence of Cd^+ could lead to sensitization as proposed in Table IV. The resonance-exchange mechanism is applicable for the Cd^+ (II) species, but exchange would not be expected to occur between Cd^{+2} sites, since it is recognized that the strength of an electric quadrupole (qq) transition is weaker by a factor of 10^{-7} than that of an electric dipole (dd) transition (12). Thus, for the propagation of energy in both the oxidized and reduced phosphors, the following mechanism is possible as shown in Table IV. (The double-headed arrows denote the resonance exchange mechanism.)

Theoretically, one would expect, for Cd^{+2}, a very weak interaction only at nearest-neighbor sites between cadmium and manganese atoms, and the corresponding luminescent efficiency should be very low as is observed experimentally. In the reduced form, Cd^+(II), the transitions are allowed (S → P), and therefore the response to excitation should be much higher.

The formation of such a species is not entirely without basis since it is well known that x-ray irradiation of alkali halide crystals containing Ca^{++}, Sr^{++}, or Ba^{++} distributed in the cationic sites will form so-called Z centers, which, according to Seitz (18), involve electrons trapped by the alkaline-earth ions at the cationic sites. The spectral characteristics of these centers are comparable to the free Ca^+, Sr^+, or Ba^+ ions. Furthermore, Lushchik and Lushchik (19) have studied the absorption excitation and emission spectra of various homologous ions in alkali halides which included Cd^+.

The shift in absorption peak due to reduction is attributed to formation of the Cd^+(II) species, and the dependence of peak absorption energy on manganese content is attributed to formation of Cd^+(II)-Mn^{+2} pairs. It is unfortunate that specific structure data are not available so that a more quantitative estimate could be obtained of the luminescent center.

It is apparent that reduction has an effect on the energy gap of $Cd_2P_2O_7$, and a possible explanation would be the injection of carriers in the valence band with consequent effects on resistivities as well as excitation energies. Perhaps photoconductive or Hall-coefficient measurements might clarify this matter.

Acknowledgment

The author is indebted to Dr. C. W. W. Hoffman for x-ray measurements, to H. D. Layman and J. E. Webster for some of the preparations, and to Dr. J. S. Smith for valuable discussions.

Manuscript received May 26, 1961; final revised manuscript received March 16, 1962. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Interface between Germanium and a Purified Neutral Electrolyte

W. H. Brattain and P. J. Boddy

Bell Telephone Laboratories, Murray Hill, New Jersey

ABSTRACT

Measurement of the differential capacity of the interface between germanium (100) and M/10 K_2SO_4, phosphate buffered to pH 7.4, yields data indicating that only the capacity of the semiconductor space charge region is observed. Analysis of the data yields the simple relationship for distribution of potential

$$\psi_s - \frac{kT}{e} \ln \lambda = V_E + K$$

where K is a constant for a given condition at the interface. Surface recombination velocity is found to be close to zero. This, coupled with the absence of capacity additional to the space charge region, indicates the absence of fast surface states under these conditions. Measurement of the surface conductivity of germanium as a function of surface potential does not agree with theory but is reproducible.

Measurements of the electrical properties of germanium surfaces in gaseous ambients have shown a marked dependence of these properties on the immediate history of the sample and the nature of the ambient. It is inferred that the variations are due either to trace impurities deposited on the surface during etching (1) or other cleaning and handling procedures, interaction with the ambient (2), or to physical defects in the surface (*e.g.*, emerging dislocations, steps, etc.) developed in different ways by different chemical environments. The variation in the observations precludes the interpretation that the properties are entirely those of the surface of a single crystal of germanium *per se*.

The object of the present work was to seek relationships between the chemical and electrical properties of such surfaces.

Recent investigations of the semiconductor solution interface have yielded detailed information on the electrical properties of both zinc oxide (3) and silicon (4). To the present time, with the exception of the work of Bohnenkamp and Engell (5), the potentially fruitful area of the germanium-electrolyte interface has been little studied from this point of view, although the basic electrochemistry of germanium is fairly well understood (6).

This paper describes some initial experiments on the electrical properties of germanium surfaces in contact with aqueous solutions. It has been found that in a properly purified solution of K_2SO_4 a germanium surface can be obtained free of fast surface states, *i.e.*, having no additional capacity over that of the space charge layer and no measurable decay of added carriers over and above body recombination.

Experimental

General.—The experiments were conducted in a Pyrex glass cell (shown schematically in Fig. 1) consisting of two compartments separated by a salt bridge containing a porous plug. The larger compartment contained the germanium electrode, which was connected to ground, and two large area plati-

num gauze electrodes connected to external circuits through 0.47 μfd capacitors. A calomel electrode was connected through a second salt bridge and the germanium electrode potential measured on a high impedance (2 x 10^9 ohm) millivoltmeter. Stirring was achieved either by rotating the germanium electrode, or by means of a magnetically operated, Teflon enclosed stirring bar in the solution. The other compartment contained a third large area platinum gauze electrode connected directly through a high-impedance current source to ground. The atmosphere above the solution was purified nitrogen or helium. Provision was made for illuminating the germanium electrodes through windows set into the bottom and side of the cell, but unless otherwise stated the experiments were carried out in the dark. The temperature throughout was close to 25°C.

Electrodes.—Germanium electrodes were of two types. The simpler ones were either square (1-2.5 cm on a side) or circular (1 cm diameter) in cross section and 1-2 cm thick. Electrical contact was made either by rhodium plating one face and holding the electrode by vacuum onto a stainless steel chuck or by attaching a platinum wire with a solder containing indium. In the latter case the platinum wire was pulled through a glass tube until the back of the electrode was firmly against the end of the tube, which was then filled with paraffin wax which had been boiled for several days in 1M H_2SO_4, 1M KOH, and finally several changes of distilled water. The electrodes were not masked. To ensure a constant superficial area exposed to the solution for a given electrode in different experiments the following procedure was used. The adjustable electrode holder was lowered into the solution until contact was made, and by visual inspection the lower surface of the electrode was aligned with the solution surface. The electrode was then lowered an arbitrary 0.19 cm further into the solution.

The second type of electrode was more complex and requires special description. It takes the form

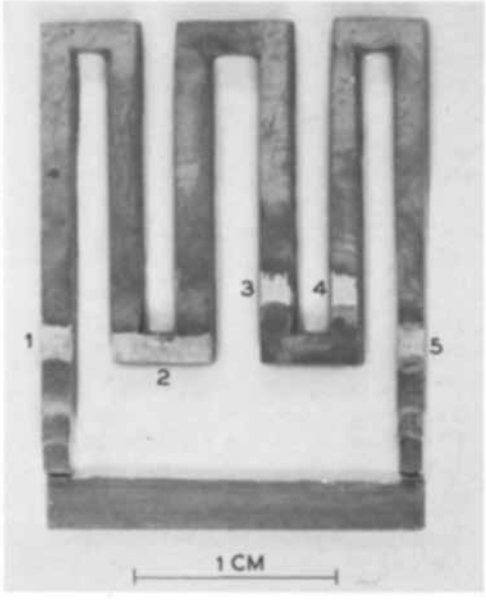

Fig. 2a. Germanium bridge. The scale is in centimeters

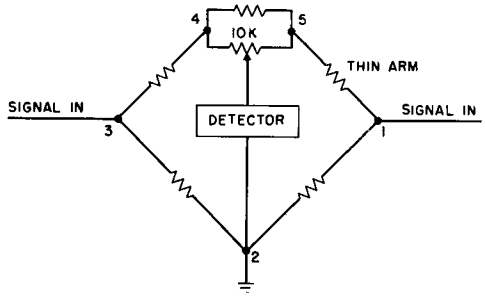

Fig. 2b. Electrical schematic of germanium bridge

of a bridge cut from a slice of single crystal germanium and is illustrated in Fig. 2a and shown schematically in Fig. 2b. The bridge had five contacts, the active arm being between 1 and 5. The other arms, which were much thicker, were not etched, their surfaces being left in a lapped or sandblasted condition making them insensitive to ambient changes. Contact to the bridge was by means of soldered platinum wires. During an experiment the thin portion of arm 1-5 was completely immersed, contacts 1 and 5, however, being kept out of the solution. The major advantage of the bridge is that it is internally temperature compensated provided there are no temperature differences in the bridge itself.

The arms were designed so that if either d-c or a-c power was applied between 1 and 3 a detector would read null between 2 and some point (x) between 4 and 5. This point was determined by adjustment of a calibrated 10,000 ohm Helipot connected between 4 and 5.

The condition for balance is

$$R_{12}R_{23}^{-1} = R_{1x}R_{x3}^{-1} = \beta \qquad [1]$$

where R_{12} is the resistance between contacts 1 and 2, etc. The added surface conductivity, $\overline{\Delta G}$, in the thin arm as defined by Brattain and Garrett (14) is

$$\overline{\Delta G} = (1 + \beta)wt(X_m - X)R_{45}(2e\mu_p\rho\mathcal{L}n_i(w + t)R_{15})^{-1} \qquad [2]$$

where X_m is the fractional helipot reading for minimum conductivity, X is the fractional reading at a point where $\overline{\Delta G}$ is to be evaluated, μ_p is hole mobility, ρ specific resistance, e electronic charge, $\mathcal{L}$ the Debye length, n_i the concentration of holes and electrons in intrinsic germanium, w and t the width and thickness of the thin part of arm 15. Due correction was made for those parts of 15 out of the solution. Appropriate measurements gave two independent estimates of the values of the resistances of each of the five arms, exclusive of contact resistance, which could also be evaluated. Since the dimensions of the arms were known, the specific resistance and its uniformity throughout the bridge could be determined. Once the bridge had been measured, any changes in the dimensions of arm 15 due to etching could be simply determined from the change in balance point at the conductivity minimum.

In the experiments contact 2 was at ground and so placed that R_{12} was equal to $R_{23} + R_{34} + R_{45}$, so that

the midpoint of arm 15 had equal resistance to ground either way around the bridge. When capacity measurements were made on this arm, contacts 1 and 5 were grounded to eliminate the potential drop to ground through the other arms.

Materials and purification.—The solutions were M/10 K_2SO_4 buffered to appropriate *p*H values. All solutions were gettered by stirring with finely crushed germanium for several hours before use. This was produced *in situ* by rapidly stirring a solution containing a few small pieces of high-purity germanium with a magnetically operated, Teflon enclosed stirring bar. Over the course of several hours collisions between the pieces produced a dense cloud of fine particles. In some cases the solutions were also pre-electrolyzed at a germanium cathode for up to 72 hr, but the data were identical in solutions which had been simply gettered. Generally, the germanium powder was left in the solution throughout the experiment. The solutions were made up either with de-ionized water or de-ionized water that had been distilled from permanganate solution. In both cases the data were identical, from which it may be concluded that the gettering process effectively removes any trace impurities originally present in the electrolyte or the D.I. water active with respect to a germanium surface. Analytical grade K_2SO_4 was used. In some experiments not described here, K_2SO_4 was recrystallized three times from distilled water and the buffer omitted. The data were exactly similar in both sets of experiments.

Nitrogen was passed over hot copper gauze. Helium was passed through anhydrite, Hopcalite, soda-lime, active copper on kieselguhr at 200°C (8), charcoal at −196°K and through a fitted disk into distilled water, the gas train being all glass. Identical results were obtained with either gas. The electrodes which were all oriented to the (100) face were etched in CP4 and rinsed in distilled water (or gettered D.I. water) before each experiment. In a few cases they were etched in M/10 potassium ferricyanide solution after the CP4. Anodic currents of 100-200 $\mu a/cm^2$ (n-type electrodes illuminated) were applied for around 5 min before data were taken. Ferricyanide appeared to produce a surface similar to that obtained after anodic etching whereas the CP4 surface (before anodic etching) was more variable with respect to the initial value of the surface potential and the behavior of the capacity.

Measurements.—The capacity of the germanium electrode solution interface was measured by means of a current pulse technique. Short duration square current pulses (up to a maximum value of 100 μa and of 1 μsec to 50 μsec duration, but most frequently 5 μsec) were applied from a pulsed constant voltage source, through a 10^6 ohm resistance and 0.47 μfd capacity in series, to one of the platinum electrodes in the larger compartment. The change of potential between the bulk of the germanium electrode and the solution was detected at the other platinum electrode in this compartment, amplified, and presented on an oscilloscope.

The form of the response, which was independent of the sign of the current pulse, is shown in Fig. 3.

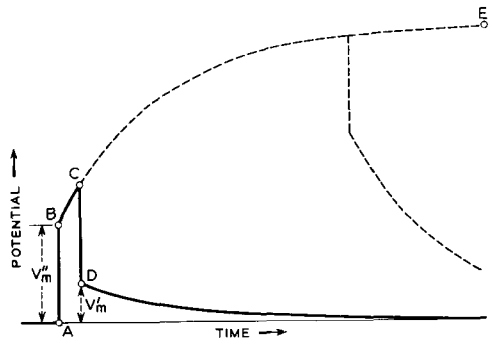

Fig. 3. Response of the interface to a short duration square current pulse.

When the pulse was turned on there was an initial potential change V''_M(A to B) which was generally vertical at the highest trace speed of our oscilloscope (0.1 $\mu sec\ cm^{-1}$). The potential increased with time from B to C where the pulse was turned off resulting in an instantaneous decrease (C to D) equal to V''_M. The residual potential V'_M at D decayed to the original potential in an exponential manner. In a typical experiment V'_M, V''_M and the time constant (τ) for decay of V'_M were measured, although in some cases only V'_M was measured. Care was taken to keep the differential pulse sufficiently small that the response was less than 25 mv. During an experiment the differential pulse was applied repetitively through the interface about 20 times per second, and the voltage response was continuously displayed.

The photovoltaic response of the electrodes was measured with a 40 cps square wave tungsten filament light source, the potential with respect to a platinum electrode in the solution being presented on an oscilloscope. The major point of interest here was to determine, as a function of doping, the electrode potential at which the "fast" response changed sign.

Both the interfacial capacity and the photovoltaic response were measured as a function of electrode potential, the bias being applied through the platinum electrode in the smaller compartment by means of a direct current source (D in Fig. 1). Two methods of varying the electrode potential were used. The first (method I) was simply to set a certain current through the electrode, wait for the electrode potential (V_E) to come to a steady value and then measure it and the quantities V''_M, V'_M and τ. Alternatively (method IIa) by manipulation of switch S the desired current could be set through the 10K ohm auxiliary resistor and then switched into the system for a brief period of time (approximately 1 sec) during which instantaneous values of V_E and V'_M were measured. The currents were such as to make the germanium anodic and were sufficiently small not to upset significantly the hole electron equilibrium in the electrodes. In an extension of the second method (method IIb) an additional current source, in parallel with D, was used to provide a continuous current (germanium anodic) superimposed on which was the manually pulsed current from D which could now be of either sign, but not sufficiently great in the negative sense to reverse the sign of the net current.

Experimental Results

The response shown in Fig. 3 does not uniquely determine an equivalent circuit. It does, however, suggest a simple combination of resistance and capacity such as shown in Fig. 4, which is basically similar to a previously proposed model (5) with the addition of R'_s. Assuming any model, one can, from pulse data, calculate a differential resistance. If the method and analysis are valid, this differential resistance should agree with the differential resistance determined from the current-voltage curve taken at

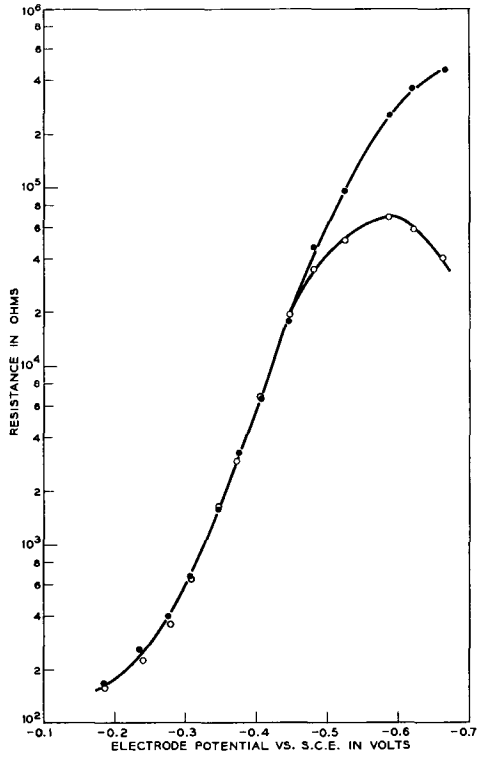

Fig. 6. Differential resistance vs. electrode potential, derived from Fig. 5 (●) and from pulse data (○).

zero frequency. The d-c data are shown in Fig. 5, and in Fig. 6 is shown the comparison of differential resistance determined graphically from Fig. 5 and from the pulse data in Table I. The agreement is excellent except at the more negative potentials. This deviation is due to the fact that in order to measure the differential resistance correctly here by the pulse method the low-frequency response of our measuring system should be good down to 0.2 sec or better, whereas it actually falls off at about 0.05 sec. The agreement is independent of the equivalent circuit chosen provided only that the circuit is consistent with the response shown in Fig. 3 and that it has a continuous resistive path from one terminal to the other.

It has been found in this case and in previous work (7) that at moderate current densities in the anodic direction the Tafel relation between d-c current and voltage is obeyed, subject to correction for a constant series resistance R_s (due to the germanium,

electrolyte, and leads) and provided the data are taken under conditions where the electron or hole concentration does not depart essentially from the equilibrium value. The departure of the current voltage curve in this region (as shown in Fig. 5) serves to determine R_s. This series resistance is found to be about one-half of the resistance necessary to explain the initial rise in V''_M in Fig. 3. This is the reason for including the resistance R'_s in Fig. 4. It should be emphasized that over most of the range of interest R_s and R'_s are small compared with R_p, and the exact values used from R_s equal to zero to R'_s equal to zero (their sum being known from V''_M) have very little effect on the calculated values of C and R_p. Assuming the circuit in Fig. 4, the following relations may be obtained

$$V''_M = i[R_s + R'_s(1 + R_s/R_p)^{-1}] \quad [3]$$

$$V'_M = C^{-1} i\, t(1 + R'_s/R_p)^{-2} \quad [4]$$

and

$$\tau = R_p(1 + R'_s/R_p)^{-1} i\, t(V'_M)^{-1} \quad [5]$$

whence

$$R'_s/R_p = t(V''_M - R_s i)(V'_M \tau)^{-1} \quad [6]$$

where i is the magnitude of the current pulse, t is the pulse duration, and τ is the decay constant for the voltage after the pulse is turned off. In these equations it has been assumed that t/τ is very small so that $\exp(-t/\tau)$ is equal to $(1 - t/\tau)$. For cases where this is not so, the appropriate correction has been made.

Typical data taken on a p-type electrode are shown in Table I. The magnitude of the current pulse was 0.1 ma and its duration was 5 μsec. R_s was taken as 80 ohms from Fig. 5. The starred values R_s*, R_p*, and C_p* are the results one would obtain if one assumed R'_s to be equal to zero, assuming V''_M and not Fig. 5 gives the correct value for R_s. The correct circuit is between these limits with the one for $R_s = 80$ ohms being the more likely. It is to be noted that for V_E more anodic than —0.300v the capacity values are considerably different in the two cases. In methods IIa and IIb, where we did not have time to take all the data shown in this table, we could not correct V'_M for t/τ being too large, and we could only calculate C on the basis of $R'_s = 0$. These two errors for very anodic potentials tend to compensate each other. For less anodic potentials it matters little which equivalent circuit one chooses.

Charge may be distributed over three distinct regions of the interface, the space charge layer in the germanium and its associated surface states ($C_{SC} + C_{SS}$), the Helmholtz region encompassing the geometrical interface, and the space charge (Gouy layer) in the solution. At the electrolyte concentrations used in this work the Gouy layer was essentially nonexistent, and all excess charge on the solution side of the interface can be considered to be in the Helmholtz layer. Typical values for the capacity of the Helmholtz layer (C_H) at a metal electrode (ca. 20 μfd/cm^2) are two to three orders of magnitude greater than calculated values for the minimum space charge capacitance in the semiconductor, so that since these capacities are in series the observed capacity at the interface is $(C_{SC} + C_{SS})C_H (C_{SC} + C_{SS} + C_H)^{-1}$ and since $C_H > 100\, C_{SC}$ the observed capacity should be C_{SC} to within about 1% in the absence of fast surface states. R'_s and R_p are the resistances to the flow of capacitative or faradaic current, respectively, from the bulk of the electrode to the bulk of the solution.

Figure 7 shows a typical curve of capacity *vs.* steady-state electrode potential at *p*H 7.4 measured on a simple electrode. An investigation of these curves as a function of *p*H indicated that over the range *p*H 5-12 they were similar in shape, but displaced along the electrode potential axis by an amount depending on the change in *p*H. Beyond *p*H 5 and 12, the curves changed shape and the minimum value increased by about a factor of 2. These data will be dealt with in detail at a later date. All the data contained in this paper were obtained at *p*H 7.4.

Figure 7 is in general agreement with Bohnenkamp and Engell (5) that a considerable part of the potential change occurs across the space charge region. Their data were taken at *p*H 0 and 14 and the minimum capacities were about a factor of 2 larger than we find at *p*H 7.4, but in agreement with our values at extremes of *p*H. It is of particular interest that our minimum capacity agrees closely with the theoretical value if the experimentally measured roughness factor of 1.3 is assumed (9).

Similar data taken instantaneously on the application of a current through the interface, method IIa as described previously, are shown in Fig. 8. Further data taken by method IIb are also shown in Fig. 8.

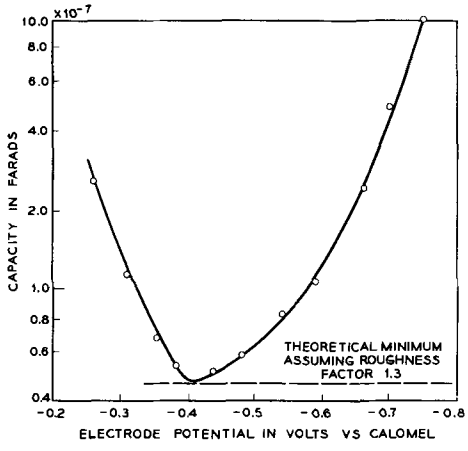

Fig. 7. Capacity *vs.* electrode potential (method I) for a 42.2 ohm-cm n-type germanium electrode.

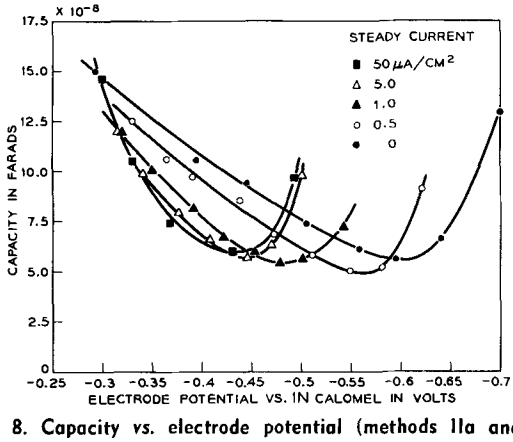

Fig. 8. Capacity *vs.* electrode potential (methods IIa and IIb) for a 25.5 ohm-cm p-type germanium electrode.

Additional experiments were conducted with the bridge electrodes. The capacity of the interface was measured exactly as for the simple electrodes, and good agreement was found for similarly doped material. The apparent variation in conductivity of the thin arm of the bridge was measured (Eq. [2]) as a function of electrode potential varied by method IIa.

The decay of photoconductivity in the thin arm was determined in two ways. The decay was compared directly with the signal from an exponential generator while the electrode potential was changed by method I. Method II does not allow sufficient time to adjust the exponential generator to an accurate reading so the procedure adopted in this case was to measure the increase in conductivity due to the 40 cps square light pulse, directed onto the thin arm only, the duration of which was long compared with the photoconductivity lifetime. Once the conductivity increase (observed as a square voltage response on the oscilloscope) was calibrated against the photoconductivity lifetime at one point (conveniently zero current density across the interface), the latter could be derived from the former by simple proportionality, the longer the lifetime the larger the photoconductive response. The results by either method yield the same result, namely, that over the accessible range of electrode potential the lifetime was essentially constant and equal to the body lifetime of the electrode material, *e.g.*, for the p-type bridge 640 ± 40 μsec.

Discussion

Dewald (6) has discussed the distribution of potential and charge at the semiconductor-aqueous solution interface and has pointed out that when the solution is sufficiently concentrated the Gouy layer is suppressed, and in the absence of a considerable number of surface states near the semiconductor Fermi level or changes in surface dipole almost all of any potential change at the interface occurs across the space charge region in the semiconductor. Hence, in the absence of these effects, or of concentration polarization in the solution, changes in electrode potential should correspond to changes in the germanium surface potential.

It is anticipated that the observed capacity is due to the space charge layer plus surface states sufficiently fast to respond to the differential current pulse (3). If the assumption is made that the measured capacity is solely that of the space charge layer, then the surface potential (ψ_s) may be deduced by comparing the experimental capacity values (divided by the roughness factor) with the theoretical curve calculated from (10)

$$C_{sc} = dQ_{sc}/d\psi_s = A(dF/dY)dY/d\psi_s \qquad [7]$$

where Q_{sc} is the charge in the space charge layer, A is the electrode-solution interfacial area, and

$$F = \pm[\lambda(e^{-Y} - 1) + \lambda^{-1}(e^{Y} - 1) + (\lambda - \lambda^{-1})Y]^{1/2} \qquad [8]$$

where $\lambda = p/n_i$, p is hole concentration, and $Y = e\psi_s/kT$, ψ_s being the electrostatic potential (in volts) across the space charge region. The assumption is made in the above form of F that the carrier density does not depart appreciably from equilibrium under the conditions of our experiments.

Theory indicates that for the same steady-state conditions in identical solutions, the surface potential will vary with the doping of the electrode by an amount kT/e ln λ compared with intrinsic (6, 11). If the capacity we observe is that of the space charge layer and there are no potential changes in the system except across the space charge layer, then for all electrodes the plots of $\psi_s - kT/e$ ln λ *vs.* electrode potential should coincide and should be straight lines with a slope of unity. The data for variously doped electrodes is shown in Fig. 9. It is seen that only the first requirement is satisfied. There are two possible explanations for this behavior. Either the capacity values and, hence, the values of ψ_s are incorrect due to the existence of a sufficient number of fast surface states within the experimental range of $\psi_s - kT/e$ ln λ or there is a potential change in some other region of the interface.

In taking the above data it was observed that the behavior of the electrode potential, particularly at low current densities, was dependent on the immediately previous condition of the electrode, *i.e.*, was a particular current density established from a higher or lower value, the data in Fig. 9 being the final steady-state values. An analysis of the data taken by method IIa, in which the long time effects are disregarded, is shown in Fig. 10. In this case, over a range of potential, the electrodes behave in an ideal fashion and obey the simple relation

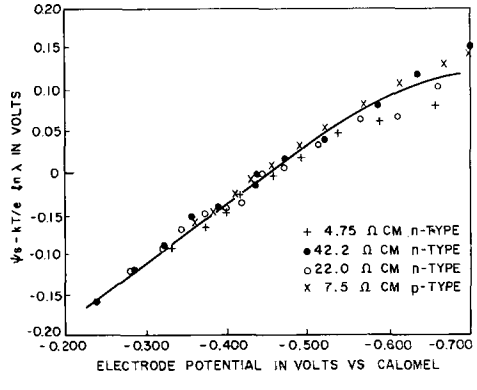

Fig. 9. ($\psi_s - \frac{kT}{e}$ ln λ) *vs.* **electrode potential (method I) for various electrodes.**

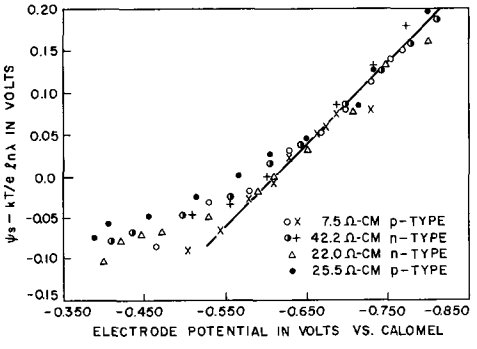

Fig. 10. ($\psi_s - \frac{kT}{e}$ ln λ) **vs. electrode potential (method IIa) for various electrodes.**

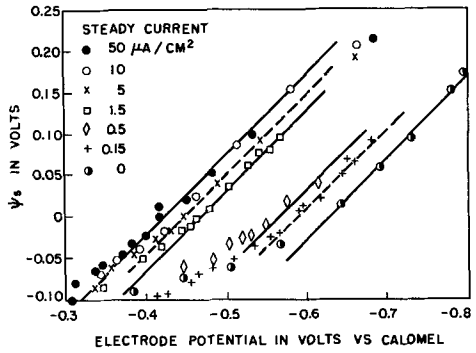

Fig. 11. ψ_s vs. electrode potential (method IIb) for a 22 ohm-cm n-type germanium electrode.

$$\psi_s = \frac{kT}{e} \ln \lambda = V_E + \text{constant} \qquad [9]$$

which has been predicted (6, 11). In Fig. 10 the points at the most negative potentials represent zero net current, while less negative potentials represent increasingly anodic polarization. Data taken by method IIb throw light on the reason for the departure from Eq. [9] at higher anodic current densities. It can be clearly observed from Fig. 11 that the constant in Eq. [9] varies with current density up to about 10 μa/cm^2, but at a sufficiently slow rate that for not too large changes in current it remains essentially constant during the time that the electrode potential and V'_M, *i.e.*, capacity, are read. The disposition of these lines is independent of the stirring rate, indicating that the potential shift is not due to concentration polarization in the solution. Concentration polarization may, however, be observed in unbuffered solutions of the same *p*H as shown in Fig. 12, where the capacity-electrode potential curves exhibit a similar shift over the range of current density from zero to approximately 10 μa/cm^2 and then, unlike the situation in Fig. 8, undergo a further shift at higher current densities.

The only remaining region where the potential shift may occur in buffered solutions is the Helmholtz layer. The potential may change appreciably in this region due either to a change in the adsorbed dipoles or to a change in the occupation of slow surface states. (The surface states must necessarily be slow since they do not respond to the capacity measurements.) The present data are not sufficient to distinguish between these two possibilities. Figure 13 shows an analysis of some data taken by method I at low current densities. The surface potentials have been computed from the capacity and hence, knowing the surface potential, it is possible to deduce how changes in the electrode potential due to small anodic current are distributed between the space charge and Helmholtz layers. The space charge potential is known absolutely, while only changes in Helmholtz potential from the zero current value are obtained. The curves for n- and p-type electrodes show a sharp step in the Helmholtz potential over a fairly narrow range of surface potential. The value of $(\psi_s - kT/e \ln \lambda)$ at which this potential change occurs is approximately the same for both n- and p-type electrodes which would be expected for a surface state localized in energy. Unfortunately, equal values of $(\psi_s - kT/e \ln \lambda)$ represent also equal current densities across the interface, and the results do not clearly distinguish between a purely electrical effect dependent on surface potential and a chemical effect dependent on current density. Slow surface states, however, are usually considered to be associated with thick oxide films and disappear when such films are reduced in thickness (12). Under the conditions of our experiments, thick films are unlikely to be present (13). For this reason, it would seem more likely that we are observing a change in surface dipole due to adsorbed molecules or ions oriented at the surface. The structure of the adsorbed layer could be strongly affected by anodic current since this actually removes the surface atoms of the electrode. The various lines in Fig. 11 might then represent a steady state attained between the formation of an oriented adsorbed layer, probably of water molecules, and its disruption by anodic etching.

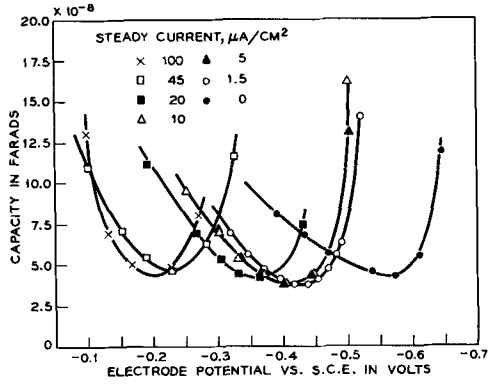

Fig. 12. Capacity vs. electrode potential (method IIa) for a 25.5 ohm-cm p-type germanium electrode in unbuffered $\frac{M}{10}$ K_2SO_4.

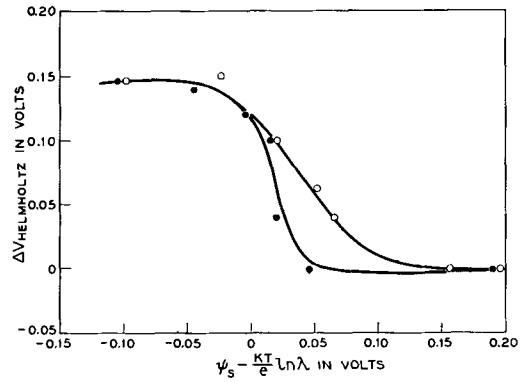

Fig. 13. $(\psi_s - \frac{kT}{e} \ln \lambda)$ vs. $\Delta V_{\text{Helmholtz}}$ for a 25.5 ohm-cm p-type electrode (○) and a 42.2 ohm-cm n-type electrode (●).

The constancy of the decay lifetime for excess carriers deduced from the bridge electrode and its close correspondence with the body lifetime indicates the absence of surface recombination centers over the investigated range of surface potential (approximately 0.2v on each side of the center of the gap).

Additional information is provided by fast photovoltaic response. In the absence of fast surface states,

this quantity should change sign at flat band (10), *i.e.*, $\psi_s = 0$. Experimentally, the range is +0.03 to −0.02v for the variously doped electrodes.

It may be concluded on the above evidence of the distribution of charge and potential and kinetic recombination effects that a germanium surface which has been recently anodically etched in nearly neutral solution is free from measurable densities of fast surface states. It should be emphasized here that this conclusion only applies to the case of the purified electrolyte. A similar conclusion with regard to the absence of fast states has recently been reached in the case of the zinc oxide electrode (3).

An attempt was made to calculate ψ_s from the bridge conductivity data. Here two questions arise. First, do the values of ψ_s calculated from the capacity changes in the thin arm of the bridge agree with results for the simple electrodes. These results are compared in Fig. 14. The agreement is reasonably good, considering that in the case of the bridge there is necessarily a distribution of potential along the thin arm and both the potential V_E and the capacity are some kind of average over this arm. The second question, how do the values of ψ_s calculated from conductivity agree with the capacity data, is illustrated in Fig. 15. Over a range of potential the agreement is fairly good, but at higher anodic potentials the two methods do not agree. The lack of success encountered in this attempt may be ascribed to two potential sources of error. There is a possibility of conduction through the solution by virtue of the fact that a potential difference must be applied across the electrode to measure the conductivity. In most cases this potential was quite small, about 10 mv between the ends of an arm 2 cm long, and the frequency of the applied signal kept low (17 cps) to reduce capacitative coupling through the solution. It is felt, however, that the major discrepancy arises from another source which is the fact that, due to the geometry of the bridge, at any interfacial current there will be a distribution of potential along the thin arm because of current flow along its length. Calculations indicate that at our maximum overvoltage of about 0.450v there is a potential difference between the ends and center of the thin arm of some 0.045v, becoming rapidly less at lower current densities. In this event there will be a fairly complicated averaging of surface conductivity along the length of the arm which could give deviations in the direction observed.

Although the conductivity experiment does not exhibit ideal behavior, the observed conductivities are a constant function of potential. This may be inferred from Fig. 16, where the bridge balance reading, being proportional to conductivity (see Eq. [2]), is plotted as a function of the electrode potential. These experiments were carried out over an extended period of time in solutions of *p*H 7.4, and include a correction for the reduction in thickness of the active arm each time it is etched, deduced from the balance reading for minimum conductivity. Insofar as capacity measurements carried out at the same time indicate a constant relationship between V_E and $(\psi_s - kT/e \ln \lambda)$, the V_E axis could be replaced by suitably normalized values of $(\psi_s - kT/e$

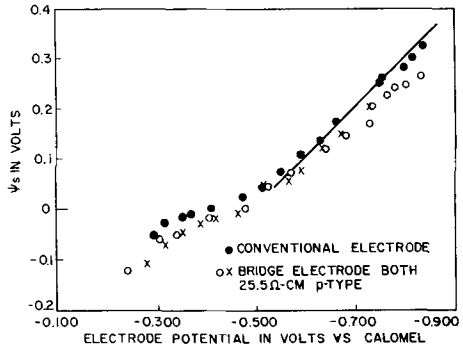

Fig. 14. ψ_s vs. electrode potential (method IIa) for a simple electrode (•), and a bridge (o,x) both 25.5 ohm-cm p-type.

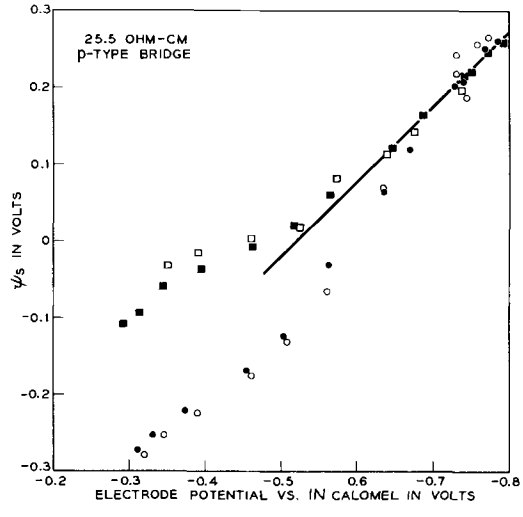

Fig. 15. ψ_s calculated from capacity (□,■) and from conductivity change (o,•) vs. electrode potential (method IIa) for a 25.5 ohm-cm p-type bridge.

$\ln \lambda$), and conductivity measurements could be used to deduce this quantity from Fig. 16.

Conclusion

The capacity of the interface between a germanium single crystal electrode and an aqueous solution of K_2SO_4 buffered to pH 7.4 when measured by a high-frequency pulse method is explicable solely in terms of the space charge capacity in the electrode and reveals no fast surface states (less than ca. $10^{0.5}$ cm^{-2}) within ± 8 kT/e measured from mid-gap. The conclusion of no fast surface states is supported by the absence of significant surface recombination phenomena. The distribution of potential across the interface in response to anodic bias is expressed by

$$\psi_s - \frac{kT}{e} \ln \lambda = V_E + K$$

where the quantity K is arbitrary and depends on steady-state current density up to 10 μa cm^{-2}, but otherwise at a given pH and for a given reference electrode is a constant.

Surface conductivity data yield incorrect values of the surface potential except at small polarizing currents, but are quite reproducible and could be used to predict surface potential if properly calibrated in terms of the capacity. It is the authors' conviction that values of surface potential deduced from the capacity are most likely the correct ones.

In other words, it is possible under these conditions to obtain an almost "perfect" germanium surface, *i.e.*, no fast states.

Investigation of Some Uncommon Surface Treatments on Germanium

W. A. Albers, Jr.* and A. M. Rickel

Research Laboratories Division, The Bendix Corporation, Southfield (Detroit), Michigan

ABSTRACT

Several surface treatments have been applied to germanium and characterized with respect to the surface energy level configuration and the sensitivity to variations in ambient atmosphere. The characterization was accomplished by making simultaneous measurements of the a-c field-effect conductivity change and the surface recombination velocity, both as functions of surface potential. Experimental results suggest certain relationships between etched germanium surface properties and those properties resulting from a subsequent surface treatment, which may be exploited to yield a surface condition that is relatively passive to ambient atmosphere variations.

Attempts to stabilize and/or passivate semiconductor surfaces for the purpose of improving manufactured semiconductor device uniformity and reliability often involve a sequence of several distinct operations. It is well known that each step of such a sequence can contribute to the ultimate electrical properties of the resultant surface. It is not generally understood, however, just how these steps contribute, in a quantitative sense, to the resultant surface properties. The purpose of this paper is to report some preliminary studies of the effect of two successive surface operations on the electrical properties of the semiconductor surface. The two steps chosen for investigation are (i) an etching operation and (ii) a surface treatment applied to the etched surface. The surface treatments investigated are "uncommon" in the sense that they have not been reported extensively in the literature.

* Present address: General Motors Research Laboratories, Warren, Michigan.

The results of the measurements to be reported suggest a method of characterization of a given surface condition that affords a first-order approach to the "engineering" of surfaces into devices. The experimental data also yield some information about the interaction of the two operations on the surface that suggests possible approaches for obtaining relatively high degrees of surface passivation. Both of these aspects of the experimental results are discussed in some detail.

Experimental Approach

Rectangular sample with their large-area surfaces oriented in either the (100) or the (111) crystallographic planes were cut from 35 ohm-cm n-type single crystals of germanium. The rectangles were subsequently lapped to a thickness of 10.5 to 11.5 mils and then etched to a final thickness of 5.0 ± 0.1 mils in either CP4A or a 1:1:1 ratio of H_2O_2, HF, and H_2O.[1] A specific sample was then subjected to one of several surface treatments, the nature of which will be detailed later. Finally leads were attached,[2] and the sample was placed in the experimental apparatus.

The method employed for the characterization of a given surface treatment was to observe, simultaneously, the large-signal a-c field effect and the surface recombination velocity (s.r.v.) as a function of surface potential in various ambient atmospheres. The data were then analyzed in the manner employed by Many *et al.* (1) to obtain surface trap densities and energies. In addition, the sensitivity of the electrical properties of the experimental sample to changes in the ambient atmosphere was also monitored. The surface treatment data were then compared to similar data obtained on the etched, untreated surfaces previously described, which were employed as controls.

The apparatus for mounting the samples in order to accommodate the simultaneous measurement of the field-effect conductivity and the s.r.v. is drawn schematically in Fig. 1. The experimental technique is similar to those employed by Wang and Wallis (2), Bath and Cutler (3), and Rzhanov *et al.* (4), with some modification. The above authors all performed simultaneous measurements of the field-effect conductivity and the conductivity change on illumination. The photoconductivity was then related to the s.r.v. through suitable theoretical expresssions [see, for example, ref. (3)]. These workers used, for the most part, nonpenetrating illumination and, in some cases, field-effect electrodes were coupled to only one of the two large area surfaces of their experimental samples. The apparatus in Fig. 1 employs a germanium filter D which is thick compared to the sample thickness. The radiation that reaches the sample C is thus penetrating. If the filter is sufficiently thicker than the sample, the generated carrier density due to illumination is nearly constant throughout the volume of the illuminated portion of the sample. The germanium filter also serves as one of the two field-effect electrodes, the other being an ordinary brass plate A. The experimental specimen is sandwiched between these two electrodes and insulated from them by the mica spacers B. The germanium filter thus serves both as a field-effect probe and as a means of obtaining a low-level,[3] uniform generation of carriers in the specimen.

The circuitry for the field-effect observations was patterned after that of Low (5). A 200-v peak, 70 cps, alternating voltage was applied to the field effect probes, and the resulting change of sample conductivity *vs.* induced surface charge was displayed on an oscilloscope. An ordinary tungsten filament projector lamp was used as a source of illumination. The light was chopped at a rate of 120 cps so that, upon illumination, the photoconductivity pulse appeared superimposed on the ordinary field-effect curve. Since the chopping rate was out of sync with the field-effect voltage, the photoconductivity pulse ran back and forth on the field-effect pattern on the oscilloscope. By employing a high persistency phosphor, a double field-effect trace is obtained, the vertical separation being proportional to the photoconductivity voltage.[4] The necessity of calibrating the intensity of illumination is eliminated by obtaining a value of the s.r.v. by the photoconductivity decay method at the equilibrium surface potential (the value of the surface potential for zero induced surface charge). This value of the s.r.v. serves to calibrate the photoconductivity voltages obtained with the field effect.

The type of data that results from the methods of observation described above is presented in Fig. 2 and 3 for some typical surface treatments[5] (the surface treatments will be referred to only by abbreviated names in the text; the physical and chemical details are presented in an Appendix). In Fig. 2 is plotted the charge in "fast" surface states, Q_{ss}, as a

[1] The CP4A etch consists of a 5:3:3 ratio of nitric, hydrofluoric, and glacial acetic acids. The chemicals employed were all reagent grade or better, the HNO_3 was 70% by weight, the HF 48% by weight, and the H_2O_2 (unstabilized) 30% by weight. The H_2O was distilled and deionized.

[2] In order to avoid contaminating the previously prepared surface, the samples were made much longer than the active surface region under investigation; the attachment of leads was thus accomplished at a distance somewhat removed from the surface area of interest.

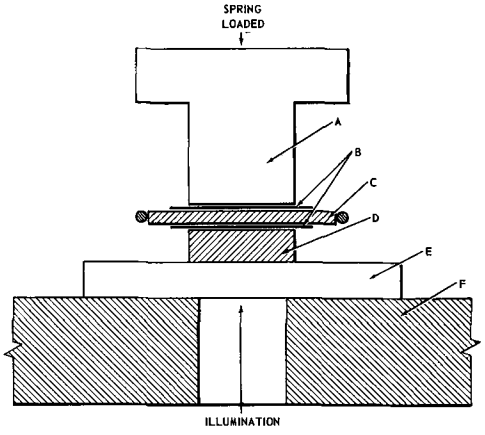

Fig. 1. Detail of sample mounting for field effect and photoconductivity measurements: A, brass field effect electrode; B, mica spacers; C, germanium sample; D, germanium filter and field effect electrode; E, quartz microscope slide mount for germanium filter; F, wall of enclosing box.

[3] The low generation level is a necessary condition for the applicability of the expressions relating s.r.v. and photoconductance (3).

[4] Photographs of oscilloscope traces like those discussed have been published by Rzhanov (4).

[5] For the purposes of this paper, a "surface treatment" is defined as an operation on the surface which does not involve the removal of germanium material, as opposed to an "etch," which does involve the removal of material.

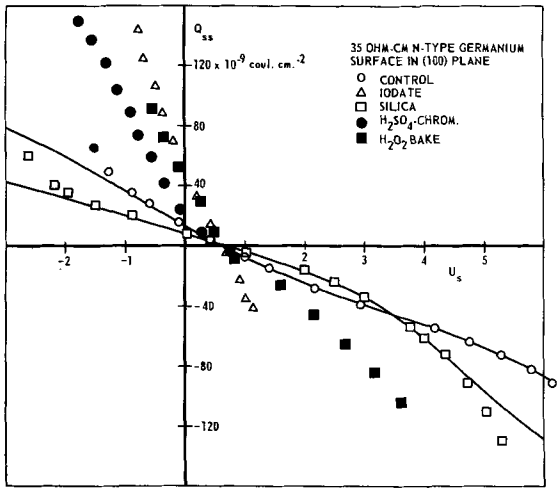

Fig. 2. Charge in fast surface states, Q_{ss}, as a function of surface potential, u_s, in units of kT/q for several surface treatments on an H_2O_2:HF:H_2O etched surface. Solid curves represent best theoretical fit for the control surface and the silica treatment.

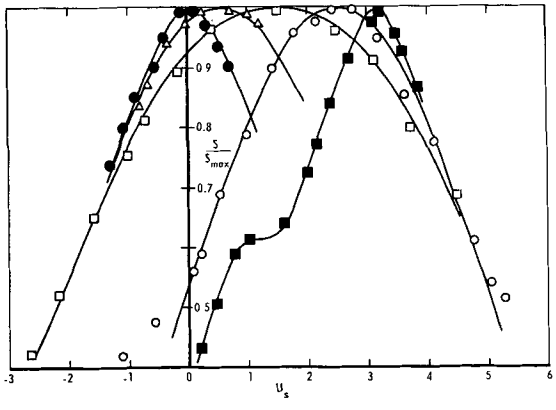

Fig. 3. Normalized surface recombination velocity, s/s_{max}, as a function of surface potential, u_s, in units of kT/q for the same samples as Fig. 2. Solid curves represent the best theoretical fit to the experimental points.

function of surface potential, u_s, in units of kT/q.[6] The corresponding curves of the normalized s.r.v., s/s_{max} *vs.* u_s are plotted in Fig. 3. The points represent data obtained experimentally while the solid curves are the theoretical curves which are the best fit with the experimental points. The result is that the densities and energies of the fast surface states can be deduced, thus partially characterizing each surface treatment.

The data of Fig. 2 and 3 were all obtained in a dry O_2 ambient atmosphere, after sufficient time was allowed for the sample surface to come to equilibrium with this atmosphere. The reason for choosing a reference atmosphere is due to the fact that the fast surface state configuration changes with varying ambient atmosphere. This effect is illustrated in Fig. 4. The data presented here are the result of varying the ambient atmosphere about a typical H_2O_2:HF:H_2O-etched surface.

It will be noted that there is an appreciable variation in some of the recombination trap parameters.

[6] The quantity u_s is defined as

$$u_s = \frac{q\phi_s}{kT}$$

where ϕ_s is the surface potential. The symbols employed for all other quantities throughout this paper follow those of ref. (1).

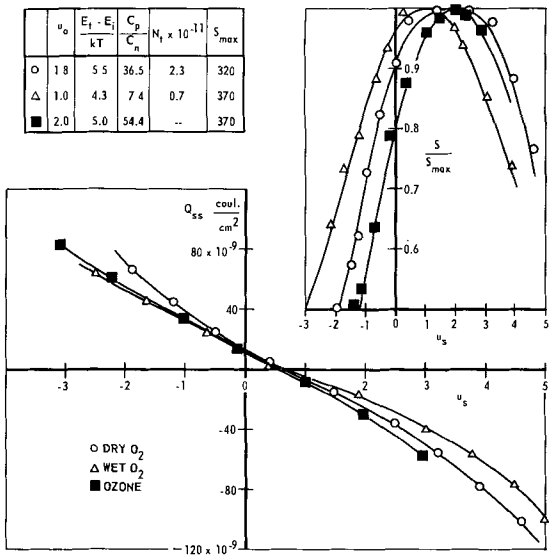

Fig. 4. Effect of varying ambient atmosphere on the surface state parameters. H_2O_2:HF:H_2O etched surface in a (100) plane of 35 ohm-cm n-type germanium.

The values of c_p/c_n, the ratio of hole-to-electron capture probabilities (which is proportional to $l\,n\,(u_o)$, u_o being the value of u_s about which the s.r.v. curves are symmetrical), and the state density, N_t, appear to vary considerably. On the other hand, the energy of the state (as measured from the center of the energy gap E_i) and the maximum value of the s.r.v., do not exhibit such drastic changes. This behavior is typical of most of the surfaces that we have investigated. It was found that a dry oxygen atmosphere yielded the most reproducible results, and thus, this atmosphere was chosen for the standard.

It follows that the variation of the surface properties with ambient atmosphere changes should be an essential part of characterizing any surface condition. We chose to do this by noting the value of the equilibrium surface potential in the field effect for two ambients, namely dry O_2 and wet O_2.[7] The difference in surface potential, Δu_s, and the mid-point of the range of Δu_s were thus obtained for these two ambients, the values of which are indicative of the sensitivity of the surface to ambient atmosphere changes. These data, along with data concerning surface state densities and energies are taken as a characterization of a given surface treatment. The data obtained on a total of 43 samples are summarized in the following section.

Results and Discussion

Some representative results, on (100) surfaces, are summarized in Table I. All of the data were obtained in a dry oxygen atmosphere at 295°K. Similar data were obtained on (111) surfaces, and, within experimental error, the data were substantially the same as those presented in Table I for the (100) surface. Although a total of 43 samples were investi-

[7] Dry O_2, in our case, was obtained by passing ordinary low dew-point compressed cylinder oxygen through a Drierite column. Wet O_2 was obtained by bubbling dry O_2 through distilled, deionized water and filtering through Pyrex wool. The sample conductivity would stabilize, typically, about 3 min after admission of wet O_2. Although there was a slow, long term drift evident for several hours in either ambient atmosphere the measurements were performed in a time interval sufficiently small that this drift was insignificant.

gated, the data for each surface condition in Table I represent results typical of, at most, three samples per surface treatment. In several cases, only two samples per surface treatment were prepared. Consequently, the results may be interpreted only in terms of trends, since the statistical sample sizes for each surface treatment were too small to establish any degree of confidence.

The data in Table I are organized into three primary groups. The first of these includes the parameters associated with energy levels which are active in recombination. The second group lists parameters of energy levels which are not active in recombination, referred to as trapping levels. The third group of data constitutes a measure of the sensitivity of a given surface condition to a variation of the ambient atmosphere. This appears in the column headed "Δu_s" in Table I. The quantity Δu_s, the total swing in surface potential, in units of kT/q, in going from a dry O_2 to a wet O_2 atmosphere, is listed along with the value of u_s at the midpoint of this swing. The midpoint values are the quantities in parentheses.

The data for each set of levels are broken up into several columns according to the following parameters: the value of the surface potential u_o about which the s.r.v. curves are symmetrical, the ratio of the capture cross sections for holes and electrons c_p/c_n, the energy of the level $E_t - E_i$ in units of kT, the density of the level N_t, the maximum surface recombination velocity s_{max}, the capture cross section for holes c_p, and the capture cross section for electrons c_n. The subscript numerals refer to two separate recombination levels while the superscript primes represent different trapping levels. In many cases, only estimates of some of these parameters are available due to the fact that the applied electric field could not induce sufficiently large swings in surface potential. Where such estimates were made are evident in Table I as represented by appropriate symbols.

The main results suggested by the data are the following:

(*A*) The only significant difference between the two etched surfaces (controls in Table I) appears in the values of s_{max} and c_p. The energy and density of the recombination levels are comparable.

(*B*) The surface energy levels can be grouped as follows: (*a*) a recombination level between about 3.0 and 6.0 units of kT above the center of the gap; (*b*) a recombination level between about 1.0 and 1.5 units of kT above the gap center; (c) a trapping level about 1.0 to 1.5 units of kT below the center; (*d*) a trapping level at an energy somewhat greater than 7.0 units of kT above the gap center; (*e*) a trapping level at an energy somewhat greater than 6.0 units of kT below the gap center.

These are all consistent with the levels reported by several authors in the literature (2, 6-9).

(*C*) The iodate and H_2O_2-bake surface treatments yielded remarkably similar results on either of the etched surfaces.

In analogy, one could expect that thermal oxidation should also be similar for the two etched surfaces. Although the H_2O_2:HF:H_2O surface was successfully oxidized thermally, similar oxidation on a CP4A surface was not achieved. This is evident from the data of Table I, but additional support of this observation appeared in the form of oxide films on the samples. The thermal oxidation treatment on CP4A surfaces did not exhibit any interference colors or patterns characteristic of thick oxide layers. The thermally oxidized H_2O_2:HF:H_2O surface, however, exhibited uniform interference colors that suggested oxide film thicknesses of the order of 1000Å.

(*D*) It will be noted in Table I that, with the exception of the H_2SO_4-chromate treatment, a surface treatment on either control surface generally preserves the energy of the first recombination level. It appears to be characteristic of treatments that are known to be oxidizing (H_2O_2-bake and thermal oxidation), that a second recombination level is introduced. The H_2SO_4-chromate surface, however, does not preserve the first recombination level, but rather introduces a second recombination level in the $1.0 < (E_t - E_i/kT) < 1.5$ range. It is to be noted further that at least an order of magnitude reduction in the electron capture cross section for the first recombination level is associated with a heavily oxidized surface.

(*E*) The Δu_s column of Table I indicates that three of the surface treatments investigated (iodate, thermal oxidation, and H_2SO_4-chromate) are relatively

insensitive to ambient atmosphere variations, suggesting that such surface treatments could possibly be employed to passivate partially a semiconductor device surface. This aspect of the data will be developed more fully in a following section.

(*F*) Although not explicitly mentioned previously, weight loss measurements were taken for all of the surface treatments listed in Table I. The iodate, H_2SO_4-chromate, and bromine treatments exhibited weight losses after processing; the other treatments did not suffer a loss of weight within experimental error. The iodate and H_2SO_4-chromate weight losses were relatively small, *e.g.*, of the order of 2-4%. The weight loss for the bromine treatment, however, was of the order of 50-75%. We conclude that each of these treatments actually etches to some degree. The bromine treatment is definitely an etch and is thus improperly placed in the category of a surface treatment. The significant point to make is that it is just these surface treatments that alter most drastically the characteristics of the control surface. Those surface treatments which do not exhibit any evidence of etching seem to preserve the characteristics of the control surfaces to some extent.

(*G*) The most widely fluctuating trap parameter for recombination levels is the capture cross section for electrons, c_n. The capture cross section for holes, c_p, varies only approximately an order of magnitude in the range of surface conditions investigated. The value of c_n, however, experiences variations over a range of three orders of magnitude. Of particular interest is the reduction of c_n consistently observed for those surface treatments which are known to oxidize heavily (H_2O_2-bake and thermal oxidation).

The data as a whole clearly indicate the existence of at least two recombination levels and three trapping levels which are always present. Whether or not these levels can be observed experimentally depends on (i) the total range of u_s covered, (ii) the relative densities of the levels, and (iii) the capture cross sections for holes and electrons for each level. Evidently, the capture cross sections are relatively small for the trapping levels, rendering them inactive as recombination centers.

Result (*D*) above suggests a possible explanation of the origin of the two different recombination centers. It can be assumed that the levels in the range $3.0 < (E_t - E_i)/kT < 6.0$ are associated with a Ge-O bond of some form, while the levels in the $1.0 < (E_t - E_i)/kT < 1.5$ are associated with lack of stoichiometry and other imperfections in the Ge-to-GeO_x transition region. If it is further assumed that the heavy oxidation mechanism is one that requires the transfer of Ge atoms from the germanium-oxide interface to the outer surface of the oxide, then the origin of the two recombination levels could be as follows: the thin, equilibrium layer of oxide which results from etches gives rise to a relatively uniform and nearly perfect transition from germanium to the oxide. Thus, the first type of recombination level dominates. On heavy oxidation, however, the Ge atoms that are transferred to the outer surface of the oxide leave the transition region disturbed and farther removed from perfection. Thus, the second type of recombination level becomes more prominent, but not at the expense of the first type. The decrease in the capture cross sections for electrons that accompanies heavy oxidation may possibly be explained through an interaction between the two types of levels.

Employing the same assumptions of the previous paragraph, one could then explain the results observed for the H_2SO_4-chromate treatment as the domination of the second type of level while the first type is rendered insignificant. This would be possible if the H_2SO_4-chromate treatment is really etching moderately, yielding a resulting germanium-to-oxide transition region which is grossly disordered. Evidence that this explanation is reasonable comes from visual observation of the H_2SO_4-chromate treated surface. The resulting surface appears slightly textured, as compared to the original H_2O_2:HF:H_2O control surface, suggestive of a large number of nucleation sites for a surface layer decidedly different from the control surface.

Now, an extension of the arguments presented for the oxide surface layer can be employed to discuss some aspects of surface passivation. It will be noted that the smaller values of Δu_s (corresponding to surfaces relatively insensitive to ambient atmosphere variations) are correlated with large surface state densities. This is expected, since large quantities of trapped charge in surface states offer a more effective shield from the influence of a variation of surface charge. Let it be further noted that the thermal oxidation on an H_2O_2:HF:H_2O surface affords the smallest value of Δu_s. Based on our assumptions regarding the origin of the recombination states, it might then be possible to reduce the value of Δu_s by another large factor by thermally oxidizing one of the other surface treatments rather than the unstable control surfaces. What we really wish to emphasize is that the data suggest a very significant relationship between the etched surface characteristics and those characteristics which result from a subsequent surface treatment. It is concluded that a fruitful approach to the problem of passivating a semiconductor surface can be found in studying, in more detail, just what these relations are and how they can be exploited.

Application to Devices

The data of Table I can be employed to anticipate the effect of the listed surface treatments as applied to a semiconductor device. Most semiconductor rectifiers and transistors require that both the surface conductivity and the surface recombination velocity simultaneously assume their lowest practical values. It is further desirable that neither of these quantities vary with varying ambient atmosphere (passivated surface) and with time (stabilized surface). Information about all but the time variations is implicit in Table I.

Consider the plot of the change in conductivity $\Delta\sigma$ *vs.* surface potential, u_s, in units of kT/q in Fig. 5. A similar plot for any resistivity and type can be reproduced from the calculations of Kingston and Neustadter (10). Now this curve is independent of the surface treatment since it depends only on the

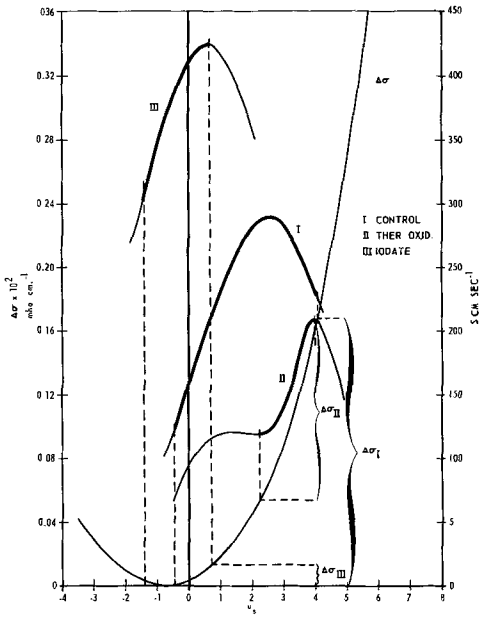

Fig. 5. Surface recombination velocity, s, and change in conductivity, $\Delta\sigma$, as functions of the surface potential, u_s, in units of kT/q for determining the range of s and $\Delta\sigma$ corresponding to a variation of the ambient atmosphere from dry to wet oxygen.

bulk potential and the surface potential regardless of how the value of surface potential is achieved. However, the surface recombination velocity as a function of surface potential does vary considerably with surface treatment (see Fig. 3). Thus, in order to establish both the value of the conductivity and the surface recombination velocity (s.r.v.) simultaneously for a given value of surface potential, it is necessary to superimpose the s.r.v. *vs.* u_s curve for each surface treatment. This has been done in Fig. 5 for three representative surface treatments (control, iodate, thermal oxidation) on an H_2O_2:HF:H_2O etched surface. The s.r.v. *vs.* u_s curves can be constructed from the data of Table I by putting the appropriate values of the listed surface recombination level parameters into the theoretical expression for the surface recombination velocity (2).

It is then possible, by employing the Δu_s column of Table I, to evaluate the ranges of conductivity and s.r.v. to be expected with a variation of ambient atmosphere from dry to wet oxygen as defined previously. Consider the s.r.v. curve I of Fig. 5, along with the $\Delta\sigma$ *vs.* u_s curve, appropriate for an H_2O_2:HF:H_2O etched surface on 35 ohm-cm n-type germanium. The Δu_s for this surface condition is 5.5 units of kT/q while the midpoint of this range is 1.8. Bracketing this range on the horizontal scale, it is found that the corresponding changes in the s.r.v. (portion of the curve that is heavy line) and the conductivity are from 125 through the maximum of 290 and back to 230 and $\Delta\sigma = 0.16$, respectively. Similar consideration of the iodate and thermal oxidation treatments yields corresponding ranges of s and $\Delta\sigma$, as indicated in Fig. 5. The significance of characterizing a surface treatment by including the Δu_s data is now apparent. It will be noted that, although the Δu_s of the thermal oxidation treatment is slightly smaller than the same quantity for the iodate treatment, the changes in both $\Delta\sigma$ and s.r.v., percentagewise, are smaller for the latter treatment. The reason for this result is that the midpoint of the Δu_s range is near the conductivity minimum (—0.4) for the iodate case, where the conductivity is varying relatively slowly as a function of u_s. The thermal oxidation case, however, exhibits a midpoint of Δu_s (3.1) which is on the portion of the conductivity *vs* u_s curve which is rapidly varying. The importance of stating not only the range of u_s but also the midpoint (or some such arbitrary reference) is thus evident.

It is conceivable, then, that extensive tabulation of data after the manner of Table I for the wide range of resistivities encountered in device technology could afford a device engineer a first-order approach to the engineering of surfaces into devices. Employing such tabulations, it should be possible to delineate the range of values of important parameters to be expected from a given surface treatment after a fashion similar to that discussed in connection with Fig. 5.[8]

There remains at least one major obstacle to device surface engineering. This has to do with the question of how the existence of a junction at the surface affects the important parameters associated with a given surface treatment. It is well known that many etches and/or surface treatments can be employed to delineate junctions in semiconductors. This, by definition, is evidence that a specific operation on a surface will yield characteristics in the vicinity of the junction that could be significantly different from the characteristics on the surface of homogeneous material. Thus, work such as that described above must be complemented with studies on materials containing junctions that come out to the surface.

Summary

An attempt has been made to define a method of characterizing a semiconductor surface condition which would be conducive to an engineering approach to the surface problem. This method consists of listing not only the surface parameters associated with surface traps, but including also the range and location, in values of surface potential, that are introduced by a specific surface condition. The methods discussed in this paper are not intended to be all-inclusive or final, but rather suggest an approach which could possibly allow for the eventual engineering of surfaces into semiconductor devices.

Features of the experimental data of particular interest are (*a*) the relatively constant capture cross sections for holes for the variety of surface conditions investigated, (*b*) the wide variation of capture cross sections for electrons, (*c*) the appearance of a second recombination level which is apparently associated with heavy oxidation, and (*d*) the reduction in sensitivity of the surface conductivity to variations of ambient atmosphere due to a relatively large concentration of charge in fast surface states which effectively "shield" the semiconductor from the influences of the atmosphere.

[8] It must be recalled that the approach considered in connection with Fig. 5 tacitly assumes that, in the range Δu_s, the surface parameters of Table I do not change. The fact that they do change is demonstrated in Fig. 4. The assumption has been made that the s.r.v. curves are not significantly different for a dry and a wet oxygen atmosphere. The ranges of s and $\Delta\sigma$ obtained are thus accurate only within the limits implied by such an assumption.

Acknowledgments

It is a pleasure to acknowledge the assistance of Mr. R. F. Voigts in the design and construction of the experimental apparatus and the procurement of experimental data.

Manuscript received Dec. 18, 1961; revised manuscript received March 9, 1962. This paper was presented in part before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

APPENDIX

Descriptions of Surface Treatments

H_2O_2 *bake.*—The sample is placed in contact with glass, flooded with a small amount of stabilized 30% H_2O_2, and baked in room atmosphere for 1 hr at 100°C.

Thermal oxidation.—The sample is placed in a flow of approximately 1 c.f.h. of dry oxygen for 72 hr at 500° ±10°C. (The sample is stored in methanol between the preparatory etch and the thermal oxidation surface treatment.)

Iodate.—The sample is treated for 1 hr at room temperature in an agitated solution containing HF, H_2SO_4, M/5 KIO_3, and H_2O in the proportions 4:1:1:2. The sample is rinsed in the sequence: H_2O, acetone, and H_2O, and is then stabilized by baking for several hours in room atmosphere at approximately 150°C.

Bromine.—The sample is placed in 4.0M KOH without agitation, warmed to 55°-60°C, held there for 20 min, and cooled to 35°C. The sample is then flooded free of KOH with a solution containing Br_2 and 4.00M KBr in the proportions 3:250, and is allowed to stand in this solution without agitation for 15 min. The KOH-bromine solution sequence outlined above is repeated as often as necessary, always flooding away one solution with the other, until visual inspection shows a uniform attack at the end of the 15-min exposure to the bromine solution. When this condition is satisfied, the sample is left in the bromine solution for 6 hr, without agitation, and is then rinsed in H_2O.

Silica.—The sample is placed in agitated HF for 1½ hr, and then silicic acid powder is added to the agitated solution until a 20% excess has been reached in 5 min according to the reaction

$$SiO_2 + 4HF \rightarrow SiF_4 + 2H_2O$$

The agitated solution is allowed to cool for ½ hr and then is flooded away with H_2O.

H_2SO_4-*chromate.*—The sample is warmed in agitated, M/20 $Na_2Cr_2O_7 \cdot 2H_2O$ solution in H_2SO_4 to 140°-145°C and is held at this temperature for 1 hr. The solution is then cooled to 35°C, and the sample is removed and rinsed in H_2O.

Descriptions of Chemicals Used

Bromine, analytical reagent.
Oxygen, "Airco" U.S.P.
Hydrofluoric acid, 49% electronic grade.
Silicic acid powder, 78% SiO_2, reagent grade.
Sulfuric acid, 97%, electronic grade.
Potassium hydroxide, reagent grade.
Potassium bromide, reagent grade.
Potassium iodate, analytical reagent.
Sodium dichromate, dihydrate, reagent grade.
Hydrogen peroxide, 30%, stabilized, electronic grade.
Acetone, electronic grade.
Methanol, absolute, electronic grade.
Water, distilled and deionized, used for all rinsing and preparation of solutions.

Selection of Germanium Transistor Parameters by Control of Moisture at Low Levels within the Device Encapsulation

Robert J. Gnaedinger, Jr., Steward S. Flaschen, Marie A. Hall, and Edward J. Richez

Semiconductor Products Division, Motorola Inc., Phoenix, Arizona

ABSTRACT

Experiments have been carried out which indicate that moisture in air at levels below 1% relative humidity (200 ppm H_2O) has a strong influence on the surface recombination velocity of germanium and on the parameters of transistor devices derived from it. By controlling the moisture partial pressure at any of various given levels within hermetically sealed transistors, it has been found possible to preselect different ranges of several, stabilized, device parameters, such as h_{fe}, I_{CO}, and I_{EO} without changing the device fabrication procedure. A method for controlling the moisture partial pressure using pairs of inorganic compounds is presented together with data obtained from its application to large-scale manufacture. In addition to showing the practical value of these controlled moisture materials, these results emphasize the need for a more precise knowledge of the moisture level present in the "dry" gaseous ambients commonly used in studies of semiconductor surface properties.

It is well-known that the chemical composition of the gas phase adjacent to a semiconductor surface plays an important role in determining the electrical properties of that surface (1-3). Water vapor is perhaps the most striking example of this fact. High relative humidities produce severe and erratic current leakage paths across the surface of silicon and germanium crystals; changes in the humidity at moderate levels produce pronounced changes in the surface conductivity and surface recombination velocity. In the manufacture of semiconductor devices it was this high sensitivity to changes in the moisture level which caused the introduction of hermetic sealing of devices. Yet, although this hermetic sealing generally removed the erratic behaviors associated with gross moisture, there remained day-to-day, seasonal, and aging variations in the parameters of production devices. In order to reduce these variations, it was found necessary to insert moisture adsorbing materials into the hermetically sealed device encapsulations. This technique yielded a more reproducible product, but it frequently accomplished this at the expense of large shifts in the levels of some of the device parameters.

It is the purpose of this paper to present the results of new experimental studies of the effects of moisture on the parameters of germanium transistors. These results indicate that the presence of moisture vapor at very low levels continues to exert a strong influence on semiconductor surface properties, a conclusion suggested by previous work (4-7), but not experimentally verified. In addition, these results show that the rather disruptive role commonly associated with moisture in the manufacture of semiconductor devices can be converted into a constructive one by selection and control of the moisture level. Lastly, these results emphasize the necessity of being able to make a quantitative, rather than qualitative, statement of the dryness level in the adjacent gaseous ambient in experimental studies of semiconductor surfaces and semiconductor devices.

Experimental Method

The experimental method consisted of establishing, in principle, a constant moisture partial pressure within an hermetically sealed semiconductor device. This controlled moisture pressure was achieved through the utilization of the thermodynamic equilibrium that exists between two chemical phases in different, but adjacent, degrees of hydration. This is illustrated by Eq. [1] where the

$$2CaSO_4 \cdot \tfrac{1}{2}H_2O(\text{Solid}) \rightleftarrows 2CaSO_4(\text{Solid}) + H_2O(\text{Vapor Phase}) \quad [1]$$

half-hydrate of calcium sulfate is shown in equilibrium with anhydrous calcium sulfate and water vapor. The equilibrium constant for this reaction is the water partial pressure (Eq. [2]). As long as specific, crystalline

$$K_{eq} = p_{H_2O} \quad [2]$$

phases of both solids are present in a closed system, and as long as sufficient time for equilibration has been allowed at a given temperature, the moisture partial pressure in the adjacent gas phase will remain constant, independent of the total amount of moisture enclosed in the system.

The equilibrium pressure of water will be temperature dependent, varying in accordance with an Arrhenius expression, as long as no phase changes occur in the two solids. In Eq. [3] $\Delta H°$ is the standard heat of reaction. ($\Delta H°$ can be

$$K_{eq} = A \exp -\Delta H°/RT \quad [3]$$

expected to have some temperature dependence. In addition, the water partial pressure will show a small dependence on total pressure if an inert gas is present in the system; this dependence is deter-

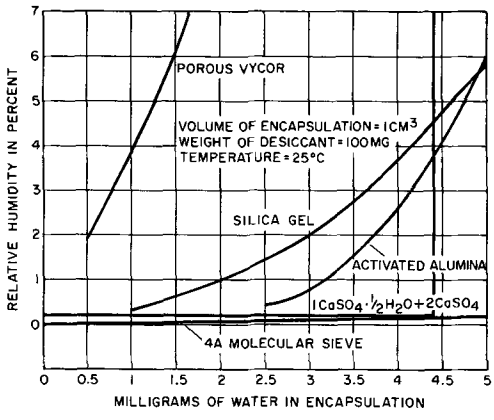

Fig. 1. Comparison of reactive and adsorptive moisture getters. Relative humidity *vs.* total encapsulated moisture.

mined by the volume change occurring in the reaction.)[1]

This type of behavior is distinctly different from the commonly used, adsorptive desiccants, *e.g.*, silica gel, activated alumina, etc., where the moisture partial pressure is strongly dependent on the total amount of moisture that is enclosed in the system. In Fig. 1[2] there is shown a comparison of the reactive type of moisture getter *vs.* the adsorptive types. This figure has been constructed for the following hypothetical situation. Consider that in a 1 cm^3 volume is 100 mg of getter. One then asks: What is the relative humidity in that volume at equilibrium at 25°C for various amounts of encapsulated water within that volume? The answer for the adsorptive getters is that there is a wide variation in the relative humidity with the amount of encapsulated moisture. In the example shown here, the molecular sieve shows variation, but at a very low level of relative humidity in comparison with the porous vycor, silica gel, and activated alumina. These curves show behaviors characteristic of true surface adsorption.[3] In contrast, the mixture of anhydrous and hemihydrated calcium sulfate shows a constant relative humidity up to the point where the anhydrous phase completely disappears. After this has occurred, the addition of further moisture causes an abrupt increase in the relative humidity.

If other chemical species are used in place of the calcium sulfate, different but similarly controlled moisture partial pressures can be achieved. In Table I are shown several systems of inorganic compounds together with calculated values of their equilibrium moisture partial pressures. All of the values shown have been computed from thermodynamic data in the literature (11), using the relation[4] given by Eq. [4]. Some have been qualitatively

$$\Delta F^\circ = -RT \ln K_{eq} \qquad [4]$$

[1] For further discussion of the subject of heterogenous equilibrium, see, for example, the treatise on the phase rule by Ricci (8).

[2] The data for this figure were obtained from Corning Glass (9) and Linde Company (10) and from thermodynamic data tabulated by the NBS (11). It was necessary to extrapolate the data to show the low relative humidity behavior of the adsorptive getters. The curves shown should be considered purely qualitative.

[3] See, for example, the treatise on surface films by Harkins (12).

[4] No value is listed for ΔF° of formation of $Ba(OH)_2$. Since it was observed that the ΔS° for the reaction $Ca(OH)_2 \rightleftarrows CaO + H_2O$, was identical to that for the $Mg(OH)_2$ reaction, this same value was assumed for $Ba(OH)_2$ in order to calculate the ΔF°. Note also that fugacity = pressure at these low pressures (13).

Table I. Equilibrium moisture partial pressures above several inorganic compound systems as calculated from thermodynamic data

System	Partial pressure at 25°C in mm of Hg
$BaO:Ba(OH)_2$	2×10^{-15} (approx)

checked by the Knudsen Method of measuring the rate of effusion through a pin hole.[5]

The materials listed above have been found experimentally to satisfy the criteria of chemical and electrical inertness with respect to germanium device surfaces, as shall be seen subsequently, apparently exerting influence on the devices primarily through their control of the moisture partial pressure.

Experimental Results

The following results were obtained by encapsulating, within hermetically sealed transistors, the specified "controlled ambient" materials in amounts sufficient to maintain the required, two solid phase system. The germanium pnp power transistors were processed normally through electrolytic etch in basic solution, rinse, and dry. The specified materials were then added and the encapsulation sealed immediately in room air. The materials were added with no attempt to prevent their contacting the germanium surface.

The high-frequency, germanium pnp transistors were processed normally through electrolytic etch, rinse, dry, and vacuum bake. The controlled ambient materials were then added and the encapsulation sealed immediately. In this case physical contact between the materials and the germanium was prevented for mechanical reasons.

Figure 2 shows the effect of different moisture controlling materials on the power gain of germanium power transistors. Each chart is a histogram showing the distribution of devices in the various power gain ranges for the given controlled ambient mixture. (The power gain range to the right of 41 db contains devices with P.G. $\geqq$ 41 db.) The ordered dependence of power gain on the calculated moisture partial pressure (Table I) at these very low levels is strikingly apparent. Increasing the moisture pressure increases the power gain.

Parameter measurements were made following a 96 hr thermal treatment at 125°C and a subsequent recovery at room temperature for a minimum time of 12 hr.

[5] Our measured values on reagent grade hemihydrate of calcium sulfate were approximately 0.06 mm of Hg at 25°C. Several phase modifications of anhydrous and hemihydrated calcium sulfate are reported in the literature. The value shown in Table I was calculated for the β-phase of each.

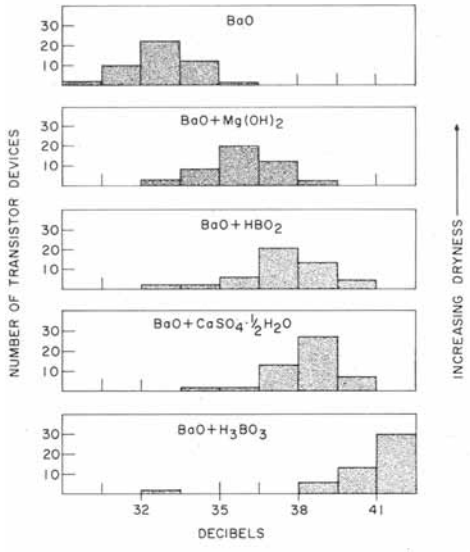

Fig. 2. Effect of moisture level on power gain of germanium pnp power transistors.

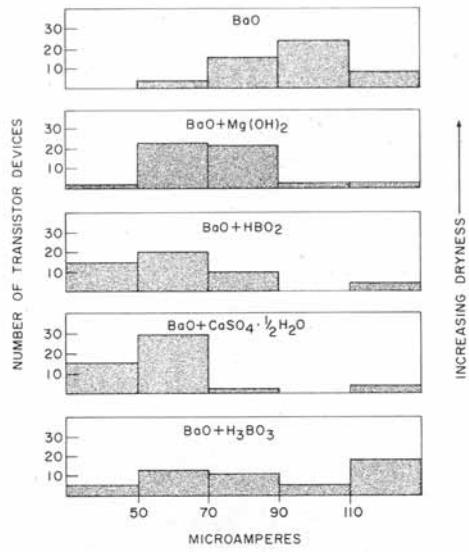

Fig. 3. Effect of moisture level on low voltage saturation current of germanium pnp power transistors.

The designed function of the BaO in these mixtures is to dehydrate a portion of the hydrated phase in order to establish the two phase equilibrium. The BaO becomes completely converted to $Ba(OH)_2$ by this process and does not apparently affect the equilibrium in any other manner. That this is, in fact, the real function of the BaO is borne out by the behavior of the data; in addition, it was verified experimentally by varying the ratio of BaO to $CaSO_4 \cdot \frac{1}{2}H_2O$ and by using mixtures of $CaSO_4 \cdot \frac{1}{2}H_2O$ and $CaSO_4$ without BaO, both of which produced results that were statistically indistinguishable from the $BaO + CaSO_4 \cdot \frac{1}{2}H_2O$ results shown in Fig. 2.

Each of the histograms in Fig. 2 was prepared from 50 devices which were randomly selected from one week's production run. Statistical analysis of the data used for Fig. 2 indicates that the difference between the mean of each mixture and that of the BaO lies in the interval shown in Table II, with 95% confidence. From this it can be seen that by reducing the moisture level from a calculated 50 ppm ($BaO + CaSO_4 \cdot \frac{1}{2}H_2O$) in air to an extremely dry condition (BaO), the power gain can be lowered by about 6 db. [It might be noted that "vacuum bake-out" plus molecular sieve getter gives power gains that are similar to the $BaO + Mg(OH)_2$ system.]

Table II. Comparison of mean power gains of pnp germanium power transistors for different controlled ambient materials

Mixture	No. of devices	Mean P.G. after thermal treatment	P.G.—P.G. (BaO) ± 95% confidence limits
BaO	240	32.9	—
$BaO + Mg(OH)_2$	46	35.8	2.9 ± 0.8
$BaO + HBO_2$	45	37.6	4.7 ± 0.8
$BaO + CaSO_4 \cdot \frac{1}{2}H_2O$	49	38.5	5.6 ± 0.7
$BaO + H_3BO_3$	48	42.6	9.7 ± 1.1

BaO represents 5 day, 48 devices per day. Remainder represent single days. Comparison is with 5 day BaO average, this being the control group. A histogram for one of these BaO groups is given in Fig. 2.

These represent good devices in the sense that both emitter and collector diodes showed reasonable reverse breakdown voltages and collector to emitter punch-through voltages were reasonably high.

The behavior of the common emitter current gain was measured and was as expected from the power gain measurements, *i.e.*, P.G. (db) $\propto \log h_{fe}$ for the same emitter current.

Figure 3 shows histograms of the low voltage saturation current for the same devices used in Fig. 2. (The cell to the right of 110 μa contains devices with $I_{CBO} \geqq 110$ μa.) The temperature of measurement was 26° ± 1°C. As can be seen, there is again an ordered dependence of I_{CBO} on the calculated moisture pressure. Increasing the moisture level decreases the I_{CBO} of these devices, except for the orthoboric acid group which shows a bimodal distribution. After further recovery at room temperature, this distribution becomes unimodal, like the other groups, with a strong peak in the cell with the lowest current. Since the power gain in this group recovers more rapidly from the 125°C heating than does the I_{CBO}, it appears that in this case those chemical processes, which affect the surface recombination velocity, stabilize within 12 hr; on the other hand, there appears to be an additional factor affecting the I_{CBO}, which factor requires a longer time for recovery than does the surface recombination velocity.

Figure 4 shows that the effect of ambient moisture control persists up to 100°C. Here each histogram includes 100 devices. The low voltage saturation currents of devices containing the metaboric acid mixtures are clearly well below those of the dryer devices which were given a "vacuum bake-out" and which contain molecular sieve.

Other device parameters were also followed in these experiments. The low voltage I_{EBO} showed a behavior that was very similar to that of I_{CBO}. The breakdown voltages of the collector junctions were approximately the same for all of the "controlled ambient" materials except for the boric acid groups which caused breakdown at lower voltages.[6] The emitter breakdown voltages behaved in a manner similar to those for the collectors.

[6] The orthoboric acid appeared to lower the breakdown voltage slightly. The metaboric acid lowered it by an average of about 20v. Thus, it appears that the boric acids may be acting in some capacity in addition to providing moisture.

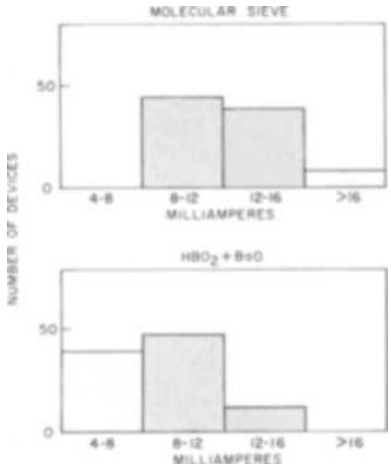

Fig. 4. Effect of controlled ambient material on low voltage saturation current of germanium pnp power transistors at 100°C.

Cold tests showed no diode looping associated with condensed water, a result consistent with the low relative humidities within these devices. Strenuous shake tests produced no changes in most parameters and only slight changes (within specifications) in others.

The effects of 1000 hr of 125°C shelf aging on the power gain and the low voltage I_{CBO} are presented in Tables III and IV.[7] These data indicate that accelerated aging at 125°C of these devices containing controlled ambient materials produces changes that are comparable to current production practice.

[7] The device groups in Tables III and IV are not the same as those in Table I. The small differences in the means for the same controlled ambient material can be ascribed to differences in group sizes and to variations in production runs.

Table III. Thermal aging of pnp germanium power transistors at 125°C for 1000 hr, effect on power gain

Mixture	No. of devices	Mean P.G. after thermal treatment	Mean P.G. after 1000 hr at 125°C	Change in mean with 95% confidence limits
BaO	19	32.4	33.0	0.6 ± 0.2
Molecular sieve	239	35.2	34.9	−0.3 ± 0.1
$BaO:Mg(OH)_2$	20	36.1	35.1	−1.0 ± 0.3
$BaO:HBO_2$	237	38.8	37.2	−1.6 ± 0.1
*$BaO:CaSO_4 \cdot \frac{1}{2}H_2O$	113	39.5	38.2	−1.3 ± 0.2

* This group received 1300 hr at 125°C.

Table IV. Thermal aging of pnp germanium power transistors at 125°C for 1000 hr, effect on low voltage I_{CBO}

Mixture	No. of devices	Median** after thermal treatment, μa	Median** after 1000 hr at 125°C, μa	Per cent change in median with 95% confidence limits
BaO	19	75.9	80.8	6.4 (2.8–10.0)
Molecular sieve	239	68.7	81.0	18.1 (16.5–19.8)
$BaO:Mg(OH)_2$	20	58.1	68.0	17.1 (4.5–31.1)
$BaO:HBO_2$	237	50.3	71.6	40.5 (37.6–43.5)
*$BaO:CaSO_4 \cdot \frac{1}{2}H_2O$	113	62.1	57.9	−4.0 (−7.4–−0.5)

* This group received 1300 hr at 125°C.
** Median computed from the formula:

Median = $10^{\overline{\log I}}$, where $\overline{\log I}$ is the mean value of log I_{CBO}.

Comparisons were made of the rate of stabilization of h_{fe}, after canning, at room temperature *vs.* that at 125°C, all measurements being made at room temperature. In the case of BaO, greater than 95% of the total drop in h_{fe} after 1000 hr at 125°C had occurred within the first day. On the other hand, the room temperature stabilization showed a continuously dropping h_{fe} out to 1000 hr, with a constantly decreasing rate. At 1000 hr the h_{fe} level was still considerably higher than in the devices that were heated at 125°C. It is not clear from these data whether or not the h_{fe} level during 25°C stabilization is asymptotically approaching the level rapidly attained at 125°C (although this is the best surmise). Likewise it is not clear that the stabilization process at 25°C is kinetically controlled by the oxidation of the germanium surface, or by the dehydration of the surface oxide, or by the desorption of moisture from the device interior, or by the uptake of water by the BaO.

The effect of power aging ($T_j = 90$°C and $V_{CE} = 40$v) is shown in Table V. Tabulated there are the power gains of eight devices of each group: BaO, molecular sieve, and $BaO + CaSO_4 \cdot \frac{1}{2}H_2O$. Measurements were made after 125°C thermal treatment at 500 hr and at 1000 hr. There appears to be little difference in power aging behavior with these different controlled ambient materials and the molecular sieve. Statistical analysis corroborates this observation for the above groups and also for $BaO + HBO_2$ and $BaO + Mg(OH)_2$, on both power gain and low voltage I_{CBO} parameters.

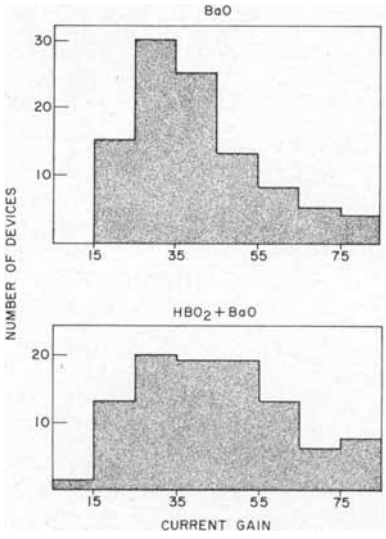

Fig. 5. Effect of moisture level on current gain of germanium pnp high-frequency transistors.

Controlled ambient materials were applied to another device, a high-frequency pnp germanium transistor. Figure 5 shows the effect of moisture control on the current gain of this diffused junction device. These histograms were each prepared from 100 devices, representing 20 random samples from the production on each of five days. The enhancement of gain achieved by controlling the moisture at a finite level over that obtained in the very dry condition is most evident in the high gain portion of the distributions. Parameters were measured on these devices after a thermal treatment of 144 hr at 125°C. The histogram was prepared from these data. The median β's in these two groups were: BaO, 35.9; BaO + HBO_2, 39.6. The median value of β has been calculated on the basis of a log normal distribution.

Figure 6 shows the effect of 125°C shelf aging on β. The initial aging pattern is distinctly better with metaboric acid than with the very dry system containing BaO. At longer times the two curves appear to age downward at about the same rate with the controlled moisture system maintaining its enhanced current gain relative to the very dry system.

Discussion

The data presented above indicate that certain parameters of germanium transistors depend very sensitively and reproducibly on moisture partial pressures at levels from about 80 ppm to below 1 ppm in air. The parameters thus affected are those which are strongly influenced by surface recombination velocity (or surface generation rate). The simplest interpretation to be made of these observations is that even at these very low partial pressures, sufficient water is adsorbed onto the germanium (or germanium oxide) surface to affect the surface properties appreciably. According to the work of Law (14), monolayer adsorption of water onto a germanium surface does not become complete until a relative humidity of about 10% is reached (this relative humidity in air at 1 atm pressure at 25°C corresponds to about 2000 ppm of H_2O). Consequently, the present results suggest that water plays perhaps its dominant role in affecting surface recombination velocity in the region below one monolayer, a conclusion that is consistent with the work of Law and Meigs (4).

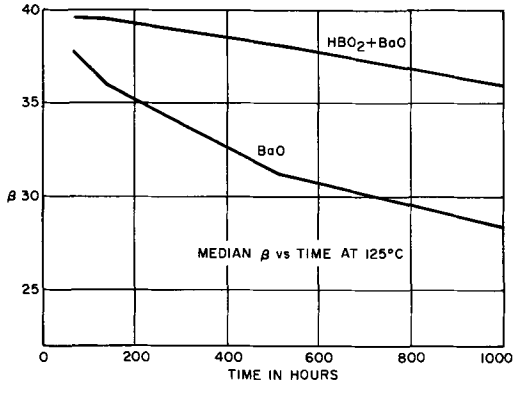

Fig. 6. Effect of ambient moisture control on elevated temperature shelf aging of β. High-frequency germanium transistors.

The detailed mechanism of how adsorbed water achieves this effect is not clear. However, since water is known to induce n-type channels (15) on p-type germanium, it has been postulated that adsorbed water molecules behave like slow, hole-trapping states. This same postulate has been used to explain observations of the effect of Brattain-Bardeen ambient cycling on the surface recombination velocity of germanium (16).[8] On the other hand, more recent work by Margoninski and Farnsworth (18), and others, has suggested that adsorbed water modifies the fast state energies and densities as well as slow state densities. (It should be borne in mind, however, that these latter studies used very moist ambients, resulting in multiple layers of adsorbed water in a region where the adsorption isotherm is rising very rapidly with increasing relative humidity. Thus, not only are films of water present, with attendant effects associated with ion drift and other electrolytic phenomena, but also the film thickness is in questionable control; severe complications in reproducibility and interpretation of measurements are present. It might be hoped that ambient cycling between a truly dry ambient and one that produces less than monolayer adsorption would give results that can be reproduced.) No structure has yet been proposed for either the slow or fast states, although it has been suggested that they are associated somehow with the formation of hydroxy groups in the surface oxide (1, 7) during a slow hydration reaction. [At higher moisture partial pressures, Hutson (19) ascribes the effect of water on surface potential to a dielectric polarization of the multilayer water film about unspecified surface donor ions; the first monolayer was specifically excluded from his analysis.]

However, the slow hole-trapping state model can be used to give a qualitative explanation of the results presented here. Figure 7 consists of a conventional energy band diagram for an n-type semiconductor as it terminates at a surface. Adsorbed water molecules are shown symbolically as H_2O $\oplus$ after

[8] Brattain and Bardeen (1), Stevenson and Keyes (16), and Many, Harnik, and Margoninski (17) consider the theory of surface recombination velocity.

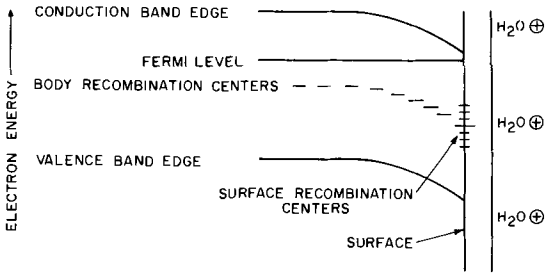

Fig. 7. Simple model of the effect on the surface recombination velocity of water adsorbed on an n-type semiconductor.

electronic equilibration with the crystal, in accordance with the slow state model. If it is assumed that the water molecules are neutral when first adsorbed, they must then give up electrons to the semiconductor during the equilibration process. These electrons may be trapped predominantly in fast surface states, if the latter are sufficiently numerous, resulting in a negligible effect on the surface conductivity and the surface potential. This was the result found in the original field-effect transistor experiments (20). However, if the fast surface states are relatively few in number, the electrostatic field associated with the ionized slow states will penetrate into the semiconductor, resulting in a strong effect on the surface conductivity and the surface potential, as shown in the Fig. 7.

This simplified model is sufficient to explain the present data as can be seen as follows: Although the electron population in the surface traps is increased by moisture, the electric field in the surface space charge region opposes the diffusion of holes toward the surface. This latter accounts for the reduction of injected carrier loss and the consequent increase in alpha with higher moisture levels. At the same time the higher electron population in the fast surface traps reduces the likelihood of thermal generation of holes at the surface since vacant electron traps are necessary. This accounts for the reduction of the surface generated component of the low voltage, reverse diode current with increasing moisture.

In order to obtain estimates of the surface recombination velocity at the different moisture levels, $h_{fe} - I_E$ plots were fitted to the Webster equation (21), which relates h_{fe} to doping, geometry, and surface recombination velocity. Figure 8 shows typical $h_{fe} - I_E$ plots for power transistors from several groups of controlled ambient encapsulants. The dominating influence of surface recombination velocity at low I_E is clear. The power gain distributions previously presented corresponded to $I_E = 0.5$ amp, where the effects of surface recombination velocity are being partially masked by strongly reduced emitter injection efficiencies due to conductivity modulation in the base.

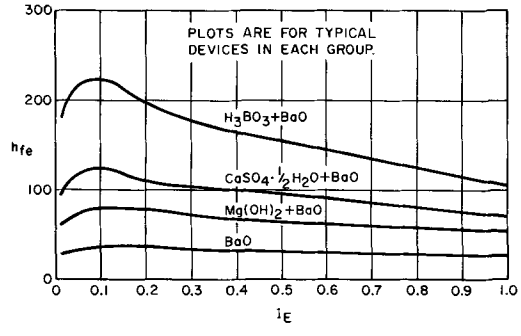

Fig. 8. h_{fe} vs. I_E for germanium pnp power transistors encapsulated with different controlled ambient mixtures.

Table VI. Surface recombination velocities for different controlled ambient mixtures as approximated using Webster's formula for germanium pnp alloy transistors

Moisture control mixture	Surface recombination velocity (approx), cm/sec
BaO	4000
$Mg(OH)_2$ + BaO	2000
HBO_2 + BaO	1000
$CaSO_4 \cdot \frac{1}{2}H_2O$ + BaO	1000
H_3BO_3 + BaO	500

Only very approximate fits to Webster's equation were made. The results are shown in Table VI. Qualitatively, they suggest that in going down from a relative humidity of approximately 0.4% (H_3BO_3 system) to very low moisture levels, one can change the surface recombination velocity by a factor of about ten.

It should be noted that the effect of adsorbed moisture (as slow states) on device parameters will depend on the distribution of fast states and other slow states already present at the surface; the effects will also depend on the conductivity type of the body region. This is clearly demonstrated in the experiments of Buck and McKim (22) on silicon.

Experiments have also been carried out with silicon devices containing controlled ambient materials. The parameters of some of these devices have been affected in a similar pronounced manner; the behavior pattern seems to be consistent with that found with germanium devices, as described above.

Conclusion

1. These experiments have indicated that moisture vapor in air within the sealed, device encapsulations has a pronounced effect on the surface recombination velocity of germanium transistors at extremely low relative humidities, relative humidities as low as 10^{-3}% (0.2 ppm).

2. These experiments indicate the necessity of carrying out studies of semiconductor surface properties with a quantitative knowledge of the moisture level present in the gaseous ambient adjacent to the surface.

3. These experiments suggest that the use of ambient control materials for the stabilization of moisture partial pressures can be an asset in semiconductor device production. These materials allow the selection and control of certain device parameter levels over wide ranges without the requirement of modifying the body construction of the device.

Acknowledgment

This study was initiated with the active and willing assistance of David A. Kallander, Camille M. Lutfy, and Dale R. Lowe. It has proceeded only because of the complete cooperation we have received from individuals in the production and quality control

departments of Motorola's Semiconductor Products Division, in particular, Valmore E. Turcotte, John R. Welty, and Leo E. Dwork. It prospered under the protective wing of our statistical guardian angel, Dr. Irwin Miller of Arizona State University. And lastly, it is our pleasure to acknowledge manuscript suggestions by Dr. Trevor E. Law, Dr. Raymond M. Warner, Jr., and the reviewers of this paper.

Manuscript received Nov. 1, 1961; revised manuscript received Feb. 23, 1962. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Role of Selenium Vapor Pressure in the Formation of Silver Doped Manganese Selenide

W. D. Johnston

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The effect of selenium vapor pressure on MnSe containing small additions of Ag_2Se has been studied by both weighing and electrical measurements. Three distinct regions have been noted. At low selenium pressures selenium is taken up by the mixture to form the mixed valence compound $Ag_xMn_{(1-x)}Se\oplus_x$. The value of $\oplus$, the hole concentrations, increases as a function of the selenium pressure until all Ag_2Se is used up and the sample becomes a single phase. At this equivalence point the pressure then increases rapidly with little change in composition. Finally, the pressure becomes sufficiently high that manganese vacancies are produced. These regions are described in terms of mass action expressions which link the vapor pressure with vacancies and electrical charge carrier concentrations.

The substitution of monovalent lithium for divalent manganese in MnSe has been shown to be possible up to 11 atomic %, *i.e.*, $Li_{0.11}Mn_{0.89}Se$ (1). Throughout this composition range the rock salt symmetry of MnSe is maintained. The products of such substitutions have been found to be electrical conductors with the conductivity increasing with lithium content. An electrically balanced formula for the composition $Li_xMn_{(1-x)}Se$ may be given as $Li^+_xMn^{+3}_xMn^{+2}_{(1-2x)}Se^=$ or alternatively $Li^+_x\oplus_xMn^{+2}_{(1-x)}Se^=$. The formulas are written for convenience in ionic form. In the latter formula $\oplus$ refers to holes and emphasizes that the holes are not localized on any particular manganese at normal temperatures (2).

A survey was made to determine what other doping additives could be used in order to induce p-type semiconductivity in MnSe. To this end Na, Cu, Ag, Au, Tl, and Cu were substituted for Mn. Selenium was replaced by As, P, and Si. The only successful doping agents proved to be Na and Ag as indicated by room temperature electrical measurements. The silver seemed to be soluble to only about 2 atomic % on the basis of a discontinuity in the thermoelectric power *vs.* resistivity curve as shown in Fig. 1. In this preliminary survey the reactants were fired iso-

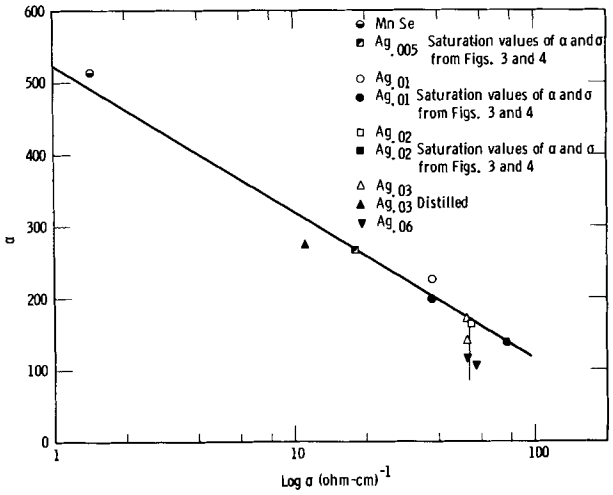

Fig. 1. α vs. log σ for $Ag_xMn_{(1-x)}Se$

thermally at 800°C in small sealed Vycor tubes. Additional qualitative experiments with silver substituted MnSe showed that the doping level decreased as selenium was removed by volatilization at elevated temperatures. The study described in this paper was undertaken in order to understand this relationship more fully. In brief the experiment performed was designed to give the stoichiometry or charge carrier concentration at various pressures of selenium vapor.

Experimental

The stoichiometry of the MnSe used in this work was critical to the success of the experiments. MnSe was prepared from −60 mesh vacuum distilled manganese and −60 mesh 99.99% selenium supplied by the American Smelting and Refining Company. The reactants, including a 10% excess of selenium, were either placed in a graphite crucible and sealed in Vycor or alternatively they were sealed in a Vycor tube which had been carbon coated by the pyrolysis of acetone. The material was heated up slowly to avoid any sudden evolution of heat to a final temperature of 700° and held for 24 hr. The product was crushed to 160 mesh and reheated for another 24 hr at which point the excess selenium was distilled off at 800°C. The recrushing was necessary to react all the manganese, and the 800° distillation quantitatively removed the excess selenium.

Products of the type $x/2\ Ag_2Se + (1-x)$ MnSe were prepared from a mixture of a −100 mesh powder composed of weighed amounts of the stock MnSe and silver and selenium powders. The powders were pressed at 15,000 lb in a 3/8 in. diameter carbide die. The pellet was sealed in a graphite crucible and Vycor tube which had been previously outgassed. The mixture was heated isothermally at 800°C for 20 hr, then one end of the tube was placed at room temperature and volatile material, if any (none was ever observed), was allowed to distill to the room temperature end. The pellets obtained in this manner were clearly composed of two phases consisting of a small amount of shiny material distributed in the black pellet.

For the vapor pressure studies a 6g pellet of $x/2Ag_2Se + (1-x)$ MnSe as prepared above was weighed and placed in a graphite boat which was sealed in a 12 in. long 19 mm diameter Vycor tube. In one end of the tube was a ½ in. long chamber which contained selenium. The pellet was held at the other end. The tube was placed in a two zone furnace such that the pellet was maintained at 800°, and the temperature of the selenium reservoir was at some lower temperature which could be chosen at will. The selenium reservoir temperature was arranged to be the coldest temperature of the tube, and thus the selenium vapor pressure was controlled by this temperature. In this manner the reaction

$$\frac{x}{4}\ Se_2\ \text{vapor} + x/2Ag_2Se + (1-x)\ MnSe \rightleftarrows Ag_xMn_{(1-x)}Se$$

may be studied. By quenching the sample tube at the end of the experiment and weighing the pellet, the uptake of selenium may be determined. Since selenium requires two electrons to be donated from the lattice to form the selenide ion ($Se^=$), creating two holes, the weight uptake of selenium may be expressed in terms of the hole concentration of the MnSe phase. It should also be noted that for each selenium added from the vapor two silvers are also added to the MnSe lattice and thus are equal to the hole content. It was found that equilibrium was achieved in less than 16 hr at all selenium pressures since an additional 16 hr or more did not result in a substantial additional weight change (generally less than ½ mg). Data were taken at random temperatures of the selenium reservoir which results in both adding and removing selenium from the sample in a random manner.

The first run however was an exception to this and was always at 600° reservoir temperature since, as will be seen later, the selenium pressure generated at 600° generally is sufficient to drive the formation reaction to completion. This first experiment thus acts as a check on the stoichiometry of the starting material. Apparently manganese and silver are not lost in any measurable amount from the pellets, nor does handling result in any appreciable weight loss since, on removal of the selenium added during a series of experiments by distilling this selenium to a room temperature reservoir, the starting weight is reproduced to within ± 1 mg.

As mentioned previously, repeat measurements are reproducible in pellet weight to ~ ½ mg. The weight changes recorded in this work range from 2-3 mg obtained at the lowest selenium additions to 30 mg at the highest selenium additions. The effect of this error is clearly visible in the wide scatter of the data at the low pressure-low selenium addition region of Fig. 2.

One must inquire as to the uptake of selenium vapor by MnSe and Ag_2Se individually in order to evaluate properly the uptake of the mixture. The MnSe case has been studied in detail, and the results are shown in Fig. 2. The change in weight of Ag_2Se maintained at 800° has been examined after equilibration with both a 600° selenium reservoir and a room temperature reservoir. In the case of the distillation to room temperature a weight loss

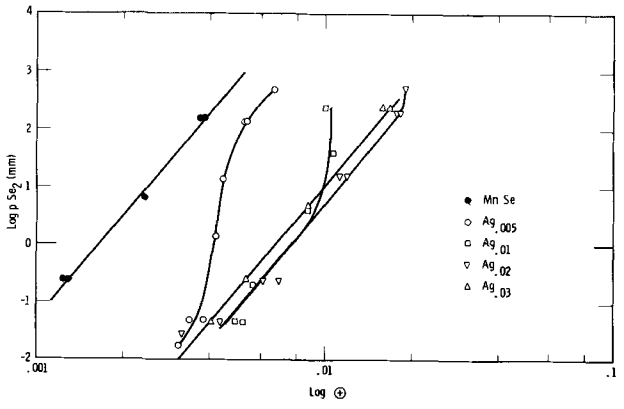

Fig. 2. Log p Se_2 vs. log $\oplus$ for $Ag_xMn_{(1-x)}Se$

of 0.24% was observed. In the case of the 600° Se reservoir experiment the sample gained a total ~ 1.1% by weight of selenium and was a liquid at 800°[mp reported (3) 897°] which liberated selenium on cooling. This weight change is negligible when one considers that only small amounts of Ag_2Se are used in the experiments combined with MnSe.

The selenium vapor pressure used is that reported by Brooks (4). It is taken as being purely dimeric Se_2. This approximation is not strictly correct since at 800°C and a pressure of Se_2 of 1 atm the pressure of the hexamer, Se_6, would be 0.02 atm (5). However, the relative pressure of the hexamer decreases rapidly with decreasing pressure of the dimer, and therefore, the 2% contribution is the worst possible case. The use of a lower sample temperature than 800°C would rapidly lead to an increased hexamer content, so 800° must be considered a minimum operating temperature to avoid this additional complication in the calculations.

After each experiment electrical measurements were made. Resistivities were measured by the standard four terminal technique and the thermoelectric power was measured as described elsewhere (6).

Samples of $Ag_xMn_{1-x}Se$ where x = 0.01, 0.02, 0.03, and 0.06 were made for the preliminary studies by firing all reactants in small isothermal sealed tubes at 800°C. In this way the samples would decompose until their equilibrium vapor pressures were reached. The samples where x = 0.03 and 0.06 were examined by x-ray and metallography. The x-ray patterns of both samples showed NaCl cubic MnSe and weak lines of β-Ag_2Se. By metallography the small amounts of a second phase appears in the grain boundaries and may have been liquid at one time.

Results

The results of the vapor pressure experiments are summarized in Fig. 2. This figure gives the appearance of a group of titration curves which in fact it is. The figure gives a plot of log vapor pressure *vs.* log of the electron hole concentration as determined by the weight of the sample pellet, assuming each selenium added permits the formation of two holes. The data can be described in terms of three distinct regions. There is the doping region in which selenium vapor is taken up while a corresponding amount of Ag_2Se is reacted. This continues until the total amount of Ag_2Se present has been reacted. At the conclusion of this region $Ag_xMn_{(1-x)}Se$ is completely formed. The next region is the equivalence point region or the controlled valence region. Finally, there is the vacancy region. The figure shows that in the doping region the curves coincide within the rather large experimental error. This region is shown on the graph as a straight line with slope = 6. As the equivalence point for each sample is reached, the curve rapidly becomes vertical. It would be expected that the vertical region would occur exactly where there is selenium uptake equal to Ag_2Se added. Any departure from this is assumed to reflect experimental error. In the sample $Ag_{0.005}Mn_{0.995}Se$, the only one where measurements could be made substantially beyond the equivalence point, the curve again assumes a slope similar to that of the doping region. Further, this region is approaching the data for MnSe containing no silver additions which also has a slope =6. This additional uptake beyond the silver equivalence point represents the creation of manganese vacancies in the lattice.

From Fig. 2 it is clear why the phase boundary suggested in Fig. 1 comes about. The data plotted in Fig. 2 are terminated at nearly 1 atm of Se_2. This occurs near the equivalence point for $Ag_{0.02}Mn_{0.98}Se$. Insufficient Se has been added for the formation of $Ag_{0.03}Mn_{0.97}Se$. In fact, this composition is impossible at a sample temperature of 800° under any circumstances. If the Se_2 reservoir temperature were increased to 800°C (the sample temperature), Fig. 2 indicates that the selenium uptake would only be sufficient for the formation of $Ag_{0.027}Mn_{0.973}Se$. The selenium pressure would be 3.5 atm at these conditions on the basis of an extrapolation of the data of Brooks (4).

The electrical conductivity data corresponding to the sample compositions in Fig. 2 are plotted in Fig. 3. The correspondence between Fig. 2 and Fig. 3 is quite apparent. The doping region is again of slope 6. The equivalence points for x = 0.005, 0.01, and 0.02 are at conductivities 19, 37, and 76 ohm^{-1} cm^{-1}. Thus the conductivities at the equivalence point es-

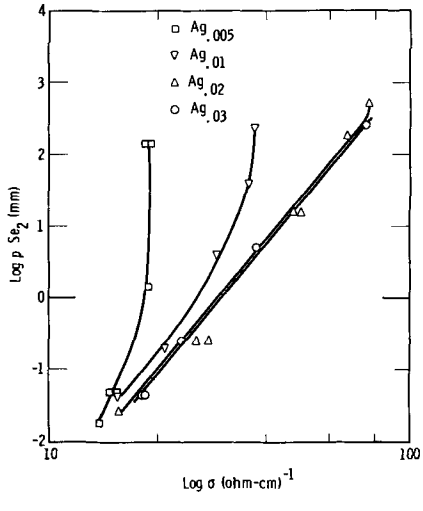

Fig. 3. Log p Se_2 vs. log σ for $Ag_xMn_{(1-x)}Se$

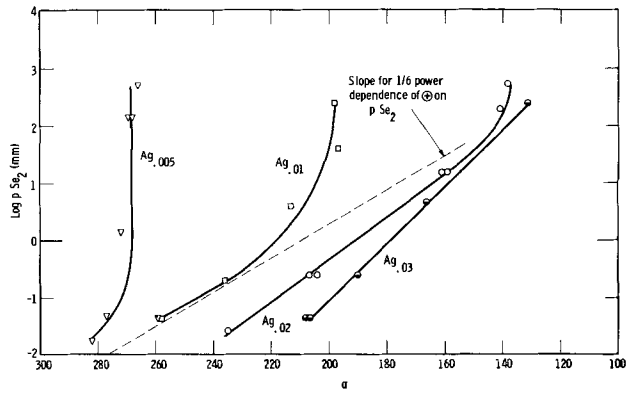

Fig. 4. Thermoelectric power of $Ag_xMn_{(1-x)}Se$ as a function of log p Se_2.

sentially double with each doubling of x, as would be expected. The data on this graph are actually probably more accurate than that of Fig. 2 since the data in Fig. 2 involves a very large weighing error at low selenium additions.

Thermoelectric power data corresponding to the compositions of Fig. 2 and Fig. 3 are plotted in Fig. 4. At the equivalence point the thermoelectric power, α, changes from +137 to +197 to +268 μv/°C for $x = 0.02$, 0.01, and 0.005. Theoretically a decrease of ~60 μv/°C for each doubling of $\oplus$ would be expected since $\alpha \sim -k/e \ln \oplus + C$ so there is agreement at this point (6). In the doping region however, the curves might be expected to coincide on the basis of Fig. 2 and 3. Actually at a given selenium pressure the higher the value of Ag in this region the lower value of α. This is due to the presence of the second phase of n-type Ag_2Se in the product which will give rise to internal circulating currents between the p- and n-phases. [Ag_2Se normally (7) has the electrical properties $\alpha = -150$ μv/°C and $\sigma = 10^3$ ohm^{-1} cm^{-1}.] As indicated earlier in Fig. 1, this has a large effect on α, but little effect on σ. In Fig. 4 a slope corresponding to that of Fig. 2 and 3 is indicated by a dotted line showing that where the silver content is low there is good agreement with this slope but, as the silver content increases, the deviation becomes marked showing the effect of increased amounts of the Ag_2Se second phase.

No data for MnSe are given in Fig. 3 and 4 in spite of the fact that considerable nonstoichiometry was indicated in Fig. 2. It was found that all MnSe samples had nearly constant values of α and σ of ~ +500 μv/°C and 1 ohm^{-1} cm^{-1}, respectively. Actually, values of α as low as ~ +280 and values of σ are high as ~15 would be expected from the figures, and further the values would be expected to vary systematically with composition. Evidently the vacancy structure of MnSe is not stable at room temperature, and the vacancies are eliminated rapidly on quenching with the probable formation of $MnSe_2$. This experience indicates the risk associated with inferring high-temperature data from room temperature electrical measurements as is frequently done. Such inferences from weight data are much more sound since weight data are not structure sensitive and processes involving changes in weight are much slower than just an atomic or electronic rearrangement. This comparison also bears out the hypothesis that has been held for some time that doped semiconductors are thermally much more stable than those relying only on nonstoichiometry for the control of charge carriers.

Discussion

A number of cases involving the relationship between the electrical conductivity and the vapor pressure of a gaseous component have been reported in the literature. These are generally cases of simple nonstoichiometry. The approach is usually through the use of mass action. The groundwork was laid in 1930 by Wagner and Schottky (8). It has been pursued experimentally by Wagner (9), Hauffe (10), and others. A graphical method of approximating these interactions has been introduced by the Phillips workers, notably Kroger and Vink (11). A similar approach using semiconductor terminology has recently been discussed by Brebrick (12). A simple mass action approach will be used in the discussion to follow.

The simplest case to be treated is that of nonstoichiometric MnSe. The chemical equation may be written

$$MnSe + \frac{x}{2} Se_2 \rightarrow MnSe_{1+x} \boxed{Mn^\circ}_x \oplus_{2x}$$

where $\boxed{Mn^\circ}$ is assumed to be a neutral (or doubly ionized) manganese vacancy, and $\oplus$ is a hole. With respect to the manganese lattice, the manganese vacancy as written has a net charge of −2 and is therefore a potential trap for holes. The mass action expression for this equation may be written

$$K_1 = \frac{\boxed{Mn^\circ}^2 \oplus^4}{p\,Se_2}$$

but since $2 \cdot \boxed{Mn^\circ} = \oplus$

$$K_1 = \frac{\oplus^6}{4\,p\,Se_2}$$

Thus it can be seen that the slope of the log p Se_2 *vs.* log $\oplus$ plot should have a slope of 6 as is indeed observed. The agreement indicates that the manganese vacancies are not trapping electron at the temperature of the experiments, in accord with the starting equation.

This same approach may be used beyond the equivalence point in the silver doped samples

$$Ag_xMn_{(1-x)}Se \oplus_x + \frac{y}{2} Se_2 \rightarrow Ag_xMn_{(1-x)}Se_{1+y} \boxed{Mn^\circ}_y \oplus_{x+2y}$$

Here the expression for the equilibrium constant turns out to be the same as before, but now $\oplus = Ag + 2\boxed{Mn^\circ}$

so

$$K_1 = \frac{(\oplus - Ag)^2 \oplus^4}{4\,p\,Se_2}$$

This is clearly not a simple exponential. A series of curves were calculated using K_1 derived from the MnSe data and the silver concentrations of the experiments and are shown in Fig. 5. The derived

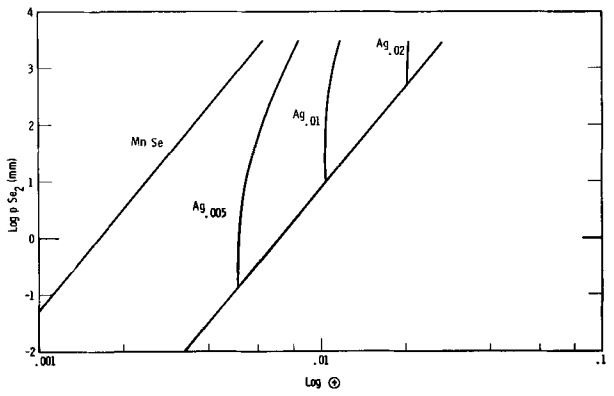

Fig. 5. Derived log p Se_2 vs. log $\oplus$ calculated using log $K_1 = -16.1$.

curves give the very slow change in composition with changing selenium pressure near equivalence points and then a less steep approach to the MnSe curve. The MnSe and $Ag_xMn_{(1-x)}Se$ curves will become indistinguishable when $\oplus >> Ag$. At that point the $Ag_xMn_{(1-x)}Se$ curve will have a slope of 6. Thus both the equivalence region and the vacancy region are described by one equation.

The region in which doping occurs has not been successfully evaluated in these terms. The over-all formation reaction may be written

$$\frac{x}{2} Ag_2Se + \frac{x}{4} Se_2 + 1 - x\, MnSe \rightarrow Ag_x \oplus_x Mn_{(1-x)}\, Se$$

If Ag_2Se is assumed to be at a fixed activity, a slope of 8 would be derived for the plot of Fig. 2. The observed slope is 6, however. The lack of agreement is believed to be due to the changing activity of Ag_2Se with selenium pressure that has been demonstrated earlier and which has also been described in the work of Wagner (13), Miyatani (14), and Rahlfs (15).

The presence of a phase containing selenium vacancies as a result of the silver addition, *i.e.*, $Ag_xMn_{(1-x)}Se_{1-x/2}\boxed{Se}_{x/2}$, instead of a two phase mixture of $x/2$ $Ag_2Se + (1-x)MnSe$ can be ruled out since it would lead to a variation in vapor pressure with the silver content at the start of the selenium addition which is far beyond the experimental error involved. Instead the data are completely independent of the silver content in this region. Moreover insolubility of Ag_2Se in MnSe has been demonstrated, at least at room temperature, by visual observation and thermoelectric power measurements. Therefore, in terms of the ternary phase diagram, the process of selenium addition can be described in terms of cutting across the tie lines of the Ag_2Se-MnSe binary field.

Finally one might consider the behavior of $Li_xMn_{(1-x)}Se$ within this framework. A rather serious attack of Vycor by lithium precludes any accurate experimental work since a continuous undoping will arise from this attack. Electrical data indicate, however, that at least in the case of $Li_{0.03}Mn_{0.97}Se$ the material probably is completely within the controlled valence range throughout the range of selenium pressures used in this work. It is also reasonable to suppose that when $x = 0.11$ in $Li_xMn_{(1-x)}Se$, which is the previously reported phase boundary composition (1), the selenium equilibrium vapor pressure has increased to the vicinity of 1 atm. This in itself would require a large extension of the range of controlled valence by the mechanism of lowering the doping curve for $Li_xMn_{(1-x)}Se$ away from the vacancy curve which is common to both systems.

Acknowledgments

The author wishes to thank Drs. R. L. Longini, A. J. Panson, Y. L. Sandler, and J. Weissbart for many useful discussions and critical review of this manuscript. Technical assistance was rendered by Mr. D. E. Sestrich. This work was done in connection with U. S. Navy Buships Contract No. NOBS-78365 WGO No. WG 79150 CE.

Manuscript received Dec. 8, 1961; revised manuscript received March 2, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Electrical Conductivity of Nonstoichiometric a-Nb_2O_5

E. H. Greener and W. M. Hirthe

College of Engineering, Marquette University, Milwaukee, Wisconsin

ABSTRACT

The electrical conductivity of reduced α-Nb_2O_5 was measured after prior reduction in 10^{-6} atm of air from 350°-1150°K for both single crystals and sintered specimens. The conductivity of single crystals was found to be exponentially dependent on temperature with an activation energy of 0.9 ev in the range from 1150°-650°K and 0.2 ev in the range from 650°-350°K. The electrical conductivity of sintered specimens was also found to be exponentially dependent on temperature, but only a single activation energy was obtained over the entire temperature range. This activation energy was dependent on defect concentration and varied from 1.0 ev for the smallest degree of reduction to almost zero at the highest degree of reduction where the behavior was essentially that of a degenerate semiconductor. An explanation based on overlapping orbitals of trapped electrons is offered to explain both the dependence of activation energy on defect concentration and the absence of a low-temperature activation energy in sintered material. Finally, two mechanisms are discussed to explain the observed conductivity of reduced α-Nb_2O_5. Comparison of conductivity data and thermoluminescence data tends to favor a model in which two trapped electrons are excited from an oxygen vacancy to the "d" band of the niobium cations.

A discussion of the past work on the electrical properties of Nb_2O_5 has been presented in an earlier paper (1). In this work α-Nb_2O_5 has been shown to be a metal-excess n-type semiconductor. The defect producing this structure is most probably an oxygen ion vacancy which has trapped two electrons. A possible energy band model for the defect oxide semiconductor appears in Fig. 1.

In near-stoichiometric α-Nb_2O_5, between 600°-900°C, the conduction band carrier concentration[1] $[\ominus]$ has been shown to obey a law of the form

$$[\ominus] = \sqrt{K_{o1}K_{o2}}\, P_{O_2}^{-1/4} \exp -(W_D + E_1)/2kT \quad [1]$$

where K_{o1} and K_{o2} are, respectively, the temperature independent terms of the equilibrium constants for the creation of the defect (Eq. [2]) and the excitation of the first electron from the oxygen vacancy trap (Eq. [3]). W_D is the energy required to create the defect, and E_1 is the energy necessary to excite the first electron from the defect into the conduction band. Experimentally, the quantity $-(W_D + E_1)/2$ was found to be 1.65 ev (Fig. 2).

These reactions may be summarized as

$$O_i'' \rightleftharpoons \frac{1}{2} O_2 + O_v^x \qquad -W_D \quad [2]$$

$$O_v^x \rightleftharpoons O_v^{\cdot} + \ominus \qquad -E_1 \quad [3]$$

[1] The temperature dependence of conduction band carrier mobility in near-stoichiometric α-Nb_2O_5 is assumed to be negligible when compared to the change in conduction band carrier concentration over the temperature range 600°-900°C. A discussion of this is included in the earlier paper (1).

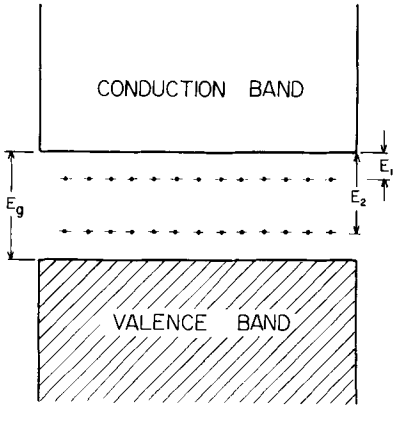

Fig. 1. Band model for a metal-excess oxide semiconductor with an oxygen ion vacancy trapping two electrons.

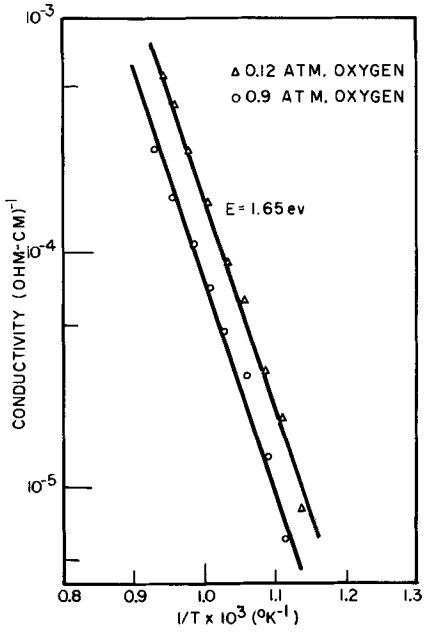

Fig. 2. Logarithm of the conductivity of sintered near-stoichiometric α-Nb_2O_5 as a function of $1/T$ for two oxygen pressures. The value of 1.65 ev calculated from the slopes of these curves represents $(W_D + E_1)/2$.

where O_i^{2-} is an oxygen ion in a normal lattice position, O_v^x is an oxygen vacancy which has trapped two electrons in its field, $O_v^{\cdot}$ is an oxygen vacancy from which an electron has been excited, and $\ominus$ is an electron in the conduction band.

It is further possible to write an analogous expression for the excitation of the second electron

$$O_v^{\cdot} \rightleftharpoons O_v^{\cdot\cdot} + \ominus \qquad -E_2 \quad [4]$$

where $O_v^{\cdot\cdot}$ is an oxygen ion vacancy from which both electrons have been excited, and E_2 is the energy necessary to excite the second electron from the vacancy trap into the conduction band.[2]

Thus, the conductivity of near-stoichiometric α-Nb_2O_5 is seen to depend on both temperature and oxygen partial pressure.

In the case of materials of near-stoichiometric composition, Eq. [2], [3], and [4] control the change in conduction band carrier concentration with temperature and pressure. Consequently, E_1 and E_2 cannot be separated from W_D. On the other hand, if the concentration of defects were increased so that the change in conduction band carrier concentration would be controlled by Eq. [3] and [4] it should be possible to determine E_1 and E_2 experimentally.

Experimental Details

Small single crystals of α-Nb_2O_5 approximately 2 mm in diameter were kindly furnished by Linde Air Products Company. Flat surfaces were ground and polished with 420 grit carborundum on the crystals for electrical contact. No chemical analysis of the Linde crystals or knowledge of their perfection was available. Since the dimensions of the Linde crystals were very irregular the data for these specimens are reported as conductance rather than as conductivity.

High-purity Nb_2O_5 powder furnished by the Fansteel Metallurgical Corporation was a mixture of α and β modifications. It was cold-pressed without a binder at a pressure of 40,000 psi and sintered at temperatures between 1300° and 1350°C for 2 hr. After this treatment, the Nb_2O_5 existed entirely as the α modification. The apparent densities of the sintered compacts were measured pycnometrically and were found to be within 80-90% of the theoretical density of 4.55 g/cm³ reported by Holtzberg *et al.* (2). Rectangular parallelepipeds approximately ½ x ¼ x 0.05 in. were cut from the sintered compacts and used for conductivity specimens, the surfaces being polished with 420 grit carborundum.

The equipment for measurement of resistance as a function of temperature in the range 300°-1000°K and oxygen partial pressure has been described previously (1, 3). Two types of apparatus were used: the first system consisted of a furnace in a vacuum bell jar, and in the second, a Vycor tube connected to a vacuum system separated the specimen from the furnace. The single crystals were investigated in the bell jar whereas the sintered specimens were investigated in the Vycor tube. Because of the size limitations, the two-probe technique was used for single crystals whereas four-probe techniques were used for sintered specimens. Compositional changes were measured by weight loss, the entire weight change being attributed to the loss of oxygen.

[2] Another possible explanation for the occurrence of a second activation energy is mentioned at the end of the paper.

Experimental Results and Discussion

In an attempt to freeze in a constant defect concentration the reduction was carried out directly in the vacuum apparatus. Specimens were held at 10^{-6} atm O_2 for from 1 to 8 hr at temperatures from 700° to 900°C. The specimens were cooled quickly (5°-10°C/min for the sintered specimens, faster for the single crystals) *in vacuo,* and resistance readings were taken on cooling. It is felt that in the case of the data reported in this paper this treatment was successful in maintaining the defect concentration produced by the high-temperature reduction. Slower cooling or holding at the higher temperatures produced discontinuities in the log σ *vs.* $1/T$ curve due to further reduction. No such discontinuities were found in the data reported in this investigation.

A typical run on a single crystal of Nb_2O_5 in a vacuum of 10^{-6} atm of air in the temperature range from 300° to 1000°K is given in Fig. 3. Essentially the same log σ *vs.* $1/T$ curve was obtained for six different specimens initially reduced at 800°-850°C for from 2 to 4 hr. The observed data can be rationalized with the normal semiconductor equation

$$\sigma = \sigma_o \exp\,(-E_D/2kT) \qquad [5]$$

where E_D is the energy of the donor level, k is Boltzmann's constant, and T is the absolute temperature. The activation energy calculated from the high-temperature slope is about 0.9 ev (E_2) and from the low-temperature slope about 0.2 ev (E_1). The break in the log σ *vs.* $1/T$ curve occurs at $1/T$ x 10^3 equal

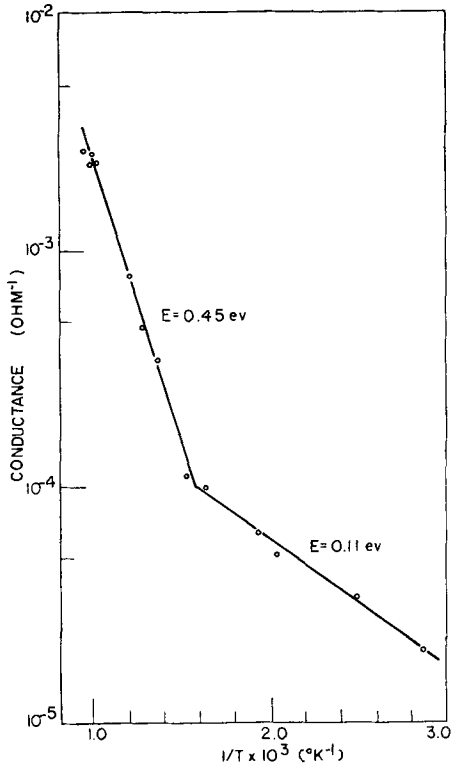

Fig. 3. Logarithm of the conductance of single crystal α-Nb_2O_5 as a function of $1/T$ after reduction at 800°C for 4 hr in a vacuum of 10^{-6} atm of air. The values of 0.45 ev and 0.11 ev calculated from the slopes of the curve represent $E_2/2$ and $E_1/2$, respectively.

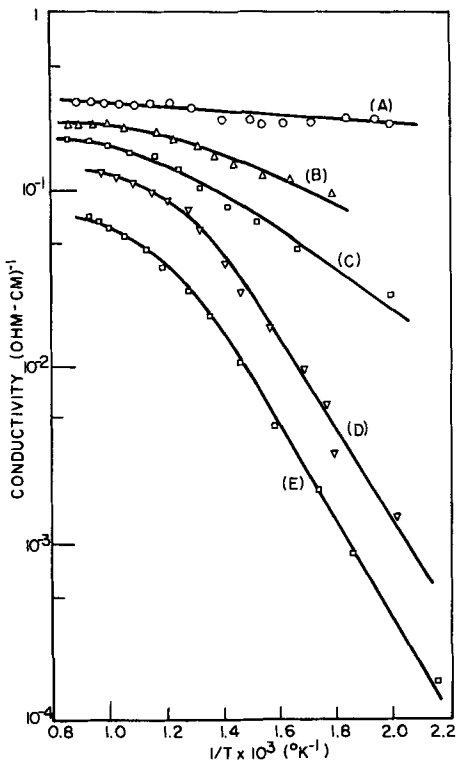

Fig. 4. Logarithm of the conductivity of sintered α-Nb_2O_5 in 10^{-6} atm of air as a function of $1/T$ for the following reduction treatments in a vacuum of 10^{-6} atm of air: (A) 8 hr at 875°C; (B) 8 hr at 860°C; (C) ½ hr at 860°C; (D) 8 hr at 750°C; (E) ½ hr at 800°C.

to 1.5 or 650°K which corresponds to a thermal energy of about 0.06 ev. The change in slope of the curve is due to the exhaustion of electrons trapped at E_1 because the thermal energy at 650°K is within $4kT$ of E_1.

Typical curves of log σ *vs.* $1/T$ for reduced sintered specimens shown in Fig. 4 can be characterized by two distinct regions. In the low-temperature region the conductivity changes exponentially with temperature and can be represented by a straight line, the slope of which will yield the activation energy from the donor level according to Eq. [5]. In the high-temperature region the conductivity is essentially independent of temperature and can be explained on the basis of an exhaustion process in which the thermal energy is large enough to excite all trapped electrons from available donor centers, but is too small for any intrinsic excitation to occur. The thermal energy for exhaustion is compared with the energy level of the donor state in Table I for all curves in Fig. 4 and can be seen to be within approximately $4kT$ of the donor level E_2. For the smallest degree of reduction attempted, the observed activation energy is (according to Eq. [5]) 1.0 ev. This is in good agreement with 0.9 ev obtained from the high-temperature slope of the single crystal curve.[3] As the degree of reduction and consequently the concentration of defect levels and trapped electrons increases, the conductivity also increases. In addition, there is a decrease in the activation energy due to the fact that the electrons trapped in donor levels can no longer be considered as isolated defects because their orbitals begin to overlap. As treated by Pearson and Bardeen (4), increasing the concentration of donor levels to the point where overlapping occurs moves the Fermi level up toward the conduction band. This will lower the activation energy necessary for electronic excitation and the beginning of the exhaustion region will occur at successively lower temperatures as is seen in Fig. 4.

[3] Since good agreement was obtained between the high-temperature activation energies of the single crystal (two-probe method) and sintered specimens (four-probe method), contact resistance was not deemed to be a problem in the case of the single crystal studies. Certainly if any problem were to exist it would have appeared in the high-temperature range of measurement where specimen resistance is lower than in the low-temperature range. Since the high-temperature activation energies agreed, it is reasonable to assume that contact resistance is not a problem in the low-temperature range of measurement.

Table I. Comparison of thermal energy for exhaustion with energy level of the donor state

Curve	Thermal energy for exhaustion from Fig. 4	Activation energy from Fig. 4
A	Degenerate	
B	0.08	0.15
C	0.09	0.23
D	0.09	0.45
E	0.10	0.50

This may be the reason why only a single activation energy is obtained with sintered materials over the same temperature range where two activation energies are found in single crystals. For obvious reasons, the kinetics of reduction of the sintered materials can be considered to be faster than that for single crystals. Consequently, even at the smallest degree of reduction in sintered specimens, the concentration of oxygen vacancies and trapped electrons would be higher than for single crystals receiving the identical reduction treatment. The electrons trapped at E_1 will be more loosely bound than those traped at E_2 (Eq. [3] and [4]) and can be thought of as having a larger orbit. Therefore a concentration of defects sufficient to cause overlapping of the E_1 levels may be insufficient to cause overlapping of the E_2 levels. In this case the E_1 level would shift toward the conduction band in a manner analogous to the shifting of the E_2 level in Fig. 4. Since from the single crystal data the E_1 level is about 0.2 ev, the smallest reduction attained in this investigation may provide a sufficient number of defects to shift the E_1 level within $4kT$ (at room temperature $4kT = 0.1$ ev) of the conduction band. If this occurs, the first level would be exhausted at all temperatures utilized in this research, and the conductivity of sintered specimens would change only through excitation of electrons from the second level into the conduction band.

At the highest degree of reduction (curve A, Fig. 4) the conductivity is essentially independent of temperature over the entire temperature range investigated, and thus the material in this region may be classified as a degenerate semiconductor, *i.e.*, both E_1 and E_2 levels are exhausted. Since in a degenerate semiconductor the Fermi level may be considered to be in the conduction band, the exponential term for the dependence of the conductivity may be replaced by unity, and the conductivity σ may be expressed as

$$\sigma = \sigma_0 Nev \qquad [6]$$

where N is the number of carriers in the conduction band, e is the electronic charge, and v is the electronic mobility. Thus, if it is possible to estimate the number of carriers and measure the conductivity, a calculation of the electron mobility could be made. From x-ray data of Holtzberg and co-workers (2), it is possible to estimate the total number of molecules in Nb_2O_5/cc as 1.2×10^{20}. This means that there would be 6×10^{20} normally occupied oxygen anion lattice sites. From measurement of weight changes, however, it was found that the compositional change from insulator to degenerate semiconductor amounted to the change Nb_2O_5-$Nb_2O_{4.95}$, with the composition $Nb_2O_{4.95}$ corresponding to about 1% vacancies per cubic centimeter. Since an oxygen vacancy can trap two electrons, N can be approximated as 1.2×10^{19}/cc. From Fig. 4 the conductivity for the degenerate case can be approximated as 10^{-1} ohm-cm. Therefore, the electron mobility is of the order of 10^{-1} cm^2/volt-sec. This value of mobility is close to that found by Breckenridge and Hosler (5) for the case of heavily reduced TiO_2 and was related by them to a conduction process in the narrow "d" band of Ti ions. Thus, by analogy to the TiO_2 case, it would be possible for the narrow "d" band of the Nb cation to act as the conduction band.

Conclusion

On the basis of the conductivity studies presented, two alternative mechanisms may be offered.

1. Excess electrons produced as a result of reduction are locally trapped at Nb^{4+} ions. Since an oxygen vacancy may be considered to have a virtual charge of +2, these Nb^{4+} ions would be found near a vacancy. Conduction might take place via excitation of an electron from an Nb^{4+} ion into the conduction band (high-temperature activation energy) or by "hopping" of an electron from an Nb^{4+} site to an Nb^{5+} site (low-temperature activation energy). The activation energies are summarized in Table IIa. Mitoff (6) has recently treated the case for hopping in NiO. He reports an activation energy of about 0.2 ev over the same low-temperature range used in this investigation. A standard diffusion analysis can treat this problem quite adequately; *i.e.*, the conductivity σ may be expressed as

$$\sigma = nev = nev_0 \exp(-E/kT) \qquad [7]$$

where n is the number of carriers trapped in defect levels, e is the electronic charge, and the term $v_0 \exp(-E/kT)$ expresses the temperature dependence of the mobility.

2. Excitation of two electrons from an oxygen vacancy trap into the "d" band of the Nb^{5+} ions according to Eq. [3] and [4]. The observed activation energies substituted into the standard semiconductor equation (Eq. [5]) yield the energies necessary to excite these electrons from a vacancy trap into the conduction band, Table IIb. Recent thermoluminescence studies by Greener, Fehr, and Angino (7) tend to substantiate this model. In this investigation specimens of powdered near-stoichiometric α-Nb_2O_5 were subjected to Co^{60} and u.v. irradiation after which they exhibited two thermoluminescence peaks. The activation energies calculated from these peaks closely correspond to those calculated from single crystal conductance data based on activation to a band from two discrete levels (Tables IIb and IIc). This suggests that the trapping mechanisms in both experiments were the same.

Table II. Summary of activation energies

	(a) Mechanism 1 (Activation energies from Fig. 3)	(b) Mechanism 2 (Activation energies from Fig. 3)	(c) Thermoluminescence
E_1	0.1	0.2	0.4
E_2	0.9	0.9	0.9

Further, two activation energies were obtained in powdered material. In the case of thermoluminescence experiments one may expect an extremely small concentration of electrons trapped at vacancies. For example, irradiation produces no color change, while reduction does. Thus no overlapping of electrons trapped at E_1 occurs, and a second activation energy is seen which is in good agreement with the single crystal conductance data. The hopping mechanism discussed earlier (mechanism 1) could not give rise to a thermoluminescence peak. It is also of interest to note that a Bohr He model for the traps predicts that the energy to excite the second electron from the vacancy is about four times the energy to excite the first. Such a relationship is evident in Table II.

Although at present the model which best explains all experimental data seems to be the excitation of two trapped electrons into the "d" band of the niobium cations, the final decision as to which mechanism occurs must depend on an experiment which can differentiate between the temperature dependence of carrier concentration and carrier mobility. In the case of excitation into a band it is the carrier concentration which is exponentially dependent on temperature whereas in the case of a hopping process the mobility is exponentially dependent on temperature. Clearly in order to distinguish between the two possible mechanisms, Hall Effect data would be most valuable.

Cross Sections and Ohmic Resistance of Diffusion Pipes in Silicon

A. Goetzberger and C. Stephens

Shockley Transistor, Unit of Clevite Transistor, Palo Alto, California

ABSTRACT

Diffusion pipes were deliberately produced by contamination with phosphorus as described previously by Goetzberger and their cross sections measured as a function of depth from the surface by removing thin layers of silicon by anodic oxidation. The results are in qualitative agreement with theory as derived from a simple diffusion model. In particular some pipes were found having diameters that increase with depth, and others were found having decreasing diameters. "Submerged pipes" were also detected experimentally for the first time. Deviations from the predicted theoretical behavior were relatively unimportant and seem to be caused by enhanced diffusion close to the surface by the finite size of the n-type source and by the influence of background doping. The proposed theoretical model was further confirmed by measurement of the ohmic resistance of pipes which was in agreement with predictions based on spreading resistance from the concentration end of the pipe.

This paper reports new investigations on diffusion pipes in silicon. In an earlier paper (1) it had been shown that pipe-like regions of high donor concentration through diffused p-layers in silicon can originate from localized sources of n-type impurity on the surface.

It had further been shown that this n-type impurity was phosphorus in the majority of cases and that pipes are formed by diffusion from the localized sources. The results reported in (1) were recently confirmed by Flint (2) who was able to detect a high concentration of phosphorus in pipes with an electron probe x-ray analyzer. According to the diffusion theory given in (1), pipes should have different profiles dependent on diffusion conditions (Table I and Fig. 1). Of particular interest are the so-called "submerged" pipes (case IV). This type of pipe cannot be detected on the surface because it does not contain a junction intersecting the surface.

In this publication evidence that all the predicted shapes exist is reported. This evidence, obtained with a sectioning technique employing anodic oxidation, is discussed below.

The results of the profile measurements were checked by measuring the ohmic resistance of a number of pipes. Since pipes result from diffusion from the surface, the resistivity along a pipe increases from the surface according to a diffusion distribution. The most important contribution to the resistance, therefore, arises from the spreading resistance in the bulk material lying beyond the end of the pipe. The area of the conducting channel through the diffused layer can thus be estimated from resistivity measurements and is found in a later section to compare with optical measurements of the pipe shape.

Table I. Pipe shapes for different diffusion conditions

Case	Condition	Shape
I	$C_{o2} > C_{o1}$, $D_1t_1 > D_2t_2$	Ellipsoid
II	$C_{o2} > C_{o1}$, $D_1t_1 < D_2t_2$	Hyperbola of rotation
III	$C_{o2} > C_{o1}$, $D_1t_1 = D_2t_2$	Cylinder
IV	$C_{o2} < C_{o1}$, $D_1t_1 < D_2t_2$	Hyperbola of rotation (submerged pipe)

Definition of symbols: C_o is surface concentration; D, diffusion coefficient; t, diffusion time; subscript 1 refers to the plane diffusion; subscript 2 refers to the spherical pipe diffusion.

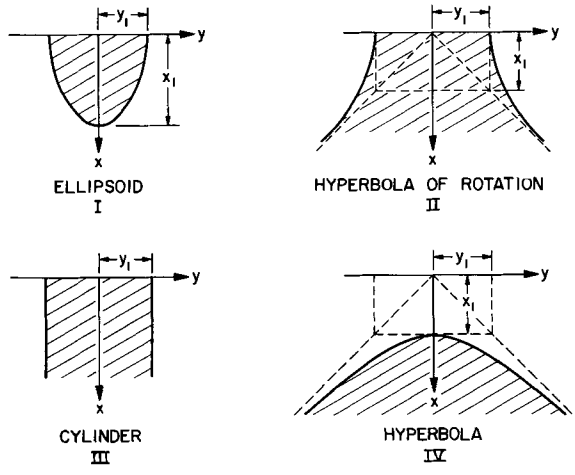

Fig. 1. Four different pipe shapes according to mathematical model.

Cross Section Measurements

Experimental procedure.—Diode preparation and observation of pipe diameter at the surface were identical to the procedures described in (1). Pipes were introduced into boron diffused p^+n planar diodes by exposure to P_2O_5 aerosol before boron predeposit and were optically observed by light emission from microplasmas at the surface.

Afterwards the thickness of the silicon slices containing diodes with pipes was reduced in small in-

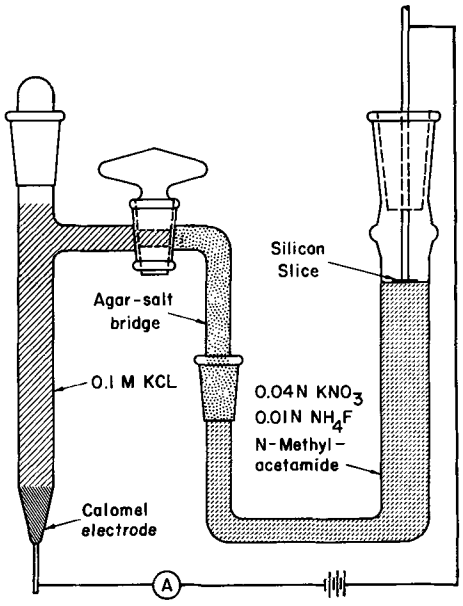

Fig. 2. Anodic oxidation apparatus

crements by anodic oxidation, and the variation of the pipe shapes studied. The technique of anodic oxidation of silicon has been described by Schmidt (3), and Tannenbaum (4). The procedure followed in this investigation had been worked out by McDonald and Collins (5). One anodization step in the apparatus shown in Fig. 2 removes approximately 0.05μ. After each anodization the oxide was removed in HF, and after every five oxidation steps the thickness of the removed layer and the diameter of the pipe were measured. Thickness was determined by weighing with a microbalance with an accuracy of $\pm$ 4 μg, corresponding to a depth accuracy of 0.016μ for a slice of 1 cm^2 area. This accuracy, however, is only applicable for slices of uniform doping over the whole surface because it has been observed during this investigation that the etching rate is different for n- and p-type and for different resistivities. Therefore the depth measurements represent only an average over the whole slice and may not apply accurately to the pipes themselves. The error is thought to be less than 10%.

The dimensions of the pipes were determined by taking photomicrographs of the diodes under reverse bias, utilizing avalanche radiation to delineate the intersection of the pipes with the surface. Some of the pipes deviated from a circular geometry. In these cases the diameter was always measured in the same direction.

An alternative to the avalanche method is the chemical staining technique (6). The avalanche method was chosen because of its greater reproducibility.

Results.—When phosphorus was introduced as an aerosol before boron predeposition, in general a greater percentage of pipes were found to have diameters which decreased with depth corresponding to the ellipsoidal type. The remainder of the pipes showed a widening with increasing depth; this type of pipes is believed to be due to unintentional contamination during or before the oxidation step with

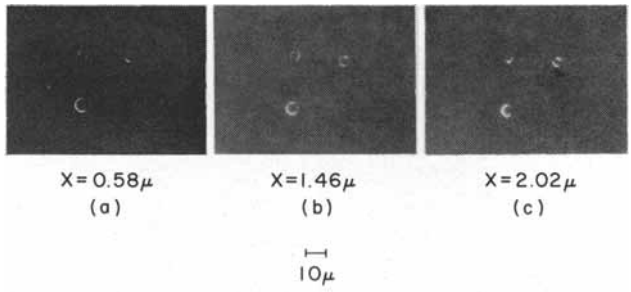

Fig. 3. Group of pipes showing constriction. Light emission photographs are taken at increasing depths. X is depth of cross section.

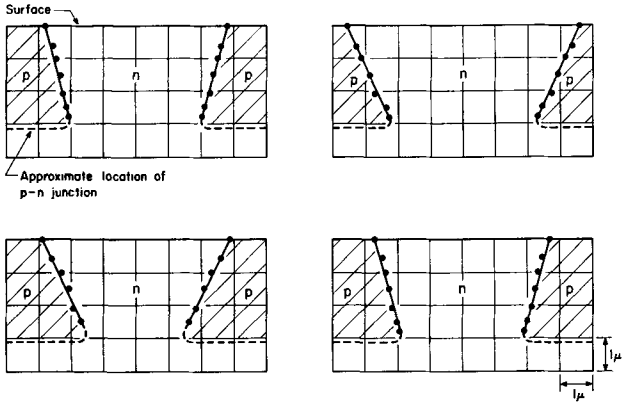

Fig. 4. Cross sections for four different pipes showing constriction

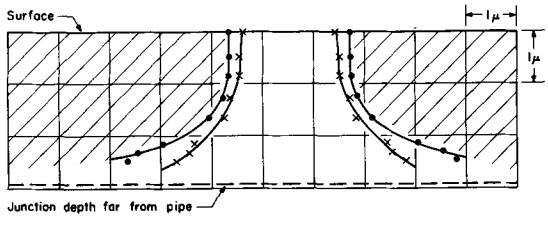

Fig. 5. Cross section of a pipe showing widening of diameter with depth.

consequently larger values of Dt for the phosphorus than for the boron.

Figure 3 a-c shows light emission from the same group of pipes as it appeared at different depths. The cross sections of two of these pipes and of some others found in the same sample are given in Fig. 4.

Figure 5 shows the cross section of a pipe with increasing diameter, the two outlines corresponding to two perpendicular directions across the pipe which was not exactly circular.

In Fig. 6 the detection of a submerged pipe during sectioning is shown. In Fig. 6a a small light spot can be seen to the left of a well-developed pipe. At greater depths this light spot developed into a ring of light characteristic for a pipe. It can be assumed that the light emission that emerges before the pipe itself is sectioned is caused by avalanche breakdown at the top of the n-region where the impurity gradient is increased.

In Fig. 7a the cross section of this pipe is given. The two traces again apply to two perpendicular directions. Figure 7b shows a similar structure found in another diode.

Discussion.—The observed pipe cross sections are in qualitative agreement with the theory given in

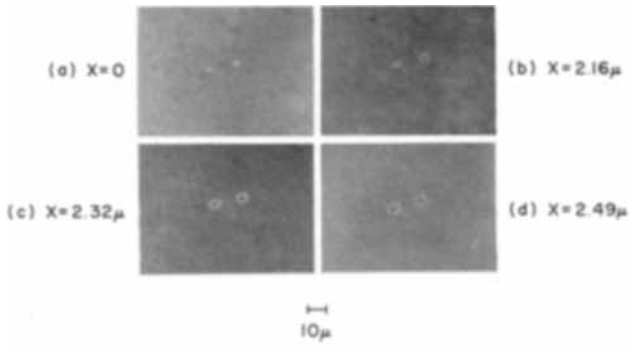

Fig. 6. Light emission photographs showing detection of a submerged pipe. X is depth of cross section.

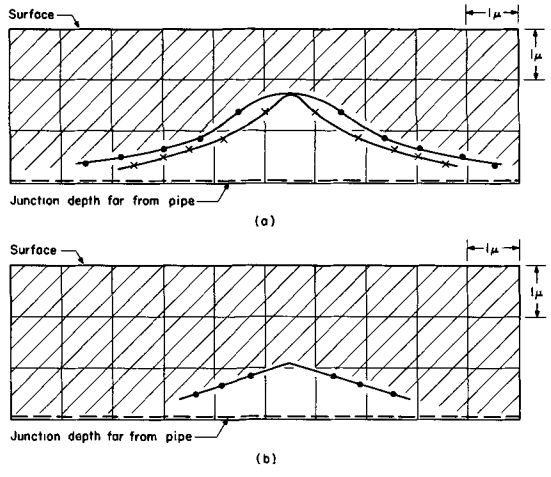

Fig. 7. Cross sections of two submerged pipes

(1). The following deviations from the expected behavior can be noticed: (*A*) Pipes which show a decrease in diameter in depth (Fig. 4) are wider at the surface than the expected ellipsoid. (*B*) Pipes showing an increase in diameter with increasing depth, including the submerged types, do not follow a hyperbolic outline exactly, but show more curvature at the bottom end.

Effect (*A*) might be caused by enhanced diffusion close to the surface as has been reported by different observers (4, 5, 7). Little is known about diffusion along surfaces, but in general it is assumed to be much faster than bulk diffusion. Because the observed effect can be explained adequately by a small modification of the bulk diffusion coefficient, it is believed to be due to enhanced bulk diffusion and probably not to surface diffusion.

Effect (*B*) can be accounted for by (i) finite extension of the source initially over the surface and (ii) influence of the doping of the crystal from which the slice was prepared; this constant concentration term was not taken into consideration in the simple mathematical model.

For several pipes an evaluation of phosphorus content was carried out using the known data of the plane diffusion and a diffusion time for the pipes corresponding to the time elapsed after introduction of phosphorus. The number of phosphorus atoms per pipe was estimated as between 10^8 and 10^9, in good agreement with earlier estimates (1) based on measurements of the growth rate of pipes.

Submerged pipes had an impurity content in the lower range, as anticipated.

It should be noted here that the lower limit for the phosphorus content which will make a pipe observable is determined by the surface concentration of the plane boron diffusion. If the surface concentration of the plane diffusion is lowered, then the number of impurity atoms required to form comparable types of pipes will be lowered by the same factor.

One of the results of the present investigation is a proof of existence of the submerged pipes (Fig. 7). This type is characterized by relatively small amounts of impurities which started diffusing a considerable time before diffusion of the p-type layer is frequently found in planar devices. The long high-temperature oxidation necessary to produce the initial oxide layer provides a chance for submerged pipes to be introduced. It appears to be very difficult to avoid contamination with phosphorus during this step. In the opinion of the authors this problem will have to be solved before large area planar devices become technically feasible in silicon.[1]

Pipe Resistance

Technique of measurement and results.—The main problem in measuring the resistance through a pipe is the small size of the pipe areas. James and Flint (8) attempted to measure the ohmic resistance by placing a fine probe in the center of a pipe. They obtained only a rough estimate of the resistance.

In this investigation a different contacting method was chosen. Contact to the pipe was made by means of a shallow diffused n^+-layer of a lateral extension smaller than the planar p-type junction containing the pipe (Fig. 8). Application of this technique is possible because, owing to the high doping level at the surface, the top part of the pipe does not contribute appreciably to its resistance. Before diffusion of the contacting emitter layer certain diodes containing pipes were photographed to obtain the pipe diameter. The n^+-layer was then produced by conventional oxide masking and photoresist techniques. Only those devices which contained a single pipe were selected for measurement. In order to be sure that no submerged pipes were also contacted by the n^+-layer, after the resistance had been measured the specimens were anodically sectioned and examined again for the presence of submerged pipes.

The arrangement for resistance measurement is shown in Fig. 8. Separate probes were used for

[1] For example, in device production submerged pipes can produce emitter-collector shorts in structures which, prior to the emitter diffusion, exhibit perfectly satisfactory collector base junctions.

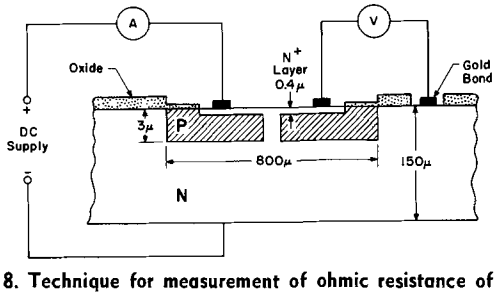

Fig. 8. Technique for measurement of ohmic resistance of pipe

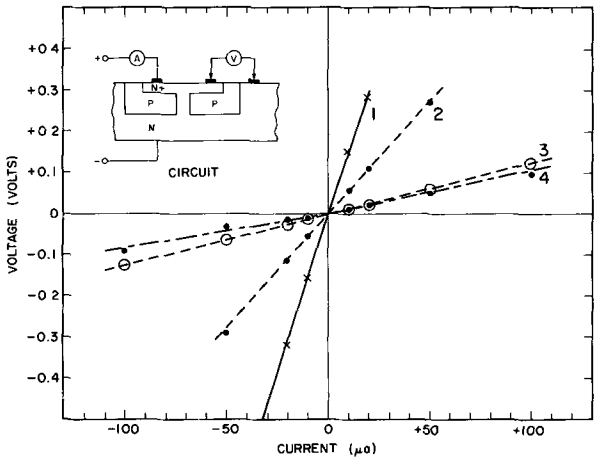

Fig. 9. V-I curves for four different pipes, which were used to determine ohmic resistance.

voltage and current readings so that the influence of contact resistances could be eliminated. All the resistances measured were ohmic in the range between −0.5 and +0.5v. At higher voltage the measurements were disturbed by injection effects within the npn structure. Voltage *vs.* current values for four different pipes are given in Fig. 9.

Discussion.—In Table II the results of the resistance measurement are presented. The first column gives the number of the pipe, the second the measured resistance. In the third column the observed diameters of the pipes at the surface are listed. These diameters had been measured before the contacting n^+-layer was diffused. For comparison the diameter of the pipe was calculated from the spreading resistance on the basis of two different models (9). The first model assumes that current spreads from a disk of negligible resistance of diameter d into the bulk silicon of resistivity ρ. Resistance in this case is given by

$$R = \frac{\rho}{2\,d}$$

In the second model resistance is thought to arise by spreading of current into the bulk from a hemisphere with negligible resistance, and diameter d

$$R = \frac{\rho}{\pi\,d}$$

(A rigorous treatment would require calculation of the spreading resistance of a hemispherical diffusion distribution whose top part is cut off by the junction.) For both cases d was calculated for $\rho = 3$ ohm-cm from the measured R values. These d-values are given in the third and fourth column of Table II.

The pipes in Table II can be separated into two groups. One group (No. 1 and 2) consists of pipes with a small diameter. For these we calculate a diameter which is too small with either model. The other group which consists of bigger pipes (No. 3 and 4) can best be approximated by the spherical model.

Table II. Results of pipe resistance measurements

No.	R measured, K ohms	d measured, μ	d_{calc}, disk model, μ	d_{calc}, spher. model, μ
1	11.0	5	1.35	0.87
2	5.5	6.2	2.7	1.75
3	1.2	8	12.5	8.0
4	1.1	10	13.6	8.7

In order to explain the disagreement for the first group, we have to assume that the diameters at the junction are smaller than at the surface. Indications for such a constriction of these pipes were indeed found when the sample containing the slice was sectioned anodically. Occurrence of surface contamination, however, prevented accurate measurements of pipe diameters close to the junction. We conclude, however, that in general the agreement with the model is satisfactorily within the limits set by experimental errors.

Conclusions

Pipes through diffused layers that were found in a preceding paper to be caused by diffusion of n-type impurity from localized specks of contamination were studied in detail in this investigation. Cross sections of pipes that were obtained by anodic oxidation were found to be in qualitative agreement with theory. Three types of pipes were found corresponding to the theoretically postulated type shapes: ellipsoid (I), hyperbola of rotation (II), and submerged hyperbola of rotation (IV). The existence of the latter type, which had only been postulated theoretically, was thus confirmed.

Deviations from the calculated shapes can be explained by enhanced diffusion close to the surface.

Measurement of the ohmic resistance of a number of pipes gave satisfactory agreement between optically and electrically determined pipe diameters.

Acknowledgments

Hysteresis in the Large-Signal Field Effect in Semiconductor Surfaces

D. R. Frankl

General Telephone & Electronics Laboratories Inc., Bayside, New York

ABSTRACT

The finite generation and recombination rates of excess minority carriers can lead to large hysteresis effects even at frequencies $<<(2\pi\tau)^{-1}$ in large-signal field effect measurements. The hysteresis loop occurs on the inversion-layer side of the conductance *vs.* field curve and widens with increasing frequency and with increasing minority carrier lifetime in the sample. Experimental results on germanium and a simple theoretical treatment are presented.

Owing to the existence (usually) of a large concentration of slow surface states in semiconductors, any changes in sample properties induced by constant transverse electric fields tend to decay to zero. In other words, equilibrium field effects usually vanish. However, since at least in most germanium and silicon surfaces there is a large separation in the time constants of the slow and fast states, it is often possible to achieve a "quasi-equilibrium" condition, with the carriers in the bands and the fast states virtually in equilibrium, but with the carriers in the slow states virtually unaffected. The usual analysis (1) of field-induced conductance changes, to obtain information about the fast states, entails the implicit assumption that this condition exists.

The experimental requirement is that the time variations of the applied field be too rapid to be followed by the slow states, yet slow enough to be followed by all other processes affecting the carrier concentrations. These include drift and diffusion of free carriers, trapping in and release from fast states, and generation and recombination of minority carriers.

The latter processes are of principal concern in this paper. As is well known (2), under small-signal a-c conditions their finite rates lead to a relaxation in the field-effect mobility, centered at a frequency $f = (2\pi\tau)^{-1}$ (τ = sample lifetime), which for ordinary samples lies in the neighborhood of 10 kcps. Under large signal conditions, this effect can lead to appreciable departures from quasi-equilibrium even at much lower frequencies, and these give rise to hysteresis in the curve of conductance *vs.* applied field. The purpose of this paper is to illustrate this hysteresis effect, and to present a simple theoretical treatment to account for the order of magnitude of the observed deviations.

Theory

We consider, for definiteness, a p-type sample, and let P, N, and N_t be, respectively, the numbers per unit area of free holes, free electrons, and electrons trapped in fast surface states, all measured relative to some arbitrary reference level such as the flat-band condition. Also let P^0, N^0, and N_t^0 be the corresponding quasi-equilibrium values of these quantities. Then the induced surface charge density at any instant is

$$CV = -e(\Delta P - \Delta N - \Delta N_t) \qquad [1]$$

where C is the capacitance per unit area between field plate and sample, V the applied voltage, Δ denotes change from zero-voltage value. The excess surface conductance is, neglecting the surface mobility correction (3) which is usually small

$$\Delta\sigma = e(\mu_n\Delta N + \mu_p\Delta P)$$
$$= e[\mu_n\Delta N + \mu_p(\Delta N + \Delta N_t - CV/e)] \qquad [2]$$

where μ_n and μ_p are the electron and hole mobilities, respectively, Hence, the departure from the quasi-equilibrium conductance is

$$\delta\sigma = e[(\mu_n + \mu_p)\,\delta N + \mu_p\delta N_t] \qquad [3]$$

where $\delta N \equiv N - N^0$, etc.

It remains to compute δN and δN_t from the rate equations governing the approach to quasi-equilibrium. These are, in general, quite complicated (4), and an exact treatment was not attempted. Instead, we introduce the following simplifying assumptions:

1. The carriers in each band are separately in equilibrium among each other. This requires that the field period be >> the time constant for redistribution, by diffusion, of localized excess carrier concentrations. From the diffusion equation, this time constant may be estimated to be $\leq B^2/D$ (D is the diffusion constant, $2B$ the sample thickness) which is, for germanium at room temperature, about 10^{-5} sec. Hence, the assumption should be reasonably valid for the low frequencies of interest here. Since the assumed distribution is essentially the same as the fundamental decay mode distribution (6) for small surface recombination velocity, this assumption permits us to write the rate equations in terms of the ordinary lifetime, as measured, for example, in photoconductive decay.

2. The transitions between the traps and at least one of the bands are so rapid (2) that the trapped carriers are always in equilibrium with this band. Then two limiting cases may be distinguished, depending on which band this is.

Case A, Traps in equilibrium with conduction band.—In this case, as the applied field is increasing electrons are generated and some of these fall into the traps. Hence

$$\frac{dN}{dt} = \frac{N^0 - N}{\tau} - \frac{dN_t}{dt} \qquad [4]$$

Note that this equation gives an underestimate for dN/dt since, in actuality, some fraction of the rate dN_t/dt comes from transitions to the valence band. This must be so because at least some of the surface states are the generation-recombination centers. In discussing this case, therefore, we are assuming that these centers comprise a negligible fraction of all the fast states. Since the latter are in equilibrium with the conduction band, we may take

$$\frac{dN_t}{dt} = \beta \frac{dN}{dt} \qquad [5]$$

where

$$\beta = \frac{dN_t}{dN} \cong \frac{dN_t^0}{dN^0} \qquad [6]$$

Then [4] becomes, in terms of the phase angle $\phi = \omega\tau$

$$\frac{d\,\delta N}{d\phi} + \frac{\delta N}{(1+\beta)\omega\tau} = -\frac{dN^0}{d\phi} \qquad [7]$$

The solution that vanishes at the accumulation-layer extreme of the voltage cycle (taken as $\phi = 0$) is

$$\delta N(\phi) = -\int_0^{\phi} d\phi' \frac{dN^0}{d\phi'} \exp\left[-\int_{\phi'}^{\phi} \frac{d\phi''}{(1+\beta)\omega\tau}\right] \qquad [8]$$

If ω is not too large, the exponential factor is very small except when $\phi' \cong \phi$, so that we may approximate [8] by

$$\delta N(\phi) \cong -\int_0^{\phi} d\phi' \frac{dN^0}{d\phi'} \exp\left[\frac{\phi' - \phi}{[1+\beta(\phi)]\omega\tau(\phi)}\right]$$

$$\cong -(1+\beta)\omega\tau \frac{dN^0}{d\phi}\left[1 - \exp\frac{-\phi}{(1+\beta)\omega\tau}\right]$$

$$\cong -(1+\beta)\omega\tau\, dN^0/d\phi \qquad [9]$$

This result states that N lags behind N^0 by the amount that the sum of $N^0 + N_t^0$ changes in one lifetime. Physically, the reason for this is that $N + N_t$ together form an equilibrium population that is generated at a rate proportional to the deficit in N only.

From [5] we have

$$\delta N_t = \beta\, \delta N \qquad [10]$$

and Eq. [9] and [10] provide the values to be inserted in [3]. The computation will be illustrated in the next section.

Case B, Traps in equilibrium with valence band.—In this case, the rapid communication with the majority-carrier band keeps δN_t always essentially equal to zero. The sole rate equation is then simply

$$\frac{dN}{dt} = \frac{N^0 - N}{\tau} \qquad [11]$$

giving, in the same approximation as was used in [9],

$$\delta N(\phi) = -\omega\tau(\phi) \frac{dN^0}{d\phi} \qquad [12]$$

Experimental Results and Discussion

The experimental method used in this work has been described in detail elsewhere (7). In brief, a small constant current is passed through the sample (a thin plate) and the voltage drop between two probes is displayed on the Y axis of an oscilloscope while the field voltage is displayed on the X axis. Thus, with suitable scale factors and with proper precautions to balance out spurious signals due to the displacement current, the oscillogram gives directly $\Delta\sigma$ *vs* V. With the addition of chopped light, τ can also be measured from the instantaneous photoconductance.

Typical dark curves for a p-type sample are shown in Fig. 1. The hysteresis occurs in the n-type surface conductivity branch of the curve and increases with increasing frequency. With n-type samples the hysteresis occurs in the other branch. And with either type of sample the width of the loop at a given frequency may vary widely depending on the surface treatment; with high-lifetime surfaces the loop is wide and *vice versa*.

The computation of the quantities entering Eq. [9], [10], and [12] is illustrated in Fig. 2, 3, and 4. Values of u_s are obtained by the usual analysis (1) of the lowest-frequency curve, and N^0 is then calculated as $N^0 = n_i L_D G(u_s, u_B)$, where n_i is the intrinsic concentration, L_D the Debye length, and G is the function tabulated by Kingston and Neustadter (8) and others (9); finally, $dN^0/d\phi$ is obtained by graphical differentiation. These quantities are shown in

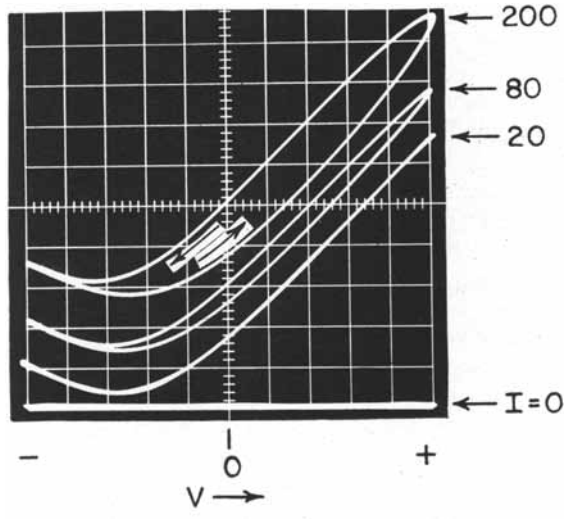

Fig. 1. Oscillograms of conductance vs. voltage on field plate at frequencies of 20, 80, and 200 cps for a p-type Ge sample. The field amplitude was about 10^5 v/cm. The line marked $I = 0$, obtained with no current through the sample, illustrates the cancellation of spurious signals.

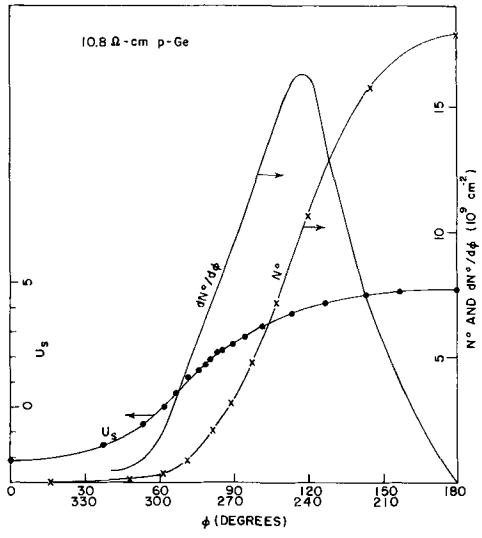

Fig. 2. Values of u_S, N°, and $dN^\circ/d\phi$, as functions of the phase angle ϕ.

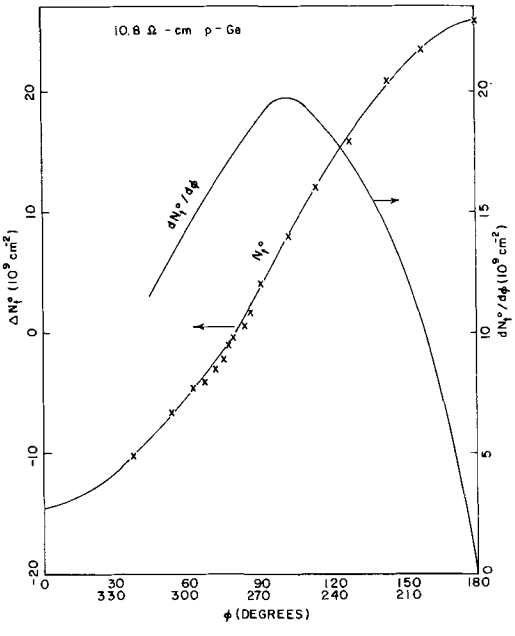

Fig. 3. Values of N_t° and $dN_t^\circ/d\phi$ as functions of the phase angle ϕ.

Fig. 2. N_t° and $dN_t^\circ/d\phi$, computed similarly, are shown in Fig. 3. Finally β, the ratio of the two derivatives, and τ, measured separately, are shown in Fig. 4.

The hysteresis data obtained on the same surface at higher frequencies are illustrated in Fig. 5. Here the total vertical separation $2|\delta\sigma|$ between the branches of the loop is plotted as function of the applied voltage. (Note that $V = -V_a \cos\phi$ as we have defined ϕ). Calculated curves for the two limiting cases discussed above are also shown. It is seen that the curve for Case A fits the data quite well at the right-hand end, but deviates markedly at the left. This deviation occurs because at these low values of u_S, the assumption of no communication between traps and valence band is untenable. At the extreme left-hand end of the loop, the curve for Case B gives an approximate fit to the data, but it is clear that over an appreciable range of surface potentials the true situation is intermediate between the two limiting cases. We shall not attempt to analyze this in detail.

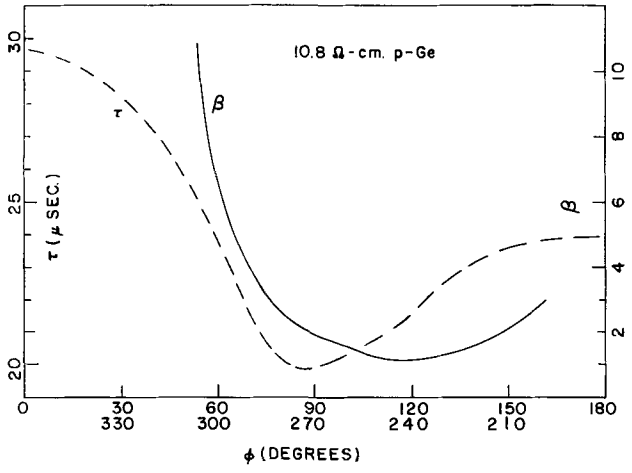

Fig. 4. Values of β and τ as functions of the phase angle ϕ

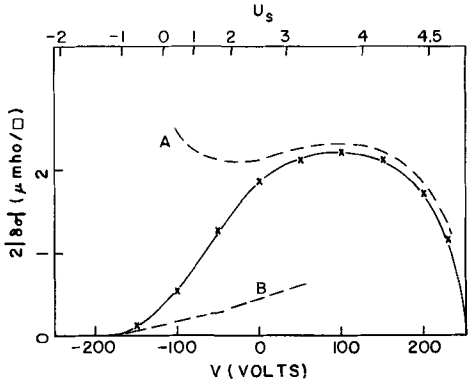

Fig. 5. Total vertical separation $2|\delta\sigma|$ between branches of hysteresis loop at 200 cps. Solid line is experimental; broken lines are theoretical for the two limiting cases discussed in the text.

The loop width at constant ϕ is found experimentally to be quite closely proportional to the frequency, as predicted by Eq. [9], [10], and [12], over the range from about 100 to 500 cps. However, below about 100 cps, the widths deviate from proportionality toward smaller values. The reason is the onset of another hysteresis mechanism, the exchange of charge with the slow surface states, which produces a loop that extends over the entire curve and widens with decreasing frequency. It is usually, although not always, possible to find a frequency at which the over-all hysteresis is negligible.

At frequencies above about 500 cps (in the present samples) still another effect was observed to set in: the mean of the two branches of the hysteresis loop sags below the equilibrium curve. This corresponds to the beginning of the field-effect mobility relaxation found by Montgomery (2). In samples with very high lifetime, this effect would set in at lower frequencies and might cause appreciable errors in field-effect measurements. This is particularly true when point-by-point methods (10) are used, since the hysteresis might easily be overlooked. It is one of the advantages of the oscilloscope method used here that any appreciable hysteresis present is clearly evident and serves as a warning that caution must be exercised in interpreting the results.

Acknowledgments

It is a pleasure to thank A. E. Feuersanger for assistance in the experiments and helpful discussions. Especial thanks are due also to H. C. Montgomery for pointing out some deficiencies in an earlier formulation of the theory.

Thermodynamic Functions for the Tantalum-Hydrogen System

M. W. Mallett and B. G. Koehl

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Equilibria in the tantalum-hydrogen system were determined in the range 300°-700°C, at hydrogen pressures of 10-1000 mm of Hg, and atomic fractions, N_H, 0.05-0.333. A single-phase solid solution of hydrogen in tantalum was produced throughout the experimental ranges. Obedience to Sieverts' law is approached at 500°C and higher for compositions below $N_H = 0.20$. The data were used to calculate the relative partial molar and total enthalpies, entropies, and free energies for formation of the solid solutions.

In order to evaluate properly the effects of interstitial elements on the mechanical properties of a metal, it is useful and, in some cases, necessary to know their kinetics of sorption by and diffusion in the metal. The literature is lacking in this type of information for the behavior of hydrogen and tantalum. At the temperatures of interest, above 300°C, the tantalum-hydrogen system shows a continuous solid solution up to compositions corresponding to $TaH_{0.5}$ and higher. It has been demonstrated (1, 2) that kinetic data for such a system are more readily rationalized when kinetic experiments are designed to produce a reaction product of constant composition. Therefore, it was necessary to know the equilibria of the tantalum-hydrogen system before starting the kinetic experiments. A number of earlier observations on the solubility of hydrogen in tantalum have been made (3). However, all of the data, with exception of those of Sieverts and Bergner and Sieverts and Brüning, appear to suffer from the impurity of the tantalum. The results show gross effects presumably of dissolved or surface oxide inhibiting reaction and quantitatively affecting the solution. Sieverts' equilibria were too limited for our purpose since they are largely for a pressure of 760 mm of Hg.

A recent paper (4) by Kofstad, Wallace, and Hyvönen gave good equilibrium data for a number of compositions of interest and for temperatures up to 400°C. Because our study was to cover temperatures up to 700°C, it was necessary to determine equilibria for the temperature range of 400°-700°C not covered by the literature. In addition, data were taken at 300°-400°C for comparison with the work of Kofstad *et al.*

Also, some thermodynamic functions readily obtainable from the equilibrium factors were calculated.

Material

The tantalum used in this work was obtained from the Wah Chang Corporation of Albany, Oregon. It had been electron-beam melted to an ingot, 3½ in. in diameter, and cold forged and swaged to a 7/16-in. diameter. Final fabrication was carried out at Battelle and consisted of cold swaging to rod, ¼ and ⅛ in. in diameter, and vacuum annealing for 1 hr at 1200°C. A length of the ⅛-in. rod was cold rolled to 0.0146-in. sheet for equilibrium experiments. The analysis of the tantalum before final fabrication is given in Table I.

Pure hydrogen was obtained from the thermal decomposition of uranium hydride prepared from dry tank hydrogen and degreased uranium chips.

Equilibrium Studies

Experimental procedure.—The method to obtain equilibrium data has been described (5). Briefly, the data were obtained as follows: A measured quantity of hydrogen was added to the calibrated reaction tube containing approximately 4g of sheet tantalum. At the desired temperature, the system was allowed to come to constant (equilibrium) pressure as measured on a mercury manometer. The equilibrium composition was calculated from the equilibrium

Results

The pressure-temperature-composition equilibria of the tantalum-hydrogen system were determined in the range 300°-700°C, 10-1000 mm Hg pressure, and atomic ratios, H/Ta, of about 0.05-0.50. These atomic ratios correspond to atomic fractions N_H for hydrogen of about 0.05-0.333. Equilibrium pressures were measured for at least three different temperatures for each composition. Figure 1 is a logarithmic plot of the equilibrium pressure against the H/Ta ratio. The plot shows that the isotherms are linear at temperatures of 500°C and higher; at lower temperatures, the isotherms show curvature which becomes increasingly marked with decrease in temperature. This curvature suggests a trend toward the formation of two phases at lower temperatures. However, since none of the isotherms shows an invariant pressure, no two-phase region was indicated in our experimental range. It seems that such a region would appear only at some temperature below 100°C.

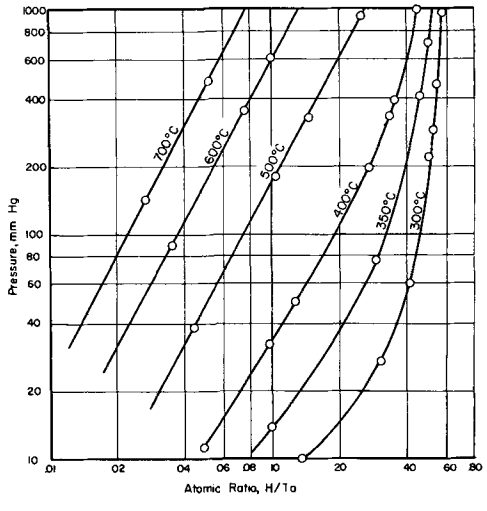

Fig. 1. Logarithmic plot of isotherms in the Ta-H system. Additional points at 300°C: 5.3 mm at H/Ta = 0.05, 7.4 mm at H/Ta = 0.10.

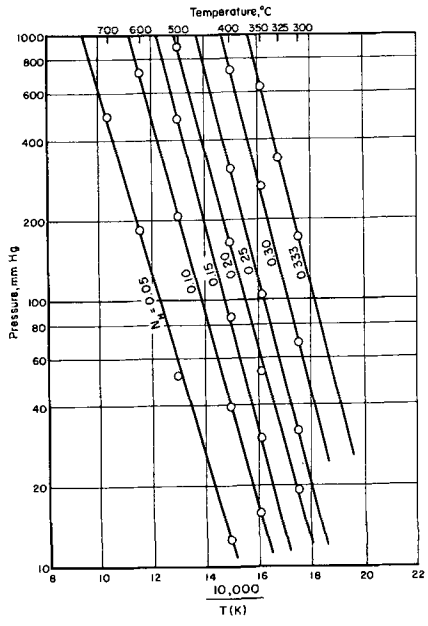

Fig. 2. Representative isopleths for the Ta-H system

After completion of this paper, a thesis by Veleckis (6) came to the authors' attention. He calculated the critical temperature to be −58.5°C at the H/Ta ratio of 0.205.

The equilibria were interpreted in terms of the conditions needed to form various products (solid solutions) having definite H/Ta and N_H ratios. This placed the data in the most convenient form for use in subsequent kinetic experiments. Several representative constant composition lines or isopleths are shown in Fig. 2. The equilibria for a given composition in these plots of logarithm of equilibrium pressure against reciprocal temperature can be expressed as

$$\log_{10} P_{mm} = -[A/T\ (K)] + B \qquad [1]$$

Values for the constants A and B determined by the method of least squares are given in Table II.

Since it may be desirable to relate thermodynamic and kinetic properties rather directly, the compositions are listed primarily according to round N_H values or atomic fractions of H.

** Values extrapolated from low-temperature isotherms.

A comparison of the equilibrium pressure isotherms of the present study and those of Kofstad *et al.* is given in Table III. The agreement between the two sets of data is reasonable. A point worthy of note is that the pressures for the higher concentrations are consistently lower for the present study. This may indicate that our tantalum contained less interstitial contamination, particularly oxygen, than the metal of Kofstad. As will be seen later, the lower pressures also are reflected in lower relative partial molar free energy values at 350°C.

Also, it appears from the collective data that the Sieverts law is obeyed approximately for the N_H composition range 0.05-0.20. This is evidenced by the (relative) invariance of the value of $\log \sqrt{P}/N_H$ for different compositions at a given temperature. Large deviations from the Sieverts law are seen for higher compositions. That these deviations are related to entropy effects rather than enthalpy changes will be shown later. Deviations were also found by Kofstad at compositions lower than those of this study.

Thermodynamic Functions

When the dissolution of hydrogen in tantalum is expressed as

$$\tfrac{1}{2}\,H_2\ (\text{gas}) \rightleftharpoons H_i\ (\text{dissolved in Ta}) \qquad [2]$$

the relative partial molar free energy of hydrogen in a given Ta-H solution (i) is

$$\bar{F}_{H_i} - \tfrac{1}{2}F^\circ_{H_2} = RT \ln (P_{H_2})^{1/2} \qquad [3]$$

P_{H_2} is the pressure of hydrogen gas in equilibrium with the solution at temperature T and R is the gas constant.

The values for the relative partial molar enthalpies, $\bar{H}_H - H^\circ_{H_2}/2$, and entropies, $\bar{S}_H - S^\circ_{H_2}/2$, were calculated by the method of least squares from plots of $\log \sqrt{P}$ against reciprocal temperature. This treatment also yielded the probable errors for these values. The free energy values were then calculated according to

$$\Delta F = \Delta H - T\Delta S \qquad [4]$$

which applies to both the integral and partial molar quantities. The calculated relative partial molar thermodynamic functions for hydrogen in solution in tantalum are given in Table IV.

The relative partial molar enthalpy (the negative of the heat of dissociation) decreases systematically with increasing hydrogen content, if the value for

* The relative partial molar free energies, enthalpies, and entropies are for 1 g-atom of hydrogen.
† These free-energy values are for 350°C only.
‡ The ± values in this table are probable error.

N_H 0.15 is omitted. This indicates an increase in hydrogen binding in the Ta-H lattice over the N_H range 0.05-0.333. This agrees with the conclusions of Kofstad who reported an increase in partial heat of dissociation.

The relative partial molar entropy also decreases rapidly with increasing hydrogen contents. This may be caused by the decreasing availability of interstitial sites as more hydrogen is added to the metal. Thus, the enthalpy and entropy changes in the tantalum-hydrogen system make for opposite deviations in behavior from Sieverts' law. However, abnormal increases in pressure are observed with increasing hydrogen concentration indicating that the entropy effect is the stronger. This, of course, is a demonstration of a rise in relative partial molar free energy, $\bar{F} - F^{\circ}_{H_2}/2$, such as shown by calculated values for 350°C given in Table IV.

The relative partial molar enthalpies and entropies of the tantalum-hydrogen system show the same trends and are of the same general magnitude as those of the niobium-hydrogen system (7). However, for a given temperature and composition, the tantalum-hydrogen system shows the higher dissociation pressure of hydrogen, *i.e.*, the relative partial molar free energy for the dissolution reaction is higher.

An equation for calculating the partial molar free energy for tantalum in a given solution and the total free energy of formation of the solution was obtained by modification of the Duhem-Margules equation (8)

$$N_{Ta}\, d\bar{F}_{Ta} + N_H\, d\bar{F}_H = 0 \qquad [5]$$

where N is the mole or atom fraction. Since $N_{Ta} + N_H = 1$

$$N_{Ta}\, d \ln N_{Ta} + N_H\, d \ln N_H = 0 \qquad [6]$$

From Eq. [3]

$$d\bar{F}_H = RT\, d \ln P^{1/2}_{H_2} \qquad [7]$$

at constant temperature. Transposing one term of Eq. 5, dividing by N_{Ta}, and then substituting the equivalent of $d\bar{F}_H$ from Eq. [7]

$$d\bar{F}_{Ta} = -\frac{N_H}{N_{Ta}}\, d\bar{F}_H = -RT\frac{N_H}{N_{Ta}}\, d \ln P^{1/2}_{H_2} \qquad [8]$$

Also, from Eq. [6] by multiplying by RT and dividing by N_{Ta}

$$RT\, d \ln N_{Ta} + RT\frac{N_H}{N_{Ta}} \ln N_H = 0 \qquad [9]$$

Subtracting Eq. [9] from [8]

$$d\bar{F}_{Ta} = RT\, d \ln N_{Ta} - RT\frac{N_H}{N_{Ta}}\, d \ln \frac{P^{1/2}_{H_2}}{N_H} \qquad [10]$$

Integrating, we obtain

$$\bar{F}_{Ta_i} - F^{\circ}_{Ta} = RT\left[\ln N_{Ta_i} - \int_{N_H=0}^{N_{H_i}} \frac{N_H}{N_{Ta}}\, d \ln \frac{P^{1/2}_{H_2}}{N_H}\right] \qquad [11]$$

which is the equation for the relative partial molar free energy for tantalum in solution. The standard reference states at any temperature are 1 atm pressure for hydrogen and the pure hydrogen-free condition for tantalum.

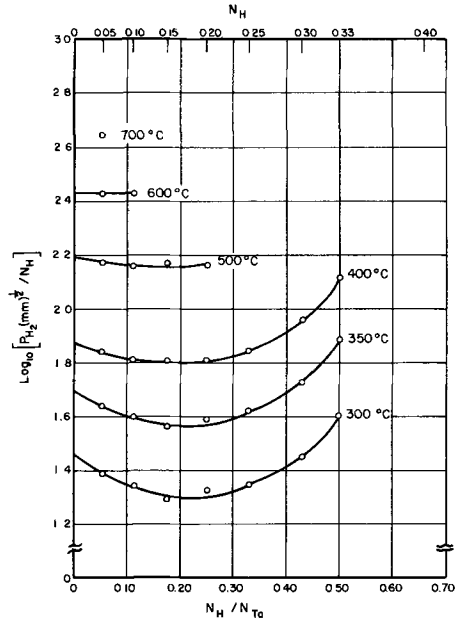

Fig. 3. Equilibrium isotherms for the tantalum-hydrogen system

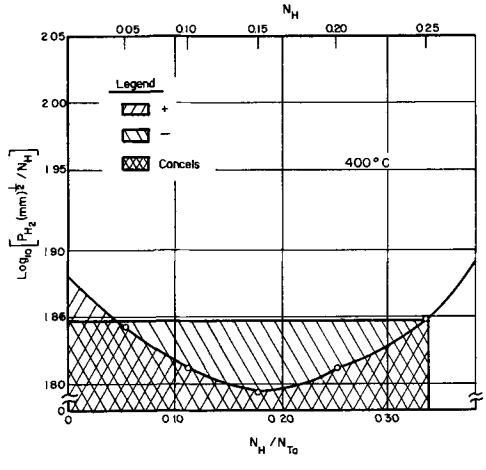

Fig. 4. Integration for $N_H = 0.25$ at 400°C

The negative integral in Eq. [11] is the natural logarithm of the activity coefficient of tantalum in a solution (i). To solve the equation it is necessary to integrate the last term graphically. To help visualize the areas to be integrated it is useful to consider the case of integration by parts where the negative integral becomes

$$-N_{H_i}/N_{Ta_i} \ln \frac{P^{1/2}_{H_2}}{N_{H_i}} + \int_{N_H=0}^{N_{H_i}} \ln \frac{P^{1/2}_{H_2}}{N_H}\, d\, N_{H_i}/N_{Ta_i}$$

Figure 3 shows several equilibrium isotherms plotted for integration. The 500° and 600°C curves approach the horizontal position which would indicate obedience to Sieverts' law. Figure 4 is a plot of a typical curve expanded for graphical integration. The negative and positive areas involved for the composition, $N_H = 0.25$ are indicated. The regions of overlap where the terms cancel each other are shown in cross-hatch. The computed relative partial

Table V. Relative partial molar free energies for tantalum in tantalum-hydrogen solutions

	$\bar{F}_{Ta_i} - F°_{Ta}$ (cal/mole of alloy)					
	Temperature, °C

0.70	—527	—576	—640			
0.666	—754	—839	—935			

molar free energies for tantalum are listed in Table V.

The equation for the total free energy of formation for a given solution (i) is a combination of Eq. [3] and [6].

$$\Delta F_{f_i} = N_{H_i}\left(\bar{F}_{H_i} - \frac{1}{2}F°_{H_2}\right) + N_{Ta_i}(\bar{F}_{Ta_i} - F°_{Ta}) \quad [12]$$

Values for ΔF_{f_i} are given in Table VI. Equations of the same basic form as Eq. [11] and [12] were used by Katz and Gulbransen (7) for calculating the thermodynamic functions for the columbium-hydrogen system.

Both the relative partial molar free energy values (for tantalum) *vs.* temperature plots and the total free energy *vs.* temperature plots for each composition were linear. Therefore, the respective enthalpy and entropy functions and their probable errors could be calculated by a least squares treatment of the data for a given composition. It follows that both functions were invariant over the experimental temperature range. The relative partial molar enthalpies and entropies of tantalum in several hydrogen-in-tantalum solutions are given in Table VII. Corresponding total enthalpies and entropies for these solutions ranging in compositions from $N_H = 0.05$ to 0.333 are given in Table VIII.

Data of Kofstad *et al.* (4) are listed for comparison in Tables VI and VIII. Although their total enthalpies ranged from 96 to 307 cal/mole higher than those of our study their total free energies were higher by only 7 to 27 cal/mole.

The uncertainties in the values of $\bar{H}_{Ta_i} - H°_{Ta}$ and $\bar{S}_{Ta_i} - S°_{Ta}$ in the present study are from 9 to 30% and 2 to 5%, respectively. Since the investigations of similar systems have either omitted presenting uncertainties in values for these functions or even the values themselves, no comparison can be made. However, because of the indirect means of deriving these values the uncertainties appear quite reasonable. It is seen that the uncertainties in the values for relative partial molar energy functions for tantalum have an insignificant effect on the total energy functions. This is evidenced by the probable errors for ΔH_f and ΔS_f which are of the order of only 1%.

New Experiments on Thermoosmosis

Charles W. Carr and Karl Sollner

Department of Physiological Chemistry, University of Minnesota, and Laboratory of Physical Biology, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland

ABSTRACT

Thermoosmosis, the transport of liquid across a membrane which separates two solutions of identical composition but different temperature, was studied by means of a specially constructed apparatus. No thermoosmosis was observed with water or aqueous solutions of nonelectrolytes. With aqueous solutions of electrolytes thermoosmosis occurs across electrically charged membranes but not across uncharged membranes. While thermoosmotic effects are small their reproducibility is good. The rate of thermoosmosis is proportional to the temperature difference across the membrane. The direction of the thermoosmotic movement depends on the sign of charge of the membrane and the nature and concentration of the electrolyte in the solution. The results confirm those of Lippmann and Aubert (1907, 1912) and prove their tentative conclusion that thermoosmosis with electrolytic solutions is an electrochemical phenomenon and related to electroosmosis. The present results show in addition that the direction and rate of thermoosmosis depend in a strikingly similar manner on those factors which determine the direction and rate of anomalous osmosis, namely, the charge of the membrane and the nature and concentration of the electrolyte. This similarity is strongly suggestive evidence of a fundamental, close relationship between the two phenomena.

The study of the fundamental aspects of membrane phenomena has almost always been carried out in isothermal systems. Very little attention has been paid to the possible effects which might arise when the temperature of a liquid on one side of a membrane is different from that on the other. This is not surprising in view of the fact that the study of nonisothermal phenomena in liquid systems, such as the Ludwig-Soret effect (that is the uneven distribution of solute due to a thermal gradient in a solution) and thermopotentials in electrolytic systems, was for a long time a neglected field of research, not only because of the inherent complexity of nonisothermal systems in general, but also because they seemed to be somewhat outside the conventional scope of physical chemistry.

In the last two decades, however, novel and to a large extent successful attempts have been made to treat nonisothermal phenomena from a theoretical point of view (1, 2). Thus experimental information on nonisothermal membrane phenomena has assumed a renewed physicochemical interest. In addition nonisothermal phenomena deserve some interest because very few processes in nature occur under completely isothermal conditions. Temperature gradients of varying magnitude certainly exist across numerous types of living membranes and could conceivably influence the transfer of solvent and solutes across such membranes.

Thermoosmosis

Only a limited number of well-controlled experiments to determine the possible magnitude of nonisothermal membrane effects are reported in the literature. Lippmann (3) and Aubert (4) (in Lippmann's laboratory) were the first to describe the phenomena which occur when a membrane separates a cold from a hot solution. A transfer of liquid across the membrane, which they called "thermoosmosis," was observed in numerous instances with solutions of electrolytes; with nonelectrolytes the effect was doubtful or nonexistent. With some membranes (parchment paper and regenerated cellulose) an osmotic flow was observed from the side of the warmer to the side of the cooler liquid. With other membranes (pig's bladder, gelatin, and animal parchment) the osmotic flow was in the opposite direction. The phenomenon also seemed to be dependent on the presence of some foreign material that could be leached from the membrane. In addition, membranes which in use had become inactive could be restored to a state of activity by traces of suitable electrolytes, and similarly, certain membranes which were naturally inactive became active in the presence of some electrolytes. On the basis of their experiments, Lippmann and Aubert concluded that the thermoosmosis which they observed was linked closely to electroosmosis. This view was shared by Freundlich who, more specifically, surmised a funda-

mental similarity between thermoosmosis and anomalous osmosis (see below) (5).

The work of Ernst, and Ernst and Koczkás (6) on thermoosmosis was criticized by Ursprung (7) and need not be considered further here. Derjaguin and Sidorenkov (8) reported that appreciable quantities of water and other liquids are transported through sintered glass filters by thermoosmosis. Hutchison, Nixon, and Denbigh (9) have repeated and expanded these experiments and conclude that the results of the former investigators are due almost entirely, if not entirely, to the thermal expansion of the liquid. They agree with Lippmann and Aubert that there is no observable thermoosmosis of pure liquids across an inert barrier such as sintered glass or porous clay. Hutchison, Nixon, and Denbigh are of the opinion that those instances where thermoosmosis definitely occurs are most likely due to some electrokinetic mechanism; they also point out that probably not a single case of thermoosmosis has been found which can be explained on the basis of classical thermodynamics.

Riehl (10) in a paper on a rapid method of determining Ludwig-Soret coefficients by the use of a membrane separating a hot from a cold solution observed the transport of moderate quantities of liquid across membranes, but did not study this phenomenon further.

Winterkorn (11) finds a very close correlation between the mass movement of water in soils under a thermal gradient and the electrokinetic properties of these systems and believes that the thermal osmotic effects in soils may be an instance of thermoosmosis.

Haase (12) expressed the feeling of those familiar with the literature when he stated recently that only a few, and in part questionable, observations on thermoosmosis in liquid systems are extant (while analogous processes in gaseous systems were proven beyond doubt and are amenable to theoretical treatment). Haase has presented theoretical considerations concerning thermoosmosis with pure liquids and with solutions of nonelectrolytes and carried out experiments to test his conclusions; he did not consider thermoosmosis in systems with electrolytic solutions.

Thermoosmosis, a Problem in the Electrochemistry of Membranes

A review of the quoted and the other available literature indicates that thermoosmosis in systems free of electrolytes, if it occurs at all, is in all instances much less pronounced than in many systems with electrolytic solutions. The published data suggest that the essential mechanism of thermoosmosis in electrolytic systems is electrochemical in nature, most likely related in some manner to electroosmosis. Thus, it seemed promising to attack the problem of thermoosmosis from an electrochemical point of view and apply to it some of the current basic information on the electrochemistry of membranes as exemplified by the classical work on the electrochemistry of membranes by Loeb (13), by Michaelis (14), the fixed charge theory of electrochemical membrane behavior of Teorell (15) and Meyer and Sievers (16), and the work on "activated" membranes carried out in our laboratories (17-24).

The degree of the electrochemical activity of ionic membranes, for instance their electromotive action, their electroosmotic efficacy, or their ability to give rise to anomalous osmosis are more pronounced the greater the density of ionic groups at the walls of the pore system which constitutes the membrane (17-24). These ionic groups may be an inherent part of the matrix material from which the membranes are prepared or they may be introduced by intentional "activation" such as a chemical reaction, *e.g.*, oxidation which creates ionic groups, adsorption of ionic materials such as polyelectrolytes or proteins on formed membranes, and mixing of polyelectrolytes with the matrix material before the membranes are cast (17-24). It is evident that the methods of activating membranes should be very helpful in determining whether thermoosmosis is really an electrochemical effect. If this is the case, activated membranes with solutions of electrolytes should show greatly enhanced thermoosmotic effects as compared with nonactivated ones.

Experimental

An apparatus similar to that used by Aubert (4), was constructed for measuring thermoosmosis; it is shown in Fig. 1 and 2.

Essentially the apparatus consists of two very narrow circular chambers separated by a membrane, the two chambers being arranged for heating and cooling, respectively (see Fig. 1a and 1b.) Two round

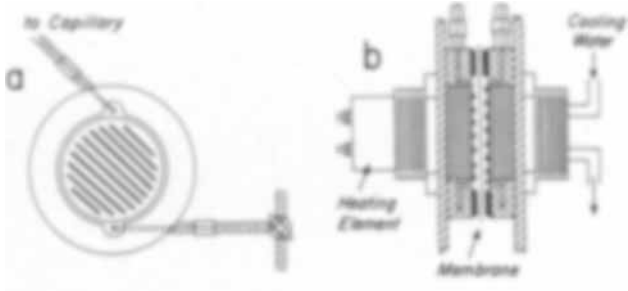

Fig. 1. Cell for the study of thermoosmosis across membranes (slightly schematic): (a) side view of a solution compartment; (b) cross-sectional view of main parts of thermoosmosis cell.

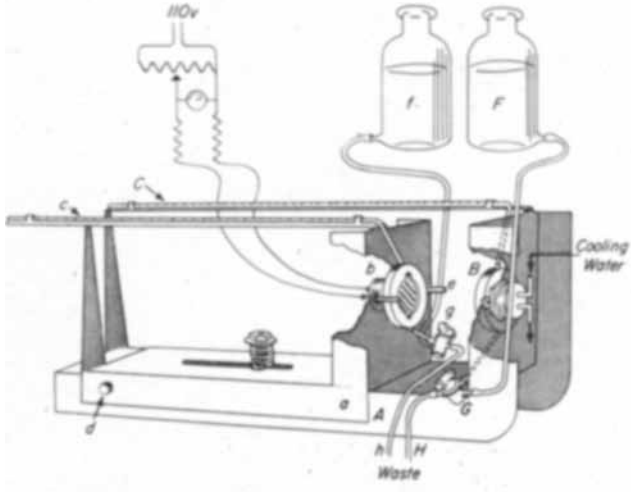

Fig. 2. Complete thermoosmosis apparatus with thermoosmosis cell and auxiliary equipment.

copper blocks of 50.7 mm diameter are set in hard rubber rings of 90 mm outer diameter. One of the blocks was heated by a 100-w (nominal at 110v) electric heater whose temperature was adjusted by a variable voltage control, routinely set at 60v (corresponding to about 30w) unless otherwise stated; the other copper block was cooled by water circulating through it, the temperature of which was maintained at 25°C. The surfaces of both copper blocks were painted with an inert and electrically insulating lacquer thus excluding corrosion and any possibility of an outside electrical connection between the solutions in the two compartments. Rubber gaskets 1 mm in thickness with an internal opening of 56 mm in diameter (and small cut outs for the inlet and outlet for the solution) were cemented to the hard rubber rings surrounding the copper blocks. To keep the membrane in an exactly defined, unchanging position, several narrow strips of the gasket material (about 1 mm in width) were cemented parallel, in opposite diagonal positions onto each of the copper blocks. When a membrane was clamped between these two parts, two cylindrical chambers were formed, each 55 mm in diameter and 1 mm in depth. The free membrane area, not blocked by the rubber strips, was about 20 cm^2. Each chamber was connected with a horizontal glass capillary. In the assembled apparatus (see below) the two capillaries were on the same level to prevent the development of any difference in hydrostatic pressure in the chambers while an experiment is in progress. A scale graduated in millimeters was attached under each capillary so that the rate of movement of the meniscus could be observed.

These essential parts of the thermoosmotic cell were mounted in the apparatus shown in Fig. 2 consisting of an L-shaped stand *A* and an L-shaped sledge *a* which can be moved back and forth along the longer limb of the stand *A*. The two assemblies (Fig. 1b) which form the thermoosmosis cell proper, *B* and *b*, connected to the measuring capillaries *C* and *c* (inner diameter about 0.9 mm) are mounted in the upright parts of *A* and *a* as shown in Fig. 2. To put the apparatus together for an experiment, it is first turned 90° into the vertical position with the sledge *a* raised and held by the catch bolt *d*. The membrane to be used is then placed over the lower copper block and rubber gasket, *B*, mounted on *A*; it should be large enough to cover all of the gasket. The assembly with the upper copper block, *b*, mounted on the sledge *a*, is then lowered onto the membrane. The two parts are then clamped tightly together with two large screws *e*. The apparatus is then returned to the horizontal position. Figure 2 shows in addition the arrangement for filling and flushing the two cell compartments by means of two solution reservoirs *F* and *f*, the three-way stopcocks *G* and *g*, and the attached waste lines *H* and *h*.

For an experiment the chambers were filled by gravity feed with the same solution from the two reservoirs. The positions of the menisci in the capillaries *C* and *c* are regulated by the three-way stopcocks, *G* and *g*. With both chambers at the same temperature, the apparatus is allowed to stand for 30 min, the position of the meniscus in each tube being observed every 5 min to ascertain that there are no leaks. When it has been established that the system is watertight, the heater for the one chamber is turned on, and the cooling water is circulated through the copper block of the other chamber. When the assembly has warmed up, a steady state is reached in which the rate of movement of the menisci in the two capillaries becomes constant; this usually requires 15-30 min after the start of the experiment. Thereafter readings of the positions of the menisci are taken every 10 or 15 min for about 1 hr, confirming thereby that the observed rate of water movement is constant at least during this period.[1] This rate is take as a measure of the magnitude of the thermoosmosis.[2]

The solutions must be carefully degassed by boiling (and replacement of the water lost by equally carefully degassed water); 15-20 min vigorous boiling were adequate. With not properly degassed solutions, gas bubbles form, particularly in the compartment of the hot solution and give rise to spurious volume readings.

The possibility of a disturbing thermometric effect must also be considered. As will be shown later, with distilled water in the apparatus no thermoosmosis is observed, *i.e.*, there is no continuous unidirectional movement of the meniscus. There is also no detectable fluctuation in the position of the meniscus after the steady state has been attained. Thus a significant contribution of the thermometric effect to the observed volume changes during the experimental period is ruled out.

All membranes used were of the porosity of conventional dialyzing membranes. They included membranes prepared from electrochemically rather inactive collodion of high purity which were used without further treatment; collodion membranes that had been made strongly electronegative by oxidation with NaOH (20);[3] and collodion membranes that had been made electropositive by the adsorption of protamine (23).[4] The preparation and properties of these types of membranes have been described previously (17-24).[5] In addition, some

[1] In the limited number of experiments which were carried out over 3-4 hr, a gradual but significant decrease in the rate of liquid movement occurred, an effect reported already by Aubert (4).

[2] The described apparatus and the technique used are obviously not suitable to determine minor thermoosmotic effects which might occur during the warming up period. Our experimental procedure, like that of Aubert, is designed to study processes which extend over periods substantially longer than the warming up period. A thermoosmotic process which comes to a stop during the warming up period and is not of the magnitude of at least a sizable fraction of the total thermometric (thermal expansion) effect occurring during this period, would not be detected. Any negative result obtained by our experimental method should be considered in this light.

[3] Collodion in contact with alkaline solution is not hydrolyzed in a straightforward manner to cellulose and nitric acid; rather, it undergoes a gradual decomposition of a complicated nature. Nitrite is formed in large quantities and the nitrocellulose is gradually oxidized. The oxidation of collodion membranes by means of alkaline solutions tends to produce membranes of higher electrochemical activity than conventional oxidizing agents.

[4] Protamines are simple strongly basic proteins, ordinarily derived from salmon sperm, with molecular weights of about 4000 in the hydroxyl form. They are of somewhat varying composition, most probably consisting of 19 molecules of arginine, a dibasic amino acid with a pK of 12.5, and six or seven monobasic amino acids. The ionizable groups in the protamine molecule, which are not blocked by the formation of peptide linkages, are: one carboxyl group, one imino group, and 19 guanidino groups.

[5] It should be noted that the activation of the wide pored membranes of the dialyzing type by oxidation (to render them acidic) or the adsorption of protamine (to make them basic in character) does not change to an extent which is significant in the present connections either their water permeability or their osmotic behavior with solutions of nonelectrolytes, while electroosmosis or anomalous osmosis across them are increased manyfold.

experiments were carried out with cellophane and animal parchment.

A shortcoming of our thermoosmosis apparatus is the lack of provisions for the measurement of the temperature difference between the two sides of the membrane.[6] For the purpose at hand, however, this shortcoming is more apparent than real, since our aim here is the comparison of the behavior of different membranes and different solutions under otherwise constant, standardized conditions. The temperature difference across membranes must vary to some extent according to their different thicknesses and water contents. However, the difference in temperature can be assumed to be virtually the same across generically related membranes of the same thickness and water content. The nonactivated, the oxidized, and the protamine collodion matrix membranes with which the bulk of the experiments were carried out fall into this category.

In the experimental results presented later, a flow of liquid from the hot side to the cold side is arbitrarily assigned a positive sign, a flow in the opposite direction a negative sign. This convention was chosen to avoid confusion in the discussion, when the flow of liquid in thermoosmosis will be compared to the flow of liquid in anomalous osmosis. The results obtained from the rates of movement of the menisci in the capillaries are expressed in $mm^3/100\ cm^2$ of membrane area per minute. It is estimated that the reproducibility of a given measurement is about $\pm$ 1 $mm^3/100\ cm^2$-min.

Results and Discussions

Our initial survey experiments were concerned with the influence of the nature of the membrane, and of the nature and the concentration of various solutes. A summary of representative data is given in Table I. The results were clear cut: In systems with pure water, thoroughly freed of all solutes, thermoosmosis does not occur to an extent detectable with our equipment, that is less than 0.3 $mm^3/100\ cm^2$-min. The same holds true with solutions of sucrose in agreement with the observation of Aubert who did not observe any thermoosmosis with solutions of various nonelectrolytes. With solutions of electrolytes, however, thermoosmosis may occur depending on the electrical charge of the membrane. The effect is not measurable in our system with cellophane membranes or membranes prepared from pure collodion, which are known to be rather inactive electrochemically, having only a few stray fixed ionic wall groups in their pores (18-20). "Activated" or inherently active membranes such as oxidized collodion membranes or protamine collodion matrix membranes or membranes of animal parchment are thermoosmotically active, corresponding to the fact that they are electrically charged, carrying numerous fixed ionic groups in their pore structure.

The direction of the thermoosmotic flow in the majority of simple systems is from the hot to the cold compartment–"positive" in our terminology.

It may be useful to add here that the thermoosmotic effect, as stated already by Aubert, becomes larger with an increase of the temperature difference between the solutions in the hot and cold compartment. It would require a special, rather elaborate arrangement to determine accurately the magnitude of the driving force, that is the temperature drop across the membrane itself.[6] We confined ourselves to the simple expedient of correlating the extent of thermoosmosis to the voltage applied to the heating element of the hot side of our apparatus. While water of 25°C flowed at a constant rate through the copper block of the cold side, a stepwise increased voltage, 30, 40, 50, 60, and 65v, was applied to the heater. The corresponding rates of thermoosmosis with an oxidized collodion membrane and 0.01*M* K_2SO_4 solution were: 1.3, 2.2, 6.3, 10.8, and 11.4 $mm^3/100\ cm^2$-min. When these values are plotted against the square of the voltage applied to the heater, they are found to lie on a straight line within the limits of the accuracy of the data and to be proportional to the square of the voltage, that is proportional to the quantity of heat which flowed across the thermoosmosis cell. The temperature drop across the membrane proper must be assumed to be proportional to the flux of heat across the cell. Therefore it can be concluded that the rate of thermoosmosis is proportional to the driving force, the temperature difference between the two membrane-solution interfaces, a not unexpected result.

The results of Table I, and of other experiments omitted here, fully confirm those of Aubert. There is excellent agreement with respect to the most important points, namely, the influence of the nature of the solute, the direction of the thermoosmosis as dependent on the nature of the membrane, and the order of magnitude of the observed effects. Our observation that the electrochemical "activation" of membranes increases thermoosmosis many-fold

[6] In the narrow solution compartments of our apparatus, which are indicated by other considerations, stirring of the liquid is due only to natural convection, and therefore rather ineffective. In addition, adjacent to the membrane, there are unstirred (Nernst) layers of solution which are of the same order of magnitude in thickness as the membrane itself. Thus, a large fraction of the temperature difference between the two bulk solutions is not operative across the membrane. In further work it will be advisable to use membranes of greater thickness, 1 mm or more, than that of the membranes used here (30-50μ), combined with effective mechanical stirring.

Table I. Thermoosmosis with different solutions across various membranes†

Membrane	Solution	Rate of thermoosmosis in $mm^3/100\ cm^2$-min*
Nonoxidized collodion	H_2O	0.0
	0.02*M* K_2SO_4	0.0
Oxidized collodion	H_2O	0.0
	0.02*M* KCl	+6.4
	0.02*M* K_2SO_4	+18.0
	Sucrose	0.0
Protamine-collodion	H_2O	0.0
	0.02*M* KCl	+5.4
	0.02*M* $MgCl_2$	+13.2
Cellophane	H_2O	0.0
	0.02*M* K_2SO_4	0.0
Animal parchment	0.02*M* NaOH	−11.3

† The voltage applied to the heater was 60v in all instances.
* A positive sign represents flow of solution from the hot side to the cold side, a negative sign the reverse.

strongly supports the hypothesis of Lippmann and Aubert that thermoosmosis is of an electrochemical nature and probably closely linked to electroosmosis.

As stated before, Freundlich had surmised that thermoosmosis might be closely related to anomalous osmosis (5). In the course of our experiments two regularities of importance in this connection have been noted consistently. First, thermoosmosis across acidic membranes, such as oxidized collodion membranes, is always stronger with uni-bivalent electrolytes such as K_2SO_4 than uni-univalent salts; with basic, electropositive membranes, such as protamine collodion matrix membranes, the effect is stronger if the electrolyte has a bivalent cation. Second, without exception the thermoosmotic effect was strongest with solutions in a medium concentration range (with most systems about 0.01-0.03*M*) and considerably smaller at lower and higher concentrations. These regularities are also very characteristic for the phenomenon that is known in the literature as "anomalous osmosis." Thus, it seems indicated to compare the influence of concentration on the transport effects arising in thermoosmosis and in anomalous osmosis.

The term anomalous osmosis is commonly used to denote those osmotic phenomena arising with solutions of electrolytes which seem to be contrary to the common experience that the flow of liquid across a membrane which separates a solution from pure solvent (or a more dilute solution) occurs ordinarily toward the side of the more concentrated solution, and at a rate roughly proportional to the concentration difference. In the very common instance of "anomalous positive osmosis" the rate of movement of liquid toward the side of the solution depends on the concentration of the solution used, the rates of flow in a medium range of concentrations being much higher than with more concentrated or more dilute solution. In the relatively rare instances of "anomalous negative osmosis" a flow of liquid occurs toward the side of the pure solvent (or the more dilute solution).

Investigators in this field agree unanimously that anomalous osmosis through porous membranes is an electrochemical phenomenon (25). Its magnitude is closely correlated with the product of the electrokinetic charge of the membrane and the dynamic membrane potential which results from the diffusion of electrolyte across the membrane as stressed particularly by Bartell (26, 27) and Loeb (13). The details of the mechanism of anomalous osmosis across porous membranes are still controversial and the subject of continuing investigation (25, 28-31). One of us proposed some time ago that anomalous osmosis arises from the interaction of pores which yield different potentials (for instance, due to their different width), when the electrolytic solute diffuses across the membrane (25, 28). Local electric circuits arise, superficially similar to the local circuits assumed generally in corrosion. One set of pores acts as the source of the driving electromotive force, another set of pores plays the role of an electroosmotic diaphragm through which the current is driven passively, thereby producing electroosmosis according to the electrokinetic charge of the pores. Schlögl, in a most ingenious manner, has developed the idea that anomalous osmosis arises in the individual pores, without interaction of different pores (29). According to Schlögl, the potential which arises at each pore due to the diffusion of the electrolyte across it, acts as a moving force on the pore water according to the electrokinetic charge of the latter. Whichever of these and similar concepts may ultimately be proven correct, the electrochemical character of anomalous osmosis seems beyond doubt.

Most experiments on anomalous osmosis have been performed with systems in which a membrane separates pure water from a solution of an electrolyte, and the pressure rise in an osmometric capillary is read after an arbitrarily chosen time (20 min in the experiments presented below). The observed effect consists of two components, the true anomalous osmosis and the normal osmotic effect as it arises also with nonelectrolytes. To avoid this uncertainty and to determine the magnitude of true anomalous osmosis Grim and Sollner had recourse to the easily demonstrated fact that anomalous osmosis does not occur with electroneutral membranes (22). Accordingly, with membranes which can be charged and discharged reversibly (without significant changes in geometrical structure), such as many proteinized membranes, the osmotic effects caused by an electrolyte can be measured both when only normal osmosis arises (with the membrane in the electroneutral state) and when normal as well as anomalous osmosis occurs (with the membrane in a charged state). The difference between these two effects is considered as the true anomalous osmosis. Using this procedure Grim and Sollner have measured the true anomalous osmotic effects arising in systems in which the concentration ratio of the two solutions separated by the membrane was 2:1. Such systems are, of course, more similar to those used in the thermoosmosis studies, where the membrane separates solutions of equal concentration, than to the conventional solution-water system.

Figure 3 presents data on the extent of thermoosmosis across an oxidized, electronegative, collodion membrane with K_2SO_4 as electrolyte (heater set at 60v), and two sets of data on anomalous positive osmosis with the same electrolyte; the one set was obtained with an oxidized collodion membrane by the pressure rise method (18), the other one by the volume method with an oxyhemoglobin collodion matrix membrane in the negative state (at pH 10.0) (22).

Figure 4 gives analogous data on thermoosmosis with $MgCl_2$ across an electropositive protamine collodion matrix membrane (heater set at 60v), and data on anomalous positive osmosis by the pressure rise method across a similar protamine collodion membrane,[7] and by the volume method across the same oxyhemoglobin membrane referred to in Fig.

[7] The data shown in Fig. 4 for the pressure rise methods were actually obtained by Abrams and Sollner (23) with $CaCl_2$ as the electrolyte. The work of Loeb (13) and experience in our own laboratories show that there is no reason to believe that the curve would be any different in its form if $MgCl_2$ had been used instead of $CaCl_2$.

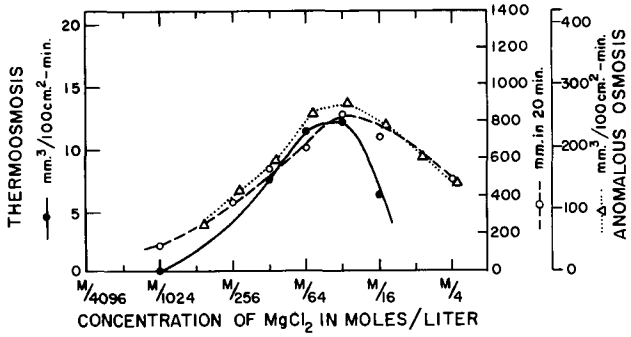

Fig. 4. Comparison of thermoosmosis and anomalous osmosis across positively charged, basic membranes; ——●—— thermoosmosis; — — ○ — — anomalous osmosis by the pressure rise method; . . . . △ . . . . anomalous osmosis by the volume transport method.

3, but now in the positively charged state (at *p*H 4.0) (22).

Figures 3 and 4 show the great similarity of the concentration dependence of thermoosmosis and of anomalous positive osmosis; the maximum effects of thermoosmosis and of anomalous osmosis occur in the same concentration range, with a fairly sharp decline both at higher and lower concentrations. In view of this correlation the next, obvious step was to test whether or not thermoosmosis occurs in the opposite direction (from the cold to the hot compartment) in systems the analogues of which are known to give anomalous negative osmosis.

Anomalous negative osmosis has been shown to arise in systems which satisfy these requirements: (i) the electrolyte must be such that its faster diffusing ion has the same sign as the charge of the membrane, and (ii) the porosity and charge density of the membrane and the concentration of the electrolyte must be adjusted so that the membrane potential is in the direction which gives the more dilute solution the same charge as that of the membrane (28).

In those instances where anomalous negative osmosis has been observed, the concentration of electrolyte necessary to produce maximal effects is considerably higher than that to produce maximal anomalous positive osmosis with the same membranes (and different electrolytes). For example, with positive membranes, acids, particularly di- and tri-basic acids, are especially effective in the concentration range of 0.5-1.0*M*; similarly, with negative membranes LiCl and strong bases will produce anomalous negative osmosis in this concentration range.

We have carried out a limited number of test experiments on thermoosmosis, simulating the above-described conditions which produce anomalous negative osmosis. In all instances the movement of liquid was from the cold to the hot compartment, that is the direction opposite to that in the experiments shown in Fig. 3 and 4. For example, with a protamine collodion matrix membrane, 0.5*M* H_3PO_4, and the same temperature gradient as used before, the rate of flow was —7.4 mm³/100 cm²-min. Similarly, with 0.02*M* NaOH[8] and oxidized collodion membranes, the rate of flow was —8.4 mm³/100 cm²-min.

These results confirm our anticipation based on the previous results which showed a strong correlation of thermoosmosis and anomalous positive osmosis. That the correlation of thermoosmosis and anomalous negative osmosis in appropriate systems is equally strong lends further strength to the hypothesis that mechanisms of thermoosmosis and anomalous osmosis are intimately related. However, we are not prepared at this time to propose a detailed mechanism for thermoosmosis. Before this can be done, it will be necessary to have measurements of the thermopotentials which arise under the conditions of the experiments. If one considers that the rate of anomalous osmosis in 2:1 concentration systems is at least 10 times larger than that of thermoosmosis under our experimental conditions (compare Fig. 3 and 4), and that the membrane potentials which arise in the former systems are of the order of 10 mv, it can be seen that the thermopotential required to produce the observed thermoosmosis may be only of the magnitude of 1 mv or less. Further, one should try to correlate the thermoosmotic mass movement with the Ludwig-Soret distribution of electrolytes across membranes. With such further information available, it will be of considerable interest to discuss possible mechanisms of thermoosmosis in the light of current theories of anomalous osmosis.

[8] This is not the optimum concentration for NaOH, but higher concentrations could not be used because the membranes are rapidly destroyed when such solutions are heated.

Acknowledgment

The authors wish to express their gratitude to the National Foundation for Infantile Paralysis under whose auspices this study was started in 1945, and to the Josiah Macy, Jr. Foundation which during the year 1946 supported the bulk of the experimental work presented in this paper.

Manuscript received Aug. 16, 1961; revised manuscript received Feb. 1, 1962. This paper was presented before the Colloid Division of the American Chemical Society at the Chicago Fall Meeting, 1946.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Anodic Oxidation of Methanol on Platinum

I. Adsorption of Methanol, Oxygen, and Hydrogen on Platinum in Acidic Solution

M. W. Breiter and S. Gilman

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The coverage of bright platinum electrodes with methanol, oxygen, and hydrogen was determined as a function of potential and bulk concentration of methanol in perchloric acid. Two different techniques which lead to the same results for the coverage with the respective species are described. The methanol coverage was obtained for equilibrium conditions at open circuit and under the conditions of a quasistationary current-potential curve. The methanol coverage is potential independent between +0.1 and +0.6v and decreases rapidly with potential above +0.6v during the anodic sweep of the current-potential curve. The oxygen coverage differs only slightly in 1*N* $HClO_4$ and 1*N* $HClO_4$ + 1M CH_3OH. Hydrogen adsorption is decreased by 75% if the saturation coverage of methanol is present on the surface.

The mechanism of the anodic oxidation of lower alcohols on solid electrodes, particularly platinum, is of great importance in connection with fuel cell technology. An intensive study of one particular system, acid methanol, was carried out since it was felt that the results would advance the understanding of similar systems. Results on the mechanism of the anodic methanol oxidation will be reported in a series of papers. The first paper deals with the adsorptive properties of platinum with respect to

methanol, oxygen, and hydrogen in 1N $HClO_4$, containing different amounts of methanol.

Current-potential curves and analytic determination of the reaction products in different solutions have been mainly used to come to conclusions on the reaction mechanism (1-7). It is assumed in the existing theories of the oxidation mechanism that adsorption of methanol plays an important role. However, little is known about the adsorption of methanol in the so-called double layer region, about a possible simultaneous adsorption of hydrogen and methanol in the hydrogen region, and of methanol and oxygen in the oxygen region. A detailed description of the three well-known potential regions can be found in a paper (8) on the adsorption of amyl alcohol at platinum in which similar problems were discussed.

Pavela (3) was the first to establish direct experimental evidence for the adsorption of methanol on platinized platinum. He kept the electrode at open circuit in solutions of water and methanol for 15 min and then briefly immersed it in distilled water. The electrode was then immersed in 1*N* NaOH and an anodic charging curve measured. An arrest is observed which Pavela attributes to the quantitative oxidation of methanol to formic acid. The adsorbed amount is computed from the transition time of the arrest and the current. Pavela found a saturation coverage for methanol concentrations $C_M > 0.5M$. The experimental adsorption isotherm is in fairly good agreement with Langmuir's isotherm.

Pavela's procedure is based on two conditions: (*A*) Methanol is desorbed only to a negligible amount during the rinsing while only an adherent liquid layer of methanol is removed. (*B*) All the adsorbed methanol is oxidized before the anodic formation of a chemisorbed oxygen layer starts. As the fulfillment of the conditions was not verified, Pavela's results may include a considerable error. Therefore other techniques were developed and used to obtain the equilibrium coverage with methanol at open circuit and the coverage under the conditions of a potentiostatic current-potential curve. A comparison of the methanol coverage under the two conditions shows that equilibrium coverage is attained in the double layer region during the anodic sweep of current-potential curves. The oxygen coverage was measured as a function of potential in the base electrolyte solution and in solutions containing methanol. The information on methanol adsorption and oxygen coverage under different conditions has not been available in the literature. The results of this paper will be used to discuss the potentiostatic current-potential curve in a second paper of the series.

Experimental

Two techniques were used for the determination of the coverage with methanol, hydrogen, and oxygen. The first method is the potentiostatic application of voltage pulses to the electrode by means of a Wenking potentiostat. The second method consists in the chronopotentiometric (galvanostatic) application of current pulses. The form of the pulses was chosen such as to meet the experimental requirements for the determination of the adsorbed amount of one of the three species.

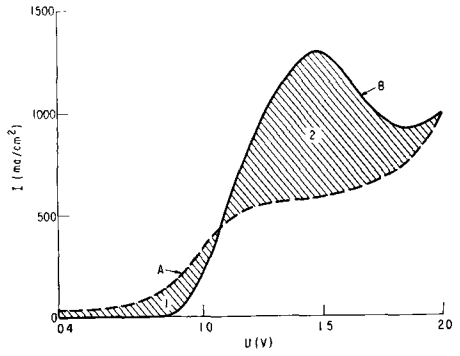

Fig. 1. Potentiostatic i-U-curves with v = 800 v/sec in *1N* $HClO_4$ + 1M CH_3OH (curve B) and in *1N* $HClO_4$ (curve A) starting from the open-circuit potential.

Potentiostatic technique.—A single triangular potential sweep of very short duration was applied to study methanol adsorption. The anodic sweep started at a desired potential and extended to 2.0v. It could also be started when the electrode potential changed linearly and periodically as under the conditions of a potentiostatic current-potential curve. The current was registered as a function of potential (or time) by means of an oscilloscope during the fast potential sweep. The nonstationary anodic current-potential curves (i-U-curves) were measured in the electrolyte (1*N* $HClO_4$) and in 1*N* $HClO_4$ with different amounts of methanol. Curve B in Fig. 1 was obtained in 1*N* $HClO_4$ + 1M CH_3OH and curve A in 1*N* $HClO_4$. The sweep started at the open-circuit potential of the platinum electrode in the respective solutions. All the potentials in this paper are referred to a hydrogen electrode in the same solution. The voltage speed of the sweep was 800 v/sec. The methanol was Spectro-quality Reagent (Matheson Coleman & Bell), the perchloric acid Analytical Reagent (Mallinckrodt), the water was double distilled with a specific resistivity of $8 \cdot 10^6$ ohm-cm at 25°C. Methanol concentrations up to 1M were used. The solutions were intensively stirred with argon before the measurements. The measurements were made in a Pyrex glass vessel with three compartments. The vessel was thermostated at 30°C. The prehistory of the electrode influences the i-U-curves markedly and is always given. The electrode pretreatment for the curves in Fig. 1 is described in the next section on the equilibrium coverage with methanol.

Shaded area 2 minus shaded area 1 (see Fig. 1) yields the charge, Q_M(coul/cm²) required for the removal of the adsorbed methanol by anodic oxidation, or

$$Q_M = \int_0^t i_B dt - \int_0^t i_A dt \qquad [1]$$

The applicability of the potentiostatic technique is based on four conditions: (*A*) The number of coul/cm² which are used for the anodic formation of an oxygen layer and for oxygen evolution during the sweep is the same in the electrolyte and in the solution containing methanol. (*B*) The same number of electrons per molecule is involved in the oxidation, independent of the adsorbed amount of meth-

anol. (*C*) The nonfaradaic currents which change the charge of the double layer are the same in the electrolyte and in the solution containing methanol. (*D*) The anodic sweep is sufficiently rapid that oxidation of methanol which diffuses to the electrode during the sweep is negligible.

The precision of the determination of $\ominus_M$ by the potentiostatic method is estimated at ± 0.1. The i-U-curves (see Fig. 1) coincide at high potentials. This shows that the electrode surface is oxidized to the same extent in the electrolyte and in the solution with methanol. Condition (*A*) is approximately fulfilled. This conclusion is supported by the result that the oxygen coverage of the electrode under the conditions of a potentiostatic current-potential curve is nearly the same at any potential independent of the methanol concentration as described in the section on the oxygen coverage. The coincidence of the i-U-curves is evidence that all the adsorbed methanol is removed during the anodic sweep. The i-U-curves have the same shape independent of the adsorbed amount of methanol. This suggests the fulfillment of condition (*B*). It was estimated that condition (*C*) might introduce an error of up to 7%. The nonfaradaic currents are relatively large due to the high voltage speed. They will differ to some extent as the double layer capacity is likely to be smaller during the sweep in the solution with methanol than in the electrolyte solution. Simultaneous adsorption of amyl alcohol and oxygen on platinum resulted in a lowering of the double layer capacity in the oxygen region (8). The same effect can be expected for methanol. To verify the fulfillment of condition (*D*), i-U-curves were measured at different voltage speed in 1*N* $HClO_4$ + 1M CH_3OH. Figure 2 represents the result. Q_M is plotted *vs.* log *v*. A limiting value for Q_M is obtained for $v > 200$ v/sec. Therefore the determination of Q_M was carried out with $v = 800$ v/sec. As condition (*D*) is fulfilled for 1M CH_3OH, it is valid for $C_M < 1M$ also.

The oxygen coverage at potentials in the oxygen region was obtained by interrupting the circuit at the desired potential and applying a potential of + 0.4v very rapidly. This was done with the Western Electric 275 C Relay. The oxygen layer is completely reduced at + 0.4v. The area under the current-time curve gives the amount Q_o in coul/cm² of adsorbed oxygen. The reduction occurs very fast

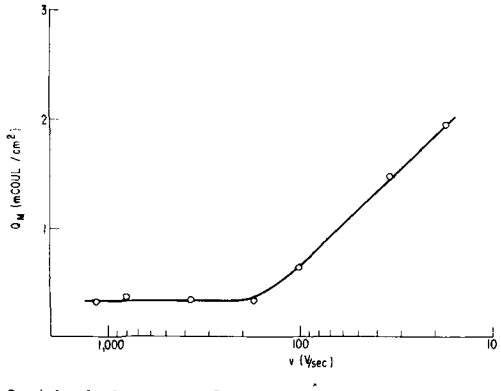

Fig. 2. Adsorbed amount Q_M of methanol in 1*N* $HClO_4$ + 1M CH_3OH as a function of the voltage speed *v* of the potentiostatic sweep.

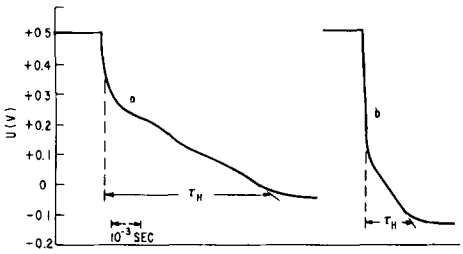

Fig. 3. Cathodic charging curves from 0.5v with 0.06 amp/cm² in 1*N* $HClO_4$ (curve a) and in 1*N* $HClO_4$ + 1M CH_3OH (curve b). The determination of the transition time τ_H for the hydrogen branch is shown.

(in about 5.10^{-3} sec). Therefore the influence of a simultaneous oxidation of methanol which diffuses to the surface is negligible.

Galvanostatic technique.—The second method consists in taking cathodic charging curves from different initial potentials. Q_o is determined as a function of potential in the oxygen region from the transition time of the oxygen branch of the charging curve and the current density (9). The length of the hydrogen branch yields the number Q_H of coul/cm² to fill the sites available for hydrogen adsorption. If the charging curve starts at a potential where methanol is adsorbed, the number N_M of hydrogen adsorption sites which are occupied by adsorbed methanol can be computed from the decrease in Q_H. Curve a in Fig. 3 is a charging curve with 0.06 amp/cm² from + 0.5v in 1*N* $HClO_4$, curve b from + 0.5v in 1*N* $HClO_4$ + 1M CH_3OH. Both curves were taken during the anodic sweep of potentiostatic current-potential curves with $v = 30$ mv/sec by switching from the potentiostatic to the galvanostatic circuit when the potential reached + 0.5v. Curve b shows a marked decrease in the length of the hydrogen branch. If ${}_sQ_H$ designates the number of coul/cm² for the cathodic formation of a completely covered surface in the electrolyte and Q_H is the value in the presence of methanol, then for potentials $U \geqq + 0.3v$

$$N_M = ({}_sQ_H - Q_H) \cdot L/\mathbf{F} \qquad [2]$$

F is the faraday and *L* is Avogadro's number. It was found from charging curves starting between + 0.8 and + 1.5v that ${}_sQ_H$ was approximately the same (0.34 mcoul/cm²) in all solutions. The above concept was used by Oikawa and Mukaibo (10) to study the adsorption of acetic acid on platinum, and by Franklin and Sothern (11) for the adsorption of nitrides on platinum. These authors took the quantity

$$\theta' = \frac{{}_sQ_H - Q_H}{{}_sQ_H} \qquad [3]$$

as a measure for the coverage with organic substance. This implies the validity of the relation

$$\theta = \frac{Q_M}{{}_sQ_M} = \theta' \qquad [4]$$

for the whole range of θ' values. The validity of relation [4] has already been questioned by one of the authors (8). The objection is based on the possibility that hydrogen atoms could be adsorbed on

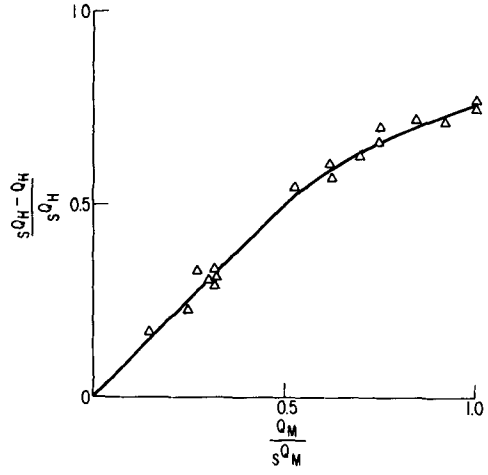

Fig. 4. Apparent coverage $\frac{{}_sQ_H - Q_H}{{}_sQ_H}$, as determined from the decrease of the hydrogen arrest of the cathodic charging curve, as a function of the coverage $\frac{Q_M}{{}_sQ_M}$, determined with the anodic potential sweep.

sites which are not accessible to methanol adsorption for geometric reasons. θ and θ' were determined for various concentrations of methanol in 1*N* $HClO_4$ under the conditions of a quasi-stationary potential sweep. The values reported for θ were obtained potentiostatically and those for θ' were obtained galvanostatically. Figure 4 gives the experimental results. Equation [4] is fulfilled for $\theta' \leqq 0.5$. Above $\theta' = 0.5$ the $\theta' - \theta$ curve bends and tends toward $\theta' = 0.75$ for $\theta = 1$. Only 75% of the sites which are accessible to the adsorption of hydrogen atoms are available for methanol adsorption. The calibration curve in Fig. 4 permits interconversion of θ and θ'. Since the galvanostatic method is simpler than the potentiostatic one, it was used in many cases. Adsorption isotherms of organic substances which were determined solely from the decrease of the amount of adsorbed hydrogen are in error for $\theta' > 0.5$. The latter statement holds for any method of determining Q_H. The fair agreement between θ and θ' for $\theta' < 0.5$ confirms the reliability of the potentiostatic and the galvanostatic method. The accuracy for θ' is estimated at $\pm$ 0.1. Precision for θ by the potentiostatic method is better than 0.03.

Results and Discussion

Adsorption Isotherm for Methanol

It is well known from reported polarization curves that methanol is oxidizable at relatively low potentials. Therefore the isotherm for equilibrium conditions can only be determined with certainty if the adsorption occurs at open circuit. The following pretreatment led to reproducible results. The electrode was polarized at 1.8v for 15 sec and at 1.55v for 30 sec while stirring with bubbled argon. Under these conditions the electrode surface is completely stripped of organic materials and is completely covered with an adsorbed oxygen layer. Desorbed organic materials are swept into the bulk solution and highly diluted. Then the stirring was interrupted and the potential held at 1.55v for 1½ additional minutes. The potential was then stepped instantaneously to + 0.4v and held there for 0.015 sec. This time is sufficient for the reduction of the chemisorbed oxygen layer. After 0.015 sec the circuit was opened. After a specified period at open circuit, Q_M was determined by the potentiostatic method. Two minutes were sufficient for establishment of adsorption equilibrium at all bulk concentrations of methanol. The described procedure was carried out in all solutions with the potentiostat and suitable circuits of Western Electric C275 Relays. The pretreatment described above not only provides a reproducible surface state for methanol adsorption, but largely excludes the possibility that oxidation products formed during the measurements or during the removal of the oxygen layer are adsorbed.

The potential shifts toward less positive values than +0.4v at open circuit in solutions with methanol. The potential which is reached after 2 min depends on the bulk concentration of methanol. Potential shifts of the described nature which start from a surface free of adsorbed oxygen and hydrogen were reported by Shlygin and co-workers (4, 5) as evidence for an electron-radical oxidation mechanism for CH_2O, HCOOH, CH_3OH, and other oxidizable substances. However, Vielstich (12) has stated that the measured open-circuit potentials are likely to be mixed potentials. Two interpretations for the potential shift, between which a distinction cannot yet be made, are more probable than Shlygin's interpretation. A small amount of hydrogen atoms is formed cathodically during the potential shift. The cathodic current is equal to an anodic current of methanol oxidation at the same electrode. As the rate of methanol oxidation becomes smaller with decreasing potential, a final open-circuit potential is approached. The amount of hydrogen formed in 2 min is still immeasurable. On the other hand the adsorbed methanol molecules may dissociate into radicals and hydrogen atoms to a small extent (1, 2). The adsorbed hydrogen atoms produce the potential shift. Traces of adsorbed hydrogen are detectable by anodic charging curves if the electrode rests for 20 min at open circuit in 1*N* $HClO_4$ + 1M CH_3OH.

Figure 5 represents isotherms of methanol adsorption at different times after opening the circuit (15

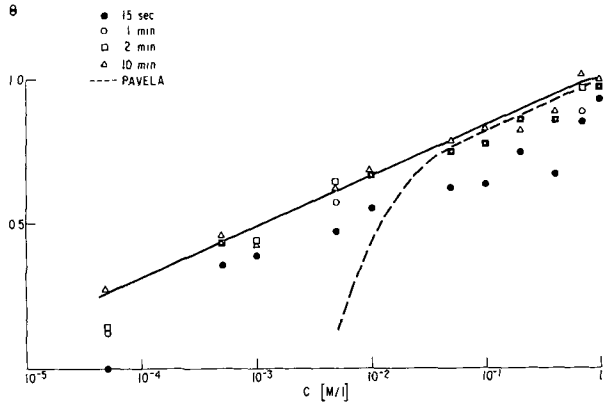

Fig. 5. Methanol coverage after different times at open circuit. The solid line represents the isotherm, the dashed line Pavela's results.

sec, 1 min, 2 min, and 10 min). Equilibrium coverage is practically achieved after 2 min. $\theta = Q_M/{}_sQ_M$ is plotted against log C_M. A semilogarithmic representation is chosen since a relatively large coverage is already found at small C_M-values. The saturation value ${}_sQ_M$ was reached for $C_M > 0.4M$ and is approximately equal to ${}_sQ_H$. It was 0.3 mcoul/cm^2 for the measurements in Fig. 5. If 0.75 ${}_sQ_H$ is taken as representing the number of platinum atoms available for methanol adsorption and if six electrons are involved in the oxidation of the adsorbed methanol, one methanol molecule occupies 4.5 platinum atoms. If the oxidation goes only to formic acid (4 electrons) the number of occupied platinum atoms is three. Both numbers appear acceptable as the cross section of the methanol molecule is about 25Å^2 (13), and the distance between platinum atoms in the (111)-plane is about 3Å.

Pavela's tabulated Q_M-values for platinized platinum were used to compute an isotherm. This isotherm is plotted as a dashed line in Fig. 5 while our results correspond to the solid line. Agreement exists at high concentrations while Pavela's values are too low at low concentrations. Obviously conditions (*A*) and (*B*) of Pavela's procedure discussed in the introduction are not fulfilled.

The adsorption isotherm in Fig. 5 is linear in a large concentration range. Temkin's isotherm describes the results to a first approximation. Such behavior is characteristic of a heterogeneous surface. Although an indication of steps is given by the experimental points, the experimental precision does not allow a decision as to whether or not these steps are a real phenomenon. The attainment of saturation coverage does not appear as pronounced on the semilogarithmic plot as on a linear plot.

Methanol-Coverage under the Conditions of a Potentiostatic Current-Potential Curve

Potentiostatic current-potential curves of fuel oxidation have peaks (1, 2, 5, 7, 12, 14) characteristic of every fuel. The method devised by Will and Knorr (15) was used here. A periodic triangular voltage sweep from +0.1 to 1.5v was applied to the electrode by means of the electronic potentiostat. The voltage speed was 30 mv/sec. After a certain potential was reached the potentiostatic circuit was interrupted manually by means of a Western 275C Relay. A cathodic charging curve was taken immediately after the interruption. The coverage was determined in the way described in the previous section. The current-potential curves became independent of time in unstirred solutions after a few cycles had been impressed.

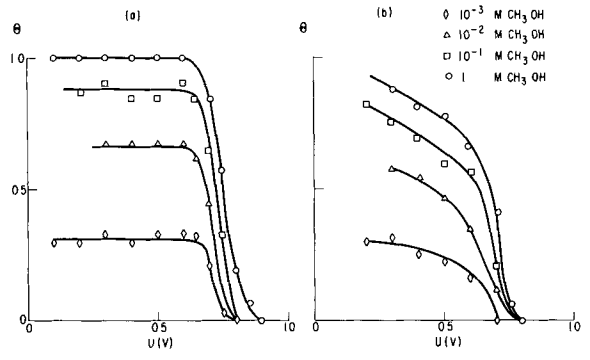

Fig. 6. Methanol adsorption at different potentials during the anodic sweep (Fig. 6a) and the cathodic sweep (Fig. 6b) of potentiostatic current potential curves in different solutions.

Figure 6a represents the coverage as a function of potential and of the bulk concentration of methanol during the anodic potential sweep, Fig. 6b during the cathodic sweep. The θ-values at +0.2 and +0.1v were determined by the potentiostatic method. The coverage is independent of potential between 0.1 and 0.6v at all concentrations during the anodic sweep. Then it decreases rapidly with potential. The θ-U-curves have a similarity with corresponding curves for the adsorption of organic substances on mercury (16) although the cause for desorption differs greatly. In this case it is due to the oxidation of methanol on platinum in the potential range of desorption. This effect will be discussed in the second paper. The methanol adsorption between 0.9 and 1.5v is very small and plotted as equal to zero in Fig. 6a and 6b where the abscissa is not extended beyond +1.0v. However, this statement may be slightly in error as the reproducibility of ${}_sQ_H$ is about ±10%.

A comparison between the θ values of Fig. 5 and the potential-independent values in Fig. 6a suggests that equilibrium is practically established under the conditions of a quasistationary potentiostatic current-potential curve. The rate of oxidation is not yet sufficient to lead to a decrease in coverage.

The coverage increases during the cathodic sweep at all concentrations and does not reach the constant value of the anodic sweep before 0.1v. The θ-U-curves show that the coverage is formed rapidly in the beginning while the attainment of a final value above 0.5 is slow. No adsorption takes place above 0.8v. The electrode remains covered with a chemisorbed oxygen layer between 1.0 and 1.5v during the cathodic sweep (see next section). Methanol adsorption starts after about 75% of the oxygen coverage is reduced.

So far it has been assumed that the coverage under the conditions of a potentiostatic current-potential curve is due to methanol adsorption. This need not necessarily be true as an oxidation peak is observed between 0.8 and 0.6v during the cathodic sweep (1, 2, 7, 12). It is conceivable that intermediates are formed then which are more strongly adsorbed than methanol and remain on the surface during the following part of the sweep. At the higher methanol concentrations the intermediates might produce as much as 50% of the measured θ-value (see Fig. 6b). However, a comparison of the potential-independent θ-value during the anodic sweep with the θ-value of the adsorption isotherm at the same concentration shows fair agreement between the two coverages. The agreement suggests that the coverage during the sweep is due mainly to methanol adsorption. The influence of intermediates is probably within the error of the θ-determination ($\leqq$10%). An accidental agreement is felt to be unlikely for all concentrations.

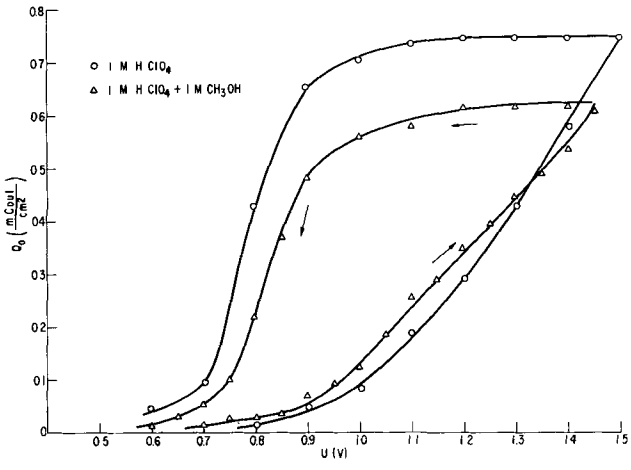

Fig. 7. Oxygen adsorption at different potentials during the anodic and cathodic sweep of potentiostatic current potential curves in 1N $HClO_4$ and in 1N $HClO_4$ + 1M CH_3OH.

Oxygen Coverage

It is well known that the anodic formation of a chemisorbed oxygen layer starts on platinum in acidic solutions at about +0.8v *vs.* a hydrogen electrode in the same solution. The coverage increases with potential. Approximately a monolayer is attained at +1.5v (9). The influence of the oxygen layer on the form of the potentiostatic current potential curves was already recognized and correctly interpreted in the early work on fuel oxidation (1, 2). However, a quantitative determination of the oxygen coverage under the conditions of a potentiostatic current-potential curve is not yet reported in literature. The oxygen coverage was determined by the potentiostatic method and the galvanostatic method at different potentials in the oxygen region during a potentiostatic current potential curve with 30 mv/sec in 1N $HClO_4$ and in 1N $HClO_4$ + 1M CH_3OH. The results obtained by the two methods agree fairly well.

The adsorbed amount Q_o obtained galvanostatically is plotted in Fig. 7 as a function of potential for the two solutions. A correction for the double layer charging during the oxygen branch of the cathodic charging curve was not made as the change of the double layer capacity with potential during the charging curve is not known. This leads to an error in the Q_o-values estimated to be less than 10%. The Q_o-U-curves are nearly the same in both solutions. This follows from the Q_o-U-curves during the anodic sweep. The potential of reversal differed by 50 mv in the two solutions. Therefore, the Q_o-U-curves are shifted against each other during the cathodic sweep. However, the same shape of the Q_o-U-curves is observed. There is an indication that the oxygen coverage is a bit larger at the same potential in 1N $HClO_4$ + 1M CH_3OH than in 1N $HClO_4$ up to +1.3v during the anodic sweep. Q_o increases more rapidly with potential above 1.3v in 1N $HClO_4$ than in 1N $HClO_4$ + 1M CH_3OH. The influence of methanol on the Q_o-U-curve is small. Therefore the Q_o-U-curve in 1N $HClO_4$ can be taken as a good approximation for the Q_o-U-curve in the presence of methanol up to $C_M = 1M$.

Manuscript received Dec. 6, 1961; revised manuscript received March 12, 1962. This paper was prepared for delivery before the Los Angeles Meeting, May 6-10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Studies on Alternating Current Electrolysis

IV. Mathematical Treatment of Reversible Electron Transfer with Alternating Voltage Control and Distorted Current

A. Edward Remick and R. A. Marcus[1]

Departments of Chemistry, Wayne State University, Detroit, Michigan and Polytechnic Institute of Brooklyn, Brooklyn, New York, respectively

ABSTRACT

A mathematical treatment is developed which yields equations relating faradaic current, voltage, and time when an alternating voltage is applied to an electrolytic cell composed of a plane and auxiliary electrodes immersed in a solution containing initially supporting electrolyte and only reversibly oxidizable or reducible species. Both oxidant and reductant are taken to be soluble, and specific adsorption is assumed to be absent. The voltage across that branch of the equivalent circuit through which only faradaic current flows is assumed to be periodic with fixed amplitude and with or without an additional direct applied voltage component; the resultant current is distorted. Diffusion controlled kinetics is postulated, and it is assumed that equilibrium is essentially established at the electrode surface. The equations developed show that a "steady state" (*i.e.*, a periodic state) is quickly attained, yield diagnostic tests of use in establishing the reversible mechanism, make it possible to determine the standard potential, and finally yield for the periodic state a relation between faradaic current and time. These results are then generalized so as to include systems in which the reversible electrochemical step is followed by a sufficiently slow secondary reaction step. One diagnostic result of interest in the latter connection is that the mean faradaic current vanishes in the periodic state, regardless of the amplitude or of the shape of the applied periodic potential, when the follow-up reaction occurs to a negligible extent.

The problem of developing a mathematical description of the chemical effects of alternating current on reversible redox systems has been attacked with varying degrees of success by several investigators (1-12) subject to the following restrictions: (*a*) undistorted voltage and current waves, and/or (*b*) both components of the redox system must either be present in the solution initially or present at the electrode's surface as the result of superimposed direct current. Berzins and Delahay (8) assumed what in the classification of Delahay, Senda, and Weis (17) may be called alternating voltage (A.V.) control [*i.e.*, controlled sinusoidal potential difference across that branch of the equivalent circuit for one electrode through which only faradaic (*f*) current is flowing]. They derived an equation for the instantaneous value of the (distorted) faradaic current as a function of time. This equation contained transient terms and a "steady-state" (or, better, a "periodic-state") term. Plane electrodes were involved.

Recently Matsuda and Delahay (13) extended the A.V. control problem to derive an equation for the transient current produced by faradaic rectification after the periodic component had reached a steady state. Their equation was restricted to small values of the A.V. and to solutions initially containing both oxidant and reductant.

Koutecky (14), assuming A.V. control, derived an equation for the instantaneous value of the faradaic current as a function of time for the general case of a periodic voltage of optional wave shape and applied it to the special cases of sine waves, square waves, and triangular waves. His equations were largely, although not entirely, concerned with the conditions characteristic of polarography (*i.e.*, dropping electrode), but his work and an initial portion of the present work are related. We shall be concerned with stationary electrodes, with a treatment for (in some ways) slightly more general systems, with a detailed treatment of the statement of the periodic state, and with devising a method of determining the standard potential and other properties (*m* and *n* below) of a reversible electrochemical step in an otherwise irreversible process.

In the present paper we shall discuss a system undergoing A.V. electrolysis with or without superimposed direct applied voltage for the case employing voltage control when the initial concentration of either oxidant or reductant is zero. Clearly, large A.V. amplitudes may be necessary to bring concentrations at the electrode surface into the poised region where reasonable accuracy in potential-concentration relationships may be achieved.[2]

This case is of only limited practical interest for

[1] Alfred P. Sloan Fellow; N.S.F. Senior Post Doctoral Fellow at Institute of Mathematical Sciences, New York University (1960-61).

[2] A certain experimental difficulty which, it has been suggested [p. 313 of ref. (17)], could complicate interpretation of the more usual (low amplitude) A. V. control systems, is absent here because of the different method used to interpret the results.

potentiometrically reversible redox reactions but should be important in the study of oxidations or reductions involving "follow-up" mechanisms, *e.g.*

$$\text{Red} \rightleftharpoons \text{ne} + \text{Ox} \text{ (fast)}$$

$$\text{Ox} \rightleftharpoons \text{products (slow)}$$

especially when the half-life period of the unstable (or highly reactive) intermediate substance is short compared to the polarographic drop time but long compared to the period of the A.V. in a usable frequency range.

General Assumptions

In the theoretical treatment along the lines indicated, the following restrictions and assumptions will be made.

(i) A plane electrode is used and conditions for the semi-infinite linear diffusion are achieved.

(ii) A. V. control is employed (A. V. alone or with a superimposed direct voltage component).

(iii) The only depolarizer initially present is the reductant. (This is an unessential restriction, as noted later, and is made only to emphasize the case that is of practical interest here.)

(iv) A supporting electrolyte eliminates migration of the depolarizer and also keeps the *p*H constant through buffer action. Convection is assumed absent.

(v) "Spontaneous depolarization" (15) occurs only by diffusion, *i.e.*, the depolarizer concentration at the electrode changes only by diffusion or electron transfer to the electrode and not by secondary chemical reaction or by convection.

(vi) Specific adsorption is absent.

(vii) Electrochemical equilibrium exists between the electrode and the concentrations of the electrochemically active species just outside the region effectively occupied by the electrical double layer.

(viii) In view of the transient nature of faradaic rectification, it will be ignored as a possible source of disturbance of over-all concentration after a steady state (*i.e.*, a periodic state) is achieved.

In principle, the above assumptions are all that are needed. In practice, however, it is desirable that the electrolytic resistance is rendered negligible by the high concentration of supporting electrolyte, and that the working electrodes of the electrolytic cell are a measuring electrode and an unpolarizable auxiliary electrode. A negligible resistance ensures an undistorted voltage wave across the faradaic branch, a very desirable restriction, as discussed later. It should also be noted that when a second faradaic process of the above type occurs, it can be treated as a parallel branch in the equivalent circuit.

Assumption (vii) that chemical equilibrium is achieved with alternating voltage does not imply that the charge transfer resistance (Grahame's θ) is zero, but it does mean that the θ is negligible in comparison with the mass transfer resistance (diffusion) for the experimental conditions, *i.e.*, that the frequency used is low enough to enable close approach to equilibrium in a small fraction of a cycle. The validity of this assumption in the case of a poised ferrocyanide-ferricyanide solution was demonstrated by Remick and McCormick (16) who showed that the introduction of the Nernst equation into Grahame's equations for the faradaic admittance (6) adequately predicted the experimentally observed relation of depolarizer concentration to polarization resistance and capacitance up to the highest frequency used, *viz.*, 5000 cps. Less reactive systems would be expected to behave reversibly only up to lower frequencies.

The assumption that electrochemical equilibrium exists between the electrode and species just outside the double layer implies that the salt concentration is high, so that the width of the double layer is appropriately small. Were this condition not fulfilled, one would have to include in the diffusion equation of the i^{th} electrochemically active species the usual migration term $(D_i e_i/RT)(\partial\phi/\partial x)C_i$, ϕ being the potential at point x, and D_i, e_i, and C_i being the diffusion coefficient, charge and concentration (at x) of species i.[3]

The system as a whole will also be undergoing a periodic buildup and disappearance of the electrical double layer at the electrode. The total current at any time is the sum of this nonfaradaic current and the faradaic current i_f calculated below. That is, as discussed by Grahame (6), the additional process of charging and discharging the double layer can be regarded as corresponding to a condenser (of capacity depending on instantaneous voltage) in parallel with the faradaic branch of the equivalent circuit. We consider first the behavior of the faradaic branch.

Boundary Value Problem

The reversible electrode reaction

$$\text{Red} \rightleftarrows m\,\text{Ox} + ne \qquad [1]$$

involves the soluble species Red and Ox whose charge types are not specified. In Eq. [1] m and n are rational numbers. The molar concentrations of these species, respectively, will be symbolized by C_R and C_{ox} and the bulk concentration of Red by C°_R. C_R and C_{ox} are functions of the time, t, and the distance, x, from a plane parallel to the electrode surface but just outside the electrical double layer region. To express diffusion control, Fick's second law will be employed as usual, expressed in terms of concentration rather than activities:

$$\partial C_{ox}(x,t)/\partial t = D_{ox}[\partial^2 C_{ox}(x,t)/\partial x^2] \qquad [2]$$

$$\partial C_R(x,t)/\partial t = D_R[\partial^2 C_R(x,t)/\partial x^2] \qquad [3]$$

where D_R and D_{ox} are diffusion coefficients. Equations [2] and [3] will be solved subject to the initial and

[3] This assumption concerning the width of the double layer will often be satisfied even when the assumption would be inaccurate for systems for which a kinetic boundary condition is appropriate (*i.e.*, a boundary condition such as $-D\partial C/\partial x = kC_{ox} - k'C_R$ at the electrode surface). In this kinetic case, Bockris (26) believed that the "zeta potential" is largely suppressed at concentrations above ca. 1*N*. This conclusion, however, was not substantiated by Breiter, Kleinerman, and Delahay (27) whose calculations (based on a theoretical equation which was found to be in accord with experimental data obtained in the polarographic reduction of iodate ions) indicated that the zeta potential might well be ca. 0.05v even in 1M solution. Since electron transfer proceeds from positions immediately adjacent to the electrode, we see that for double layer effects to be negligible in the kinetic case, the double layer should be narrower than a few Angstroms. In the electrochemical equilibrium case (assumption vii), however, to satisfy our assumption, it merely suffices that diffusion be rapid across the double layer so that concentration ratios inside it are given by a local Nernst (i.e., Boltzmann) relation. Accordingly, our assumption will often be valid when it is not valid to neglect double layer effects on rate constants for electron transfer to the electrode.

boundary conditions (and to the assumption of a bounded solution):

$$C_R(x, 0) = C^\circ_R \quad [4]$$

$$C_{ox}(x, 0) = 0 \quad [5]$$

$$D_{ox}\,\partial C_{ox}(x, t)/\partial x + m\,D_R\,\partial C_R(x, t)/\partial x = 0 \quad \text{at } x = 0 \quad [6]$$

plus a condition on $C_{ox}(0, t)$.

If one considers instead of [5] the alternative condition that $C_{ox}(x, 0)$ equals a nonzero quantity C°_{ox}, Eq. [7], [13], and [15] remain valid, if $C_{ox}(x, t)$ in [7] is replaced by $C_{ox}(x, t) - C^\circ_{ox}$, and f in [13] and [15] by $f - C^\circ_{ox}$. Equation [8] remains intact, but in Eq. [9] and [14] the second C_{ox} and f should be replaced by $C_{ox} - C^\circ_{ox}$ and $f - C^\circ_{ox}$, respectively.

In Appendix I, Eq. [2] to [6] are solved by[4] the Laplace transform method. The solution is given by

$$i_f = -nFA\,(D_{ox}/\pi)^{1/2}\frac{\partial}{\partial t}\int_0^t C_{ox}(0, t-\tau)\,\tau^{-1/2}\,d\tau \quad [7]$$

As the boundary condition at $x = 0$, we employ the Nernst relation between $C_{ox}(0, t)$ and $C_R(0, t)$ for $t > 0$:[5]

$$\tilde{E}_f p(\omega t) = E'_o + (RT/nF)\ln\{C_{ox}(0,t)^m/C_R(0,t)\} \quad [8]$$

where $\tilde{E}_f$ is the amplitude of the applied alternating voltage, $p(\omega t)$ is any continuous periodic function of ωt, of period 2π and of unit amplitude, and E'_o is a quantity defined later.

From Eq. [8] and Eq. [24] of Appendix I, it follows that for $t > 0$, $C_{ox}(0, t)$ in Eq. [7] satisfies the relation:

$$[C_{ox}(0, t)]^m = [C^\circ_R - (D_{ox}/D_R)^{1/2}\,C_{ox}(0, t)/m]\exp[(nF/RT)(\tilde{E}_f p(\omega t) - E'_o)] \quad [9]$$

The quantity E'_o is defined through the following argument: Since the electrolytic resistance is assumed negligible, the potential difference across the cell is the sum of the two half-cell potentials, $E_a + E_c$, where E_c is the half-cell potential across the auxiliary unpolarizable electrode. If E_d is the direct component of the applied potential, we thus have

$$E_a = E_d + \tilde{E}_f p(\omega t) - E_c \quad [10]$$

Writing E_a in terms of its standard potential E_o of the reversible step of the half-cell, we have

$$E_a = E_o + (RT/nF)\ln\{C_{ox}(0, t)^m/C_R(0, t)\} \quad [11]$$

From Eq. [10] and [11], Eq. [8] is obtained with E'_o given by

$$E'_o = E_o + E_c - E_d \quad [12]$$

Delahay, Senda, and Weis (17) have emphasized the desirability that, in specifying the type of control used, both the alternating and mean components of the current or voltage control should be designated. The argument of the preceding paragraph shows that we are here dealing with the case of A.V. control, with $\overline{E}_{cell} = E_d$ (when the mean value of $p(\omega t)$ is zero), *i.e.*, with $\overline{E}_a = \overline{E}_c - E_d$.

It sometimes happens that $\tilde{E}_f p(\omega t)$ is treated as a piecewise continuous function,[6] for example, when it is treated as a square wave applied potential. Strictly speaking, it is continuous, but is approximated by this discontinuous function. To adapt Eq. [13] to this case, one uses the fact that the derivative of a step function is a Dirac δ-function (19).[7]

Applications of Equations [7] and [9]

Silverman and Remick (18) observed oscillographically that a periodic state was achieved very rapidly using $\tilde{I}_{cell}$-control, [*i.e.*, A.C. control (17)], plane electrodes, and solutions initially containing only one component of a reversible redox system. We know of no comparable experimental demonstration involving A.V. control; however, Eq. [7] and [9] can be shown to predict the attainment of a periodic state. Moreover, this periodic state is a convenient one for application of the equations to experimental data. Accordingly, we first show how these equations lead to the periodic state.

For this purpose, it is very convenient to introduce a function $f(\omega\theta)$ which agrees with $C(0, \theta)$ for $\theta > 0$, but which is the periodic continuation of $C(0, \theta)$ for $\theta \leq 0$.

In Appendix II it is then shown that Eq. [7] can be rearranged to give

$$i_f = nFA\,(\omega D_{ox}/\pi)^{1/2}\left\{\int_0^\infty \frac{\partial}{\partial y}[f(\omega t - y)]\,y^{-1/2}\,dy - \tfrac{1}{2}\int_{\omega t}^\infty f(\omega t - y)\,y^{-3/2}\,dy\right\} \quad [13]$$

where $f(\omega t - y)$ satisfies Eq. [14] for all t. Equation [14] is obtained from Eq. [9] by replacing $C_{ox}(0, t)$ by $f(\omega t - y)$.

$$[f(\omega t - y)]^m = [C^\circ_R - (f(\omega t - y)/m)\,(D_{ox}/D_R)^{1/2}]\exp\{(nF/RT)[\tilde{E}_f p(\omega t - y) - E'_o]\} \quad [14]$$

In Appendix II, it is shown that $f(\omega t - y)$ is bounded by some quantity, M say, so the second integral in [13] tends to zero as ωt tends to infinity

[4] Equation [7] can also be obtained, after a somewhat involved series of substitutions, from the first half of Eq. [21] of ref. (14). However, the derivation given in Appendix I of this paper has certain advantages for our purposes and is referred to later.

[5] The apparent discontinuity between the limit which this $C_{ox}(0, t)$ approaches as $t \to 0$ and that which Eq. [5] approaches as $x \to 0$ causes no difficulty. It is indeed a standard type of discontinuity (22) in diffusion and heat conduction problems.

[6] It may be recalled that a piecewise continuous function is one which has in any finite interval at most a finite number of discontinuities.

[7] In the case of piecewise continuous $p(\omega t)$, one may utilize Eq. [22] and [9] as follows. Piecewise continuous $p(\omega t)$ implies piecewise continuity of the function $C_{ox}(0, t)$ defined by Eq. [9], and even (Appendix II) its finiteness for the $p(\omega t)$ of interest. Its Laplace transform $\overline{C}_{ox}(0, s)$ therefore exists and has "nice properties." Consider now the contour integral expression obtained for $C_{ox}(x, t)$ by applying the usual Inversion Theorem (23) to Eq. [22], where $\overline{C}_{ox}(0, s)$ has just been described. This expression has the desirable convergence behavior outlined in ref. (23) (uniform convergence in x and in t) and one may proceed to test as discussed in ref. (23) whether it and the corresponding contour integral for $u(0, t)$ (u is defined in Appendix II) satisfy the differential equations and boundary conditions. $\partial C_{ox}(x, t)/\partial x$ and thereby i_f may be obtained then by differentiating under the integral sign. Indeed, some of the proofs in Appendices II and III might well have been shortened through use of the contour integral.

Equations [13] and [15] do not apply at those times t for which $f(\omega t)$ is discontinuous since Eq. [24] of Appendix I (and hence Eq. [9]) does not.

since its majorant, $M\int_t^x y^{-3/2}\,dy$, behaves in this way. Hence, this integral is a transient term. The first integral in [13] is periodic in ωt, because $f(\omega t - y)$ is periodic in ωt (as shown in Appendix III), its derivative, therefore, being periodic also, and because its limits are not functions of t. This integral, therefore, describes the periodic state.

An equivalent form of Eq. [13], derived in Appendix II, is given by Eq. [15], the first integral being the periodic term and the second being the same transient term as in Eq. [13].

$$i_f = -\tfrac{1}{2}\, nFA(\omega D_{ox}/\pi)^{1/2}\{\int_0^x [f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy + \int_{\omega t}^{\infty} f(\omega t - y)y^{-3/2}\,dy\} \quad [15]$$

Using these equations, it is shown, incidentally, in Appendix III that the mean value of the periodic state integral in Eq. [13] or [15] is zero, for arbitrary periodic functions $p(\omega t)$ and for arbitrarily large amplitudes. This theorem generalizes earlier discussions by other investigators for small amplitudes. It should have diagnostic value since it would obviously be false if the irreversible follow-up reaction occurred appreciably.

To examine a possible way for determining E'_os and other properties, it is convenient to convert the integral for the periodic state into a "reduced" form. That is, we proceed to deduce an "equation of corresponding states" for the faradaic current and for its dependence on applied potential.

We see from Eq. [14] that at any given temperature $f(\omega t - y)$ depends on nE'_o, m, C°_R and on the value of the function nE_f at the time $\omega t - y$ (taking $\sqrt{D_{ox}/D_R} \cong 1$). Therefore, we may write (for given T), $f(\omega t - y)$ as a function of C°_R, of nE'_o, of m, of the value of nE_f at time ωt, and of y.[8] Similar remarks apply to the y-derivative of $f(\omega t - y)$. Accordingly, the periodic state term in either [13] or [15] satisfies the formal relation:

$$i_f = nFA(\omega D_{ox}/\pi)^{1/2}\int_0^\infty h(y, nE'_o, m\, nE_f, C^\circ_R)\,dy \quad [16]$$

where the function h can be written in the two equivalent forms (forms which differ only by a quantity whose integral from 0 to ∞ vanishes):

$$\left.\begin{aligned} h &\equiv y^{-1/2}\,\partial f(\omega t - y)/\partial y \\ h &\equiv \frac{1}{2}\, y^{-3/2}\,[f(\omega t - y) - f(\omega t)] \end{aligned}\right\} \quad [17]$$

Equation [16] is a convenient one for our purposes, for we see from Eq. [13] that at a given temperature, C°_R and electrode area A, a plot of nE_f *vs.* $i_f/n\,(\omega D_{ox})^{1/2}$ depends only on nE'_o and m. Therefore, by adjusting the direct voltage E_d and (in multiples of some preassigned amplitude) $\tilde{E}_f$, the E_f *vs.* i_f plot could be made to conform to a standard shape, a shape which, for any preassigned nE'_o, $n\tilde{E}_f$, C°_R and T, depends only on m. From the value of E_d needed to attain this specified nE'_o, E_o could be calculated from Eq. [12], n could be determined from the $\tilde{E}_f$ needed to attain the standard shape, and m could be determined from the C°_R-dependence of the data. (For example, for $m = 1$ Eq. [14] shows that $f(\omega t - y)$ is directly proportional to C°_R, so h and hence i_f in [16] are directly proportional to C°_R, for any given E_f.) Again, Eq. [16] provides other diagnostic tests. A plot of $i_f/\omega^{1/2}$ *vs.* E_f should be independent of ω and of $\tilde{E}_f$.[9]

Instead of plotting E_f *vs.* i_f, i_f can be plotted *vs.* ωt, after first writing Eq. [16] for the periodic state in the appropriate reduced form. Since $E_f = \tilde{E}_f p(\omega t)$, the integrand in [16] can be written as a function of ωt and of $n\tilde{E}_f$ as well as of y, nE'_o, m, and C°_R. Once again, for any given C°_R, T and electrode area, the adjusting of E_d and, in multiples of some amplitude, of $\tilde{E}_f$, would lead to a standard shape which depends on m. The values of E_o and n could then be determined as before, and m could be determined from the C°_R dependence of the plot. Again, as before, diagnostic tests could be devised: The plot of $i_f/\omega^{1/2}$ *vs.* ωt should be independent of ω and, if $m = 1$, should be proportional to C°_R.

In actual fact, one measures total current rather than only the faradaic branch. The nonfaradaic component is independent of C°_R, so that a plot of i *vs.* E_f or *vs.* t would now be a linear function of C°_R when $m = 1$. On the other hand, no standard shape of a plot of i *vs.* E_f or t can be attained simply by adjusting E_d and $\tilde{E}_f$.[10]

Accordingly, in this situation, recognizing that under the assumptions listed earlier, the total current is the sum of the faradaic and nonfaradaic branches and that the nonfaradaic component is independent of C°_R, the value of i_f corresponding to any particular phase angle of E_f can be obtained by subtracting from the measured, instantaneous current the value of that current when $C^\circ_R = 0$. Examples where this type of subtraction has been made in potentiometric work may be found in ref. (25) and (16). If the condition mentioned earlier that the iR be negligible had not been imposed, no such subtraction process would be permissible for obtaining i_f, for the iR drop at any given t would cause the instantaneous potential drop across the electrode to depend on C°_R, contrary to assumption. Furthermore, since the cell is a nonlinear circuit element, the iR drop through the bulk of the solution would contain harmonics which would invalidate the assumption of a sinusoidal E_f.

Information about the characteristic behavior of the integral in Eq. [16], and hence about the faradaic current, can be deduced either from numerical integration or from investigation of the properties of known reversible systems. However, some prelimi-

[8] The value of E_f at $(\omega t - y)$ is determined if one knows for all t its value at ωt and if one knows y, i.e., $E_f(\omega t - y)$ is a function of the function $E_f(\omega t)$ and of y.

[9] To be sure, at small values of $\tilde{E}_f$, points on this plot corresponding to large values of i_f will not be attained. Note that although i_f and E_f depend on $\tilde{E}_f$, the plot does not.

[10] For, if nE'_o and $n\tilde{E}_f$ were each made to conform to their preassigned values by such adjustments, the nonfaradaic current *vs.* E_f plot would then differ from system to system: Any two systems normally differ in E_o and hence, for a preassigned nE'_o, in E_d (cf. Eq. [12]). But for a given E_d, a plot of nonfaradaic current *vs.* E_f would be a standard one only for a preassigned E_d and $\tilde{E}_f$.

nary insight into its behavior as far as the dependence of i_f on E_f in Eq. [16] can be obtained as follows. We shall consider, by way of a concrete example, the important case in which $m = 1$, $D_{ox} = D_R$, and $p(\omega t)$ is sin ωt. The integral for the periodic state in Eq. [16] becomes (using it in the form of Eq. [13], after introducing Eq. [14] and performing the differentiation:

$$i_f = -\frac{nFA\,C^\circ_R\,nF\,\tilde{E}_f}{(\pi/\omega D_{ox})^{1/2}\,RT}\int_0^\infty \frac{\exp\left[nF(\tilde{E}_f \sin(\omega t - y) - E'_o)/RT\right]\cos(\omega t - y)\,y^{-1/2}\,dy}{\{1 + (D_{ox}/D_R)^{1/2}\exp\left[nF(\tilde{E}_f \sin(\omega t - y) - E'_o)/RT\right]\}^2} \quad [18]$$

When $|nF\,E'_o/RT| >> 1$ and $\tilde{E}_f << |E'_o|$, the coefficient of $y^{-1/2}\cos(\omega t - y)$ in the integrand, is very small at all times, *i.e.*, for all $|E_f| \leq \tilde{E}_f$.[11] Accordingly, i_f is then small for all such E_f, a result expected on physical grounds. In the very special instance that $\tilde{E}_f$ is sufficiently small, the integral in Eq. [18] becomes[12]

$$\pi^{1/2}\cos\left(\omega t - \frac{\pi}{4}\right)\exp(-nFE'_o/RT)/[1 + (D_{ox}/D_R)^{1/2}\exp(-nFE'_o/RT)]^2 \quad [19]$$

When $\tilde{E}_f$ becomes comparable in magnitude with E'_o, however, the current will become large at the appropriate times and, because of the sensitivity of the exponential terms to $\tilde{E}_f$, this effect should presumably occur fairly suddenly as $\tilde{E}_f$ is increased. Indeed a plot of faradaic current *vs.* $\tilde{E}_f$ may ultimately provide a convenient way for the determination of E'_o.

Up to this point, we have restricted our attention to reversible systems. If in addition, the reversible electrochemical step [1] is followed by an irreversible decomposition of the product of [1] to yield an electrochemically inactive substance, Eq. [3] to [6] remain unchanged, as does Eq. [8]. Only Eq. [2] is modified, namely, through the addition of the reaction rate term. If the irreversible step is very slow, this additional term represents only a minor perturbation of Eq. [2]. Physical considerations indicate that the solution for i_f should depend continuously on the value of the reaction rate constant in this perturbation term. When this constant is sufficiently small, therefore, the results will approach those previously obtained. That is, our final equations are still applicable, provided the irreversible step is sufficiently slow. As mentioned earlier, it is this situation where the present equations are likely to be of the most interest.

[11] For $E'_o > 0$, the numerator is then very small and the denominator is about unity. For $E'_o < 0$, the denominator is very large compared with unity, so that the first factor in the integrand approximately equals $(D_R/D_{ox})\exp\{nF[E'_o - \tilde{E}_f \sin(\omega t - y)]/RT\}$ which is very small.

[12] Upon expanding $\cos(\omega t - y)$ and recalling that

$$\int_0^\infty y^{-1/2}\cos y\,dy = \int_0^\infty y^{-1/2}\sin y\,dy = (\pi/2)^{1/2}$$

and noting that $\cos\omega t + \sin\omega t = \sqrt{2}\cos(\omega t - \frac{\pi}{4})$, Eq. [19] is obtained.

Manuscript received May 29, 1961; revised manuscript received April 10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

APPENDIX I
Derivation of Eq. [7]

We let $u(x,t)$ denote the quantity

$$u(x,t) = C^\circ_R - C_R(x,t) \quad [20]$$

Seeking a bounded solution of Eq. [2] to [6], we introduce boundary conditions [4] and [5] into the Laplace transforms of Eq. [2] and [3], respectively, and obtain two differential equations in the domain $x > 0$ which can easily be solved to give equations for the transforms, $\bar{u}$ and $\bar{C}_{ox}$:

$$\bar{u}(x,s) = \bar{u}(0,s)\,\exp(-s^{1/2}x/D_R^{1/2}) \quad [21]$$

$$\bar{C}_{ox}(x,s) = \bar{C}_{ox}(0,s)\,\exp(-s^{1/2}x/D_{ox}^{1/2}) \quad [22]$$

where s is the Laplace variable.

Differentiation of these equations with respect to x followed by evaluation at $x = 0$ and combination with the transform of Eq. [6] yields

$$\bar{C}_{ox}(0,s) = \bar{u}(0,s)m(D_R/D_{ox})^{1/2} \quad [23]$$

Taking the inverse transform of Eq. [23] gives

$$m\,u(0,t) = C_{ox}(0,t)\,(D_{ox}/D_R)^{1/2} \quad [24]$$

except at points of discontinuity, using a uniqueness theorem (24).

The instantaneous anodic current, i_f, is related to the flux according to Eq. [25]

$$i_f = nFAD_{ox}[\partial C_{ox}(x,t)/\partial x]_{x=0} \quad [25]$$

wherein we use the convention that an anodic current is negative, and where A denotes the electrode area. The term $[\partial C_{ox}(x,t)/\partial x]$, may be calculated from the preceding equations as follows. Differentiating Eq. [22] with respect to x and setting $x = 0$, one finds

$$[\partial \bar{C}_{ox}(x,s)/\partial x]_{x=0}$$

$$= -\bar{C}_{ox}(0,s)\,(s/D_{ox})^{1/2} = -s\bar{C}_{ox}(0,s)\,(D_{ox}s)^{-1/2}$$

$$= [-s/(\pi D_{ox})^{1/2}] \int_0^\infty e^{-st}\, C_{ox}(0,t)\,dt \int_0^\infty e^{-\epsilon t}\, t^{-1/2}\,dt \quad [26a]$$

$$= [-s/(\pi D_{ox})^{1/2}] \int_0^\infty e^{-st}\, [\int_0^t C_{ox}(0,t-\tau)\tau^{-1/2}\,d\tau]dt \quad [26b]$$

$$= -(\pi D_{ox})^{-1/2} \int_0^\infty e^{-st} \left[\frac{\partial}{\partial t}\int_0^t C_{ox}(0,t-\tau)\tau^{-1/2}\,d\tau\right]dt \quad [26c]$$

where we have introduced into (a) the fact that $s^{-1/2}$ is simply the Laplace transform of $(\pi t)^{-1/2}$. In obtaining (b) we have employed the convolution theorem for Laplace transforms, and in obtaining (c) we have used the standard relation between the Laplace transform of a function (here of $\int_0^t C_{ox}(0,t-\tau)\tau^{-1/2}\,d\tau$) and of its derivative.

It is now immediately apparent from [26c] that

$$[\partial C_{ox}(x,t)/\partial x]_{x=0} = -(\pi D_{ox})^{-1/2}\frac{\partial}{\partial t}\int_0^t C_{ox}(0,t-\tau)\tau^{-1/2}\,d\tau \quad [27]$$

Equation [7] of the text is then obtained from [25] and [27].

APPENDIX II

Derivation of Eq. [13] and [15] from [7]

We shall consider the behavior of Eq. [7] for times greater than 0, and we may therefore replace $C_{ox}(0,t-\tau)$ in that equation by the function $f(\omega t - \omega\tau)$, which satisfies Eq. [14] for all values of the argument of f, positive or negative. The time derivative in Eq. [7] can then be written as in Eq. [28], after first performing the differentiation and making use of the identity

$$\partial f(\omega t - \omega\tau)/\partial t = -\partial f(\omega t - \omega\tau)/d\tau$$

$$\frac{\partial}{\partial t}\int_0^t f(\omega t - \omega\tau)\tau^{-1/2}\,d\tau$$

$$= f(0)t^{-1/2} - \omega\int_0^t\left[\frac{\partial}{\partial(\omega\tau)}f(\omega t - \omega\tau)\right]\tau^{-1/2}\,d\tau \quad [28]$$

where f(0) is to be obtained from Eq. [14] by setting $\omega t - y$ equal to zero there.

Introducing into Eq. [28] a change of variable, $y = \omega\tau$, the right-hand side of the equation becomes:

$$f(0)t^{-1/2} - \omega^{1/2}\int_0^\infty\left[\frac{\partial}{\partial y}f(\omega t - y)\right]y^{-1/2}\,dy$$

$$+ \omega^{1/2}\int_{\omega t}^\infty\left[\frac{\partial}{\partial y}f(\omega t - y)\right]y^{-1/2}\,dy \quad [29]$$

It is evident from Eq. [14] that $f(\omega t - y)$ is a bounded function[13] of $\omega t - y$, so that upon integrating the third term of [29] by parts we get in place of [29]

[13] For any value of $\omega t - y$, $f(\omega t - y)$ is the positive root of an algebraic equation, all of whose coefficients are finite. The roots of such equations always lie in a finite region of the complex plane.

$$-\omega^{1/2}\int_0^\infty\frac{\partial}{\partial y}f(\omega t - y)\,y^{-1/2}\,dy + \frac{\omega^{1/2}}{2}\int_{\omega t}^\infty f(\omega t - y)\,y^{-3/2}\,dy \quad [30]$$

From Eq. [7], [28], and [30], Eq. [13] then follows.

The first integral in Eq. [13] can also be written in the alternative form

$$\lim_{\epsilon\to 0^+}\int_\epsilon^\infty\frac{\partial f}{\partial y}(\omega t - y)\,y^{-1/2}\,dy \quad [31]$$

Upon integrating by parts, this term becomes

$$-\lim_{\epsilon\to 0^+}\left[f(\omega t - \epsilon)\,\epsilon^{-1/2} - \frac{1}{2}\int_\epsilon^\infty f(\omega t - y)\,y^{-3/2}\,dy\right]$$

$$= -\frac{1}{2}\lim_{\epsilon\to 0^+}\left[\int_\epsilon^\infty f(\omega t - \epsilon)\,y^{-3/2}\,dy - \int_\epsilon^\infty f(\omega t - y)\,y^{-3/2}\,dy\right] \quad [32]$$

where we have introduced the identity

$$\epsilon^{-1/2} = \frac{1}{2}\int_\epsilon^\infty y^{-3/2}\,dy$$

Rewriting the integrals in [32] as:

$$[f(\omega t - \epsilon) - f(\omega t)]\int_\epsilon^\infty y^{-3/2}\,dy + \int_\epsilon^\infty [f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy \quad [33]$$

and proceeding to the limit $\epsilon = 0$, the first expression in [33] varies as (constant) (ϵ) $(\epsilon^{-1/2})$ using the conditions on f specified in footnote[14] and so vanishes. Introducing the second integral of [33] into [31], Eq. [15] is obtained.

APPENDIX III

Proof that the Mean Value of i_f Equals Zero in the Periodic State

In this section we consider the behavior at positive times, and it follows therefore that $t >> t_o$. Thus, we may replace C_{ox} by f.

It is first noted that physical arguments show that there can be only one positive solution of Eq. [14] for $f(\omega t - y)$, even when this equation has more than one solution (*i.e.*, when $m \neq 1$). All other solutions must either be negative or partly imaginary. We further note that since $p(\omega t) = p(\omega t + 2\pi)$, $f(\omega t - y)$ and $f(\omega t - y + 2\pi)$ satisfy the same Eq. [14]. Because of the uniqueness of the physically real $f(\omega t - y)$ just mentioned, it then follows that for our positive f's, $f(\omega t - y + 2\pi) = f(\omega t - y)$, *i.e.*, $f(\omega t - y)$ is also a periodic function of ωt with the same period as $p(\omega t)$.

We next observe that the mean value of the integral describing the periodic state is obtained by averaging it with respect to ωt over a period of 2π. Using Eq. [15], the integral which occurs in this average can be written in the equivalent form

$$-\frac{1}{4\pi}\int_\theta^{\theta+2\pi}\left[\lim_{\epsilon\to 0^+}\int_{y=\epsilon}^\infty [f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy\right]d(\omega t) \quad [34]$$

where θ is any large value of ωt. It can easily be shown[14] that the convergence of the y-integral as $\epsilon \to 0^+$ is uniform in ωt and, hence, lim and $\int$ can be interchanged, using a standard theorem [20]. Thus we obtain

$$-\frac{1}{4\pi}\lim_{\epsilon\to 0^+}\int_{\omega t=\theta}^{\theta+2\pi}\left[\int_{y=\epsilon}^\infty [f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy\right]d(\omega t) \quad [35]$$

[14] For ϵ small and y lying in the interval $(0, \epsilon)$, $|f(\omega t) - f(\omega t - y)| \cong |\frac{\partial}{\partial \omega t}f(\omega t)| \cdot y$, whence $|\int_0^\epsilon [f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy| \leq N\int_0^\epsilon y^{-1/2}\,dy = 2N\epsilon^{1/2}$, where N, an upper bound to the derivative, is independent of ωt. Actually the differentiability of $f(\omega t)$ needn't have been used. The milder Hölder condition, $|f(\omega t) - f(\omega t - y)| \leq$ constant $\cdot\, y^\alpha$ but where $\alpha > \frac{1}{2}$, would have sufficed.

Because of the readily proven convergence of the y-integral with respect to the upper limit (∞), uniform in ωt, [35] may be written as

$$-\frac{1}{4\pi}\lim_{\epsilon\to 0^+}\lim_{L\to\infty}\int_{\omega t=\theta}^{\theta+2\pi}\left[\int_{y=\epsilon}^{L}[f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy\right]d(\omega t) \quad [36]$$

The integrals $\int_{\epsilon}^{L}[f(\omega t) - f(\omega t - y)]y^{-3/2}\,dy$ and $y^{-3/2}\int_{\theta}^{\theta+2\pi}[f(\omega t) - f(\omega t - y)]d(\omega t)$ exist for any $\epsilon > 0$ and L, and the double integral also exists not only for continuous $f(\omega t)$ but also for piecewise continuous $f(\omega t)$. It then follows from a standard theorem [21] that the order of integration can be interchanged. We obtain

$$-\frac{1}{4\pi}\lim_{\epsilon\to 0^+}\lim_{L\to\infty}\int_{y=\epsilon}^{L}y^{-3/2}\left[\int_{\theta}^{\theta+2\pi}[f(\omega t) - f(\omega t - y)]d(\omega t)\right]dy \quad [37]$$

But, since $f(\omega t)$ was seen earlier to be a periodic function of ωt, it is true that

$$\int_{\theta}^{\theta+2\pi}f(\omega t)\,d(\omega t) = \int_{\theta}^{\theta+2\pi}f(\omega t - y)\,d(\omega t) \quad [39]$$

since it is easily shown that the value of a periodic function averaged over its period is independent of the initial value of the phase angle.

We see, therefore, that the ωt integral in Eq. [37] must vanish which proves the desired result.

This result of Appendix III can be proven under milder restrictions, such as piecewise continuity of $f(\omega t)$. As pointed out in the text, Eq. [15] for i_f is valid for piecewise continuous $f(\omega t)$, except at the isolated points of discontinuity of the latter. The derivation of Eq. [35] from [34] proceeds as before, when points ωt of discontinuity of f are excluded. The derivation of [37] from [35] and the use of [38] remain valid. Thus, if one defines i_f arbitrarily but finite at the isolated points of discontinuity of $f(\omega t)$, the mean value of i_f is zero in the periodic state for piecewise continuous functions $f(\omega t)$.

SYMBOLS

A, area of electrode's surface, cm^2.
C_{ox}, concentration of oxidant, mole l^{-1}.
C_R, concentration of reductant, mole l^{-1}.
C^o_R, concentration of reductant in bulk of solution, mole l^{-1}.
D_{ox}, diffusion coefficient of oxidant, cm^2 sec^{-1}.
D_R, diffusion coefficient of reductant, cm^2 sec^{-1}.
E_a, half-cell potential difference of measuring electrode, v.
E_c, half-cell potential difference of auxiliary, nonpolarizable electrode, v.
E_f, half-cell potential difference between electrode and the solution just outside of electrical double layer, in Ox-Red system under investigation, v.
E_d, direct component of applied cell potential, v.
$\tilde{E}_f$, amplitude of the periodic E_f wave, v. $E_f = E_f p(\omega t)$.
E_o, standard potential of the Ox-Red system, v.
E'_o, $E_o + E_c - E_a$.
$\overline{E}_{cell}$, mean cell potential, v.
f, function of, (a particular function).
f, (as a subscript) faradaic.
F, faraday (96514 abs.-coulombs g-equiv.$^{-1}$).
h, function of, (a particular function).
i_f, instantaneous faradaic current, amp.
m, number of oxidant molecules produced from oxidation of 1 mole of reductant.
n, number of electrons involved in oxidation of 1 mole of reductant.
R, gas constant (8.3166 x 10^7 erg deg^{-1} mole^{-1}).
t, time, sec.
T, absolute temperature.
u, $C^o_R - C_R$.
x, perpendicular distance from a plane which is parallel to the planar electrode of Ox-Red system, but which is just outside the electrical double layer region.
ω, angular frequency of alternating voltage, sec^{-1}.

Technical Notes

The Discharge Properties of α-PbO_2 in Dilute H_2SO_4 Electrolyte

Harry B. Mark, Jr.

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina

The discharge properties and discharge mechanism of β-PbO_2 in H_2SO_4 electrolyte have been studied in considerable detail (1-3). There is disagreement as to the mechanism (1-3), but the experimental characteristics of the discharge, such as reduction overpotentials, shape of the potential-time discharge curves, etc., are well known (1, 3). Although some of the electrochemical properties (electrodeposition conditions and self-discharge) of α-PbO_2 have been the subject of considerable study (4-8), there is little information in the literature concerning the properties of pure α-PbO_2 under an applied discharge current (3, 4, 9). Almost no work has been reported on the properties of pure α-PbO_2 in dilute H_2SO_4 electrolyte, although a previous paper (3) showed that the discharge properties of β-PbO_2 change considerably and in an unexpected way as the acid strength of the electrolyte decreases. The discharge capacities of lead storage batteries, which have positive plates containing a mixture of α-PbO_2 and β-PbO_2, have been studied (10), and there is a brief description of the discharge curve obtained in 4.4M H_2SO_4 for an anodized Pb electrode (6). Microphotographs of the cross section of this electrode and x-ray and electron diffraction patterns seemed to indicate that there is a layer of a mixture of the two modifications of PbO_2 between the lead metal and the β-PbO_2 film which was in contact with the electrolyte (4). The discharge of an electrode, which consists of a layer of α-PbO_2 between a layer of β-PbO_2 and a Pt support, in a 4.4M H_2SO_4 electrolyte has been reported (9).

In this investigation the discharge in dilute (0.1M) H_2SO_4 of α-PbO_2 and β-PbO_2 have been studied, as

also electrodes consisting of a layer of α-PbO_2 on top of a layer of β-PbO_2 and *vise versa*. The effect of variation of discharge current and theoretical discharge capacity were also studied. A comparison of the experimental results obtained by this study indicate that the discharge mechanism of the two forms in dilute H_2SO_4 are quite different. These property differences were not very apparent in the experimental results reported in the work which used a more concentrated acid electrolyte, which may mask the effects arising from the two different mechanisms or may result in yet a third discharge mechanism. Both forms might discharge by this third or combination mechanism in the concentrated acid electrolyte.

Experimental Procedure

Preparation of electrodes.—The PbO_2 was electrodeposited on Pt cylinders sealed in glass as described in previous work (3). The electrodes had an apparent surface area of 8 cm^2. The β-PbO_2 was deposited from a solution of 0.020M $Pb(NO_3)_2$ and 0.3M HNO_3 with a current density of 10 ma/electrode (1.25 ma/cm^2) at room temperature for 4 to 40 min. The α-PbO_2 was deposited from a solution of 1.5M NH_4OH and 6.5M $NH_4C_2H_3O_2$ saturated with $Pb(C_2H_3O_2)_2$ (3,5) with a current density of 10 ma/electrode for 3 to 40 min at room temperature.

Discharge apparatus.—The discharge cell used was described previously (3). A saturated calomel electrode (SCE), which was used as the reference electrode, made contact with the solution in the cell through an agar-agar KCl bridge. A stream of nitrogen was used to stir the electrolyte, and a cylindrical sheet of lead metal was used as the anode.

Currents for discharge were furnished by an electronic constant-current source (11). The electromotive force of the cell was applied to a high input impedence (about 10^{11} ohms) follower amplifier of gain of −1. The output of the follower amplifier was fed first to a voltage inversion amplifier (gain of −1) and then to a voltage divider to attenuate the signal. The signal was then recorded by a Sargent model SR recorder. The follower and inversion amplifiers were constructed from plug-in analog computer amplifiers using circuits designed by DeFord (12).

When the electrodes had come to open-circuit equilibrium, as shown by constancy of potential for 15 min, a current, either continuous or interrupted (3), was introduced into the circuit. Previous work (3) has shown that under the conditions used no corrections are necessary for iR drop, electrolyte concentration polarization, and self-discharge.

Results

Examples of the discharge curves for α- and β-PbO_2 in 0.10M H_2SO_4 saturated with $PbSO_4$ and with excess solid phase are shown in Fig. 1. Curve 1 is for α-PbO_2 when an interrupted discharge current of 3 ma/electrode was passed. The α-PbO_2 electrode does not reach a steady-state closed-circuit potential in the time allowed, and the electrode recovers, when the current is interrupted, to a lower equilibrium open-circuit potential than it had before discharge. Thus, reliable and reproducible overpotentials could not be obtained for α-PbO_2 electrodes (3). Curve 2 is a typical continuous discharge of α-PbO_2 (a current density of 5 ma/electrode was passed in this example). The electrode does not reach a steady-state closed-circuit potential even under prolonged continuous discharge. Toward the end of discharge the potential decreases more and more rapidly. The actual discharge capacity of this electrode was only 40 ma-min, although the theoretical capacity was 250 ma-min. The actual capacity of all α-PbO_2 electrodes tested in H_2SO_4 electrolyte was considerably less than the theoretical and was independent of the theoretical capacity. When an α-PbO_2 electrode had reached the state of discharge indicated by point e of curve 2, it was removed from the cell and placed in a solution of KI and $HC_2H_3O_2$. The formation of considerable I_3^- indicated that appreciable PbO_2 remained undischarged. The surface of an α-PbO_2 electrode, that was initially very smooth and shiny black, was observed at point e to be covered with a white and strongly adhering uniform film of $PbSO_4$ (4). If this film was removed by a solution of $NH_4C_2H_3O_2$ (6) and the electrode returned to the cell, the initial open-circuit potential was reattained and the electrode rejuvenated. Further discharges could then be made. The surface of the α-PbO_2 after removal of the $PbSO_4$ was black but no longer smooth and shiny. By washing the electrode with $NH_4C_2H_3O_2$ each time the potential broke down sharply and then continuing the discharge, 80-90% of the theoretical discharge capacity can be obtained. Much larger current densities could be passed through α-PbO_2 than could be passed through β-PbO_2 (3) without destruction of the electrode. No potential minimum was found on the second discharge of α-PbO_2 as was reported by other investigators (9) using a 4.4M H_2SO_4 electrolyte.

The above experiments suggest that the $PbSO_4$ film may be the only cause of the poor discharge

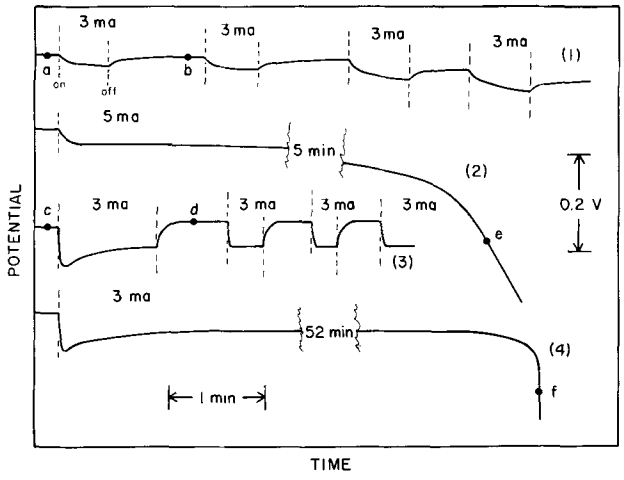

Fig. 1. Potential-time curves of α- and β-PbO_2 electrodes discharging under constant current. The electrolyte was 0.1M H_2SO_4 (sat. with $PbSO_4$): curve 1, α-PbO_2 under successive short constant current discharges of 3ma/electrode; curve 2, α-PbO_2 under continuous constant current discharge of 5 ma/electrode; curve 3, β-PbO_2 under successive short constant current discharges of 3 ma/electrode; curve 4, β-PbO_2 under continuous constant current discharge of 3 ma/electrode.

capacity of α-PbO_2. To check this, two discharges were made in 1.0M $HClO_4$ electrolyte which gave 93 and 94% of the theoretical capacity (based on 100% current efficiency on electrodeposition). The Pt electrodes were entirely bare at the end of discharge.

The curves for the interrupted discharge of β-PbO_2 (curve 3 of Fig. 1) were quite different from those of α-PbO_2 (curve 1) under similar conditions. The potential of the first discharge went through a pronounced minimum before reaching a steady-state closed-circuit potential and, on subsequent discharges, passed through very slight minima which were barely detectable. The β-PbO_2 electrode recovers to a more positive open-circuit equilibrium potential after the first discharge than it had initially, and recovers to this new emf after each subsequent discharge until the electrode breaks down (3). Discharge overpotentials for single β-PbO_2 electrodes are quite reproducible (3). On continuous discharge β-PbO_2 electrodes go through a potential minimum, reach a steady closed-circuit potential which remains constant for a long time, and finally the potential drops very rapidly, as shown by curve 4 of Fig. 1. Removal of the electrode at point f in the discharge shows that most of the PbO_2 (70-95%) has been reduced. Some I_3^- is formed on placing the electrode in acidic KI, but bare Pt is seen over much of the surface. For the particular electrode used as the example in curve 4, a test showed that about 75% of the PbO_2 had discharged electrolytically. All attempts to rejuvenate β-PbO_2 electrodes at this point by washing with $NH_4C_2H_3O_2$ were unsuccessful. Although there were some crystals of white $PbSO_4$ (before washing) widely scattered on the PbO_2 surface, there was no white film as observed for α-PbO_2.

Partially discharged α-PbO_2 electrodes which were allowed to recover to open-circuit equilibrium were washed with 40% $NH_4C_2H_3O_2$ solution to strip off the $PbSO_4$ on the surface and the wash solution analyzed for Pb^{++} by a dithizone method (13). This test indicated that practically all of the $PbSO_4$ produced on discharge of α-PbO_2 remained on the surface of the electrode, as shown in Table I. Blank tests showed that the correction for the reduction of PbO_2 by the 40% $NH_4C_2H_3O_2$ was negligible. A similar test on partially reduced β-PbO_2 electrodes showed that only part (16-50%) of the $PbSO_4$ produced on discharge remained on the surface after recovery, as shown in Table II.

Table I. Per cent $PbSO_4$ on the surface of α-PbO_2 electrodes at open-circuit equilibrium following discharge in an electrolyte of 0.1M H_2SO_4 saturated with $PbSO_4$

The overpotentials obtained for interrupted discharges of α-PbO_2 were considerably less than those for β-PbO_2, and the rates of growth and decay of polarization were greater for β-PbO_2 than α-PbO_2, as shown by comparing curves 1 and 3 of Fig. 1. The initial open-circuit potential of α-PbO_2 was somewhat higher than that of β-PbO_2, in agreement with other work (6, 7). The larger overpotentials of β-PbO_2 may be a result of smaller true surface areas of β-PbO_2 electrodes which would increase the double layer capacity of the electrodes. However, the much rougher appearance of the β-PbO_2 surface indicates that it has the larger surface area.

Rüetschi and Cahan (6) studied the discharge of a film produced by anodizing Pb and Pb alloys (film consists of a layer of a mixture of the two modifications of PbO_2 between an external layer of pure β-PbO_2 and the metal). They found that the discharge curve went through an initial potential minimum before reaching a closed-circuit plateau. As the discharge continued, the potential went through a second minimum and came to a second, still lower, steady-state potential. The potential then dropped sharply as the film of PbO_2 was completely discharged. They suggested that the two potential plateaus represented the discharge of α- and β-PbO_2, respectively, and the difference between the plateaus represented the differences in the overpotential for the two modifications. Because the present investigation showed that the shapes of the discharge curves of the two pure modifications are quite different, these characteristics could be used in studies of the discharge properties of electrodes consisting of layers of the two modifications.

Electrodes were made consisting of a thin layer of α-PbO_2 (theoretical discharge capacities varying from 30 to 70 ma-min) on the Pt and a thin exterior layer of β-PbO_2 (capacities varying from 30 to 150 ma-min). The β:α ratios varied from 0.6 to 3. These electrodes were discharged by passing constant currents of 3-12 ma/electrode, and the discharge potentials were recorded. All the discharge curves had the characteristic shape of curve 2 of Fig. 2. In no case were two plateaus and two minima observed. Initially the discharge curves resembled that of pure, undischarged β-PbO_2 electrodes. As the capacity of the β-PbO_2 layer was nearing exhaustion, about point h of curve 2, the potential started to drift downward, and the electrode from there to the end of the discharge resembles that of an α-PbO_2 electrode which was partially discharged. If the current was interrupted at a point along the line

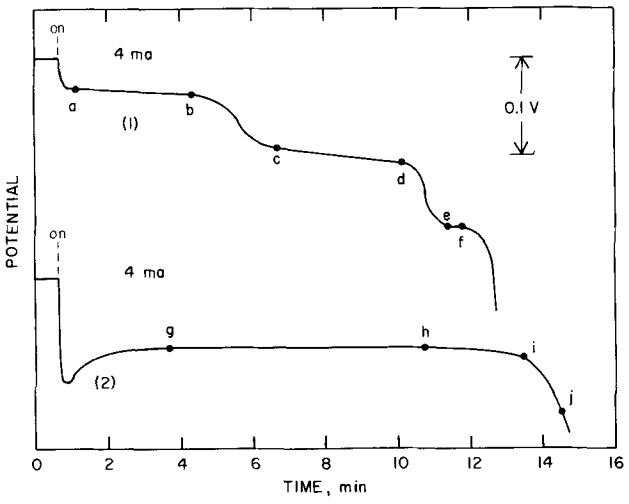

Fig. 2. Potential-time curves. The electrolyte was 0.1M H_2SO_4 (sat. with $PbSO_4$): curve 1, electrode consisting of a layer of β-PbO_2 (discharge capacity of 40 ma-min) on Pt support and layer of α-PbO_2 (capacity of 70 ma-min) on the β-PbO_2 surface, under a continuous discharge of 4 ma/electrode; curve 2, electrode consisting of a layer of α-PbO_2 (capacity of 40 ma-min) on Pt and a layer of β-PbO_2 (capacity of 60 ma-min) on the α-PbO_2 surface, under a continuous discharge current of 4 ma/electrode.

hi and the electrode allowed to recover before resuming discharge, the resulting curves for the growth and decay of polarization show rates and shapes characteristic of α-PbO_2 and not of β-PbO_2. If the electrode at point j was washed with 40% $NH_4C_2H_3O_2$, the electrode was rejuvenated and on subsequent discharge behaved like pure α-PbO_2. The potential minimum was least pronounced for the electrode having the smallest β-PbO_2 layer (30 ma-min capacity).

Electrodes consisting of a thin layer of β-PbO_2 (theoretical capacities varying from 40 to 70 ma-min) on Pt and a thin layer of α-PbO_2 (capacities varying from 30 to 120 ma-min) on the β-PbO_2 surface were also made. The α:β ratios varied from 0.75 to 2. These electrodes were discharged by currents varying from 2 to 5 ma/electrode. The discharge curves, for the most part, had characteristic shapes as shown by curve 1 of Fig. 2. Three distinct plateaus were observed. Initially (to point b) the discharge curves resembled that of pure α-PbO_2. Interrupting the current along line ab, allowing the electrode to recover, and then resuming discharge, resulted in decay and growth of polarization curves having the characteristics of pure α-PbO_2. Interruption, recovery, and resumption of discharge along the second plateau (line cd) resulted in curves that had characteristics between those of α- and β-PbO_2 (rate of growth and decay of polarization greater than for α-PbO_2 but less than for β-PbO_2). These rates increased from point c to d. The same treatment along the third plateau (line ef), yielded curves which had the characteristics of pure β-PbO_2 (no minimum was detected, but this might not be expected at the recorded sensitivity used).

One electrode gave a discharge curve differing from that of curve 1 of Fig. 2. For the electrode having the largest capacity of the external α-PbO_2 layer (120 ma-min), the curve had only one plateau and was no different from that of a pure α-PbO_2 electrode (see curve 2 of Fig. 1).

It had been suggested (3) that an expansion of the crystal lattice of β-PbO_2 early in discharge caused the minimum and the rise in the open-circuit potential, and that the lattice of α-PbO_2 did not undergo this expansion. Powder x-ray diffraction patterns of the oxide films were made for β-PbO_2 before and after the first discharge (point c and d in curve 3 of Fig. 1). Patterns were also before and after the first discharge of α-PbO_2. The β-PbO_2 patterns failed to reveal any appreciable shift in the lines which would indicate an expansion of the lattice. If the expansion does occur, it is too small to detect by this method.

Discussion

The studied discharge characteristics of the two modifications of PbO_2 in 0.1M H_2SO_4 show that the $PbSO_4$ produced on the discharge of α-PbO_2 remains as a tightly adhering film on the surface of the remaining undischarged α-PbO_2, and that produced on discharge of β-PbO_2 remains only in part on the surface and not as a film but as widely dispersed crystalline nuclei. This suggests that the discharge mechanism of the two forms may be quite different. The adherent $PbSO_4$ film on the α-PbO_2 electrode suggests that the Pb(II) reduction product reacts without leaving the electrode surface to form $PbSO_4$. The corresponding product in the reduction of β-PbO_2 passes into solution and then deposits on existing $PbSO_4$ crystals, only part of which are on the surface. Experiments in 4.4M H_2SO_4 electrolyte (9) seem to indicate that an adherent $PbSO_4$ film forms of both modifications on discharge. Although the discharge properties of PbO_2 electrodes in the more concentrated acid electrolytes and the conclusions drawn from these properties (9) were, for the most part, very different from those of this study in 0.1M H_2SO_4, these differences are not too surprising. A previous study of the discharge properties of β-PbO_2 as a function of H_2SO_4 concentration in the electrolyte (3) also revealed unexpected results at the higher acid concentrations. The magnitude of the overpotentials was at a minimum at about 0.1M H_2SO_4, and the rates of growth and decay of polarization were at a maximum at this value. No satisfactory explanation of this behavior has yet been found.

The discharge characteristics of the electrodes consisting of a thin layer of α-PbO_2 between the Pt surface and the β-PbO_2 layer indicate that the outer β-PbO_2 layer reacts first, and not until this layer has been nearly exhausted does the α-PbO_2 layer begin to react. This is in agreement with the conclusions drawn by Ikari, Yoshizawa, and Okada (9) for the discharge of a similar electrode in 4.4M H_2SO_4. These authors found, however, two distinct plateaus in the discharge curve, while only one plateau was observed under the conditions of this paper. They, also, found one minimum which preceded the first plateau. Rüetschi and Cahan (6) found two plateaus and two minima in the discharge curves of their two layer electrodes, which consisted of a layer of an α-PbO_2-β-PbO_2 mixture (4) between a

Pb or Pb alloy surface and a pure β-PbO_2 layer. They suggested that the α-PbO_2 probably discharged first. Although it is possible to argue that the modification having the higher electrode potential might discharge first at low current densities, that is not probable with the relatively large apparent current densities (0.1-1.0 ma/cm^2) used in all these investigations. Under these conditions the species, β-PbO_2, which is in more immediate contact with the electrolyte, will discharge first.

The discharge curves of the electrodes consisting of a thin layer of β-PbO_2 between the Pt surface and the thin outer layer of α-PbO_2 indicate that the α-PbO_2 alone starts to reduce first (initial plateau), followed by a "mixed" reduction of both forms (second plateau), and finally a reduction of the β-PbO_2 only (third plateau).

Acknowledgment

The author wishes to thank Dr. Warren C. Vosburgh, Department of Chemistry, Duke University, for his interest and suggestions concerning this research and preparation of this manuscript. He also wishes to thank Dr. J. C. Morrow, Department of Chemistry, University of North Carolina, who made the x-ray diffraction patterns.

This manuscript received Jan. 17, 1962; revised manuscript received March 14, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Electrolytic Polarization Resulting from Longitudinal Current in Electrodes

Walter W. Harvey

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

Longitudinal current in a metal wire contacting an electrolyte leads to polarization of the interphase. If the variation in potential within the metal along the contact with the electrolyte is not negligibly small, *i.e.*, if the resistance or longitudinal current is sufficiently large, some portion of the current will be conducted through the electrolyte. That this must be so can be seen from the following argument. With no current flowing in the wire or in the electrolyte, the magnitude of the potential difference (p.d.) between the interior of the electrolyte and the interior of the wire will be the same over the entire length of the wire; measured with respect to a reference half-cell, this difference in potential is the "rest potential" of the given metal-electrolyte half-cell. If now a p.d. is impressed across the ends, causing current to flow through the wire, the result is that different parts of the wire will be at different potentials, so that the metal-electrolyte p.d. can equal the rest potential at only one position along the contact. It follows that electrolysis will take place, the current densities normally being greatest at the ends of the metal-electrolyte contact, where the anodic and cathodic overpotentials have their maximum values.[2] Similar considerations have been expressed before, particularly with reference to palladium wires containing hydrogen (1, 2); however, to the author's knowledge, the problem has not previously been analyzed quantitatively.

For the reasons indicated, the apportionment of current between wire and electrolyte will not be determined by the ratio of their resistances, as for a parallel arrangement of resistors, but (for a given wire) by the current density-overpotential characteristic of the given electrode material in the given electrolyte. Owing to polarization, the instantaneous current across the contact can be considerably greater than the steady value, so that the apparent resistance of an immersed wire from a-c measurements would be expected to decrease with increasing frequency (3). It goes without saying that the significant current density-overpotential characteristic is that pertaining to the conditions of the resistance measurement, *e.g.*, instantaneous or steady-state current densities for the d-c characteristic. It is equally clear that the desired characteristic would not be obtained using a fine wire electrode because of the anticipated nonuniform current density distribution.

Although we shall not be concerned here with mapping the paths of current flow in the electrolyte, it is reasonable to conclude that they extend to some small distance from the interface. Thus, in the immediate vicinity of the wire, the electric field in the electrolyte has a longitudinal component. If it is

[1] Operated with support from the U.S. Army, Navy, and Air Force.

[2] This statement requires modification if passivation effects are encountered.

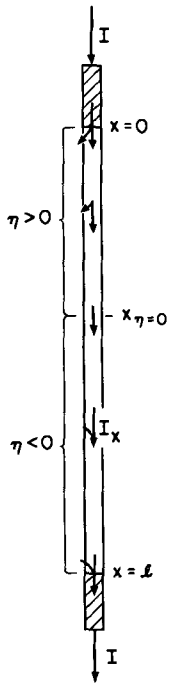

Fig. 1. Distribution of longitudinal current in a wire contacting an electrolyte.

true that the establishment of a potential gradient in a wire leads to current flow in the surrounding electrolyte, the converse must also be true. Accordingly, if a second wire is placed close to the wire carrying current, some current will flow in the second wire in addition to that flowing in the electrolyte. Apart from magnetic effects, therefore, an arrangement of closely situated parallel wires immersed in an electrolyte would be expected to exhibit coupling in a-c impedance measurements (4).

Derivation of the Potential Distribution

We treat the case of a uniform wire, a portion of whose surface contacts an electrolyte. The x-direction is taken parallel to the wire, and I_x denotes the longitudinal current in the wire. I_x varies with position along the wire-electrolyte contact, having a minimum value at the position of zero overpotential (see Fig. 1); in the pre-contact regions, $x < 0$ and $x > l$, I_x has the value I.

At points in the electrolyte sufficiently removed from the wire, the potential will be unaffected by longitudinal current in the wire. Thus, the p.d. between interior of the electrolyte and interior of the wire will vary as the potential $V(x)$ in the wire. That is,

$$\frac{d}{dx}(\phi_{\text{metal}} - \phi_{\text{electrolyte}}) = \frac{dV}{dx} \qquad [1]$$

The total metal-electrolyte p.d. appropriate to Eq. [1] is made up of a potential drop across the interphase plus any additional potential drop in the body of the electrolyte:

$$\phi_{\text{metal}} - \phi_{\text{electrolyte}} = \Delta\phi_{\text{interphase}} + \Delta\phi_{\text{electrolyte}} \qquad [2]$$

The electrolytic overpotential $\eta(x)$ is determined by the potential drop across the interphase; more particularly,

$$\frac{d}{dx}(\Delta\phi_{\text{interphase}}) = \frac{d\eta}{dx} \qquad [3]$$

Therefore, to the extent that $\Delta\phi_{\text{electrolyte}}$ is small in comparison to $\Delta\phi_{\text{interphase}}$, the gradients of potential and overpotential will be equal.

The potential gradient along the wire is

$$\frac{dV}{dx} = -\frac{\rho}{\pi r^2} I_x \qquad [4]$$

where ρ is the resistivity, and r the radius of the wire. We write the complete electrolytic current density-overpotential characteristic as $j = j(\eta)$, assigning positive values to j and η for anodic polarization. Then the integrated electrolytic current at position x is given by

$$i = 2\pi r \int_0^x j(\eta)\,dx \qquad [5]$$

whereupon I_x may be formulated as

$$I_x = I - 2\pi r \int_0^x j(\eta)\,dx \qquad [6]$$

and the potential gradient as

$$\frac{dV}{dx} = -\frac{\rho}{\pi r^2} I + \frac{2\rho}{r}\int_0^x j(\eta)\,dx \qquad [7]$$

According to our basic postulate, dV/dx may be set equal to $d\eta/dx$, so that on taking derivatives Eq. [7] becomes

$$\frac{d^2\eta}{dx^2} = \frac{2\rho}{r}\frac{d}{dx}\int_0^x j(\eta)\,dx \qquad [8]$$

from which we wish to obtain $\eta = \eta(x)$. Substituting $f(x)$ for j (η), the derivative of the integral is simply $f(x)$, leading to

$$\frac{d^2\eta}{dx^2} - \frac{2\rho}{r} j(\eta) = 0 \qquad [9]$$

subject to the boundary conditions

$$\left.\frac{d\eta}{dx}\right)_{x=0} = \left.\frac{d\eta}{dx}\right)_{x=l} = -\frac{\rho I}{\pi r^2} \qquad [10]$$

A possible distribution of potential along the wire in accordance with Eq. [9] and conditions [10] is shown in Fig. 2. Identical considerations apply to a metal strip; the potential distribution for a thin strip is given by Eq. [9], with the radius r of the wire replaced by the thickness δ of the strip.

Unless $j(\eta)$ has a particularly simple form, it will not be possible to obtain an analytical solution to Eq. [9]. We illustrate the procedure for a linear characteristic $j(\eta) = b\eta$, such as often pertains at potentials not too far removed from the rest potential. It is evident that for a linear characteristic, η will be zero at $x = l/2$. The equation

$$\frac{d^2\eta}{dx^2} - \frac{2\rho}{r} b\eta = 0 \qquad [11]$$

obtained by substituting $j(\eta) = b\eta$ into Eq. [9] has the general solution

$$\eta = c_1 e^{\alpha x} + c_2 e^{-\alpha x} \qquad [12]$$

where

$$\alpha = (2\rho b/r)^{1/2} \qquad [13]$$

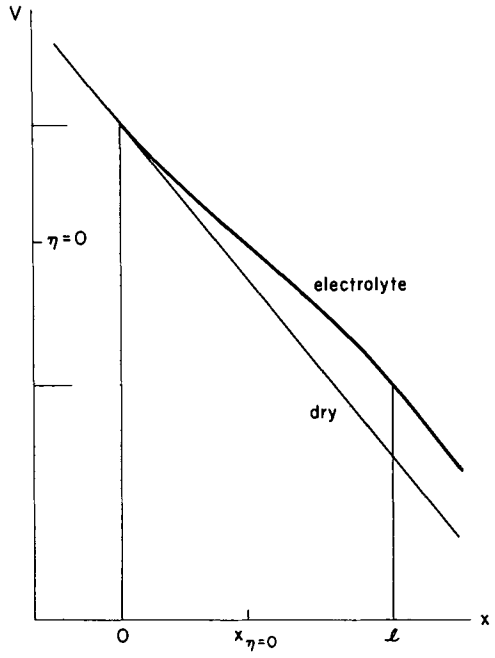

Fig. 2. Distribution of potential in a wire contacting an electrolyte

The constants c_1 and c_2 are evaluated from the boundary conditions [10] leading to the following analytical solution

$$\eta = \frac{\alpha I/b}{4\pi r \sinh \alpha l}\left[(e^{-\alpha l}-1)e^{\alpha x} + (e^{\alpha l}-1)e^{-\alpha x}\right] \quad [14]$$

Using this result, the current carried by the electrolyte is evaluable either as the total anodic current

$$i_+ = 2\pi r \int_0^{l/2} b\eta\, dx = I\left(1 - \operatorname{sech}\frac{\alpha l}{2}\right) \quad [15]$$

or the total cathodic current

$$i_- = 2\pi r \int_{l/2}^{l} b\eta\, dx \quad [16]$$

with, of course,

$$i_+ + i_- = 0 \quad [17]$$

For the general characteristic $j(\eta)$, the total electrolysis current is obtained from

$$i_+ = 2\pi r \int_0^{x_{\eta=0}} j(\eta)\, dx \quad [18]$$

Remarks

The distributions of potential and longitudinal current in an immersed metal wire through whose ends a current I is passed are seen to be determined by the radius and resistivity of the wire, the length of the contact with the electrolyte, and the current density-overpotential characteristic $j(\eta)$. The resistivity of the electrolyte does not enter explicitly since its influence is indirect, being confined to polarization effects which are included in the measured $j(\eta)$. The analysis on which the foregoing statements

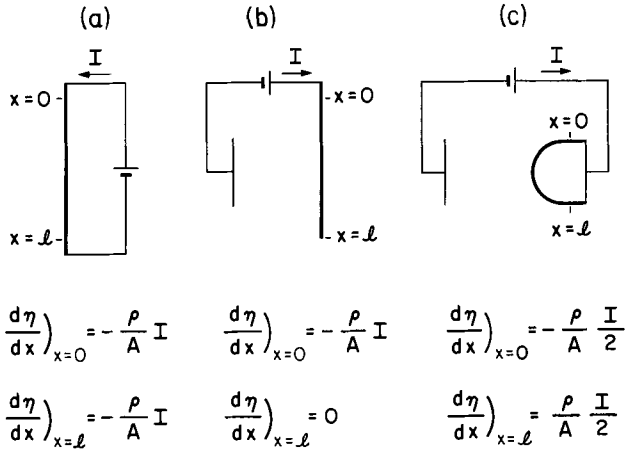

Fig. 3. Boundary conditions for (*a*) longitudinal current in an immersed wire, (*b*) a wire electrode with metallic contact at one end, (*c*) a wire electrode with metallic contacts at both ends. $A = \pi r^2$.

are based presupposes the condition $\Delta\phi_{\text{interphase}} >> \Delta\phi_{\text{electrolyte}}$. If this condition does not pertain in a practical case, details of the current flow in the electrolyte must be worked out. Even so, the method of treatment developed above should provide a useful approximation to the actual distributions of potential and current in the wire.

In most instances, the fraction of current conducted through the electrolyte will be small. For example, for a 10-cm length of 10-mil platinum wire and for a linear characteristic with $b = 100$ ma/v, i_+/I would be 0.002 according to Eq. [15], increasing roughly proportionally with b. However, for a very thin metal strip or film, or for a semiconductor, the fraction can be appreciable. For a 10-cm length of 0.00005-in. gold sheet and for the same $j(\eta)$ as in the previous example, the electrolytic current would be 5% of the total.

The basic Eq. [9] can be applied to other situations of interest including that of a wire electrode of the usual sort, with metallic contact at one end, or a wire electrode, possibly in the form of a wide loop, with metallic contacts at both ends. The three configurations which have been considered are compared in Fig. 3, where the appropriate boundary conditions are also to be found.

The Anodic Dissolution of Nickel in Acetonitrile

Thomas C. Franklin and Charles R. Parsons[1]

Chemistry Department, Baylor University, Waco, Texas

Nickel normally occurs in solution as nickel(II). However, there are a number of complex compounds containing nickel(I) (1). Ni(I) has also been postulated as an intermediate in the electrodeposition of nickel (2) and anodic dissolution in aqueous systems (3). It has also been indicated that nickel dissolves anodically in acetonitrile to produce a mixture of nickel(I) and (II) (3). This is a report of a further investigation of the anodic dissolution of nickel in dimethylformamide and acetonitrile.

Experimental Method

Determination of oxidation number by weight loss of nickel.—The electrolysis cell was a 400 ml beaker containing a 100 ml porous porcelain cup as the anode compartment. The constant current was supplied by a regulated 500v d-c power supply and a series resistor. Most of the runs were for 1000 to 5000 sec with a current of approximately 0.1 amp and a current density of approximately 0.0004 amp/cm^2. The current was maintained constant by frequent manual adjustment. The cathode and anode were coils of 14 gauge nickel wire.

Fisher certified Reagent Grade acetonitrile and dimethylformamide were used as solvents. Tetramethylammonium chloride was used as an electrolyte in both the anode and cathode compartments.

Determination of nickel(II) concentration in solution.—In order to check on the possibility of nickel entering solution by a secondary process a colorimetric comparison was made between the amount of nickel(II) in solution and the amount of nickel(II) that would be expected in solution if the nickel had dissolved as nickel(II).

The standard curve for nickel(II) was prepared by dissolving 23 mg of dried reagent grade nickel chloride in 100 ml of acetonitrile. This was then diluted to form a series of standards and measured on a Klett Summerson colorimeter.

The anodic dissolution curves were obtained using an apparatus and procedure similar to that of Franklin and Roth (4) in which the anode compartment, the cell of a Klett Summerson colorimeter, was connected by an acetonitrile tetramethylammonium chloride bridge to the cathode compartment. A constant current of 0.0020 amp was passed (approximately 0.0002 amp/cm^2), and the colorimeter readings were taken at regular intervals. The cell was open to the atmosphere, but it was bubbled with nitrogen prior to and during the anodic dissolution.

Coulometric titration of nickel(I).—In order to determine if nickel(I) were actually present in solution, the solution was titrated coulometrically with iodine. It was very difficult to detect visually the iodine color in the solution already colored with nickel; therefore, the Klett-Summerson colorimeter was again used. Following an anodic dissolution run, potassium iodide was added to the solution. The colorimeter filter was changed from the red one used with nickel dissolution to a green one, and the colorimeter zero adjustment was changed to coincide with the reading before the filter change. The nickel anode was replaced with platinum wire and a current of 2.0 ma was passed. The colorimetric readings were recorded as a function of time.

Results and Analysis of Results

The experiments on the loss in weight of the nickel anode showed that in all experiments in acetonitrile

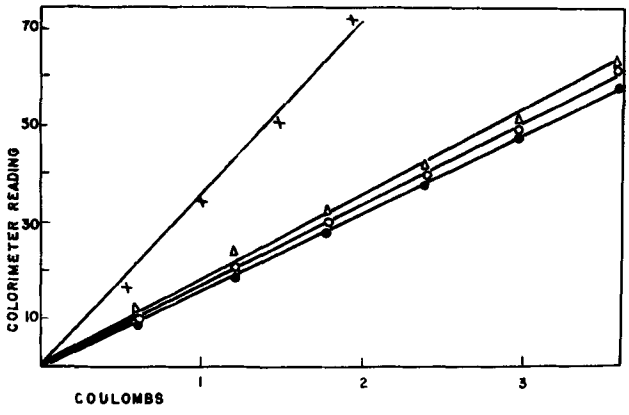

Fig. 1. Anodic dissolution of nickel in acetonitrile using a colorimetric coulometer: X, standardization curve of nickel (II) prepared from nickel (II) chloride; △, ○, •, runs 1, 2, and 3 for the anodic dissolution of nickel in acetonitrile.

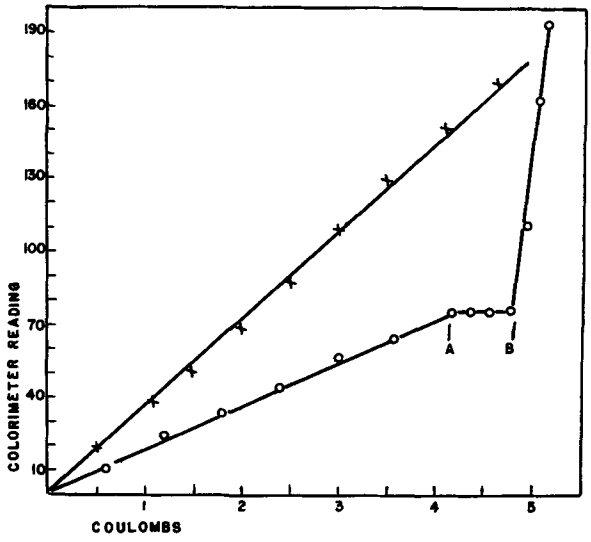

Fig. 2. Anodic dissolution of nickel in acetonitrile and coulometric titration of nickel (I) in a colorimetric coulometer: x, standardization curve of nickel (II) prepared from nickel (II) chloride; ○, anodic dissolution and titration curve for the titration of nickel (I).

[1] A student at La Vega Junior High School, Waco, Texas, at the time this work was done. He is now a student at Douglas MacArthur High School, San Antonio, Texas.

and dimethylformamide nickel dissolved with an oxidation number less than two. In dimethylformamide the average oxidation number for 5 runs was 1.66±0.12. For acetonitrile experiments the average oxidation number for twelve runs was 1.39±0.17.

Figure 1 shows typical data on the comparison of the nickel(II) concentration in solution as determined colorimetrically with that that would be in solution if the nickel had dissolved as nickel(II). As can be seen in all cases, there was less nickel(II) in solution than would be expected if nickel(II) were the only anodic product.

Figure 2 shows a typical run in which the nickel was anodically dissolved up to point A. Potassium iodide was then added, and the nickel anode was replaced with a platinum anode. As can be seen, the nickel(I) is titratable with the iodine generated, and the sudden break at B is the end point for this titration. The displacement of the anodic dissolution curve indicates that 2.0 coulombs of nickel dissolved as nickel(I). The titration indicates that 0.7 coulombs of nickel was present in solution as nickel(I). In all experiments the amount titrated was less than the colorimetric data indicated it should have been, probably because of air oxidation since the system was open to the air.

In summary, it has been shown that nickel dissolves anodically in acetonitrile and dimethylformamide containing tetramethylammonium chloride as a mixture of nickel(I) and nickel(II). The nickel(I) was shown to be stable enough in acetonitrile to be titrated with iodine.

On the Crystallinity of GaAs Grown Horizontally in Quartz Boats

L. R. Weisberg, J. Blanc, and E. J. Stofko

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

While transparent fused quartz boats have been previously found to provide the highest purity GaAs grown by the horizontal Bridgman technique (1), the crystallinity of the GaAs has frequently been unsatisfactory. Therefore, a study has been carried out of factors affecting the crystalline quality of GaAs, such as boat treatment, arsenic pressure, furnace gradient, growth speed, melt temperature, impurities, and seeding. Over 50 crystals have been prepared, each roughly 9 cm long, and weighing 20g. Subsequent to growth, the crystals were examined for surface markings before and after "sand" blasting, and samples were removed for emission spectrographic analysis and Hall measurements. Several ingots that were essentially single crystals were x-ray analyzed for their axial orientation. Prior to growth, the transparent fused quartz boats were given either of two cleansing treatments: boats were either etched in HF acid for 10 min, or alternatively, sand blasted. In either case, the final treatment was an etch in 1:1 $HCl:HNO_3$ acid followed by extensive rinsing.

Two factors were observed to have a major effect on the crystallinity, namely, the boat treatment and the arsenic pressure. Concerning the former, crystals grown in HF treated boats generally had a poor crystal structure, with many small angle grain boundaries running through the crystal. However, crystals grown in sand blasted boats at growth speeds of 1.9 cm/hr were consistently of good quality. Visual observation of the ingot cross section showed that, without exception, ingots with good crystallinity wet the boat either not at all or to only a small degree. However, the absence of wetting proved to be only a necessary condition for good crystallinity and not a sufficient one, since many polycrystalline ingots were produced in HF treated boats when no wetting occurred. Furthermore, nucleation of new grains could not be correlated directly with places where wetting of the boat occurred. These results suggest that the crystallinity can be affected in part by a growth poison (2) which is introduced by the HF etching of the quartz boat. The effect of sand blasting the boat is both to prepare a more passive surface and also to reduce the contact area between the melt and the boat.

The second major growth factor was the arsenic pressure over the melt. A series of 22 GaAs crystals were grown with arsenic reservoir temperatures between 585° and 660°C, using growth speeds of either 1.3 or 1.9 cm/hr. When a reservoir temperature below 600°C was employed, the melt had a strong tendency to supercool, and the ingots were polycrystalline. As higher arsenic temperatures were used, the crystallinity continually improved; however, porosity began to occur, due to the escape of excess arsenic at the freezing interface. Porosity was encountered at 640°C using a growth speed of 1.3 cm/hr., and at 630°C using a growth speed of 1.9 cm/hr. However, the porosity does not destroy the crystallinity, since nearly single crystals of

GaAs have been prepared with an arsenic temperature of 640°C with a growth speed of 1.9 cm/hr. In general, an arsenic temperature of 625°-630°C is desirable for good crystallinity.

Only minor and inconsistent effects on the crystallinity were produced by most other growth factors such as variations in growth speed between 0.4 and 2 cm/hr, furnace temperature gradients between 5° and 24°C per cm across the freezing interface, and melt temperatures between 1250° and 1275°C. With respect to seeding experiments, it was observed first that there was no marked preferred growth direction for GaAs. Of ten unseeded single crystals, none had orientations close to the three principal crystallographic directions <001>, <011>, and <111>, and only four had orientations at all close to each other, clustering about the <013>. Twenty-one GaAs crystals were grown using seeds with either a <013>, <112>, or <011> orientation, but the seeding did not produce a significant improvement in the crystallinity.

No correlation could be observed between the crystallinity and the presence of any spectrographically detectable impurity in the as-grown ingots, which contained silicon, magnesium, copper, aluminum, and iron in quantities varying from 0.1 to 50 ppm in different crystals. Next, a series of crystals were grown, doped separately with either silicon, oxygen, carbon monoxide, water vapor, hydrogen, or copper. No noticeable effect on the crystallinity occurred for additions of up to 0.04 mg of oxygen, 0.8 mg of carbon monoxide, 0.03 mg of hydrogen, and 1 mg of copper. In two attempts, additions of 1 mg of silicon caused the melt to wet the boat appreciably, and the crystallinity was poor, indicating that the silicon acted differently when added in elemental form than when introduced due to reaction with the boat in an as-grown ingot where oxygen may be simultaneously introduced. Water vapor had the most pronounced effect. Two ingots, one doped with 56 mg and the other with 0.5 mg of water, adhered very badly to the boat resulting in very polycrystalline porous ingots containing cracks. In addition, the water vapor caused several grams of the GaAs ingot to be transported to the cooler end of the tube. This result implies that trace quantities of water vapor, perhaps due to the outgassing of the quartz ampoule, can be deleterious to the crystallinity of GaAs.

Acknowledgments

The authors are grateful to Mr. H. H. Whitaker for the spectrographic analyses, to Mr. G. Neighbor for the x-ray analyses, and to Mr. P. G. Herkart for important cooperation in some growth experiments. Epitaxial Silicon Thin Films

K. J. Miller, R. C. Manz, and M. J. Grieco

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Study of silicon epitaxial film growth by the hydrogen reduction of silicon tetrachloride (1) has shown that constant deposition temperature affords a high degree of run-to-run thickness reproducibility. The process has been found to have a versatility especially useful for fabrication of grown junctions.

Hydrogen was bubbled through thermostated $SiCl_4$ and carried over an R. F. heated (111) oriented silicon sample in a quartz reaction chamber. If the reaction

$$SiCl_4(g) + 2H_2(g) \rightleftarrows Si(s) + 4HCl(g)$$

is assumed to be the idealized deposition reaction and reactants and products are in their standard states, calculations based on data in the literature (2) show that this reaction proceeds with the absorption of heat according to the equation

$$\Delta H_T^\circ(\text{cal.}) = 60.2\text{x}10^3 - 6.51T + 1.23\text{x}10^{-3}T^2 - 2.67\text{x}10^5T^{-1} \quad (298\text{-}1000^\circ\text{K})$$

The standard Gibbs free energy change, ΔG°, is favorable above about 1225°C. The curve obtained from the equation

$$\Delta G_T^\circ(\text{cal.}) = 60.2\text{x}10^3 + 15.0T\log T - 1.23\text{x}10^{-3}T^2 - 1.33\text{x}10^5T^{-1} - 85.9T \quad (289\text{-}1000^\circ\text{K})$$

was extrapolated beyond 1000°K. The flow conditions during epitaxial growth favor the reaction proceeding spontaneously at a lower temperature, however, because of the actual product and reactant activities, a, which are related to the free energy change, ΔG, by the equation

$$\Delta G = \Delta G^\circ + RT \ln \frac{a^4_{HCl}}{a_{SiCl_4}\, a_{H_2}{}^2}$$

Figure 1 shows the deposition reaction chamber. A Pt-10% Rh-Pt thermocouple sensing element provided a control voltage and was located in a well drilled in the susceptor on which samples were placed. The control temperature obtained from the thermocouple was held constant to $< \pm 1^\circ$C. The temperature control apparatus was similar to that conventionally used for growing semiconductor single crystals from the melt and included a recorder-controller (Leeds and Northrup Co., Model S AZAR recorder and C.A.T. Control Unit) used with a 10 kw, 4 M.C., R. F. generator. Sample surface temperature was measured by an optical pyrometer through a right angle prism and a quartz optical

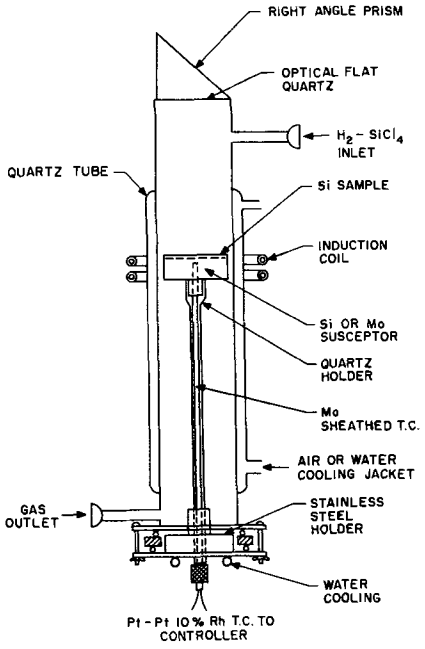

Fig. 1. Epitaxial silicon deposition reaction chamber

flat sealed to the top of the reaction chamber as seen in Fig. 1. Sample temperatures could be measured optically with a precision of ±3°C.

Films have been deposited with $SiCl_4$ concentrations of 1-2 mole % and with 1-3 l/min total hydrogen flows. Reaction chambers used have had inside diameters from 1 to 2 in. depending on sample size. Films up to 1¼ in. in diameter have been deposited in this apparatus using both silicon and molybdenum susceptors. When high resistivity silicon susceptors were used, infrared lamps were used initially to heat the silicon to increase R. F. coupling.

With ½ in. diameter substrates, a run-to-run control of film thickness as a function of time of deposition of approximately ±3% was obtained as compared with a ±15% reproducibility usually obtained for manual temperature control. For a sample temperature of 1200°C and a 2 l/min hydrogen flow through a 1 in. ID reaction chamber and with 1.3 mole % $SiCl_4$, the rate of deposition was 1.7 μ/min. At 1300°C the rate was found to be 2.1 μ/min. These deposition rates give $\Delta(\text{rate})/\Delta(\text{temp °C}) \cong 0.2\%/$°C. As an example, for a 5 min deposition at 1250°C, with a 1°C temperature difference from the control temperature, the film thickness difference should be 0.02μ from a 9.5μ predicted thickness.

Thicknesses measured interferometrically by angle-lapping-staining have been found to be uniform within measurement error across ½ in. diameter substrates. However, film smoothness has been found to vary across samples in proportion to the smoothness of the substrate material. For ½ in. diameter samples no center to edge temperature gradient was observed during epitaxial deposition. For 1¼ in. diameter samples heated on silicon susceptors, a 20°-25°C temperature gradient has usually been observed, which should contribute approximately 0.5μ to a film thickness variation for 10μ thick films. By angle-lapping-staining across 1¼ in. diameter samples, interference measurements have shown maximum deviations of ±0.5μ from 5-6μ mean thicknesses. When 1¼ in. diameter samples were heated on molybdenum susceptors, this temperature gradient was observed to be approximately 5°-10°C.

Higher temperature has been found to favor increased orientation of depositing silicon atoms. Epitaxial growth of silicon films with a high degree of crystalline perfection has been found to require a 1200°-1275°C temperature of deposition. Using the conditions outlined, films grown below 1050°C often are polycrystalline, while those films grown between 1050° and 1200°C generally have growth defects.

Water-free as well as oxygen-free hydrogen has been necessary to prevent the formation of oxide films on sample surfaces. The Deoxo Puridryer (obtained from Engelhard Industries, Inc.) and liquid nitrogen cold traps used have proven adequate to maintain the moisture level below 1 ppm. However, air as well as dust particles are introduced when samples are placed in the deposition apparatus. Sample surface defects sometimes observed are believed to be primarily caused by such contamination.

Doping of films to obtain desired resistivities has been accomplished by addition of PCl_3 to the $SiCl_4$. Film resistivity has been measured with a 4-point probe using films of the opposite conductivity type from the substrate and by capacitance^{-2} *vs.* reverse bias plots obtained from alloyed aluminum dot diodes fabricated on the films. Percentage variation of film resistivity across a sample has been found to be proportional to the nonuniformity of film thickness and to the magnitude of the film resistivity.

Reverse diode characteristics of some epitaxial film-substrate junctions have been studied. An example of an epitaxial film-substrate junction can be seen in Fig. 2a. The reverse I-V characteristics measured on 9 x 10 mil mesa etched diodes are shown in Fig. 2b. The n-type, 2 ohm-cm, film was 6μ thick and was deposited on a 1 ohm-cm, p-type silicon substrate. Measurements of capacitance^{-2} as a function of reverse voltage showed a linear relation for diodes and indicated that the interface was a step junction. The substrate in Fig. 2 was prepared for deposition by chemical polishing. The reverse current just before breakdown was less than 0.1 μa and the breakdown voltages of the diodes were found to agree with those usually obtained for step junction

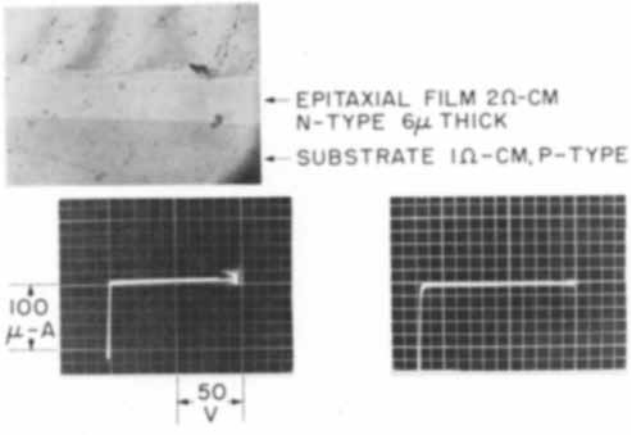

Fig. 2. a (top) Epitaxial film to substrate junction; Magnification, approximately 80X; b (bottom) reverse diode characteristics obtained for junction shown in a.

avalanche breakdown voltage as a function of resistivity.

Extent of Solid Solution in the GaSb-InSb System from Crystal Pulling Experiments

F. A. Trumbore, P. E. Freeland, and A. D. Mills

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The literature contains a number of conflicting reports on the extent of solid solution in the GaSb-InSb pseudo-binary system. Reports of limited solid solubility (1-3) have been discredited by various workers (4-8) who showed that the system contains a complete series of homogeneous solid solutions. The latter workers used experimental techniques such as long term annealing of powders, slow directional freezing, and zone equalization. The purpose of the present paper is to report successful attempts to grow these solid solutions by the crystal pulling technique together with the results of x-ray measurements which are interpreted in terms of the phase diagram.

Experimental

Conventional rf induction heated crystal pulling machines (9) were used to pull ten GaSb-InSb samples under a hydrogen atmosphere at pull rates of 3-5 mm/hr and rotation rates of 140-144 rpm from alloy melts containing between 9 and 92 mole % InSb. Seed crystals of randomly oriented GaSb were used. In one case a crystal of GaSb-InSb solid solution grown in a previous run was used as a seed. Single crystals were often obtained, even when pulled from melts containing as much as 60 mole % InSb. The other samples usually contained large grains, and the x-ray powder patterns were quite sharp except for slight fuzziness in the case of crystals grown from melts containing about 70-80 mole % InSb. A number of the melts were doped with zinc or germanium, both of which acted as acceptors in the solid solutions. However, the concentrations of these dopants were negligible insofar as their effect on the x-ray results are concerned. X-ray powder patterns were taken with Straumanis-type Norelco cameras (114.6 mm diameter) using CuKα radiation. For five of the crystals the melt compositions were determined from weight loss measurements and were corrected for the composition of the grown material as calculated from the x-ray data. Weight losses, presumably due to evaporation of antimony, were only on the order of 0.1% or less. For the other five crystals, grown prior to the decision to study this system more extensively, the melt compositions were assumed to be weighed-in compositions. The uncertainty introduced by this assumption was small because the samples for x-ray analysis were taken from as near the seed as possible, and the size of the crystals was small compared to the total melt volume.

Results and Discussion

The results of the x-ray measurements are summarized in Table I together with the mole fraction of InSb in the melt, x^{L}_{InSb}. With the exception of three samples, as noted in Table I, the x-ray lines were essentially as sharp for the GaSb-InSb solid solutions as for the pure GaSb and InSb samples.

In order to obtain the compositions of the solid solutions from the measured lattice parameters it was first assumed that Vegard's law is valid for the GaSb-InSb system as indicated by Woolley and Smith (7). However, more recent work (10) indicates the presence of small deviations from Vegard's law. Accordingly, we have recalculated the alloy compositions by using the experimental x-ray data supplied by Woolley (10). While the calculated compositions of the InSb-rich solid solutions do not differ appreciably from the Vegard's law results there is a significant difference for the GaSb-rich alloys, at least in terms of x^{S}_{InSb}, the mole fraction of InSb in the solid solution. This is shown in Fig. 1 which is a plot of log k_{InSb} *vs.* x^{L}_{InSb} where k_{InSb} is the distribution coefficient defined by $k_{InSb} = x^{S}_{InSb}/$

Table I. Lattice constants of pulled GaSb-InSb solid solutions

Sample No.	x^{L}_{InSb}	Lattice constant, Å
GaSb (pure)	—	6.095 ± 0.003*

† Melt compositions determined from weight loss measurements. Should be most reliable points.

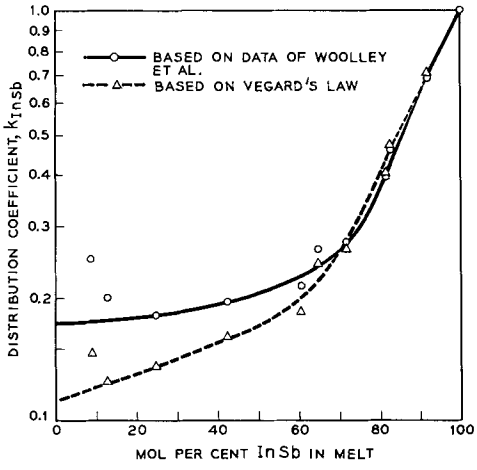

Fig. 1. Plot of log k_{InSb} as a function of x^{L}_{InSb} from the crystal pulling data. The dashed curve corresponds to the results if Vegard's law is used to calculate the alloy compositions from the x-ray data in Table I. The solid curve is derived from the x-ray data in Table I and Woolley and Smith's work on the variation of the lattice parameter with composition showing deviations from Vegard's law. In extrapolating k_{InSb} to $x^{L}_{InSb} = 0$ the points corresponding to samples No. 5EP and No. 7EP (Table I) were essentially neglected since the uncertainties in x^{S}_{InSb} were relatively large due to the small changes in lattice parameter compared to pure GaSb. The curves have also been drawn to favor those points obtained from the runs where weight loss measurements were made.

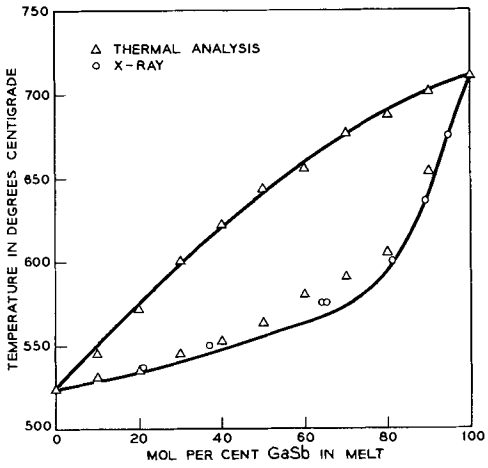

Fig. 2. GaSb-InSb phase diagram. The experimental points are those of Woolley and Smith. The liquidus curve has been drawn by the authors through these points. The solidus curve was calculated from the liquidus curve and distribution coefficient data obtained from the solid curve in Fig. 1.

x^{L}_{InSb}. The scatter in the points at the GaSb-rich end of the curve reflects the sensitivity of the calculation of x^{S}_{InSb} to slight errors in the lattice parameters and to the way we have drawn a curve to fit Woolley *et al.*'s x-ray data.

If the distribution coefficient data in Fig. 1 are equilibrium values, a knowledge of the GaSb-InSb liquidus curve would be sufficient to construct the equilibrium solidus curve for this system. Phase diagrams have been determined by Woolley and Smith (7) and Gorshkov and Goryunova (5). Although both diagrams indicate a complete series of homogeneous solid solutions, there are quantitative differences in the positions of the liquidus and solidus curves. (Some of the differences are due to the use of two different melting points for pure GaSb.) It appears that the work of Woolley and Smith is the more extensive and more reliable of the two sets of data, and we have plotted their experimental points, determined from x-ray data and from thermal analysis, in Fig. 2. The liquidus curve drawn through these points is our estimate of a reasonable curve considering the scatter of the data. The solidus curve in Fig. 2 was then calculated from the liquidus curve and the k_{InSb} data (Fig. 1), taking into account the reported departures from Vegard's law.

It is seen in Fig. 2 that the agreement between the calculated solidus curve and the experimental data of Woolley and Smith, especially the x-ray data, is relatively good. If one considers the latitude available in drawing the liquidus curve, the shallow solidus curve in the InSb-rich region where the importance of a slight error in temperature is magnified and the other possible sources of error in the present work and in that of Woolley *et al.* the agreement is probably within experimental error. Hence, it appears that the crystal pulling technique is capable of yielding equilibrium solid solubility data in systems of this type.

Conclusion

To the best of our knowledge this study represents the first application of the crystal pulling technique to the relatively complete coverage of a homogeneous alloy system of this type. The relative ease of growth and the short period of time involved (hours instead of days or months for some methods) indicates that more extensive application of the pulling technique to the study of phase diagrams would be profitable. Although a liquidus curve is necessary to obtain the complete phase diagram from crystal pulling data, a preliminary survey of a given system with the pulling method would serve to minimize confusion such as that caused by the erroneous reports of a miscibility gap in the GaSb-InSb system.

Acknowledgments

The authors gratefully acknowledge the assistance of E. M. Porbansky who grew the first GaSb-InSb crystals for this study and stimulating discussions with C. A. Burrus whose interest in these alloys led to the present work.

Preparation of Small Samples of Ductile Titanium and Zirconium from the Isotopic Oxides by Iodide Refining

N. D. Veigel and J. M. Blocher, Jr.

Battelle Memorial Institute, Columbus, Ohio

To provide material for thin-foil work at the Argonne National Laboratory, 1-2g samples each of ductile titanium-46, -47, -48, -49, -50, and zirconium-90, -91, -92, and -94 in the form of 1-in. long rods were prepared by calcium reduction of the isotopic oxides[1] followed by two-step iodide refining. Iodide refining of titanium and zirconium is described by van Arkel (1). Information on calcium reduction of the oxides is given by Kubaschewski and Dench for TiO_2 (2) and by Lilliendahl, Gregory, and Wroughton for ZrO_2 (3).

The oxide was placed in a shallow molybdenum boat which straddled a bed of calcium chips in a horizontal cylindrical molybdenum tube provided with a tight-fitting cover. The oxide was reduced by exposure to calcium vapor overnight at 1000°C. After the resulting calcium oxide was leached out by water continuously neutralized with HCl, the crude metal powder was dried and treated again with calcium vapor for 5 hr at 1000°C. The resulting zirconium powder was heated to 900°C in vacuum to insure complete removal of excess calcium. In the case of titanium prepared similarly, it was necessary to heat the crude metal at 1300°C for 1 hr in vacuum to remove the excess calcium. Removal of the calcium is essential to prevent "tie up" of iodine as nonvolatile stable CaI_2 in subsequent iodide processing.

A small Pyrex glass van Arkel-de Boer bulb containing 0.5g of iodine and provided with two 1-in.-long 0.005-in. diameter tungsten filaments was used to refine the crude metal which was contained in the original molybdenum boat placed about 1 in. below the filaments. One filament was energized for transfer of the metal from the crude. When transfer to the first was complete (in about 4 hr), the second filament was energized and the first allowed to cool for the final transfer. A bulb (condensed TiI_4) temperature of about 135°C, a feed temperature of about 250°C, and a filament temperature of 1200°-1300°C were used for the titanium deposition. A bulb temperature of about 230°C, a feed temperature of about 300°C, and a filament temperature of 1200°-1300°C were used for zirconium deposition.

[1] Obtained from the Oak Ridge National Laboratory.

The effectiveness of the two-step refining is evident from the fact that the final products could be cold rolled directly to foil less than 0.025 mm thick while the products of the one-step process cracked in attempts to reach this thickness. The improved fabricability is consistent with the fact that hardness of the two-step products ranged from 71 to 150 KHN (50-g load), as compared with that of a previous single-step product which ranged from 250 to 350 KHN. To conserve the isotopic product it was desirable to measure hardness on the curved as-deposited surface of the crystal bar. Hence, the reported hardnesses are considered to be only indicative of the relative purity and are not directly comparable with hardness measured on flat surfaces. Hardness measurements taken on the as-deposited surface of a natural iodide titanium sample were 38% higher than those obtained on a sectioned and polished sample of the same material. The extent to which crystal orientation is a factor was not determined.

The relatively high contamination in the single-step process is attributed to a lower ratio of product weight to processing equipment surface than is normally encountered in iodide processing. The two-step process is believed to have resulted in intermediate gettering of the residual gaseous impurities in the processing bulb.

The ductility of the final product indicates low contamination by interstitial elements. The following Table compares spectrographic analyses of the one sample of titanium oxide and single-step refined titanium product for which analyses were obtained. The accuracy of the spectrographic procedure is reported to be ±50% at an impurity level

Table I. Spectrographic analysis (w/o) of titanium oxide and titanium prepared by calcium reduction and single-step iodide refining

	Si	Mg	W	Al	Cu	Ca	Zr	Fe	Mo	Sn	Ni
TiO_2	>0.1	0.03	N.D.	>0.1	0.001	0.05	0.03	0.01	0.005	0.003	<0.001
Deposited Ti as TiO_2	0.02	0.005	>0.1 (Core wire)	<0.03	0.001	0.01	<0.01	0.01	<0.001	0.003	0.002

of 0.0X w/o and ±100% at a level of 0.00X w/o.

Over-all recoveries of 70-90% of the isotopic zirconium and titanium were obtained.

A Transistorized 60 cps Sine Wave Commutator for Resistance and Potential Measurements

G. F. Pollnow[1] and Robert M. Kay

Research Division, Allis-Chalmers Manufacturing Company, Milwaukee, Wisconsin

The use of half-cell potentials in studying the nature of electrode processes is well known, and for processes at very low current densities there is usually no great experimental difficulty in making accurate measurements. However, at high current densities an error in the potential measurement is introduced by the large internal *IR* drop between the working electrodes. The *IR* drop between the reference electrode and the electrode of interest can be minimized by means of a Luggin capillary. In some systems the geometry of the cell precludes the use of a Luggin capillary; hence, a device to measure the potential of the electrode in its polarized state, but independent of the purely ohmic resistance, is desirable. A number of such mechanical and electronic current interrupters have been described in the literature (1-5), most of them operating on square waves and having the problems associated with generating such distortion-free, high-amplitude, and high-frequeincy wave forms. The present apparatus was designed primarily to obtain reliable, resistance-free terminal and half-cell potentials in connection with fuel cell research and development. In addition, the direct measurement of the ohmic voltage drop provides a convenient method of determining the resistance and the specific resistivity of the electrolyte in its working environment.

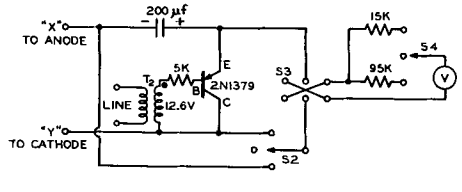
TEST CIRCUIT



MEASURING CIRCUIT

Fig. 1. Commutator circuit

Theory

The instrument described herein is a transistorized modification of a device reported by Kordesch and Marko (3) and is based on the same half-wave rectified 60 cps sine wave principle. The circuit shown in Fig. 1, however, possesses several advantages over the one previously mentioned. In particular, use of a power transistor with inverse bias in place of the diode rectifier reduces the external current at zero applied voltage from 60 ma to 25 μa when a 1.5v source of emf is under test. Second, the stability of the voltage measuring clamping circuit allows the direct measurement of the difference voltage, corresponding to the *IR* drop, to better than ± 1 mv. The bridge circuit employed by Kordesch and Marko requires zeroing before each measurement because of the aging of the bridge diodes employed and is not stable enough to measure the *IR* drop with the required precision.

Loading of the test cell is accomplished by means of the Powerstat controlled input to the transformer, T_1, whose output is rectified by the 2N677 power transistor. The bias supplied to the power transistor by the 1.5v dry cell keeps the current at zero in the load circuit until the input voltage from the transformer exceeds this voltage. Since no current is drained from the dry cell in operation, its life expectancy is sufficiently long to render uneconomic its replacement with an a-c rectifier. With the 2N677 power transistor mounted on a 3 x 4 x 1/16 in. copper heat sink, currents of 9-10 amp can be safely obtained. Greater currents can be obtained by decreasing the 1 ohm current limiting resistor and providing for the increased heat dissipation of the transistor.

Figure 2 shows the waveform of the current, I, through the cell, the voltage across the cell, V_b, the voltage across the capacitor, V_c, and the voltage across the clamping transistor, V_t, as a function of time.

As the current, I, is passed through the cell, the terminal voltage, V_b, decreases because of its inter-

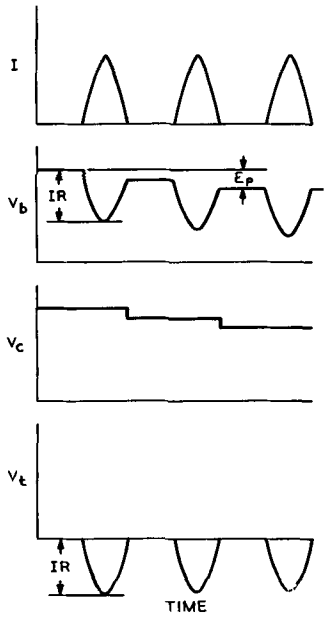


Fig. 2. Waveforms in the commutator circuit

nal ohmic resistance, R, and polarization voltage, E_p, as shown in Eq. [1]

$$V_b = E - IR - E_p \qquad [1]$$

The small filament transformer, T_2, supplies an alternating voltage to the base of the clamping transistor. When the base is negative, the emitter to collector path becomes a very low impedance. With a positive base voltage this path becomes essentially an open circuit. The voltage from T_2 is in phase with the voltage from T_1 so that the clamping transistor is conducting when the current through the test cell is zero. V_t then is zero, and the ohmic-free potential of the test cell in its polarized state is given by Eq. [2]

$$V_c = E - E_p \qquad [2]$$

On the other half cycle, current flows through the test cell and the clamping transistor becomes a very high impedance. V_c cannot change during this half cycle and so

$$V_t = E - E_p - IR - V_c = -IR \qquad [3]$$

This operation can be seen from the waveforms of Fig. 2. The open-circuit voltage E is obtained prior to loading of the cell.

In order to use the apparatus only for half-cell measurements with a calomel reference electrode, the capacitor should be reduced in size to 1-10 μf, and a high impedance voltmeter substituted for the built in meter. Half-cell measurements *vs.* a fiber type calomel electrode, with a microammeter in series, showed that even with the 200 μf capacitor the transient charging current did not exceed 20 μa and persisted for only a few seconds during the initial closing of the circuit. No permanent polarization of the calomel electrode was apparent, and once the capacitor was charged the current through the calomel electrode did not exceed 1 μa during further loading. A single pole, function selector switch, S_2, connects the internal voltmeter, V, across the capacitor, across the transistor, or permits opening the circuit to allow for an external high impedance voltmeter which for half-cell measurements is connected across the capacitor. In all cases, the four terminal method of voltage measurement is used to eliminate the IR drop due to the resistance of contacts and current carrying leads. The double-pole, double-throw switch, S_3, reverses the polarity of the 20,000 ohms/v voltmeter as required when the cell under test is changed from a source of emf to a pure resistive load. Connection of the clamping circuit leads to the test cell must be such that the correct polarity is maintained at all times on the electrolytic capacitor.

For cells having a small internal resistance a three-way range switch, S_4, to the voltmeter is provided, having positions of 0-1.0v, 0-5.0v, and one for an open circuit.

Experimental Results

A set of precision resistors were used to calibrate the commutator over the full range of the instrument. From the set of calibration curves shown in Fig. 3, it is apparent that the commutator is direct reading, well within the ±3% accuracy of the meters used to measure the current and the IR drop.

In order to demonstrate the equivalence of the commutator and the Luggin capillary when making half-cell measurements, a solution of 1M H_2SO_4: 2M CH_3OH, at 25 C° was subjected to the pulsed discharge of the commutator applied to two parallel, 1 in. by 1 in., electrodes placed 1 cm apart. Results are

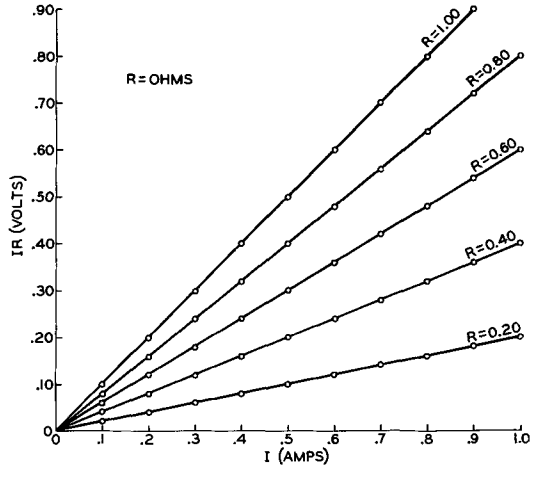

Fig. 3. Calibration of the commutator with a precision resistance box.

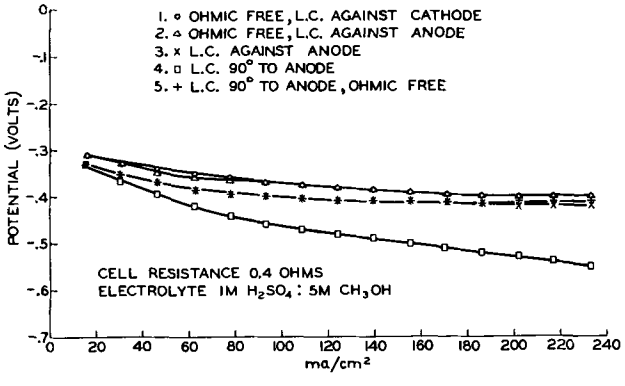

Fig. 4. Terminal and ohmic-free anode potentials vs. the saturated calomel electrode.

shown in Fig. 4. For curve 1, a Luggin capillary was first placed against the back side of the cathode while half-cell measurements, V_c, *vs.* a saturated calomel electrode were made with the VTVM across the capacitor as the current density was varied from 0 to 240 ma/cm^2. Next, the Luggin capillary was placed against the rear side of the anode and the foregoing procedure repeated to yield the data shown in curve 2.

The coincidence of curves 1 and 2 demonstrate that the half-cell potential measurements are, indeed, free of any ohmic component; however, their absolute accuracy is of course dependent on the rapidity with which the activation polarization decays.

Curves 3 and 5 demonstrate the equivalence of the Luggin capillary and the commutator with the capillary in the latter case turned through 90° away from the anode. With the Luggin capillary in this position, and the VTVM connected directly to the calomel electrode and the anode, curve 4 was obtained. It is interesting to note that the large *IR* drop shown here occurred even with the reference electrode behind the anode and clear of the field between the working electrodes. The small displacement of curves 3 and 5 from 1 and 2 is due to the change in geometry of the cell which occurred when the anode and cathode were interchanged with respect to the Luggin capillary; hence, curve 4 is to be compared to curves 3 and 5.

Conclusions

A 60 cps sine wave transistorized commutator has been constructed which measures directly, and displays on a meter, the internal ohmic *IR* drop and the ohmic-free terminal or half-cell voltage. Calibration of the instrument shows it to be direct reading within the ±3% accuracy of the meters employed. It has also been demonstrated that this device virtually eliminates the need for a Luggin capillary when making half-cell measurements on load, providing the decay time of the activation polarization is substantially less than 1/120 of a second.

Brief Communication

Directional Thermal Expansion Coefficients of β-MnO_2

R. C. Bradt and J. S. Wiley

Research Division, Fansteel Metallurgical Corporation, North Chicago, Illinois

Directional thermal expansion coefficients of β-MnO_2 were determined over the range 25° to 500°C using high-temperature x-ray methods. This was accomplished by employing relationships between lattice constants and the angular shift of Bragg reflections (1). Thermal expansion coefficients obtained using x-ray techniques have been demonstrated to compare very favorably with those obtained by the more familiar dilatometric methods (2).

Samples were prepared by the thermal decomposition of manganous nitrate solution (J. T. Baker Reagent Grade) a well-established method of producing β-MnO_2 (3). Chemical analysis by total manganese and available oxygen determinations showed the sample to have the formula $MnO_{2.00}$ (0.04-0.09 H_2O). The samples were ground to pass a 200 mesh screen and the powder used to make an ether slurry which was painted on a platinum high-temperature sample holder for x-ray observation.

Using a G. E. Model XRD-5 diffractometer, and Fe-$K_{\alpha 1}$ radiation, observations were made in air from room temperature to 500°C, where decomposition to

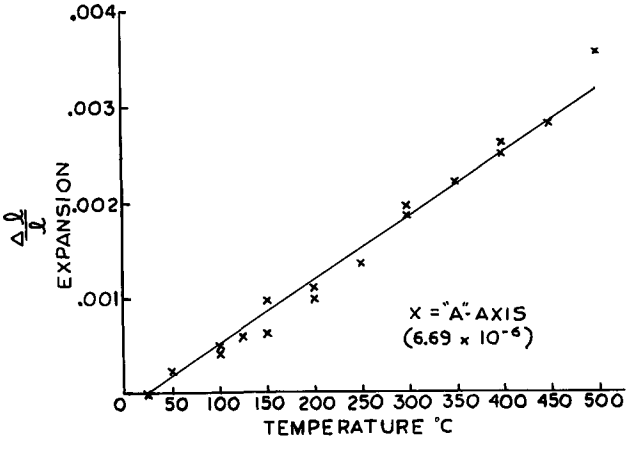

Fig. 1. Thermal expansion of MnO_2

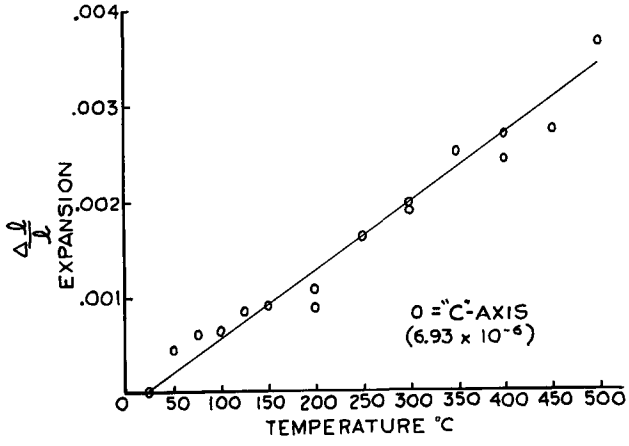

Fig. 2. Thermal expansion of MnO_2

Mn_2O_3 prevented further data accumulation. Except for the initial observation, where total decomposition occurred, the heating and cooling observations agreed quite favorably. Data were treated using the least squares method. Figures 1 and 2 show the results.

The measurements showed that the tetragonal unit cell of β-MnO_2 has a thermal expansion coefficient of 6.69 x 10^{-6} cm/cm-°C along the "a"-axis and 6.93 x 10^{-6} cm/cm-°C along the "c"-axis over the temperature range of 25°-500°C.

Manuscript received Feb. 19, 1962.

The Sodium|Tin Liquid-Metal Cell

Robert D. Weaver, Stanley W. Smith, and Norman L. Willmann

Delco-Remy Division, General Motors Corporation, Anderson, Indiana

ABSTRACT

Preliminary studies of the liquid-metal cell have shown it to possess promising characteristics for application to the conversion of thermal energy. Polarization effects commonly associated with electrochemical cells are essentially absent; charge-discharge curves are straight lines passing through the open-circuit intercept. The conductivity of the fused electrolyte, 2.3 mhos, provides for low internal losses. Nongalvanic losses occur causing an apparent loss of reactants to the extent of 0.018 amp/cm^2. It is shown that a cell constructed of the materials and electrolyte employed in the study should allow operation at 0.7 amp/cm^2 at maximum power and that the coulombic efficiency would be 95% when continuously operated at this current density during balanced charge and discharge periods.

The thermally regenerative liquid-metal cell, which has elsewhere been conceived and described (1-3), effects the transformation of thermal power to electrical power by the thermal decomposition of the products of electrochemical reaction. The reactants are liquid metals which combine to form alloys and to produce electrical energy. It is this liquid alloy which is then thermally decomposed, at a higher temperature, to the original liquid-metal reactants. The transducing system is, therefore, limited to Carnot efficiencies.

The liquid-metal cell, employing Na and Sn as examples of reactants, may be represented as $Na|Na^+$ electrolyte$|Na\cdot Sn$, in which oxidation occurs at the Na electrode. The potential of this cell is greater than that of a simple concentration cell due to the decrease in Na activity at the Sn cathode due to the formation of compounds represented by $Na_x\cdot Sn_y$. Since high potentials are desirable, the concentration of Na in the cathode will be maintained at levels usually less than 10 weight per cent (w/o). The electrochemical reaction involves the transfer of Na^+ formed at the anode, through the electrolyte, to the cathode. Thus, it is desirable to employ electrolytes which are chemically stable to Na metal and in which the only cation present is that of Na. Such electrolytes are provided by fused Na salts. The use of a fused-salt electrolyte will further provide high electrical conductivity.

The use of electrochemical cells to acquire thermodynamic data of liquid-metal alloys is well established (4, 5). Solid electrolytes have usually been employed in such cells, and none have been capable of producing power at high current densities. One other electrochemical transducer has been described which involves thermal decomposition of the electrochemical product, in this case LiH, (6-8).

This paper presents a study of the electrochemical cell associated with the liquid-metal system. Because of the novelty of this cell system and the problems attendant to the use of reactive liquid metals in a cell which is operated at high temperatures, this paper is devoted to a description of the experimental techniques involved, the materials employed, and the preliminary results obtained.

Experimental Procedures

The use of Na at high temperatures in a cell requires that a containing material be employed which is an electrical insulator, is inert to Na, is nonporous (*i.e.*, impervious), and is capable of withstanding high temperatures. Aluminum oxide has been found to be such a material. To study cell behavior, cells were constructed, as shown in Fig. 1, consisting of an alumina crucible[1] whose composition is given as 99 + % Al_2O_3. It has been found that low silica-content alumina is necessary for this work. The cell must be sealed in order to prevent long-time loss of Na through vaporization, and this has been accomplished by use of a ground tapered joint between the cell and a solid alumina cap. The angle of the joint is 5°, and the grinding is accomplished by use of diamond grinding techniques.

[1] Norton Company, Crucible No. MD 70319 B.

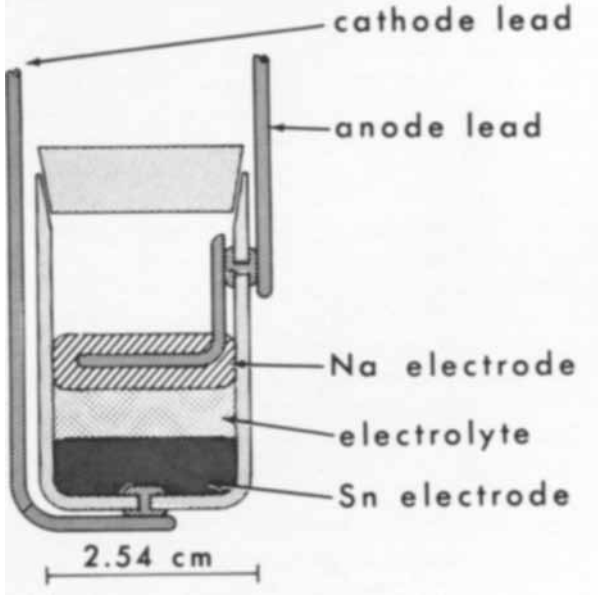

Fig. 1. Static Na|Sn cell

Electrical leads are necessary through the cell walls and necessitate a metal-to-alumina seal which is vapor tight. Such seals are made by grinding a 0.03 cm oversize hole in the cell wall and inserting a steel rivet. The rivet is seated by use of a spot welder which allows the rivet to be heated to a cherry-red heat and which supplies pressure to flatten the rivet end. Electrode wires may then be spot-welded to either end of the rivet as necessary. Such seals are quite satisfactory, but require some experience to effect a tight seal which will not crack the alumina as the rivet contracts.

The densities of the metals and the electrolytes are such that the layers are stable as shown in Fig. 1. The projected area of the metal electrodes is 3.87 cm^2. A cell such as this allows the static performance (*i.e.*, the liquid metals are not flowing) of the system to be evaluated. The cell must be operated in an inert atmosphere of N_2 or A as a safety precaution, for cracks and leaks may occur. This is accomplished by placing the entire cell in a bottomed glass tube, wires and inert gas being introduced through a rubber stopper. The lower half of the tube, containing the cell, is then placed in a vertical tube furnace.

Both cell resistance and cell voltage are functions of temperature, and it is therefore necessary to provide for a constant temperature environment for the cell. During short duration runs it is possible to control furnace temperature by means of manually operated adjustable autotransformers. Line voltage variations overnight were found to cause temperature excursions of as much as 50°C. To achieve satisfactory temperature regulation, an inexpensive thermocouple-controlled galvanometer relay[2] was employed to control furnace temperature.

The galvanometer relay was set up to short-circuit a resistor in series with the furnace heater. Temperature level was established by means of an autotransformer, and the value of the series resistor was chosen to accommodate the effects of daily line-voltage variations. The temperature of the cell was controlled for a one-month interval with variations of less than 2°C by this technique.

The use of aluminum oxide in this work is, as stated, necessary, but entails some difficulties. Thus, a cell of more than simple geometry is difficult to fabricate from a single solid block while, on the other hand, further seals are required if the cell is fabricated from parts. It has been found possible to effect a liquid-metal tight seal between pieces of alumina tubing by use of the tapered joint already described, and by use of a tapered joint which has been sealed by formation of a spinel of $MgO-Al_2O_3$ between the alumina surfaces.[3] It is also possible to effect a seal between flat surfaces of alumina and steel by use of a pressure seal. The surfaces of such a seal must be ground flat and polished to a near gauge-block finish. Electrical leads may be incorporated by use of the rivets as described, or if in a metal surface, successful performance has been

[2] Simplytrol P. R. Controller, Assembly Products, Inc., Chesterland, Ohio.

[3] Further particulars of this technique may be obtained from the Technical Development Department, Refractories Division, Norton Company, Worcester, Mass.

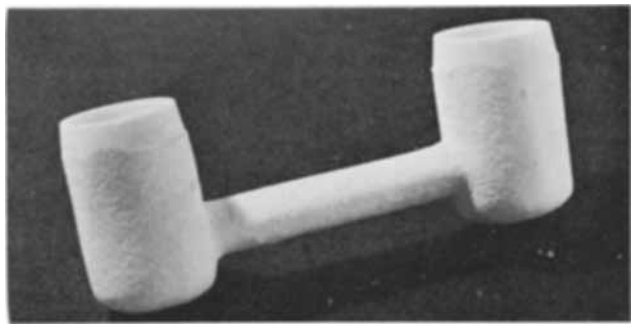

Fig. 2. Flame-sprayed alumina "H" cell

achieved by use of brazed nickel-to-alumina feed-through terminals[4] which may then be welded to the metal surface. The machining of solid alumina in intricate shapes has been found to be readily performed employing high-frequency abrasive cutting techniques.

In the search for methods by which sufficient cell complexity might be achieved to allow half-cell voltage measurements to be taken,[5] an approach to a cell fabrication was made employing flame-spraying techniques. The "H" cell of Fig. 2 was prepared by flame-spraying[6] a wood mandrel, shaped to the desired inside dimensions of the "H" cell with Al_2O_3. The thickness of the flame-sprayed layer was about 3 mm. The wood mandrel was then removed by charring in a furnace at temperatures increasing from room temperature to 260°C over an 8-hr period. The charred wood residue was then removed, and the hollow cell leached with dilute HCl, dilute HNO_3, and H_2O and finally fired to 1090°C. The porous flame-sprayed cell was then reduced to near zero porosity by high-temperature firing.[7] This procedure resulted in a liquid-tight cell. Further attempts at this technique are expected to provide vacuum-tight apparatus of sufficient strength and of proper design to allow half-cell measurements to be performed.

For cells which are to be operated in an environment of vibration or with the liquid metal electrodes in a vertical position, it is necessary to separate the two liquid metals to prevent internal short circuits. Attempts to effect such separations are being made by use of an electrolyte-impregnated matrix of a porous, nonconducting substance. Various forms and compositions of alumina and MgO have been tested, the 99+% Al_2O_3 matrix having thus far been found to be best for this application. A commercially available filter disk[8] of 99% Al_2O_3, a nominal porosity of 36%, and a permeability of 20-30% has most frequently been employed as a matrix in these studies.

A liquid-metal cell, operated as a fuel cell, will be operated with a closed-ended anode, *i.e.*, the Na stream will terminate in the cell. At the cathode,

the Sn stream, low in Na content, will enter the cell, pass by the electrolyte, and exit from the cell enriched in Na content. The fact that the Sn cathode is moving past the electrolyte will tend to reduce any concentration polarization in the Sn cathode. To allow a determination of the influence of Sn velocity upon concentration polarization, the cell of Fig. 3 and 4 was constructed. Each cell-half consisted of an end plate, through which fittings allowed the reactant to be introduced and removed, and an electrode plate which allowed the liquid metal to assume a known geometry. The channel for the liquid metals in the electrode plate was a rectangle of 2.540 cm length, 1.270 cm width, and a depth of 0.0508 cm. The flow streams are therefore believed to be of uniform velocity past the electrolyte and of a known area. The assembled cell was made leak tight by use of the pressure seals already mentioned and with pressure supplied by the vice shown. The bolts employed were 5/16-18 and were tightened to a torque of 1.4 to 2 kg-m. The porous matrix was contained with a zero-clearance fit in a frame of impervious alumina.

All potential measurements were made employing potentiometers or strip-chart potentiometric recorders. Reagent grade chemicals were employed. The N_2 or A was passed over Cu turnings at a temperature of 450°C, and H_2O was removed with $CaSO_4$ drying towers. Temperatures were measured with

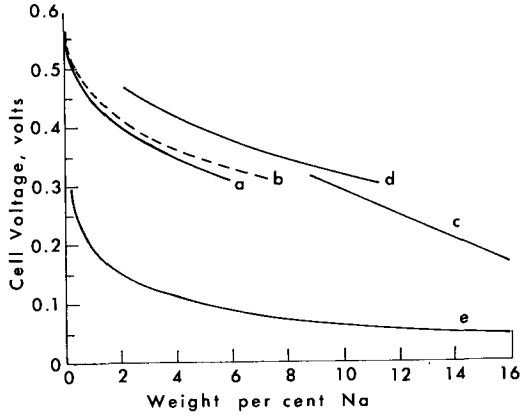

Fig. 5. Variation for Na|Sn cell voltage with Na concentration

chromel-alumel single-junction thermocouples. Electrolyte mixtures were prepared from stock reagents, in correct weight proportions, then fused to further remove traces of water.

Results

A search for a suitable electrolyte was made of the salts of Na. Anions found to be chemically compatible were: the halogens, CN^-, $CO_3^=$ and $S^=$. The electrolyte employed in these studies was an eutectic of 62.5 mole % NaI, 37.5 mole % NaCl, mp = 562°C. Cell data presented were obtained employing this electrolyte in cells which were maintained at 625°C. A low melting composition of 20.3 mole % Na_2CO_3, 47.3 mole % NaI, 32.4 mole % NaCl, mp = 520°C, has also been found. In addition a low melting mixture, mp = 512°C, for the NaI-NaCN system, of an approximate composition of 35 w/o NaCN has also been found.

Static-Cell Studies

Cell voltage *vs.* Na concentration data are presented in Fig. 5. Data for curve (a) were obtained employing the static cell loaded with Sn, the electrolyte, and Na, and raised to operating temperature. Known quantities of coulombs were then withdrawn from the cell, the open-circuit potential measured, and the weight per cent of Na in the Sn calculated. The open-circuit voltage of the cell continuously decreases during the period in which the electrolyte is molten. This nongalvanic voltage loss is presumably due to the solubility of Na in the melt or to chemical or physical decomposition of the electrolyte (I_2 coloration may be seen in the fused, evacuated melt). For this reason, the Na concentration calculated by coulomb measurement is a minimum value. Employing the results of the life-test to be described, the results presented in curve (a) have been corrected to an approximate true concentration, and these corrected data are presented in curve (b). Curve (c) was obtained from the data of ref. (4), p. 23, for a Na|Sn cell operated at 480°C and curve (d) obtained from ref. (10) for the cell operated at 500°C. Curve (e) was obtained by calculating the potential of the cell assuming behavior due to a simple concentration cell.

Charge-discharge data were obtained by employing the static cell. Such data were collected at dif-

ferent levels of Na concentration in the Sn layer. Experience with these measurements resulted in the design of the cell of Fig. 1. The data accumulated with this cell were corrected for the resistance of the leads which provided electrical contact from the top of the inert-gas enclosure to the cell rivets. The precise and repeatable measurement of the resistance of these leads, which were subject to a temperature gradient of 600°C, was found to be difficult. For this reason, the cell of Fig. 1 was modified by the addition of two rivets which served to allow the potential between the Na and Sn electrodes to be measured while passing current through the other two leads. In all cases, a plot of cell voltage against current density resulted in a straight line passing through the open-circuit intercept. The measurements were repeatedly taken to current densities of 0.775 amp/cm². From these data the conductivity of this electrolyte was calculated. The results of three identical experiments provided a value of the conductivity of 2.5 ± 0.1 mho at 625°C. Measurements of the conductivity using conventional techniques with glass conductivity cells whose constants were above 100, provided a value of 2.3 mho. This value was unaltered by the use of Ag, Pt, or 3 w/o Na in Sn electrodes. This difference in conductivity value is attributable to the assumption that the liquid-metal electrodes were flat, *i.e.*, meniscus free, which is not the case. The value of 2.3 mhos is believed to be valid.

Life-Test Studies

Most of the experiments performed with the static cell were run for not more than five days, and during these times most data were manually collected. In order to study the long-time behavior of the cell, an automated life test was established. By means of a relay which was driven by a synchronous motor, a cyclic sequence of cell operations was established, and the information obtained during each phase of the cycle was recorded with a single potentiometer strip-chart recorder. The sequence of events and the fraction of the cycle devoted to each phase were: open-circuit voltage, 10%; charging current, 40%; open-circuit voltage, 5%; cell temperature, 5%; discharge current, 40%. Each cycle was of 20-min duration, and the length of time devoted to either charging or discharging the cell was thus 8 min. Since the cell was on open-circuit during the measurement of cell temperature, the total time per cycle that the cell was on open-circuit was 4 min.

The results of this life test are presented in Fig. 6. The charge and discharge currents were adjusted during the early part of the run in an attempt to keep the voltage after charge and discharge at a constant level. The degree to which these adjustments were successful is presented in Fig. 6, curve (A) showing the variation in open-circuit voltage of the cell after the charge and discharge cycles. The cell may be considered to have operated in a stable manner during most of the 31 day period. The ratio of equivalents of Na consumed during a discharge cycle to those recharged during the charge cycle are presented in Fig. 6C. The coulombic efficiencies of the cell approached a maximum of 70% during the

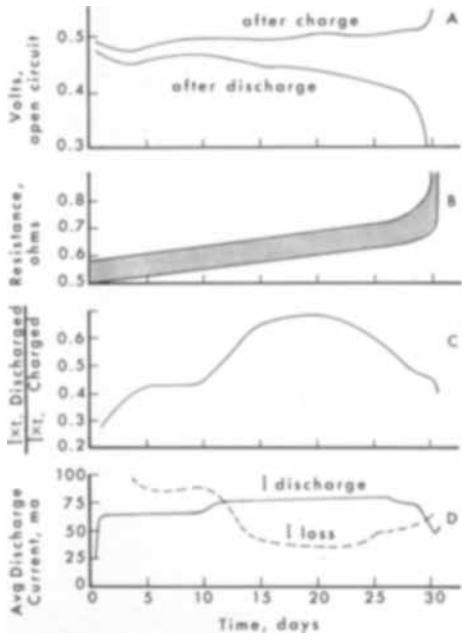

Fig. 6. Na|Sn cell life-test results

run. The average coulombic efficiency was 50.6% and 1.97 equivalents of Na were discharged during the run. Since the cell contained 0.116 equivalents at the start of the run, the quantity of electricity withdrawn from the cell was 16 times that represented by the original quantity of Na placed in the cell. The discharge current during the run is shown in Fig. 6D. The average discharge current for the entire cycle was 71.0 ma corresponding to 18.3 ma/cm². This value corresponds to an average discharge current of 45.9 ma/cm² during the 40% portion of the cycle. The difference between charge and discharge current averaged over the complete cycle, I_{loss}, is plotted as the dashed line of Fig. 6, curve (D). Measurements of cell resistance during charge and discharge were taken periodically during the run. These values were obtained by measuring the change in cell voltage due to a known current flow, both charging and discharging. The results were variable and are presented as the range of resistance shown in Fig. 6B. Based on the average coulombic efficiency and the average discharge current, the loss in current due to nongalvanic processes in calculated to be 17.9 ma/cm². This value has been applied as a correction to the data of Fig. 5, curve (b).

Inspection of the cell after the conclusion of the life test showed that cell failure was caused by loss of Na from the cell due to an imperfect seating between the cell and the cell cap. The alumina and the rivets showed no sign of attack, other than a surface blackening of the alumina, presumably due to the reduction of traces of SiO_2. The porous matrix employed showed no major attack, but after washing with water, the disk exhibited a loss of mechanical strength.

The studies performed with the static cells demonstrated that the concentration polarization was not of a magnitude to observe with the techniques employed. It was difficult to decide between concentration polarization and pen-lag effects even though the cell voltage during the life test was re-

corded employing the 12.5 mv span of a recorder whose pen-response speed was 1 sec for full-scale deflection of 25 cm. Such a low extent of concentration polarization is not significant to the operation of cells in which the greatest voltage loss is due to resistivity, and it was thus unnecessary to study this polarization further. Nevertheless, the cell of Fig. 4 was assembled and run to study the behavior of the seals and the matrix. It was found that the pressure sealing techniques were quite satisfactory and were capable of preventing liquid-metal leaks at absolute pressures as high as 2.3 atm. It was discovered, however, that the matrix employed allowed the pores to be flooded with Na metal, causing almost immediate cell failure. This short-circuiting was presumably due to the use of too large a pore size.

The high conductivity of the electrolyte, the excellence of kinetic behavior as indicated by the linear charge-discharge curves, and the low extent of nongalvanic processes have thus been demonstrated. On the basis of these results, a cell constructed of a 3 mm thick, 40% permeable matrix of the type used in these studies, employing the NaI-NaCl eutectic, should allow operation at 0.767 amp/cm^2 at 0.25v, the maximum power capability of a cell of 0.5v open-circuit potential. Such a cell would exhibit 95% coulombic efficiency when continuously operated at this current density during balanced charge and discharge periods.

Acknowledgments

The authors wish to express their gratitude to the management and personnel of development laboratories of the Norton, Alite, and Cincinnati Metal-Blast Companies. The assistance provided by these groups made possible the construction of the experimental apparatus necessary to this study.

Formation of Porous Metal Plates by Electrolytic Reduction

I. Electrolytic Reduction of Metal Compounds under Controlled Physical Pressure

C. M. Shepherd and H. C. Langelan

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

Porous metal plates having high surface areas and considerable mechanical strength were produced by the reduction of pasted metal compounds under controlled physical pressures in an electrolytic cell. The porosity of the metal plate is a function of the pressure applied during electrolysis and the metal content of the compound being reduced. Successful reduction depends upon using the proper combination of metal compound and electrolyte. Porous metals formed successfully by this technique included Ag, Fe, Bi, Sn, Sb, Zn, Cu, Cd, Pb, and the following mixtures, Sn-Pb, Zn-Hg, Cd-Zn, Ag-Cu, and Cu-Zn. Porosities as low as 42% and as high as 89% were obtained. A small variation in the porosity of such a metal electrode may have a serious effect on its capacity as a battery anode.

A large number of metal compounds can be mixed with a suitable liquid, pasted on a metal screen, and reduced to the corresponding metal when made the cathode in an electrolytic cell. If such an electrode is suspended openly in the electrolyte, the pasted compound may be shed from the screen before it has a chance to be reduced. If a metal deposit is obtained in this manner, it is apt to be

crumbly, slightly adherent, and have little strength. Zinc oxide gives such a deposit in a potassium hydroxide electrolyte. However, when a cell assembly consisting of pasted zinc oxide cathodes, silver anodes, and separators is packed into a tight fitting cell case and charged in a potassium hydroxide electrolyte, the zinc oxide is reduced to a compact, adherent, porous zinc plate which has considerable physical strength. It seemed probable that the tight packing of this cell assembly placed a pressure on the pasted zinc oxide which was responsible for the reduced zinc being in a compact form. Special equipment was designed for reducing pasted electrodes in an electrolytic cell under controlled physical pressure.

Metal plates formed in this manner are highly porous, resistant to crumbling in most cases, and have a large surface area that is readily contacted by liquids upon immersion. They are particularly excellent for use as battery anodes that are to be discharged at high rates.

The purpose of this study was to determine some of the factors that are involved in the formation of porous metal plates by the electrolytic reduction of pasted metal compounds under pressure.

Experimental

A paste of the proper composition was made from the particular compound and electrolyte, and it was applied evenly to both sides of a 3.8 cm^2 fine-mesh, wire screen. Enough material was used to give metal plates approximately 0.2 cm thick. The pasted screen was pressed in a die to remove any slight excess of liquid present, to remove air bubbles, to give better adherence to the wire screen grid, to distribute the paste evenly over the grid, and to give the flat, parallel surfaces that were necessary in the subsequent cell assembly. The paste extended well above the surface of the wire screen in which respect it was different from the average commercial battery plate where the paste is inside the pockets of the grid. The problems involved in pasting are so serious that they have been made the subject of a separate study (1).

The order of assembly of the charging equipment is shown in Fig. 1. The pressed electrode was placed between two flat-sheet, inert anodes, generally nickel, each of which was wrapped in a single layer of unsealed cellophane. The electrode assembly was then put in a cell case which consisted of a snug-fitting, flexible bag made of 3-mil polyethylene. The cell assembly was put in a rigidly secured container and placed solidly against one end. A thick polystyrene pressure plate was placed against the other side of the cell assembly. The rounded tip of the lever arm was placed in the rounded indentation in the center of the pressure plate. The upper extension of the lever arm was kept level as weights were added to the hook to give the desired pressure on the pasted electrode. The applied pressure is a linear function of the weight used and was determined theoretically and checked by calibration. After the pressure was applied to the cell assembly, the current was turned on and sufficient electrolyte was added to cover the electrodes. The cells were charged at a rate that gave complete reduction in about 18-24 hr. In general, the charging conditions did not appear to be critical.

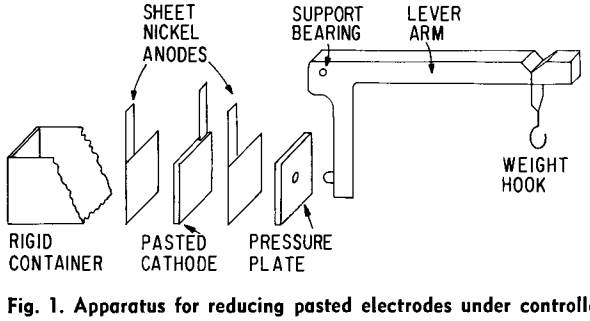

Fig. 1. Apparatus for reducing pasted electrodes under controlled pressure.

At the end of the charge, the porous metal electrode was removed from the cell, thoroughly washed, dried in a vacuum and stored in an inert atmosphere. The porosity, P, which is defined as that fraction of the total volume of the plate that is occupied by pores or void spaces, was determined by liquid absorption. The results were reproducible to ± 0.0007.

Results

Sixty grids were pasted with a mixture of 5.0g ZnO and electrolyte and then reduced in 32.6% KOH to form porous zinc plates approximately 2 mm thick and containing 4.0g of zinc. The average porosity obtained at various pressures is plotted in Fig. 2 and was found to decrease from 0.81 to 0.71 as the pressure was increased. The rate of decrease was fastest at the lowest pressure where the porosity was highest and the physical structure was weakest. When the initial pressure on the cell assembly was greater than 0.2 kg/cm^2, the paste generally flowed to a certain extent and formed a bulge around the edge of the electrode which reduced to give a crumbly metal. This undesirable condition was avoided by holding the pressure during the first 20 min or so of charging at 0.2 kg/cm^2. The paste was then stiffened by the presence of reduced metal, and the pressure could be increased to as much as 0.8 kg/cm^2. At the end of approximately another 20 min the pressure could be increased to as much as 1.6

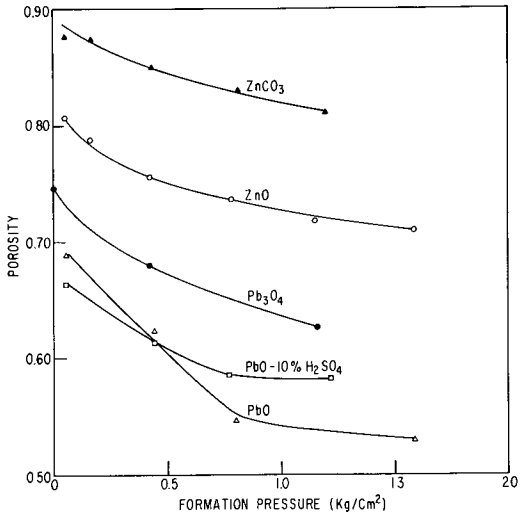

Fig. 2. Effect of formation pressure on porosity

kg/cm². An increase in the length of these initial forming periods at low pressures was accompanied by an increase in the porosity. The optimum length of the initial low-pressure formation periods varied somewhat with the material being reduced and the conditions of reduction.

Porous zinc electrodes were also produced by the reduction of $ZnCO_3$ in 32.6% KOH. Results are shown in Fig. 2.

A number of these zinc electrodes were discharged individually in an alkaline cell between two AgO cathodes at 20°C and 10 amp using 10 cc of 40% KOH electrolyte. Under these conditions, the zinc electrode was the limiting factor on cell capacity. In Fig. 3, the capacity in minutes is plotted against per cent porosity. A peak is reached at a porosity of 82%. At higher porosities, the physical structure is weakened and the zinc crumbles during discharge, and at lower porosities the electrode is stronger physically, but the total surface area is less; therefore, the current density is higher and the capacity is lower. The curves in Fig. 2 and 3 show that the capacity was seriously affected by the porosity and consequently was also affected by the pressure used during the electrolytic reduction. The maximum capacity was obtained only under a fairly narrow range of porosities. Careful control of these conditions is essential if one is interested in specialized characteristics such as high current density discharge rates or minimization of battery weight.

The porosity-pressure curves for lead plates formed by the reduction of Pb_3O_4 and PbO are shown in Fig. 2. Pb_3O_4 can be reduced at zero pressure to give a solid physical structure. Many materials that reduce satisfactorily in an electrolytic cell under pressure, either fail to reduce at all if no pressure is applied or reduce incompletely or reduce to give a nonadherent, spongy metal deposit. All of the reductions discussed here were made with a 32.6% KOH electrolyte unless otherwise indicated on the porosity-pressure curves. PbO was reduced in a 32.6% KOH and also in a 10% H_2SO_4 solution. The difference between the two pressure-porosity curves for PbO is not nearly as large as the difference between the PbO and Pb_3O_4 curves. In the case of a particular metal, changing the compound to be reduced probably has more effect on the porosity than changing the electrolyte that is being used with a given compound.

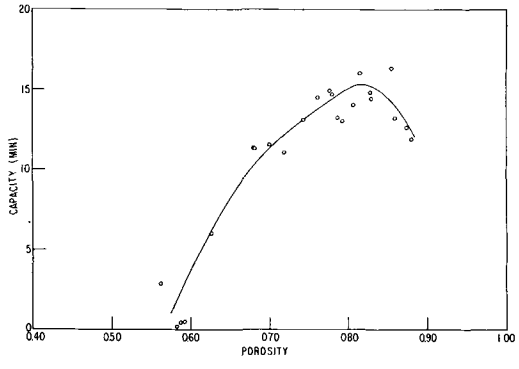

Fig. 3. Effect of porosity on cell capacity

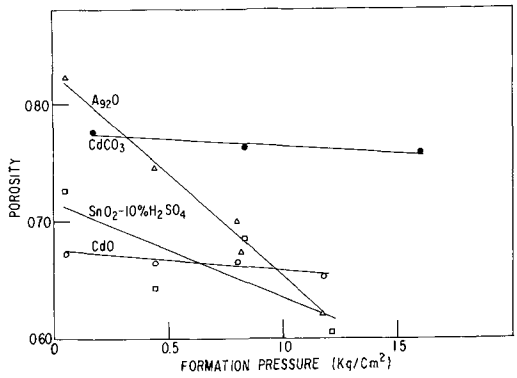

Fig. 4. Effect of formation pressure on porosity

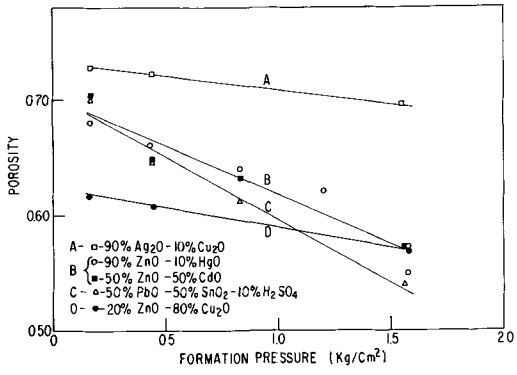

Fig. 5. Effect of formation pressure on porosity

Porosity-pressure curves for the formation of porous plates of cadmium, tin, and silver are shown in Fig. 4. Results obtained from the reduction of various mixtures are shown in Fig. 5. Satisfactory porous plates were not obtained whenever a mixture of compounds was tried that contained an appreciable amount of a compound that would not reduce by itself. Porosity curves for copper and antimony are given in Fig. 6. By using three different compounds, it was possible to prepare copper plates covering most of the range between 0.40 and 0.90 porosity.

In addition to the compounds shown in Fig. 2, 4, 5, and 6 successful reductions to satisfactory porous metal plates were also obtained using FeS, AgO, $Bi_2O_2CO_3$, and PbO_2 in KOH electrolyte. The reduc-

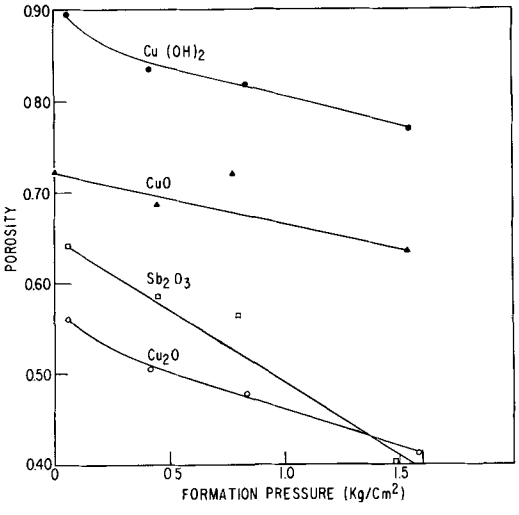

Fig. 6. Effect of formation pressure on porosity

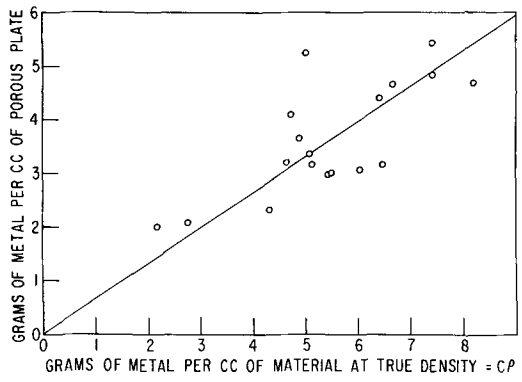

Fig. 7. Estimation of porosity from the amount of metal in the original material. Pressure = 1.5 kg/cm².

tion of HIO_3 in a saturated solution of KIO_3 gave a porous plate of iodine that was adherent and had some physical strength. This was the only porous plate of a nonmetallic substance that was formed by electrolytic reduction.

A wide range of porosities was obtained from the various compounds that were successfully reduced. In the case of a particular metal such as zinc, lead, cadmium, or copper, the compound that contained the lowest percentage of that metal gave a porous plate having the highest porosity when reduction was made at constant pressure. This is illustrated in Fig. 2, 4, and 6. In Fig. 7 the grams of metal per cubic centimeter of porous plate have been plotted against the grams of metal per cubic centimeter of compound at its true density for a formation pressure of 1.5 kg/cm². Similar curves were obtained at other formation pressures, and in all cases a straight line through the origin gave a reasonable fit and was statistically significant.

An approximate prediction of the porosity may be made from the empirical equation

$$P = 1 - (0.472 + 0.127p)C\frac{\rho}{\rho_m} \qquad [1]$$

where P is the porosity expressed as a fraction, ρ_m is the density of the metal, p is the formation pressure, C is the per cent of metal in the compound being reduced, and ρ is the true density of the compound. Porosities were calculated by means of Eq. [1] on all available data and found to have an average deviation of 0.056 from the measured values.

The shape and slope of the porosity curve may be a function of the particular metal involved. In Fig. 2, it can be seen that the $ZnCO_3$ porosity-pressure curve is roughly equidistant from the ZnO curve, and the curve for Pb_3O_4 is roughly equidistant from the two PbO curves. In Fig. 4 the straight lines for $CdCO_3$ and CdO are nearly equidistant and the same is true for the CuO, Cu_2O, and Cu $(OH)_2$ porosity-pressure curves in Fig. 6. Although these data are too limited to be conclusive, they do indicate that the porosity-pressure curves for various compounds of a given metal may be approximately equidistant.

Discussion

Not all metals can be formed into porous plates by electrolytic reduction using the techniques described here. All but one of the metals that were reduced in this manner were observed to have 18 electrons in their penultimate electron shell.

On the basis of their behavior in electrode systems and various other properties, Piontelli (2) divided metals into three classes, namely normal, inert, and intermediate. Lyons (3) has discussed Piontelli's classification of metals on the basis of their electrodeposition from aqueous solutions. These divisions are shown in Table I which omits some of the metals that cannot be electrodeposited readily. All but one of the metals that formed porous plates by reduction was in the normal group. One success was obtained in the inert group.

The normal metals have considerable variation in their properties, particularly in regard to their electrodeposition from aqueous solutions. A study of these anomalies shows that they can be reconciled by dividing the normal metals into two sub groups, the normal-electropositive, which contains the normal metals having a low electronegativity and the normal-electronegative which contains the normal metals having a high electronegativity. The normal-electronegative metals can be electrodeposited readily from aqueous solutions, and most of them are plated commercially at efficiencies of approximately 100%. The amount of ionic character in a bond involving a metal of this group is considerably less than for the corresponding compound involving a metal of the normal electropositive group.

All of the porous metals that were formed by the technique described here belong to this normal-electronegative group with the exception of iron and of antimony which is on the border line and possibly should be reclassified. No failures were obtained within this group. However, no experiments

were conducted using gold, gallium, indium, and thallium. Attempts to reduce porous plates from arsenic, selenium, and tellurium compounds were unsuccessful, even though some reduction could be obtained. Most of the 15 inert metals lying to the right of vanadium in Fig. 1 can be electrodeposited successfully from the proper aqueous solution with current efficiencies that vary from quite low on up to 100% in a few cases. However, all attempts to produce pure porous plates of these metals were failures. A considerable number of unsuccessful attempts were made using various electrolytes and a good many different compounds of nickel, cobalt, iron, manganese, chromium, molybdenum, and tungsten. All attempts were unsuccessful that used mixtures of these compounds and other compounds that reduced readily such as HgO. However, FeS containing 20% graphite reduced readily in a 15% KOH solution. When success is obtained with any of these metals, it probably will be under conditions that are much more restricted than those observed in the normal-electronegative group.

Given a metal that can be formed by reduction using these techniques, it is necessary to find the proper combination of metal compound and electrolyte that will make this reduction possible. Whenever a compound of a metal in the normal-electronegative group that was slightly soluble in the electrolyte was tried, successful reduction to a porous metal plate was always achieved. A slight solubility is not a necessary condition and probably not a sufficient one. If the compound was highly soluble in the electrolyte, failure resulted due to the paste dissolving off the grid. In the case of moderately soluble compounds, the reduction is generally more apt to be successful if the electrolyte is saturated with the compound to be reduced. The solubility of the material indicated that electrodeposition from the metal ion could be the major factor in the reduction mechanism.

A number of compounds were found that could be reduced to a porous metal plate even though they were very insoluble in the electrolyte. Most of these could be checked in the literature and were found to be relatively good conductors of electricity. This suggests the possibility that the compound is reduced to metal in the solid state without first going into solution.

Some compounds might be reduced by atomic hydrogen evolved at the cathode. Sancelme (4) has proposed this mechanism for the reduction of certain oxides. His compounds were placed loosely on top of a platinum cathode, and consequently their reduction might also be explained on the basis of other mechanisms.

Formation of Porous Metal Plates by Electrolytic Reduction

II. Electrode Pasting

C. M. Shepherd and H. C. Langelan

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

The successful formation of a porous metal plate from a pasted electrode under pressure in an electrolytic cell depends on the use of an ideal paste wherein the individual particles of the pasted material are compacted closely together. Just enough liquid is present to fill the interstices between the particles and to take care of what is adsorbed on the surface and in the pores of the particles.

Ideal pastes were prepared from 29 water-insoluble, inorganic metal compounds, and it was found that the ease of pasting and the quality of the paste improves markedly with decrease in particle size of the material being pasted. The best pasting conditions are obtained with materials whose particle size distribution has a geometric mean diameter of less than 0.7μ. The best estimate of pasting quality can be obtained from R, the ratio of the true density of a material to its tap density. When R is greater than 3.8 for a material, it has good pasting qualities.

In using the techniques of Shepherd and Langelan (1) to prepare a porous metal plate by electrolytic reduction of a pasted compound under controlled pressure, successful results depend on several essential factors, one of which is the pasting properties of the compound or mixture that is being used. There is an optimum range of pasting conditions which must be maintained in order to obtain a good porous metal plate. For some materials, this range is very narrow and difficult to maintain. For other materials the range is somewhat wider; satisfactory pasting is comparatively easier to achieve, and the quality of the reduced metal plate is better. The problem is aggravated by the fact that the com-

pound is spread as a stiff paste on top of a wire screen which has a minimum of support to hold it in place and then is immersed in an electrolyte which may tend to cause shedding. A much simpler problem exists in the pasting of commercial battery plates, where the paste is held in pockets and can vary in consistency from very stiff to soft and mushy.

A brief study was made here of each of a large number of compounds in an attempt to find some of the general principles involved in pasting. Although the substances surveyed were limited to metal compounds that were insoluble in water, it is highly probable that the results of this study will apply to many other types of materials. The metal compounds tested included many that could not be reduced to porous metal plates.

Experimental

Five to ten grams of powdered material plus a suitable amount of liquid were made into a paste and applied evenly to both sides of a 3.8 cm^2 wire screen. The pasted screen was wrapped in a single layer of facial tissue to prevent sticking, then put between two Teflon sheets, placed in a close fitting metal die the size of the screen, and pressed in a Carver press at enough pressure to give a final, flat, smooth homogeneous pasted electrode. The plunger was made slightly smaller than the cavity of the die, thus avoiding a waterproof seal and making it possible to press excess liquid out of the pasted plate. An ideal paste was completely retained under these conditions. When the first increment of the pressure was applied to a properly prepared paste, the paste flowed some and was accompanied by a flow of liquid out of the paste. Consequently, the pressure dropped. Further increments of pressure were applied fairly rapidly until a pressure was reached that held steady for several seconds before it started to drop. This pressure was called the minimum pasting pressure. At this point the pasted grid was finished and ready to remove from the die. Large variations of the pasting pressure had no detectable effect on the porosity of the final metal plate as long as the minimum pasting pressure was achieved.

If the compound was to be reduced to metal, the plate was removed from the die and placed quickly without drying or curing into a special cell where it was reduced electrolytically under a controlled physical pressure.

Experimental Results and Discussion

It was found that a porous metal plate having optimum properties in regard to such characteristics as strength and resistance to crumbling could be produced whenever the individual particles in the pressed paste were compacted closely together and had just enough liquid present to fill the interstices. Pastes of this type, prepared from various compounds, were found to have a number of physical properties in common and are defined here as ideal pastes. The ideal paste has a dry appearance, is slightly flexible, and yet is not crumbly. The percentage of liquid present in a particular powder-liquid combination is fixed within fairly narrow limits. An excess of liquid tends to separate from the ideal paste, particularly when it is subjected to pressure. A deficiency of liquid causes the paste to be dry and crumbly. In this condition it readily absorbs liquid. This description of an ideal paste is not limited to pastes that can be reduced electrolytically to a porous metal plate. This study was made using a large number of various water-insoluble, reducible, and irreducible metal compounds pasted with water or aqueous electrolytes and undoubtedly can be extended to pastes made from many other types of compounds and liquids. If the compound was to be reduced electrochemically to the metal, the liquid medium used to prepare the paste was some of the electrolyte in which the reduction was to take place. If the material being pasted was slightly soluble, then a saturated solution of the material in the electrolyte was used in most cases as the pasting liquid. All of the numerical data presented here were obtained from pastes made with a liquid binder of pure water.

The amount of liquid used is the main factor that has to be controlled in making a satisfactory paste. The best results are obtained by using a very slight excess of liquid in forming the paste. This excess is pressed out and can be detected when the pasted grid is removed from the die. Under ideal conditions the excess liquid is accompanied by no more than a very slight trace of the material being pasted. The reading of the minimum pasting pressure is clear on a paste containing the proper amount of liquid. If the paste is too dry, it does not flow well under pressure and forms low spots in the electrode where the amount of paste is less than average. A dry paste does not wet the grid properly and will not be adherent. It is grainy, crumbly, and tends to shed, particularly on edges and corners, whenever it is handled and when the electrolyte is added. When this dry paste is charged, reduction may be incomplete in the low spots, and any metal formed there may be crumbly and nonadherent. The pressure present in the electrolytic cell is light and is applied mainly to the high spots where the paste is thickest and these areas reduce satisfactorily.

If the paste is too wet, it is sticky and tends to pull off the screen when removed from the die. If the paste is excessively wet it flows off the screen like water when pressure is applied in the die.

There is a considerable variation in the pasting properties of various compounds. It was possible to divide all of the compounds tested into five arbitrary groups depending on their ease of pasting and quality of the paste. These groups were labeled "very poor," "poor," "fair," "good," and "very good." Since these divisions were based on the judgment of the operator, they were not sharp and there was a certain amount of overlapping. It was very difficult to maintain proper pasting conditions with compounds in the very poor group. The poor group was somewhat better. Compounds in the good group pasted satisfactorily by using a little care. Compounds in the very good group were pasted successfully over a fairly wide range of conditions, and the pasted grids were subjected to considerable handling and other abuse without showing any appreciable deteriora-

tion. The liquid content in the paste had a wider range of acceptable limits for a very good material than it had for a very poor material. Compounds in the good and very good groups were the only ones that came close to forming "ideal" pastes. The fair to very poor groups deviated to some extent from the above description. Thus, the ideal paste can be looked on as a limit that is approached as one moves from a very poor to the very good material. Very poor compounds when pasted and reduced electrolytically under pressure generally gave porous metal plates that were grainy and crumbly whereas the good and very good compounds gave porous metal plates that had good physical properties and were not crumbly. The fair and poor compounds also produced good porous metal plates, if they were properly pasted.

At this point the concept of an ideal paste and the outline of pasting conditions as given here are qualitative descriptions based on the qualitative observations and personal opinion and evaluation of the authors. A more scientific evaluation of pasting is needed. It is desirable to have some quick reproducible test or measurement that will predict the pasting properties of a powdered material, thus simplifying industrial control and also making it possible to evaluate the relationship of pasting properties to other variables. The liquid content and minimum pasting pressure give a fairly good estimate of the paste group, but can be determined only after the material has been successfully pasted and consequently the pasting properties are already known.

It was found that good predictions of pasting properties could be made from the quantity R_1, which is defined as the ratio of the true density to the apparent density. The apparent density is defined as the grams per cubic centimeter of unpacked material, which is free from pockets or unfilled cavities. In this condition, adjacent particles are as close together as they will get without being subjected to some compacting, mechanical force such as tapping. In Fig. 1 the pasting properties of the various materials under study are plotted against values of the dimensionless quantity R_1. The compounds and mixtures are listed from top to bottom in the order of their ease of pasting. The paste groups are also indicated. These materials cover a wide range of water-insoluble metal compounds. There are a few materials of this type that would not fit into this analysis such as MoS_2 which does not wet and $CaSO_4$, which hardens.

The data in this report are subject to considerable variation because the relationships are not exact and because the assignment of paste groups is an arbitrary factor. By the use of statistical procedures all of the relationships presented in this paper were shown to be highly significant. The Spearman rank coefficient of correlation, r_s, for the data in Fig. 1 is 0.914. Values of r_s for other relationships are given in Table I.

An excellent prediction of the paste groups can be made from

$$R = \frac{\rho}{\gamma}$$

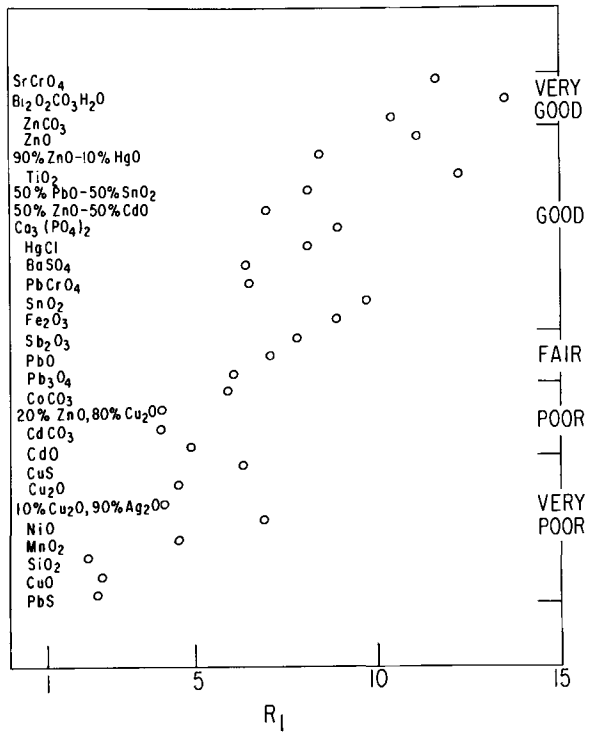

Fig. 1. Relationship between the ease of pasting and R_1, the ratio of the true density to the apparent density.

where ρ is the true density of the material and γ is its tap density. The tap density which has also been called packed density, bulkiness, and bulk density is the density in grams per cubic centimeter obtained by placing the powder in a cylinder and tapping to a constant volume. There are a large number of factors in the determination of the tap density that may cause variations as high as 7% in the results (2-5). All of the measurements used here were made with a glass cylinder which weighed 22g and had an internal diameter of 1.15 cm. The height of powder at the end of the tapping was approximately 6 cm and the tapping rate was 30 times per minute. The cylinder was inclined 10° from the vertical and dropped in a free fall of 2 in. on a hardwood base. If a loose layer formed on the top of the powder, it was either poured off or compacted by rapid vibration. Tapping was continued until no change in volume was observed for eighty taps. Under these fixed conditions the results were reproducible in most cases to within 2% if ordinary care were taken.

Average values of R for the various paste groups are shown in Table I. R can be determined in a few

Table I. Properties of the paste groups

Paste group	Average value of $R = \frac{\rho}{\gamma}$	Average value of particle size, d_g μ	Average value of the minimum pasting pressure kg/cm²	Average H_2O content vol-%
Very good	5.48	0.303	4.16	59.7
Good	4.61	0.536	59.7	54.2
Fair	3.22	0.780	156	42.8
Poor	2.53	0.971	194	36.5
Very poor	2.12	1.240	245	32.1
Spearman rank coefficient of correlation, r_s	0.918	0.794	0.834	0.821

minutes and gives an excellent estimate of the pasting properties. All of the materials in the good and very good paste groups had values of R greater than 3.8. All of the materials that were more difficult to paste were in the very poor, poor, and fair paste groups and had values of R less than 3.8.

Roller (2) and Shapiro and Kolthoff (6) have shown that the bulkiness of various powders increases rapidly as the particle size decreases below a critical value. As a consequence, R should increase with decrease in particle size, and the particle size should decrease in going from the very poor to the very good paste group. The particle size distribution was determined microscopically on the materials listed in Fig. 1. The geometric mean diameter, d_g, was chosen as the typical particle size. It is defined by the formula

$$\ln d_g = \sum f \left(\frac{\ln d}{n} \right)$$

where n is the number of particles and f is the frequency of occurrence for particles having a particular measured diameter, d. The average values of d_g for each of the paste groups are shown in Table I. From a practical viewpoint most materials that had a value of d_g less than 0.7 microns fell in the good or very good paste groups and could be pasted easily. This was not a particularly sharp division and did not give as good a separation of the paste groups as R. Moreover, it was much more difficult to determine. However, it seems likely that the particle size distribution is the most important factor in determining the paste group of a given material. Consequently, a poor pasting material can be converted in most cases into a good pasting material by preparing it in a finer size.

The average values of the minimum pasting pressures for each of the paste groups are shown in Table I. The very poor paste group had an average minimum pasting pressure that was more than 50 times as large as the average for the very good group.

The average water content of the different paste groups is shown in Table I. Humidity changes affect the pasting of a very poor compound since the volume of liquid used is quite small and must be held within very narow limits. For a very good material the volume of pasting liquid can be varied over much wider limits and still give satisfactory pasting conditions over a moderate range of humidities. If a satisfactorily pasted screen is allowed to dry, it cracks and becomes crumbly. The time of storage in open air before this deterioration occurs depends on the humidity and was about 2 min for a very poor paste and about 20 min for a very good paste. Longer storage periods can be achieved by the use of controlled humidity chambers.

The pasting properties of a particular compound depend to a certain extent on the liquid used in making the paste. A better, more homogeneous paste is obtained in most cases if the compound is slightly soluble in the liquid or reacts chemically with it to a limited extent. An excessive reaction or a high solubility is generally undesirable. Water is a comparatively poor liquid for pasting water insoluble compounds. Ten per cent H_2SO_4 is much better. The best liquid tested was 32.6% KOH, and this was used for pasting most of the compounds that were reduced electrolytically. Tests on a number of compounds using these three liquids show that, if the compounds are labeled by rank according to ease of pasting with a particular liquid, there is a good correlation with the results obtained by using another pasting liquid. Thus, the compounds that paste best with water paste best with 32.6% KOH and the ones that paste poorest with water are poorest with KOH even though water gives poorer over-all results. The difference in the pasting properties of liquids showed up mainly in the fair, poor, and very poor groups. All of the numerical data presented in this report were obtained by using pure water as the liquid medium.

In preparing a porous metal electrode of controlled porosity by electrolytic reduction of a pasted metal compound a number of difficulties are encountered due to the fact that the paste rests on top of the grid and is subjected to physical pressure. These difficulties are minimized by preparing an ideal paste of controlled composition and physical properties from a material having a fine particle size distribution.

Manuscript received Oct. 20, 1961; revised manuscript received April 11, 1962. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Multiple Rate Transitions in the Aqueous Corrosion of Zircaloy

B. Griggs, H. P. Maffei, and D. W. Shannon

Hanford Atomic Products Operation, General Electric Company, Richland, Washington

ABSTRACT

The weight gain of Zircaloy-2, -3, and low nickel Zircaloy-2 during water and steam corrosion is shown to go through two or more repetitive cycles. The evidence indicates these weight gain curves truly represnt the corrosion kinetics. Several corrosion mechanisms are considered in the light of these kinetics. While no definite mechanism can be established, a supposition that stresses in the film periodically cause it to crack at or near the oxide-metal interface appears consistent with the data. Preliminary micrographic evidence supporting the existence of a cyclic corrosion process also is shown.

The rate of corrosion of Zircaloy-2 in high-temperature water has usually been represented (1, 2) as an initial cubic relation of weight gain to time, followed by a linear relation. The "transition point" between these two modes of corrosion is sometimes accompanied by a change in the appearance of the oxide film (2, 3) from black to gray or white. Most of the previous data have indicated only one transition point in the corrosion process. More recently, there has appeared (4, 5) some evidence that the cubic portion of the curve is followed by two linear curves, the first a short steep curve and the second a flatter curve for the balance of the test.

The "weight gain *vs.* time" data for several Zircaloys presented were obtained over several years at the Hanford Atomic Products Operation. These weight gain curves demonstrate a cyclic corrosion process with several rate transitions. The two-step transition (4, 5) would be interpreted as the second cycle of this repetitive process.

Experimental Details

Zircaloy coupons were exposed in refreshed autoclaves at 360° and 400°C. Deionized water (4 ppm O_2 from air) was pumped through the preheater, through the AISI 316 stainless steel autoclave, and out through a cooler and relief valve. The 5-gal, 360°C autoclave was operated at a flow of about 8 l/hr. The 1-liter, 400°C autoclave was operated at a flow of 0.4 l/hr. The coupons were suspended on AISI 347 stainless steel wire racks.

The coupons were rolled sheet material of Zircaloy-2, -3, and low nickel Zircaloy-2 (Table I), prepared by chemical etching 2 mils of each surface in 33 w/o HNO_3-1.85 w/o HF, and thorough rinsing. The etched coupons were weighed, autoclaved, dried at 110°C for 1 hr, reweighed, and returned to the autoclave for further exposure.

Coupons were weighed to ±0.02 mg and measured to ±0.002 dm^2. The samples in Fig. 4, however, were weighed to only ±0.2 mg and measured to

± 0.002 dm^2. Coupons were about 7 to 13 cm^2 of surface area. Corrections for edges and holes were included in the areas. Weight gains were not corrected for hydrogen pickup. Errors in weight of ± 0.02 mg could give rise to a maximum deviation of ± 0.3 mg/cm^2 and ± 0.2 mg/cm^2 for samples of 7 cm^2 or 13 cm^2, respectively.

Discussion

The corrosion of Zircaloy-2 in high-temperature water and steam produces adherent layers of zirconium oxide on the surface of the metal. Inert marker experiments indicate that the corrosion takes place by the diffusion of oxygen ions through the oxide film to form new film near the metal surface (1, 2). This oxide is quite inert and has not been removed quantitatively without damage to the metal. Therefore, corrosion measurements on Zircaloy are determined by weight gain until it becomes apparent the oxide is sloughing. Using weight gain as a true measure of corrosion involves several assumptions. These assumptions are:

1. The ZrO_2 corrosion product is not lost from the sample. During the period prior to the first transition, the black oxide adheres tightly and there is no evidence of spalling. After the first transition, some alloys spall severely and thereby make weight gain measurements useless. However, Zircaloy-2 is noted for its adherent oxide and even after extensive corrosion, weight gains are thought to indicate the corrosion process, although some errors result. Zirconium oxide is very insoluble in water and losses from this source are insignificant.

2. Substances other than oxygen are not picked up from the system. Since all the corrosion experiments were done with high-quality demineralized water, there is no possibility for salt deposition nor were any foreign deposits observed. The weight gains of samples in different stages of the corrosion process, all of which were exposed in the same autoclave at the same time, differ considerably. Presumably any deposition would be more or less uniform on all samples. Thus there is no apparent deposition on the samples. From 5-50% of the corrosion hydrogen is absorbed by the metal. However, even at 100% absorption, the hydrogen weight gain cannot exceed 13% of the oxygen weight gain. Usually, the hydrogen analysis is destructive, and thus hydrogen cannot be corrected for until testing is complete. For normal Zircaloy-2, the hydrogen weight is negligible except for very long exposures.

3. The composition of the corrosion product is known and constant. X-ray analysis of the film before and after transition shows the film to be ZrO_2 and indicates no gross change in its composition. The oxide is said to absorb some water (6), but no hydrates are known, and the film is assumed to have constant water content after drying at 110°C.

These assumptions have been considered correct in most previous studies of zirconium corrosion. If so, the weight gain and the corrosion process go through a series of repetitive patterns, finally approaching a linear relation with time. This repetitive pattern was common to all alloys tested.

The weight gain data and the corrosion rates of Zircaloy coupons is seriously affected by minor surface or metal impurities (1, 11). Graphs of different runs using different coupon stock, different autoclaves, different surface preparation, and different autoclaving conditions show the generality of this repetitive process (12). Figures 1 and 2 are characteristic of good Zircaloy in 360°C water or 400°C steam, respectively. Figure 3 shows the corrosion curve for a poor alloy.

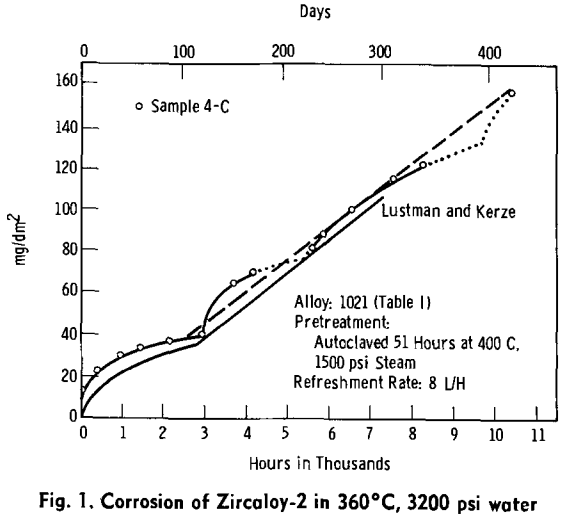

Fig. 1. Corrosion of Zircaloy-2 in 360°C, 3200 psi water

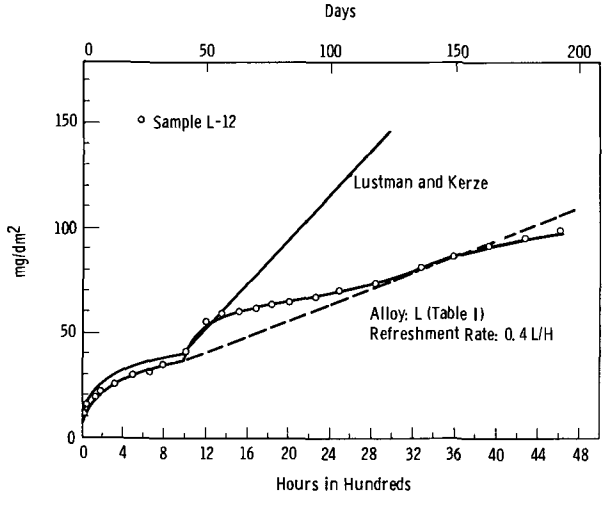

Fig. 2. Corrosion of low nickel Zircaloy-2 in 400°C, 1500 psi steam.

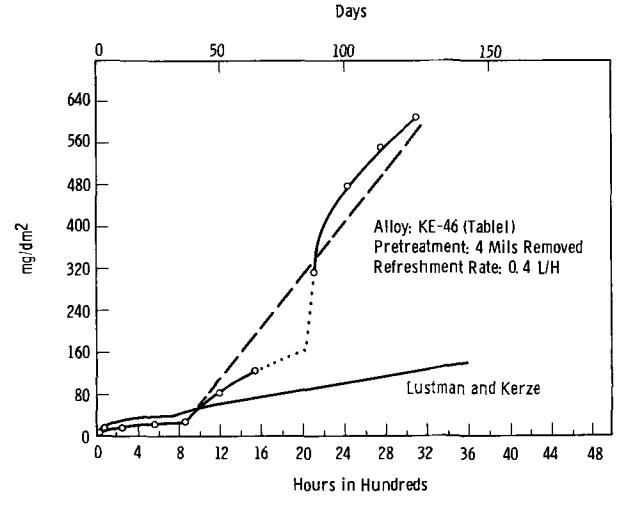

Fig. 3. Corrosion of low nickel Zircaloy-2 in 400°C, 1500 psi steam.

The weight gain of a sample *vs.* time appears in the form of at least two, and as many as four, more or less repetitive curves which resemble the initial cubic curve. Since the weight gain is more accurate than the deviations from linearity, the cycles cannot be explained by experimental error. The successive cycles of the weight gain curve are similar, but not identical. In general, the weight increase during the second cycle is somewhat lower than during the first cycle. The slope at the end of the cycle increases slightly with each cycle, finally approaching a straight line drawn from the transition point. The repetitive effect can also be observed in data from other laboratories (4, 5, 7).

Although all cycles on all coupons have nearly the same period, there is enough difference in their periods to make the use of average weight gains for several coupons misleading. There is also a difference in corrosion from one grain to the next (8), making the weight gain of a single coupon an average for many grains. Therefore, as the number of cycles increases, the coincidence of their periods could decrease and the resultant curves appear as a linear relation with time. The average corrosion of a large number of samples should cause the corrosion curve to appear as a linear function much sooner than would that of the individual samples. An example of this is shown by Fig. 4. These data show an almost linear relation with time. However, this curve was not constructed from repetitive measurements on the same sample, but from samples removed from test for each point. The cyclic behavior is lost due to variation from sample to sample.

It is not possible to define the corrosion mechanism with the available data. However, a mechanism based on mechanical stresses in the film which periodically causes the film to break away from the metal appears consistent with the data. In this model, the ZrO_2 film grows until the stresses, continually set up in the oxide, are relieved by a series of microcracks parallel to the corroding surface. This crack layer is connected to the surface by a network of larger transverse cracks, illustrated in Fig. 6, thus making the bulk of the oxide porous and not protective. After these cracks form, the diffusion path to the metal through any remaining adherent oxide is much shorter; hence, the corrosion rate increases and initiates a second cycle. This alternating process of growth and cracking continues until differences in cycle period from grain to grain become sufficiently out-of-phase to make the average weight gain of the sample appear linear with time.

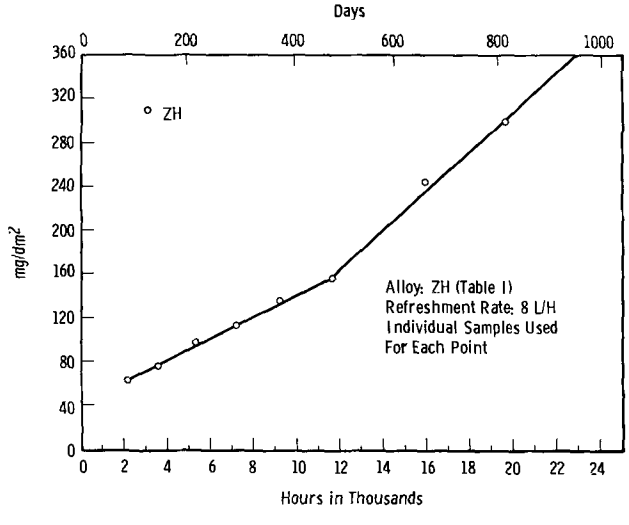

Fig. 4. Corrosion of Zircaloy-2 in 360°C, 3200 psi water

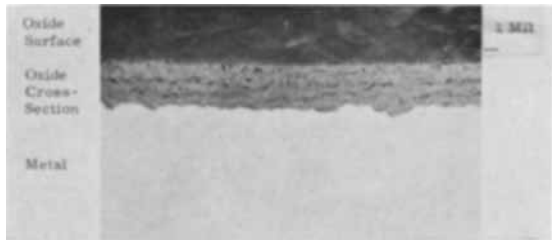

Fig. 5. Cross section of oxide on Zircaloy-2 coupon exposed 10,414 hr in 360°C water. Polishing angle: approximately 20° to oxide surface; etch: vacuum cathodic etch; magnification, 250X, bright field.

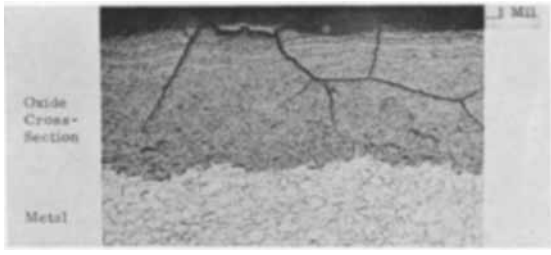

Fig. 6. Cross section of oxide on low nickel Zircaloy-2 coupon exposed 3100 hr in 400°C, 1500 psi steam. Polishing angle: approximately 20° to oxide surface; etch: vacuum cathodic etch; magnification, 75X, bright field.

Several mechanisms of Zircaloy corrosion after the "transition point" have been proposed, but none have gained universal acceptance (1, 2). These include phase transformation of the oxide film at the transition point (1) and cracking of the film at a critical thickness (1, 9). A mechanism similar to the above cracking has been described for titanium in oxygen (10).

A metallurgical section of a Zircaloy-2 coupon exposed to 360°C water for 10,414 hr is shown in Fig. 5. (The corrosion curve is in Fig. 1.) A low nickel Zircaloy-2 exposed in 400°C steam for 3100 hr is shown in Fig. 6. (The corrosion curve is in Fig. 3.) These coupons show a layered structure with the number of layers corresponding to the number of apparent cycles on the weight gain curve. This agreement tends to confirm the conclusion that the corrosion process is cyclic.

The corrosion rate curves presented by Lustman and Kerze in their Fig. 11.38 (1) are plotted to show agreement or disagreement of our data with theirs. The 360°C data agree fairly well. The 400°C data do not agree (Fig. 2 and 3). The KE-46 low nickel Zircaloy-2 is higher than the Lustman and Kerze curve. For reasons not as yet known, the other alloys corrode at a rate lower than the Lustman and Kerze data. Superior corrosion resistance in more recent lots of material may be part of the answer.

It is not possible to tell whether the Lustman and Kerze data show the cyclic process. First, their data do not cover a sufficient time span. Second, only the averages are probably represented and thus any

cyclic behavior is masked. On the other hand, their data are not inconsistent with a cyclic process.

In summary, the weight gain data of several zirconium alloys of various pretreatments all show periodic changes in corrosion rate. Layers observed in the corrosion product oxide further substantiate the cyclic character of the corrosion past the transition point.

The Growth of Electrodeposits

J. M. Keen and J. P. G. Farr

Department of Industrial Metallurgy, The University, Birmingham, England

ABSTRACT

The crystal habit of copper electroplate has recently been explained in terms of the aggregation of growth layers. Experiments are described to test the applicability of this, the concept of "bunching," to the development of other electrodeposits. Zinc has been electroplated from acid sulfate solutions on zinc polycrystalline and single crystalline cathodes and on copper single crystal surfaces. The surface features observed are explained and related to those of copper electrodeposits, in terms of the supposed atomic structure of the substrate surface, of the bulk crystal structure of the deposited metal, and of the growth process. Exploratory work on the deposition of lead, cadmium, and iron on the same metals, respectively, indicates that, although the idea of "bunching" may be of wide application, caution is required in explaining growth features where chemical or electrochemical processes may be structure determining.

Recent work by Storey and Barnes (1) has indicated that the conclusions drawn from a study of the electrolytic growth habit of single crystals of copper (2-4) can be applied to the growth of polycrystalline copper substrates. Electropolished and electroetched surfaces behaved similarly. Briefly, Pick and his colleagues found, for copper, that epitaxial growth occurred with coarse crystallographic facets developing on the surface of the electroplate, up to 50 ma/cm^2. The structure could be related to the atomic configuration of the original substrate surface and to the conditions at the interface between the metal and the electrolyte. In particular the structures were consistent with the supposition that growth occurs by a bunching mechanism (5).

In normal laboratory solutions, as in practical plating solutions where additives are absent, there is an abundance of surface active material, impurity that will compete with depositing atoms for available growth sites on the substrate. Thus, if growth occurs by the spreading of atomic layers, these will tend to coalesce because of the continuous deactivation of growth sites; the coarsening will eventually be observable under the microscope, and ultimately non-epitaxial nucleation will be required if growth is to be maintained at a given rate. "Break-away" then occurs.

While the idea of "bunching" gives a satisfactory qualitative explanation of growth and it may lead to useful experiments on both the plating process and on the metallurgy of the metal produced, it is clearly not without inadequacies. It is not quantitative, even as applied to electrodeposition under laboratory conditions, but explains the growth process as being to a large extent controlled by adsorption of adventitious substances of unknown chemical nature, specific effect, or concentration. However, the concept is a general one and should apply not only to the deposition of copper; an important test of the idea is to compare the electrolytic growth of other metals. For this reason a metallographic and crystallographic study has been made of the growth of zinc electrodeposits from acid zinc sulfate solutions under conditions which were thought to be

comparable with those under which the study of copper had been made. Zinc has been plated onto single crystalline and polycrystalline substrates and onto single crystal copper surfaces. The electrolytic growth of lead, cadmium, and iron have also been examined.

Experimental Part

Preparation of the cathodes.—(In general the anodes were of similarly prepared metal.)

Copper.—Single crystal substrates were prepared as by Pick et al. (2). After electropolishing, the mounted specimens were washed with dilute phosphoric acid (6) and with water immediately before plating.

Zinc.—Large-grained polycrystalline cathodes were prepared by the critical strain-anneal method; single crystals were grown by a modified Bridgman technique. Crystals were cut and mounted in cold-setting resin. Such specimens had a heavily deformed surface layer which had recrystallized to a depth of some 900μ. After mounting they were polished carefully metallographically, the deformed layer remaining after diamond polishing being removed by electropolishing. The best surfaces were produced in a 50% by volume orthophosphoric acid-ethyl alcohol solution using a stainless steel cathode with the anode held horizontally. Optimum polishing conditions were found to exist between 1.6 and 2.0v with the solution at room temperature. All traces of deformation were removed by polishing for 4 to 6 hr.

Immediately before plating the specimens were given a further electropolish for 5 min, washed with methanol, aqueous sodium hydroxide and briefly (2-3 sec) with concentrated nitric acid. They were then washed thoroughly with water and transferred to the plating bath.

In experiments on cleavage surfaces, these were produced by cleaving a suitable crystal at liquid nitrogen temperature. A number of such faces were plated without further preparation, the remainder were mounted and etched as has been described.

Cadmium.—This metal is exceptionally soft so mechanical polishing was avoided in the later stages of electrode preparation. Coarse-grained 99.995% cadmium cathodes were prepared by the strain-anneal method. Immediately before plating they were electropolished in an aqueous phosphoric acid bath, etched lightly in dilute nitric acid, and washed with water.

Lead.—Large-grained cathodes were obtained by annealing at 150°C in vacuum. These were masked, electropolished in perchloric acid-aqueous ethanol and immediately before plating lightly etched in dilute nitric acid followed by washing with water.

Iron.—Large-grained electrodes were prepared from 99.985% N.P.L. iron by the strain-anneal method. Before plating they were electropolished in perchloric acid-acetic acid, lightly etched in dilute nitric acid, and washed.

Where "stopping-off" was required, "Lacomit" (supplied by W. Canning & Company Limited, Great Hampton Street, Birmingham) was used.

The plating solution.—Zinc.—"Analar" zinc sulfate, "M.A.R." sulfuric acid, and double-distilled water were used. The following solutions were examined: 0.5M zinc sulfate containing 0.5M, 0.1M, 0.05M, 0.025M, and 0.005M sulfuric acid, respectively. As hydrogen was evolved at the cathode, the efficiency of plating was not 100%, but the evolution was not sufficient to necessitate an increase in concentration of the zinc ions in order to maintain the comparison with copper.

Cadmium.—The electrolyte was a solution of 180 g/l "Analar" cadmium sulfate and 27.1 m/l "M.A.R." sulfuric acid in double distilled water.

Lead.—The electrolyte was prepared by saturating a dilute aqueous solution of perchloric acid containing 118.2 ml of "Analar" grade perchloric acid (S. G. 1.70), with "Analar" lead monoxide and filtering. To this was added a further 118.2 ml of "Analar" perchloric acid and the volume made up to two liters with double distilled water, giving 0.5M lead perchlorate in 0.5M perchloric acid.

Iron.—"Analar" grade ferrous sulfate and "M.A.R." sulfuric acid were used. The following three electrolytes were tried: (i) 0.5M ferrous sulfate, 0.5M sulfuric acid; (ii) 0.5M ferrous sulfate, 0.025M sulfuric acid; (iii) 0.5M ferrous sulfate, 0.025M sulfuric acid, 0.01M hydrazine sulfate.

The plating cell.—The electrolyte was contained in a 2 liter beaker suspended in a constant temperature bath normally maintained at 25°C ± ¼°. The relative positions of anode and cathode were fixed by means of a perspex jig, out of contact with the electrolyte. The current used was supplied from a 12v battery through variable series resistances.

The plating technique.—This was so designed that the cathode could be transferred to the cell and brought up to full current density with the least possible delay. After plating the current was switched off, the specimen removed from the cell and immersed in water. It was washed with methanol and stored in a vacuum dessicator over phosphorous pentoxide.

Examination of the deposits.—The cathodes were examined before and after plating by a selection of the following techniques.

Optical microscopy.—The structures were examined using direct and oblique illumination and line profile techniques. A number of plated specimens were sectioned to reveal surface contour and the metallurgical nature of the deposit.

Optical goniometry.—The Miller indices of the growth facets on deposits grown on single crystal substrates were deduced from their inclination to the cathode surface as was determined using a two-circle goniometer.

X-ray diffraction.—The complete orientation of single-crystal cathodes was determined before and after plating by the back reflection Laue method. Strain or distortion in the surface or deposit could also be detected. The interpretation of the diffraction pattern, as is fully described by Greninger (7) and by Barrett (8), was simplified by the low symmetry of zinc. It was found that, using white copper radiation produced at 18 ma and 40 kv with an ex-

posure time of 25 min, zinc deposits were penetrated to a depth of 35.8μ by the x-rays. This is a thickness twice that corresponding to the passage of 36 coulombs in a standard deposition experiment. However, although complications arose occasionally, in general the reflection from the base through the deposit was weak compared with reflection from the deposit, and any misorientation between the two was immediately obvious.

Reproducibility.—It is probably true that all workers who have investigated the surface topography of electrodeposits have found difficulty in obtaining reproducibility. The experiments described did not prove exceptional, and it was regarded as essential to apply a criterion to test that solutions gave reproducible structures in the deposition of zinc. During work by Pick *et al.* (2) on copper a satisfactory criterion was developed which fulfilled the requirements of structure sensitivity and convenience. This was based on the sensitivity of the structures obtained on a copper (100) surface to solution impurity. The structure accepted as typical of a satisfactory solution is shown in Fig. 9; all the structures described by Pick and his co-workers were obtained from solutions tested to give this structure on a copper (100) substrate. It was decided to use a similar criterion for zinc; a zinc single crystal surface, with an (0001) orientation, was plated at 10 ma/cm^2 for 60 min in a solution of 0.5M zinc sulfate, 0.5M H_2SO_4 maintained at 25°C. Figure 1a shows the deposit structure considered typical from such a solution. From solutions of different acidity the structures were not identical and secondary standards were necessary. These are also illustrated in Fig. 1.

Results

As far as possible the results of this investigation are given pictorially and in comparison with the growth of copper deposits.

The first point of note is that, in general, zinc deposits give less variety of structure than do copper. Figure 2 shows the variations in crystal habit produced in plating zinc onto zinc cathodes of orientations shown in Fig. 3; these structures may be compared with those observed in copper deposition (4). The crystallographic indices of facets developing as determined by goniometry are given in Table I.

The second point is that, unlike in copper deposition, hydrogen is evolved and also zinc is an amphoteric metal. It may be thought that the effect of hydrogen evolution is trivial; however, the volume of gas evolved is sufficient to lead to a marked disturbance of the layers of electrolyte in the immediate vicinity of the cathode. Figure 4 gives some indication of the relative effects of acid concentration and current density. There are more inclusions at low acidity and low current density; under these conditions it is thought that the pH may rise locally allowing basic salts to form (9).

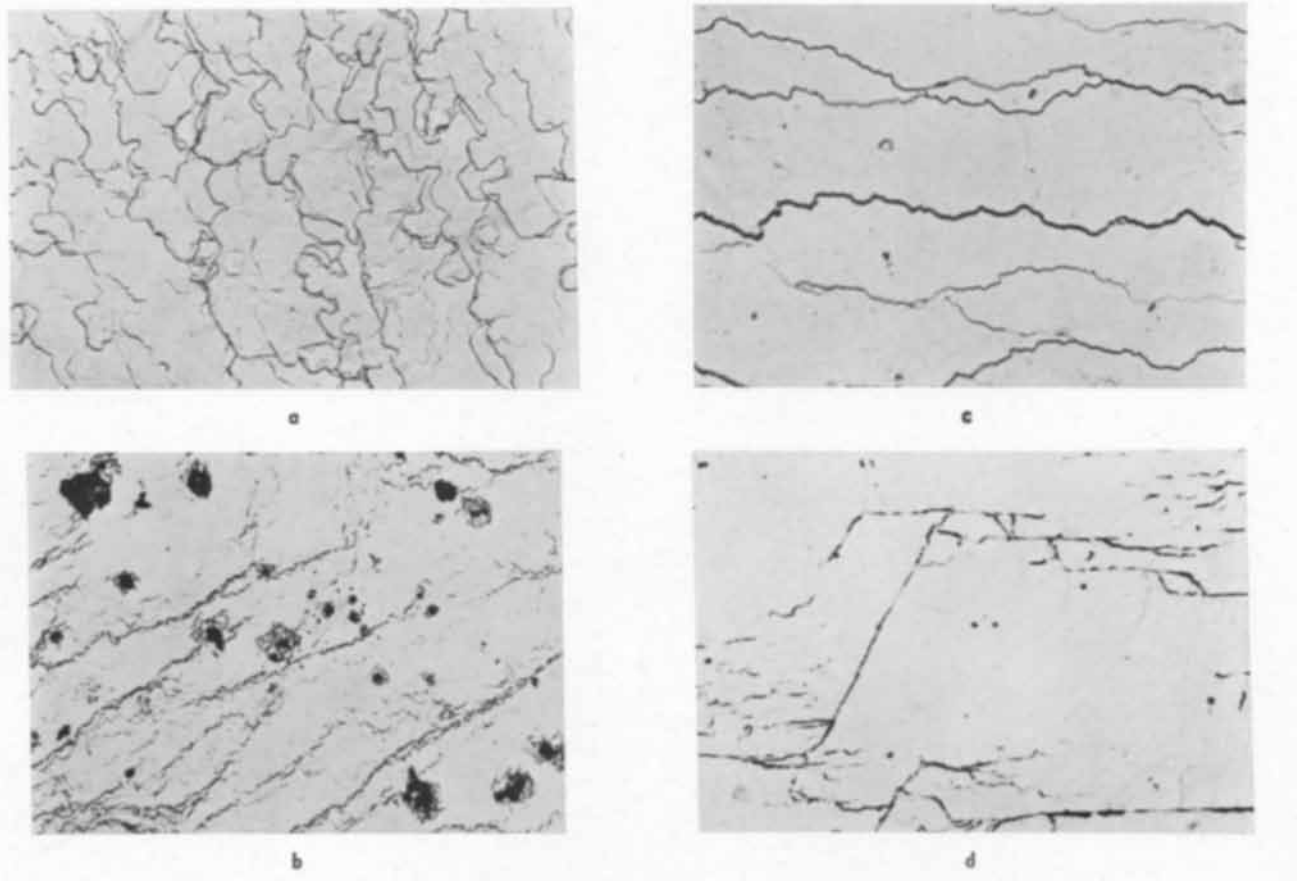

Fig. 1a. Reproducibility test, standard structure; deposit produced at 10 ma/cm^2 for 60 min at 25°C in 0.5M $ZnSO_4$, 0.5M H_2SO_4 electrolyte on a (0001) electropolished face; magnification 900X. Fig. 1b 270X; Fig. 1c 270X; Fig. 1d 86X. (Fig. 1b, c, d. Secondary standards; reproducible structures.) Fig. 4. Effect of acid concentration and current density on the structure of deposits formed on single crystal bases with an orientation within 4° of (0001). (a) 5 ma/cm² 0.5M H_2SO_4; (b) 5 ma/cm² 0.1M H_2SO_4; (c) 5 ma/cm² 0.05M H_2SO_4; (d) 5 ma/cm² 0.005M H_2SO_4; (e) 30 ma/cm² 0.1M H_2SO_4; (f) 30 ma/cm² 0.05M H_2SO_4; (g) 30 ma/cm² 0.005M H_2SO_4. Deposition was for 36 coulombs/cm² and the concentration of zinc sulfate was 0.5M in each case.

The third notable feature is that deposit structures developed with time in a way directly comparable with the growth of copper; see, for example, Fig. 5. Some analysis of the coarsening exhibited was possible.

The effect of temperature was complex; it is shown in Fig. 6, but no explanation for the variation in structure is offered at this stage.

Influence of the Substrate

The influence of the nominal orientation of the etched zinc single crystal cathode has been shown in Fig. 2. Deposits on unetched cleavage surfaces were very different from those shown in this figure. In general such deposits were not epitaxial and were

fine but nonuniform [cf. Cavallero and Bolognesi (10)]. Hexagonal growth features and spirals were sometimes visible. The deposits on etched cleavage surfaces were quite different from those obtained on electropolished surfaces near (0001); compare Fig. 7 and 4. Certain areas of the cleaved surfaces were heavily twinned; the deposit structure on the twin was typical of that on orientations away from (0001), but around the twin growth was typical of the cleavage plane. Cleavage steps only influenced the deposit locally.

More interest attaches to the deposition of zinc on prepared copper surfaces. The deposits coarsened with time, an effect that might be expected if conventional bunching occurs, but the deposits showed a marked difference from the development of copper on the same substrates; compare, *e.g.*, Fig. 8 and 9. In Table II the results of a goniometric examination are given.

Figure 10a shows the structure of a grain of a polycrystalline zinc cathode after the passage of 36 coulombs during electrodeposition. Figure 10b shows the same area after removing part of the electrodeposit by mechanical and electropolishing, and etching the surface so produced. Clearly the development of the crystal habit is continuous, and the distribution of etch pits indicates that the regions where neighboring growth features impinge are disordered and probably contaminated.

Finally, in Fig. 11 and 12, examples are shown of the growth of cadmium and lead polycrystals. The comparison of the structures observed with the habit of copper electrodeposits [*e.g.*, Fig. 9, also ref. (4)] is discussed below. No iron was deposited on iron or copper electrodes from electrolytes (i) and (ii) described above. Iron was deposited with very slight evolution of hydrogen from solutions containing hydrazine sulfate. X-ray diffraction photographs taken of the deposit on individual grains showed them to be polycrystalline. Iron deposits on copper single crystals were discontinuous. The growth of iron under our conditions clearly could not be compared with the growth of the other metals considered and will not be discussed further.

Discussion

Deposit Topography

At first sight, the considerable differences between the crystal habits of electrodeposited copper

and zinc are disconcerting, but some understanding can be obtained from a consideration of the crystallography of the two metals. Pick, Storey, and Vaughan (2) have explained the structure forms on copper in terms of the arrangement of atoms in the substrate surfaces; the surface atoms of zinc substrates are arranged very differently due to the difference in crystal structures. The close-packed planes are normally present in the final form, to the exclusion of planes of higher indices, and so the number and symmetry of these has a direct bearing on the deposit topography. Copper, having a greater symmetry has many more close-packed planes than zinc and so one would expect to find different structures on zinc electrodeposits if growth occurs by a bunching mechanism. However, the arrangement of the surface atoms in the copper (111) and zinc (0001) planes are identical; correspondingly very similar deposit structures have been obtained by the deposition of (*a*) zinc onto a zinc (0001) plane; (*b*) zinc onto a copper (111) plane; (*c*) copper onto a copper (111) plane (Fig. 13).

The apparently complex structures observed on the various zinc substrates orientations shown in Fig. 2 can be interpreted in terms of one basic model. Ball models of facets of the zinc crystal show clearly that apart from the (0001) basal plane the faces of the $\{10\bar{1}\bar{1}\}$ zones are far more important than the remainder, and these faces do not vary very much in importance one from the other. For any base orientation away from the (0001) plane there are no planes suitably orientated, sufficiently close packed and isolated to predominate over the remainder. Thus a simple platelet, block, or ridge

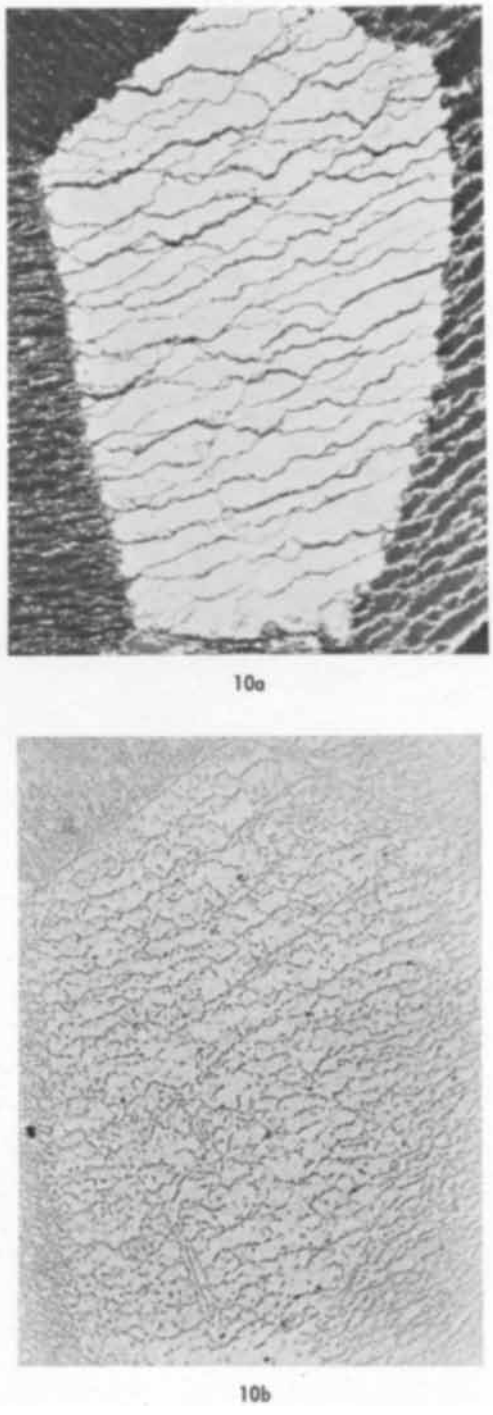

Fig. 10a (top). Deposit on a single grain of a zinc polycrystalline cathode after passing 36 coulombs/cm^2; Fig. 10b (bottom) Etched horizontal section through the same deposit. Magnification 320X.

structure is not formed. One has, instead, complete zones of faces developing. This is illustrated in Fig. 14b which is an idealized structure for an orientation near a $(1\bar{1}00)$ plane. As can be seen from the stereographic projection illustrating the facets developed on this orientation in practice (Fig. 14a) there is some complication of the idealized structure by a few minor facets which develop between two adjacent $\{10\bar{1}\bar{1}\}$ zones. Figure 14b shows only one step edge whereas a real surface will be covered by many such steps; the density and closeness of packing of these will be determined by the base orientation.

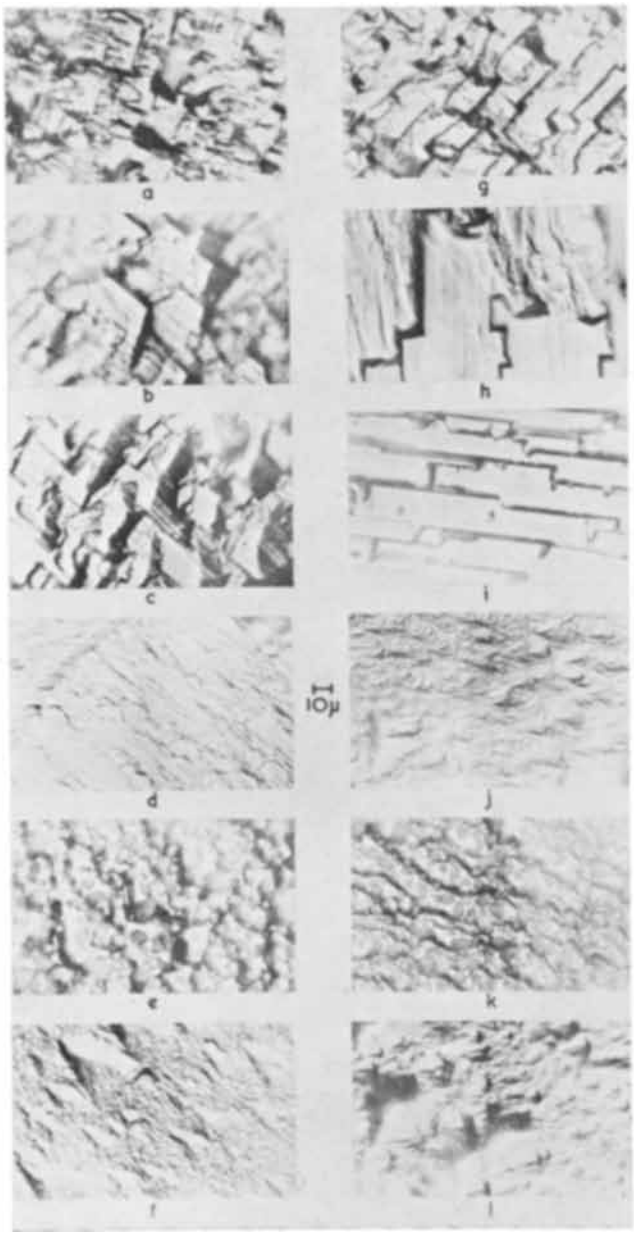

Fig. 11. Structure of cadmium deposits on cadmium polycrystals, produced by plating in 1.4*N* $CdSO_4$, *N* H_2SO_4 electrolyte at 25°C. (a) to (f) current density 10 ma/cm²; (g) to (l) current density 30 ma/cm².

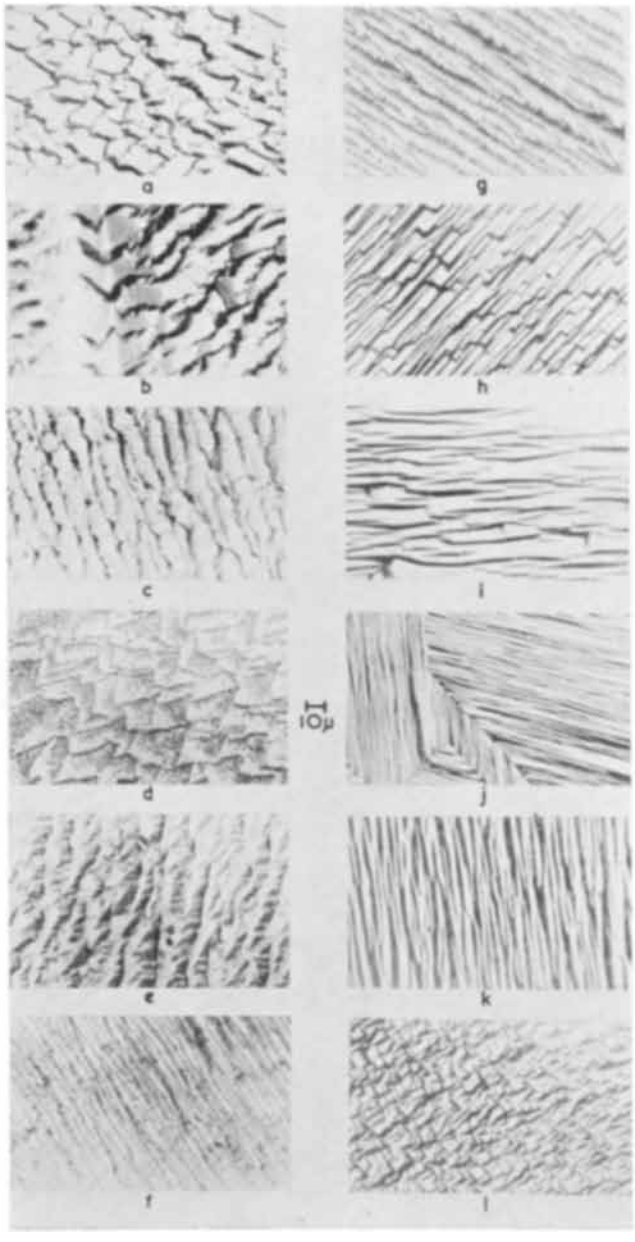

Fig. 12. Structure of lead deposits on lead polycrystals, produced by plating in 0.5M lead perchlorate, 0.5M perchloric acid electrolyte at 25°C; (a) to (f) current density 10 ma/cm²; (g) to (l) current density 20 ma/cm².

The structure on any substrate orientation is made up of "unit blocks" which can be obtained from the one in Fig. 14b by rotating that structure with respect to the plane of the paper until the desired substrate orientation is obtained. Thus for base orientations near a $\{1\bar{1}01\}$ zone there is one zone of $(1\bar{1}01)$ faces with their close-packed direction parallel to the surface and a second zone at approximately 60° to the surface. Hence the deposit structure consists of long lands of the former zone of planes terminated by facets of the second zone, *i.e.*, a pencil-like type of structure (Fig. 2 a, b, g).

As the substrate orientation approaches the (0001) plane the (0001) face becomes increasingly dominant, and at the same time the angles which the zones subtend at the surface decrease, the differences between these angles decrease, and so the zones became more equivalent to each other. Thus in the limiting case–the (0001) basal orientation–each of the three $\{10\bar{1}1\}$ zones are of equal importance and an hexagonal structure results (Fig. 1). Just off this orientation a platelet structure will be formed.

From Fig. 14c it can be seen that on base orientations on a $\{2\bar{1}\bar{1}1\}$ zone, two zones of $(10\bar{1}1)$ faces will develop to an equal extent, and on orientations between this and a $\{10\bar{1}1\}$ zone or the (0001) plane there will be a gradual transition in structure similar to that already described. It is worth noting that at a $(2\bar{1}\bar{1}2)$ orientation the (0001) $(10\bar{1}0)$ and $(1\bar{1}00)$ planes lie symmetrically in the surface. With the development of the two $\{10\bar{1}1\}$ zones and the basal plane a pyramidal structure results as is shown in Fig. 2j. Figure 15 shows the development of this type of structure.

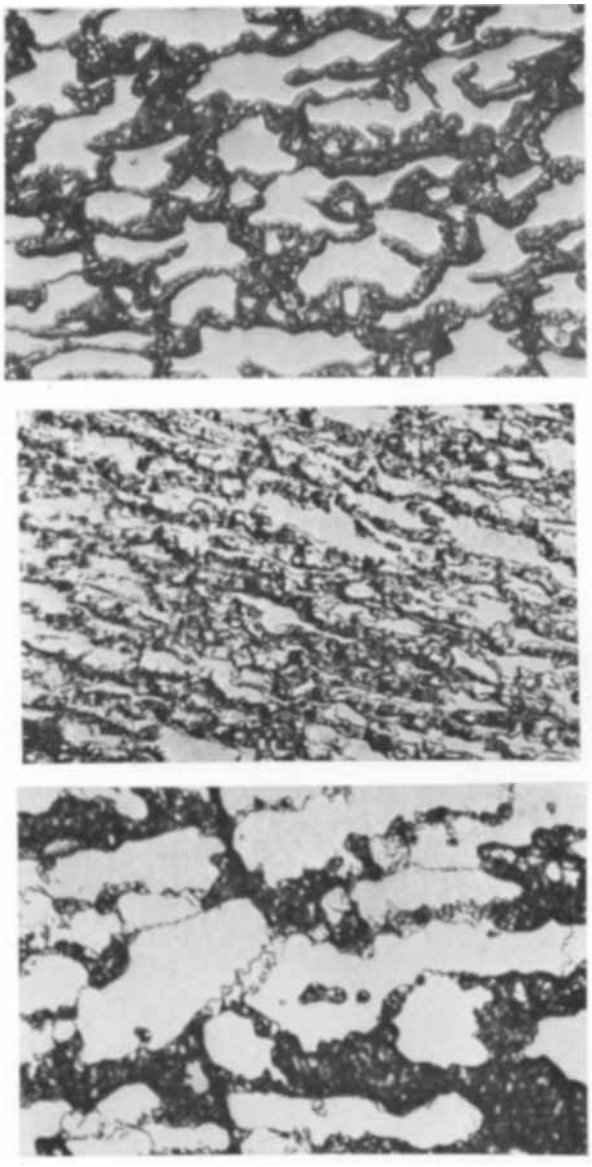

Fig. 13. Comparison between the structure obtained by Pick, Storey, and Vaughan (2) on a (111) face of a copper single crystal and structures obtained during the present investigation by plating zinc on a copper (111) face and zinc on a zinc (0001) face. Deposits of Zinc on Copper Single Crystals

The final structure of the zinc deposits is influenced by the copper substrate in the very early stages of deposition. During this time the crystallographic orientation of the deposit will be fixed. Once the copper substrate is covered, the electrochemical conditions are those where zinc is plated on a zinc substrate; the deposits are influenced by variations in current density and electrolyte composition in exactly the same way as deposits on zinc cathodes, and for the same reasons.

The deposits obtained were epitaxial, usually with the basal plane parallel with the closest packed copper plane in the surface, and with the close-packed directions of the two lattices parallel.

The lattice parameters for the zinc and copper structures are widely different, as are the crystal symmetries. However, the spacings along the [11$\bar{2}$0] and [110] directions (*i.e.*, the close-packed directions) are 2.644Å and 2.556Å, respectively, a misfit of only 4.22%. The degree of misfit between the deposit and the base will depend on the orientations of one with respect to the other. The orientation of the deposit will be determined by the energies involved which will be minimized by having the close-packed directions parallel and the basal plane parallel to the low index plane, thereby minimizing the misfit. Due to the high symmetry of copper, this results in a platelet structure on all orientations (Fig. 8). The angle of the platelets to the surface is determined in the first instance by the angle of the nearest (111) or (100) plane to the surface. In the case of a (110) orientation (Fig. 8) this is at 35° to the surface giving platelets a ridgelike appearance. These ridges are not identical with those obtained in copper deposits on this orientation (Fig. 9). The basal plane is not always parallel to a low index plane because a smaller degree of misfit can sometimes be obtained by having the close-packed and densely packed zones parallel.

Deposits on Cleavage Surfaces

Zinc deposits on lightly etched zinc cleavage surfaces were markedly different from structures on lightly etched electropolished faces of the same nominal orientation. Electropolished surfaces are known to be undulating, providing an abundance of growth sites and steps for growth by bunching. Zinc cleavage surfaces are not perfect [see, *e.g.*, Bassett, Menter, and Pashley (11)]; they contain cleavage steps, twins, and a certain rumpling due to basal plane bending and kinking. In the vicinity of imperfections the deposit structures were similar to those on electropolished surface. It is presumed that, on the remainder of the surface, there are insufficient step sites for the number of atoms arriving and growth proceeds by way of epitaxial nucleation. This is indicated by the circular layers on the upper surfaces of the large hexagonal growth features (Fig. 7), remote from the edges. The structure of the deposit away from the hexagons was very similar to the substructures on the hexagon, which suggests that the whole of the deposit, except possibly the initially formed hexagons, grew by a nucleation process, bunching following during the growth process. On unetched cleavage surfaces deposit structures were anomalous, possible indicating that under the present conditions the freshly prepared surface rapidly became contaminated.

Development of Zinc Deposit Structures with Plating Time

The principles of the "bunching" process have been mentioned earlier, and the results shown in Fig. 5 support the hypothesis. Howes (16), in particular, has shown that the average step height of a copper deposit increases with time, and that steps

Fig. 14. Surface topography of zinc electrodeposits. (a) Stereographic projection of the facets developed (as indexed by optical goniometry) on a substrate of orientation Z, near $(1\bar{1}00)$ (actually orientation b, Fig. 3). The strength of reflection is indicated. Zones of planes B, C, D occurred, together with basal plane A. (b) Idealized structure corresponding to the reflections indicated in Fig. 14(a). The plane of the paper corresponds to the point P in the stereographic projection. The lettering corresponds to the zones. In reality, because the basal plane A lies at an angle to the plane of the paper in the idealized drawing, A intersects zones B, C, D so that re-entrant facets probably do not occur at the step edges. α, β, γ correspond to the $(1\bar{1}00)$ $(1\bar{1}01)$ and $(1\bar{1}02)$ faces, respectively. (c) Stereographic projection of facets developing on a substrate oriented on a $\{1\bar{1}21\}$ type zone, *i.e.*, at orientation f, Fig. 3. (d) Stereographic projection of facets developing on a substrate oriented at $(2\bar{1}12)$, *i.e.*, Fig. 3j.

of small height are gradually eliminated. During the present investigation, it was found that the number of platelets per square centimeter varied exponentially with plating time. The rate of bunching corresponded roughly to a first order process.

Deposits of Lead and Cadmium
Electrochemical Effects

It should be emphasized that this discussion has concerned the accommodation of flux of atoms in the growing crystal lattice. Of course the electrochemistry of deposition cannot be ignored; Frumkin (12) recently reviewed the effect of the structure of the electrolytic double layer on the kinetics of electrode processes. It is not possible to study these effects in a conventional electroplating experiment because of the overwhelming interference of transport effects. Even the extent to which the idea of "bunching" may be applied is limited by the electrochemistry of the deposition process. Figures 11 and 12 show cadmium and lead deposits. Clearly the structures observed in these exploratory experiments indicate a growth process that may resemble that of copper and zinc. The lead deposits show ridge and platelet structures similar, but not identical, to those on copper. Lead has the same crystal structure as copper but with a larger lattice spacing ($a = 4.9495$Å for lead, 3.6153Å for copper), and it would appear that the crystallographic influences of the base are similar. However, the deposit structures obtained on cadmium were dissimilar to those obtained on zinc, although crystallographically the two metals are very similar. They are both close-packed hexagonal with axial ratios greater than ideal, and their equilibrium crystal forms, as calculated by Stranski (13) are identical. Work is needed on large-grained or single crystalline cathodes to clarify the relation between substrate orientation and the growth forms, but it is likely that the exchange current for cadmium is much greater than that for zinc from sulfate solutions, hydrogen is not evolved, and the conditions for the adsorption of surface active material are widely different. It would be of interest to know whether the electrodeposition of cadmium occurs predominantly directly at growth sites, or if an appreciable surface diffusion of adatoms is involved [c.f., Conway and Brockris (14)].

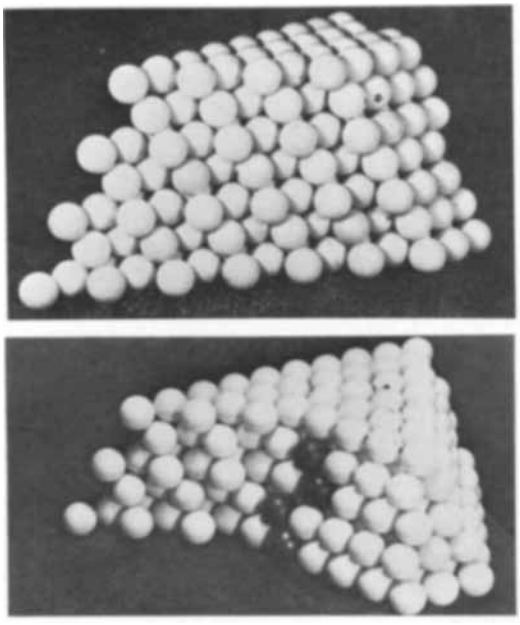

Fig. 15a. (top) Model of the (11$\bar{2}$1) plane in zinc; Fig. 15b. model showing the development of a (11$\bar{2}$1) face into a ($\bar{1}$101) face by bunching.

Conclusions

It is concluded from this examination of zinc electrodeposited on zinc and copper substrates that the concept of "bunching" may be applicable to a range of electroplating systems.

Limitations in the application of the bunching hypothesis result from the many chemical and physical processes involved in a single electrodeposition. Most of these factors are uncontrollable except under special laboratory conditions. The idea may only apply where deposition involves a surface concentration of adatoms rather than deposition directly onto active sites.

Decay of Cathodoluminescence and Nonradiative Processes in Manganese Activated Phosphors

ABSTRACT

Cathodoluminescence emission spectra and decay processes have been investigated as a function of primary electron energy and density for single crystals, evaporated layers, and powder layers of manganese activated calcium fluoride and zinc silicate. The emission spectra were found to be unchanged by the conditions of excitation. The value of the decay constant for powder layers was also unchanged, but that for single crystals and evaporated layers increased as the primary energy was decreased. This behavior is explained in terms of an Auger recombination leading to an interaction between the luminescence centers and the high density of electrons in the conduction band at low primary voltages. It is shown that for such an effect to occur the rate of nonradiative recombination of electrons in the conduction band of the host lattice must be small. This criterion is satisfied in the case of single crystals and evaporated layers, but not in microcrystalline powder layers.

Cathodoluminescence represents the final stage of a series of processes beginning with the absorption of an electron beam in a crystal and ending with the emission of radiation. Information regarding the intermediate stages in the process can only be inferred from the characteristics of the final emission. In many phosphors, the nature of the final radiative transition is uncertain and deductions about the pre-

ceding stages may be ambiguous. The inclusion of manganese as an activator ion in several crystal lattices is known to give rise to an emission resulting from a spin-flip transition within the 3d shell of the manganese ion itself. Under ultraviolet excitation, such a phosphor is characterized by an exponential growth and decay of emission with a time constant independent of the intensity of excitation. Such a phosphor should be of use in experiments designed to investigate the intermediate stages in the cathodoluminescence process.

Many investigations of cathodoluminescence emission spectra and growth and decay time constants have been reported in the literature. Almost without exception, the measurements have been made on phosphors in the form of microcrystalline powders. It is possible that the properties of a phosphor in this form differ from that of the same material in the form of a single crystal. In the present work, the cathodoluminescence of zinc silicate and calcium fluoride with controlled concentrations of manganese has been investigated with special reference to the effect of primary electron energy and density on the emission spectra and decay constant. The phosphors were studied in three different forms, single crystals, evaporated layers, and microcrystalline power layers.

Experimental

Single crystal specimens of calcium fluoride approximately 1 mm in thickness were obtained from large single crystals containing different amounts of manganese. These crystals were grown from the melt by the Stockbarger technique (1) at the Department of Natural Philosophy of the University of Aberdeen. The plates were either cleaved directly from the bulk or cut with a wire saw and polished, using diamond paste. The results reported in this paper were obtained for specimens cut from a crystal containing 0.9% manganese. Powder layers were formed by grinding the single crystal and settling the powder from an aqueous suspension. Evaporated layers were produced by vacuum evaporation of a calcium fluoride-2% manganese fluoride powder mixture with subsequent heat treatment of the evaporated layer (2). Evaporated and powder layers of zinc silicate were prepared in a similar manner with an activator concentration of between 1 and 2% manganese. No large single crystals of zinc silicate were available, but measurements were made on a sintered layer formed by fusing the powder at a temperature close to the melting point. After cooling, the face of the sintered layer was ground smooth with carborundum and polished using diamond paste.

The phosphors were examined in a demountable cathode-ray tube for primary electron potentials of 1-15 kv, and for a steady and uniform excitation of 1-10 $\mu a/cm^2$ over a selected phosphor area. Emission spectra were measured by means of a double monochromator and photomultiplier system, while decay measurements were obtained by measuring the fall of emission after cut-off of steady excitation using a photomultiplier and cathode-ray oscilloscope. The specimen temperature could be varied from room temperature up to a few hundred degrees centigrade. With the system used secondary electron emission characteristics could not be measured, and in order to reduce spurious effects from this source most specimens were aluminized by vacuum evaporation, the coating being connected to the final anode of the cathode-ray tube. Several measurements using unaluminized specimens were also performed to check that the results obtained were independent of the aluminum coating.

Results

Emission spectra.—No significant change in the emission band due to manganese was found as the electron potential or beam current density were varied over a wide range. Small shifts in the spectrum to longer wavelengths were found as the manganese concentration was increased in the case of calcium fluoride. The shift occurred for concentrations at which spin-spin interaction was beginning to be evident in electron resonance spectra of the same specimens. From these results it is evident that the high concentration of electrons at low primary energies has little effect in any direct way on the 3d shell energy levels.

Decay of the emission.—In contrast to spectral measurements, the measurements of decay constant showed variations with form of specimen and with primary electron energy. The results for calcium fluoride and zinc silicate are shown in Fig. 1 and 2, respectively. In all cases powder layers showed

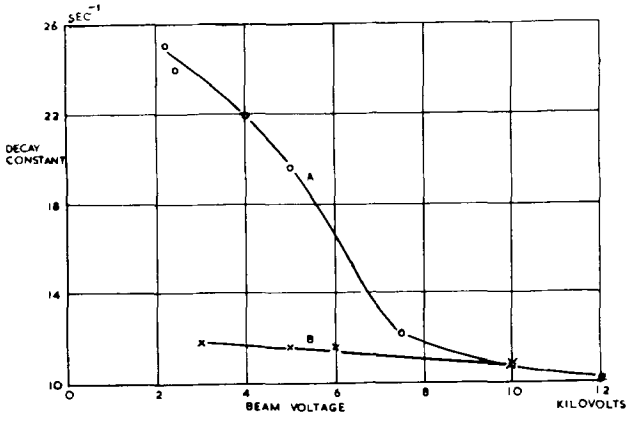

Fig. 1. Decay constant vs. primary electron energy for manganese activated calcium fluoride: (A) single crystal; (B) powder layer.

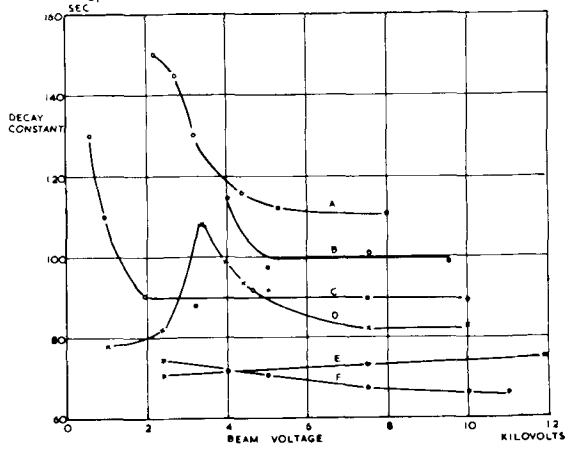

Fig. 2. Decay constant vs. primary energy for manganese activated zinc silicate: (A), (B), (C), evaporated layer; (D), sintered layer; (E), (F), powder layer.

little change in decay constant with electron energy, the value being identical with that measured using ultraviolet excitation, and characteristic of the Mn^{2+} center in the particular host lattice. This is in agreement with the results of other workers (3). The behavior of single crystals and evaporated layers was more complex. For single crystals, the decay constant was high at low primary energies and decreased as the electron energy was increased until the value approached that for powder layers. The variation with primary electron energy was relatively independent of whether the crystal surface facing the electron beam was polished, freshly cleaved, or coated with aluminum. This result is shown more effectively by the logarithmic plot of the change in decay constant $\delta - \delta_\infty$, where δ_∞ is the decay constant at large primary energies, *vs.* primary energy shown in Fig. 3 and 4 for calcium fluoride and zinc silicate, respectively. Except at low primary energy, these plots are linear with approximately the same slope. This suggests that the decay constant may be represented by a relation

$$\delta - \delta_\infty = CV^{-p} \qquad [1]$$

where C and p are constants. The average value of p obtained from the graphs is 3.0 ± 1.0 for calcium fluoride and 3.6 ± 0.2 for zinc silicate. The existence of an aluminum coating on the surface was not critical, the principal effect being an over-all shift of the curve to higher voltages. Further changes along the voltage axis could be tentatively attributed to the method of surface preparation, *e.g.*, the curve for a cleaved crystal appeared at a lower voltage than that for the polished specimen. A similar dependence on electron energy was observed for evaporated layers, although the over-all decay constants were usually higher than those for either powders or single crystals. This over-all increase was attributed to an increase in the transition probabilities of the luminescence centers due to perturbations introduced by the imperfect host lattice. In a few cases, the most notable being the sintered zinc silicate layer, the decay constant showed a maximum at an intermediate primary energy. This behavior is a guide to the interpretation of the results and will be discussed later.

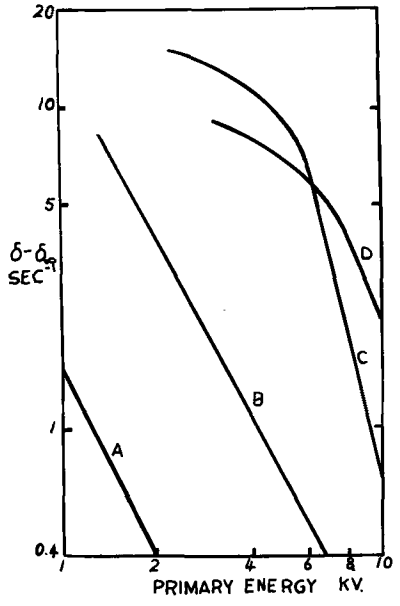

Fig. 3. Change in decay constant $\delta - \delta_\infty$ *vs.* primary energy for single crystal specimens of calcium fluoride: (A) cleaved unaluminized; (B) cleaved, aluminized; (C), (D) polished, aluminized.

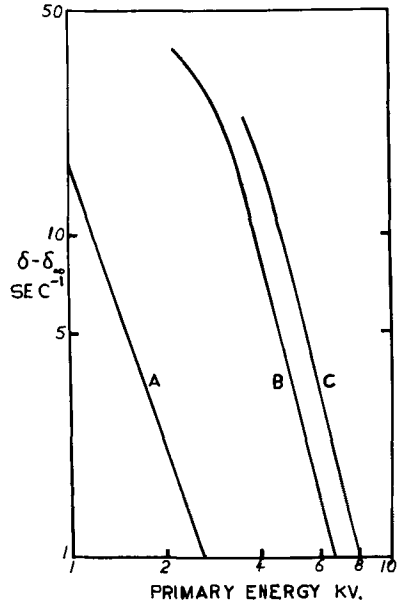

Fig. 4. Change in decay constant $\delta - \delta_\infty$ *vs.* primary energy for zinc silicate: (A) *evaporated layer unaluminized;* (B) *evaporated layer,* aluminized; (C) sintered layer, aluminized.

Variation of the beam current density produced a change in the decay constant at low primary energy, but was less effective at higher primary energies. This behavior in a crystal of calcium fluoride is shown in Fig. 5.

Effect of phosphor temperature.—The change in decay constant with temperature was relatively independent of the primary beam energy and density and agrees with that for photoexcitation. This is shown in Fig. 6 for a single crystal of calcium fluoride. The effect of nonradiative transitions within the emission centers was only noticeable at temperatures between 100° and 200°. The absolute luminescence efficiency at ordinary temperatures was only a few per cent.

Discussion of Results

The important effect shown in the above experiments is the change of decay constant with primary energy for single crystals and evaporated layers,

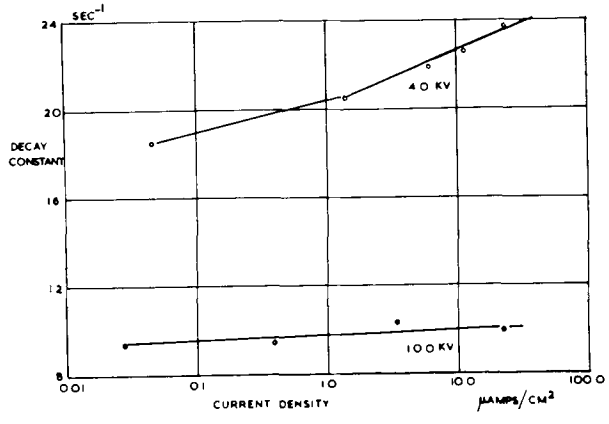

Fig. 5. Decay constant *vs.* beam current density for a single crystal of calcium fluoride: Mn: (A) 4 kv; (B) 10 kv.

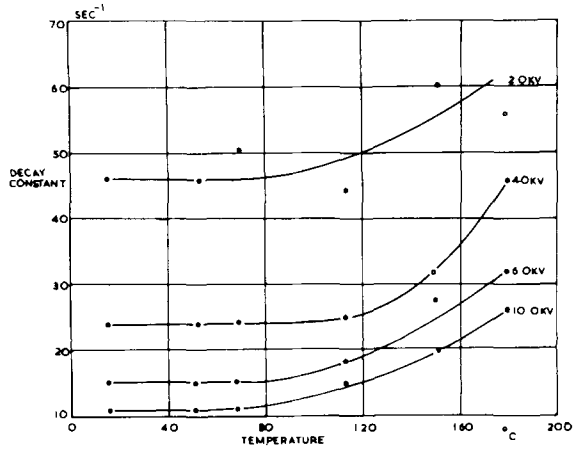

Fig. 6. Decay constant vs. temperature at different primary energies for a single crystal of calcium fluoride: Mn.

which is in contrast with the negligible effect for powder layers. The energy of the primary electrons is a measure of the penetration of the beam into the crystal, the most generally accepted relation being of the form $R = AV^n$, where R is the penetration depth, V is the primary voltage, and A and n are constants characteristic of the material (4, 5). The most obvious interpretation of the results is that the change in decay constant is due to either (*a*) a 'dead' surface layer or (*b*) thermal effects arising from the increased density of power dissipation at low primary voltages. If (*a*) is the case, the effect should be enhanced in powder layers in which the surface area is greatest. This disagrees with experiment. If macroscopic thermal effects are involved, a crystal temperature of the order of 200°C would be required to give the observed decay constants at low beam voltages. Calculations involving the thermal conductivity of the crystals indicate that under the given experimental conditions the crystal temperature rises by a maximum of 1°-2°C. A third possibility is in the increase of electron density within the crystal at low primary energies, due to the power-law dependence of the penetration depth on the primary energy. This may be considered in conjunction with the model for the cathodoluminescence process shown in Fig. 7.

Electron transitions may occur either in the lattice or in the luminescence centers. Due to the small number of activator ions, the bulk of the excitation is assumed to take place in the lattice, with subsequent transfer of energy to the luminescence centers. The emission spectrum is unchanged for optical and electron excitation; hence it may be assumed that the emission arises from a self-contained, monomolecular transition within a luminescence center with radiative and nonradiative transition probabilities δ and ϕ, respectively. The lattice excitation arises from the production of secondary electrons in the conduction band and positive holes in the valence band. As an approximation, if recombination is neglected, it may be assumed that the primary beam excites

$$n_1 = \mathrm{I} = [i_0 V/\Delta E \cdot AV^n] \qquad [2]$$

secondary electrons, where ΔE is the energy required to produce a hole-electron pair, and i_0 is the beam current density. Under these conditions, bimolecular recombination kinetics are to be expected in the lattice with a nonradiative recombination probability β (this includes both band-to-band and impurity transitions) and a probability for energy transfer to a luminescence center γN, where N is the total number of centers. The detailed kinetics of such a model have been treated elsewhere (6). It is found that the maximum value of decay constant is determined by the sum of the transition probabilities for the center $(\delta + \phi)$ sec^{-1}. This would be the value obtained in a measurement using ultraviolet radiation for direct excitation of the center. If the excitation takes place via the lattice a value of $(\delta + \phi)$ sec^{-1} is obtained if recombination processes in the lattice are completed in a time short compared to the lifetime of the radiative decay. Any process which increases the rate of lattice recombination is therefore ineffective to explain decay constants greater than $(\delta + \phi)$ sec^{-1}. A marked change can occur if the lifetime of a free lattice electron is comparable with that of an excited center, but this is again ineffective since the analysis shows that the decay constant is decreased under these circumstances. This is also the case if the effect of saturation of luminescence centers is included. Thus an increase in decay constant cannot be attributed to a change in any lattice process, but can only be a property of the luminescence center itself.

If any form of interaction between the electron density in the conduction band and the luminescence centers is to be reflected in the magnitude of the decay constant, two criteria must be satisfied: (*a*) the electron density must be large, (*b*) the lifetime of electrons in the conduction band must be comparable with that of the luminescence centers. Both criteria are principally determined by the parameter β, since it can be shown that (6)

$$n_1 = I/(\beta + \gamma N)^{1/2} \qquad [3]$$

and the lattice time constant

$$b = (I/(\beta + \gamma N)^{1/2} \qquad [4]$$

In a region of heavy recombination, *e.g.*, the surface regions of a crystal, β is large, and therefore n_1 is small and also decays in a time short compared to the lifetime of an excited center. Thus interaction between the electron density and the centers occurs for a very small fraction of a center lifetime. In the relatively perfect lattice of a crystal, recombination will be reduced, β is small, n_1 is large and remains

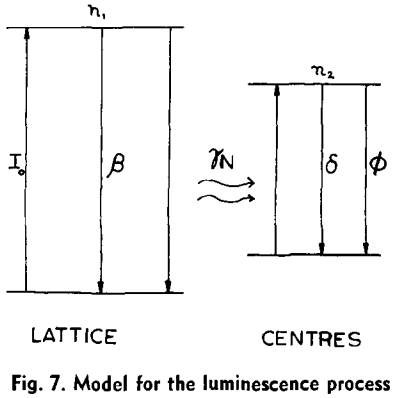

Fig. 7. Model for the luminescence process

appreciable throughout a large portion of the center lifetime. In this case a perturbation of the centers may be observed. Note that the effect of the surface will be enhanced in microcrystalline powders in that the average penetration depth is less than that for a single crystal due to the random orientation of the individual crystallites to the primary beam. A maximum in the value of decay constant is to be expected if the disordered surface region extends for a considerable depth into the crystal.

This behavior is observed in the sintered layer of zinc silicate (Fig. 2, curve D) and may also explain the nonlinearity at lower voltages of curves C and D of Fig. 3 for the polished specimens of calcium fluoride. The presence of such a region would also give rise to a shift of the curves along the voltage axis in the direction of higher voltages. Further comment may be made for the case of the evaporated layers. It has been shown that increased lattice recombination cannot increase the luminescence decay constant beyond that defined by the center transition probabilities $(\delta + \phi)$ sec^{-1}. Thus the over-all increase in decay constant in the evaporated layers must be due to an increase in the center probability $(\delta + \phi)$ sec^{-1} caused by perturbations in the imperfect crystal field surrounding the activator atoms. However, interaction with the excited lattice electron density can still occur as in the single crystal since the localized electron density is still predominantly determined by lattice recombination processes independent of the centers.

The specific nature of the interaction between the secondary electron density n_1 and the luminescence centers requires interpretation. A purely electrostatic interaction between the electron-hole plasma in the lattice and the luminescence centers is difficult to formulate. However, it has been well established in semiconductors such as germanium and silicon that at large majority carrier densities a recombination process proportional to the square of the carrier density is observed (7, 8). This is termed Auger recombination and involves three carriers—an electron and hole which recombine, transferring energy to a third electron. It is suggested that this process is observed in the present experiments. Two forms of interaction may be possible: (*a*) Auger recombination between a free hole, a free electron, and an excited luminescence center; the energy transferred to the center could raise its effective temperature for a short time with a resulting increase in nonradiative transition probability; (*b*) Auger recombination involving two free electrons and a bound hole in the vicinity of an excited center, the energy imparted to the second electron being dissipated by phonon generation in the vicinity of the center. This again results in an increase of nonradiative transition probability. Both processes may be termed a form of microscopic thermal quenching.

A quantitative estimate of the decay constant-beam voltage may be made on this basis since

$$\delta = (\delta + \phi)_\infty + Bn_1^2 \qquad [5]$$

where B is a constant.

If the approximation is made that n_1 is constant for a time comparable to the center lifetime, substituting for n_1 from [2]

$$\delta - (\delta + \phi)_\infty = B\left\{\frac{1}{\Delta E}\frac{i_o V}{AV^n}\right\}^2 = D\left\{\frac{i_o}{V^{n-1}}\right\}^2 \qquad [6]$$

Using the reported values of n (4), the decay constant should show a power law dependence on V with exponents 3.8 and 4.0 for calcium fluoride and zinc silicate, respectively. Considering the many approximations involved in the calculations, these values are compatible with the experimental values of 3.0 ± 1.0 and 3.6 ± 0.2, respectively. Note that the relation also indicates that the variation of decay constant with current density is greater at low rather than high primary voltages. This is also in agreement with experiment.

Conclusion

It has been shown that a rise in decay constant at low primary electron energies may occur in phosphors in which the rate of lattice recombination is relatively small. The suggestion that the rise is due to an interaction between the conduction electrons and the excited luminescence centers by means of Auger recombination in the lattice is borne out by the quantitative agreement between experiment and theory.

Transient Effects in Cadmium Sulfide-Cadmium Selenide Type Photoconductors

Ronald D. Weiss[1]

Clairex Corporation, New York, New York

ABSTRACT

Cadmium sulfide and cadmium selenide sintered polycrystalline layers have been investigated with respect to the transient effects in their photoconductive rise and decay curves. Under suitable conditions both types of layers exhibit a maximum in the rise curve and a minimum in the decay curve. The specific results are strongly dependent on the excitation history of the layer. The relationship of these effects to trapping processes is discussed, and some comparisons with earlier experimental works are made. The dependence of photosensitivity on these effects is emphasized.

A transient effect was previously found to be associated with single crystal photoconductors of both CdS (1) and CdSe (2). The experiments of Bube and others have shown that, because of their excitation history, the photoconductive response curves of CdS and CdSe single crystal photoconductors exhibit both a maximum in the rise curve and a minimum in the decay curve. The present paper will show that the effect is more strongly evidenced with CdS and CdSe polycrystalline sintered layers at room temperature.

Figure 1, curve a, is representative of most room temperature photoconductive response curves reported by others. In the same figure, curve b represents the general shape of the photoconductive response curve, which was obtained for these sintered layers under similar conditions. It is interesting to note that at the onset of the excitation the latter curve goes through a maximum before approaching its long time equilibrium or steady-state photocurrent value. The area between the long time equilibrium value and the maximum of curve b is the principal subject of this work, *i.e.*, the additional amount of photocurrent above the long time equilibrium value [overshoot (2)]. A result similar to the forementioned may be obtained by replacing the initial dark or quenching[2] history, required prior to the onset of the excitation, by a relatively high light intensity or excitation history. In this instance the photoconductive response curve must be taken from the high light intensity to the lower light intensity (the level at which the long time equilibrium value had been previously established). This second curve will be of the same shape as curve b, except for its inverted nature, *i.e.*, the photocurrent will now pass through a minimum below the long time equilibrium value before approaching this value [undershoot (2)].

[1] Present address: Applied Research Laboratory, General Instrument Corporation, Newark, New Jersey.

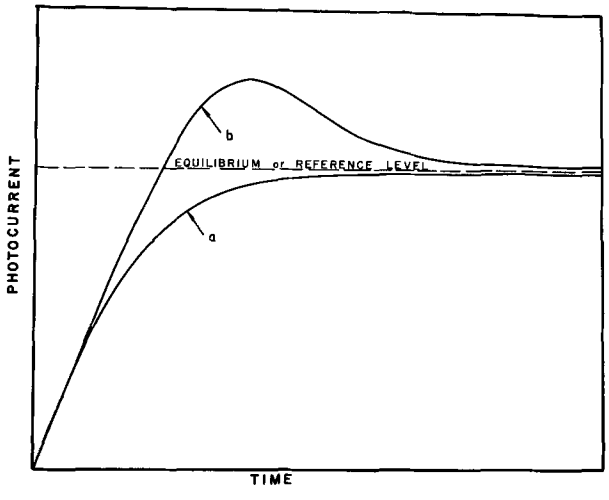

Fig. 1. Comparison of the general nature of the photoconductivity curves (until the equilibrium condition is established) of the works being discussed.

Experimental Apparatus and Procedure

Since the transient effect evidences itself in the growth of the photoconductivity a special procedure was devised to measure the true effect. The experimental procedure consists of three basic operations. The first operation is to determine the long time equilibrium value of the sintered polycrystalline layer at the reference light level of the experiment. This long time equilibrium value is defined by the steady-state photocurrent of the layer after it has been subjected to the reference light level for a considerable length of time. The time required for the steady-state photocurrent condition is primarily dependent on several factors, *i.e.*, the type of photoconductor, the intensity of the light, and the previous history of the layer. To ensure attainment of the steady-state photocurrent in all the layers of a particular group, the group was subjected to the necessary conditions for a period not less than ten days. This time had proved more than sufficient for all the layers in question. The second operation is to expose the layer to either an intense light, semidark, or dark environment for fixed amounts of time. This second operation will determine the type of transient obtained in the photoconductive response curve. The intense light environment will produce a minimum (with respect to the equilibrium value), whereas

[2] The term "quenching" is generally associated with the emptying of filled traps. In most photoconductors this quenched condition is obtained by either storage in a dark environment, heating of the photoconductor, or excitation with infrared. The net result of these methods is a de-excited photoconductor, a condition which can be reproduced.

the dark or semidark environment will produce a maximum. The third and final operation involves the measurement of these layers, at fixed intervals, at the reference light level established in the first operation.

The measuring circuit used was a series circuit consisting of a 1.34v Mallory Mercury battery (RM 42R), a Hewlett Packard ammeter (Model 412a), and the photocell. Provisions for taking these measurements requires an accurate light source which is stable and reproducible over long periods of time. This requirement is necessary in order to determine accurately photocurrent variations from the equilibrium value. It is for these reasons that the photometer used has been operated by means of the circuitry recommended by the National Bureau of Standards (3). The photometer bulbs used are of the GE No. 1763 series. They have been aged or seasoned prior to this application to avoid drift during the long periods of their use. The GE No. 1763 bulb is a secondary standard (operating color temperature 2870°K) which is checked periodically against a set of primary standards (4). In this manner, all available light levels have been maintained to within 1 or 2% over indefinite periods of time. In very low light level applications a series of Bausch and Lomb neutral density filters, which were found to be linear in the visible spectrum, were used. It should also be noted that the photoconductive layers were in the form of hermetically enclosed units. The hermetic enclosure gives some assurance that the measurements will not be affected by daily changes in atmospheric conditions. Since the results of one photoconductive layer could be misleading, measurements have been made with several layers of the same type. The statistical averages of these groups were used for all the data contained herein.

Experimental Results

Transient Maxima

Most of the data presented at this time deal specifically with transient maxima (overshoot) rather than minima (undershoot). The present data on transient maxima seem to indicate that at very high light levels there exists a saturation point at which no maximum or overshoot will be observed; however, to date this saturation point has not been determined accurately. It is quite reasonable to assume that this saturation point is related to a situation where the saturation of photocurrent (5), by means of light intensity, can occur.

Both transient maxima and minima have been shown to be functions of several factors aside from temperature (1, 2).[3] Recent experimentation has confirmed that these transients are strongly dependent on reference levels, time of exposure to the excitation, and type of photoconductive material used. This section will attempt to discuss these factors in greater detail. At this time a short explanation of the notation used throughout the paper will be helpful. The changes due to the transient effect have been designated as $\Delta I/I_o$, where ΔI is the change in photocurrent from the equilibrium value (I_o). I_m is the current value associated with the maximum height of the transient obtainable for a given set of conditions. In most curves presented 100 $\Delta I/I_o$ ($\Delta I/I_o\%$) is plotted as a function of time or time intervals. The ΔI is the maximum change in photocurrent, observed at the onset of the excitation, above the equilibrium value (I_o).

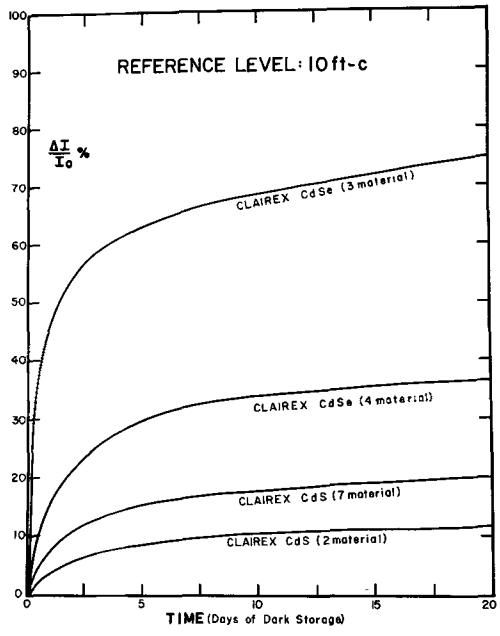

Fig. 2. Transient maxima or overshoot of several CdS and CdSe photoconductive layers obtained for a reference level of 10 ft-c.

Maxima or overshoot experiments, as described above, were performed on several polycrystalline cadmium sulfide and cadmium selenide photoconductive layers. The results of these experiments are shown for a particular reference level, in Fig. 2, for layers coming from a dark history. It can be seen from this set of curves that under the same conditions the cadmium selenide materials exhibit greater transient maxima than do the sulfides. This characteristic of cadmium selenide has been found to be true at all the reference levels thus far tested. It should also be noted that the maxima curves are all of an exponential nature, indicating that there is an upper limit for maxima ($\Delta I/I_o$), at each reference level, for a particular material. Figure 3 is a comparison of transient maxima of several commercially available photoconductors (all of the polycrystalline sintered layer type). These curves were taken at a reference level of 2 ft-c. Although the RCA prepared photoconductive layers show more of a transient maxima effect than the Clairex ones, it does illustrate that the effect is inherent in sintered polycrystalline materials at room temperature. As previously indicated experimentally it would normally be expected that CdSe layers would exhibit greater transient maxima than would CdS layers, but our data indicate that the RCA prepared CdS layers exhibit greater transient maxima than even the Clairex CdSe layers. This anomaly as well as other evidence suggested that this transient effect may be either a function of the layer thickness and/or the activation of the layer. These two possibilities were investi-

[3] It is known that heating effects will often cause similar overshoots. However the circuit used in the experimental set up is so designed that any joule heating (I^2R) within the layer is negligible.

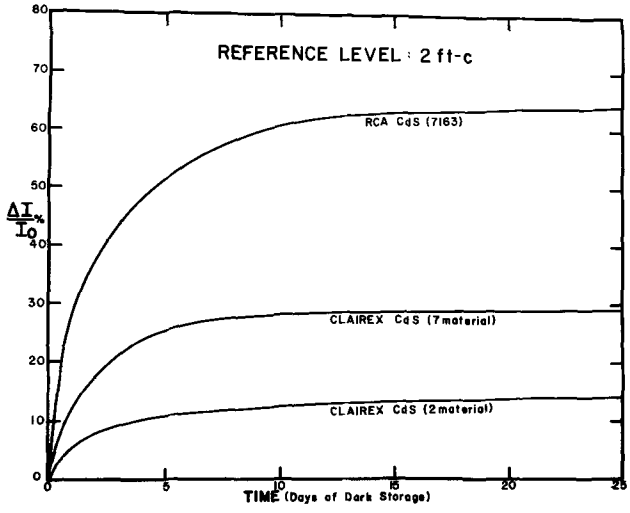

Fig. 3. Transient maxima or overshoot of several commercially available CdS photoconductive layers obtained for a reference level of 2 ft-c.

gated and yielded the results shown in Fig. 4 and Fig. 5. The data in Fig. 4 represent transient maxima, obtained at one reference level, for a particular CdS material which was varied in layer thickness. The thickness of layer (b) was 2-3μ, 4-6μ for (a), and 8-10μ for (c). It is evident from this phase of the data that the transient effect is not a function of the layer thickness. The second part of this investigation, however, yielded more interesting results. In this instance, variation of the copper activator concentration was made for a particular group of CdS layers, all having the same thickness. Thus, for a reference level of 10 ft-c we obtained the data in Fig. 5. These data illustrate that the transient effect, among other parameters, is directly dependent on the concentration of activator within the photoconductive layer. This experiment was repeated using several of the known photoconductor activators, and similar results were obtained as those already reported here for copper. Figure 5 shows the increase in the transient effect as a function of activator concentration. In addition these data show that the transient effect as a function of activator concentration also reaches an ultimate value.

In order to verify some of the room temperature transient data previously reported for single crystals of CdSe (2) and to gain additional information on room temperature transient data in CdS, if any, some

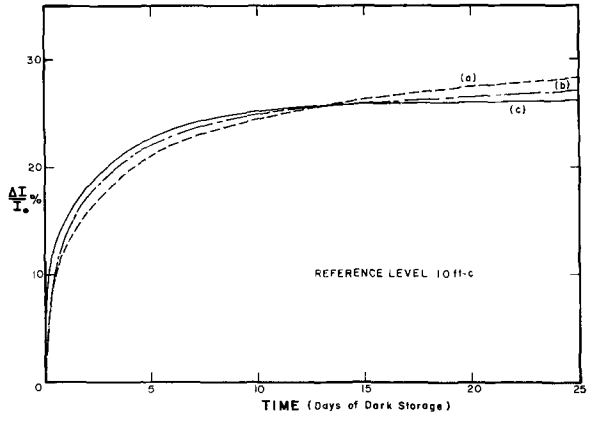

Fig. 4. Comparing transient maxima or overshoot of the same type CdS layers for which the layer thickness is the variable.

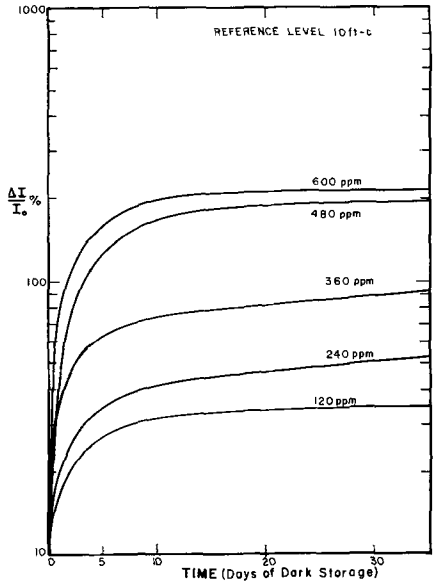

Fig. 5. Comparing transient maxima or overshoot of the same type CdS layers for which the activator concentration is the variable.

single crystals of these types were mounted and hermetically sealed in glass enclosures. They underwent the previously described experimental procedures, and transient maxima were observed in both types of crystals at room temperature. We believe that this is the first time that transient maxima have been reported for CdS single crystals at room temperature. It should be noted that single crystal transient maxima obtained for similar conditions were not as uniform, from crystal to crystal, as are the polycrystalline layers from layer to layer. This nonuniform result had been anticipated with single crystals because of the individuality of these crystals. This individuality is not as predominant with polycrystalline layers because of the statistical distribution that one gets with the many small fused single crystals. Because of this individuality of single crystals no direct comparison with the available data can be made at this time.

The reference level for which the long time equilibrium values are established is an extremely important factor in relation to the transient effect. Figure 6 is a comparison of transient maxima curves

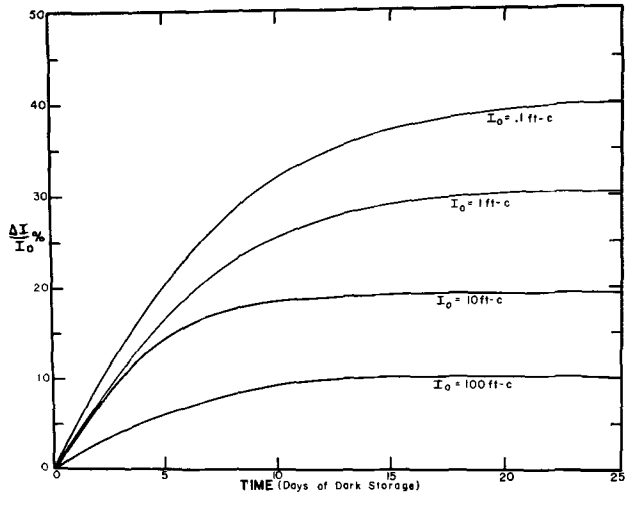

Fig. 6. Comparison of transient maxima or overshoot of the same type CdS photoconductive layers for which the reference level is the variable.

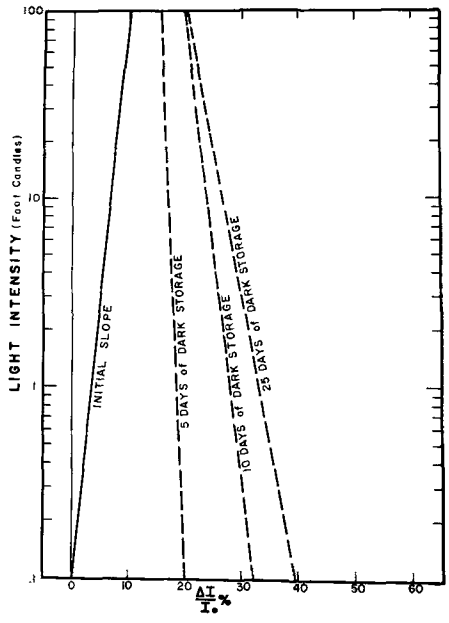

Fig. 7. The "initial slope" is based on some arbitrary photocurrent at 0.1 and 100 ft-c after the equilibrium condition has been established. The change of slope with time of dark storage is due to the fact that transient maxima or overshoots at high light levels are considerably smaller than those associated with the low light levels.

for the same CdS layer at several different reference levels (ranging from 0.1 to 100 ft-c in various steps). These data establish the fact that the transient maxima effect is more pronounced at low reference levels than at high reference levels. When considering this aspect it is easy to conceive that the slope of the photocurrent *vs.* light intensity curve will be strongly dependent on the excitation history of the layer prior to the taking of measurements. Figure 7 is a plot of the slopes for a group of CdS layers corresponding to various days of dark storage. These slopes are based on the data presented in Fig. 6. It is from these data that one may also envisage that at some high light level no transient maximum will be observed.

Decay of the Transients

The transient effect, as its name implies, is not a permanent effect, and photoconductors evidencing this effect have the ability, with light irradiation and time, to return to their long time equilibrium condition. The experimental results obtained for the recovery of sintered polycrystalline photoconductive layers to such an equilibrium condition, is presented herein.

A large group of these sintered layer photoconductors was subjected to an absolute dark environment for several months. The photoconductors were individually taken out of the dark and subjected to various light intensities for approximately 20 hr of continuous exposure. The initial photocurrent readings (I_m) of transient maxima from the dark were taken for the purpose of this experiment as the 100% value. The percentage decrease in photocurrent with time of light exposure is represented by $\Delta I/I_m\%$; this will be the expression used for this decaying effect. The data for the curves of Fig. 8 were taken with a Multi-Ranger Rustrak recorder (Model No. 111-A) which directly recorded the current readings of the

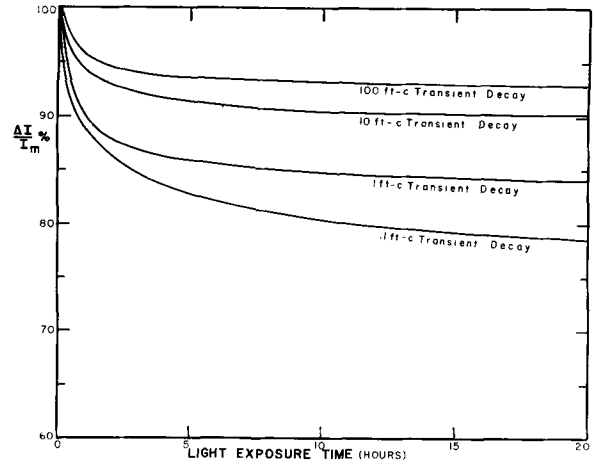

Fig. 8. Transient maxima or overshoot decay for a period of 20 hr for CdS type layers at various constant light intensity levels.

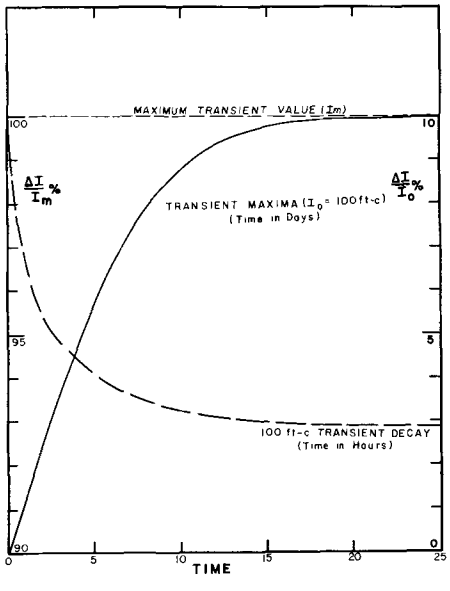

Fig. 9. Comparison of the growth of the transient maximum with the decay of that maximum for a reference level of 100 ft-c.

Hewlett Packard ammeter in the series circuit previously described. It should be noted, percentagewise, that there is less decay, with exposure time, from maxima at high light levels than from maxima at low light levels. This is apparent since there is correspondingly less overshoot associated with the higher light levels than the lower ones. Again attention should be called to the exponential nature of these transient decay curves.

In Fig. 9 the transient decay curve of Fig. 8 (for the 100 ft-c reference) has been superimposed upon the maximum curve of Fig. 4 (also for the 100 ft-c reference). We have equated the 100 ft-c maximum with I_m at 100 ft-c (the 100% level of the decay experiment). The superimposed curves show that in 20 hr of light exposure, at least for the case of the 100 ft-c reference, most of the transient maximum associated with this reference level has been erased or disposed of. These data also suggest that at low light levels the existence of these transient maxima will be of long time duration.

Rise Times

These experiments, as well as previously reported data (6-8), have evidenced the fact that photocon-

ductors coming from long time dark histories had much longer rise times than the same photoconductors which had a long time light history. The difference between these two conditions is approximately 37% for the case of the CdS layer under discussion, with a 10 ft-c reference. Specifically, those photoconductive layers taken from the dark had an average rise time of 31.5 msec, whereas the same layer with a long time 10 ft-c light history had an average rise time of 19.8 msec. Here again the excitation history of the layer plays a decisive role in their respective rise and decay times.

Discussion

When considering the data already presented in this paper, it is plausible to associate the transient effect with some trapping mechanism. It is at this time that a comparison of these data with some related data (2, 6, 9) and corresponding photoconductivity models is made.

The major difference between most previously reported works and this work is the manner in which the respective samples reach their true equilibrium condition. In Fig. 1 this difference has been shown by superimposing the general shapes of photoconductivity curves obtained from the aforementioned works with those obtained here (curve a is that curve which was reported by others (7-9) and curve b for the work reported herein). The general assumption of the band model necessitates an attempt to explain the transient effect in terms of what has already been recognized. Bube (2) has taken this first step by analyzing the transient effect as follows. He has asserted, in terms of the dual trap theory (8, 10), that the slow rise of the photocurrent from a quenched state is due to both the simultaneous increase of the concentration of holes in recombination or type I centers (*i.e.*, centers which have a greater probability for recombination than for thermal freeing) and a decrease in the concentration of holes in compensated acceptor or type II centers (*i.e.*, centers which have larger capture cross sections for holes than electrons). This theory implies that most holes are located in class II centers initially. Considering this aspect and the conditions set forth for transient minima (undershoot) it may be postulated that for transient maxima (overshoot) the density of free plus shallow trapped electrons must be greater than the density of holes in the Class II centers. Now, on excitation, the rate of ejection is greater than the rate of recombination, and simultaneously during this process both the free and shallow trapped electrons are being drained off rapidly. Thus the free electron density will eventually decrease until equilibrium is reached. A set of equations similar to those presented for undershoot (2) can be presented for overshoot by considering the rate of change of the density of free electrons (dn/dt) in the presence of excitation. By equating this term to zero, n_{max} can also be calculated, whence for the case of overshoot n_{max} must be greater than n_{equil}.

It has been stated that the prerequisite condition of this theory is that most holes must initially be located in centers of type II in order for the transient effect to be observed. For the case of CdS, elevated temperatures (above 100°C) were believed necessary to reproduce this situation (2). Nevertheless the existence of this transient effect at room temperature has been found for all CdS photoconductors reported here. In light of these results there now appears to be some correlation between the transient effect at high temperature with lightly activated materials and that at room temperature with highly activated materials. More specifically the degree of activation will strongly effect the temperature at which CdS will exhibit these transients.

The decreasing amount of overshoot observed with higher light intensities is obviously related to the previously obtained results on undershoot. Bube has reported (2) that if sudden changes in light intensity are made, whereby the lower light intensity of the change lies above the supralinear range,[4] no undershoot can be observed. Thus, it can now be said that above the supralinear range no undershoot nor overshoot can be observed in CdS or CdSe-type photoconductors.

If one assumes the transient effect is common to all photoconductive type materials, some clarification of conflicting rise time data can be made. Earlier papers (6-8) on CdS-type photoconductors convey the idea that the equilibrium value can be immediately reached by the first excitation of a quenched photoconductor (Fig. 1, curve a). Although the photoconductors prepared for this study follow curve b of Fig. 1 , it is still possible, under certain conditions, to reproduce most experimental variations in rise times that have been previously associated with photoconductors that follow curve a. The earlier papers have shown that previously quenched photoconductors will exhibit a decrease in their response times (to the equilibrium value) when subjected to a short quenching history and re-excited a second time. This decrease in response time, under similar conditions, has also been observed (see section on Rise Times) with photoconductors characteristic of curve b, Fig. 1. However there exists one major difference, *i.e.*, the decrease is observed only if the response time is taken with respect to the transient maximum and not the equilibrium value. In another work (11) the authors have shown that previously excited photoconductors exhibit an increase in their response time (to the equilibrium values) when also subjected to a short quenching history and re-excited again. Duplication of this result can be obtained only if the photoconductors under discussion have also had an initial excitation history. However, in both these cases the response time is obviously taken with respect to the true equilibrium value and not the transient maximum. The experimental data show that one can observe entirely different results by mistaking the equilibrium value for the transient maximum. The importance of recognizing this difference for the proper evaluation of photoconductive rise times is also emphasized.

[4] It is known that the photocurrent *vs.* light intensity curve is usually divided into three distinct ranges, *i.e.*, at low light intensities, a range where the photocurrent varies as the square root of light intensity; at intermediate light intensities, a range where the photocurrent is proportional to the light intensity; and at high light intensities, a range where the photocurrent rises supralinearly with the light intensity.

Acknowledgment

The author wishes to extend his gratitude to the members of the Clairex Corporation for making this paper possible. It is also his pleasure to acknowledge the many helpful discussions with Dr. Bernard Kramer of New York University.

Manuscript received Dec. 27, 1961; revised manuscript received March 20, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Dember Effect in ZnS-Type Materials

F. F. Morehead and A. B. Fowler

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

A convenient system is described for measuring the diffusion current pulse produced by the sudden incidence of strongly absorbed radiation (Dember effect) on powder materials of the ZnS type. A model adequately representing the physics of the effect is given. It is shown that it is desirable to eliminate d-c contact effects in order to obtain reliable and reproducible results. The sign of the Dember current pulse indicates the sign of the more mobile carrier when the incident radiation is in the strongly absorbed, fundamental region. Reversals in the sign of the pulse are often encountered for weakly absorbed, longer wavelengths and are attributed to the effect of fast surface states. The excitation spectra for the Dember effect, photoluminescence, and electrophotoluminescence in a ZnS phosphor are given and correlated.

The relaxation processes involved in the Dember effect have kinetics determined by many factors: the variable dark times between light pulses, temperature, irradiation with long wavelength light during "dark" times, etc. These effects are described. It is found, for example, that the spectral dependence of the relaxation effected by long wavelength radiation correlates with the photoluminescence quenching spectrum of phosphor materials. Some of the potentialities of the Dember effect in studying these materials are pointed out.

One of the many photoeffects discovered before 1935 is the Dember effect, a diffusion dependent photovoltage. Strongly absorbed radiation incident on only one face of a crystal produces a diffusion current of the more mobile carrier away from the illuminated surface. The sign of the current is determined by the sign of the mobile carrier. The effect was first reported by Dember in Cu_2O (1) but except for a few papers by Russian workers, notably Zhuze and Ryvkin (2), and Bukke (3), and recent reports on AgCl (4) and GaAs (11), little use of the Dember effect has been reported in the evaluation of photoconductors and phosphors.

The technique employed in the present work and described in detail in a later section is essentially the transient condenser method (2) in which the possibility of spurious effects from illuminated contacts between the electrodes and the phosphor is eliminated. Several approximate quantitative treatments of the basic equations governing the effect are in the literature (5, 6), but even for the simplest, steady-state cases the results are too complex to be of much value in interpreting experimental results. A simple, phenomenological treatment, based on experiments, will be pursued in describing the physics involved in the measurements.

The purpose of this paper is simply to show that the Dember effect is an easily made measurement which gives information concerning the sign of the more mobile, or majority, carrier in materials for which Hall effect or thermoelectric power measurements are extremely difficult. Dember measurements can detect the approximate position of the absorption edge, its shift with temperature, the existence of significant impurity absorption and of fast surface states. The results of these measurements usually show useful correlation with the photoconductive, photoluminescent, electroluminescent, and electrophotoluminescent properties of these ZnS-type materials.

Experimental Technique

The experimental arrangement for observing this effect in polycrystalline material is shown in Fig. 1. A suitable mixture of the powder and an insulating

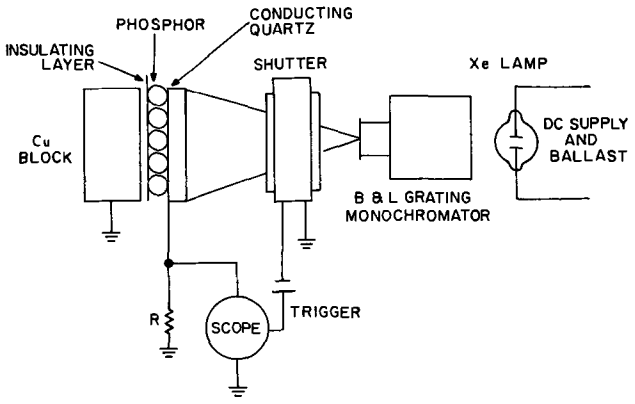

Fig. 1. Schematic arrangement of Dember pulse apparatus

binder (which is sometimes omitted) is compressed between the two plates of what is essentially an electroluminescent cell. One or more layers of ¼ mil Mylar are usually included to eliminate the possibility of electrode effects. None of the latter has ever been observed, however, with the Mylar omitted, and so in most measurements the layer between the powder and the silica disk which bears a conducting coat of SnO_2 is omitted. This latter arrangement permits transmission of intense u.v. down to below 300 mμ. When strongly absorbed light is flashed onto the transparent electrode, a current pulse is observed in the external circuit, a typical oscillogram of which is shown in Fig. 2a. The diffusion of the more mobile carrier away from the illuminated electrode leaves this electrode charged oppositely to that of the diffusing carrier, so that the positive current pulse shown in Fig. 2a identifies these carriers as electrons. A return pulse of lower peak value and opposite sign results when the shutter is closed, as shown in Fig. 2b.

A high pressure Xenon lamp is used as a source. The 250 mm Bausch and Lomb grating monochromator emits equal photon intensities (about 4 x 10^{14} photons/cm^2/sec) for appropriate slit width settings determined at each wavelength with a thermocouple. The Graflex 1000 shutter flashes the full intensity onto the cell in less than a millisecond. For studies of the temperature dependence of the effect, both the insulating layer and the binder are omitted. The latter omission causes considerable loss in signal, but it is important to eliminate effects which might be caused by the temperature dependence of the dielectric constant of the binder. The cell chamber can be evacuated to a pressure below 1μ Hg and the Cu block electrode cooled to liquid nitrogen temperature or heated to above 200°C.

Experimental Results and Discussion

The physics of the effect.—A brief description of the phenomenological physics of the "condenser method" for measuring the Dember effect in powdered materials may prove helpful in the subsequent examination of results. It will be shown that in addition to the fast displacement current there exists a slow interparticle contact current. This latter current can be observed either as a steady-state short circuit d-c current in the absence of an insulating layer or as the long tail on the displacement current pulse when the insulator is present. It will also be shown that the fast, displacement current is the more reliable and reproducible indication of the type and quantity of the more mobile carrier and that the effects of the contact current should be minimized. The rise time of the Dember current pulse (cf. Fig. 2a) is the same order as the shutter opening time t_s (about 1 msec) and is never significantly slower. The fall time from the current maximum can be related roughly to an exponential decay time, RC. The peak current i_m is given by

$$i_m = (i_m)_0 \frac{RC}{t_s}(1 - e^{-t_s/RC})^1 \qquad [1]$$

where $(i_m)_0$ is the maximum peak current that would occur for t_s/RC equal to zero. This equation relates only the effect of shutter speed for a given material in a given set of experimental conditions. This relationship has been found to hold experimentally by varying the shutter speed. A fast shutter is therefore advantageous.

A long tail with a much slower time constant (cf. Fig. 2c) is considered to be due to the direct flow of current between particles, although the detailed mechanism is unknown. This latter current flow must depend on the effect of internally scattered radiation in changing the contact emf between particles and evidently requires a much longer time to establish than the photodiffusion emf responsible for the fast displacement current pulse. Since the contact photovoltages must involve accumulation or depletion of space charge, it is reasonable that they should require a longer time to reach a peak value. This slow current will be discussed further later.

The fast current pulse is due to the charge which moves in the external circuit corresponding to the diffusion of the more mobile carriers away from the

[1] A "curtain" shutter, moving with velocity v, exposes fresh areas of the cell with maximum current I_m amp/cm^2 at the instant of exposure which subsequently decays exponentially with a time constant RC. For a square cell of width w and length l, along which latter the shutter moves, the shutter opening time $t_s = v$. For $t \leq t_s$, the measured current at time t from the start of the shutter movement

$$i(t) = I_m w \int_0^x e^{-\frac{x}{vRC}} dx$$

$$= (I_m wl) \frac{RC}{t_s}[1 - e^{-t/RC}]$$

where $x = vt$. For $t \geq t_s$

$$i(t) = i_m w \int_0^l e^{-\frac{t-x/v}{RC}} dx$$

$$= (I_m wl) \frac{RC}{t_s}[e^{t_s/RC} - 1]\, e^{-t/RC}$$

The maximum value of $i(t)$ occurs at $t = t_s$

$$i_m = (I_m wl) \frac{RC}{t_s}(1 - e^{-t_s/RC})$$

which, for $(i_m)_0 = I_m wl$ is Eq. [1].

illuminated surface of the top layer of particles. It is independent of interparticle contacts and the more reliable and reproducible indication of the quantity and type of mobile carriers in the material. One therefore should choose those experimental parameters (intensity of incident light, cell thickness, volume fraction of material in the phosphor-liquid dielectric mixture, etc.) which enhance the fast pulse and minimize the slow interparticle current.

The RC decay time of the fast displacement current pulse arises from a capacitance C which is experimentally equal to the cell capacitance and an R which apparently arises from isolated photoconducting areas on the particle surfaces parallel to the direction of the measured current. Incident light (which is not absorbed by the imbedding medium) can be scattered into the interior of the cell and illuminate these parallel particle surfaces. Hence the equivalent circuit can be characterized as a series resistance R and capacitance C. R can be estimated from the reduction in current pulse height caused by the insertion of a large resistor in series with the cell. R varies directly with cell thickness in the range of 50-500μ; it decreases with increasing light intensity as shown in Fig. 3. C can be estimated from the value of R and the exponential decay time of the pulse. This value of C agrees well with the capacitance of the cell computed from the current produced by applying a high frequency a-c field. C is very nearly independent of light intensity (cf. Fig. 3). As long as the oscilloscope input resistance used to measure the Dember current is small compared to R, the decay time of the current (the fast part) is independent of the cell thickness, since R varies directly and C inversely with thickness.

The charge Q moves a diffusion length d from the surface of the top layer of particles. The fraction of this charge which contributes to the pulse current observed in the external circuit is d/l, where l is the thickness of the cell. Since the exponential decay time RC is independent of l, the peak external current

$$i_m = \frac{Q(d/l)}{RC} \qquad [2]$$

varies inversely with the cell thickness l. Typically $(i_m)_0$ varies with the intensity of the incident light as shown in Fig. 3 for a ZnS:Cu, Cl phosphor for 320 mμ excitation.

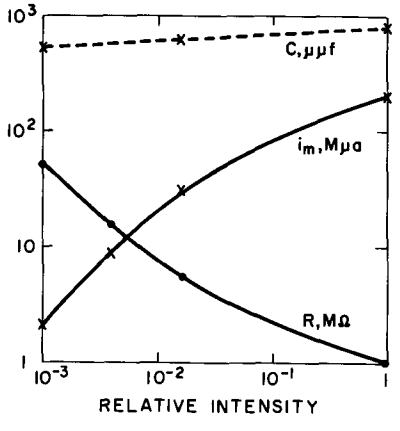

Fig. 3. Variation with incident intensity of 320 mμ light of: i_m, the peak pulse current; R, the effective resistance; and C, the capacitance. See text.

One can estimate a lower limit for the diffusion distance d from the peak current, $(i_m)_0$, produced by a known photon flux $W_{h\nu}$ falling on a cell of known thickness l. Because of the insulated contact each photon striking the surface of the cell can produce at most one mobile carrier to diffuse away from that surface an average distance d and contribute to $(i_m)_0$ in the ratio d/l. Since

$$(i_m)_0/e < W_{h\nu}\frac{d}{l} \qquad [3]$$

we have

$$d > l[(i_m)_0/e\, W_{h\nu}] \qquad [4]$$

The maximum estimate of the lower limit of d is obtained at that incident intensity for which the current is varying most strongly with intensity. Experimentally this variation is at most linear and occurs in Fig. 3 for a value of the intensity 2 x 10^{-8} times the maximum photon flux used, which is 2 x 10^{15} photons/sec. For this case $W_{h\nu}$ is 4 x 10^{12} photons/sec, l is 55μ, and i_m is 5 x 10^{-9} amp. Substitution of these values in Eq. [4] shows that d must be at least 0.4μ. This distance represents an appreciable penetration into the particle bulk and at least indicates that more than the surface is involved in these measurements.

The effect of variation of the volume fraction of the active material in the imbedding medium on $(i_m)_0$ can be summarized as follows: For thin cells (less than 100 microns) $(i_m)_0$ increases first linearly with increasing volume fraction of the phosphor, but appears to saturate above 40%. For thicker cells the saturation occurs at lower values of the volume concentration. The value of the volume concentration of the active material used in most measurements was 30%.

In the absence of an insulating layer a direct photocurrent is produced by the incident, strongly absorbed radiation. It is probably due to the photovoltaic effects at the interparticle contacts. One can measure an open-circuit voltage and a short-circuit current with an electrometer and from these values compute an effective d-c resistance, assuming ohmic character. With the insulating Mylar present, this interparticle current and the fast displacement current build up a charge on the Mylar which is measurable as an open-circuit voltage on the electrometer. This voltage increases with cell thickness, indicating that most of the charge accumulating on the insulating layer is carried by the interparticle contact current since the fast displacement current pulse decreases linearly with increasing cell thickness, as described above. The open-circuit voltage of a cell without the Mylar layer increases with increasing cell thickness. This result is as one might expect since the photovoltages of a larger number of contacts add to give a larger value for a thick cell than for a thin cell.

The decay of the slow, interparticle contact current, which forms the tail of the Dember pulse as shown in Fig. 2c, can also be characterized as the exponential decay of a series RC circuit. The capacitance is that of the ¼ mil Mylar layer and the

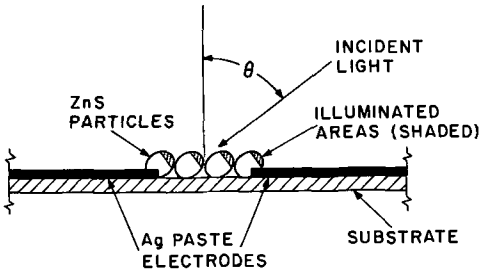

Fig. 4. Experimental arrangement used to measure the angular dependence of a d-c Dember voltage. See text.

resistance is the effective d-c photoresistance of the cell without the insulating layer, calculated from the open-circuit voltage and the short-circuit current of the latter cell. This agreement of the decay time of the Dember pulse tail with the product of the capacitance of the Mylar and the computed resistance of the d-c cell substantially identifies the two effects. That is, the direct photocurrent and the slow Dember pulse tail have the same origin, probably interparticle contact photovoltages.

This interparticle contact current depends on a gradient in the incident flux, as the following experiment demonstrates. A mixture of ZnS and binder was laid on two silver paste electrodes as shown in Fig. 4. A measurable open-circuit direct photovoltage (or a short-circuit current) is produced which is a function of the angle θ between the direction of the field between the two electrodes and the direction of the incident light. For θ different from zero there will be a component of the incident light in the same direction as that of the electrodes; this parallel component is proportional to sin θ. Since the measured photovoltage varies as the ¼ power of the intensity over two orders of magnitude in intensity, while the intensity of the light incident on the sample varies as cos θ, the expected variation in the open-circuit photovoltage is

$$V_{oc} = (\overline{V_{oc}})_m \cos^{1/4}\theta \sin\theta \qquad [5]$$

Equation [5] fits the experimental values of V_{oc} quite well for $(\overline{V_{oc}})_m = 1.8$v, correctly predicting a maximum of 1.3v at $\theta = 63° 25'$.

Experimentally it has been found that the value of the peak pulse displacement current is far more reproducible than the d-c contact photovoltage, both for measurements made at different times on the same sample and for different samples prepared in the same way from the same starting material. The uncertainty concerning the exact mechanism of the d-c effect makes it a less reliable indication of the sign of the more mobile carrier than the displacement current pulse. However, for fundamental radiation, the two effects do have the same sign for all samples examined thus far.

In summary the experimental conditions that have been found to favor the displacement pulse and to minimize the interparticle contact current tail are the following: (i) high intensity of incident light, (ii) as thin a cell as feasible, (iii) not too high a volume concentration, to minimize interparticle contacts, and (iv) the fastest available shutter speed.

Effects observed in ZnS *phosphors–general remarks.*—A large difference in depth between the electron trapping states and hole trapping states is the usual situation in ZnS. This fact, plus the higher microscopic mobility of electrons, leads to the possibility that not only completely compensated but also a significant range of p-type samples will yield electronic Dember currents. (An experimental technique for distinguishing the two types when both give electronic Dember currents will be described later.) At room temperature the absorption of fundamental radiation by compensated or n-type ZnS results in a concentration gradient in both holes and electrons. The holes are quickly trapped at the compensated and hence ionized acceptor levels which usually lie around 1 e. v. up from the valence band edge. The electrons are not strongly trapped at the shallow (~ 0.25 e. v.) ionized donor levels (in both compensated and n-type material) and therefore readily diffuse in the concentration gradient established by the strongly absorbed incident light. An electronic Dember current results.

Despite the rather large energy difference between acceptor levels and the valence band in ZnS, which allows almost no dark conductivity for even strongly p-type materials at room temperature, a p-type Dember current from fundamental radiation has been observed in such samples. Band gap radiation at the surface produces, as always, both electrons and holes in a strong gradient. In strongly p-type material, electrons will first be captured in the uncompensated and therefore unionized acceptors before the diffusion current of the holes is impeded by the resulting ionized acceptors, which are hole traps. More holes than electrons can move in the concentration gradient and a net hole current is observed. It should also be remarked that a given number of uncompensated acceptors per unit volume can produce a hole current only if the number of compensated acceptors (hole traps) is small. If this latter number is large, an electron Dember current results.

Excitation spectrum of the Dember effect, photoluminescence, and electrophotoluminescence.—Figure 5 shows the spectral distribution of the size and

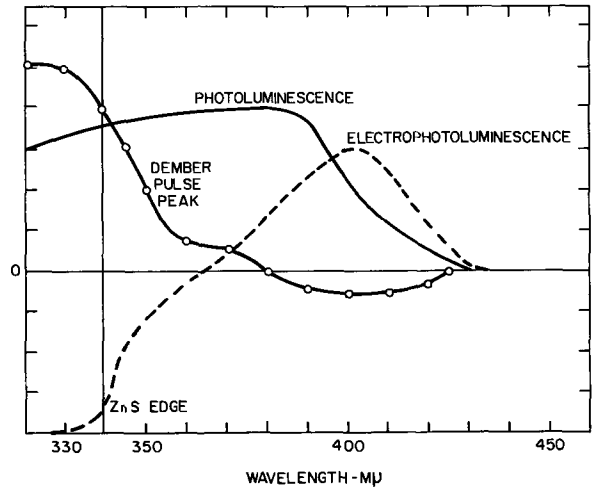

Fig. 5. Excitation spectra of photoluminescence, Dember pulse, and electrophotoluminescence for a ZnS:Cu,Cl phosphor. See text.

sign of the peak Dember pulse current for a ZnS phosphor containing 4 x 10^{-3} (mole fraction) Cu and 3 x 10^{-3} Cl. Significant absorption by impurities is shown by the finite positive current (indicating electron diffusion) extending up to 380 mμ. Unactivated ZnS yields a significant Dember pulse below 350 mμ at room temperature, indicating an absorption edge at around 340 mμ. The weaker absorption of wavelengths above 380 mμ by the Cu, Cl activated phosphor results in a reversal of the direction of the Dember pulse. This reversal is ascribed to the effect of fast surface states whose rapid capture of electrons produces a net flow of these carriers toward the illuminated surface and hence a negative pulse [cf. ref. (4)]. The weakly absorbed long wavelength light produces too moderate a concentration gradient in the mobile carriers to overcome their rapid depletion by the surface states. An attempt to change the occupation and hence the effect of the surface states with various ambient gases was unsuccessful. The close-packed and necessarily enclosed structure of the cell may have been responsible for this failure.

The excitation spectrum of the green photoluminescence of this ZnS:Cu, Cl phosphor is also shown in Fig. 5. No luminescence is excited by wavelengths greater than the Dember pulse cut-off around 450 mμ.

The electrophotoluminescence excitation spectrum in Fig. 5 shows the effect of a pulsed electric field applied to the cell on the luminescence excited at each wavelength. In the long wavelength region the usual Godden-Pohl (7) effect appears. A pulsed enhancement of the photoluminescence occurs for both the application and the reversal of the electric field. This behavior is depicted in Fig. 6a for 400 mμ. The field (of either polarity) served to empty filled traps, either by direct field ionization or by the impact of field-accelerated electrons, and a temporary increase in emission results. It is interesting to note that the applied fields required to produce this effect are only of the order 5 x 10^3 v/cm for electroluminescent ZnS:Cu, Cl phosphors, but over 5 x 10^4 v/cm are necessary for nonelectroluminescent ZnS:Cu, Cl phosphors. This observation corroborates the postulated existence of regions of much higher than average fields in the electroluminescent material (8).

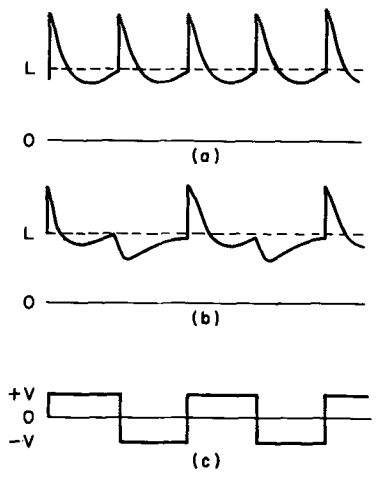

Fig. 6. Field modulation of photoluminescence in a ZnS:Cu,Cl phosphor (electrophotoluminescence): The effect of pulsed electric field (c) on the luminescence excited by 400 mμ (a) and 320 mμ (b). The dashed line is the unmodulated photoluminescence.

For short wavelengths a different type of modulation of the luminescence by the field occurs, which has been described by Halsted (9). Here the field apparently moves the mobile carriers into or out of the narrow excitation region determined by the absorption constant of the material for the incident light. If electrons are the more mobile carriers and if the radiative recombination is that of a free electron and a trapped hole, then making the illuminated surface positive will increase the luminescence by pulling more electrons into the excitation region. Application of a negative voltage to the surface produces a temporary diminution in the emission. This type of electrophotoluminescence is illustrated in Fig. 6b for which the exciting wavelength is 330 mμ. The electrophotoluminescence excitation spectrum in Fig. 5 shows the peak relative change (arbitrary units) in the photoluminescence produced by applying a negative field of 3 x 10^4 v/cm. At 365mμ there is a change in sign of this electrophotoluminescence, denoting a transition from one effect to another. Above 365 mμ the field has the effect of emptying electron traps while below this point the field moves the free carriers in and out of the excitation region. For the field of opposite polarity (positive) the sign of the electrophotoluminescence is opposite to that shown in Fig. 5 below 365 mμ and the same as shown above that wavelength. The results of the electrophotoluminescence and Dember measurements are consistent with mobile electrons and the radiative recombination of free electrons and trapped holes.

Relaxation and temperature effects.—In most instances the size and in some cases the direction and shape of the Dember pulse is a sensitive function of the time the cell has remained in the dark since last exposed to the exciting light. When the wavelength of the incident radiation is in the fundamental region, longer dark relaxation times give larger peak Dember currents. The more time that is available for the relaxation of the polarization field produced by a previous exposure to the strongly absorbed radiation, the greater the diffusion current which can flow when the excitation is again applied to the sample. In many cases the maximum current flows following a definite dark time. Both longer and shorter dark times can result in a smaller pulse peak. There are at least two possible explanations for the occurrence of this maximum. One possibility is the increase in the effective mobility of the carriers caused by filling some of the traps in the excitation region. The degree to which these traps are filled is greatest for short dark intervals.

One other possible explanation invokes the undoubted heterogeneity of the powder samples. A distribution of p-type and n-type (or compensated) particles is assumed. The electronic displacement in the n-type particles relaxes after only small dark intervals; the polarization of the p-type particles relaxes much more slowly since the holes are

trapped in much deeper levels than are the electrons (~1.0 e. v. for holes, ~0.25 e. v. for electrons). At the dark time for which the maximum electron Dember current is produced nearly all of the electrons in the n-type particles and only a few of the holes in the p-type particles have returned to the region from which they were excited near the surface. Longer dark times allow the return of an appreciable number of holes, so that the net electron Dember current pulse is reduced.

In some instances the sign of the Dember current pulse for sufficiently long periods of dark relaxation is opposite (p-type) in sign to that measured for short periods in the dark (n-type). A relatively short exposure (1 min) to intense long wavelength radiation (over 600 mμ) produces the same reversal (or reduction in value) in the Dember pulse (at 320 mμ) as the extended dark period (overnight). The effect of the long wavelength light will be discussed in more detail in the section on optical relaxation effects.

One can conclude from the above model that a Dember signal that monotonically increases with increasing dark time characterizes n-type or completely compensated material. A maximum pulse at a particular dark time indicates an appreciable amount of p-type material. A more convenient experimental criterion is the following: the Dember pulse is measured after 1 min in the dark (Pulse A) and after 1 min exposure to intense IR (Pulse B). Figure 7 schematically illustrates the four experimental possibilities and lists the nature of the material deduced from the experiment. If Pulse B is equal to or greater than a positive Pulse A, then there is no detectable p-type material. For Pulse A positive and greater than Pulse B (positive or negative), the absolute value of B − A is taken as a measure of the degree of p-type uncompensation in the sample. If Pulse A as well as Pulse B is negative, the value of Pulse B alone measures the degree of p-typeness, since there is apparently no measurable electron current. The deduced Pulse C is, in each instance, a measure of the p-typeness of the material.

Since the interparticle contact photocurrent does not, in general, reverse its direction at the same wavelength as the Dember pulse (cf. Fig. 5), quite complicated pulse shapes are possible in this re-

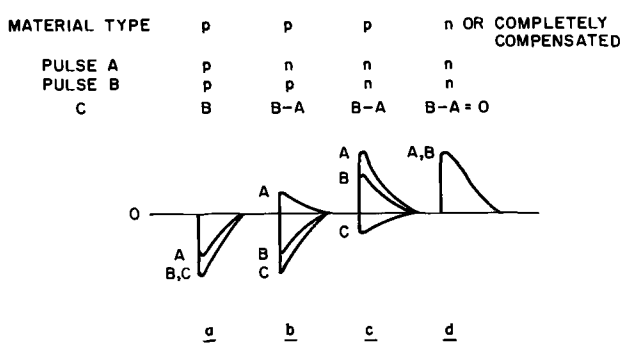

Fig. 7. Four possible Dember pulse combinations obtained from ZnS materials: Pulse A, after 1 min dark relaxation; Pulse B, after 1 min infrared exposure; Pulse C, deduced p-type current in Pulse B. See text.

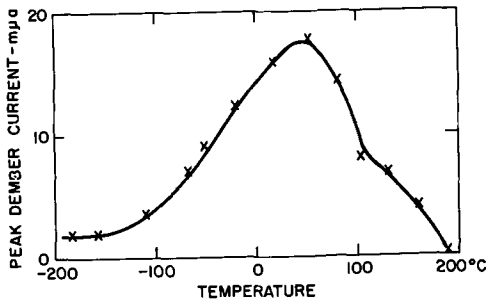

Fig. 8. Temperature dependence of the Dember pulse peak (30 sec dark interval) for a ZnS:Cu,Cl phosphor.

versal region. At least two extrema are observed when the reversal is present. The relative size and position of these extrema depend on the dark relaxation time, the wavelength, and the intensity of the exciting light. Some materials have given as many as four extrema in this reversal region.

A typical dependence of the height of the Dember pulse on temperature is shown in Fig. 8, for a ZnS:Cu, Cl 4 x 10^{-3} phosphor. The exciting wavelength was 320 mμ and a dark interval of 30 sec was used at each point. The Dember pulse is smaller at high temperatures for n-type or compensated specimens for either of two reasons. One is that both electrons and holes can diffuse in the concentration gradient, yielding a lower net electron current; the other is that the electron mobility could decrease at high temperatures. At low temperatures the electrons are frozen at shallow (~ 0.25 e. v.) traps. In the region of maximum response only the holes are immobilized at deep (~ 1 e. v.) hole traps, resulting in a large electron diffusion current. Shorter (< 30 sec) dark times tend to shift the temperature of maximum response to higher temperatures.

For a specimen of unactivated ZnS fired at 1200°C in a sealed vacuum and presumed (because of the higher volatility of S_2 compared to Zn) to contain excess Zn and therefore some uncompensated donors (sulfur vacancies) an interesting behavior was observed. At room temperature only a small peak Dember current (<10^{-8} amp) appeared for reasonable dark times of the order of minutes. This current could be increased to around 1.0 x 10^{-7} amp by very long periods of relaxation in the dark or by heating to above 150°C and returning to room temperature before flashing with the 320 mμ. After cooling the sample to nitrogen temperature from room temperature and subsequent exposure to the 320 mμ light, the measured current was 1.5 x 10^{-7} amp. If the sample was first heated to 150°C before cooling to −180°C, a peak Dember pulse of 2 x 10^{-7} amp was measured. The second pulse at −180°C is in every case negligibly small, less than 10^{-9} amp. The high value of the first pulse at this temperature may be due to the freezing of the dark electrons on the uncompensated donors, with a consequent decrease in the scattering due to charged, ionized donors present at room temperature. Thus a higher Dember current pulse results than for even the completely relaxed sample at room temperature (2 x 10^{-7} *vs.* 1 x 10^{-7} amp). ZnS materials expected to be completely compensated do not exhibit this behavior.

Optical relaxation effects.—The continuous exposure of the test cell to a beam of radiation other than that which is flashed onto it to produce a pulse of diffusion current usually results in lower peak value. This reduction of the pulse height is most prominent when the two beams of radiation are the same wavelength. An exception to this behavior is the case in which the continuous exposure is to wavelengths in the fundamental and the pulsed beam is in the reversed region at longer wavelengths. (cf. Fig. 5). The extrinsic carriers ionized by the weakly absorbed long wavelength radiation move in the polarization field maintained by the strongly absorbed fundamental radiation. The result is an increase in the reversed pulse normally observed in this wavelength region. In fact, to obtain this increase, simultaneous exposure is not necessary in some cases, so that a previous exposure to fundamental radiation suffices to enhance the reversed current in the long wavelength region. Hence, in order to obtain unambiguous results from long wavelength excitation, one should proceed from long to short wavelengths in measuring the spectral dependence of the Dember effect, using a sample kept in the dark for a prolonged period.

In some cases ZnS materials which yield positive (electron current) Dember pulses for short dark time intervals not only give reduced positive signals for long relaxation periods, but for sufficiently long dark times produce a negative (hole current) Dember pulse. This reversal in sign (for fundamental excitation) can also be effected by exposure to long wavelength radiation. Figure 9a shows the size of the Dember pulse peak obtained at 320 mμ for a ZnS sample after relaxing for 30 sec while exposed to the radiation whose wavelength is indicated on the abscissa. The unactivated ZnS was fired for 24 hr at 900°C in a sealed quartz tube in a sulfur pressure of

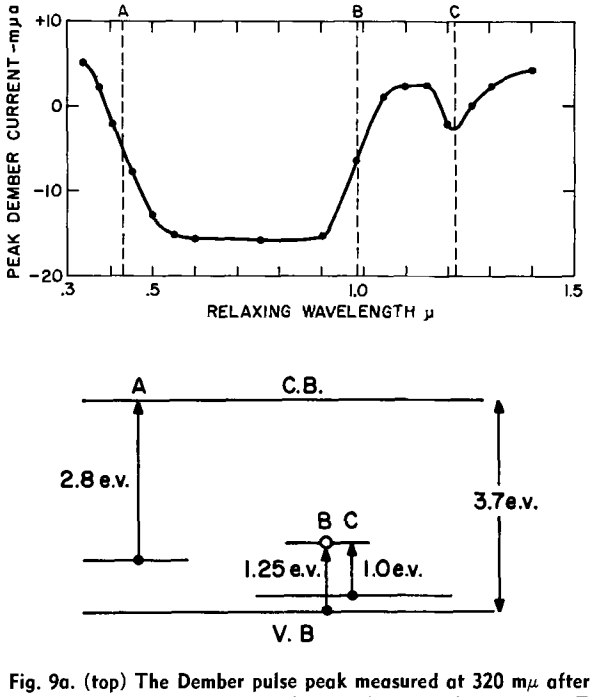

Fig. 9a. (top) The Dember pulse peak measured at 320 mμ after 1 min exposure to the plotted wavelengths for an undoped p-type ZnS sample. Fig. 9b (bottom) The energy levels deduced from (a). The transitions A, B, and C are described in the text.

6 atm. There is no luminescence. Figure 9b shows an energy level scheme consistent with the data of Fig. 9a. Wavelengths between 450 mμ (A) and 1.0μ (B) raise electrons from the valence band to the ground state of an unionized acceptor, freeing a hole in the valence band to return to the excitation region and relaxing the sample (transition B). Radiation of 1.2μ (C) lifts an electron from an excited hole state of the unionized acceptor (which is in thermal contact with the valence band) to the ground state of the unionized acceptor (transition C). The hole, which is now situated at the excited hole state of the acceptor, can now be thermally released into the valence band. Wavelengths below 450 mμ (A) are more effective in ionizing electrons from a filled center (transition A) than holes from an empty center, increasing the probability of a positive (electron current) Dember pulse. The proposed energy level structure of the acceptor is remarkably close to that deduced by Apple and Prener (10) from the infrared fluorescence and diffuse reflectance of ZnS into which Cu had been fired under sulfur pressure to produce uncompensated acceptors. Whether the acceptor in the present material is due to impurities such as Cu which were present in the "pure" (RCA luminescent grade) unactivated material or simply arise from a singly ionized zinc vacancy is uncertain.

A ZnS:1.5 x 10^{-3} Cu, 1.0 x 10^{-3} Cl blue-green emitting phosphor also exhibited this reversal of a positive (electron current) pulse at 320 mμ after relaxing with long wavelength radiation. A relaxation spectrum similar to Fig. 9a was obtained. The Dember pulse in the 350 to 420 mμ region, which is negative for short dark times, becomes positive after long wavelength relaxation. The complete Dember current spectrum (cf. Fig. 5) is reversed in this instance in going from short dark times to long wavelength relaxation between pulses. One possible explanation of the positive (electron current) pulses obtained in p-type samples such as those described above for short dark times is that of holes going toward the surface, from which they could escape (depolarize) more readily than from the bulk where they might be trapped more deeply. Since going to longer exciting wavelengths could hardly reverse this process, as it does in the present instance, this explanation must be discounted.

For the above phosphor (ZnS:1.5 x 10^{-3} Cu, 1.0 x 10^{-3} Cl) the blue-green photoluminescence produced by 365 mμ ultraviolet is strongly quenched when infrared radiation is also shone on the sample. The spectral dependence of the quenching effect is in close agreement with the relaxation spectrum. This result confirms the hypothesis that the release of holes into the valence band from the empty activator level (transitions B and C in Fig. 9b) is the first step in both the quenching of luminescence and the optical relaxation of the Dember polarization.

Measurements on other materials.—Some measurements have been performed on other compounds than ZnS in powder form, including CdSe, ZnSe, ZnTe, and mixed crystals of ZnS and ZnSe. The results are of the same form as for ZnS, yielding information on the type of carrier which is either more mobile or a true majority carrier. The shift in band

edge of ZnS, ZnSe alloys as a function of composition, as well as its shift with temperature, is easily measured, for example. Shifts in stoichiometry produced by various thermal treatments have been followed in at least a semiquantitative sense with CdSe as well as ZnS.

Similar measurements are possible with thin films deposited on a conducting substrate. A piece of conducting quartz separated from the film by a quarter mil Mylar layer forms the second electrode of the Dember cell. Films of p-type CdTe and both p- and n-type CdSe have been prepared (by G. Somorjai) and measured in this manner.

Summary and Conclusions

The pulsed Dember effect measured as described above is a useful tool for indicating the type of mobile carrier and to a degree the extent of activation of powder and thin film materials of the ZnS type. The displacement current pulse is probably a more reliable and certainly a more reproducible measurement than a direct current measurement relying on interparticle contacts. Careful control of such experimental parameters as cell thickness, volume concentration of the material, and radiation intensity are necessary for good reproducibility.

The change in size and direction of the Dember pulse can be used to follow shifts in stoichiometry and impurity content resulting from various treatments. For example, unactivated ZnS fired in sealed quartz tubes under various sulfur pressures shows a shift from n- to p-type pulses with increasing sulfur pressure. The algebraic value of the peak current is linear with $\sqrt{p_{S_2}}$. Uncontrolled impurities in the starting material have lead to ambiguous results in many cases, however. Experiments of this type are still being pursued.

In luminescent materials, measurements of the Dember effect and of the electrophotoluminescent response can unambiguously determine the nature of the radiative recombination under certain conditions. Often a relaxation spectrum such as that shown in Fig. 9a can be obtained. Information on the existence and nature of such levels as shown in Fig. 9b can thus be obtained and correlated with, for example, the photoluminescence excitation and quenching spectrum of the same material. Such levels can even be demonstrated to exist in materials that are otherwise uncommunicative, that is nonluminescent.

Acknowledgments

The writers wish to thank Drs. S. P. Keller, R. S. Title, F. Jona, G. Mandel, L. Suchow, and G. Somorjai for much helpful discussion and many suggestions. The services of Mr. J. A. Kucza for many preparations and Mr. W. N. Hammer for assistance in making many of the measurements is gratefully acknowledged.

Manuscript received Jan. 15, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Effect of the Phosphor-Embedding Medium on the Performance of Electroluminescent Cells

Gabriel P. Katona[1]

Corning Glass Works, Corning, New York

ABSTRACT

The higher the dielectric constant of the phosphor-embedding medium, the higher is the field on the embedded phosphor. When working with ZnS-type phosphors, not much is to be gained from embedding media having dielectric constants higher than 50. In the case of embedding media having a low dielectric constant the emission can be increased by making the embedding medium of greater loss materials. This move will not necessarily lower the efficiency, but at points it will even improve it. It is shown that maximum efficiency can be obtained when the dielectric constant of the embedding medium and the phosphor are identical.

The primary goals of research for better electroluminescent lamps and devices are to develop materials and structures that will result in higher brightness and better luminous efficiency. Much has been reported in the literature of the work to achieve these aims through improved phosphors. In this paper the effect of the dielectrics on the brightness and efficiency of electroluminescent cells is discussed.

[1] Present address: Nolte and Nolte, New York, N. Y.

Dielectrics perform two basic roles in electroluminescent structures: (*a*) they act as embedding media, (*b*) they are used as breakdown protecting layers. The second function will be discussed in a later article.

The properties of the embedding medium have a multifold effect on the performance of an electroluminescent lamp. Such effects can be due to dielectric properties of the materials, physicochemical interaction between the phosphor and dielectric, viscosity of the dielectric allowing movement of the embedded phosphor, moisture penetrability of the dielectric affecting maintenance, etc. This paper investigates the effect of the dielectric properties.

The availability of embedding materials embracing a wide range of dielectric properties is rather limited. Therefore, the considerations to be presented may aid in the selection of the materials that are most suitable for a required purpose.

The same green emitting ZnS:Cu, Cl electroluminescent phosphor was used throughout the investigation; thus the considerations presented can be assumed to be valid in case of other phosphors only when the voltage response of the other phosphor is similar to that of the phosphor used here. Definitions of the symbols used are listed at the end of the paper.

Effect of the Dielectric Constant

Roberts (1) and Kerner (2) have shown that the internal field, directly acting on the embedded phosphor, is related to the applied field by

$$E_o = E_2 \frac{3K_1}{2K_1 + K_2 - N(K_2 - K_1)} \qquad [1]$$

The value of $K_2 = 10$ was used for the dielectric constant of the phosphor in the subsequent calculations. This is an approximate average of the various values reported in the literature for ZnS-type electroluminescent phosphors.

The internal field was calculated as a function of the dielectric constant of the embedding medium, by means of Eq. [1]. The results are shown in Fig. 1. The arbitrary value of 23% by volume of phosphor was used. The applied field was 100 v/cm.

As Fig. 1 and Eq. [1] indicate, by choosing embedding media having a dielectric constant higher than the dielectric constant of the phosphor, the internal field acting on the phosphor becomes greater than the field applied across the cell proper.

Using the above example of 23% by volume phosphor and 100v applied across a thickness of 1 cm, it is possible to obtain internal field values which are higher than the applied electric field. When the dielectric constant (permittivity) of the embedding medium is infinite, it allows unimpeded passage of the applied field, which then appears across a continuous phosphor layer that is in effect 0.23 cm thick. The resultant field across the phosphor then is 100/0.23 = 435 v/cm.

The results obtained by using Eq. [1] were used to plot the effect of the dielectric constant of the embedding medium on the emission intensity. A cell was prepared by embedding a commercial EL phosphor in glass[2] and the brightness values, measured as a function of voltage on this cell, were used for the calculations. The phosphor concentration was 23% by volume, and the frequency was 1000 cps. The dielectric constant of the embedding glass was about 5.

[2] Corning Code 1970, a glass specially developed for electroluminescent phosphor-embedding purposes.

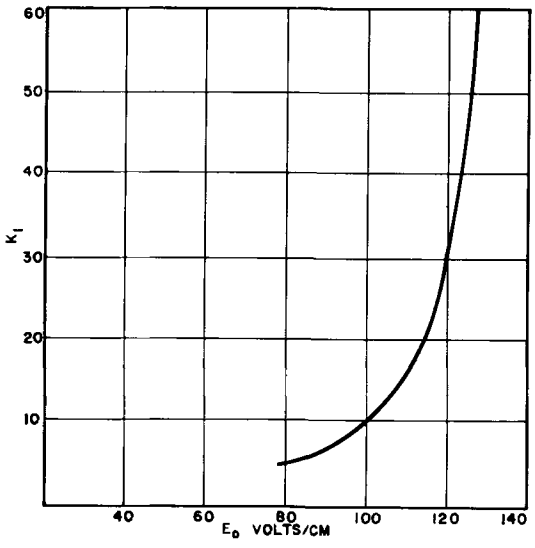

Fig. 1. Effect of the dielectric constant of the phosphor embedding medium on the internal field.

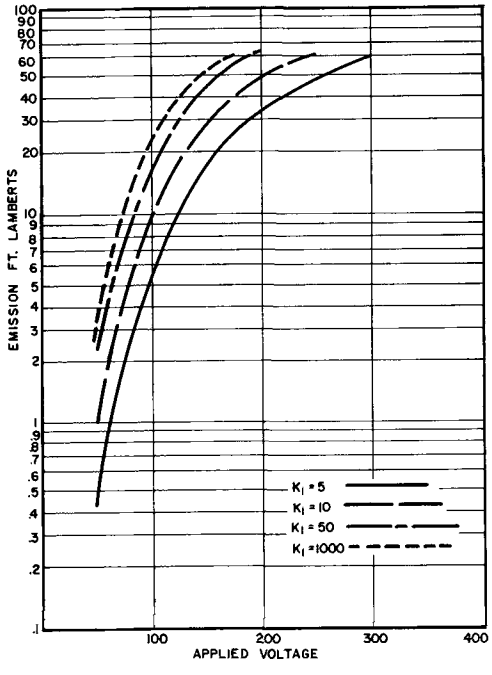

Fig. 2. Effect of the dielectric constant of the phosphor embedding medium on the emission intensity.

As Fig. 2 shows, by raising the dielectric constant of the embedding material from 5 to 10, a brightness gain of about 100% can be predicted. By further raising the dielectric constant from 10 to 50 a further brightness gain of nearly 100% can be predicted. By raising the dielectric constant from 50 to 1000, a brightness gain of only about 30% could be realized theoretically within the validity of Eq. [1]. These data indicate that, when striving to raise the dielectric constant of the presently available embedding media by intensified materials development efforts, a practical limit of 50 would be adequate.

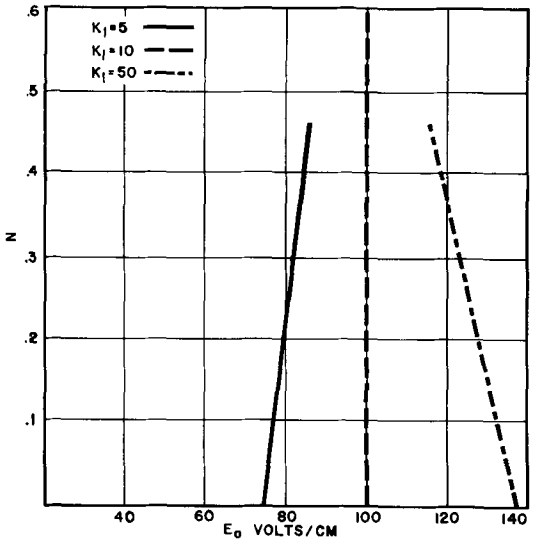

Fig. 3. Effect of the phosphor volume ratio on the internal field

Effect of Phosphor Concentration

Equation [1] can also be used to calculate the effect of phosphor concentration on the field distribution within the electroluminescent layer. Figure 3 shows the internal field as a function of the volume fraction of the embedded phosphor. As above, the dielectric constant of the phosphor was assumed to be 10, and the applied field, 100 v/cm.

Effect of the Loss Tangent

The complex dielectric constant of the form

$$K^* = K' - jK'' \qquad [2]$$

was substituted into Eq. [1] for the dielectric constants of the embedding medium (K_1) and the phosphor (K_2). Thus one obtains

$$E_o = E_2 \frac{3(K'_1 - jK''_1)}{(K'_1 - jK''_1)(2+N) + (K'_2 - jK''_2)(1-N)} \qquad [3]$$

By using the loss characteristics of the phosphor that was used throughout this work (3) it was found that the phosphor can be represented only by its dielectric constant and that neglecting the phosphor loss has only a very small effect on E_o in case of phosphor concentrations in the 20% by volume range.[3] Consequently Eq. 3 was modified to read:

$$E_o = E_2 \frac{3(K'_1 - jK''_1)}{(K'_1 - jK''_1)(2+N) + K_2(1-N)} \qquad [4]$$

By substituting $K''_1 = K'_1 \tan\delta$ one obtains for the absolute value of the internal field:

$$E_o = 3E_2 \sqrt{\left\{\frac{K'_1K_2(1-N) + K'^2_1(2+N)(1+\tan^2\delta)}{[K_2(1-N) + K'_1(2+N)]^2 + [(2+N)(K'_1\tan\delta)]^2}\right\}^2 + \left\{\frac{(1-N)(K'_1K_2\tan\delta)}{[K_2(1-N) + K'_1(2+N)]^2 + [(2+N)(K'_1\tan\delta)]^2}\right\}^2} \qquad [5]$$

The values of E_o *vs.* tan δ are shown in Fig. 4 for different values of K'_1. The phosphor concentration was chosen to be 20% by volume and the applied field was 27.39 kv/cm (69.57 v/mil). The calculations were executed by a Royal McBee LGP-30 digital computer. The corresponding tan δ *vs.* emission curves are plotted in Fig. 5 and were obtained by utilizing the E_o *vs.* emission values of the same phosphor. This curve was calculated from an experimental E_2 *vs.* emission curve, using Eq. [1].

The curves indicate that, in the case of embedding media having a relatively low dielectric constant, the emission can be considerably enhanced by choosing a lossy material. Only small effects can be achieved by progressing from a low loss value to about tan δ = 0.5. There is no reason to believe that Eq. [5] should not be valid for higher values of tan δ, because (except for the assumption of spherical phosphor particles) the equation was derived by rigorous mathematical treatment from Eq. [1].

By using the values plotted in Fig. 5, one can observe that, when an embedding medium with a dielectric constant of 2.5 (approximately the permittivity of polystyrene) is used, the emission of the electroluminescent cell theoretically can be increased by a factor of 6, by theoretically increasing the loss tangent to 1 (45°). When an embedding medium having a dielectric constant of 5 (approximately Corning Code 1970) is used, the emission theoretically can be doubled by increasing the loss tangent from a low value to 1.

It is evident that it would be more advantageous to select embedding media with a high dielectric constant, if one wishes to increase the output of the lamp. If such a material is not available, the same effect can be obtained by using a higher loss material, although possibly at the cost of lower efficiency and heating of the lamp.

An attempt was made to check Eq. [5] and Fig. 5 experimentally. The dielectric constants and loss tangents of various liquids were measured on a General Radio 650A impedance bridge at 1 kc, using a GE three terminal, liquid sample holder (G. E. Co., Cat.

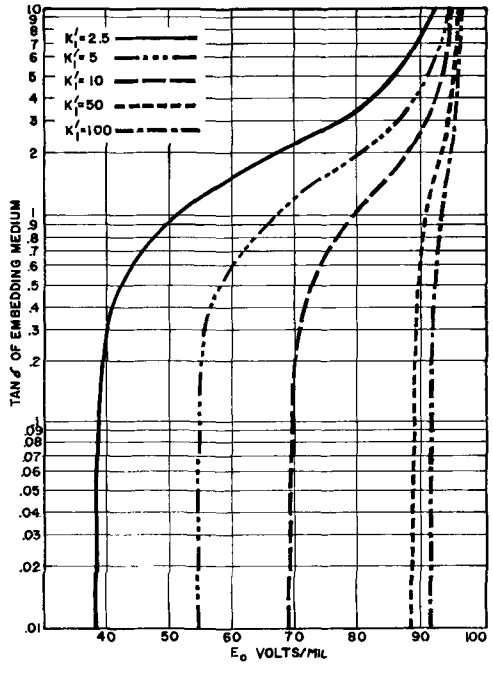

Fig. 4. Internal field as a function of the loss tangent of the phosphor embedding medium.

[3] This is not necessarily applicable to all electroluminescent phosphors and phosphor-embedding medium combinations. For detailed discussion on the subject see: A. N. Ince and C. W. Oatley, *Phil. Mag.*, 46, 1081 (1955); W. Lehmann, *This Journal*, 103, 24 (1956).

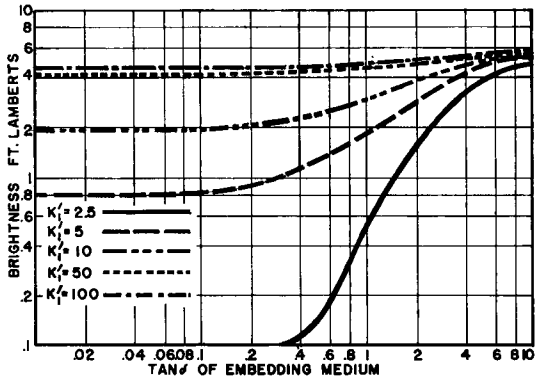

Fig. 5. Emission intensity as a function of the loss tangent of the phosphor embedding medium.

5100774). The measurements were made with the phosphor and the liquid being in a sample holder with a 0.00584 cm (2.3 mil) gap. An audio oscillator and a high powered amplifier were used as power source. The emission measurements were made with a VISCOR visibility correcting filter-equipped Weston 856 type photocell and a L&N Type E galvanometer. In instances where tan δ was very high, a resistance had to be used in a series with the cell, to limit the current.

Table I contains the measured dielectric properties and the results of the electroluminescent evaluation, together with the calculated values. The phosphor was the identical phosphor used in the earlier parts of the study where it was used in a glass embedding medium. 20% by volume was used, the emission was measured at 1 kc, and the applied field was 27.39 kv/cm. To obtain the values in the "calculated" column of Table I, the value of E_o was calculated and the corresponding brightness value was obtained from the E_o *vs.* brightness curve of the phosphor.

The fact that all experimental data are lower than the calculated ones led to a reexamination of Eq. [5]. Small discrepancies in the values of K_2 and N cannot account for the difference. Only two significant figures were obtained in the measurement of the dielectric constant and loss tangent because the balance of the bridge was rather broad, due to the relatively high loss values. The K'_1 and loss tangent values of most of these liquids are extremely frequency-sensitive. For example, in case of acetone at 10 kc, values were measured of $K'_1 = 23$ and tan $\delta = 0.7$; therefore an inaccurate frequency adjustment may have been a large source of error. The effect of orientation of the phosphor in the liquid medium under the applied field was not considered. In the light of the above considerations, the agreement between the measured and calculated values can be considered good.

Table I. Calculated and measured emission intensities of an electroluminescent phosphor in various phosphor embedding media

Liquid	K'_1	Tan δ	Brightness/ft-L	
			Calculated	Measured
Acetone	1300	25	5.1	4.8
Benzene	2.3	0.01	(<0.4)	(<0.4)
Castor oil	4.7	0.082	0.7	0.6
Glycerol	90	3.7	5.0	3.9

Power Requirement and Efficiency

The calculation of power input and efficiency from the available data can be made with the aid of the following equation:

$$P = 2\,\epsilon_o\, f\, V^2 K'' \frac{A}{D} \qquad [6]$$

A similar formula has been quoted by von Hippel (4).

The results of the power and efficiency calculations are shown in Fig. 6 and 7. It is interesting to note that in case of a dielectric constant of 2.5 there are three different solutions for the same efficiency. This means that a brightness increase by a factor of 25 can be obtained at no loss of efficiency by increasing the tan δ of the embedding medium. With higher dielectric constants that effect rapidly diminishes.

Figures 6 and 7 indicate that the maximum obtainable efficiency, regardless of the brightness, can be obtained with embedding media having a dielectric constant somewhere between 5 and 50. The efficiencies were calculated for a series of dielectric constant values in order to determine the maximum. Figure 8 shows the results of these calculations for a value of tan δ of 0.01 in each case. The curve shows the maximum efficiency is obtained at a point where K'_1 is near 10. At this point the assumed dielectric constant of the phosphor and the dielectric constant of the embedding medium are identical.

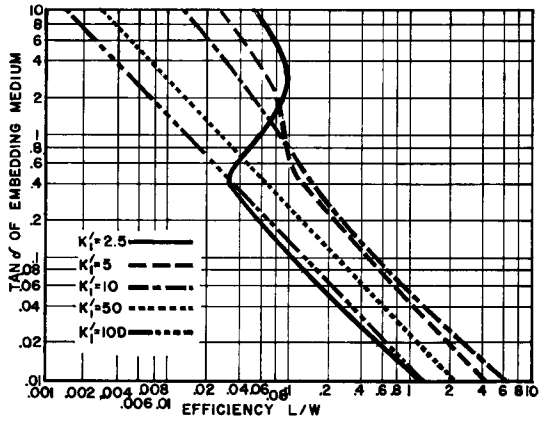

Fig. 6. Effect of the loss tangent of the phosphor embedding medium on the efficiency.

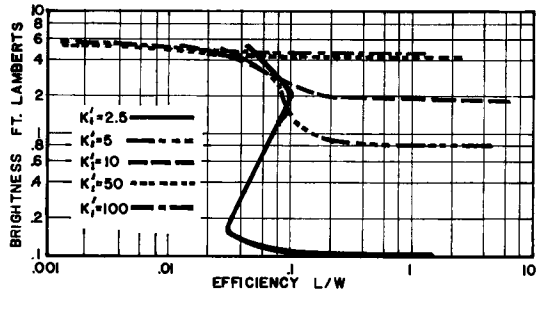

Fig. 7. Efficiency as a function of the emission intensity and the dielectric constant of the embedding medium.

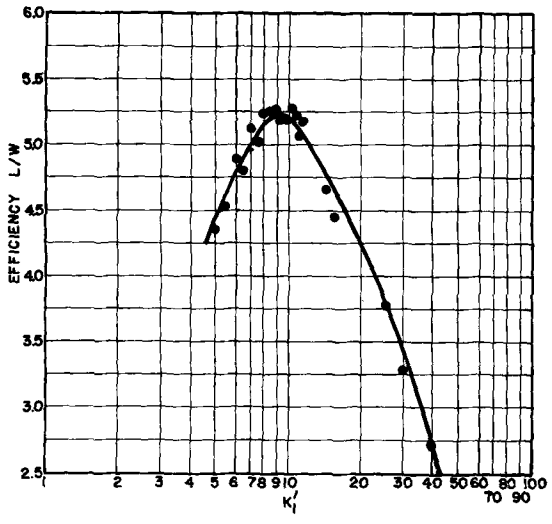

Fig. 8. Maximum efficiency of an electroluminescent cell as a function of the dielectric constant of the phosphor embedding medium.

The incidence of maximum efficiency when the dielectric constants of the phosphor and the embedding medium are identical can be considered only indicative at the most, because the voltage value substituted into Eq. [6] was not the voltage at which peak efficiency (5) can be obtained, but was the same arbitrary voltage used in earlier parts of the study.

Summary

The effect of the dielectric properties of electroluminescent phosphor-embedding media on brightness and efficiency have been examined. Using a formula by Roberts (1), it was established that an increase in the dielectric constant of the embedding medium above a value of 50 does not result in an appreciable gain in emission.

By expanding Roberts' formula to include the loss factor, the effect of the loss tangent of the embedding material was investigated. The results show that from a low loss tangent value of 0.01 to about 0.5, very little change in light emission can be obtained, but above 0.5 a rapid increase in brightness occurs. At successively higher dielectric constant values this increase diminishes. The theoretical calculations were in good agreement with experimental measurements.

In case of a lower dielectric constant embedding media, three different emission values can be obtained at the same efficiency if the loss tangent is varied. Consequently, in such a case the brightness can be increased substantially at no cost in efficiency. Indications are that maximum efficiency can be obtained when the dielectric constant of the phosphor and the embedding medium are identical. In this case the applied field equals the internal field.

Acknowledgments

The valuable suggestions made by Drs. R. V. Harrington and V. D. Mochel and Mr. W. H. Barney are greatly appreciated. Mr. K. R. Kiehl programmed the computer. Miss M. T. Splann has made the dielectric and Mr. J. C. Pinkston the electroluminescent measurements.

K_2, Dielectric constant of phosphor.
N, Volume fraction of embedded phosphor.
K^*, Complex dielectric constant.
K'_1, Real dielectric constant of embedding medium.
$K''_1 = K'_1 \tan \delta$, Loss factor of embedding medium.
$\tan \delta$, Loss tangent (of embedding medium).
V, Voltage, rms.
f, Frequency, cps.
A, Area, cm^2.
D, Thickness, cm.
ϵ_o, Permittivity of free space $= 8.85 \times 10^{-14}$, Farads/cm.
P, power, watts.
Eff., Efficiency, lpw.

Neutron-Activation Study of Gallium Arsenide Contamination by Quartz

Werner Kern

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

Gallium arsenide crystals were synthesized by the horizontal Bridgman method in neutron-activated boats of natural and synthetic fused quartz. Instrumental radiochemical techniques were applied to determine the silicon concentrations from Si^{31} radioactivity measurements and to identify other trace elements transferred to the gallium arsenide during the process. All crystals were found completely enveloped in an impurity-enriched surface layer containing silicon concentrations up to 1500 ppm. Bulk concentrations of silicon ranged from 1×10^{17} to 3×10^{18} atoms/cm^3 GaAs, and varied in different sections of the crystals within a factor of 1.7. Evidence of several types of transfer mechanisms was obtained. Other impurities that originated from natural fused quartz and were detected in the form of their radioactive isotopes in the crystals include copper, gallium, antimony, and gold at concentrations below 10^{16} atoms/cm^3; the concentrations of these contaminants were effectively decreased by use of high-purity synthetic quartz.

The majority of gallium arsenide crystals made for use in semiconductor devices have been synthesized by the horizontal Bridgman technique (1) using reaction vessels of fused quartz. Experience has indicated that gallium arsenide becomes contaminated by silicon from the quartz during the processes of preparation. In fact, silicon has been detected consistently in gallium arsenide crystals as one of the major impurities and has been recognized as the main electron donor in this semiconductor compound (1). Because the degree of purity is one of the most important quality parameters in semiconductor-grade gallium arsenide, the present investigation was undertaken to provide more knowledge concerning the role of contamination by quartz.

A radiochemical method of analysis appeared to be most promising because of its inherent sensitivity and specificity for trace quantities. Gallium arsenide was synthesized in a neutron-activated quartz boat, and the crystal samples were then analyzed by radiocounting and gamma-ray spectrometry. The experiments were designed primarily to provide information on the extent of silicon contamination. Other impurities originating from the quartz and encountered in the course of this work were identified as a secondary objective.

Bombardment of pure quartz with neutrons in a nuclear reactor leads to several known nuclear transformations (2, 3). Considerations of the relative quantities and half-lives of the product nuclides and the prevailing experimental conditions show that the only reaction of importance in this work is the Si^{30} (n, γ) Si^{31} transformation which takes place between the Si^{30} isotope present in natural silicon and the thermal neutrons from the re-

actor. The Si^{31} decays with a half-life of 2.62 hr to stable P^{31} by emitting one 1.471 Mev negatron per disintegration. In addition, one gamma photon of 1.26 Mev energy is emitted in 0.07% of the disintegrations. Part of the accumulating P^{31} is in turn activated during the bombardment to P^{32}, which transmutes by 1.707 Mev negatron emission with a 14.3-day half-life to stable S^{32}. However, the presence of P^{32} does not conflict in the analysis because of its long half-life with respect to that of Si^{31}.

Possible interference from neutron-activated impurities in fused quartz manufactured from natural sources can be anticipated. Impurity concentrations in three types of quartz from various sources (4-6) are summarized in Table I; also included are some neutron-activation analysis data obtained during this work. A multitude of radionuclides can be expected to arise when these elements are bombarded with nuclear reactor neutrons of thermal and high energies. In the early stages of the radioactivity analysis, the beta activity in the quartz from any of these impurities is relatively small in comparison to the Si^{31} activity. The situation in the gallium arsenide, however, cannot be predicted. One impurity nuclide which could seriously interfere with the radiochemical silicon analysis is Mn^{56}, if it were present in the gallium arsenide crystals. This nuclide has a 2.58-hr half-life and emits beta and gamma rays; it is produced by the thermal-neutron reaction $Mn^{55}(n,\gamma)Mn^{56}$ and by the fast-neutron reaction $Fe^{56}(n,p)Mn^{56}$. The other predictable thermal-neutron activation products have half-lives of either less than 0.5 hr or more than 12 hr and can be resolved from the Si^{31} radioactivity by decay counting.

Experimental

The quartz boats were cleaned before and after activation by submersion in concentrated nitric acid for 20-60 min, followed by extensive rinsings with deionized and doubly quartz-distilled water. The boats were then placed in quartz tubes and irradiated in the water-cooled nuclear reactor of the Industrial Reactor Laboratories, Inc., at Plainsboro, New Jersey. The fluxes employed for the five experiments varied depending on the reactor core position available and ranged between 2×10^{13} and 9×10^{13} thermal neutrons cm^{-2} sec^{-1}, as determined by separate measurements with flux monitor foils and nuclear counters. An irradiation period of 8 hr was chosen to obtain an 88% saturation activity yield of Si^{31}, and to minimize the activation of impurity elements yielding longer-lived nuclides. The activated boats were extracted from the reactor, allowed to "cool off" for 1 hr to decrease the high radiation levels from short-lived nuclides, and were then transferred into the "hot cell" for remote manipulations.

The gallium arsenide synthesis and crystal growth were maintained as close to the normal standard techniques as possible, except that smaller ingots (7g) were prepared and shorter growth periods were employed than usual to minimize radioactivity losses of the rapidly decaying Si^{31}. A weighed quantity of >99.9999% pure gallium as obtained from the manufacturer was placed in the activated quartz boat and introduced in the reaction tube of natural fused quartz. A stoichiometric quantity of >99.999% pure arsenic, plus an excess sufficient to produce an operating pressure of 1 atm, was placed in a second quartz boat, which was not activated, and was positioned in the reaction tube. The tube containing the two boats was first evacuated to 10^{-6} mm Hg and outgassed for purification purposes for 1 hr at temperatures of 200°C for the As and 600°C for the Ga zone. The tube was tipped off in vacuum and introduced into the preheated resistance furnace. A temperature of 1240°C was maintained around the boat zone in which the gallium arsenide crystal was growing during a period of either 3 or 5 hr, while the arsenic reservoir temperature was kept at 600°C. Gallium arsenide crystals were grown at speeds of up to 2 in./hr. The temperature was then reduced to 900°C, the tube was pulled out of the furnace, cooled, and opened on a cutting machine. The vicinity of the radioactive boat was kept closely shielded at all times to minimize radiation hazards. The gallium arsenide crystal was then removed for radioscanning, surface treatments, sectioning, powdering, and radioactivity measurements. Radioactive silicon standards were prepared by crushing and powdering the activated quartz boat and intimately mixing portions weighed on an analytical balance with inactive gallium arsenide powder as diluent; the radiation emitted from the quartz was thereby modified in a similar manner to the radiation from the gallium arsenide samples.

Gas-flow counting was selected as the primary method for beta radioactivity measurements to provide a high sensitivity for the Si^{31} beta radiation and to minimize interfering gamma radiation from activated impurities. The counting rates were normalized and corrected according to radiochemical standard techniques and expressed as relative specific activities, cpm/g GaAs or SiO_2. Survey radiocounting was made with Geiger-Mueller end-window and probe counters connected to a count-rate meter. Integral gamma counting was performed with a scintillation counting unit. Gamma-ray spectrometry was carried out with a heavily shielded 3 x 3 in. thallium-activated sodium iodide crystal as a detector; pulses were transmitted to the linear amplifier of either a 100- or a 200-channel differential pulse-height analyzer. Spectral-data presentation by an automatic programmed printer and an automatic plotter provided scanning curves of differential counting rates *vs.* pulse heights. Energy calibration and counting efficiency of the spectrometers were made with gamma-rays from suitable radionuclide reference sources. Spectra chosen for complete evaluation were plotted in terms of net counting rate per channel as a function of channel number and gamma-ray energy.

The silicon concentrations in gallium arsenide samples were determined from beta radiation counting data which was plotted semilogarithmically as a function of the time. Graphical resolution of the decay curves into the components made it possible to obtain the 2.62-hr Si^{31} activity. The quantity

of silicon was calculated on the basis of the specific net beta Si^{31} activities in the gallium arsenide samples and the corresponding quartz standards of known silicon contents, analyzed under similar conditions. Determination of the decay half-lives and the maximum beta energies of the resolved components aided in the identification of beta-radiation-emitting nuclides.

Gamma-ray emitters were identified by gamma scintillation spectrometry on the basis of their characteristic energy spectra and decay constants, using standard spectra (7) as comparison. Absolute disintegration rates were calculated by integrating the areas under the characteristic photopeaks resulting from the successive graphical resolution (8) of the spectra into the components. Typical spectra from gallium arsenide and the corresponding quartz standard are shown in Fig. 1 and 2. Concentrations of the detected elements were determined from the total number of disintegrations and the method of absolute neutron-activation calculation (9).

Results

Successive removal of thin surface layers by lapping showed that each of the five gallium arsenide crystals grown in activated quartz boats was completely enveloped in an impurity-enriched surface skin less than 0.02 mm thick. Silicon concentrations in these layers ranged up to 1500 ppm (Table II) for gallium arsenide crystal surfaces that had been in direct contact with the quartz during the preparation. The radioactive impurities in various sections and layers below the surface skin were rather homogeneously distributed, showing variations within a factor of only 1.7. Because of the fast crystal-growth rates necessary, no systematic gradient freeze segregation was expected, and none was detected. The concentrations of silicon inside the five crystals varied from 1 to 28 ppm by weight, as shown in Table II. In some experiments the radioactivity decay measurements of gallium arsenide and quartz standard samples were continued for 30 days following the neutron bombardment of the quartz boat. Resolution of the decay curves obtained identified component activities with half-life and beta-radiation-energy values corresponding closely to those of Si^{31}, Cu^{64}, Na^{24}, Sb^{122}, and P^{32}.

Depending on the time of analysis, different radionuclides were observed by gamma spectrometry. For instance, 30 hr after the quartz boat activation the nuclides indicated in Fig. 1 and 2 dominated the spectra. The maximum at 0.511 Mev in the Cu^{64} spectrum is caused by the annihilation radiation from the positrons associated with the Cu^{64} disintegrations. The unidentified peak at the 1.05 Mev energy position in Fig. 1 had a half-life of 14 hr. Numerous spectra were taken several days and weeks later when the radioactivity of the 15.0 hr-Na^{24}, 12.8 hr-Cu^{64}, and 14.2 hr-Ga^{72} had decreased below the detection limit. The major gamma component in gallium arsenide crystals grown in natural fused quartz boats had a gamma energy peak and a half-life corresponding to Au^{198} (0.412 Mev, 2.69 days). Energy and half-life measurements of other

components in these gamma spectra revealed the presence of Sb^{122} (0.564 Mev, 2.75 days), Sb^{124} (0.605 Mev, 60 days), and possibly Cr^{51} (0.323 Mev, 27.8 days). Corresponding gamma spectra from the natural fused quartz were dominated by the full energy photopeaks associated with the disintegration of the Sb^{122} and the Sb^{124} nuclides. The energy peak of the Sb^{124} isotope became observable after the shorter-lived activity from Sb^{122} with a similar energy maximum had disappeared from the spectra. Both radioisotopes were formed by the (n, γ) reaction from natural antimony (57.25% Sb^{121}, 42.75% Sb^{123}) contained in the quartz.

Although the gamma spectra of various gallium arsenide crystals from the natural fused quartz boats were similar in composition, the crystal grown in synthetic fused quartz had considerably more complex spectra which were difficult to resolve by instrumental analysis. Na^{24} and Ga^{72} were positively identified, while the identity of Zn^{65m}, K^{43}, Cu^{64}, Sb^{122}, W^{187}, La^{140}, and Au^{198} was not conclusively established. Concentration levels calculated on the basis of (n, γ) reactions are summarized in Table III. Synthetic fused quartz also has gamma spectra which are different from those of natural fused quartz brands and are characterized by impurity concentrations orders of magnitude lower (Table I).

Discussion

The radioactivity measurements of the gallium arsenide samples could not be started until at least 12 hr after the neutron bombardment of the quartz boats had been terminated because of the necessary manipulations, preparations, and crystal growing. This time delay is the severest of the difficulties in the analysis because of the diminishing sensitivity and accuracy of the Si^{31} radioactivity measurements and cannot be substantially reduced unless the synthesis conditions are altered unrealistically.

Furthermore, an unfavorable change of the radioactivity composition in the gallium arsenide samples takes place. The beta-radioactivity decay curve of natural fused quartz showed that the Si^{31} concentrations during the early stages of radiocounting are about two orders of magnitude greater than the longer-lived background radiation levels; in gallium arsenide samples, however, the relative Si^{31} activity is sharply reduced. These differences in the radioactive impurity concentrations in quartz and gallium arsenide indicate that the contamination process proceeds selectively with respect to different impurities. The transfer is not simply a dissolution process of quartz, but involves diffusion of trace impurities to various degrees. Gamma-ray spectrometry supported these findings and extended them to additional impurity elements. For instance, Au^{198} represented the major radioactive constituent in a "one-week-old" gallium arsenide sample, but could not be detected in the corresponding spectra of the quartz tube from which the boat had been made. In contrast, Sb^{122} and Sb^{124} were taken up by the gallium arsenide to a limited extent only, but represented the major residual radioactivity in the quartz

after decay of the shorter-lived nuclides. Controlled etching experiments with activated fused quartz excluded the possibility that the impurities originated from the quartz surface, indicating that they must have diffused from the bulk toward the inner surface of the quartz boat.

The possible sources of error in the analysis were carefully examined. The homogeneity of the neutron flux within the sample area was demonstrated by measuring the induced radioactivity in samples from various positions of the quartz boats. Flux hardening and self-shielding effects (10) by strong absorption of thermal neutrons are considered negligible at the quartz thickness of only a few millimeters. Surface contamination of the quartz boats was minimized by acid cleaning before and after the work at the nuclear reactor facility.

The estimation of impurity elements other than silicon should be considered as semiquantitative because it was not possible to include standards during the neutron activation. Consequently, it was necessary to use theoretical calculation methods which are based on several assumptions. The neutron flux was known with an accuracy of not better than $\pm$ 25%. Nuclear reactions with fast neutrons may contribute to the formation of a particular radioactive nuclide. For instance, besides the main reaction Na^{23} (n, γ) Na^{24}, radiosodium is also formed by the reactions Al^{27} (n, α) Na^{24} and Mg^{24} (n, p) Na^{24}. However, calculations showed that the errors introduced were less than the uncertainties in the neutron flux.

The possibility of changes in the properties of the irradiated quartz used as boat material and their effect on the results were evaluated in the light of present literature (11-13), but seemed to impose no critical complications under the activation conditions used. While all samples of activated natural quartz were typically purple colored from the ionization of impurity-atoms, synthetic fused quartz remained colorless, which is consistent with the extremely low impurity concentrations in this material. Although the formation of color is the most immediately apparent radiation effect, it is easily reversed by annealing at elevated temperature.

Systematic errors in the radioactivity measurements were avoided by use of the usual corrections, calibrations, and statistical treatments of the data. The determination of the silicon concentration in the gallium arsenide was based on a direct comparison with the induced Si^{31} activity in the quartz boat used, so that error factors associated with the activation and the radiocounting were essentially eliminated. The accuracy of the silicon analysis was curtailed by large proportions of extraneous radioactivity from which the Si^{31} had to be resolved. The specificity of the Si^{31} analysis was ascertained by demonstrating the absence of interfering radioactivity levels from other nuclides with half-lives similar to Si^{31}. Mn^{56}, the most critical potential impurity in gallium arsenide, was looked for by both beta-radiation transmission measurements designed to detect the energetic 2.86 Mev beta rays and by gamma-ray spectrometry to discover the characteristic 0.845 Mev major gamma photons emitted by this nuclide. Chemical separation of the silicon from the gallium arsenide was considered, but was avoided after exploratory experiments showed that more work was needed to develop a rapid method.

The radiochemically determined silicon concentrations in the five surface-treated gallium arsenide crystals ranging from 1 x 10^{17} to 3 x 10^{18} Si atoms/cm^3 (Table II) checked with the emission spectrographic analyses for total silicon, but are higher than those presently obtained with more refined crystal growing techniques. Additional reasons might be the polycrystallinity of these ingots, their small size which introduced a larger quartz surface area per unit weight of gallium arsenide than in normally grown crystals, and the rapid pulling rate which prevented gradient freeze segregation. For comparison, typical published (1) silicon concentrations compiled from 100 gallium arsenide crystals ranged from 5 x 10^{15} to 5 x 10^{18} Si atoms/cm^3, with the majority of data falling between 5 x 10^{16} and 5 x 10^{17}.

As shown in Table III, the concentrations of other radiochemically detected impurity elements in the gallium arsenide were in nearly all cases less than 10^{16} atoms/cm^3. Emission spectrographic analysis also showed the usual concentrations of impurities at or below the detection limits, including copper, iron, and magnesium.

The transfer of impurities from the quartz to the gallium arsenide appears to be possible by several routes: (i) adhesion of quartz particles to the crystal, (ii) dissolution of quartz in the melt, (iii) gas phase transport of volatile impurities, and (iv) diffusion of impurities through the quartz and the gallium arsenide.

Adhesion of quartz particles to the ingot was observed with synthetic quartz. Irregular areas of high radioactivity were located by microprobe counting on the bottom side of the crystal prior to surface treatments. A high degree of wetting of the gallium to the boat was observed during the bake-out, and the gallium arsenide crystal adhered to the surface after removal from the furnace. Although this condition cannot be considered typical, it has been observed irregularly in production with Spectrosil boats and may be caused by the high water-vapor content of this quartz, which lowers its softening point (5).

The electrical properties of silicon at concentrations normally encountered in gallium arsenide suggest that this impurity is present in the elemental state. Experimental evidence indicates that silicon is formed by a chemical reaction of gallium with quartz. Silicon dioxide can be reduced by gallium at high temperature to free silicon and volatile gallium suboxide (14). Some of the silicon formed dissolves in the gallium or the gallium arsenide melt. Furthermore, free silicon gives rise to volatile silicon monoxide by reacting with quartz and may subsequently deposit on the exposed gallium arsenide surfaces.

It is clear from the data presented that the exclusive application of synthetic fused quartz for

the preparation of gallium arsenide offers distinct advantages in minimizing the impurity transfer. It is important, however, that the entire surface of the crystals be completely removed before further processing. This removal is best accomplished by abrasive blasting, followed by chemical etching. Other factors which are beneficial include effective surface treatments of the quartz by nitric acid cleaning, water rinsing, and vacuum baking; reduction of the reaction temperature and time as far as permissible; and reduction of the gallium arsenide-quartz contact area by growth of large-diameter crystals.

Acknowledgments

The author wishes to thank L. J. Vieland for his suggestion of neutron activation of quartz boats for investigating crystal contamination; D. A. Ross and R. F. Bailey for their cooperation and contributions in the activation phase, T. H. Baker and W. Oshinsky in the synthesis phase, and H. M. Hyman and G. Hornberger for the emission spectrographic analyses; G. M. Loiacono for his conscientious technical assistance in the project; and A. Mayer for critically reviewing the manuscript.

Manuscript received Jan. 15, 1962; revised manuscript received March 23, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961. The work described in this paper was sponsored by the Electronic Technology Laboratory, Aeronautics Systems Division, Air Force Systems Command, United States Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Evaluation of Germanium Epitaxial Films

J. R. Biard and Stacy B. Watelski

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

A method has been developed for rapid and accurate determination of the resistivity of p-type epitaxial germanium films deposited on p^+ germanium substrates. Determination of the resistivity is not dependent on a knowledge of film thickness. Data are presented for films with resistivities of 0.05-7.0 ohm-cm deposited on 0.002 ohm-cm substrates; film thicknesses range from 0.15 to 0.6 mil.

Several methods have been proposed and used to determine the resistivity of a p-type epitaxial germanium film deposited on a p^+ germanium substrate. Most of these methods relate breakdown, diffusion depth, or junction capacitance to resistivity and require a lengthy fabrication cycle employing exactly repetitive diffusion runs. The most serious objections to these methods of resistivity determination are the requirements for an optimum surface treatment and a precise junction delineation. In specific instances the resistivity and thickness of the films may also become serious objections. The simultaneous epitaxial deposition on an n-type pilot slice along with the normal p^+ substrate suffers from partial or complete thermal conversion of the pilot slice and yields erroneous results.

The purpose of this investigation was to develop a rapid and accurate technique for measuring the resistivity of p-type epitaxial germanium films deposited on p^+ germanium substrates. This technique, which has been developed, is called the elevated temperature technique and is based on the characteristic variation of resistivity with temperature exhibited by most semiconductors. The use of temperature as a parameter makes it possible to determine the resistivity of an epitaxial film without requiring a knowledge of the film thickness.

The characteristic variation of resistivity with temperature for noncompensated p-type germanium is theoretically calculated using the Brooks-Herring mobility theory. Only lattice and impurity scattering are considered in these calculations; other scat-

tering phenomena such as coulomb, neutral, and dislocation scattering are considered to have no first order effects on the mobilities. The calculated resistivity *vs.* temperature characteristics are compared with those empirically measured using homogeneous p-type germanium and found to be in good agreement. Results of the empirical tests form a standard of comparison for measuring any p-type germanium epitaxial film deposited on a p^+ germanium substrate with an accuracy of ± 20% (95% confidence limits) between 0.1 and 4.0 ohm-cm.

Discussion

The resistance of a semiconductor sample is determined by the size and shape of the sample and its resistivity. Due to the low value of the coefficient of expansion of germanium, variations in the resistance of a semiconductor sample with temperature are almost entirely due to the temperature dependence of resistivity. The equations used for calculating variation of resistivity with temperature are given in the Appendix. As indicated by Eq. [1] of the Appendix, resistivity is controlled by the number of free carriers and their mobilities; a discussion of the theoretical temperature variation of mobility and carrier concentration follows.

Only impurity scattering and lattice scattering mobilities will be considered of prime importance for this discussion. The impurity scattering mobility, Eq. [7], may be simplified for analysis as

$$\mu_I = K_1 T^{3/2} \left[\frac{1}{\ln(1 + K_2 T^2) - \dfrac{K_2 T^2}{1 + K_2 T^2}} \right]$$

At increasing temperatures above 100°K the bracketed expression remains relatively constant and the resulting mobility curve follows the $T^{3/2}$ slope. For temperatures below 20°K the bracketed term is dominant and, in conjunction with the $K_1 T^{3/2}$ term, yields a mobility curve with a $T^{-5/2}$ slope. The lattice scattering mobility Eq. [6], Fig. 1, yields a slope of $T^{-2.33}$. When these two mobilities are combined as in the Brooks-Herring equation (1), Eq. [7] of the Appendix, the resultant mobility curve μ_{LI} is as shown in Fig. 1.

Referring to Eq. [3], as temperatures increase into the intermediate (extrinsic) range, $P_I \rightarrow N_e$. That is, the number of free holes caused by ionization of the impurity atoms approaches the magnitude of the net impurity concentration and remains constant. Since for normal doping ranges $p_i << N_e$, p (the total number of free holes) also approaches N_e and $n << p$. At high temperature (in the intrinsic region) the number of free holes caused by intrinsic ionization, p_i, increases due to the dominant exponential term as does the number of free electrons, n_i, $(n \approx p)$. Thus, the total number of free holes, p, is determined by P_I at intermediate temperatures and p_i at high temperatures while the number of minority carrier electrons is negligible at intermediate temperatures and determined by n_i at high temperatures. The curve representing the magnitude of p *vs.* temperature is shown in Fig. 1.

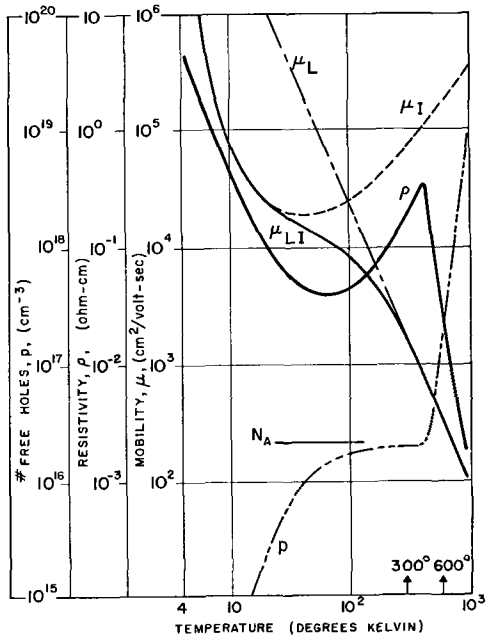

Fig. 1. Calculated mobility, resistivity, and free hole concentration *vs.* temperature, p-type germanium, $N_A = 2 \times 10^{16}$ atoms/cm³.

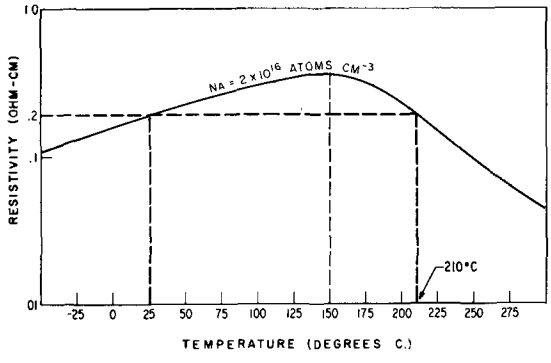

Fig. 2. Resistivity *vs.* temperature, p-type germanium

The variation of resistivity with temperature may be calculated by combining the characteristic curves of p, μ_{LI}, n, and μ_{LN} as dictated by Eq. [1].[1] One such curve of ρ *vs.* T for a wide range of temperature is shown in Fig. 1.

Note that the point at which the total number of free holes, p, begins to increase sharply (≈400°K) corresponds to that point at which the resistivity, ρ, reaches its inflection point, *i.e.*, beginning of intrinsic conduction.

The two arrows at the bottom of Fig. 1 indicate the range of temperature (300°-600°K) with which this report is mainly concerned.

Figure 2 shows the calculated resistivity *vs.* temperature characteristics of 0.2 ohm-cm p-type germanium. A resistor made from this material exhibits the same value of resistance at 25°C (extrinsic

[1] The contribution of the minority carrier electrons is negligible except in the intrinsic range where lattice scattering dominates. Therefore only the lattice scattering mobility, μ_{LN}, is used for electrons in Eq. [1].

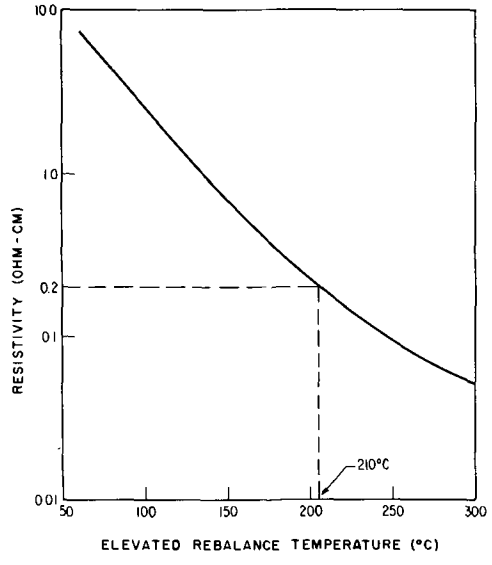

Fig. 4. Calculated resistivity *vs.* elevated rebalance temperature

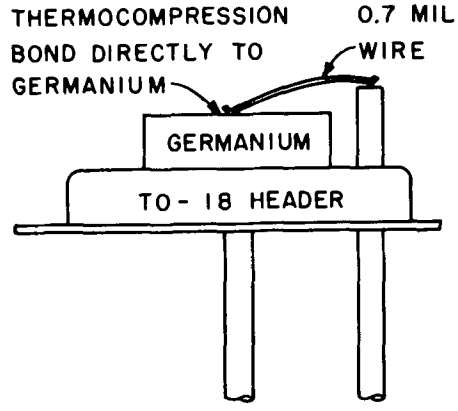

Fig. 5. Ohmic device. Resistance, $R = \frac{\rho}{2d}$, where ρ is the resistivity in ohm-cm and d the diameter of contact in cm; d remains constant throughout temperature range. $\therefore R \propto \rho$.

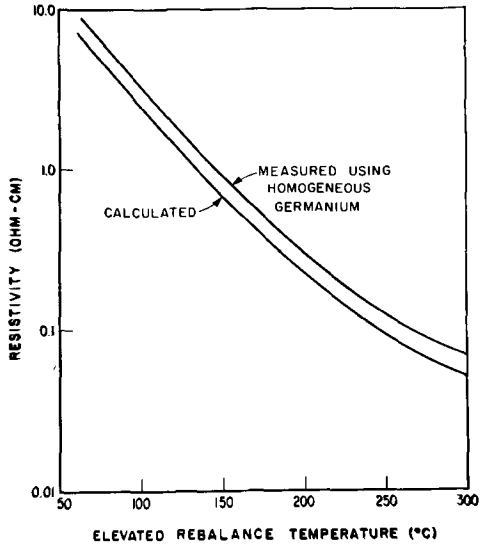

Fig. 6. Calculated and measured resistivity *vs.* elevated rebalance temperature.

range) and 210°C (intrinsic range). From Fig. 3 it is seen that the elevated temperature at which the resistivity is equal to the room temperature value is uniquely related to the resistivity. Thus, a resistivity measurement may be made by balancing a germanium resistive element in a low-frequency a-c bridge at room temperature and determining the elevated temperature of the resistive element at which the bridge returns to the balanced conditions.

Note in Fig. 3 the relatively constant resistivity corresponding to a doping level $N_A = 1 \times 10^{19}$ atoms cm^{-3}. This doping level is representative of p^+-type substrate material used in epitaxial depositions.

A calculated curve of resistivity *vs.* elevated rebalance temperature is presented in Fig. 4.

Figure 5 illustrates the construction of the homogeneous germanium resistors used for calibration purposes. The resistance of these ohmic devices is pure spreading resistance, $R = \rho/2d$, where d is the diameter of the contact (2). The resistance of the device is directly proportional to the resistivity as a result of the constancy of the contact diameter throughout the temperature range. Figure 6 compares the measured and calculated curves of resistivity *vs.* elevated rebalance temperature as determined from homogeneous resistive elements of known resistivity. Note that in the experimental case a unique relationship exists between resistivity and elevated rebalance temperature. Thus it is possible to generate an experimental calibration curve for a given test set using known homogeneous samples.

The construction details for epitaxial resistive devices are shown in Fig. 7; this type of mounting is used in determining the resistivity of the epitaxial layer. In order for the elevated temperature technique to give accurate results on epitaxial samples, it is necessary to construct the ohmic devices such that the temperature sensitive part of the total resistance is contributed by the epitaxial layer. Such a construction is possible due to:

(*a*) the use of small contact diameter (≈1.5 mil) to take advantage of spreading resistance in the substrate (substrate resistance is usually less than 2% of the total except for heavily doped thin epitaxial layers where it may approach 15%); (*b*) the fact that the resistivity of the heavily doped sub-

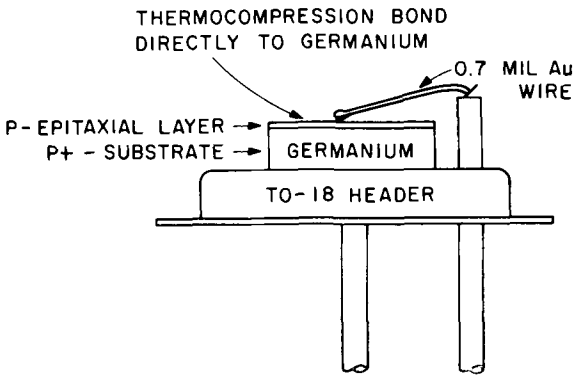

Fig. 7. Ohmic device. Epitaxial layer resistance, $R_E = \frac{\rho t}{A}$; substrate resistance, $R_S = \frac{\rho}{2d}$, where ρ is the resistivity in ohm-cm, t the thickness of epitaxial layer in cm; A the area of contact in cm^2; and d the diameter of contact in cm. t and d remain constant throughout temperature range. $\therefore R \propto \rho$.

strate material (≈0.002 ohm-cm) is nearly independent of temperature (corrections for the substrate may be applied where necessary).

The test set is composed of a temperature chamber, an a-c resistance bridge, and a phase-sensitive detector.

Results

Based on a statistical analysis of resistivity data the accuracy of the test set is ± 20% (95% confidence limits) between 0.1 and 4.0 ohm-cm, with reduced accuracy outside this range. These limits are based on resistive elements constructed from homogeneous material of known resistivity. By exercising extreme care in construction of the temperature chamber and the individual resistive elements it may be possible for an accuracy of ± 10% to be achieved.

It should be pointed out that the elevated temperature resistivity measurement is a destructive test; however, the volume of material required for the resistive element is small. If this technique is to be used as a measure of carrier concentration it is subject, like the 4-point probe, to errors due to compensation and inhomogeneous material.

The indicated rebalance temperature for an inhomogeneous film yields an "average" value for the film resistivity which is a function of the impurity profile within the film. From Fig. 3 it may be seen that the portion of the film having a resistivity higher than the indicated "average" is at a temperature greater than its rebalance temperature, while the lower resistivity portion is at a temperature less than its rebalance temperature. The profile of the film resistivity may be incrementally derived from elevated rebalance temperature vertical profile data. These data may be conveniently obtained by bevel lapping and staggered bonding.

An experiment was performed to determine the quantitative effect of the interfacial diffusion gradient on this measurement technique. A high resistivity (>8 ohm-cm) p-type epitaxial film was deposited on a highly doped p-type substrate; film thickness was 0.25 mil with a diffused gradient width of 0.06 mil as determined by chemical delineation. Consistent rebalance temperature readings were obtained throughout the film thickness, except for those within the interfacial diffused region.

Conclusions

The elevated temperature technique for resistivity measurement is a powerful tool for evaluating p-type germanium epitaxial films deposited on p$^+$ germanium substrates. Aside from routine evaluation of epitaxial film resistivity the technique has also been used to determine resistivity profiles at 5.0 mil increments across the face of epitaxial deposits. Used in conjunction with bevel lapping and staggered bonding, epitaxial deposits may be profiled for resistivity through the thickness of the layer in 0.05 mil increments.

Acknowledgments

The calculated resistivity *vs.* temperature data were supplied by Henry Riser and the statistical analysis of experimental data was performed by Vic Paulos. The test set was built and operated by Jack Leezer. Special fabrication techniques were supplied by Nadene Bedford and O. J. Lewis.

Thickness Measurement of Epitaxial Films by the Infrared Interference Method

M. P. Albert and J. F. Combs

Monsanto Chemical Company, St. Louis, Missouri

ABSTRACT

The infrared interference measurement has proved to be an accurate and nondestructive means for evaluating the thickness of epitaxially grown films on silicon. The measuring technique is discussed and the necessary relationships are presented. A fringe wavelength *vs.* film thickness chart is constructed, which enables rapid thickness determination without calculation. The chart is derived for use with silicon films of relatively low carrier concentration deposited on silicon substrates of high carrier concentration (0.007 ohm-cm-N-type). The chart is most useful for low order interference fringes including 12th order. Similar charts are applicable for other semiconductor materials.

Of the various methods examined for making thickness measurements on epitaxial films, the infrared interference method described by Spitzer and Tanenbaum (1) has proved to be best suited for most measuring applications. This method has the advantages of being accurate, quick, nondestructive, and well adapted for routine measurements. Interference fringes are observed only if there is a difference between the optical properties of epitaxially grown film and those of the substrate. This relationship between film thickness and the optical wavelengths of interference fringe maxima is given by a chart which is useful for rapid and accurate data reduction without calculation.

The Beckman spectrophotometers IR-4 and IR-5A equipped with NaCl optics and the Beckman specular reflectance attachment were used for this work. Additional measurements have also been made with KBr and CsBr optics.

Optical Properties of Epitaxial Films on Silicon

The primary requirement for production of interference fringes by reflection from a film is that the optical constants of the film differ from those of the substrate material. The optical constants of a silicon epitaxial film and substrate do not differ significantly unless the free carrier concentration at one side of the interface is very high, approaching degeneracy.

The reflectance at the interface between a nonabsorbing medium (n_1) and an absorbing substrate (n_2,k_o) at normal incidence is

$$R = \frac{(n_1 - n_2)^2 + k_o^2}{(n_1 + n_2)^2 + k_o^2} \quad [1]$$

where R is the reflectance, n is the refractive index, and k_o is the extinction coefficient of the substrate.

$$k_o = \frac{\alpha\lambda}{4\pi} \quad [2]$$

where α is the absorption coefficient and λ is the wavelength.

The influence of the very large free carrier concentration on the electrical susceptibility is such that as the optical wavelength is increased the refractive index decreases, and at still longer wavelengths the absorption effect predominates (2).

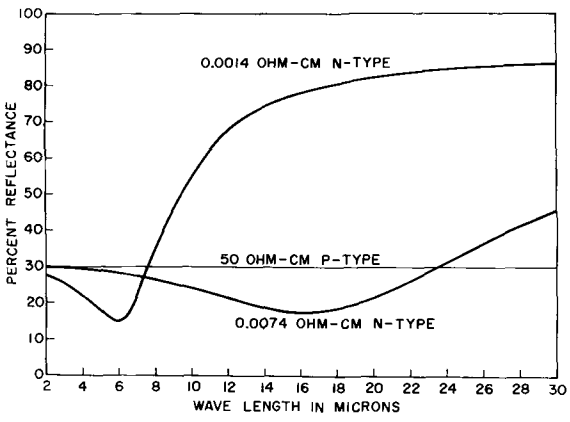

Fig. 1. Reflectance spectra of silicon samples showing the effects of carrier concentration on the optical constants. Decreasing reflectance, below 30%, indicates decreasing refractive index and large increasing reflectance indicates large increasing extinction coefficient.

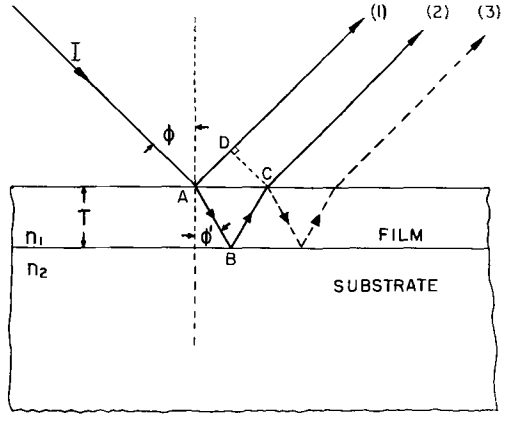

Fig. 2. Ray diagram for reflection from a film deposited on a thick substrate. The amplitudes of rays 1, 2, 3, etc., add vectorially resulting in maxima and minima in the reflectance spectrum.

The reflectance curves of Fig. 1 were obtained from silicon wafers prior to film deposition. The dip and subsequent rise in the reflectance curves for 0.0074 ohm-cm and 0.0014 ohm-cm N-type silicon, similar to reflectance curves shown in a paper by Spitzer and Fan (3), identify the decreasing refractive index and high absorption portions of the spectrum. Contrasted to the very low resistivity samples is the 50 ohm-cm sample which exhibits a nearly constant reflectance indicating a relatively constant refractive index.

Production of Interference Fringes

Figure 2, a ray diagram showing reflection from an epitaxial film at oblique incidence, is used to calculate the optical path difference between the first and second surface reflections. Interference fringes are observed when the first and second surface reflected rays interfere locally as the wavelength is varied.

The optical path difference is

$$\delta = n_1(AB + BC) - AD \qquad [3]$$

The refractive index, n_1, multiplies the apparent optical path in the film, (AB + AC), converting it to an equivalent air path.

Using Snell's law ($\sin \phi = n_1 \sin \phi'$) and Eq. [3] it can be shown that

$$\delta = 2Tn_1 \cos \phi' \qquad [4]$$

where T is the film thickness, ϕ is the angle of incidence, and ϕ' is the angle of refraction.

At point A, in Fig. 2, the reflected ray undergoes a phase change of π or $\lambda/2$ while the transmitted ray remains in phase with the incident ray. These phase relationships apply to reflection from an optically more dense (greater refractive index) dielectric.

At point B the reflected ray undergoes a phase change which may vary from 0 to π depending on the optical constants at the reflecting interface. However, if we limit this discussion to the spectral region where the reflecting substrate is known to have a lower refractive index than the film and also a negligibly small extinction coefficient, k_0, the phase change at point B can be taken as zero.

At point C, both the transmitted and reflected rays are in phase with the incident ray, BC.

For some wavelength, λ_0, the optical path difference will be

$$\delta = \lambda_0/2$$

At this wavelength ray 1 is advanced by $\lambda_0/2$ and ray 2 retarded by $\lambda_0/2$ giving a net difference of λ_0. It is assumed that maxima will occur at wavelengths where ray 2 is in phase with ray 1. The first (zero order) fringe will occur at λ_0, the next fringe (first order) will occur at λ_1, where

$$\delta = \lambda_1 + \frac{\lambda_1}{2} \qquad [5]$$

and the mth order fringe maxima will occur at λ_m where

$$\delta = \left(m + \frac{1}{2}\right)\lambda_m \qquad [6]$$

Minima occur at intermediate wavelengths where $\delta = m\lambda$, (m, an integer).

The additional reflections which occur within the film interfere with the resultant of rays 1 and 2. Each succeeding ray is delayed an additional amount δ relative to the preceding ray. At a fringe maximum these additional reflections alternately aid and oppose with a net result of decreasing the fringe maxima by a small amount. The additional reflections also reduce the values of the fringe minima. The fringes grow in intensity as the difference in refractive index between film and substrate increases. Fringe intensity is observed to increase with both wavelength and doping level of the substrate. These effects are predictable from the influence of wavelength and carrier concentration on the susceptability (1, 3).

Deviations from parallelism within the film and low gradient interfaces are common causes for fringe cancellation when it would appear that there is a sufficient difference of optical constants for fringes to occur.

As the extinction coefficient increases with increasing wavelength it predominates in determining the interface reflectance, Eq. [1]. Relatively high

interface reflectance is characteristic of this spectral region yielding large intensity fringes. The transition between low refractive index and high extinction coefficient is accompanied by a varying phase change upon reflection from the interface. The phase change is nearly zero if k_0 is small enough to be neglected in Eq. [1], and it increases approaching π for long wavelengths and large k_0 (5).

The transitional region should be avoided when making thickness measurements because of the varying phase change which introduces thickness measuring errors. Successive fringe pairs yield different thickness values in this region.

Thickness Computation

A convenient thickness relationship can be obtained from [4] and [6] utilizing two wavelengths corresponding to fringe maxima, λ_m and λ_{m+x}.

$$T = \frac{x(\lambda_m \lambda_{m+x})}{2n_1 \cos \phi' (\lambda_m - \lambda_{m+x})} \qquad [7]$$

where x is an integer representing the number of fringes occurring from λ_m to λ_{m+x}. An equivalent expression applies to linear wavenumber spectra where the fringe period is uniform.

Equation [7] can be applied to fringe minima as well as maxima and it is also independent of the phase change which may occur at the interface, provided the phase change is constant in the interval λ_m to λ_{m+x}.

The value for the refractive index of the film given by Salzberg and Villa (4) for optical grade silicon at 10μ is 3.4179, which is rounded to 3.42 and assumed constant over the 6-16μ range. The reflectance data also verifies this value.

The angle of incidence, ϕ, for the Beckman specular reflectance attachment is 30°, which corresponds to an angle of refraction of 8.4° and $\cos \phi' = 0.99$. The rays within the film are nearly normal to the surface, which makes the measurement relatively insensitive to ϕ.

The constant, $2n_1 \cos \phi' = 6.77$, when used with Eq. [7] gives film thickness in the same units as those used for wavelength.

The conditions imposed for the development of Eq. [7] were:

1. Fringe maxima occur at wavelengths where the first and second surface reflections are in phase (the phase difference is $2\pi m$, m an integer).

2. The phase change at the interface is zero or constant from λ_m to λ_{m+x}.

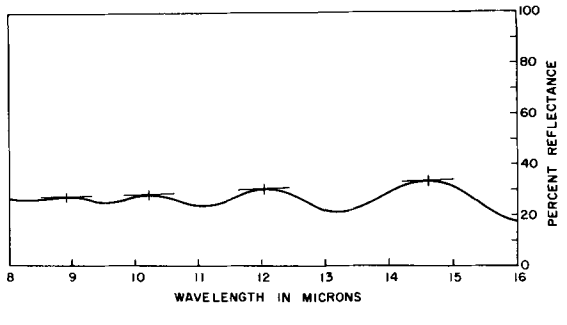

Fig. 3. Reflectance spectrum of a silicon epitaxial film showing the evaluation of fringe maxima.

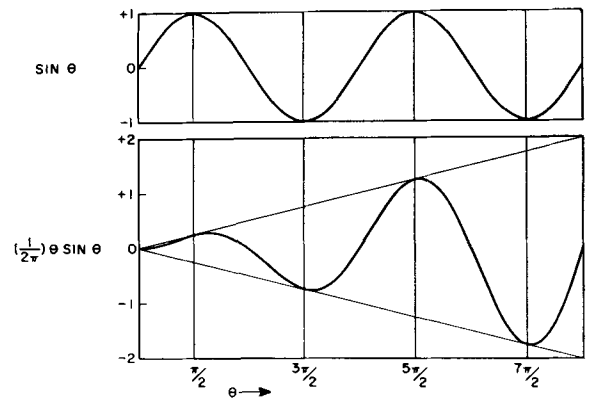

Fig. 4. Fringe model demonstrating the error which can arise by evaluating simple maxima. The desired phase relationship is satisfied at the points of tangency to the fringe envelope.

Evaluation of Fringe Maxima

In the preceding section the interference relationships given were based on wavelength values for which fringe maxima occur, as stated in condition 1. Condition 1 is correct only for equal intensity fringes, and it is incorrect for epitaxial films where the fringes grow in intensity with increasing wavelength. Figure 3 shows a typical reflectance spectrum, obtained from an epitaxial film as described in this paper, illustrating the growing intensity of the fringes.

A simplified model which illustrates the error made in condition 1 is given in Fig. 4. Interference fringes produced by two beams of constant intensity (independent of wavelength) would be of uniform intensity also. However, the second surface reflection from an epitaxial film varies with wavelength, and thus the fringes vary in intensity also. For this condition the simple maxima of the fringe no longer corresponds to the wavelength of $2\pi m$ relative phase shift. The $2\pi m$ relative phase shift can be shown, by differentiation, to correspond to the wavelength for which the fringe curve is tangent to the envelope of the fringes.

The wavelength values needed for the calculation of film thickness utilizing Eq. [7] are obtained by a method of tangents. For each point a tangent line is drawn approximating the slope of the envelope function. The resulting point of tangency is the desired value and will be termed the adjusted maximum. Large intensity fringes can be evaluated at the simple maxima with small error.

Fringe Chart

By using Eq. [4] and [6], it is possible to express film thickness in terms of the fringe order and wavelength of the fringe maxima

$$T = \frac{\left(m + \frac{1}{2}\right) \lambda_m}{2n_1 \cos \phi'} \qquad [8]$$

Equation [8] includes a phase change of π at the first surface but no phase change at the interface, which is the situation for silicon films on 0.007 ohm cm N^+ substrate in the 6 to 16μ range. Plotting Eq. [8], Fig. 5, with thickness as a function of wavelength for

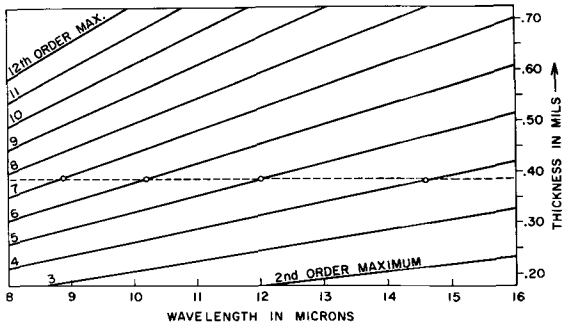

Fig. 5. Fringe chart for silicon epitaxial films, giving the wavelengths of fringe maxima as a function of film thickness. Thickness is determined by fitting fringe maxima data on this chart as shown by the dashed line.

integer values of m, results in a family of straight lines of constant fringe order. A horizontal line, T = constant, intersects the fringe order lines at wavelength values corresponding to the fringe maxima for that thickness.

Use of the Fringe Chart

For low order fringes, through 10th or 12th order, the chart can be used to simplify conversion of fringe wavelength data into accurate film thickness values. An important step is determining the correct fringe wavelength values by the tangent method. This wavelength evaluation method is also important when Eq. [7] is used. Errors up to 5% can occur if simple maximum values are used instead of the adjusted values, especially if only 2 or 3 fringes are available.

The chart will give reliable thickness values with three well-defined fringes. Improved accuracy achieved by use of the chart is due to the fact that all fringe maxima are used, showing up faulty data points.

Once the adjusted maximum values have been determined, a straight edge is positioned horizontally on the fringe chart lining up the wavelength of one of the fringe maxima and a fringe order line for a trial fit of the remaining fringes. Fringe maxima should fall at the intersections of the horizontal line with successive fringe order lines (see Fig. 5). If a good fit of the data is not possible at that thickness, a second trial should be made by moving the initial point up or down to the next fringe order and checking once more to see if the other fringes fit on a horizontal line. When a good fit is obtained, the horizontal line is extended to the right margin to read film thickness.

To aid in using the chart the wavelengths of adjusted maxima can be marked on a calibrated straight edge as they are read from the spectrum. The straight edge is then moved vertically across the chart, maintaining a horizontal position and wavelength reference until a thickness value is found where the marks are located on consecutive fringe order lines. Adjacent solutions should be tried, thicker and thinner, until the best solution is obtained.

Good accuracy will result if four or more fringes are located on the chart. Three fringes will give dependable results through 9th or 10th order. Equation [7] should be used in preference to the chart for fringes of 10th order and higher.

Very thin films are difficult to measure because only one or two fringes are observed. Additional data points can be obtained from the fringe minima which can also be included on the fringe chart. Equations [7] and [8] are converted to equivalent minima expressions by subtracting ½ from the integer values. When using Eq. [7] the interval between a maximum and the next minimum is ½ fringe. The method of tangents also applies to the evaluation of minima.

Experimental Check

An experimental check by an independent thickness measuring method was performed to verify the accuracy of the interference method. The cleavage method was chosen as the most desirable alternate measuring method. The cleaved wafer is etched for 10 to 15 sec in an HF, HNO_3 acetic acid (1-3-10 volume parts) etch and then measured directly with a microscope. The etch delineates the NN^+ interface very well, and the measurement is reasonably easy to make. The major disadvantage of the cleavage method is that it is destructive. This method can be utilized as a periodic check on the interference method and for films which are not sufficiently parallel to produce fringes.

Five different samples were measured by both cleavage and interference methods. The results of these measurements are tabulated.

Sample No.	1	2	3	4	5
T in mils, interference	0.24	0.26	0.33	0.83	0.43
T in mils, cleavage	0.26	0.28	0.32	0.82	0.42
Percentage difference	8%	7%	3%	1.2%	2%

Sample 4 was evaluated by Eq. [7], and the other samples were measured using the chart.

The agreement between the two methods is very good. The cleavage method has been reported to be accurate to ±10%. It is felt that interference methods as described are within a ±5% accuracy range.

Other Materials

Interference methods are applicable to epitaxial films of other semiconductors (1). A similar fringe chart can be constructed for use with materials other than silicon. Equation [8] used to construct the chart includes the refractive index of the film and the angle of refraction. These values must be evaluated for each particular material and reflectance apparatus. Should the refractive index of the film vary over the spectral range, where the fringes are observed, the chart can be constructed to include this variation. The chart would then be a set of curved lines. Should the film have a lower refractive index than the substrate, the chart equation should be rewritten to include the π phase shift at the interface. However, this situation will be very complex due to the attendant high absorption of the film and varying refractive index.

Ultrafine Tungsten and Molybdenum Powders

H. Lamprey and R. L. Ripley

Technology Department, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

A process is described for producing tungsten and molybdenum metal powder of 0.01-0.1μ average particle diameter by hydrogen reduction of the metal chlorides. Some of the physical and chemical properties of this material are discussed, together with data pointing to metallurgical uses of the product. Safety precautions to be observed in handling these fine powders are also described.

There is considerable evidence to indicate that metal compacts made by sintering ultrafine metal powders have improved engineering properties. The pronounced effect of grain size on the mechanical properties of iron and steel (1-5), copper (6), zinc (7), and other metals (8), is clearly shown in the literature. In general, a reduction in grain size is accompanied by an increase in hardness, yield strength, and fracture strength, and by a decrease in the ductile-brittle transition temperature. Ultrafine grain structure is also said to be the key to improving the properties of dispersion-strengthened metal and alloy systems (9,10).

In order to extend our knowledge of such effects to the refractory metals, it was decided to produce tungsten and molybdenum powders for metallurgical evaluation. Theory predicts that the maximum mechanical benefits should be found in sintered products having grain diameters smaller than 0.1μ, and so our efforts were directed toward producing the powders in the 0.01-0.1μ range. This paper will be restricted to describing production by a chemical process, namely, hydrogen reduction of tungsten and molybdenum chlorides in the vapor state.

There are two keys to the production of ultrafine metal powder by chloride reduction processes: one is to carry out the reduction in the vapor phase, whereby, through control of dilution, only a minimum number of atoms or molecules of the reacting species can get together to form agglomerates; the other is to carry out the reaction in free space, away from solid walls on which a continuous metal plating can deposit.

Thermodynamic data compiled by Glassner (11) indicate that the by-product HCl is more stable than any of the tungsten and molybdenum chlorides by 10-20 kcal/g atom of chlorine over the temperature range from 25° to 900°C. Thus, the reaction should proceed readily at elevated temperature, and no back reaction is to be expected as the product is cooled.

The apparatus used for carrying out the reaction is sketched in Fig. 1. Purified hydrogen and tungsten or molybdenum chloride vapors, carried in a stream of argon if desired, are preheated to the chosen temperature and brought together in a large reaction space; the gases react immediately on contact to form submicron metal powder and hydrogen chloride vapor.

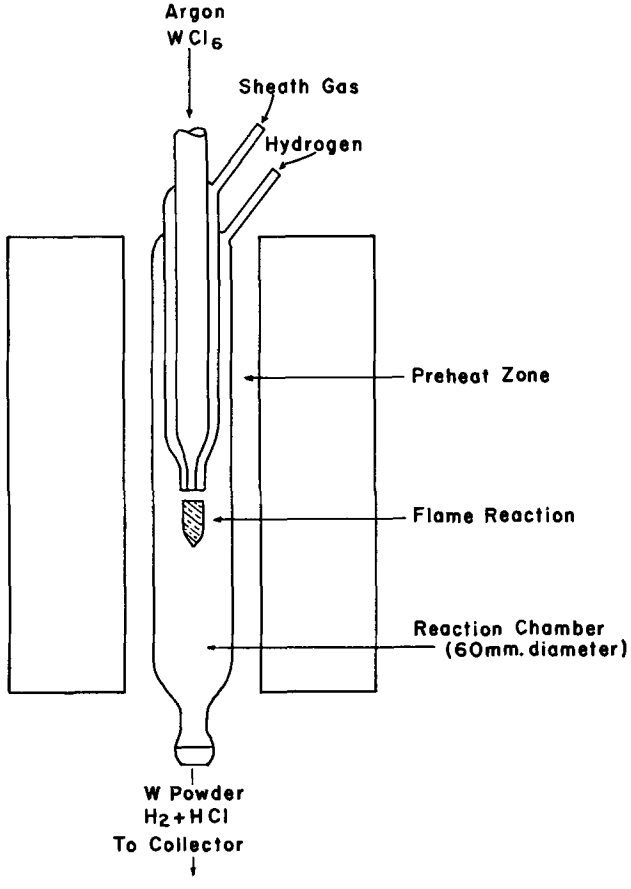

Fig. 1. Quartz apparatus for producing ultrafine tungsten and molybdenum by a flame reaction.

One purpose of flowing argon or chlorine through the sheath gas nozzle in Fig. 1 is to prevent formation of metal at the metal chloride orifice tip, with consequent plugging of the apparatus. Chlorine is somewhat more effective than argon for this purpose. The gases issuing from the concentric tubes react as a flame and the sheath gas serves to position the metal chloride-hydrogen flame at some distance from the orifice.

The metal may be collected by gravity settling with or without the use of an electrostatic precipitator; or the reaction gases may be filtered through a large diameter column of steel wool, the trapped powder shaken free of the wool and separated from small steel fragments by magnetic means. When using electrostatic precipitation, it is necessary to prevent bridging the gap between the electrodes with a conducting film of tungsten powder. When this bridging occurs, the alternating high potential field (20,000-50,000v) is no longer positioned between the collecting electrodes but between the inside and outside walls of the glass sheath over the "hot" electrode. While this over-all process works well for producing submicron powder down to 0.01μ particle size, various chemical and mechanical refinements are necessary to the process in order to control particle sizes within narrow ranges, to operate with high materials efficiency, and to produce powder of high purity.

The quality of the powder produced depends on a number of factors; one of them is the reactant preheat temperature just prior to mixing. As this temperature increases, the powder product becomes somewhat finer (Table I), and the amount of chlorine impurity is reduced.

Runs 1 through 5 were all carried out in the apparatus shown in Fig. 1. The mole ratio of hydrogen to chlorine in the system was maintained at 3 and the inert gas flow was held constant. Ultrafine molybdenum powder was also prepared in the same apparatus at a preheat and reaction chamber temperature of 800°C. This powder contained 0.15% oxygen, 0.35% chlorine, 0.01% silicon, 0.1% carbon, and had a surface area of 11.1 m^2/g corresponding to an average particle size of 0.05μ.

In most of the tests run thus far, the powdered product has analyzed approximately 99.5% metal, the balance being largely chlorine, oxygen, and carbon, with very small amounts, on the order of 0.01% or less, of nitrogen, silicon, and hydrogen. Tungsten and molybdenum chlorides commonly contain oxychlorides, and some of this oxygen finds its way into the powder. The carbon impurity gets into the system during a prior purification of chlorine by passing it over hot carbon to remove oxygenated compounds. This carbon impurity could be reduced or eliminated if necessary.

Table I. Production of ultrafine tungsten powder by the hydrogen reduction of tungsten hexachloride at various temperatures

Run No.	Preheat and reaction chamber temp, °C	% Chlorine in product	Product diam, μ
1	430	1.82	0.029
2	620	0.24	0.025
3	695	0.10	0.031
4	800	0.27	0.026
5	905	0.13	0.021

Oxygen and chlorine impurities in the metal powder products are present as lower valent compounds and as chemisorbed gases.[1] X-ray diffraction patterns show the presence of W_3O in the tungsten powder. Part of the oxygen and chlorine can be removed by post-treatments of various kinds. Vacuum pumping, alone, is relatively ineffective. A product analyzing 0.39% oxygen and 0.24% chlorine with a surface area of 12 m^2/g was heated to 800°C for 24 hr under a flow of dry hydrogen. The oxygen content was reduced to 0.21% and the chlorine content to 0.04%. Simultaneously, the surface area decreased to 6.49 m^2/g as a result of this treatment. Obviously, a tungsten powder product low in oxygen and carbon content is more easily obtained by a careful distillation of the tungsten hexachloride. This distillation removes the oxychlorides and chlorinated hydrocarbons which commonly contaminate tungsten hexachloride made from commercial chlorine.

Powder Properties

The particle sizes of the tungsten powders were determined by surface area measurements (12) and confirmed by electron micrography. Figure 2 shows a typical photomicrograph obtained at a magnification of 50,000 diameters. The particles approach spheres in shape. There is considerable aggregation of particles in this photomicrograph.

The bulk density of the powder as collected was approximately 0.2 g/cc. This is remarkably low for tungsten with a density of 19.3.

The chemical properties of the ultrafine powder are greatly modified by the presence of the chemi-

[1] All oxygen analyses in this study were determined by a vacuum fusion analysis in which the encapsulated sample is dropped into an iron-carbon melt at 1800°C, and the resulting carbon monoxide is measured.

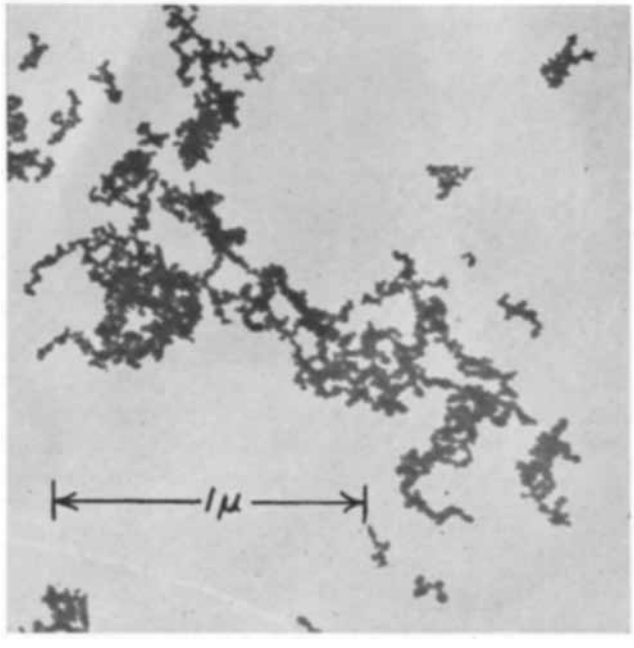

Fig. 2. Photomicrograph of ultrafine tungsten powder. Magnification 40,625X.

sorbed gas films. Powder which is relatively free of chlorine and oxygen appears to be much more reactive than powder made as described above. Finely divided metal powder is sometimes pyrophoric. Great variability in the reactivity of tungsten powder toward air and water has been encountered. Some samples oxidize rapidly on exposure to air. For example, when a sample containing 1.5% of adsorbed chlorine was exposed to air at room temperature, thermocouples embedded in the powder showed temperature rises of 10-20°C due to air reaction, but no ignition occurred. When a red-hot wire was placed in the powder, the material in the vicinity of the wire reacted, turning yellow-green, the color of WO_3, but the remainder of the powder was not affected. Other samples exposed to air have become red hot on the surface within a few seconds' time. Factors such as the rate of heat loss from the powder and the degree of packing of the sample also affect the possibility of ignition.

More usually, however, the tungsten powder is completely inert. For example, a sample of powder analyzing 0.10% oxygen, 0.09% chlorine, 0.01% carbon, and 0.01% silicon, and having an average particle diameter of 0.02μ, was heated in air on a thermogravimetric balance of 1 mg sensitivity, *i.e.*, 0.1% of the weight of the sample. No measurable weight gain occurred until the temperature reached 140°C, when the powder converted rapidly and completely to tungstic oxide. The same result was obtained when oxygen was substituted for air, or when the tungsten powder was pretreated with hydrogen at 800°C, or when it was treated with chlorine until 1% by weight was adsorbed; the ignition temperature in air or oxygen was, in all cases, 130-140°C on the thermogravimetric balance. Powder of the same particle size, from another batch, containing 0.20% chlorine, 0.24% oxygen, 0.16% carbon, and 0.16% silicon, behaved identically.

The submicron tungsten powder physically adsorbs water reversibly at 25°C and does not react appreciably with water up to 1200°C. This powder chemisorbed several per cent of chlorine when exposed to a 20:80 chlorine-argon mixture at room temperature; the chlorine, unlike water vapor, was not driven off by dry argon at room temperature, but was removed, together with a little tungsten chloride, by argon heated to above 350°C.

These tests indicate that the fine tungsten powder can be handled safely if a few simple precautions are taken. However, any finely divided metal powder, mixed with air or other oxidizing agent, is a potential source of uncontrollable reactions. For example, when an operator inadvertently let a small amount of the fluffy tungsten powder come in contact with hot chlorine gas in a large glass receiver, a violent reaction shattered the equipment and could have injured the operators if they had not been wearing safety clothing and goggles. There is a limit to how casually any ultrafine powder can be handled. Currently this problem is being studied further to try to determine the cause of the variability in pyrophoricity of different lots of powder.

Uses

A few tests have been made to determine whether pressed compacts of ultrafine tungsten powder would have improved mechanical properties, as theory predicts. Specimens of rather impure powder (0.6% oxygen and 0.3% chlorine) were pressed at 40 tons/in.^{2}, giving compacts of only about 40% theoretical density, probably because of incomplete removal of entrapped air. The green strength was, however, very good. These specimens sintered poorly at 1750°C, giving compacts of 80% theoretical density. However, grain growth was excessive at these temperatures, *i.e.*, to about 30μ, and it was immediately apparent that low-temperature sintering would have to be possible if the desired fine structure is to be retained. Later, similar green compacts were sintered at 1550°C for 30 min in hydrogen atmospheres to give products of 94% theoretical density.

These results point up a rather remarkable property of ultrafine tungsten powder: that it can be sintered effectively at temperatures nearly a thousand degrees lower than conventional tungsten powder. This seems to be a general phenomenon, not restricted to tungsten. Lowering of the sintering temperature with other ultrafine metal powders has been observed in the same way.

Metallurgical data are currently being collected on these fine powders, including pressing, rolling, extruding, slip casting, dispersion strengthening, and so on. Some of these results should be available soon for publication. The powders, because of their unusual sizes and surface characteristics, may have unique applications as catalysts, fillers, fuels, nucleation agents in alloy production, and other diverse applications.

Effect of Adsorbed Anions on Reduction Processes on Passive Stainless Steel

F. A. Posey and R. F. Sympson[1]

ABSTRACT

The effects of sulfate, thiocyanate, chloride, and hydroxide ions on the reduction of cupric ion on passive stainless steel have been studied by use of potentiostatic techniques. Specific adsorption of the anions catalyzes the rate of the reduction reaction, and analysis shows that the adsorption follows a potential-dependent Langmuir isotherm. A simple model is proposed, based on electrochemical kinetic theory, which yields isotherms having properties in good agreement with experimental observations.

Studies on the kinetics of electrode processes have shown that anions exert specific effects in many systems. Among numerous contributions to the literature on this subject are papers concerned with the effect of anions on the exchange current of redox systems (1), on the corrosion of metals (2, 3), and on electrode reactions at a mercury surface (4). Frumkin (5, 6) and Piontelli (7) have reviewed anion effects in electrocapillarity and electrode kinetics, and the influence of anions in polarography was the subject of a review by Brdicka (8). Electrode processes occurring on passive metals are also affected by anions, and the sensitivity of the electrode potential of iron passivated in $CrO_4^=$, TcO_4^-, $MoO_4^=$, or $WO_4^=$ to additions of Cl^- or SCN^- was noted by Sympson and Cartledge (9). In a previous paper (10), the reduction of cupric ion on passive stainless steel in sulfate solution was studied by use of potentiostatic, galvanostatic, and tracer techniques. This reaction is catalyzed by the addition to solution of certain anions (11, 12), and the purpose of the present paper is to present results of electrochemical measurements on the effects of Cl^-, $SO_4^=$, OH^-, and SCN^- ions on the kinetics of reduction of Cu^{++} on passive stainless steel.

In order to obtain detailed information on the nature of the anion effects, a series of potentiostatic experiments was performed. The effect of SCN^- on the reduction of Cu^{++} on passive stainless steel was determined in various H_2SO_4-Na_2SO_4 solutions. These results suggested that both sulfate ion concentration and acidity are important variables in the kinetics of the reduction reaction. Hence further experiments were performed in aqueous perchlorate media in order to minimize any effect of complexing of cupric ions by anions in solution. Experiments in perchlorate solutions included the effects of Cl^-, $SO_4^=$, and, in particular, OH^- (acidity) on the kinetics of Cu^{++} reduction as a function of electrode potential and temperature. Since it was desirable to distinguish between complexing and adsorption aspects of the anion effects, accurate values of association quotients were determined spectrophotometrically for the association of Cu^{++} with the anions studied under conditions prevailing in the potentiostatic experiments. The results of the electrochemical measurements are presented below and analyzed on the basis of electrochemical kinetic theory.

Experimental

The experimental cell was a five-necked, spherical reaction flask of 500 ml capacity, fitted with a water-cooled condenser for use with heated solutions. Standard taper ports provided space for a thermometer, the entry and egress of gas, a platinum polarizing electrode, the stainless steel electrode assembly, and for additions of aliquots of stock solutions. Temperature was controlled by means of a Glascol heating mantle operated from a Variac supplied with regulated voltage. The constancy of the ambient temperature ensured control of the solution temperature to approximately $\pm 0.5°C$ over long periods of time. Purified helium or nitrogen effused into the solution at a constant rate through a sintered glass disk; the flow was sufficient to ensure vigorous stirring. Residual oxygen was removed from the gas by use of a tube furnace containing heated copper turnings, and columns of Drierite and Ascarite provided further purification.

Electrode potential measurements were made using a L&N *p*H Indicator (No. 7664) as a potentiometer coupled with a Brown recorder. Potentials were measured and recorded with time by the direct method, using a Luggin capillary bridged to a saturated calomel reference electrode maintained at room temperature. The concentration of the electrolyte was such that no significant ohmic potential drop occurred in solution between the electrode and the tip of the reference electrode capillary over the entire range of polarizing currents employed.

[1] Present address: Department of Chemistry, Ohio University, Athens, Ohio.

Galvanostatic circuitry consisted of high-capacity batteries furnishing 135v output, together with large load resistors in series with the cell. The concentration of cupric ion in solution was always such that comparatively small currents (usually no greater than 10 μa/cm^2) were sufficient to allow observations over the entire usable potential range of passive stainless steel in the chosen environments. Currents were measured by recording voltage drop across precision resistors in the circuit. The potentiostat used in these studies was developed in this laboratory for the special purpose of providing an all-electronic instrument suitable for precise control of electrode potentials in polarizable systems over extended periods of time. The potentiostat, a single-amplifier type, was constructed using a Reeves Instrument Corporation A-400 Dual D. C. Amplifier (REAC); this is a chopper-stabilized operational amplifier of high gain. Maximum output voltage was ±100v and output current could attain ±20 ma. Electrode potentials were constant to within ±0.1 mv at all times when the potentiostat was controlling, as could be ascertained oscilloscopically. Because of the chopper stabilization, response time was slow compared to potentiostats of the straight-amplifier type, but this was a negligible disadvantage for the present purposes considering the gain in long-term stability and precision afforded by the design adopted.

Electrodes were machined from type 347 stainless steel[2] in cylindrical form with a diameter of 1 cm and a height of 2 cm, thus permitting an exposed geometrical area of 7 cm^2 when mounted on the electrode holder. A Teflon cylinder abutted one end of the steel electrode and was followed by a conical Teflon piece machined to fit the standard taper joint of the cell. The entire assembly was tightened by use of a stainless steel rod which penetrated cylindrical and conical pieces axially and threaded into the steel electrode. A solution-tight seal was easily made, and no further attention was necessary during the life of the electrode. The surface of the stainless steel electrodes was electropolished in a solution of 60% by volume of 85% H_3PO_4 + 20% of 95% H_2SO_4 + 20% of H_2O at 65°C for 3-5 min at a current density of 0.5 amp/cm^2. This procedure produced a mirror-like surface of reproducible polarization characteristics in the solutions studied. Electrodes were stored between measurements in triple-distilled water.

All solutions were prepared using triple-distilled water, obtained by redistilling tap distilled water from the laboratory supply in a two-stage quartz still manufactured by Heraeus-Quarzschmelze. All reagents used were analytical grade. Recrystallization of crystalline reagents was found to be without appreciable effect on the results, and most experiments were performed using analytical grade chemicals without further purification.

In potentiostatic experiments, stainless steel electrodes were allowed to attain steady states at a preselected value of electrode potential. This procedure was time-consuming, as long-term transients are observed on passive stainless steel, especially in perchlorate solutions.[3] After attainment of steady states, aliquots of concentrated stock solutions were added to the experimental solution by micropipettes and the applied current necessary to maintain the chosen potential constant was recorded with time. Most experiments were performed in 0.3f $NaClO_4$ acidified with $HClO_4$. Stock solutions of 1f Na_2SO_4 and 5f NaCl in 0.3f $NaClO_4$ were used in experiments on the effects of $SO_4^=$ and Cl^-, respectively. In experiments on the effect of SCN^-, which were performed in dilute H_2SO_4-Na_2SO_4 solutions, freshly prepared stock solutions of 0.25f KSCN dissolved in the experimental solutions were used. Experiments on the effect of acidity were performed in $10^{-5}f$ $HClO_4$ + 0.3f $NaClO_4$ by adding aliquots of stock solutions of 1f $HClO_4$ + 0.3f $NaClO_4$ or concentrated $HClO_4$.

Results

Data from a series of potentiostatic experiments on the effect of SCN^- on the reduction of Cu^{++} on passive stainless steel in dilute sulfate solution are shown in Fig. 1. Cupric ion concentration was 2.5 or 5.0 x $10^{-6}f$ in this series; the over-all formal rate constant, $\bar{k}$, was calculated by dividing the current density in amp/cm^2 by the cupric ion concentration in moles/liter. The sigmoid curves observed in Fig. 1 are typical of all the data obtained in experiments on the SCN^- effect. Evidently the rate of reduction of Cu^{++} approaches a limiting value at high [SCN^-]. Solid lines drawn through the experimental data of

[2] Commercial type 347 stainless steel, although by no means a simple alloy, was chosen as a working material because its electrochemical behavior is typical of that of a large number of steels of similar composition. In addition, our experience has shown that the kinetics of reduction reactions are relatively insensitive to the type of stainless steel used, provided a standardized method of surface preparation is employed.

[3] The half-times of transients were found to depend greatly on the acidity of the solution, being least (approximately 5 min or less) in solutions of high pH (approaching neutrality), and increasing to values of the order of half an hour at low pH. The necessity of waiting for true steady states in these passive systems cannot be overemphasized. Whatever the nature of the transients, whether they be due to readjustment of charge distribution in the passive oxide film, to change in the film thickness, or to slow processes akin to a reaction capacity at the oxide-solution interface (or a combination of all of these), considerable charge is required to establish a new steady state. Premature judgment of the existence of steady states or arbitrary selection of times for changing parameters such as added ion concentration, electrode potential, or applied current result in confusion of the desired properties of the Faradaic processes in the system with properties of the non-Faradaic processes occurring during the transients.

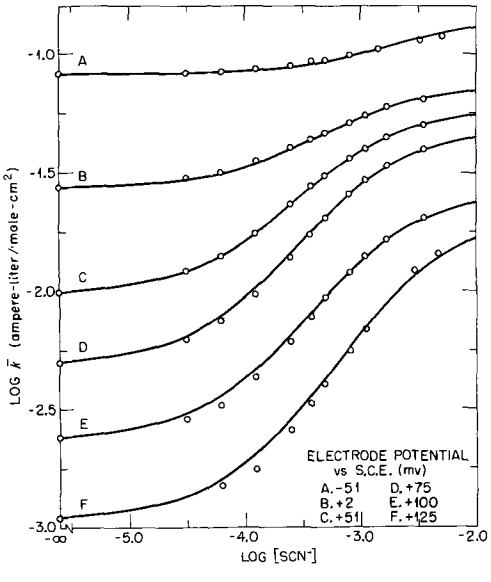

Fig. 1. Effect of SCN^- on the reduction of Cu^{++} on passive stainless steel in 1 x $10^{-3}f$ H_2SO_4 plus 9 x $10^{-2}f$ Na_2SO_4; 65°C, nitrogen atmosphere. Potential vs. S.C.E. at room temperature.

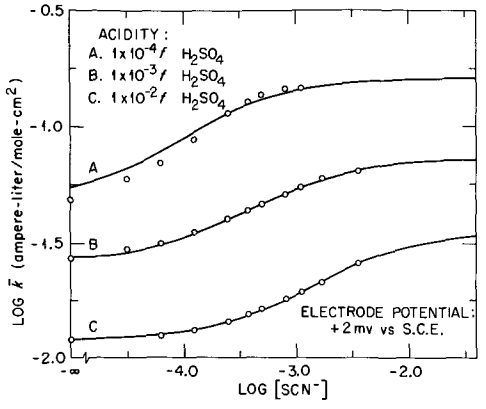

Fig. 2. Effect of acidity and SCN^- on the reduction of Cu^{++} on passive stainless steel in 9 x $10^{-2}f$ Na_2SO_4; 65°C, nitrogen atmosphere. Potential vs. S.C.E. at room temperature.

Fig. 1 are least-squares fits of the data with an expression of the form of Eq. [1].

$$k = (\alpha + \beta\gamma[X])/(1 + \gamma[X]) \qquad [1]$$

In Eq. [1], the formal electrochemical rate constant, $\bar{k}$, is a function of added anion concentration, [X], and of the three constants, α, β, and λ. The constant α is the rate constant for the reduction reaction in the absence of added anions, β is the limiting rate constant for large [X], and γ may be regarded as an equilibrium quotient for the interaction between anions and system reactants. The meaning of the constants of Eq. [1] is considered further below.

Experiments on the SCN^- effect were run at several acidities and at several over-all concentrations of sulfate ions. The effect of total sulfate ion concentration was found to be slight over the range 10^{-4} to $10^{-2}f$ Na_2SO_4. At constant $[H^+]$, little difference exists between rate constants at $10^{-4}f$ and at $10^{-3}f$ Na_2SO_4; some change of rate constant occurs at $10^{-2}f$ Na_2SO_4, but even here the difference is small. On the other hand, the effect of SCN^- on the reduction of Cu^{++} depends greatly on the acidity of the solution, as shown in Fig. 2. Changing the acidity of the solution not only affects the rate constants but also shifts the curve parallel to the log $[SCN^-]$ axis.

Data on the effect of $SO_4^=$ on the reduction of Cu^{++} on passive stainless steel in perchlorate solutions are shown in Fig. 3. Exploratory experiments had proven that NO_3^- and ClO_4^- ions have no effect on the kinetics of the reduction reaction, so that $0.3f$ $NaClO_4$ was chosen as inert electrolyte for experiments on the effects of $SO_4^=$, OH^-, and Cl^-, and crystalline $Cu(NO_3)_2 \cdot 3H_2O$ was used as the source of cupric ions. Even at $10^{-2}f$ $SO_4^=$, there is little change in the reduction rate of Cu^{++}, especially at lower acidity. These data are not extensive enough to show definitely whether or not a limiting value of rate constant is attained at high $[SO_4^=]$, but the aspect of the curves suggests not only the possibility of a limiting value but also the possibility of a common value independent of acidity.

The effect of acidity on cupric ion reduction is shown in Fig. 4 as a function of electrode potential. In addition to studies at 25°C, potentiostatic experiments were run at 45°, 67°, and 85°C. Figure 5, showing data on the effect of temperature at constant electrode potential, demonstrates that sigmoid curves are also obtained at the higher temperatures. Solid lines in Figs. 4 and 5 are least-squares fits of Eq. [1] to the experimental data. A limiting rate constant is attained at lower acidities in analogy to observations on the SCN^- effect; this effect is more pronounced at higher temperatures as may be seen in Fig. 5. In addition, a limiting rate is observed at the higher acidities (up to $10^{-1}f$ $HClO_4$).

Results of potentiostatic experiments on the effect of Cl^- on the reduction of Cu^{++} are shown in Fig. 6 as a function of electrode potential and acidity. Solid lines through data obtained in $10^{-5}f$ $HClO_4$ are least-squares fits; lines through data referring to $10^{-2}f$ $HClO_4$ are visual fits. The results at low acidity are similar to those shown in Fig. 1 for the effect of SCN^-. However, the experiments at higher acidity revealed a more complex behavior. Curve E of Fig. 6 shows the existence of a minimum in the $\bar{k}$ *vs.* $[Cl^-]$ relationship at ±0 mv *vs.* S.C.E. The influence of the phenomenon responsible for the minimum in curve

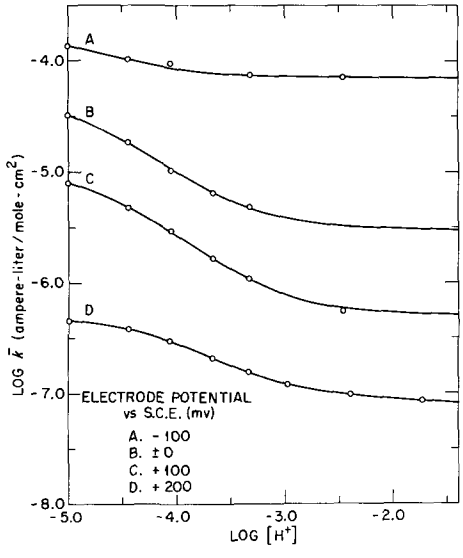

Fig. 4. Effect of acidity on the reduction of Cu^{++} on passive stainless steel in 3 x $10^{-1}f$ $NaClO_4$; 25°C, helium atmosphere.

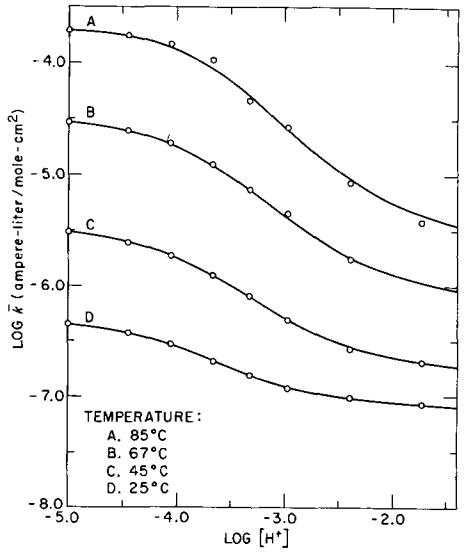

Fig. 5. Effect of temperature on the reduction of Cu^{++} on passive stainless steel in 3 x $10^{-1}f$ $NaClO_4$; helium atmosphere. Electrode potential: +200 mv vs. S.C.E. at room temperature.

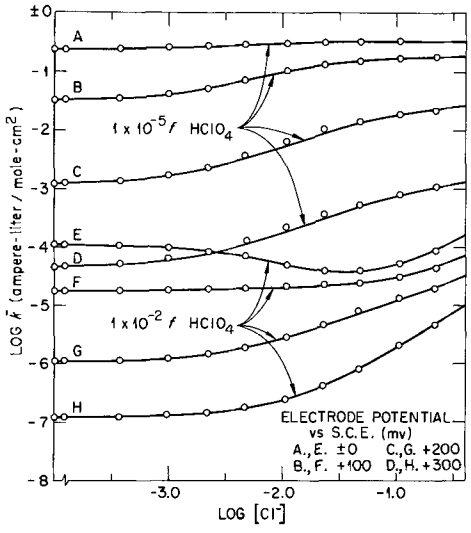

Fig. 6. Effect of Cl^- on the reduction of Cu^{++} on passive stainless steel in 1 x $10^{-5}f$ $HClO_4$ or 1 x $10^{-2}f$ $HClO_4$ plus 3 x $10^{-1}f$ $NaClO_4$; 85°C, helium atmosphere. Potential vs. S.C.E. at room temperature.

E seems to extend also to curve F, the behavior of which is more closely akin to the usual sigmoid relation obtained at lower acidity. Since meaningful data could not be obtained at chloride ion concentrations much larger than those shown in Fig. 6 without drastic changes in the ionic strength of the solution, evidence is insufficient on the question of whether or not rate constants are independent of acidity at high [Cl^-].

Discussion

Attempts to interpret the previous observations quantitatively on the basis of a complexing explanation encountered difficulties. Assuming that cupric ion and the anions studied react to form 1:1 complexes in solution and that rate constants differ for reduction of aquo ion and complex, one may derive an equation for the over-all rate constant which has the form of Eq. [1]. In this instance, the constant γ of Eq. [1] becomes the association quotient for the 1:1 association reaction. Values of γ were calculated from experimental data[4] for comparison with values of the 1:1 association quotients obtained from independent measurements. Examination of the literature showed that measurements of the 1:1 association quotients of Cu^{++} with the anions $SO_4^=$ and SCN^- were not reported for the experimental conditions of this study. Therefore, these quotients were measured spectrophotometrically as a function of temperature at ionic strengths of interest. Comparison of calculated values of γ with measured values of the 1:1 association quotients revealed sharp disagreement between the orders of magnitude. Furthermore, it was found that values of γ vary systematically with electrode potential. These observations forced abandonment of a complexing explanation as the predominant factor in the effect of anions on the reduction of Cu^{++} in the present system.

[4] If log $\bar{k}$ is plotted against log [X], the coordinates of the inflection point of a curve obeying Eq. [1] are given by the following equations; $\bar{k}$(infl.) = $\sqrt{\alpha\beta}$; [X](infl.) = $(1/\gamma)\sqrt{\alpha/\beta}$. These equations are useful for estimating γ from graphical data. However, the alternative procedure of calculating γ from a least-squares fit of Eq. [1] to experimental data was used here.

The previous data are better understood if it is assumed that the role of the anions lies in their affinity for the surface of passive stainless steel. The anions may be specifically adsorbed at the surface, thereby affecting the kinetics of rate processes occurring at the oxide-solution interface. An expression of the form of Eq. [1] may be derived by assuming that the number of adsorbed anions is related to anion concentration in solution by a Langmuir isotherm. The Langmuir isotherm is derived from considerations of coverage, without regard to lateral interaction effects or change of adsorption energetics with number of adsorbed particles (13). It can be expected to hold best for localized monolayer adsorption where adsorbed particles are relatively nonmobile and the adsorption bond is relatively nonlabile. At constant electrode potential the data of Fig. 1, 2, 4, 5, and 6 are represented by Eq. [1] to a good approximation, and this suggests that adsorption of anions on passive stainless steel involves strong specific interactions with the substrate. As shown below, combination of Langmuir adsorption model with the formalism of electrochemical kinetics leads to equations which adequately describe the results obtained in this study.

It has been shown previously (10) from analysis of polarization curves that the reduction of Cu^{++} on passive stainless steel proceeds by a two-stage mechanism involving a cuprous intermediate. In order to derive an expression for the effect of anions on the overall reduction rate, we assume for simplicity that three types of surface are available as reaction sites for the reduction of Cu^{++}: (i) the surface present at high acidity, which probably consists of adsorbed H_2O molecules and may be called the "aquo" surface; (ii) the surface present at low acidity because of adsorption of OH^- ions (or because of desorption of H^+ from the aquo surface), which may be called the "hydroxy" surface; and (iii) the surface resulting from specific adsorption of anions, which may be called the "anionic" surface. Equations [2], [3], and [4] show the reaction schemes at aquo, hydroxy, and anionic

surfaces, respectively, together with appropriate formal electrochemical rate constants for the individual charge transfer steps.

$$Cu^{++} \underset{\bar{k}_2}{\overset{\bar{k}_1}{\rightleftharpoons}} Cu^{+} \xrightarrow{\bar{k}_3} \text{products} \quad \text{(aquo surface)} \qquad [2]$$

$$Cu^{++} \underset{\bar{k}_5}{\overset{\bar{k}_4}{\rightleftharpoons}} Cu^{+} \xrightarrow{\bar{k}_6} \text{products} \quad \text{(hydroxy surface)} \qquad [3]$$

$$Cu^{++} \underset{\bar{k}_8}{\overset{\bar{k}_7}{\rightleftharpoons}} Cu^{+} \xrightarrow{\bar{k}_9} \text{products} \quad \text{(anionic surface)} \qquad [4]$$

If the fraction of the total electrode surface existing as hydroxy surface is designated by θ, the fraction as anionic surface by η, and the fraction as aquo surface by $(1-\theta-\eta)$, the total current density for reduction of cupric ion is given by Eq. [5].

$$j/\mathbf{F} = K_1(1-\theta-\eta) + K_2\theta + K_3\eta \qquad [5]$$

K_1, K_2, and K_3 are the rates of reduction on aquo, hydroxy, and anionic surfaces, respectively, in units of equivalents/cm²-sec, $\mathbf{F}$ is the Faraday, and j is current density in amp/cm². K_1, K_2, and K_3 are given by Eq. [6], [7], and [8], respectively.

$$K_1 = \bar{k}_1 C_0(a) + (\bar{k}_3 - \bar{k}_2) C_R(a) \qquad [6]$$

$$K_2 = \bar{k}_4 C_0(\theta) + (\bar{k}_6 - \bar{k}_5) C_R(\theta) \qquad [7]$$

$$K_3 = \bar{k}_7 C_0(\eta) + (\bar{k}_9 - \bar{k}_8) C_R(\eta) \qquad [8]$$

$C_0(a)$ and $C_R(a)$ refer to concentrations of cupric and cuprous ions, respectively, at the interface of the aquo surface, with analogous definitions for $C_0(\theta)$, $C_R(\theta)$, $C_0(\eta)$, and $C_R(\eta)$.

The flux of each of the six species in Eq. [6], [7], and [8] may be related to the bulk concentration of cupric ions in solution by using the Nernst diffusion layer approximation to Fick's first law. When this is done, the results may be substituted into Eq. [6], [7], and [8] to give explicit expressions for rates of reduction on the several types of surface; these are given in Eq. [9], [10], and [11].

$$K_1 = C^\circ \frac{\bar{k}_1(D_0/\delta_0)(2\bar{k}_3 + D_R/\delta_R)}{\bar{k}_1(\bar{k}_3 + D_R/\delta_R) + (D_0/\delta_0)(\bar{k}_2 + \bar{k}_3 + D_R/\delta_R)} \qquad [9]$$

$$K_2 = C^\circ \frac{\bar{k}_4(D_0/\delta_0)(2\bar{k}_6 + D_R/\delta_R)}{\bar{k}_4(\bar{k}_6 + D_R/\delta_R) + (D_0/\delta_0)(\bar{k}_5 + \bar{k}_6 + D_R/\delta_R)} \qquad [10]$$

$$K_3 = C^\circ \frac{\bar{k}_7(D_0/\delta_0)(2\bar{k}_9 + D_R/\delta_R)}{\bar{k}_7(\bar{k}_9 + D_R/\delta_R) + (D_0/\delta_0)(\bar{k}_8 + \bar{k}_9 + D_R/\delta_R)} \qquad [11]$$

In these equations, C° is the concentration of cupric ions in the bulk of the solution, and D_0/δ_0 and D_R/δ_R are ratios of diffusion coefficient to thickness of Nernst diffusion layer for cupric ions and cuprous ion intermediates, respectively.

The pertinent adsorption equilibria are given by Eq. [12], [13], and [14].

$$OH^- + \text{aquo surface} \underset{\bar{k}_\beta}{\overset{\bar{k}_\alpha}{\rightleftharpoons}} \text{hydroxy surface} \qquad [12]$$

$$X + \text{aquo surface} \underset{\bar{k}_\delta}{\overset{\bar{k}_\gamma}{\rightleftharpoons}} \text{anionic surface} \qquad [13]$$

$$X + \text{hydroxy surface} \underset{\bar{k}_\alpha'}{\overset{\bar{k}_\gamma'}{\rightleftharpoons}} OH^- + \text{anionic surface} \qquad [14]$$

Since charge is transferred during adsorption or desorption of anions, it is necessary to use formal electrochemical rate constants to allow for the potential dependences of the several processes. Equation [14] represents an anion exchange process which is possible when more than one kind of anion is available for adsorption on the surface. In the cases of $X = SCN^-$ or Cl^-, this process probably is only slightly potential dependent since no net charge transfer is involved.

Equations relating the rate of change of hydroxy and anionic surface fractions to adsorption process rate constants and concentrations of OH^- and X in solution may be solved for θ, η, and $(1-\theta-\eta)$ at equilibrium. These are given by Eq. [15], [16], and [17].

$$\theta = (1/\Delta)\left\{(\bar{k}_\alpha/\bar{k}_\beta)[OH^-] + \bar{k}_\alpha'/\bar{k}_\delta[OH^-]\cdot\left[(\bar{k}_\alpha/\bar{k}_\beta)[OH^-] + (\bar{k}_\gamma/\bar{k}_\beta)[X]\right]\right\} \qquad [15]$$

$$\eta = (1/\Delta)\left\{(\bar{k}_\gamma/\bar{k}_\delta)[X] + (\bar{k}_\gamma'/\bar{k}_\beta)[X]\cdot\left[(\bar{k}_\alpha/\bar{k}_\delta)[OH^-] + (\bar{k}_\gamma/\bar{k}_\delta)[X]\right]\right\} \qquad [16]$$

$$1-\theta-\eta = (1/\Delta)\left\{1 + (\bar{k}_\alpha'/\bar{k}_\delta)[OH^-] + (\bar{k}_\gamma'/\bar{k}_\beta)[X]\right\} \qquad [17]$$

The denominator Δ which is common to all three equations is given explicitly by Eq. [18].

$$\Delta = 1 + (\bar{k}_\alpha/\bar{k}_\beta)[OH^-] + (\bar{k}_\gamma/\bar{k}_\delta)[X] + (\bar{k}_\alpha'/\bar{k}_\delta)[OH^-]\left[1 + (\bar{k}_\alpha/\bar{k}_\beta)[OH^-]\right] + (\bar{k}_\gamma'/\bar{k}_\beta)[X]\left[1 + (\bar{k}_\gamma/\bar{k}_\delta)[X]\right] + \left[(\bar{k}_\alpha\bar{k}_\gamma' + \bar{k}_\alpha'\bar{k}_\gamma)/\bar{k}_\beta\bar{k}_\delta\right][OH^-][X] \qquad [18]$$

Finally the equation for the over-all rate constant is obtained by combining Eq. [5], [9], [10], [11], [15], [16], [17], and [18] and dividing through by C° to give $\bar{k} \equiv j/\mathbf{F}C^\circ$.

The quantity Δ occurring in the denominators of Eq. [15], [16], and [17] is also the denominator of the general equation for $\bar{k}$. When the theoretical expression for $\bar{k}$ is put into the form of Eq. [1], we find that the equilibrium quotient γ takes the form of Eq. [19], provided [X] of Eq. [1] is taken to be the same as the added ion concentration [X] of Eq. [18], etc.[5]

$$\gamma = \frac{\frac{\bar{k}_\alpha[OH^-]}{\bar{k}_\beta[X]}\left(1 + \frac{\bar{k}_\alpha'}{\bar{k}_\delta}[OH^-]\right) + \frac{\bar{k}_\gamma}{\bar{k}_\delta} + \frac{\bar{k}_\gamma'}{\bar{k}_\beta}\left(1 + \frac{\bar{k}_\gamma}{\bar{k}_\delta}[X]\right) + \left(\frac{\bar{k}_\alpha\bar{k}_\gamma' + \bar{k}_\alpha'\bar{k}_\gamma}{\bar{k}_\beta\bar{k}_\delta}\right)[OH^-]}{1 + \frac{\bar{k}_\alpha'}{\bar{k}_\delta}[OH^-]} \qquad [19]$$

[5] [X] in Eq. [1] may be $[Cl^-]$, $[SO_4^=]$, $[SCN^-]$, or $[OH^-]$, while [X] of Eq. [18], etc., may be $[Cl^-]$, $[SO_4^=]$, or $[SCN^-]$.

For certain special cases, γ becomes much simpler. If no anions other than OH^- are present, the equation for the over-all rate constant as a function of $[OH^-]$ possesses the form of Eq. [20].

$$\bar{k} = \frac{K_1 + K_2\bar{k}_\alpha[OH^-]/\bar{k}_\beta}{C^\circ(1 + \bar{k}_\alpha[OH^-]/\bar{k}_\beta)} \qquad [20]$$

γ for this special case is simply the ratio $\bar{k}_\alpha/\bar{k}_\beta$, the equilibrium quotient for the adsorption reaction of Eq. [12]. On the other hand, the theoretical form of $\bar{k}$ for experiments performed in strong acid solution on the effect of X is given by Eq. [21].

$$\bar{k} = \frac{K_1 + K_3\bar{k}_\gamma[X]/\bar{k}_\delta}{C^\circ(1 + \bar{k}_\gamma[X]/\bar{k}_\delta)} \qquad [21]$$

Under these conditions γ is the simple ratio $\bar{k}_\gamma/\bar{k}_\delta$, which is the equilibrium quotient for the adsorption reaction of Eq. [13]. Evidently the complications of Eq. [19] arise when the exchange reaction of Eq. [14] is important.

Values of a quantity proportional to the equilibrium quotient for adsorption of OH^- on passive stainless steel are shown in Fig. 7 plotted against electrode potential. The quantity γ of Fig. 7 is related to $\bar{k}_\alpha/\bar{k}_\beta$, the true adsorption quotient (cf. Eq. [20] and [12]), by Eq. [22].

$$\gamma = (\bar{k}_\alpha/\bar{k}_\beta)K_w^c \qquad [22]$$

K_w^c of Eq. [22] is the ion product of water ($K_w^c = [H^+]\,[OH^-]$) expressed in concentration units. Use of Eq. [22] is convenient since values of γ were determined by least-squares fits of Eq. [1] to experimental data with $[X] \equiv 1/[H^+]$.

The potential dependence of the equilibrium quotient $\bar{k}_\alpha/\bar{k}_\beta$ is assumed to be given explicitly by Eq. [23], where $\Delta\phi_{ads}$ is the inner potential difference between the layer of specifically adsorbed hydroxide ions and the solution and λ is the absolute value of the charge on the adsorbed ions ($\lambda = 1$ for OH^- adsorption).

$$\bar{k}_\alpha/\bar{k}_\beta = (k_\alpha/k_\beta)\exp(+\lambda\mathbf{F}\Delta\phi_{ads}/RT) \qquad [23]$$

$\Delta\phi_{ads}$ may be assumed to vary with changes in the over-all inner potential difference between metal and solution, $\Delta\phi_T$, the latter being composed additively of the potential difference between metal and oxide layer, the potential drop across the passive film, the potential between the oxide layer and the position of the adsorbed ions, and the potential difference $\Delta\phi_{ads}$. Changes of the equilibrium quotient, $\bar{k}_\alpha/\bar{k}_\beta$, with the over-all potential $\Delta\phi_T$ depend on the variation of the specific rate constants for adsorption and desorption steps of the reaction of Eq. [12] with $\Delta\phi_{ads}$, the latter being some fraction of $\Delta\phi_T$. Combination of Eq. [22] and [23] and differentiation with respect to $\Delta\phi_T$ leads to Eq. [24].

$$\frac{d\ln\gamma}{d\Delta\phi_T} = \frac{\lambda\mathbf{F}}{RT}\left(\frac{d\Delta\phi_{ads}}{d\Delta\phi_T}\right) \qquad [24]$$

The slope of the line in Fig. 7 is $+6.75 \times 10^{-3}$ (mv^{-1}) and $2.303\,RT/\mathbf{F} = 71$ mv at 85°C, so that $(d\Delta\phi_{ads}/d\Delta\phi_T) = 0.48$. On the basis of the stated assumptions, this result suggests that a change in $\Delta\phi_{ads}$, which affects adsorption processes, accounts for only approximately half of the total change in those components of the over-all interfacial potential difference ($\Delta\phi_T$) which change their values appreciably during polarization.

The temperature dependence of $\bar{k}_\alpha/\bar{k}_\beta$, the equilibrium quotient for adsorption of OH^-, is shown in the Arrhenius-type plot of Fig. 8. Values of $\bar{k}_\alpha/\bar{k}_\beta$ were computed from Eq. [22] using values of K_w^c calculated according to the method given by Harned and Owen (14). The solid lines of Fig. 8 are least-squares fits of the data; in spite of scatter, which is expected because of the approximate nature of the model used, the slopes of the lines are roughly the same. Evaluation of the ratio k_α/k_β of Eq. [23] in terms of thermodynamic quantities leads to Eq. [25],

$$k_\alpha/k_\beta = \exp(+\Delta S^\circ_{ads}/R)\exp(-\Delta H^\circ_{ads}/RT) \qquad [25]$$

where ΔS°_{ads} and ΔH°_{ads} are standard entropy and enthalpy of adsorption, respectively. Combination of

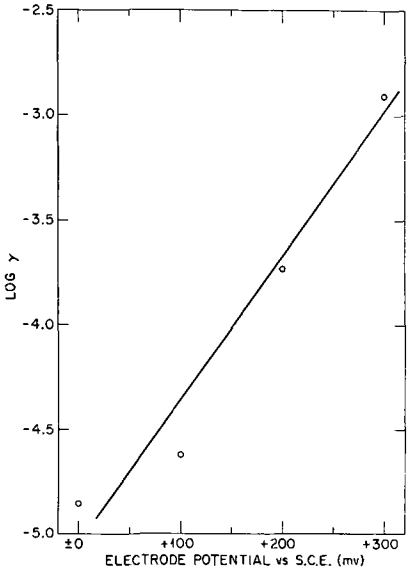

Fig. 7. Potential dependence of equilibrium quotient for adsorption of OH^- on passive stainless steel in 3 x $10^{-1}f$ $NaClO_4$ at 85°C. Potential vs. S.C.E. at room temperature.

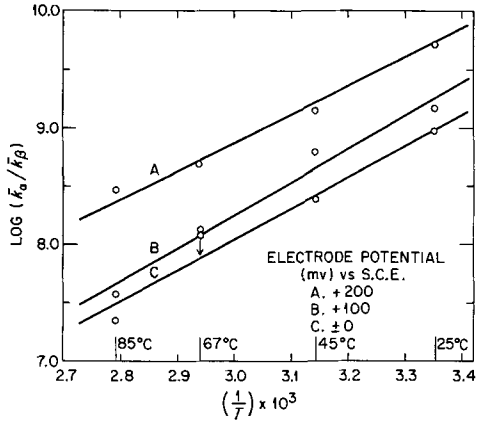

Fig. 8. Temperature dependence of equilibrium quotient for adsorption of OH^- on passive stainless steel in 3 x $10^{-1}f$ $NaClO_4$. Potential vs. S.C.E. at room temperature.

Eq. [23] and [25], followed by differentiation, leads to Eq. [26] relating the slope of the lines in Fig. 8 to the apparent standard enthalpy of the adsorption reaction (ΔH°_{app}).

$$\Delta H^\circ_{app} \equiv \Delta H^\circ_{ads} - \lambda \mathbf{F} \Delta\phi_{ads} - (\lambda \mathbf{F}/T)[d\Delta\phi_{ads}/d(1/T)]_{\Delta\phi_T} = -R[d \ln (\bar{k}_a/\bar{k}_\beta)/d(1/T)]_{\Delta\phi_T} \quad [26]$$

Use of Eq. [26] with the data of Fig. 8 leads to $\Delta H^\circ_{app} = -11.3$, -13.0, and -12.3 kcal/mole for curves A, B, and C, respectively. Therefore the adsorption reaction is exothermic. Using an average value of $\Delta H^\circ_{app} = -12.2$ (± 0.6) kcal/mole and neglecting the potential dependence of the apparent enthalpy of adsorption (cf. Eq. [26]), calculation of the standard entropy of the adsorption reaction from the data in Fig. 8 leads to $\Delta S^\circ_{ads} = +1.7$ (± 1.4) e.u. Instead of adsorption of OH^- onto an aquo surface as in Eq. [12], an alternative and electrochemically equivalent reaction scheme is given in Eq. [12′].

$$\text{aquo surface} + H_2O \rightleftharpoons \text{hydroxy surface} + H_3O^+ \quad [12']$$

The low value of standard entropy of adsorption calculated from these data is consistent with the mechanism of Eq. [12′], since proton transfer from an aquated surface probably involves less configurational entropy change than a process involving adsorption of hydroxide ion.

Results shown in Fig. 2 on the SCN^- effect receive qualitative explanation on the basis of Eq. [19]. For most choices of rate constants, the numerator of Eq. [19] essentially determines the effect of acidity, and γ increases with $[OH^-]$ as observed. Evidently SCN^- displaces adsorbed OH^- more readily than adsorbed H_2O, although information is needed on the relative magnitudes of the ratios $\bar{k}_\gamma/\bar{k}_\delta$ and $\bar{k}_\gamma'/\bar{k}_a'$, the equilibrium quotients of the reactions in Eq. [13] and [14], before definite conclusions can be made. As seen in Fig. 3, the opposite situation appears to hold with $SO_4^=$ higher $[SO_4]$ being required to produce a significant change in rate constant at low acidity than at high acidity.

Under certain conditions, the over-all rate constant $\bar{k}$ varies with added ion concentration [X] in the manner shown in curve E of Fig. 6. Analysis of the theoretical model shows that this behavior is possible provided the association quotients of Eq. [12], [13], and [14] have appropriate values. Specifically, these quotients must satisfy the inequality of Eq. [27].

$$\left(\frac{\bar{k}_\gamma}{k_\delta} - \frac{\bar{k}_a}{k_\beta} \cdot \frac{\bar{k}_\gamma'}{k_a'}\right) << 0 \quad [27]$$

The left-hand side of Eq. [27] must be sufficiently negative to compensate for positive terms appearing in the equation for the slope of a plot of over-all rate constant against added ion concentration. Mechanistically, the ratio of aquo to hydroxy surface increases to a maximum at low added ion concentrations before decreasing at higher [X] because of the peculiarities of the mixed isotherm when the mechanism of Eq. [14] is important. Since $K_1 << K_2 < K_3$ in the present system ($[X] = [Cl^-]$), the over-all rate constant goes through a minimum with increasing [X]. Analysis further shows that no minimum should be observed at very high or very low acidity, and this is in accord with experimental observation.

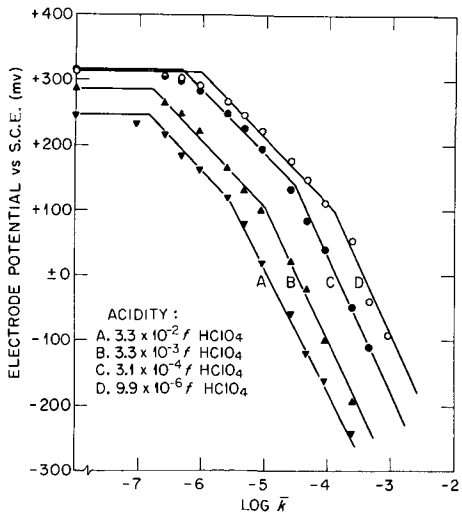

Fig. 9. Effect of acidity on polarization curves for reduction of Cu^{++} on passive stainless steel in 3 x 10^{-1} f $NaClO_4$; 67°C, helium atmosphere. Potential vs. S.C.E. at room temperature.

Polarization curves for the reduction of Cu^{++} on stainless steel in perchlorate medium are similar to those observed previously (10) in dilute sulfuric acid solution. A typical set of curves is shown in Fig. 9; closely analogous results were obtained from galvanostatic measurements at other temperatures. The change of slope of the polarization curves results from a change with potential of the rate-determining step in the mechanisms of Eq. [2] and [3]. Examination of Eq. [9] shows that, neglecting diffusion ($D_0/\delta_0 >> \bar{k}_1$ and $D_R/\delta_R << \bar{k}_2 + \bar{k}_3$), the rate of reduction of Cu^{++} on the aquo surface reduces to the form of Eq. [28].

$$K_1 = C^\circ 2\bar{k}_1\bar{k}_3/(\bar{k}_2 + \bar{k}_3) \quad [28]$$

At low potentials $\bar{k}_3 >> \bar{k}_2$ and K_1 is proportional to $\bar{k}_1$, the rate constant for the reduction of Cu^{++} to the cuprous intermediate. At high potentials, $\bar{k}_2 >> \bar{k}_3$ and K_1 becomes proportional to $\bar{k}_1\bar{k}_3/\bar{k}_2$, implying that in this potential region there is virtual equilibrium between cupric and cuprous species and that reduction of the cuprous intermediate is rate determining. Rate control by diffusion (plus convection in stirred solution) becomes important at potentials more negative than those shown in Fig. 9. The results of Fig. 9 show that the transition between high and low potential regions of the polarization curve is essentially independent of acidity. Since the transition occurs when $\bar{k}_2 = \bar{k}_3$, this observation supports the assumption implicit in the derivation of the isotherm that the rate constants of the charge transfer steps in the mechanisms of Eq. [2], [3], and [4] are independent of acidity. When plotted as a function of temperature at constant acidity, polarization curves show that the potential of the transition region increases with temperature, implying different ener-

getics for the alternative modes of decomposition of the cuprous intermediate.

Values of differential capacity for the present system were estimated by analysis of recordings of the initial potential-time transients observed during the establishment of new steady states in galvanostatic measurements. Although this manual procedure is inexact, reasonably reproducible numbers were obtained. In units of microfarads/cm^2, the capacity of the interface was 35 to 40 at +300 mv *vs* SCE., 40 to 50 at +200 mv, 60 to 80 at +100 mv, 90 to 120 at ±0 mv, and 110 to 160 at −100 mv. Slight increases of capacity with temperature were observed, the range of values in the above listing corresponding to measurements at 25° and 85°C. Values of capacity were found to be independent of the current density of the Cu^{++} reduction reaction at the oxide-solution interface. A slight acidity effect was detected; values of capacity increased with acidity at constant potential, but in no case did the capacity change by more than a factor of two over the acidity range, 10^{-5} to 10^{-2} *f* $HClO_4$. Capacities were also essentially independent of added anion concentration, so that measurements of capacity in the present system did not appear to include a contribution from the reaction capacity of the adsorption processes. The foregoing observations allow the speculation that the capacity of the interface is determined largely by the properties of the passive oxide; *i.e.*, the smallest capacity in the interfacial system depends on the thickness and the charge distribution within and on each side of the oxide layer.

We conclude from the evidence presented that the rates of reduction reactions on passive stainless steel are sensitive to specific adsorption of anions from solution. To a good approximation this specific adsorption follows a potential-dependent Langmuir isotherm. Analysis of data on the adsorption of hydroxide ion yields results in good agreement with theory, thus permitting calculation of the energetics of the adsorption reaction. Adsorption of anions other than hydroxide follows a similar, although much more complex isotherm, the properties of which allow qualitative interpretation of salient observations. Similar anion effects undoubtedly occur for other reduction reactions and in other passive systems, for which the foregoing analysis may also prove to be useful.

Acknowledgment

The authors wish to express appreciation to their colleagues, Dr. G. H. Cartledge and Dr. R. E. Meyer, for stimulation and encouragement during the course of this work.

A Solid Electrolyte Fuel Cell

J. Weissbart and R. Ruka

Chemistry Department, Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A high-temperature oxide electrolyte galvanic cell of the type H_2/H_2O, Pt || $(ZrO_2)_{0.85}(CaO)_{0.15}$ || Pt, O_2 is described. Experimental data for reaction of oxygen with hydrogen-water and methane-water mixtures are given. Open-circuit voltages for the hydrogen-oxygen reaction are close to theoretical, and current-voltage curves show that the output of the cell is limited essentially by the resistance of the electrolyte. The data suggest that solid oxide electrolyte cells of this general type may offer attractive possibilities as fuel cells for utilizing hydrocarbons as fuel and oxygen or air as oxidant.

High-temperature galvanic cells with solid oxygen ion conducting electrolytes have features which may make them attractive as fuel cells. Catalytic problems are reduced at high temperatures, and a mechanically stable electrode-electrolyte interface is possible with an all-solid construction.

Schottky (1) discussed the problem of solid electrolytes from the theoretical point of view in 1935 and two years later Baur and Preis (2) constructed the first solid oxide-electrolyte fuel cell. The electrolyte was in the form of a ceramic tube of $(ZrO_2)_{0.85}(Y_2O_3)_{0.15}$, a material which Nernst had previously

shown to possess a relatively high ionic conductivity. The tube was filled with coke to form the anode and surrounded with iron oxide in an air atmosphere to form the cathode. An output of less than 1 ma/cm^2 of electrolyte area at 1050°C and 0.65v was obtained and it was concluded that sufficient cation conductivity[1] was occurring to damage the cell.

A number of researches have contributed information on the physical and chemical properties of ceramics with high oxygen ion mobility. Nernst (3) observed qualitatively the electrolytic evolution of oxygen from a rod of $(ZrO_2)_{0.85}$ $(Y_2O_3)_{0.15}$ (Nernst glower). More recently Weininger and Zemany (4) made a quantitative measurement of the electrolytic evolution of oxygen from a Nernst glower of similar composition and found that 7-80% of the current could be accounted for by ionic conduction, depending on temperature, current flow, and previous history of the material.

Wagner (5) proposed in 1943 that oxide solid solutions such as $(ZrO_2)_{1-x}$ $(CaO)_x$ or $(ZrO_2)_{1-x}$ $(Y_2O_3)_x$ contain vacant oxygen ion sites, one vacancy occurring for each Ca^{+2} or two Y^{+3} ions that substitute for Zr^{+4} ions in the fluorite-type crystal structure. He assumed that this would lead to high oxygen ion conductivity. Hund (6) determined the density of these oxides by x-ray and pycnometric methods. The data are consistent with the oxygen ion vacancy model.

Kingery (7) and co-workers calculated the oxygen ion mobility in $(ZrO_2)_{0.85}$ $(CaO)_{0.15}$ from the Nernst-Einstein relation[2] and the diffusion coefficient obtained from measurements of the rate of exchange of oxygen in the oxide with O^{18}. Comparing this data with measurements of electrical conductivity of the oxide they concluded that the conductivity is wholly ionic and that the transference number is near unity for the oxygen ion.

Kiukkola and Wagner (8) and several other authors have obtained high temperature thermodynamic data using galvanic cells with electrolytes of zirconia of thoria containing CaO, Y_2O_3, La_2O_3, and other oxides.

Weissbart and Ruka (9, 10) have constructed vacuum tight cells of the type

$$O_2\ (p_1), Pt \mid\mid (ZrO_2)_{0.85}(CaO)_{0.15} \mid\mid Pt, O_2(p_2)$$

in which the electrode reactions at temperatures above 600°C were shown to correspond closely to the reversible reaction

$$O_2 + 4e^- \rightleftharpoons 2\,O^= \qquad [1]$$

The voltages obtained are in good agreement with the theoretical emf E calculated from the thermodynamic relationship for reversible transfer of oxygen from cathode to anode at the given pressures.

$$E = \frac{RT}{4F} \ln \frac{P_{O_2}\ (\text{cathode})}{P_{O_2}\ (\text{anode})} \qquad [2]$$

This shows that the cells act as oxygen concentration cells.

[1] Cation conductivity is undesirable since it results in transfer of electrolyte from anode to cathode of the galvanic cell. This would damage the electrode-electrolyte interfaces.

[2] $D_i = B_i kT$ where D_i is the self-diffusion coefficient and B_i is the absolute mobility of the i-th species.

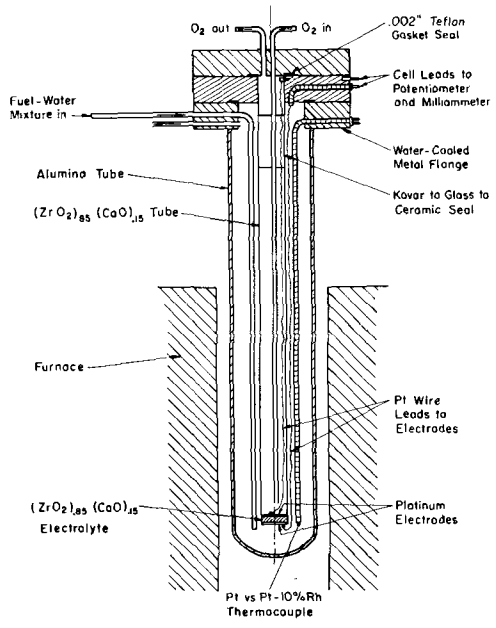

Fig. 1. Schematic diagram of galvanic cell with solid oxide electrolyte.

Faraday's laws were found to be obeyed closely for current flow through a cell of this type as determined by microweighing of the oxygen transferred. The electronic contribution to the total conductivity was found to be less than 0.5% near 1000°C in an oxygen atmosphere.

Experimental

The construction of the galvanic cell is illustrated schematically in Fig. 1. It is similar to that previously described (9) except that it is arranged to flow gases past both electrodes.

The essential elements of the cell are the flat bottom portion of the $(ZrO_2)_{0.85}(CaO)_{0.15}$ tube, which acts as the electrolyte, and two porous platinum electrodes (9) of less than 0.001 in. thickness. Cell dimensions were of the order of 2.5 cm^2 area and 0.15 cm thickness. For these cells contact resistances of the order of 1-2 ohms were encountered depending on the thickness of the porous platinum films.

For all experiments pure oxygen at atmospheric pressure flowed slowly past the cathode, and the various water-hydrogen or water-methane mixtures flowed at a faster rate through the anode chamber. The experimental arrangement of the cell is designed for current-voltage measurements rather than for optimum conversion of fuel. An appreciable fraction of the total gas flowing through the anode chamber does not come in contact with the electrode. Consequently a high flow rate of gas was used to minimize concentration polarization and thermal diffusion effects. The volume of preheated gas flowing per minute into the anode chamber was about 3.7 times the volume of the chamber. For a decrease in flow rate to one-third of this value the temperature of a thermocouple placed near the anode changed less than 1°C.

The hydrogen or methane was first passed through water bubblers and the effluent gas from the anode chamber was analyzed for H_2, H_2O, CO, CO_2, and

CH_4. Calculations of the theoretical emf for the experiments are based on these analyses.

Results and Discussion

When current is drawn from a galvanic cell the voltage may be lower than the open-circuit value due to (*a*) activation polarization, (*b*) concentration polarization, (*c*) ohmic resistance of the cell. The voltage drop due to each of these is a function of the current density. (*a*) depends on the particular rate-determining chemical and electrochemical reactions at the electrodes, (*b*) involves mass transfer of reactants and products, and (*c*) ordinarily depends largely on electrolyte resistance.

Activation polarization is frequently encountered in low temperature cells, and significant reaction of hydrocarbons at the fuel electrode is particularly difficult to attain. In addition, the oxygen electrode reaction proceeds by a peroxide mechanism which even in the presence of peroxide decomposing catalysts results, according to Kordesch (11), in a lower voltage than the ideal oxygen electrode value.

At higher temperatures the mechanism at the oxygen electrode is different. Thus the peroxide reaction is not detected in a fused carbonate cell which has been shown to act as an oxygen-carbon dioxide concentration cell by Chambers and Tantram (12).

The present solid oxide cell involves even less complicated electrode reactions since it acts as a simple oxygen concentration cell (9). If hydrogen is present at the anode, we write the cell diagrammatically as

$$H_2/H_2O, Pt \;||\; (ZrO_2)_{0.85}(CaO)_{0.15} \;||\; Pt, O_2$$

The emf E is given by the standard thermodynamic relation

$$E = E^\circ + \frac{RT}{4\mathbf{F}} \ln P_{O_2}\,(\text{cathode}) + \frac{RT}{2\mathbf{F}} \ln \frac{P_{H_2}}{P_{H_2O}}\,(\text{anode}) \qquad [3]$$

Figure 2 shows a comparison of experimental and theoretical open-circuit voltage values *vs.* the $H_2/(H_2 + H_2O)$ ratio for a constant oxygen pressure at the cathode. The theoretical curve is calculated from Eq. [3]. The experimental points are based on the measured emf and the analytically determined $H_2/(H_2 + H_2O)$ mole ratio. Agreement is within 5 mv of the theoretical value. This is within the error of the H_2 and H_2O analyses.

Figure 3 shows current-voltage curves for the hydrogen-oxygen reaction in the cell at four temperatures at approximately constant $H_2/(H_2 + H_2O)$ ratios and oxygen pressure. The curves are all straight lines with slopes $\Delta E/\Delta I$ agreeing within 5% of the values of resistance determined directly by 1000 cycle a-c resistance measurements. Figure 4 shows further current-voltage curves at two temperatures for two different water-hydrogen ratios. The two sets of parallel lines indicate that the d-c resistance was the same at the same temperature. Although the internal resistance of a cell stayed nearly constant during measurements of individual current-voltage curves, variations in either direction were found over longer periods of time, even

on open circuit. Open-circuit voltages were reproducible to about 1 mv in duplicate runs, independent of this effect, while the slopes of the current-voltage curves changed in accordance with the measured resistance changes. According to Dietzel and Tober (13) the lower temperature limit for existence of the fluorite phase in the zirconium-calcium mixed oxide lies in the neighborhood of 850°C, but phase boundaries are very uncertain since equilibrium was not attained over a wide temperature range. This suggests that resistance changes under open-circuit conditions encountered in the present work could possibly be associated with slow phase changes occurring as a function of temperature, composition and homogeneity of the mixed oxide.

Figure 5 shows the current-voltage curve obtained for a mixture of 3.8% methane, 2.1% water and 94.1% N_2 as fuel. The rate of fuel flow was sufficiently rapid that chemical equilibrium was not attained for the reforming reaction and 80% of the methane remained undecomposed by passage through the cell. The open-circuit voltage of 0.945v

is within 5 mv of the value calculated for the simple hydrogen-oxide reaction and approximately 50 mv lower than the value for the carbon monoxide-oxygen reaction. The calculations are based on the H_2/H_2O and CO/CO_2 ratios in the effluent gas from the anode chamber and the known oxygen pressure at the cathode. At slower flow rates a higher percentage of methane was converted, probably largely by the reforming reaction $CH_4 + H_2O \rightarrow CO + 3H_2$. This results in higher H_2/H_2O and CO/CO_2 ratios and thus higher open-circuit voltages. The data indicate that the major electrochemical reactions probably involve the reformed gases, H_2 and CO rather than CH_4. The moles of CH_4 and H_2O decomposed is consistent with the CO, CO_2, and H_2 formed as determined from the analysis of the exit gases. This shows that carbon formation did not occur within the cell. However, analysis of exit gases indicated that carbon formation did occur in some other experiments at similar low H_2O/CH_4 ratios.

The ultimate life expectancy of the cell under optimum conditions has not been determined, although an individual cell of this type using a 30 to 1 H_2/H_2O mixture as fuel has been operated continuously at 10 ma/cm² of electrolyte area for two months at temperatures between 1000° and 1200°C. Some platinum loss from electrodes by evaporation, possibly as an oxide, occurs at these temperatures.

The current-voltage data indicate that the cell has an output for the hydrogen-oxygen reaction which is essentially resistance limited and thus should be capable of higher output by simply decreasing the thickness of the electrolyte, provided contact resistances are low.

The studies necessary to improve the cell include investigations of the cation conductivity and phase stability of the electrolyte, the electrode structure, properties of thin films of the electrolyte and substitution of other electrodes and electrolytes.

Studies of the Electrochemical Kinetics of Indium

I. Kinetics of Deposition and Dissolution in the Indium + Indium Sulfate System

B. Lovrecek and V. Markovac

Institute of Electrochemistry and Electrochemical Technology, Faculty of Technology, University of Zagreb, Zagreb, Yugoslavia

ABSTRACT

The kinetics of the deposition and dissolution of indium (from indium amalgam) in indium sulfate solutions at pH 2.5 have been studied by observing variations of overpotential during individual constant current pulses. The electrode was in the form of a hanging drop of the amalgam, which was renewed for each pulse. The steady-state activation overpotential was reached approximately 1 msec after application of the pulse, which corresponds to a mean value of double layer capacity of 25.4 μF/cm^2. Plots of the activation overpotential *vs.* log current density show good Tafel relations in both the cathodic and anodic regions. Analysis of these data shows the mechanism to consist of three consecutive electron transfer steps

$$In^{3+} \underset{e^-_0}{\overset{+e^-_0}{\rightleftarrows}} In^{2+} \underset{e^-_0}{\overset{+e^-_0}{\rightleftarrows}} In^{1+} \underset{e^-_0}{\overset{+e^-_0}{\rightleftarrows}} In^0$$

The rate-determining step for both anodic and cathodic polarization is

$$In^{3+} \underset{e^-_0}{\overset{+e^-_0}{\rightleftarrows}} In^{2+}$$

for which the transfer coefficient α was determined to be approximately 0.83.

The mechanism of electrochemical deposition and dissolution of metals, because of its great theoretical and practical importance, has been the subject of numerous studies and discussions. This paper deals with the mechanism of deposition and dissolution of indium, in which studies methods similar to those used by Gerischer (1), Berzins and Delahay (2), and Mattsson and Bockris (3) have been applied. Kangro and Weingärtner (4), and Duić, Kovac, and Lovrecek (5) have already established that the deposition of indium(III)-ion and the dissolution of metallic indium, respectively, follow in a "many step" electrode process over an ion of lower valency, but have not determined either the electrochemical step in question or the rate-determining step. The kinetics of the system have been studied[1] on basis of theoretical expressions for the kinetics of "many step" electrode reactions (6), with due consideration to possible reaction steps in the electrochemical deposition and dissolution of indium.

Experimental

Apparatus.—The apparatus (Fig. 1) comprised an electrolytical cell with nitrogen purification unit and electrical device.

The electrolytic cell resembles those used earlier (1, 2) and comprises a main compartment and a reference electrode compartment. The main compartment is shaped like a vessel with a cap through which a carrier for measuring electrode, a capillary with an amalgam reservoir on the top, a spoon for catching of the amalgam drops, and a bubbler are fixed. The carrier is a glass tube with a thin platinum wire sealed into the top. After sealing the wire was cut level with the glass and electrolytically gold-plated. The measuring electrode is a hanging drop of amalgam, of determined surface area, on which the polarization takes place. The carrier for the measuring electrode passes through the center of the cap into the cell following its vertical axis. The capillary resembles those used in polarography. The capillary with reservoir is connected to the mercury pressure system by means of a tygon tube. The pressure system regulates the pressure in the reservoir and thus regulates the rate of dropping through the capillary. The spoon for catching drops

Schematic diagram of apparatus: A, main compartment of electrolytic cell; B, reference electrode compartment; C, nitrogen tank; D, washing bottle; E, mercury security valve; F, electric furnace with active copper; G, washing bottle; H, drop collector containing glass wool; I, capillary with amalgam reservoir; J, pressure system; K, glass spoon; SPG, square pulse generator; DCA, direct current amplifier; CRO, cathode-ray oscilloscope; O, hanging drop electrode; P, reference electrode (S.C.E.).

[1] Further experiments with this system and description of details of the apparatus and procedure will be found in the Ph.D. thesis of V. Markovac.

is fastened by its handle to the cap by a cylindrical ground glass joint and revolves freely in the direction and around its vertical axis. It catches the drop of amalgam from under the capillary and hangs it on the tip of the carrier.

The main compartment of the cell has in its side a tube for the introduction of nitrogen, which is introduced before the electrolysis so as to remove the dissolved oxygen from the electrolyte, and immediately proceeding each measurement, to level the concentration. In the opposite side of the main compartment of the cell an electrolytical bridge is built in, connecting this compartment with the reference electrode compartment. The electrolytical bridge is executed so that one end enters the main compartment of the cell approximating the form of a capillary to the hanging drop of the measuring electrode (distance of 3 mm). At the bottom of the cell there is a quantity of amalgam of the same composition as the hanging drop, *i.e.*, the measuring electrode. This quantity of amalgam is continually increased by the drops discharged from the carrier of measuring electrode. In the reference electrode compartment there is a standard saturated calomel electrode in the electrolyte of the same composition as that in the main compartment of the cell. During the pre-electrolysis, a platinum electrode is put into this compartment to serve as an anode instead of the calomel electrode.

Before the electrolysis and immediately proceeding each measurement, purified nitrogen is forced through the cell and the electrolyte. The ordinary tank nitrogen is purified (oxygen removed) in the manner introduced by Meyer and Ronge (7), by forcing the gas through a column filled with active copper, spread on the infusorial earth. The column is heated to 200°C by an electric heater in the sheath around the column. The electrolytic cell and purification units are made of Pyrex glass. All joint and stopcocks are made in the ground glass technique and sealed with distilled water.

The electrical device (Fig. 2) has three main components: a square-wave pulse generator SPG, a direct current amplifier DCA, and a cathode-ray oscilloscope CRO.

A relay RE built into the generator synchronizes the beginning of the square-wave pulse and the time

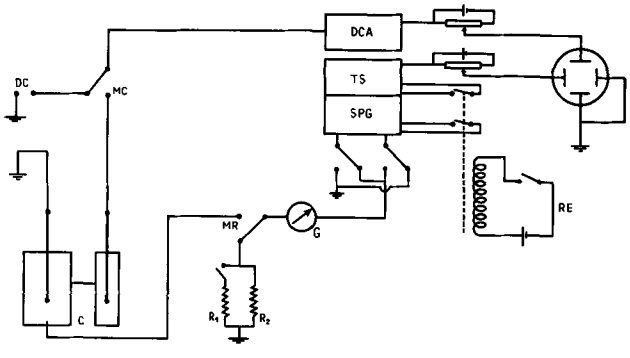

Fig. 2. Schematic diagram of electrical arrangement: RE, relay; SPG, square pulse generator; TS, time sweep; DCA, direct current amplifier; CRO, cathode-ray oscilloscope; AC, switch anodic-cathodic polarization; G, galvanometer; MR, switch measurement regulation; R_1 and R_2, resistors (5.6 KΩ and 56Ω); MC, switch measurement-calibration; DC, calibration device; C, electrolytical cell.

sweep TS, so that the time sweep begins a little earlier, for safety's sake. The time sweep, built into the generator, regulates the recording time in a 0.3 msec to 3 sec range. The square-wave pulse is electronically stabilized by means of a penthode, so that changes in the resistance of the cell do not influence the constant current of a pulse. Pulses obtained cover the range of 2.0×10^{-6}-8.0×10^{-2} amp. The switch AC serves to change the direction of the pulse current. Before the measurement the selected current is read on the galvanometer G by passing the current through a combination of resistors R_1 and R_2, instead of through the cell. The rise time of a pulse is less than 10 μsec.

The direct current amplifier DCA is constructed to let pass a 10 MHz span of frequencies, which makes possible the observation of pulses with rise time up to 1 μsec. The factor of amplification is up to 1.700. The switch MC and a device DC serve for the calibration of the amplifier.

Procedure.—Before the experiments the glass apparatus was washed in chrom-sulfuric acid (16 hr), washed out in running water, and then washed in distilled water (16 hr).

The composition of the electrolyte used was $0.116N$ $In_2(SO_4)_3$ in $0.5N$ K_2SO_4, $pH = 2.5$ solution. The electrolyte was prepared by the dissolution of a wire of very pure indium[2] in the calculated amount of H_2SO_4 with regard to indium sulfate and potassium sulfate. Once the dissolution was completed the corresponding amount of KOH solution was added successively until a certain pH value was reached. Chemicals used were of the analytical reagent grade.

As the measuring electrode a hanging drop of 0.3% by weight In-amalgam was used. In-amalgam in such concentrations has the physical properties of liquids (8). It is prepared in the reservoir of the capillary, covered by electrolyte in the stream of nitrogen. The rate of dropping is regulated by the change of pressure of nitrogen in the pressure system. The presence of nitrogen eliminates the possibility of oxidation of In-amalgam (9). The size of the drop in the electrolyte depends on the diameter of the capillary. It was determined by weighing a number of drops, and from the weight the surface of a drop was set at 2.78×10^{-2} cm².

The electrolyte is in the main compartment of the cell and in the reference electrode compartment. Before the experiments purified nitrogen is forced through the cell (12 hr). Pre-electrolysis with the current of 0.32 ma is undertaken as a last purification step (10 hr). The mass of amalgam on the bottom of the main compartment of the cell serves as a cathode. A platinum electrode in the reference electrode compartment serves as an anode.

Single d-c square-wave pulses of selected intensity pass through the hanging drop as the measuring electrode and the amalgam mass as the counter electrode. Resulting overpotential changes are recorded in relation to the reference electrode (S.C.E.) over the d-c amplifier, on the screen of the

[2] For the preparation of electrolyte and In-amalgam a wire with the guaranteed minimum purity of 99.95% of indium was used (Dr. E. Durrwächter, DODUGO K.G. Pforzheim, West Germany).

cathode-ray oscilloscope as the overpotential-time ($\eta_t - t$) curves. The duration of pulses and the degree of amplification is suited to the intensity of current so that the overpotential can reach a constant value before the concentration polarization sets in. Measurements were made from low current densities to higher ones. For each pulse a new drop of amalgam was used. All the cathodic transients were taken first and then the anodic ones, covering the current density range of 8.1 x 10^{-5} to 2.1 x 10^{-1} amp/cm^2.

The overpotential-time curves on the screen of the cathode-ray oscilloscope were photographed on Ilford-HPS 6 x 9 cm film with a Rolleicord camera.

Results

Overpotential-time relationship.—An example of experimentally obtained $\eta_t - t$ curve for anodic polarization is shown in Fig. 3. The ohmic overpotential η_Ω is represented by the gap at the initial part of the curve, as has already been done by other authors (3, 10). In cathodic curves the part of the ohmic overpotential is very small in relation to the total overpotential η_t, which is not the case in anodic $\eta_t - t$ curves, so it is very difficult to obtain exact and precise values by experimentation. To obtain the values, the sensitivity of the measuring device was increased and only the initial part of the $\eta_t - t$ curve was recorded, regardless of the fact

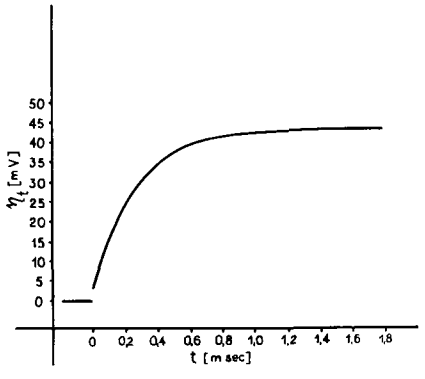

Fig. 3. Curve η_t — t for anodic current density 3.6 x 10^{-3} amp/cm^2.

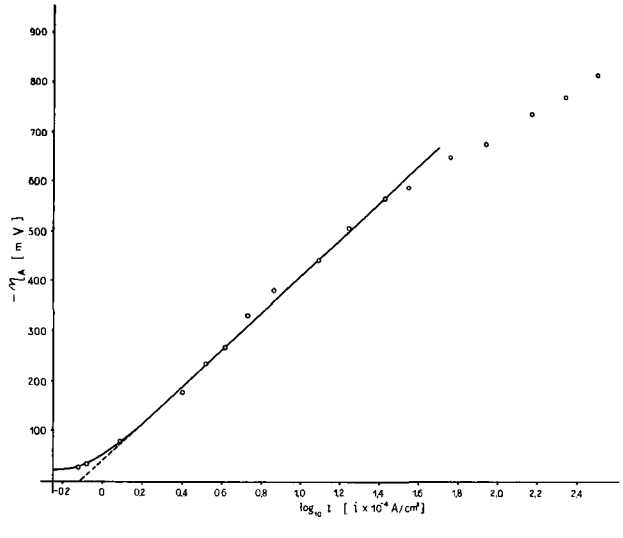

Fig. 4. Tafel line for cathodic polarization, $\alpha = 0.844$

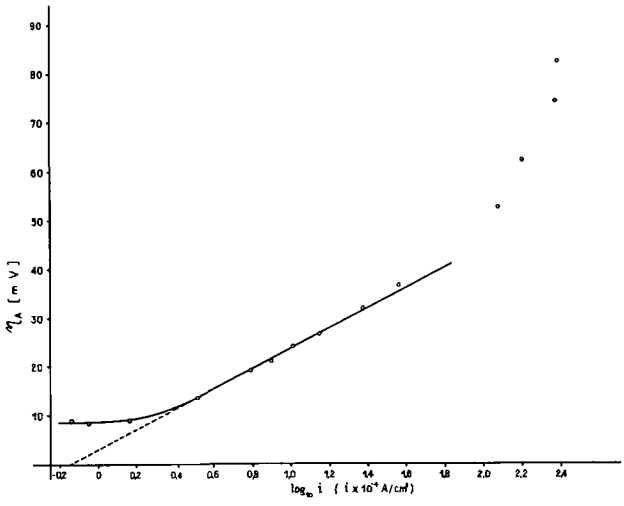

Fig. 5. Tafel line for anodic polarization, $\alpha = 0.800$

that overpotential did not build up to its steady-state value.

The change of potential, minus the ohmic overpotential, until the building up to the steady-state value, represents activation overpotential η_A.

The linear part of the curve $\eta_t - t$ (Fig. 3) corresponds to the charging of double layer, and from the slope of this part of the curve the double-layer capacity can be calculated (11).

$$C = i\left(\frac{dt}{d\eta}\right)_{t \to 0} \qquad [1]$$

The mean value, obtained from the experimental data, is 25.4 μF/cm^2.

Activation overpotential-current density relationship.—When the experimental values of activation overpotential η_A were plotted against the logarithm of c.d. $\log_{10} i$, curves obtained of cathodic and anodic polarization (Fig. 4, 5) show in one region Tafel's linear relation.

Further, experimental Tafel lines were treated with an earlier developed method (6) using expression for the slowest reaction step, *i.e.*, rate-determining step.

$$\frac{\partial \log i_-}{\partial V} = -\frac{\mathbf{F}}{2{,}303\,RT}(n_c^* - \alpha) \qquad [2]$$

$$\frac{\partial \log i_+}{\partial V} = \frac{\mathbf{F}}{2{,}303\,RT}(n_a^* - 1 + \alpha) \qquad [3]$$

i_- and i_+ being parts of the total cathodic and anodic c.d. used in the slowest reaction step, ∂V the change of potential, n_c^* and n_a^* the ordinal numbers of the slowest reaction step for the cathodic and anodic polarization (small integer), α the transfer coefficient ($0 < \alpha < 1$), **F** the Faraday, R the gas constant, and T the absolute temperature.

As mentioned earlier (6) the left sides of the Eq. [2] and [3] represent the slopes of the experimental Tafel lines, so out of the experimental data it was possible to obtain α, n_c^*, and n_a^*.

The calculations indicate that the slowest reaction step for the cathodic polarization is the first, and for the anodic the third; for results see Table I.

Table I. Parameters for the deposition and dissolution of indium in 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, pH 2.5

Mean of experiments 1-5.	2.77	48.6	0.840	0.817

Discussion

Overpotential-time curves.—Ohmic overpotential η_Ω plotted against the current for individual measurements shows, as was expected, a linear relation (Fig. 6). The corresponding resistance R represents the slope of the line and has the mean value of 33.04 ohms. The general expression for the calculation of resistance between the Haber-Luggin capillary and the electrode, given by Mattsson and Bockris (3), is

$$R = \frac{1}{4 \cdot \pi \cdot \kappa} \left(\frac{1}{r} - \frac{1}{x} \right) \qquad [4]$$

where κ is the specific conductance of the solution, r the radius of the electrode, and x the distance between the tip of the Haber-Luggin capillary and the center of the electrode. Using in our case the κ-value (for 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, pH = 2.5) 4.45 x 10^{-2} mhos/cm, the radius of the amalgam drop r = 4.7 x 10^{-2} cm, x = 3 mm, the value of R = 32.1 ohms, in agreement with the experimental values.

The double-layer capacitance is calculated from the slope of the initial linear part of the curve η_i —t. The experimentally obtained value of 25.4 μF/cm^2 is within the limits of expected values for similar systems.

The slope of the curve η_i — t gradually levels off, and after some time, t_A, the potential value becomes almost constant. This value diminished by ohmic overpotential represents the activation overpotential η_A. The state of the "constant" potential, in relation to the duration of the pulse, is defined as $t_A < \tau$, τ^{12} being the transition time (for flat surfaces)

$$\tau^{1/2} = \frac{\pi^{1/2} \cdot n \cdot \mathbf{F} \cdot C \cdot D^{1/2}}{2\, i} \qquad [5]$$

n being the number of electrons involved, **F** the Faraday, C the concentration of In^{3+} in mole/cm^3, D the diffusion coefficient of In^{3+} with the value set at 0.5 x 10^{-5} cm^2/sec, and i the c.d. in amp/cm^2.

Only after a time t_c, t_c being $t_c > \tau$, more marked concentration polarization occurs, which manifests itself in the rise of the potential. Considering the short duration of the current pulse (Fig. 3) there is hardly any concentration polarization, consequently it can be considered that the buildup to the constant values of the potential indeed does represent the activation overpotential.

Activation overpotential-logarithms of current density curves.—When the experimental values of activation overpotential η_A were plotted against the logarithms of c.d. $\log_{10} i$ the curves (Fig. 4, 5) of the cathodic and anodic polarization were obtained. Both curves show in the c.d. range 2.5 x 10^{-4}-2.5 x 10^{-3} amp/cm^2 a marked Tafel linear relation.

Considering Eq. [2] and [3] and the theoretical discussion (6) it is clear that the slope of the Tafel line is directly indicative of the determination of the parameters of the electrode kinetics of electrochemical processes with several reaction steps.

The slope of the linear part of the curve of the cathodic polarization (Fig. 4) is some 20 times more steep than the slope of the anodic curve (Fig. 5), and it can be shown easily that small experimental errors, while having a negligible influence on the slope of cathodic curves, can seriously influence the slope of anodic curves. Besides, the Tafel line of anodic polarization forms itself in a narrow region of the activation overpotential (η_A = 10 — 40 mv) and in the expression

$$i = i_a - |i_c| \qquad [6]$$

the corresponding cathodic part of c.d. i_c must not be neglected. From expression [6] it follows that

$$i_a = i + |i_c| \qquad [7]$$

which means that to get the correct anodic c.d. under these conditions the measured value i ought to be corrected by the corresponding cathodic c.d. i_c. The cathodic c.d. which would correspond to individual measuring points of the anodic polarization can be obtained graphically if the Tafel line of the cathodic polarization is extrapolated to corresponding anodic overpotentials. The execution of this procedure has shown, as is expected, that the correction values i_c for the measuring points of low anodic overpotentials are such that correction is justified, while for the higher values of the anodic overpotential the corrective i_c are so small, that correction is of no essential importance, *i.e.*, that the second element on the right side of Eq. [6] can be ignored. Such corrections of the measuring points of the low overpotentials of the anodic polarization prove the correctness of the extrapolation of the Tafel line, because the corrected measuring points fall just into

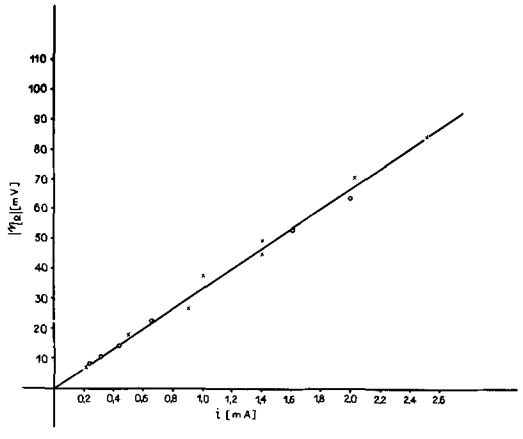

Fig. 6. Curve η_Ω — i. Slope — R = 33.04 ohms
x — cathodic data; o — anodic data

the extrapolated line. This of course enables a more accurate determination of the linear part of the Tafel line, especially if it is formed in the narrow area of low overpotentials.

Considering the fact that in our case the experimental errors influence the anodic curves more, the use of values obtained by extrapolation from the cathodic curves is justified, while the reverse is not the case.

For the electrochemical process of deposition and dissolution of indium in an aqueous solution the following reactions are assumed

$$In^{3+} \xrightarrow{+e^-_o} In^{2+} \xrightarrow{+e^-_o} In^{1+} \xrightarrow{+e^-_o} In^{o} \qquad [8]$$

$$In^{o} \xrightarrow{-e^-_o} In^{1+} \xrightarrow{-e^-_o} In^{2+} \xrightarrow{-e^-_o} In^{3+} \qquad [9]$$

On grounds of expressions [2], [3], [8], and [9] and the experimentally obtained slope of the linear part of Tafel line for the cathodic and anodic polarization, calculations indicate that the slowest reaction step for the cathodic polarization is the first, and for the anodic the third.

Consequently

$$In^{3+} + e^-_o \xrightarrow{\text{slow}} In^{2+} \qquad [10]$$

and

$$In^{2+} - e^-_o \xrightarrow{\text{slow}} In^{3+} \qquad [11]$$

From this it follows that the reaction step

$$In^{3+} \underset{-e^-_o}{\overset{+e^-_o}{\rightleftharpoons}} In^{2+} \qquad [12]$$

is the rate-determining step for the over-all electrochemical process of deposition and dissolution of indium.

Experiments have shown that when c.d. is increased above 2.5 x 10^{-3} amp/cm^2 the measuring points do not follow Tafel line, but show reproducible deviations. There are indications that in this current region there may be some other processes which interfere in the processes described above. The phenomena will be treated in detail in further investigations.

Technical Notes

A Continuous Flow Cell for Electrochemical Synthesis

M. J. Allen

Chemical Research Department, Electro-Optical Systems, Inc., Pasadena, California

One of the more important aspects of organic electrochemistry which has received little attention in the literature, is the design, construction, and performance of electrolytic cells. Two cells have been described which utilize porous carbon electrodes (1) and a third designed for use with a mercury cathode (2). Unfortunately neither of the designs can be used with solid or amalgam type electrodes. Therefore a cell was developed (Fig. 1) which was not only suitable for the type of electrodes mentioned, but also had in common with the previously reported cells the advantages of continuous flow operation for extended periods.

This cell consists of 22 compartments constructed of "annealed" polystyrene, ½ in. thick x 5 in. wide x 6 in. high. A center section is removed leaving a chamber 2 in. wide x 4½ in. high. A ¼ in. hole is drilled on one side so that it is flush with the bottom of the center section, and on the other side so that the hole is 2⅜ in. to center from the top. Approximately ½ in. of the outside portion of each of these holes is bored out (approximately 13/32 in.) so as

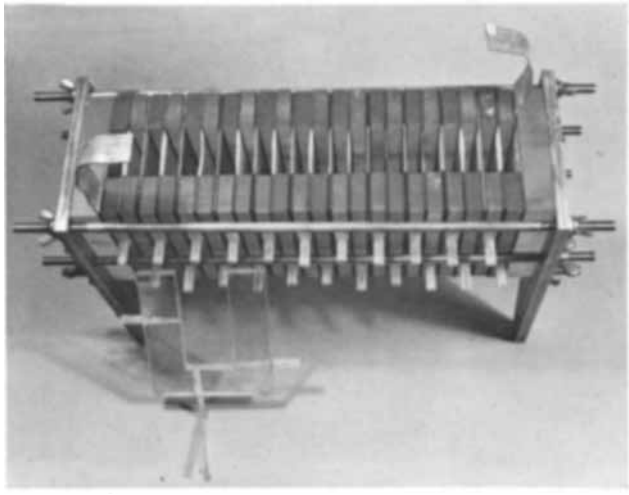

Fig. 1. Cell for continuous flow operation

to loosely accept a 1½ in. length of ¼ in. ID polystyrene tubing. These are cemented in place by dropping methylene chloride with a hypodermic syringe and fine needle in the space between the polystyrene tubing and the plate. The bond is quite solid and leak-free within an hour. A bottom outlet for drainage of each compartment is fabricated in the same manner.

The end plates consist of ½ in. stock steel through which seven holes have been drilled to accommodate 21 in. lengths of ⅜ in. rod, threaded on each end. Next to the inner face of these end plates is placed a 1 in. thick x 5 in. wide x 6 in. high polystyrene sheet, followed by an electrode (approximately 1/16 in. thick) with a connector flap, a neoprene gasket (1/16 in. thick), a polystyrene compartment, an ion-exchange type membrane between 2 neoprene gaskets, another compartment, a floating electrode between 2 neoprene gaskets, another compartment, etc. Each compartment contains approximately 54.5 ml. The active electrode area was 32.26 cm².

In practice the opposing electrolyte, *e.g.*, catholyte and anolyte, are pumped through alternate tygon tube connected compartments, utilizing a Sigmamotor pump. The rate of flow is so adjusted that when the electrolyte containing the depolarizer comes from the last compartment, the reaction is complete. If cooling is found necessary in the process, it is possible to place glass cooling coils within each compartment. It is, of course, obvious that the surface of the first floating electrode facing the cathode, for example, will be positive, its reverse surface negative, and so on to the power connected anode.

Experimental

In order to study the operational characteristics of this cell, the reduction of p-hydroxybenzaldehyde to its corresponding hydrobenzoin was investigated at a tin cathode. For comparison purposes, batch-type experiments were performed under controlled potential, as well as constant current density conditions. In each batch-type experiment the catholyte consisted of 12g (0.098 mole) p-hydroxybenzaldehyde dissolved in 100 ml 2*N* NaOH. The anolyte consisting of 2*N* NaOH was separated from the catholyte by an "Alundum"[1] membrane. The tin electrode area was 93.3 cm². A platinum anode was used in these experiments and the temperature maintained between 24°-26°. The reference potential used in the controlled potential experiments was similar to that previously reported in the literature (3). At a potential of −1.8v *vs.* SCE the initial current density was 0.064 amp/cm². The current plateaued at 0.0048 amp/cm², and during the course of the reaction 1.14 times the theoretical current (10,850 coulombs) was passed, yield 9.8g (81.3%), mp 214°-215° (3), current efficiency 71%. Utilizing constant current density conditions (0.064 amp/cm²) for 1.14 times theory in order to duplicate the 10,850 coulombs passed in the previous typical controlled potential experiment gave a yield of 7.9g (65.6%), current efficiency 57.3%. The lower efficiency of the constant current density experiments was due to the partial use of the current toward the latter part of the experiment for hydrogen production. This was indicated by gas evolution at the cathode during this period. An experiment was performed at the lower current density of 0.0048 amp/cm². After the passage of 10,850 coulombs the catholyte was examined and found not to contain any detectable amount of the desired hydrobenzoin.

The catholyte for a typical continuous flow cell experiment consisted of 244g (2.0 mole) p-hydroxybenzaldehyde dissolved in 2000 ml 2*N* NaOH. The anolyte was a solution of 2*N* NaOH. The 11 cathode compartments were filled with approximately 600 ml of the catholyte from the reservoir; the anode compartments were filled with the 2*N* NaOH. A current density of 0.064 amp/cm² (2.1 amp/electrode) was used. The probe, a saturated calomel electrode placed at the surface of the first and last cathode, initially indicated a reference potential of −1.8v. The catholyte was recirculated through the cathode compartments at the rate of 25 ml/min until the reference potential at the last cathode reached a potential of −2.0v, at which time the reacted catholyte was delivered to a receiver and fresh unreacted catholyte permitted to enter the cell. The rate of flow was then so adjusted that the potential and the last cathode did not go above −2.0v *vs.* SCE. The flow rate for the catholyte was 12.5 ml/min and for the anolyte 5 ml/min. The applied voltage varied from 30-36v. After 162 min a total of 224,000 coulombs (1.16X theory) has been passed. Yield 184.7g (75.7%), mp 214°-215°, current efficiency 65%.

Discussion

From the results obtained a continuous flow cell appears to be more efficient than a batch type cell operating under the same constant current density conditions. This increased efficiency can be attributed to the fact that, in a flow cell operation of the type described, the potential at the electrode surface does not reach destructive heights which might result in undesirable side reactions; the depolarizer is being replenished at the electrode surface at such a rate as to enable maximum use of the electric

[1] Norton Company, Worcester, Mass.

current for the reduction process; we are dealing essentially with a flowing film in which the path the depolarizer must travel to reach the electrode is shorter than in a stirred solution.

Thermal Oxidation of GaAs

Henry T. Minden[1]

General Electric Company, Syracuse, New York

Oxide masking (1) is the key technique in the fabrication of modern silicon semiconductor devices. If a silicon single crystal wafer is exposed to oxygen under controlled conditions an amorphous layer of silica will form (2). This layer is impervious to the diffusion of doping impurities into the wafer. By etching holes in the silica, diffusion can be localized for the purposes of device preparation, and the oxide protects the p-n junctions from attack by ambients.

To determine whether this technology can be carried over to gallium arsenide, a brief study of the thermal oxidation of this material was undertaken. Wafers were placed in a simple tube furnace through which gas flowed in the conventional manner. Best results in terms of the evenness of the oxide were obtained with pure oxygen, and a flow rate of about 1.3 l/min was used in the runs reported here. Temperatures between 600° and 900°C were used. Below 600° the oxidation was negligible, while above 900° the sample tended to burn up. In general, increasing the temperature merely increased the rate of oxidation, while the character of comparable films was the same.

Films of intermediate thickness (1000Å to ~6000Å) showed typical interference colors. Films which were either too thin or too thick to show interference colors were gold or brown. Even thicker films were transparent and glassy in appearance. The thickest films which were formed at 900°C were white, obviously crystalline, and somewhat waxy in texture. In some experiments water vapor was introduced into the oxygen stream. This had no discernable effect at temperatures below about 800°. Above 800° white, hard crystalline spots formed; these spots grew to cover almost the whole surface. This oxide could easily be flaked off the wafer, whereas the thinner layers were quite adherent.

Oxidation on the (110) surface of gallium arsenide was slower and more uniform than on either (111) surface. Fine white pits tended to form under the oxide on the latter surfaces, whereas even, gold films could readily be produced on the (110) surface by oxidation at 700° for ½ hr. Thicker films tended to have extensively pitted and irregular surfaces under the oxide layer. The extent of oxidation on polycrystalline surfaces varied markedly from grain to grain. No difference was noted between the oxidation of n and p material.

Electron diffraction pictures consisted of sharp rings which had spots characteristic of partial orientation of the crystallites in the film. Indexing of the rings showed unequivocably that the film consisted of β Ga_2O_3, the commonest form of gallium oxide. This was the only phase found in all the films investigated, regardless of the thickness of the film and the temperature of oxidation. In none of the samples investigated were there any electron diffraction rings which could be attributed to an arsenic containing phase. The white oxide formed in the presence of water vapor was flaked off and examined by powder x-ray diffraction. This too revealed the presence of only β Ga_2O_3.

Several samples of n GaAs were oxidized on the (110) face at 700° for ½ hr to form an attractive, uniform gold film. Part of the surface was covered with black wax, and the oxide on the exposed surface was dissolved in warm concentrated hydrochloric acid. The wax was removed, and the sample was sealed in an evacuated tube with a trace of zinc metal. The zinc was diffused into the wafer at 800° for ½ hr. After diffusion the remaining oxide was removed with warm hydrochloric acid and the surface probed with a hot point. The surface was p at both the masked and unmasked areas. The penetration of the zinc through the oxide could not be correlated with any macroscopic imperfection in the film. It is presumed that the microcrystalline nature of the oxide film allowed extensive grain boundary diffusion to the surface of the gallium arsenide. Finally an oxidized and an unoxidized wafer were simultaneously heated to 950° in an argon atmosphere overnight; both samples were reduced to a droplet of gallium. It is felt that the oxide does not prevent the outdiffusion of arsenic from gallium arsenide.

From these discouraging but fairly clear results, it does not appear that thermal oxide masking is readily applicable to gallium arsenide.

Solid Solubilities of Antimony, Arsenic, and Bismuth in Germanium from a Saturation Diffusion Experiment

F. A. Trumbore, W. G. Spitzer, R. A. Logan, and C. L. Luke

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

In the course of growing arsenic-doped germanium crystals for Esaki diodes, it was noted (1) that anomalously low carrier concentrations were obtained in crystals grown from the more heavily doped melts. Minden (2) and Cardona and Sommers (3) also have reported that only a fraction of the arsenic present in heavily doped material is electrically active. Furthermore, it has been shown (4) that appropriate heat treatment and quenching procedures can lead to significant increases in carrier concentrations, thus indicating a precipitation effect. Even after quenching, however, there remained a discrepancy of about a factor of two between the carrier concentrations and the arsenic concentrations expected from available solidus curve data (5). As pointed out previously (5), the evaporation technique used to determine this solidus curve was quite conducive to the formation of occlusions containing arsenic and hence could lead to high results.

In order to obtain an unambiguous check on the solidus curve a long term saturation diffusion experiment has been carried out at a temperature where a solid solubility of arsenic in germanium in excess of 1×10^{20} atoms/cc would be expected from the solidus curve. By using a diffusion technique the presence of germanium arsenide occlusions, formed in grown crystals by trapping of the melt during growth, should be eliminated. In addition to arsenic, antimony and bismuth were also diffused into germanium in the same experiment. The purpose of the present paper is to present the results of chemical, optical, and electrical measurements on the resulting samples.

Experimental

Available diffusion coefficient data (6) indicated that at a temperature of about 865°C one might obtain essentially complete saturation of germanium samples of a reasonable thickness in a reasonable length of time. Accordingly, the samples were diffused for 97 days at a temperature of 865° ± 5°C.

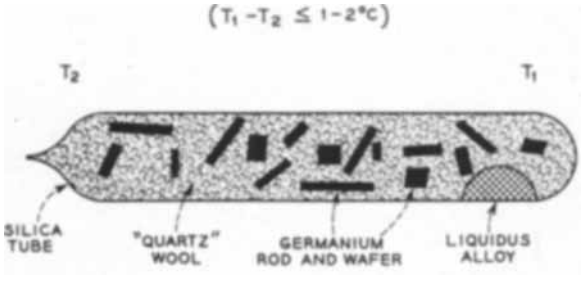

Fig. 1. Schematic diagram of the experimental arrangement during the diffusion run.

Square wafers and rods of single crystal undoped germanium were sealed, together with high-purity (> 99.9999%) arsenic, antimony, or bismuth, in evacuated ($\sim 10^{-6}$ mm Hg) vitreous silica tubes. The wafers [150 x 150 x (10-25) mils] and rods [500 x (15-25) x (15-25) mils] were of various thicknesses to permit a check for saturation at the end of the experiment. As shown in Fig. 1 "quartz" wool (99.9% pure) was used to separate the various samples to permit free access of the impurity vapor. To prevent random melting of the germanium samples the tubes were placed in a slight thermal gradient (only $\lesssim$ 1-2° over the length of the sample tube). The amounts of the group V impurity elements contained in the tubes were sufficient to form and maintain a liquidus alloy with some of the germanium in the hotter ends of the tubes during the course of the experiment. Since the partial pressure of arsenic (and, in this temperature range, probably that of antimony) over the liquidus alloys decreases with increasing temperature (4) no melting of the germanium should occur in the cooler portions of the tube. In the case of bismuth where the predominant vapor species is the monomer, instead of the tetramer or dimer, as in the case of the other two impurities, it is doubtful whether the bismuth partial pressure behaves in the same way. In fact, there was evidence of random melting in the tubes containing bismuth.

One striking feature of this experiment was the presence of a considerable amount of transport of germanium through the vapor phase, especially in the tube containing arsenic. This is illustrated in Fig. 2 which shows two examples of deposition of germanium on the germanium wafers. The presence of this vapor transport caused some difficulty since the rods became tapered and were unsuitable for Hall effect or resistivity measurements. The mechanism responsible for this transport is not known. One interpretation of the present results is that transport in the slight thermal gradient via a volatile Ge-As species was a factor since the amount of transported material was so much greater in the tubes containing arsenic. However, the presence of oxygen and transport via GeO(g) is a distinct possibility and perhaps either or both mechanisms were operative. Holonyak, Jillson, and Bevacqua (7) have observed a similar transport of silicon with group V impurities and do not believe that oxygen is responsible.

The arsenic- and antimony-doped germanium samples were analyzed chemically for the impurity concentration by using spectrophotometric methods. (The concentration of bismuth was too low for

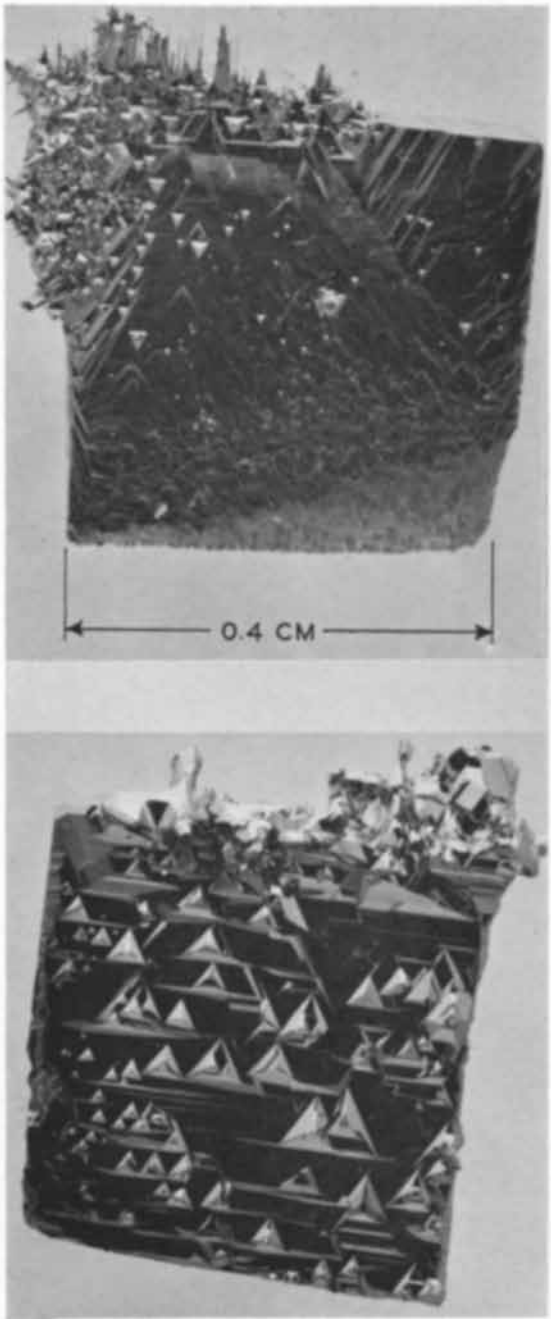

Fig. 2. Two examples of vapor transported germanium deposited on the Ge wafers. The major faces of the wafers are {111} surfaces.

analysis by these techniques.) In both cases the germanium was removed by distillation as the chloride. The antimony and arsenic contents were then determined by the iodoantimonite and heteropoly molybdenum blue methods (8, 9), respectively. In order to insure that only diffused material was analyzed, the wafers were lapped to eliminate any trace of vapor deposited germanium (Fig. 2). The samples were then etched to remove any contaminants introduced in the lapping process and analyzed. In the case of arsenic one of thickest and one of the thinnest wafers were analyzed to determine whether sufficient time had elapsed for saturation of the germanium by arsenic.

Optical reflectivity measurements were made on the arsenic- and antimony-doped samples by using the same techniques described previously (4). The carrier concentrations were determined from the known variation of the reflectivity minimum with carrier concentration in heavily doped materials (4). (The optical method is not applicable to the bismuth-doped samples because of the low concentration of bismuth.) To test for saturation in the antimony-doped samples one wafer was measured near the surface and then lapped down for a measurement near the middle of the sample. One arsenic sample was heated to 850° ± 5°C for 30 min and quenched in a jet of nitrogen as described previously (4), following which the reflectivity was measured.

By using van der Pauw's method (10) room temperature Hall effect and resistivity measurements were made on disks cut from the wafers. The carrier concentration, n, was calculated from the Hall coefficient assuming a Hall to drift mobility ratio of unity. As a check on the resistivity measurements, two-point probe measurements were made on some rods cut from the wafers. The results agreed to within 3% or better with the data obtained by the disk method.

Results and Discussion

The most important results of the various measurements are summarized in Table I which gives n and C_I^s, the concentration of the impurity. A more detailed discussion of the individual systems is given below.

Antimony.—Saturation of the germanium by the antimony was achieved as evidenced by the fact that within experimental error the positions of the reflectivity minima at the surface (14.2-14.5μ) and near the middle (14.3-15.1μ) of a 23 mil thick wafer were identical. (The attenuation distance for the optical measurement is $\lesssim$ 1 mil for these samples.) The chemical analyses, performed on two sets of four wafers each, yielded identical results of 0.036 w/o antimony, believed to be accurate to better than ±5% of the antimony content. The agreement among the impurity and carrier concentrations summarized in Table I is well within experimental error. The most likely value of the equilibrium solid solubility is believed to be (1.00 ± 0.05) x 10^{19} atoms/cc.

The available solid solubility data (4, 5, 11-13) are presented in Fig. 3 in the form of a log k *vs.* $1/T$ plot, where k is the distribution coefficient, based on the liquidus data of Thurmond and Kowalchik (14). Included in this plot is a point obtained from resistivity measurements on a polycrystalline sample grown at ~ 708°C by the sealed tube ther-

Table I. Summary of chemical, optical, and electrical data

Impurity	n (cm^{-3}) (reflectivity)	n (cm^{-3}) (Hall effect)	C_I^s (atoms/cc) (chemical)
Antimony	$1.08 \pm 0.07 \times 10^{19}$	1.02×10^{19}	9.5×10^{18}
Bismuth	—	3.5×10^{16}	—
Arsenic	5.0×10^{19}	4.8×10^{19}	7.3×10^{19}
Arsenic*	7.5×10^{19}*	7.4×10^{19}*	—

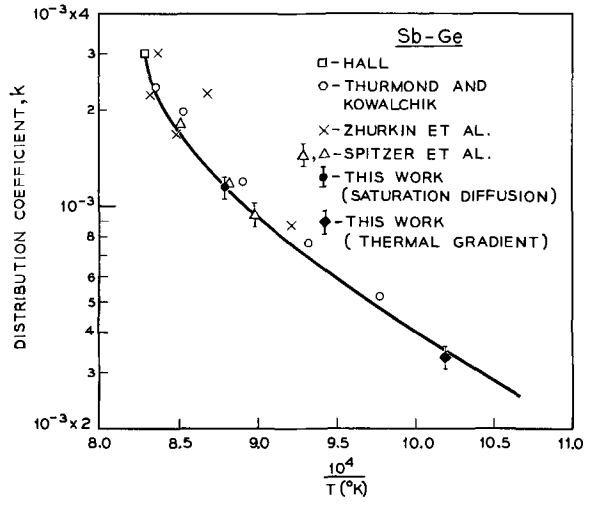

Fig. 3. Plot of log k as a function of $1/T$ for antimony in germanium.

mal gradient technique described previously (15).[1] With the exception of a few of the points due to Zhurkin *et al.* (13), there is good agreement among the various sets of data which were obtained by crystal pulling (12, 13) radiotracer diffusion profile (11), solvent evaporation and cooling (4), thermal gradient, and saturation diffusion methods. Since the saturation diffusion technique should yield an unambiguous equilibrium solid solubility and since the agreement with an adjacent solvent evaporation-cooling data point is very good, the curve has been revised from that given in ref. (4) to favor the lower values of k obtained from these experiments and from the thermal gradient experiment.[2] This results in a relatively slight modification of the previous solidus curve (5). The revised solidus curve, shown in Fig. 4, is based on the log k *vs.* $1/T$ plot in Fig. 3 and on the liquidus curve (14).

Arsenic.—Chemical analyses on two wafers of different thicknesses (10-15 and 20-25 mils) gave identical values of the amount of arsenic (0.17 w/o) indicating saturation had been achieved. (The chemical analysis is believed to be accurate to better than ±10% of the arsenic content.) This fact and the excellent agreement between the value of n in the quenched sample and the arsenic concentration indicate that a reliable value of the equilibrium solid solubility has been obtained.[3] The saturation diffusion value obtained here is about a factor of two lower than expected from the solidus curve reported previously. Hence, the latter is in error, probably due to failure to eliminate arsenide occlusions.[4] A revised solidus curve is plotted in Fig. 4 based on available liquidus data (14) and on the log k *vs.* $1/T$ plot shown in Fig. 5 which includes the crystal pulling data of Jillson and Scheckler (18) and the radiotracer diffusion profile data of Thurmond and Kowalchik (19).[5]

These experiments also indicate that the presence of micro-occlusions of germanium arsenide is not necessary for nucleation of the precipitation of arsenic as postulated earlier (4). The probability is that dislocations serve as nucleation sites. In the present samples the dislocation density of the original wafers was the order of 10^3-10^4 cm^{-2}. However, even if one should start with dislocation free germanium, Prussin (20) has shown that dislocations may be introduced in the process of diffusion.

Bismuth.—Since no chemical analyses were made, the identification of n in Table I with the bismuth

[1] This sample contained small amounts of occluded antimony which could not be separated chemically from the antimony-doped germanium so that no reliable chemical analyses could be run. However, two rods were cut from sections which appeared to contain no significant number of occlusions. The resistivities of these two rods were 1.25 × 10^{-3} and 1.42 × 10^{-3} ohm-cm corresponding to a carrier concentration of (8.8 ± 0.5) × 10^{18} cm^{-3}.

[2] The agreement between the saturation diffusion point and the adjacent solvent evaporation-cooling point of Spitzer *et al.* in Fig. 3 indicates that equilibrium data were also obtained from the latter experiments and also supports the earlier conclusion that no significant "facet" effect (16, 17) was present in the crystal growth work (4).

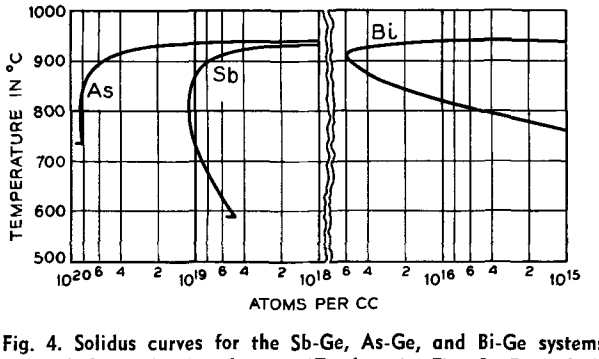

Fig. 4. Solidus curves for the Sb-Ge, As-Ge, and Bi-Ge systems calculated from the log k *vs.* $1/T$ plots in Fig. 3, 5, and 6, respectively.

[3] The fact that the Hall effect and resistivity measurements on the arsenic- and antimony-doped samples are consistent with our earlier resistivity *vs.* n curves (4) demonstrates conclusively that the difference in mobility between antimony- and arsenic-doped material is an inherent property and is not due to the presence of occluded material such as germanium arsenide.

[4] One further observation remains to be explained, namely, the apparent attainment of a very small amount of 0.0003-0.0004 ohm-cm material in a thermal gradient crystal (4). From the present work it would seem that this was just a spurious result. However, it is possible that this small region grew on a {111} facet and by the facet effect trapped in a nonequilibrium amount of arsenic. A facet effect of about a factor of two has been reported for arsenic in germanium (17).

[5] The curvature in the log k *vs.* $1/T$ plot derives from the results of the quenching experiments on As-doped samples prepared by thermal gradient crystallization reported earlier (4). The present quenching experiments indicate that the total arsenic in solid solution can be quenched in the electrically active state. Therefore, it was assumed that the maximum figure for the quenched-in carriers, 8.1 × 10^{19} cm^{-3}, represented the arsenic concentration corresponding to a melt composition between 25 and 40 mole % arsenic [see Table I, ref. (4)]. The points joined by the dashed tie line in Fig. 5 represent the values of k and $1/T$ corresponding to the melt compositions of 25 and 40 mole % arsenic, the true value lying somewhere along the tie line. If the 8.1 × 10^{19} cm^{-3} figure was not the total arsenic concentration, then a minimum value should lie somewhere on the tie line.

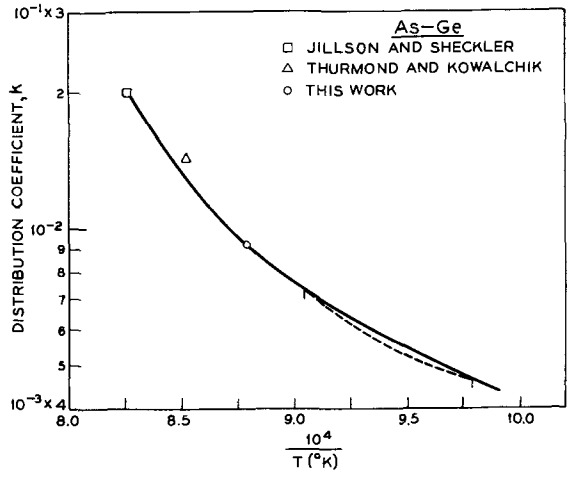

Fig. 5. Plot of log k *vs.* $1/T$ for arsenic in germanium. The dashed curve is a tie line on which one point is located (see footnote 5).

concentration is obviously not as certain as in the arsenic and antimony experiments due to the possibility of impurity contamination. However, the likelihood of significant contamination is slight in view of (*a*) the relatively low concentrations of the more soluble impurities in the silica and bismuth, (*b*) the low diffusion coefficient of these impurities (*e.g.*, Al and B) and (*c*) perhaps most important, the "gettering" action of the liquid Bi-Ge phase. Thus, we believe the value of n may be taken as equal to the bismuth concentration. Except for a value of the distribution coefficient at the melting point of germanium, no other solid solubility data have been reported for bismuth.

Utilizing these two data points, an approximate estimate of the temperature dependence of the distribution coefficient, k, may be obtained as shown in Fig. 6. This estimate is based on considerations of the departures from ideality in the liquid and solid phases as discussed previously for the Al-Ge and Ga-Ge systems (15). Specifically, the distribution coefficient is given by $k = \gamma^L/\gamma_n{}^S F_n$ where γ^L is the activity coefficient of the impurity in the liquidus alloy, $\gamma_n{}^S$ is the activity coefficient of the neutral impurity species in the solid (both referred to the same standard state), and F_n is the fraction of the impurity atoms which remain neutral in the solidus alloy. It is reasonable to assume that log $\gamma_n{}^S$ is a linear function of $1/T$. Thus, by plotting log k'' *vs.* $1/T$, where $k'' \equiv kF_n/\gamma^L = 1/\gamma_n{}^S$, for the two available data points and extrapolating one can obtain k'' and hence k at a lower temperature if one knows F_n and γ^L. The values of F_n were obtained from the treatment of Blakemore (21) while γ^L was approximated from the data of Thurmond and Kowalchik (14). In the temperature range covered only a small departure from linearity is predicted as shown in Fig. 6. An estimate of the solidus curve based on this approximation is plotted in Fig. 4. It should be stressed that there are several possible sources of error in this approximation which is carried out here in lieu of other experimental data.

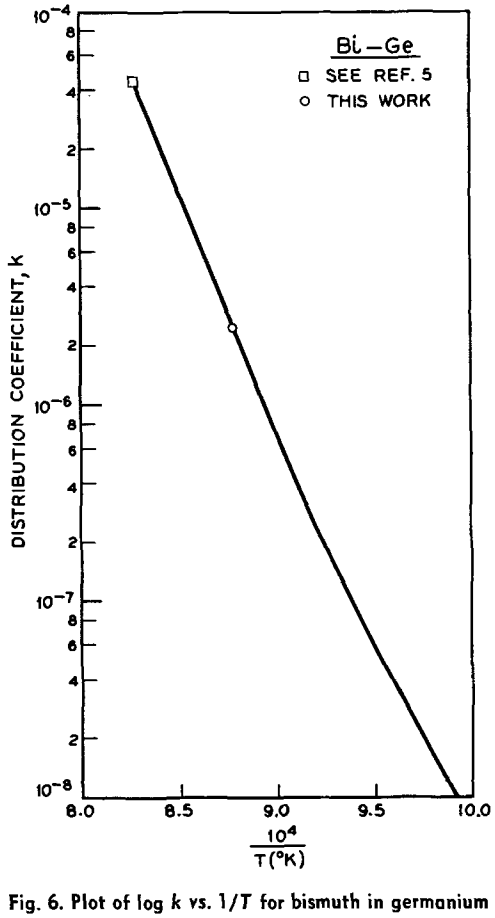

Fig. 6. Plot of log k vs. $1/T$ for bismuth in germanium

Summary

The present work has yielded unambiguous determinations of the equilibrium solid solubilities of arsenic and antimony at one temperature. It is believed that these data represent the most definitive equilibrium solid solubility measurements to date for any impurity in germanium or silicon except perhaps for fast diffusers such as copper, lithium, etc., where saturation is readily achieved. While the antimony result agrees well with previous measurements, the arsenic value indicates the previous solidus data are in error by about a factor of two. An estimate of the Bi-Ge solidus curve has been made based on a solid solubility measurement which was not quite as conclusive as the arsenic and antimony results.

Acknowledgments

The authors are indebted to J. F. Gilbert for the Hall effect measurements and for performing the quenching experiment, to L. Howarth for some of the reflectivity measurements, to M. Kowalchik for assistance in carrying out the diffusion experiment, to Miss A. Mills for some of the resistivity measurements, and to A. A. Tartaglia for the photographs.

A Simple Technique for Seeding and Growing Oriented, Relatively Unstrained, Single Crystal Antimony, Square-Sectioned Rods

Seymour Epstein[1]

U. S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

Systematically preparing oriented, square-sectioned, long, single crystal rods of antimony and its dilute alloys with tin, having uniform and reproducible electrical properties and dimensions, presents many difficulties. For example, mechanical cutting, in addition to cold working the crystal, usually introduces fissures; these frequently cause large changes in the resistivity or break the specimen, according as the principal plane is parallel or not parallel to the rod's longest dimension. Acid cutting, on the other hand, is characterized by nonuniform rod faces. These difficulties can be avoided by growing oriented crystals in the desired shape, a technique first used by Kapitza (1) for bismuth and soon after by others (2) for bismuth and higher melting point materials. In principle, any one of these modified apparatuses are directly applicable to antimony, and Rausch (3), using Hasler's modification, has grown circular-sectioned antimony rods in the two principal orientations. However, our experience with these modifications and the conditions implied or specified (slow rates) is that we were able to seed and grow only rods in which the c-plane is parallel to the rod axis. The same result was obtained with our own modified apparatus only until both a fast rate of crystallization, not less than 2 cm/min, and a crucible material of low thermal conductivity relative to antimony were used. Under these conditions seeding and growing single crystal antimony rods, whose axes are at either 0°, 45°, and 90° with the <111> direction, becomes almost a routine operation. The rods are 6 cm or more long and have nearly square, 3 mm × 3 mm, cross sections.

Our modified apparatus also allows for easy control of the binary axis orientation, and the growth of rods seeded in arbitrary orientations appears possible. The fast rate of growth also minimizes the segregation of added impurities and does not appear to strain the rods.

In these experiments the undoped antimony is nominally 99.997% pure and is used as supplied by the Bradley Mining Company, San Francisco, California.

[1] Most of this material is included in a Dissertation on the "Galvanomagnetic Effects and Band Structure of Pure and Tin-Doped Antimony Single Crystals," submitted in partial fulfillment of the requirements for the Doctor of Philosophy (in Physics) degree at the Polytechnic Institute of Brooklyn (1961), to be submitted for publication.

Description of Apparatus and Procedure

The technique combines many of the desirable features of the earlier ones (1, 2). It consists of seeding and recrystallizing precast rods in a partly enclosed crucible mold. The motion of the temperature gradient through the rod is obtained by cutting off the heater power; both furnace and crucible are stationary. The latter can be taken apart, permitting strain free removal of the recrystallized rod. The furnace, crucible mold, seed orienting jigs and procedure, and seeding and growing procedure are next described.

Furnace.—By not insulating the furnace from its ambient room temperature, rapid heat dissipation and cooling rates are made possible. Simple in design and construction, it consists of two concentric, clear Vycor tubes, 1 and 3 in. in diameter, with a continuous nichrome heater element uniformly wound on the outside of the inner tube. The spacing between adjacent turns is about ⅜ in. so that the furnace charge can be seen. Two temperature zones, one 40° above the other, are used; a slight gradient exists within each. The two zones and their gradients are obtained by stretching the heater element, initially, a close wire-wound helix. For a wire diameter of 0.062 in. and a total zone length of 5 in. the heater resistance is 12 ohms; about 600 watts are sufficient to melt antimony. The gradient, the furnace and rod axes, and the growth direction are parallel.

Crucible mold.—Square cross sections are obtained in the manner prescribed by Hasler (2). Square precast rods are recrystallized in a crucible chamber of the same shape and dimensions as the rod. This technique also serves to minimize straining of the single crystal rod due to antimony's expansion upon solidification. Straining while removing the rod from the mold is avoided by designing the mold so that it can be taken apart.

The basic crucible, Fig. 1, is made up of two thin slats for side walls, a thin bottom slat, a top cover (not shown), and two channeled holding blocks. It is taken apart by axially sliding the hold-

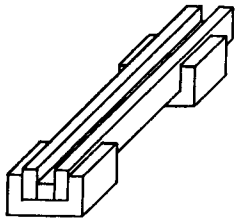

Fig. 1. Basic crystal growing crucible. The crucible is held together by the two channelled blocks. After the rod is recrystallized it is separated from the crucible by taking the latter apart.

ing blocks away from the slats, which, if they do not adhere to the rod, simply fall away. The slats are 1/16 in. thick; their remaining dimensions are determined by the size of the rod. The top cover is about ¼ in. thick for added weight.

Many crucible materials exist which neither adhere to nor react with antimony at temperatures below 700°C in the argon atmosphere used. In addition, a suitable material must have a low heat conductivity relative to the substance being crystallized (4). One such material is the mineral pyrophyllite.[2] Its advantage over most other materials is that it can be easily machined before it is fired, and it was chosen because of this additional property. (With carbon crucibles, we were able to obtain only the 90°-oriented rods, where the growth direction is the preferred one, and at lower yield.)

Seed orienting jigs and procedure.—Three orienting jigs, schematically shown in Fig. 2, have been conveniently used, although with truly perpendicular rod faces only one is required. A holding block is part of each jig and positions it accurately in relation to the rod chamber. The remaining parts of the jigs are, of course, used to orient the principal and binary crystallographic axes. The jig of Fig. 2(a) provides a flat horizontal surface which is parallel to and at the same level as the bottom of the crucible chamber; that of Fig. 2(b) provides an inclined plane at 45°; the third jig, Fig. 2(c), aligns a screw, on which a 90°-vee is grooved, along the crucible axis.

The initial seed is a single crystal chip cleaved in the principal plane. The binary directions are known from the directions of three lines in the principal plane which make acute angles of 60° with one another. To seed a 90°-oriented rod, the cleaved plane is placed in contact with the flat of jig 2(a) and the binary axis direction at the desired angle with the crucible axis. Because the resulting 90° rod's vertical faces may not be precisely at right angles to the bottom surface, jig 2(b) is used for generating seeds in the 45°- and 0°-orientations. The bottom surfaces of the 90° rod and, in turn, of the 45° rod it seeds, are placed on the incline. Alignment of the seed rod and crucible axes is assured if a part of each seed rod is inserted into the mold chamber. To change the binary axis orientation of the 0°-oriented rods, jig 2(c) is used. The seed is placed in the groove and the screw turned through an appropriate angle.

Once a set of accurately oriented square-sectioned seed rods is obtained, each orientation is reproduced by innoculating other rods. No special jig is required. Each seed rod is simply placed in the crucible chamber with its bottom face referenced against the bottom of the mold.

Seeding and growing procedure.—Successful seeding is not difficult. It is neither necessary to fuse the seed to the precast rod with a reducing flame prior to melting in the crucible nor to use freshly cleaved or etched surfaces, as some of the earlier researchers found necessary for bismuth (2). Satisfactory contact is obtained simply by pushing one against the other. The rod and seed are joined by melting the former back to the latter at the time the single crystal is to be grown. As a general rule, a minimum of the seed is melted; usually 3 mm or less is satisfactory. However, the amount appears not to be critical because seeding was successful when lengths up to 15 mm were inadvertently used. For a given heater power the position of the seed junction in the furnace determines the amount of the seed melted. This position also appears to be a factor which influences the frequency of successful seeding. The optimum location is the region of the steep gradient between the zones.

In order not to stress the junction and to watch the wetting process, about 2 mm of the precast rod and the seed are not covered. Because of this, surface tension may act to form a blob at the junction. If the blob extends too far above the crucible walls, the seed orientation frequently does not survive.

The procedure for melting and resolidifying the precast rod is simple, once the optimum position and the corresponding heater power are determined. With the seed junction properly placed the system is flushed with argon; a positive pressure is maintained and the heater circuit is closed. Melting begins in nearly 10 min and is completed in about 2 min. A few seconds after the seed is wetted, the heater circuit is opened. Although the growth rate could not be determined accurately, it is not less than the 2 cm/min rate mentioned nor greater than 10 cm/min; more than likely, it is about 6 cm/min. The resulting rods are either thermally etched or etched in dilute aqua regia to bring out any gross grain structure.

[2] Spectroscopic analysis of the recrystallized rods does not show contamination.

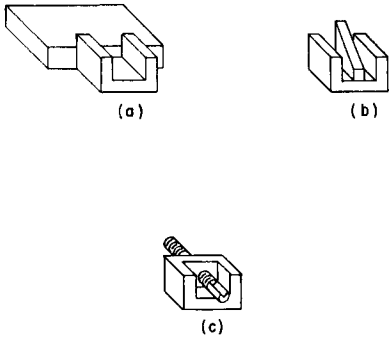

Fig. 2. Schematic representation of orienting jigs. Jig (a) can be used to obtain arbitrary orientations, jig (b) to obtain the 45° and 0° orientations, or multiples of the inclination angle, from 90°-oriented rods; jig (c) to adjust secondary axis orientation of 0° rods. Each jig is attached and referenced to the crucible by the channelled holding block which is an integral part of each jig.

Evaluation of Crystals

A measure of the quality of the rods is obtained by describing some of their physical properties and, where possible and meaningful, by comparing these with those of both slow-grown cast single crystal antimony rods and other single crystal specimens cut from large slow-grown ingots. The properties examined are their room temperature mechanical behavior, their ability to recrystallize in the solid, their room temperature galvanomagnetic coefficients, the segregation of added impurity due to normal freezing, their fine structure, the variation of one of the two principal resistivity coefficients with temperature, and the liquid helium-room temperature resistivity ratio. Our characterization is for the most part qualitative.

Allowing for anisotropy in mechanical behavior, the unworked undoped antimony rods are invariably more plastic than correspondingly oriented machined specimens. Unworked rods of the 45° and 90° orientation can be bent and twisted easily; the 0° rods are brittle. For orientations where it is not parallel to the rod axis, the c-plane is the one along which the rods break when dropped or otherwise stressed. Where the principal plane is very close to being parallel, the rods almost invariably break along secondary cleavage planes whose traces on the c-plane are the lines giving the binary axes directions. The cleavages and breaks are sharp and well-defined as shown in Fig. 3. Alloy rods are in general less plastic than their undoped antimony counterparts and appear to become brittle as tin is added.

Before breaking, not all rods of a given orientation deform to the same extent. This nonuniformity may be due to the fact that the one rate of growth used, or some unspecified factor(s), unknowingly and uncontrollably varied slightly. An exceptionally plastic rod, which we have not been able to reproduce, has been bent through nearly 95° and twisted. The rod is a single crystal in the region of deformation whose <111> axis is neither parallel to the lateral faces nor makes an angle of 0°, 45°, or 90° with the rod axis. Another interesting difference between our cast and cut single crystal rods is that many of the latter recrystallize in the solid at temperatures just below the melting point and none of the former do.

The nonuniformity also extends to the room temperature electrical properties in the form of spurious fluctuations about an average value for a given alloy. An example of this is the spread in ρ_{11}, the resistivity in the c-planes, and ρ_{33}, the resistivity across the c-planes. Values for these are, respectively, 43-46 x 10^{-6} ohm-cm and 32-36 x 10^{-6} ohm-cm for pure antimony and 38-39 x 10^{-6} ohm-cm and 42-45 x 10^{-6} ohm-cm for nominally 0.8% tin-doped specimens. These numbers show the percentage fluctuation to be orientation dependent, and, indeed, the spread in resistivity for 45° oriented rods of a given alloy is almost midway between the spreads for the 0° and 90° rods. On this basis it can be concluded that the nonuniform qualities of the rods are caused by minor flaws and inhomogeneities associated with the principal planes, probably the same ones which determine the planes of highest stress, or the weakest ones, at which a rod will break. The numbers, together with the spread in resistivities for our 0.2% alloys, also show the fluctuations to decrease on the addition of tin in amounts up to 0.8%.

Compared to independently obtained published values measured on specimens cut from Bridgman grown ingots of the same nominal and probably lower purity stock (5), our average values for ρ_{11} and ρ_{33} at room temperature agree to within 3% but our Hall coefficients and most of the magnetoresistance coefficients are lower by 10% and 20%, respectively. This agreement for the ρ's and the disagreement for the Hall and magnetoresistance coefficients, the latter larger than the former, cannot be accounted for by differences in purity and are compatible with different states of strain in the unworked and cut rods. A positive assignment is not possible from our data. Theory, however, does point to strain dependent coefficients (6).

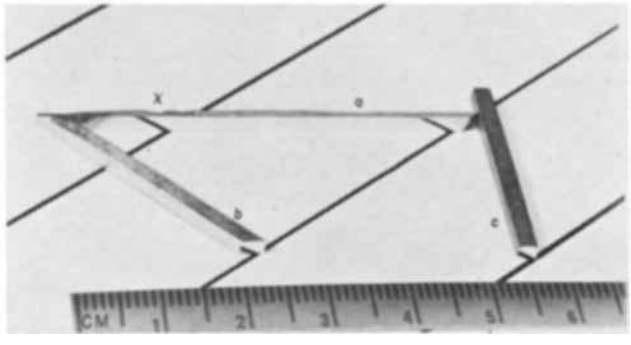

Fig. 3. Oriented single crystal antimony rods cleaved in the principal plane. The cleaved surfaces are unpolished and mirror the black stripes. Rod a has been grown in the 0° orientation; rods b and c in the 45° and 90° orientations, respectively. The region marked x is the seeding junction. The 45° and 90° specimens are cleaved by placing the tip of a thin blade on the edge of the rod and, with the blade parallel to the cleavage plane, pressing the blade into the rod; rod a is split by inserting the blade into a small crack obtained in the way just described and then sliding the blade, which is parallel to the cleavage plane, along the rod. A secondary cleavage plane on which fracture takes place bounds the right end of rod a.

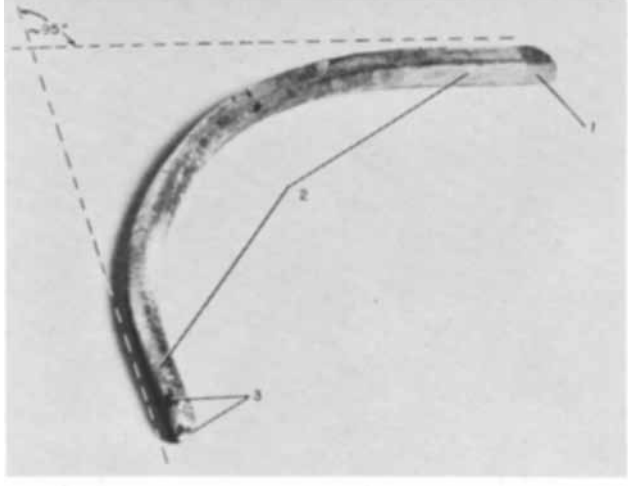

Fig. 4. An exceptionally plastic antimony rod. In response to a slight torque, the rod has simultaneously bent and twisted in the large single crystal region shown by the number 2. The traces of slip planes can be seen at the bend. Differently oriented grains at the ends of the rod, marked by 1 and 3, are clearly visible.

The segregation of tin due to normal freezing in the rods was checked by measuring ρ_{11} or ρ_{33} and spectroscopic sampling along the rod. On some long specimens where the resistivities did vary with length, the end-to-end change is less than 1% and orientation independent. Spectroscopic sampling shows some local fluctuations in doping, but these can be minimized by using zone-levelled starting stock.

As to fine structure, the dislocation density on a (111) plane appears to be about the $10^4/cm^2$ value recently reported by Wernick and co-workers for zone-refined, 99.999% pure, slowly grown, antimony crystals (7). We also find, in agreement with their observations, low-angle grain boundaries on some principal plane surfaces. Because our etching techniques are rather crude and not reproducible, our agreement and disagreement may not be significant.

Consistent with low-angle grain boundaries but not necessarily directly related to them are slightly split back reflection Laue spots. The amount of splitting is less than that obtained from specimens grown by Bridgman and horizontal techniques at slow rates and slightly more than that obtained from one carefully selected slow-grown Czochralski specimen. The slight degree of misorientation does not prevent the rods, as we have stated before, from being sharply cleaved at room temperature, nor does it distort the image mirrored in the principal cleavage plane, Fig. 3.

A complete evaluation should include extensive data on their electronic properties at low temperatures. In this connection our remarks are limited to the general features of the temperature variation of resistivity between room temperature and 77°K and to a brief discussion of known values for $\rho_{11}(4.2°K)/\rho_{11}(\sim 295°K)$. Our undoped and 0.2% tin-doped crystals respectively reproduce Lane and Dodd's (8) curves for cast, 3 mm diameter (9), undoped and 0.25% tin-doped, slow-grown, single crystal rods, and our 0.8% alloy data fall on their 0.5% alloy curve. Also in good agreement with the cast undoped antimony curve are a few of our undoped specimens cut from large slow-grown ingots. The remainder, however, have the same temperature coefficient of resistivity but prescribe curves which are shifted upward by constant arbitrary amounts. Although a detailed definitive explanation of these observations is not warranted because the possible variables involved were not systematically controlled, it would appear that the amount of defects in the cast slow- and fast-grown rods, and in selected specimens cut from large slow-grown ingots, is about the same. We would also expect to reproduce Browne and Lane's (9) value of 0.0012 for $\rho_{11}(4.2°K)/\rho_{11}(297°K)$ even though their nominal purity is 99.94%, for Steele (5), on cut specimens of about 0.5 mm x 2 mm, obtained a value of 0.014 on what appears to be the same antimony stock as ours but zone-refined to 99.999%. With higher purity materials a value of 0.0017 (10) has been reported for roughly 2 mm thick specimens (11). Using ultrapure antimony, less than 1 part in 10^7, Datars (11), who, incidentally, gives 0.0017 as the upper limit for cyclotron resonance in antimony, reports a value of 0.0005. This marked dependence of the 4.2°K resistivity on low-level impurity content plus our tentative conviction about the internal condition of our cast rods suggest that the technique described can yield low resistivity ratio crystals.

Conclusion

From the observed properties, the unworked single crystal antimony rods grown at a fast rate appear to be relatively unstrained compared to rods prepared by most other techniques. Their properties are reproducible within specifiable limits, and, although some properties differ from those of cut rods, the differences appear to reflect favorably on the technique. The rods are adequate for measuring the room temperature galvanomagnetic coefficients of pure and tin-doped antimony, the purpose for which this technique was developed, and ought to be satisfactory for cyclotron resonance and anomalous skin effect experiments where a long mean free path is necessary provided sufficiently pure starting material is used. The technique is applicable to the bismuth-antimony alloy system, and antimony-rich alloy rods have been grown in the nonpreferred, 0° orientation with the conditions optimum for pure antimony.

Steady-State Evaporation Method for Composition Control of Thin Films Prepared by Halide Reduction

H. C. Theuerer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

A widely used method for the preparation of thin films of elemental and compound semiconductors or metals is the hydrogen reduction of the appropriate halides. The inherent flexibility of this method makes it possible to prepare films with a large variety of compositions by appropriate adjustments of the vapor phase introduced to the reduction vessel. However, the precise composition control required for research and device purposes has, heretofore, made it necessary to meter accurately the very small amounts of halide vapors required in the reduction process. Metering of components is eliminated with the steady-state evaporation method, herein discussed. In essence, this is a simple and efficient method for maintaining a fixed vapor phase composition during the evaporation of binary or multicomponent solutions, the composition obtained being that of the starting liquid used.

The objective in steady-state evaporation is to promote evaporation from the surface of a liquid column using a carrier gas such as hydrogen with thermal and mechanical agitation of the liquid eliminated. Under these conditions, the surface layers of the liquid become enriched in the constituents with lower vapor pressures. Diffusion in the liquid results in an exponential concentration gradient in the region near the surface. Steady state is reached when the composition at the liquid surface is such that the gas phase in equilibrium with this liquid is that of the bulk liquid. For an ideal binary system, steady state is realized when the liquid surface has the composition $N_a p_b^\circ / N_b p_a^\circ$ where N_a/N_b is the mole ratio of the constituents initially, with p_a° and p_b° being the vapor pressures of the pure constituents.

Using this evaporation method, once steady state has been established, the gas phase composition will remain invariant so long as the gas flow rate, temperature, and the composition gradient near the liquid surface are not changed significantly. Conventional means of maintaining temperature and gas flow are adequate, and control of the liquid concentration gradient can be realized by containing the liquid in a porous medium such as a glass frit filter. The fine capillaries in such filters effectively block thermal and mechanical agitation. Moreover since the quantity of liquid held in the frit is small and the rate of liquid transport through the capillaries is high the diffusion gradient is restricted to a small region near the frit surface. In consequence, this evaporator design is insensitive to minor fluctuations in temperature and gas flow rate. A major change in either temperature or flow rate will result in a large transient change in composition of the evaporating liquid. It should be noted that as soon as the new steady state is established the evaporating liquid will revert to its original composition. Since the same steady state is achieved for any temperature at which the solution remains liquid and for any maintainable evaporation rate, control of these variables makes it possible to vary the quantity of vapors introduced to the reaction vessel over a wide range.

The apparatus for steady-state evaporation and halide reduction is shown in Fig. 1. With this apparatus it is possible to carry out all operations required to obtain steady state by proper manipulation of the stop cocks. Initially, the halide mixture is forced above the glass frit by applying hydrogen pressure to the reservoir. The pressure within the reservoir and evaporation chamber is then equalized which allows the liquid to drain back into the reservoir. Due to capillarity, the liquid column will remain in contact with the frit, and the upper surface of the frit will be uniformly wet. The liquid level in the reservoir should be below the frit, but other control of this height is not required since capillarity and the cohesive strength of the liquid will support the column in contact with the frit against an appreciable gravity head. After these preliminary operations, the desired hydrogen flow is maintained for a period of 10 min which is adequate to establish steady-state conditions. Following this, the gaseous mixture can be introduced to the reduction chamber for film deposition.

While this evaporator has been designed primarily to maintain a uniform vapor phase composition for the preparation of films with uniform composition, it is possible when desired to produce temporarily sharp concentration gradients by perturbing the evaporation rate. With an increase in

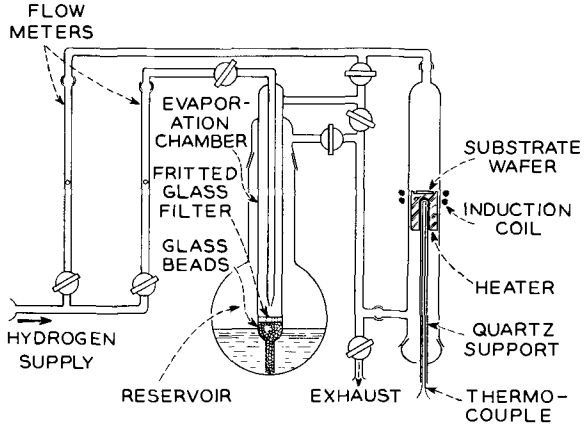

Fig. 1. Apparatus for steady-state evaporation and halide reduction.

evaporation rate, solutes with lower vapor pressure than the solvent will increase in concentration, the effect being greater the larger the difference between the solute and solvent vapor pressures. Solutes with higher vapor pressures than the solvent similarly decrease in concentration for an increase in evaporation rate. A decrease in evaporation rate from the initial steady-state rate results in solute concentration changes the opposite of those stated above. Since the composition of the vapor differs from that of the liquid only during the transient period while steady state is being reestablished, it is possible to produce sharp gradients in the deposited films. In the case of semiconductors, with the proper balance of donor and acceptor halides, in for example $SiCl_4$, it should be possible to produce p-n junctions. The mechanism here is analogous to that for rate grown junctions from the melt. The mathematics for solute distribution during solidification has been developed by Smith, Teller, and Rutter (1) and this may be used as a guide in utilizing the perturbed steady-state evaporator.

Nature of the Damaged Layer on Abraded Silicon Specimens

R. Stickler and G. R. Booker

Research and Development Center, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

The damaged layer associated with semiconductor surfaces after abrasive treatments has been investigated extensively during the last few years; for a review see ref. (1). However, most of the work was directed toward determining the depth of the layer rather than the nature of the layer. Several investigators (2-5) hold the view that the damaged layer consists of a narrow outer region of cracked material together with a wide inner region of high dislocation density material. On the other hand, Pugh and Samuels (6) recently concluded that the entire layer consists of cracked material, and that dislocations are not present. However, both groups of investigators(6, 7) found that dislocations were formed if abraded specimens were subsequently annealed. We have investigated the damaged layer associated with abraded Si specimens by chemically thinning the specimens and examining them by transmission electron microscopy. Some preliminary results are described.

Procedure and Results

Silicon slices were cut, chemically polished with CP4 to remove the surface damage arising from the cutting, and abraded unidirectionally for a few minutes on one side using a No. 400 SiC paper with water as a lubricant. The slices were then chemically polished from the unabraded side using an HNO_3/HF solution (8) until portions of the slices were only a few 1000Å thick. These specimens were then mounted on a tilting specimen stage, and the thin portions were examined in transmission in the electron microscope.

The micrographs show areas corresponding to regions below the Vs of grooves gouged out of the surface by the abrasive particles. Directly beneath the Vs, two types of structure were observed. The less common type (Fig. 1) consisted of numerous single, and sometimes superposed, electron interference fringe systems. The fringes were in general curved and were not oriented along crystallographic directions. These fringes are of the kind which would result if small blocks of material located directly above one another were slightly misaligned, as in cracking.

The second more common type of structure (Fig. 2) consisted of an irregular network running along the length of the grooves. The structure comprised intersecting lines oriented along crystallographic directions and appears to be a severely strained dislocation network.

The regions directly adjacent to these two types of structure mainly exhibited only a surface texture structure. The appearance of this structure sug-

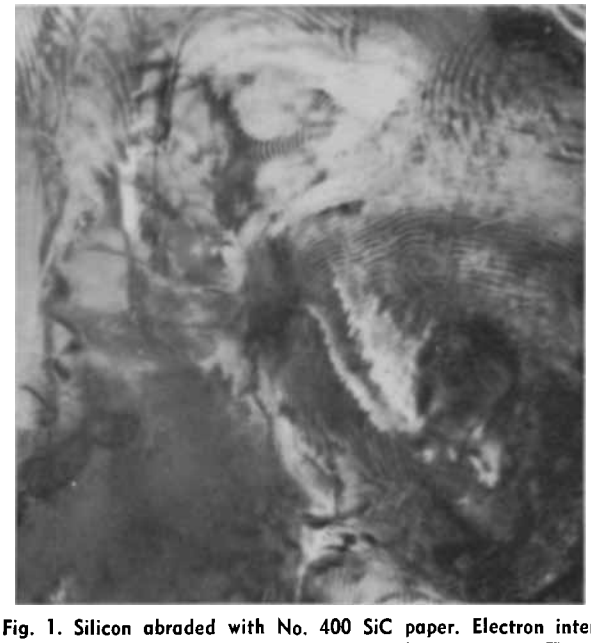

Fig. 1. Silicon abraded with No. 400 SiC paper. Electron interference fringes arising from cracked material are present. Transmission electron micrograph 50,000X.

Fig. 2. Silicon abraded with No. 400 SiC paper. Severely strained dislocation network is present. Transmission electron micrograph 100,000X.

gested that it arose during the abrasion process by small pieces of material being chipped away from the surface.

If the type of structure shown in Fig. 2 does consist of strained dislocation networks, then one would expect the dislocations to rearrange themselves during an annealing treatment and to assume a more equilibrium form, ideally a hexagonal network. Accordingly, Si slices were abraded with No. 400 SiC paper, annealed at 850°C for 1 hr in a hydrogen atmosphere and then prepared for transmission electron microscope examination as previously described.

The annealing treatment had two effects. First, a rearrangement of the dislocations in the networks occurred (Fig. 3), many areas adopting an approximately hexagonal form. Second, single dislocation lines ran outward from the edges of the networks (Fig. 3) into the surrounding, previously dislocation-free, regions. It is presumably this latter type of dislocation which was revealed by Faust (7) and Pugh and Samuels (6).

Summary and Conclusions

When silicon specimens were abraded with No. 400 SiC paper, the regions directly beneath the grooves gouged out by the abrasive particles were heavily damaged. The damage consisted of severely strained dislocation networks and cracks. Annealing of the abraded specimens at 850°C caused the dislocations within the networks to rearrange themselves into an approximately hexagonal form, and

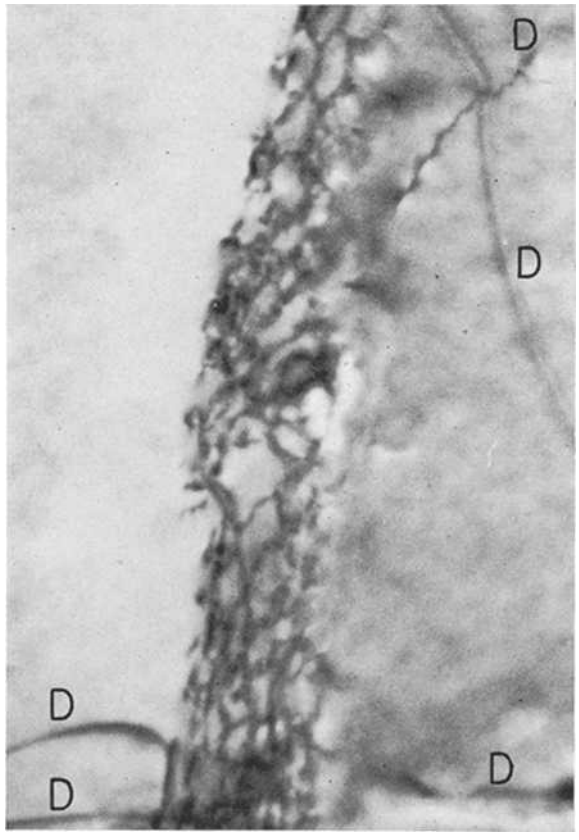

Fig. 3. Silicon abraded with No. 400 SiC paper and annealed at 850°C for 1 hr. Dislocations within the network have rearranged themselves into an approximately hexagonal form, and single dislocations (D) have propagated from the network into the surrounding regions. Transmission electron micrograph 50,000X.

single dislocation lines to propagate outward from both networks and cracks into the surrounding regions.

Conventional metallographic techniques would in most instances not reveal the individual dislocations of such networks because of the small distance between the dislocations (<1000Å). Moreover, such networks would etch as grooves, and hence would not be distinguishable from cracks. However, the single dislocations formed during annealing are relatively widely spaced, and are readily revealed.

Silver-Silver Chloride Electrodes Using Optical Silver Chloride Crystals

J. Greyson

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

For a current investigation of membrane potentials, we require silver-silver chloride electrodes which can maintain stability for long time periods even when subjected to frequent moves from one dilute (less than 1M) aqueous chloride solution to another. A very simple preparation which requires only routine laboratory precautions and yields electrodes with excellent stability is described in this note.

Electrode Preparation

Silver chloride optical crystal sheet,[1] 1 mm thick, is cut into small sections about 0.5 cm on an edge. A piece of 0.030-in. silver wire[2] is heated over a bunsen flame until the end melts to a small sphere and while hot is pressed into an edge of one of the sections. The wire must be hot enough to melt the crystal around itself to secure an adequate electrical and mechanical connection. A piece of glass tubing, somewhat shorter than the silver wire, and previously filled with Apiezon W is warmed to soften the filling. The wire is pushed through the tube drawing the crystal as close to the end as possible. After the assembly has cooled, the crystal is rinsed several times successively and briefly in reagent grade concentrated nitric acid, water, and concentrated ammonium hydroxide, and is finally washed for several minutes in distilled water. Using the crystal as the cathode and platinum wire or foil as the anode, a deposit of metallic silver is developed on the crystal surface by immersing it in a 0.05-0.1*N* redistilled hydrochloric acid solution and then slowly withdrawing it while passing about 10 ma of current. The silver deposit forms at the contact of the crystal and the wire and grows down the surface in a thin jagged line. After obtaining the initial deposits, a group of electrodes are cathodized in the same solution for 30-40 min at a current of 2-3 ma per electrode. During this period the initial deposits broaden and become more diffuse. The current is reversed on completion of cathodizing and the electrodes are anodized at 0.2-0.3 ma/electrode for 2-3 min. They are then washed for a few minutes in distilled water and can be used.

Electrode Performance

Taniguchi and Janz (1) have defined "bias potential" as the difference in potential between a pair of identical electrodes immersed in a uniform solution. The term is used throughout the following to characterize electrode performance.

Bias potentials of all electrode pairs were measured, initially and for one week thereafter, in 0.1*N* HCl. After the first week, the medium was changed periodically. No attempt was made to stir the solutions or free them of oxygen. Potential measurements were made with negligible current flowing by using a microvoltmeter with a 6 megohm input impedance or a Rubicon Portable Potentiometer in conjunction with a Keithley 151R Null Detector with an input impedance of 100,000 ohms.

Three groups of electrodes were prepared at different times, the second group four hours after the first and the third, four days later. Of the first group of four, two were removed and used for measurements of cell potentials. All possible pairs in the second two groups, each composed of six electrodes, and the remaining two of the first group were compared at regular time intervals. The two in use for cell potential measurements were periodically returned to the bias potential cell and compared with all the rest.

Within any of the groups of electrodes which were prepared simultaneously, the bias potentials never exceeded ± 0.1 mv (and frequently were less than ± 0.05 mv) within 30 min after completion of anodizing. The average of the absolute values of the bias potentials for electrode pairs within a simultaneously prepared group was about 0.07 mv initially. After 100 hr in hydrochloric acid this average value decreased to about 0.05 mv. Changes in media (*i.e.*, 0.01*N* lithium chloride, 0.1*N* sodium chloride) caused an initial rise in bias potentials, but within 30 min the average of the absolute values reduced to that in the hydrochloric acid. The electrodes which were periodically returned to the bias cell always compared to those of the same group within 0.1 mv within 30 min.

A newly prepared electrode was usually about 1 mv negative with respect to an old one. This value increased to -0.15 mv in about 100 hr with a half time of about 15 hr. Changes in the nature of the surrounding solutions did not affect the magnitude of the potentials between new and old electrodes. It is interesting to note that in using standard preparative techniques, new electrodes are positive with respect to older ones. Janz (2) has discussed this effect and has pointed out that it may arise from a depletion of solute in the electrode pores during long anodizing periods. In the present technique the ratio of cathodization to anodization is high, and solute may concentrate in the electrode pores giving rise to a reversal in polarity.

We have examined several other characteristics of these electrodes. The electrical resistance of a pair is approximately 500 ohms. In dilute ethanol-HCl solutions, bias potentials were larger by an

[1] Harshaw Chemical Company, Cleveland, Ohio.

[2] Spectroscopically analyzed grade, Jarrell-Ash Co., Newtonville, Mass.

order of magnitude (> 1.0 mv) than in aqueous solutions. Over the temperature range 5°-100°C, bias potentials remained less than 0.1 mv. After passing 10 μa for 1 min, the bias potential reduced to the prepolarizing value in under 60 min with a half time of about 1 min.

These electrodes are used as probes to measure membrane potentials between chloride solutions. Within 15 min after cell assembly the potential reaches a value (P_1) which remains steady within 20 μv for 30 min or more. The electrodes are interchanged, and a potential P_2 is determined in the same way. The cell potential is taken as $\frac{1}{2}(P_1 + P_2)$ while $\frac{1}{2}(P_1 - P_2)$ may be compared with the bias potential B for the same electrodes in a mixture of the solutions in the two cell compartments. We find $\frac{1}{2}(P_1 - P_2) - B$ is at most 40 μv. A slow variation in bias potential has been noted in moving the probes through a succession of solutions of varying composition and concentration but the absolute magnitude has never exceeded 0.15 mv even after several weeks of use.

Acknowledgment

Ionic Conductivity of Zirconium Phosphate

R. P. Hamlen

General Engineering Laboratory, General Electric Company, Schenectady, New York

Ion exchange membrane hydrogen-oxygen fuel cells employing proton or hydroxyl ion conducting membranes as the electrolyte and gas barrier are under development at present (1-4). The organic ion exchange membranes employed in these cells have high conductivities (5), so that the internal resistances of these cells are relatively low. However, it would be desirable in some cases to employ solid electrolytes with greater thermal stability, oxidation resistance, and resistance to ionizing radiation. The operation of a cell employing such an electrolyte, zirconium phosphate, has been reported by Dravnieks and Bregman (6).

Since ionic solids in general are noted for being relatively poor ionic conductors at low temperatures when compared with aqueous electrolyte solutions, it is pertinent to mention the desired conductivity, and the order of magnitude of the conductivity observed for some types of ionic conduction in solids. Broers (7) has estimated that the specific resistance should be no higher than 10 ohm-cm in order that the ohmic voltage drop in the electrolyte will not be too great. Ionic conduction by lattice vacancy migration usually yields room temperature specific resistances of the order of 10^5 to 10^{11} ohm-cm. It is possible to increase the number of vacancies, and also the conduction, by doping with the proper impurity, but in general the maximum conductivity observed at room temperature is of the order of 10^{-5} $ohm^{-1}cm^{-1}$. Doped oxides of Zr, W, etc., have been employed in fuel cells (7) as oxide ion conductors, but in order to increase the conductivity to a reasonable value the temperature must be maintained at or above 1000°C.

In a few isolated cases the conductivities encountered in interstitial ion migration are very high. AgI undergoes a phase transition at 146°C wherein the silver ions become almost completely mobile in a fixed lattice of iodide ions (8), and batteries have been designed around this property (9). However, measurement of the proton conductivity in solid hydrated acetylene dicarboxylic acid, which has a high density of acid groups (although a weak acid), yields a specific resistance of 3 x 10^5 ohm-cm at 50°C (10). Ice has been doped with HF to increase the proton density, thereby producing a mode of conduction somewhat analogous to that of aqueous solutions, but in so doing the specific resistance was decreased to only about 10^5 ohm-cm (11).

The specific resistances of hydrated organic ion exchange membranes can run as low as 10 ohm-cm. Because of the large difference between this value and the values mentioned above, reasonable conductivities might be attained only in a material which conducts by a similar aqueous mechanism, such as in zirconium phosphate (6). The amorphous aluminosilicates and the zeolites also show cation exchange properties (12), but they are relatively unstable in acids, so that they are not readily hydrogen-exchanged to form proton-conducting solid electrolytes.

Recent investigations of inorganic ion exchangers for use in nuclear reactor water purification have dealt with the phosphates, arsenates, tungstates, and molybdates of zirconium, thorium, and titanium (13). Amphlett (14) has made an extensive study of the properties of zirconium phosphate, which appears to be one of the more stable hydrogen exchangers. He reports that it can be refluxed in water for several weeks without appreciable breakdown. It is an amorphous solid formed by the precipitation of a soluble zirconyl salt with phosphoric acid, consisting essentially of an O-Zr-O-Zr chain with $-O-PO(OH)_2$ groups attached to each Zr atom. Naturally the number of phosphate groups per Zr atom is going to depend on the conditions under

which it is made, and the cross linkage between adjacent phosphate groups by dehydration is going to depend on the thermal treatment of the product. Zirconium phosphate prepared using an excess of phosphoric acid and not subjected to high temperature has a high density of replaceable protons and is relatively insoluble.

Experimental

Preparation of zirconium phosphate.—The zirconium phosphate employed in these conductivity measurements was prepared as follows: 20g of $ZrO(NO_3)_2 \cdot 2H_2O$ were dissolved in 500 cm^3 of water. To this a solution of 50 cm^3 of 86.3% phosphoric acid in 250 cm^3 of water was added rapidly. The solution was stirred rapidly during the addition of the reagents, and the stirring was continued for about 5 min. Water was added so that the total volume was increased to 3.5 liters, and the solids were allowed to settle. The solids were washed by decantation several times, and were finally filtered and dried overnight at 60°C. More water was added to the solid product, and the gel particles broke apart with audible crackling to a final product having a particle size in the range 0.1-0.5 mm.

During the preparation the ratio of phosphorus to zirconium in the starting solutions was high, approximately 10, so that the solid product would be the normal phosphate $ZrO(H_2PO_4)_2$, which has the maximum hydrogen content.

Preparation of powder compacts for conductivity measurements.—Since there were no particles of the product large enough for use in conductivity measurements, it was necessary to employ powder compacts. These were 17.0 mm in diameter and about 3 mm thick. The densities of the compacts fell in the range 2.0-2.2 g/cm^3. On soaking in water, the pellets were observed to undergo a 20-30% increase in volume, although the pellets retained their shape and appeared to suffer no degradation of mechanical properties. Because of this expansion conventional electrodes, such as those made from conducting paints, could not be employed. In order to overcome this difficulty, 100 mg of finely divided zirconium phosphate and 50 mg of platinum black were mixed, and one half of this mixture was spread over each face of the compact after it had been formed at a pressure of 13,000 psi. After a final pressing at 33,000 psi the electrode layers showed no tendency to peel off when the pellets were soaked in water. The electrodes so formed showed a resistance of only a few ohms from one point to another on each face.

Conductivity measurements.—For measurements of conductivity *vs.* temperature the apparatus shown in Fig. 1 was placed in an oven. Platinum disks were pressed against each face of the compact, and silicone rubber gaskets prevented the escape of water vapor from the apparatus. Therefore, the measurements were conducted under conditions of constant water content. A General Radio Company type 1650A Impedance Bridge was used for the measurements, with a variable capacitor across one leg of the bridge to balance out capacitive effects in the sample.

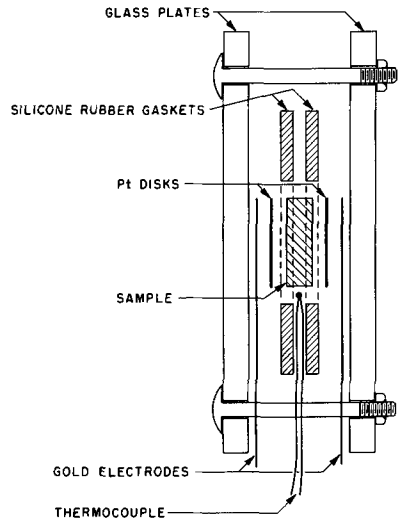

Fig. 1. Conductivity apparatus

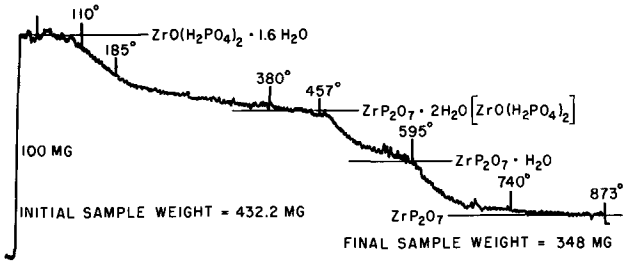

Fig. 2. Thermogram for zirconium phosphate

The frequency dependence of the conductivity was low, as is seen in Table I, an indication that electrode polarization effects were absent (15).

Results and Discussion

Thermogravimetric analysis.—In order to obtain a rough idea as to the thermal stability of the zirconium phosphate a thermogravimetric analysis was conducted on the material as dried at 60°C at a heating rate of 5°C/min. This is shown in Fig. 2. When prepared in the manner described previously it should have a composition near $ZrO(H_2PO_4)_2 \cdot XH_2O$. If one assumes that the final product has the empirical formula ZrP_2O_7, as is done in the standard phosphate analysis for zirconium, the two breaks in the curve correspond closely to the loss of one water molecule at 470°C and another at 600°C by the condensation of adjacent phosphate groups. The water lost at lower temperatures is water originally retained in the gel structure, and the initial composition is then approximately $ZrO(H_2PO_4)_2 \cdot 1.6H_2O$.

On soaking in water the volume of the compact used for the conductivity measurements increased

Table I. Frequency dependence of conductivity

50	4.02
25	4.02

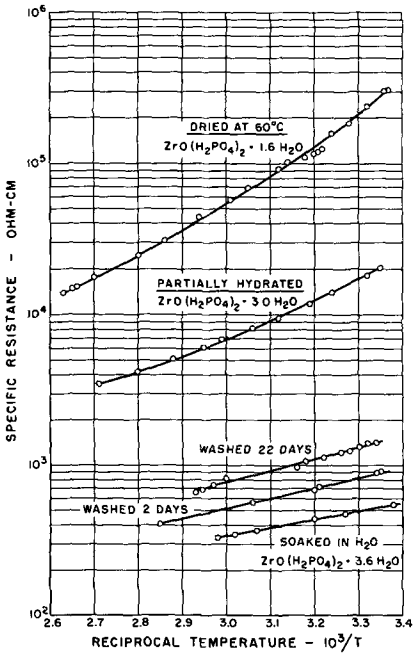

Fig. 3. Specific resistance of zirconium phosphate *vs.* $1/T$

by 22%. Assuming the increase in volume was due to the addition of water with a density of 1.0, and since the density of the compact initially was 2.0, the composition of the soaked compact should be approximately $ZrO(H_2PO_4)_2 \cdot 3.6H_2O$.

Conductivity measurements.—Measurements of conductivity *vs.* temperature were carried out on a pellet immediately after pressing from zirconium phosphate dried at 60°C, and on the same pellet after partial and complete hydration. The temperature dependence of resistivity ρ can usually be expressed over narrow ranges by an equation of the form $\rho = \rho_0 e^{E/RT}$, where E is an activation energy for the conduction process. Therefore, E can be obtained from the slope of a plot of log ρ *vs.* $1/T$. Figure 3 contains plots of log ρ *vs.* $1/T$ for the samples in each of the three states of hydration. It is seen that the activation energy decreases from 9.8 kcal/mole to 2.6 kcal/mole as the sample becomes more hydrated. The activation energy for the soaked pellet falls in the range normally found for conduction in aqueous solutions (5). If the assumption is made that there is a solution of $2H_3PO_4$ units for every $3.6H_2O$ molecules, a rough calculation of the expected conductivity can be made using the second ionization constant of phosphoric acid. The above ratio of H_3PO_4/H_2O corresponds to a 75% solution of phosphoric acid, which would have a density of 1.58 g/cm^3. K_2 for phosphoric acid at 25°C is 6.2 x 10^{-8} (16), and this would result in a proton concentration of about 9 x 10^{-4}g equivalent/liter. Since each cubic centimeter of solid would contain about 0.80 cm^3 of the above solution, and since the equivalent ionic conductance of protons is about 350 ohm^{-1}-cm^2, the conductance would be of the order of 3 x 10^{-4}ohm^{-1}. This would correspond to a specific resistance for the solid of about 3000 ohm-cm. This is about a factor of 5 greater than the specific resistance of 550 ohm-cm observed on this material at 25°C. Considering the assumptions involved, especially the assumption that K_2 for the phosphoric acid is not affected by reaction with the hydrated zirconium oxide, the agreement is within reason. It has already been observed by Amphlett that a titration curve of zirconium phosphate *vs.* NaOH does not give two inflection points characteristic of K_2 and K_3 for phosphoric acid, but gives a relatively smooth curve.

Activation energies were calculated from the slopes of the three curves at the low end of the temperature range. They are 9.8, 6.4, and 2.6 kcal/mole for increasing degrees of hydration. The last value corresponds to the temperature variation observed in aqueous solutions as a result of the decrease in viscosity with increasing temperature.

Effect of continuous washing on the conductivity.—Because of the nature of the zirconium phosphate, it would be expected that continuous washing would hydrolyze the solid, releasing phosphoric acid and eventually converting the zirconium phosphate to zirconium hydroxide (hydrous zirconium oxide). The compact employed in the measurements above was washed continuously, and the conductivity was measured after 2 and 22 days. These results are also shown in Fig. 3. The figure shows that the conductivity decreased, although the slope of the plot remained relatively constant. This would indicate that the mode of conduction remained the same, namely, transport of H^+ ions in an aqueous system, but that the number of current carriers (H^+ ions) decreased as a result of the hydrolysis mentioned above.

Fuel cell using a zirconium phosphate membrane.—A cell similar to that of Dravnieks and Bregman was prepared by pressing a 1 mm thick disk from 90% zirconium phosphate and 10% powdered Teflon at a pressure of 35,000 psi. This was soaked in water, each face was sprinkled with Pt black, and a Pt screen was placed against this in a simple hydrogen-oxygen fuel cell configuration. The polarization curve for this cell is shown in Fig. 4. The resistance of the membrane as calculated from the slope of the polarization curve was 110 ohms, which agrees roughly with the measured value of 150 ohms. This value of 110 ohms corresponds to a specific resistance of about 6000 ohm-cm, showing that the Teflon binder in this case decreased the conductivity sub-

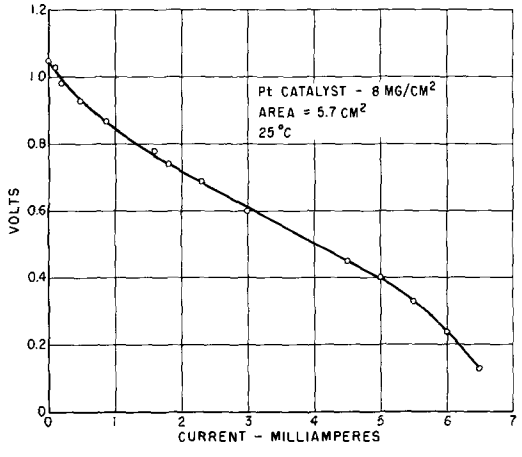

Fig. 4. Polarization curve for H_2-O_2 fuel cell with zirconium phosphate membrane.

stantially. Obviously, it is desirable to increase the conductivity by better membrane construction and by the use of higher temperatures. Because of the aqueous mechanism of ion transport pressurization would be required above 100°C.

It is evident that such a membrane has two major drawbacks from the standpoint of fuel cell applications: (*A*) Low conductivity. This might be partially overcome if sufficiently thin membranes could be fabricated. (*B*) Changes due to hydrolysis.

Brief Communications

The Chemical Polishing of Rare Earth Tellurides

P. Bro

Research and Advanced Development Division, Avco Corporation, Wilmington, Massachusetts

There is a growing interest in the semiconducting compounds of the rare earth metals, and several compounds have been reported (1) with interesting thermoelectric properties. One of the problems associated with the electrical measurements on these compounds is the preparation of reproducible surfaces. Mechanical polishing can be employed, but it generates a strained surface which gives rise to anomalies in the surface properties of the samples. A chemical or electrochemical method generally is preferred in the preparation of semiconductor surfaces for electrical and optical measurements.

We have investigated a variety of chemical etches for the rare earth tellurides and the main problem was that of finding a reactive medium that could dissolve the metal and the tellurium at comparable rates under conditions which would produce a polished surface. A satisfactory chemical polish was found for the sesqui- and higher tellurides, and it consisted of 10 ml glacial acetic acid and 1 ml bromine. It gave an etch rate on La_2Te_3 at room temperature of 0.84 g/sec m^2 when freshly prepared. An etching period of 20-60 sec appeared satisfactory. The etch rate could be increased by the addition of ethyl alcohol, and an etch rate of 1.63 g/sec m^2 was obtained with 5 ml HAc, 5 ml EtOH, and 1 ml Br. The gradual heating of the latter etch due to the exothermic Br/EtOH reaction also increased the etch rate. An inferior polish was obtained in the presence of excess amounts of alcohol or when the etch was not strictly fresh.

An interesting observation was obtained with La_2Te_3 in etches composed of HBr, H_2O, and Br, *e.g.*, 10 ml fuming HBr, 30 ml H_2O, 1 ml Br. Initially, the sample acquired a high apparent polish, but a continued exposure to the etch under quiescent conditions led to the formation of long, twisted tellurium whiskers which grew profusely and very rapidly from the surface of the sample. The initial polish was found to be due to the formation of a tellurium phase on the surface which could be removed quite readily. The growth of the tellurium whiskers appeared to depend on the formation of highly mobile tellurium atoms in the crystal lattice by the preferential dissolution of the rare earth metal, and it is a phenomenon which lends itself to experimentation in the interesting field of crystal growth mechanisms.

Acknowledgments

The synthesis of the rare earth tellurides was carried out by W. Mularz and his assistance is gratefully acknowledged.

Gallium Phosphide Crystal Growth by Vapor Phase Iodide Transport

A. S. Roy[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The growth of small GaP crystals from the vapor phase has been reported by Antell and Effer by mixing GaI and phosphorus and slowly cooling from 1050°C in a quartz tube (1). Gershenzon and Mikulyak (2) allowed Ga_2O to react with phosphorus at about 1000°C in a sealed quartz tube and obtained thin whiskers and filaments of GaP up to 0.2 mm in width. Epitaxial films of GaP have been grown by Frosch and Foy (3) and by Moest and Shupp (4). Holonyak reported growth of massive polycrystals of GaP using halides as transport agents (5).

[1] Present address: Israel Atomic Energy Commission, Rehovoth, Israel.

The experiments reported here describe the growth of GaP single crystals whose sizes were up to 2 mm in each dimension. Growth was from the vapor phase at temperatures between 780° and 935°C and about atmospheric pressure in a sealed quartz tube containing a polycrystalline GaP source (about 0.5g), H_2, and I_2, with initial mole ratios of 8:7:1. The tube was 18 cm long and of 2 cm inside diameter. A temperature gradient provided the potential for the net reaction of transferring GaP from the source to a lower tempera-

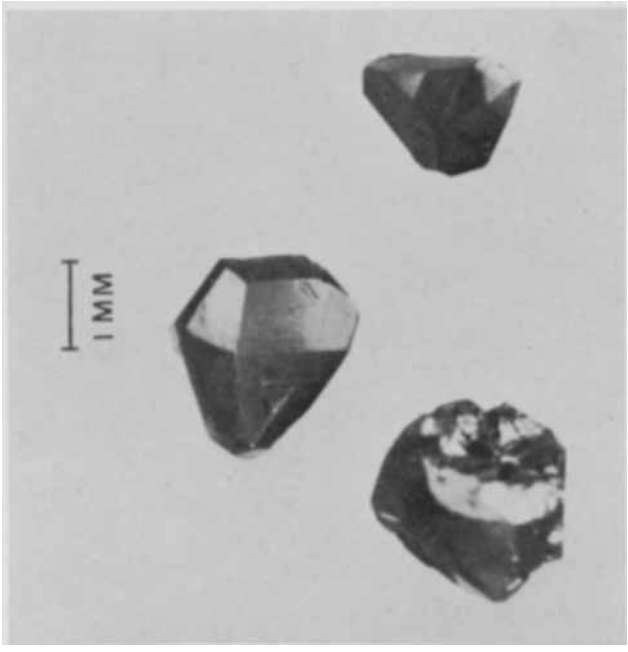

Fig. 1. GaP single crystals grown at 946°C at a point of 5°C below source temperature.

ture. Larger crystals were obtained when the gradient along the tube was small. The largest crystals were, in general, found at the middle of the tube rather than at the coolest end. Figure 1 shows several crystals over 2 mm in size grown at 946°C at a point 5°C below the temperature of the source material. Smaller crystals were obtained with larger gradients. When the cold end was reduced to 780°C with the source at 950°C, aggregates of crystallites approximately 0.02 mm in size deposited at the cold end. In one case, a similar gradient produced GaP needles with typical dimensions of 0.1x0.4x2 mm. The transport rate increased with the source temperature. For a temperature difference of 50°C between the source and the colder end of the tube and with the source at 850° and 950°C, the transport rates were 25 and 75 mg/hr, respectively.

The crystals adhered strongly to the quartz. The contact area was observed by reversing the temperature gradient and transferring the GaP to a cooler region of the tube. Gallium phosphate and α-quartz crystals ~0.1 mm in size were side reaction products. These were identified by x-ray diffraction measurements. Typical GaP crystals were analyzed spectrographically after removing the regions adhering to the quartz by etching. The concentrations of detectable impurities, Ca, Mg, Al, Si, Fe, and Ni, were less than 50 ppm. The crystals were always n-type, suggesting that Si was the dominant electrically active impurity.

The results of these preliminary experiments indicate the feasibility of relatively rapid growth of large GaP crystals at comparatively low temperature and pressure.

Polarization Studies on High-Temperature Fuel Cells

M. L. Kronenberg

Research Laboratory, Union Carbide Consumer Products Company, Division of Union Carbide Corporation, Parma, Ohio

ABSTRACT

Immobilized-electrolyte, high-temperature fuel cells of nonconventional design were operated successfully on a wide variety of fuel gases. This design permits the incorporation of a reference electrode and avoids gasketing problems for low-pressure operation. The performance of these cells was compared with preliminary results on free electrolyte and solid electrolyte cells. Oscilloscopic observations of polarization decay indicated that ohmic rather than concentration or activation polarization limits the performance of matrix cells in most instances.

It is well known that gaseous fuel cell reactions take place within a relatively restricted reaction zone since the fuel must make simultaneous contact with the electrode and electrolyte. There are three general approaches that have been used in the development of high-temperature fuel cells which in principle fulfill this requirement. These are matrix cells, solid electrolyte cells, and cells using gas diffusion electrodes in free electrolyte. Most of the results presented here are concerned with matrix cells, although some preliminary results on gas diffusion and solid electrolyte cells are also presented as a comparison.

The advantage of a solid electrolyte in achieving a three-phase reaction zone without the difficulties of wetting was recognized by Schottky (1). However, it was Baur and co-workers (2-4) who conducted extensive experiments on solid electrolyte cells. No practical solid electrolytes were found despite the many systems that were studied. In his well-known thesis on high-temperature fuel cells, Broers (5) concluded that a good solid electrolyte might never be found and that a salt which transports oxygen-containing ions such as a carbonate salt would be second best to an ideal solid electrolyte. The cell he developed with these thoughts in mind essentially consists of a carbonate-impregnated disk covered with metal catalyst powders and current collectors and with anode and cathode compartments built up by gaskets and spacers.

This disk-type construction served as a starting point for our research on high-temperature cells. Fuel cells of this design were run on a wide variety of fuel gases. The performance data obtained were about the same as reported by Broers (5), *i.e.*, a current density of 50 ma/cm^2 at approximately 0.7v on hydrogen with slightly lower operating levels on carbon monoxide and hydrocarbon fuels. However, because of the high operating temperatures and corrosive nature of the carbonate melt under these conditions, it was difficult to obtain a well-gasketed system with this design.

A tubular cell design was decided to be a better laboratory approach to the matrix cell since gasketing problems would be eliminated. A cell of this type is shown in Fig. 1. The porous ceramic tube is impregnated by immersion at 700°C with a ternary eutectic alkali carbonate which has a melting point slightly under 400°C (6). The inside of the tube is catalyzed as an anode or fuel electrode and the outside as a cathode. Catalysts were normally applied as slurry powders to the surface and baked at 500°C prior to fixing the perforated foil collector in place. Air and carbon dioxide are the cathode gases normally used.

This construction readily permits the incorporation of a reference electrode as shown. The reference electrode in this case should be reversible to O_2 and CO_2 which are the active cathode gases. Broers (5) suggested that silver was a good CO_2, O_2 electrode, but did not report the use of a reference electrode in his studies. The reversibility of the silver electrode was checked in a concentration cell of the type represented in the following equations

$$1/2\ O_2 + CO_2 + 2e \underset{\text{anodic}}{\overset{\text{cathodic}}{\rightleftharpoons}} CO_3^{=} \qquad [1]$$

$$Ag, CO_2(P^c), O_2(P^c)/CO_3^{=}/O_2(P^a), CO_2(P^a), Ag \qquad [2]$$

$$E = \frac{2.3\,RT}{2F} \log \frac{(P^a_{O_2})^{1/2}\ P^a_{CO_2}}{(P^c_{O_2})^{1/2}\ P^c_{CO_2}} \qquad [3]$$

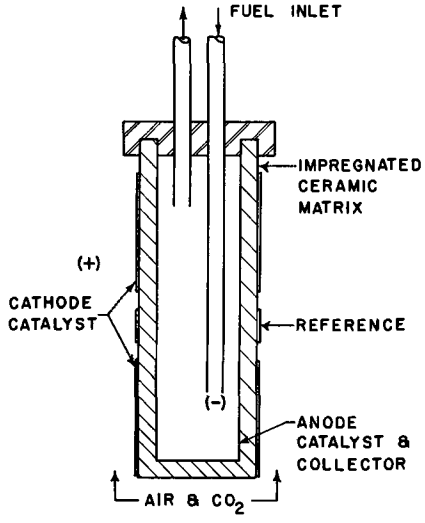

Fig. 1. Tubular fuel cell

Equation [1] represents the reversible reaction; Eq. [2] is a representation of the concentration cell, and Eq. [3] is an expression for the Nernst potential one would calculate at low and moderate pressures for a reversible electrode.

By holding three partial pressures constant and varying the fourth, Nernst dependence of potential was observed on variation of either CO_2 or O_2 partial pressures. This is shown for CO_2 variation in Fig. 2. The solid line was obtained from experimental results and the lower curve from potentials calculated using the Nernst equation. The 2-mv displacement that is observed is attributed principally to errors in flow-meter adjustments. The Nernst slope consistently observed in these experiments demonstrated the reversibility of the powdered silver electrode as a CO_2, O_2 electrode. Nernst dependence was observed down to 400°C.

Figure 3 shows one of the ways tubular cells can be simply built into batteries by joining tapered sections. The series connections can then be made internally and common gas feeds used. Several tubular multicell batteries have been made, and no special difficulties were encountered in their operation.

In Figure 4 are shown typical anode-reference, resistance-free[1] polarization curves for several gases. The reference electrode in all cases is carbon dioxide and oxygen on powdered silver. There is very little polarization outside of resistive effects for these gases above 600°C. One cannot be sure if the hydrogen-containing gases are actually galvanically utilized or whether they are running on thermally produced hydrogen. The carbon monoxide was carefully dried to contain less than several ppm water vapor, so that a direct galvanic utilization appears to be the case. However, one cannot overlook the possibility that any of the fuels may act as a reducing agent to keep the oxygen partial pressure low, resulting in a concentration cell based on the reaction given in Eq. [1], which has been shown to be reversible on silver. The cell potential would correspond to the partial pressure difference of oxygen across the cell caused by chemical utilization at the anode by the fuel. Identical products are normally obtained whether the fuel reacts chemically first or whether it is galvanically utilized directly. So, the question of whether or not the fuel is galvanically utilized in a high-temperature cell cannot be decided on the basis of product analysis.

In Figure 5 are shown the operating cell voltages as a function of current density for several fuels. The potentials are much lower than for the anode-reference (resistance-free) polarization curves of the previous figure. The dotted line represents the resistance-free cell potential drawn in as a comparison. So, while resistance-free potentials at prac-

[1] The resistance-free polarization data were obtained using a Kordesch-Marko pulse-current interrupter (7). The instrumentation used to distinguish between ohmic and activation polarization was similar to the electronic commutator described in the literature by Staicopoulous and co-workers (8).

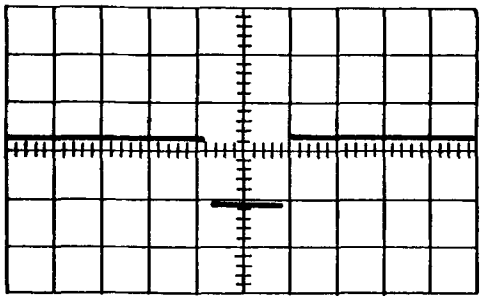

Fig. 6. Oscilloscope trace of anode-reference potential for methane at 500°C and 25 ma/cm².

tical current densities look quite promising, the high cell resistance drastically reduces the cell output.

Oscilloscopic observations of polarization decay indicate that above 500°C there is virtually no activation polarization associated with any fuel, even methane at moderate current densities. Figure 6 shows an oscilloscope trace of the anode-reference potential for methane at 500°C and 25 ma/cm². The long line represents the anode-reference potential during the current-on period. The current-off period is approximately 80 μsec. There is no evidence of activation polarization here since this would show up as a sloped line or curve on this time scale. The virtually instantaneous potential change is attributed to ohmic polarization and corresponds to approximately 90 mv. There also appears to be about 150 mv of concentration polarization since the open-circuit potential is that much below the current-off portion of the trace. This latter difference from open-circuit voltage may also be partially attributed to voltage drops within the pores of the porous electrodes, but this is not believed to be a significant contribution since this difference is only several millivolts when hydrogen is used as fuel.

The high concentration polarization, in this case, suggests that hydrogen resulting from the thermal decomposition of methane is the galvanically active species under these conditions. This possibility was discussed above. With increasing temperatures, concentration polarization decreases to approximately 80 mv at 600°C. At temperatures above 800°C, there was no appreciable concentration polarization difference between hydrogen and methane. This question could not be resolved since methane polarization curves at several temperatures could not be reproduced with a dilute mixture of hydrogen in inert gas with our fuel cell system.

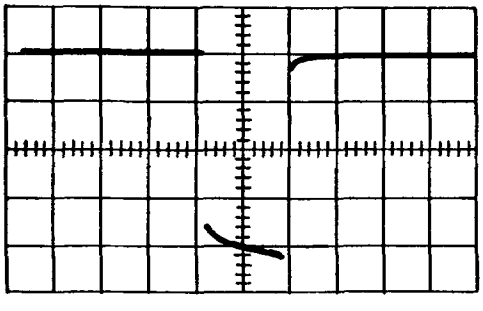

Fig. 7. Oscilloscope trace of anode-reference potential for propane on a poorly catalyzed electrode.

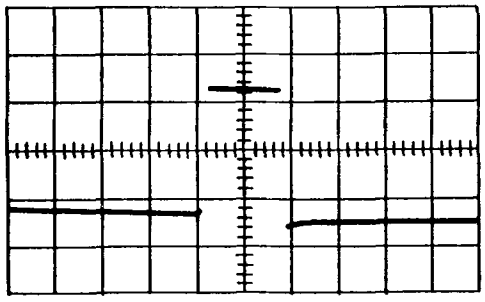

Fig. 8. Oscilloscope trace of anode-cathode potential for methane at 600°C and 25 ma/cm².

Evidence of activation polarization on a poorly catalyzed electrode is shown in Fig. 7. This was for propane fuel at 25 ma/cm² at 600°C. The differential capacitance obtained from the initial slope of the activation polarization was approximately 6 μF/cm² on this electrode. This indicates that the effective surface area is probably less than the geometrical surface area. In Fig. 8 is shown the anode-cathode potential at the same current density which shows the 200 mv of ohmic polarization associated with the whole cell at 25 ma/cm² and 600°C. Methane was the fuel gas used. This shows also that there is no evidence of activation polarization at the cathode under these conditions.

As evidenced by the performance data presented, the main limitation on the performance of matrix cells is the high cell resistance. The resistivity of the melt is increased because of its dilution in the ceramic matrix and the contact resistance is high because it results from a series of point contacts rather than a continuous contact area. A continuous contact area cannot be used because of the 3-phase requirements of gas electrodes and the required nonelectronic conducting properties of the matrix. The minimum dilution effect on potential can be estimated from the following considerations assuming a minimum current density of 100 ma/cm² is required for practical operation.

$$E = IR = I\frac{\rho}{D}\frac{l}{A}$$

$$= 0.1 \text{ amp} \times \frac{1.0}{0.3} \text{ ohm cm } \frac{0.4 \text{ cm}}{1 \text{ cm}^2} = 0.133\text{v} \quad [4]$$

where E is the potential loss, I the current (0.1 amp), ρ the resistivity of melt (1 ohm-cm), R the cell resistance ($\rho l/A$), D the dilution effect of 30% porous matrix, and l the thickness of matrix (0.4 cm).

Contact resistances for 1 cm² were determined experimentally. For porous impregnated matrices, 0.4 cm in thickness, the contact resistance/cm² at each face was approximately equal to the resistance/cm² of the impregnated matrix. Therefore, the over-all loss in cell voltage due to ohmic effects above for a matrix cell using a 30% porous matrix is 0.133 + 2(0.133), or approximately 0.4v. This reduces working voltages at 100 ma/cm² to at least 0.8v without considering forms of polarization and is in accord with working voltages observed experimentally.

The longest period a tubular matrix cell has been run was for 10 weeks of intermittent operation. The

cell was turned off at night and heated up again the next morning and consequently went through approximately 50 heating and cooling cycles. In order to maintain operation for even this length of time, it was necessary to provide for periodic addition of carbonate to the matrix. This was accomplished by using a reservoir cap, containing ternary alkali carbonate, which was directed into the tube wall through carefully machined tube channels. The procedure was only partially successful. It prolonged the life of the cell, but resulted in the accumulation of excess electrolyte at the base of the cell. Failure was attributed principally to cracks and deterioration of the MgO matrix and to loss of electrolyte.

Because of the inherent limitation on performance attributed to the high cell resistance of matrix cells, controlled porosity metal electrodes used directly in the melt have been investigated in ours and other laboratories (9, 10). Here the important 3-phase reaction sites are provided within the pores of an electronic conductor, and the electrolyte is not diluted so that cell resistance is much lower than with matrix cells. However, the free carbonate electrolyte represents a highly corrosive environment under these conditions. Some preliminary results that have been obtained with diffusion cells are summarized in Fig. 9. The "a" curves represent resistance-free potentials for matrix, 1, and free electrolyte, 2, cells. Although resistance-free potentials are significantly higher for matrix cells than for the porous metal electrodes used thus far, the working cell potentials ("b" curves) are much higher at moderate and high current densities for free electrolyte cells due to their low cell resistance.

Polarization measurements have been made on solid electrolyte cells using the calcia-stabilized zirconia electrolyte investigated by Kingery (11), Wagner (12), and others (13), and which has been ap-

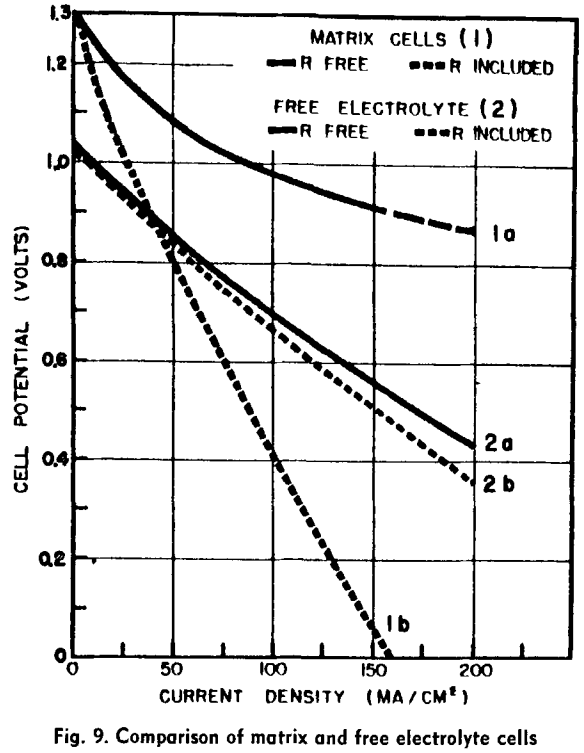

Fig. 9. Comparison of matrix and free electrolyte cells

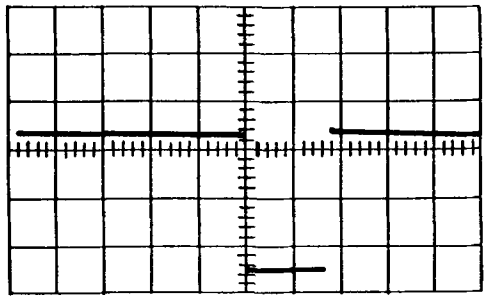

Fig. 10. Oscilloscope trace of anode-reference potential for hydrogen at 900°C and 10 ma/cm².

plied to high-temperature fuel cell technology by groups at Westinghouse (14, 15) and the Institute of Gas Technology (16). Figure 10 shows an oscilloscope trace of the decay pattern for this type of cell. The fuel gas was hydrogen, oxygen was the cathode gas, and the operating temperature was 900°C. No carbon dioxide need be added to the cathode gas since the cathode reaction is believed to be as given in Eq. [5].

$$1/2\ O_2 + 2e = O^= \qquad [5]$$

Oxide ion transport from cathode to anode occurs via oxide ion vacancies introduced in the cubic zirconia lattice by substitution of calcium (+2) cations for zirconium (+4) cations.

No activation polarization was observed at the anode at these temperatures and a current density of 10 ma/cm², although there is considerable ohmic polarization due to the high resistivity of the solid electrolyte. The electrolyte thickness was 1.5 mm, and the effective resistivity for the electrolyte and catalyst used was approximately 1000 ohm-cm.

The current density at practical operating voltages was only a few ma/cm². The high resistivity of the solid electrolyte is principally responsible for the relatively low operating level. Practical cells, therefore, would require the use of thin, impervious, solid electrolyte films.

In conclusion then, on the basis of work on matrix cells and preliminary work with gas diffusion and solid electrolyte systems, it appears that, although formidable problems remain to be solved with each approach before dependable high-temperature fuel batteries will be produced, most of these problems are of a practical nature. The output of matrix cells and solid electrolyte cells was limited principally by high cell resistance rather than other forms of polarization. The life of matrix and especially gas diffusion cells was limited mainly by the lack of inexpensive, stable materials which were able to withstand the combination of high temperature and corrosive environment.

The solid electrolyte cell because of its simplicity, apparent stability, less corrosive nature could become a practical high-temperature fuel cell system if operating levels are improved. At any rate, it appears attractive compared to the highly corrosive molten carbonate systems.

The Lithium Hydride Electrode

Maurice E. Indig and Richard N. Snyder

Delco-Remy Division, General Motors Corporation, Anderson, Indiana

ABSTRACT

The anodic character of a soluble lithium hydride electrode was studied electrochemically in the lithium chloride-potassium chloride eutectic for possible consideration as a high-energy, low-weight electrode material. The results show that current densities as high as 1.55 amp/cm^2 (10 amp/in.^{2}) can be maintained on the lithium hydride anode without appreciable polarization. Variation of coulombic efficiency and gassing studies led to the postulation of a one and two electron oxidation of lithium hydride. The oxidation was found to be quite dependent on current density and the physical nature of the grid.

Lithium hydride, molecular weight 7.95, is one of the saline hydrides with a well-known reducing character. While undergoing chemical or electrochemical reactions, the negative hydride ion can be oxidized to the H° or the H^+ state. Certainly free energy considerations allow for the one-electron oxidation. A calculation found in Latimer (1) based on the solid hydride and the metal ion gives an E° for the reaction $LiH \rightarrow Li^+ + \frac{1}{2}H_2 + 1e$ as 2.32v. In the electrolysis of molten lithium hydride by Moers (2) and later by Peters (3), it was noted that hydrogen was liberated solely at the anode, which indicated the one-electron oxidation of the negative hydride ion. However, a study by Gianatasio (4) of solid-solid reactions of lithium hydride with lithium chloride and beryllium chloride indicated the two-electron oxidation can occur. In the latter work both lithium chloride and beryllium chloride were reduced to the metals by lithium hydride with hydrogen chloride evolved as one of the products.

Although lithium hydride reacts spontaneously with water, it has been found to dissolve without decomposition in the 60-40 mole % lithium chloride-potassium chloride eutectic (5). The use of LiH in a fused salt-type battery appeared attractive due to its low molecular weight and even lower equivalent weight, based on the two-electron oxidation.

Experimental

Cell studies.—In the initial experimental work small pellet cells, which consisted of a lithium hydride anode, a LiCl-KCl eutectic electrolyte, and a $CaCrO_4$ cathode, were compacted in a dry argon atmosphere. The compaction was accomplished with a jackscrew press under 2100 kg/cm^2 (15 tons/in.^{2}) and resulted in pellets that were 0.95 cm (0.375 in.) long with an exposed electrode area of 0.97 cm^2 (0.150 in.^{2}).

The pellet cells were encased in silver cups which served as containers and electrode connectors. Activation heat was supplied externally. The pellet cells were discharged through an external variable resistor which held the cells at a constant voltage. In all the experimental work reagent grade LiH, as supplied by the Lithium Corporation of America, was used.

Single electrode studies.—In order to characterize the properties of the LiH electrode, a series of single electrode studies was conducted. Powdered LiH and dry eutectic electrolyte, 0.35 and 35g, respectively, were loaded into a 347 stainless steel crucible, which contained a nickel screen electrode of 50 mesh with an exposed electrode area of 6.45 cm^2 (1 in.^{2}) and a nickel wire reference electrode. The stainless steel crucible also served as the counter electrode. Details

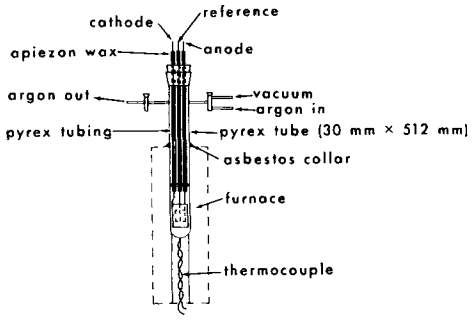

Fig. 1. Discharge cell assembly

of the cell assembly are shown in Fig. 1. The stainless steel crucible was loaded into a Pyrex furnace tube and resistively heated to 300°C under continuous vacuum. At this temperature a stream of dry argon was introduced, and the heating was continued until fusion occurred. At 380°C the LiH was anodically discharged by means of a d-c power supply. Single electrode measurements were obtained between the nickel working electrode and nickel reference electrode with a potentiometer. The potential determining species on the nickel working and nickel reference electrodes were lithium hydride and its oxidation products.

In separate runs the current was varied from 0.0775 to 1.55 amp/cm² (0.5-10 amp/in.²). In the higher current discharges from 0.775 to 1.55 amp/cm² (5-10 amp/in.²), the LiH concentration was increased to 3.3% in the electrolyte in order to increase the run time. In these discharges the argon flow was cut off, and the gas evolved during the oxidation of the LiH was collected in a 1000 ml gas buret. At open-circuit conditions, just prior to any discharge and just after termination of a discharge, the voltage between the reference and the working electrode was zero.

In addition to the nickel screen electrodes of 50 mesh size, nickel screen electrodes of 100 mesh size and nickel battery plaques of 80% porosity were used as discharge electrodes.

The coulombic efficiency was determined by considerations of the weight of a lithium hydride sample and the total coulombs passed during discharge, as compared to the theoretical coulombic capacity, based on the two-electron oxidation.

Concentration potential studies.—The effect of concentration on the potential of the LiH electrode was studied in a cell shown in Fig. 2. Nickel screen electrodes of 100 mesh size were suspended in each compartment of the cell, which contained different amounts of LiH dissolved in the KCl-LiCl eutectic. The furnace apparatus and methods of preparation were similar to those described in the constant-current discharges. Potential measurements were obtained under open-circuit conditions between 385° and 575°C.

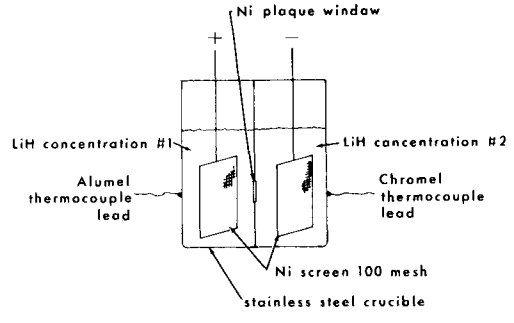

Fig. 2. Concentration cell

Results and Discussion

The Ag-LiH/KCl-LiCl/$CaCrO_4$-Ag pellet cells gave an open-circuit voltage of 2.15v. Flash currents of 3.1 amp/cm² (20 amp/in.²) could be obtained. During a typical discharge the cell voltage was held constant at 1v and in a 4-min period the current density gradually decreased from 0.775 to 0.31 amp/cm² (5-2 amp/in.²). When the cell voltage dropped below 1v, the discharges were terminated. These pellet cell discharges indicated that LiH could serve as an effective anodic depolarizer.

The effect of the different electrode materials in the constant current discharges is shown in Fig. 3, 4 and 5. In Fig. 3 it is observed that the polarization voltage, including the ohmic contribution, was higher for the 50 mesh nickel screen electrodes than for the plaque electrodes, although the effective discharge times for the screen electrodes were longer than for the plaque electrodes. In Fig. 4 the current-voltage plots indicate the polarization of the plaque electrodes was 50 mv lower than the screen electrodes throughout the discharges. The 100 mesh nickel screen electrodes had extrapolated polarization values that were in close agreement with the plaque electrodes. The slope of the current-voltage plots was 0.108 ohms. This is in excellent agreement with the 0.105 calculated resistance of the internal discharge circuit. Thus, the plateau polarization values, excluding IR drop, were constant in all the

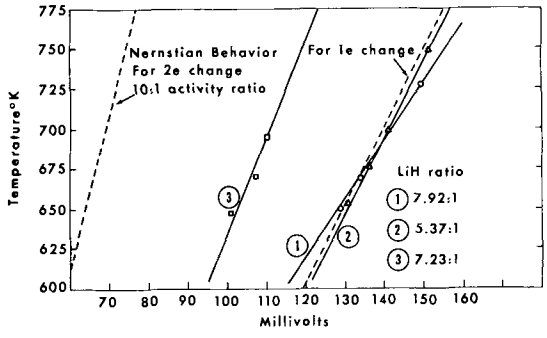

Fig. 7. Temperature *vs.* voltage for concentration cell

measured cases and had values of 50 mv for the plaque and 100 mesh nickel screen electrodes and 100 mv for the 50 mesh nickel screen electrode.

The screen electrodes gave consistently higher coulombic efficiency than the plaque electrodes as shown in Fig. 5. Based on the proposed two-electron oxidation, a coulombic efficiency of 71% was calculated for a particular discharge. The variations of the coulombic efficiency and the large amount of hydrogen gas produced during discharge suggested that two competing reactions were occurring. These may be given as:

$$LiH \rightarrow Li^+ + H^+ + 2e \qquad [1]$$

$$LiH \rightarrow Li^+ + \tfrac{1}{2}H_2 + 1e \qquad [2]$$

It is evident that reaction [1] would result in twice the coulombic efficiency of reaction [2]. In order to verify the proposed reactions, a V-tube stainless steel apparatus, shown in Fig. 6, was built to measure hydrogen evolution at the anode or cathode under various loads. If hydrogen was detected at the anode, reaction [2] had occurred. If hydrogen was detected at the cathode, reaction [1] had occurred followed by a reduction of the hydrogen ion. It can be said that hydrogen was produced at both the cathode and anode compartments. However, the gassing at the cathode compartment was slight at low current densities and reached a maximum at 0.31 to 0.465 amp/cm² (2-3 amp/in.²), which corresponds to the maximum in Fig. 5, the coulombic efficiency curve for the 50 mesh nickel screen.

The effect of concentration on potential can be seen in Fig. 7. In this case, if a one-electron process is assumed, the slope of the lines is 2.30 R/F, and if concentrations are substituted for activities, the behavior is essentially Nernstian. The dashed lines represent Nernstian behavior for the one- and two-electron processes assuming a 10 to 1 activity ratio. It can be noted that the behavior under open-circuit conditions closely approaches the one-electron process.

One of the most interesting and puzzling facts to emerge from the data is the difference in coulombic efficiency between the LiH electrodes of 50 mesh nickel screen and the plaque electrodes. Apparently the one-electron oxidation of LiH takes place on the plaque electrodes, and a mixed anodic oxidation occurs on the 50 mesh screen, the two-electron process occurring most readily at a current density between 0.31 to 0.465 amp/cm² (2-3 amp/in.²).

The lower polarization values on the plaque and 100 mesh screen are explained by their larger effective surface area. However, the increased polarization on the 50 mesh screen electrodes could drive the oxidation of LiH toward the two-electron process and thus account for the higher coulombic efficiency.

A calculation of $i \cdot t^{1/2}$, where i is current in amp/cm² and t is time in seconds, at the knees of the discharge curves for the 50 mesh Ni screen, led to a constant average value of 10.2. This suggested that the oxidation is a diffusion-limited situation and, when the hydride concentration in the bulk electrolyte decreases below a certain value, polarization becomes appreciable. At current densities below 0.155 amp/cm² (1 amp/in.²) this model breaks down. This is not unexpected as, at low current densities, diffusion limitations would become negligible.

Crystallogenesis in the Forming of Plates for the Lead-Acid Storage Battery

A. C. Simon and E. L. Jones[1]

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

Changes in microstructure have been observed during the forming of the positive and negative plates which provide clues as to the optimum conditions for formation. The microstructure produced was found to be dependent on the conditions under which forming took place. The conversion to lead dioxide in the positive plate was found to be initiated on the surface of a definite type of crystal, as yet not identified. The quantity, size, and shape of this crystal varied with the temperature and specific gravity of the electrolyte and with the current density employed. The indications were that a basic sulfate crystal was being converted directly to lead dioxide, without change in external form, through some solid-state reaction. The conversion to lead in the negative plate was definitely by solution of the lead sulfate and deposition of reduced lead. The form and size of the lead crystals in the negative could also be varied with method of forming, but not to the extent of those in the positive plate. While there was indication that subsequent life of the positive plate might depend on the microstructure developed during forming, there was no such correlation found for the negative plate.

Plates for lead-acid storage batteries of the type used for automotive purposes usually have as a support a lead alloy grid into which is spread a pastelike material consisting of a mixture of lead oxides to which sufficient dilute sulfuric acid has been added to produce a workable paste. Reaction of the oxides with the sulfuric acid produces a mixture of lead sulfate and basic lead sulfates that sets the paste into a cementlike mass. Electrolysis in dilute sulfuric acid then produces an oxidation to lead dioxide at the positive plate and reduction to a spongelike mass of lead crystals at the negative. The chemistry of this process has been very thoroughly investigated, but the physical changes that accompany these reactions have been largely ignored, and little or no attempt has been made to determine the crystallogenesis in the process.

Using the methods that have been described previously (1) an attempt was made to study the changes in microstructure that accompany the so-called forming, or conversion of the lower oxides of lead to lead dioxide and sponge lead. The experimental methods were extremely simple, and hindsight has shown that the microscopical observations should have been supplemented with data concerning single electrode and cell potentials during operation, the capacities developed by the various treatments, etc. These derelictions will be remedied in future investigations, but at the time this experiment was begun it was intended only to investigate the suitability of the method. The wealth of information obtained from the study of the few samples prepared was far beyond expectations and produced more questions than could be answered with the limited data that had been recorded concerning the experimental conditions. Experimentation is continuing under conditions conducive to the attainment of more complete data, and the results will be reported. Meanwhile, in view of recently published work by other investigators it appears advisable to report on this phase of the investigation and to point out its possible correlation with their data.

As will be shown in the description of the experimental results and subsequent discussion, the following observations, among others, were made which are considered of prime importance in influencing the course of future investigation.

1. There were observed to be two or more distinct species of crystal present in the positive plate. These could be formed either during mixing and drying or at a very early stage of formation. These separate crystal species could be readily distinguished by microscopic examination because of radically different crystal habit and chemical reactivity. They have not, as yet, been separated and identified with a definite chemical composition, but are assumed to be among the forms of sulfate which have been found in unformed battery paste by various workers. These forms are: normal lead sulfate, $PbSO_4$; monobasic lead sulfate, $PbSO_4 \cdot PbO$; the monohydrate of lead tribasic sulfate, $PbSO_4 \cdot 3PbO \cdot H_2O$; and tetrabasic lead sulfate, $PbSO_4 \cdot 4PbO$.

2. One of these crystal forms, in the unformed positive plate, consisted of needlelike or rectangular crystals, usually with much greater length than breadth. The conversion to lead dioxide was always observed to initiate on the surface of crystals of this type, which were in contact with the metal grid, and to spread from one crystal to another of this type at points of contact. The crystals were thus converted into lead dioxide without change of form. Crystals of this type will be referred to as type A in the subsequent discussion. From evidence accumulated by

[1] Died March 1, 1962.

others it is concluded that the large type A crystals must consist of either the monohydrate of tribasic lead sulfate, $PbSO_4 \cdot 3PbO \cdot H_2O$, or the tetrabasic lead sulfate, $PbSO_4 \cdot 4PbO$. After crystals of this type had been converted to lead dioxide there was a slower but continuous conversion of another type of crystal also found in the unformed paste.

3. This second form of crystal in the unformed positive plate always consisted of very small, regular polyhedrons of nearly equal size which were not changed in size, shape, or quantity by any method of forming used in the experimental series. This crystal form, subsequently referred to as type B, appeared to convert to lead dioxide with greater difficulty than did the type A crystals, and was converted only after a long time and after the prior oxidation of the type A. It is believed that this type of crystal represented either monobasic lead sulfate, $PbSO_4 \cdot PbO$, or normal lead sulfate, $PbSO_4$.

4. It was noted that the lead dioxide that formed on the surface of the large crystals of rectangular or needlelike form (type A) was always harder and more dense than that which formed on the small regular polyhedrons (type B). Evidence accumulated by others supports the assumption that α-PbO_2 is formed on the type A crystals while β-PbO_2 is formed on the type B crystals.

5. The large rectangular or needlelike crystals (type A) were sensitive to the forming conditions, and the size, shape, and quantity of these crystals could be altered considerably by changes in temperature, specific gravity of electrolyte, or current density. Under certain conditions the size and shape of these crystals became such that, on formation, the α-PbO_2 that formed on their surfaces created a hard, dense network or cellular structure throughout the active material.

6. Examination of cycled and floated plates obtained from commerical sources indicated that this network remained unchanged by service conditions which suggested that the creation of such a cellular structure would aid materially in positive plate active material retention, and it has been found by examination of a limited number of commercial plates that active material retention is indeed better in the presence of such a structure.

It should be realized that the experimental data from a microscopic examination of this sort consist of numerous photomicrographs which are best examined simultaneously or in various definite combinations to detect crystallographic changes. The limitations imposed by publication require a condensed written description that is admittedly confusing and lacking in conviction. For those sufficiently interested, more complete reports with additional illustrations are available (1) which cover various phases of this work.

The reminder should also be included that this series of experiments, dealing with the mechanism of forming, was performed on automotive type plates of one composition and manufacture only. Preliminary examination of other types of plate indicate that, in general, their crystallogenesis is somewhat different, but forming behavior is similar to that outlined for this plate. Exceptions have been found, however, even in such a preliminary examination so that it would be unwise to regard this behavior as universal.

Experimental Procedure

The microscopical method was based on the impregnation of samples, obtained at various stages in the forming process and under various controlled conditions of forming, with an epoxy resin and the subsequent examination at both low and high magnification of the microstructure revealed by sectioning and polishing the specimens. For convenience the experiment was divided into two parts. The first dealt with an examination of the changes in structure that occurred as the forming process proceeded, the second with the changes that could be induced by altering the forming conditions from those commonly employed by industry.

For the first part of the experiment a series of cells were constructed each consisting of one positive and one negative plate separated by a distance of approximately 1.3 cm. These plates were obtained in an unformed but dried condition from a manufacturer of storage batteries. The electrolyte consisted of sulfuric acid diluted with water to a specific gravity of 1.05. No effort was made to control the temperature of this experiment, but it remained fairly constant at about 27°C.

Following the information given by Vinal (2), the current density used was 0.25 amp/dm^2 (approximately 2.5 amp/ft^2). The cells were connected in series so that the same current passed through all. A cell was removed at ½-hr intervals during the first 8 hr, at 1-hr intervals for the next 4 hr, and finally at 2-hr intervals until no further change could be detected. The plates were thoroughly washed immediately after removal and after drying were impregnated with an epoxy resin, using vacuum. The plates were then cut in such a manner that sections could be obtained across the grid thickness both horizontally and vertically and also parallel to the plate surface but at varied depths beneath the surface. In this manner and after suitable polishing a rather complete picture of what had happened could be obtained.

To produce the second series of samples individual cells were prepared as in the previous case. The cells were arranged in groups with each group having acid of a different specific gravity, ranging from 1.05 for the lowest to 1.45 for the highest. One cell from each acid group was then placed in a constant temperature bath, and these cells when connected in series were all operated at the same current density. This was repeated at current densities of 0.023, 0.23, and 2.3 amp/dm^2. The water bath was then raised to a higher temperature and the process repeated with a new set of samples taken from each acid group as before. Temperatures employed varied from 4° to 80°C. The time that current flowed was so adjusted that regardless of current density each cell received the same total quantity of electricity. An automatic leveling device added water to maintain the electrolyte at constant level. In this and also the previously described series the unformed plates were allowed to

stand for 30 min at room temperature in electrolyte of the same concentration as employed in the experiment to insure that the plates were thoroughly wet with electrolyte and that gas evolution, apparently from carbonates which had formed in the dried plate, was finished so that electrolyte could enter the pores of the plate. As mentioned above all cells received the same total quantity of electricity, an amount selected so that no cell would have plates so completely formed as to make observation and comparison difficult and which would result in approximately one-third the amount required for theoretically complete formation.

As before, the samples were prepared for microscopical examination immediately on removal from the electrolyte. The samples were compared for similarities and differences at various magnifications ranging from a low of 13 diameters to a high of 1000 diameters to avoid the possibility of overlooking any feature because of its magnitude.

Observations

The progress of the forming process, the accompanying changes in color, and the variation in the relative amount of lead dioxide and lead produced under different conditions of forming were readily visible to the unaided eye on examination of the polished sections, but the details of the process were not revealed until microscopic examination was made of each specimen. Initially the unformed positive plate was a light yellow color while the unformed negative appeared gray. Under the microscope, using polarized light, both the positive and negative plates appeared to be yellow, although the negative was of a much lighter hue. The initial soaking caused considerable increase in the amount of sulfate which was made evident to the unaided eye by a fading of the yellow color in the positive plate, but which did not become evident in the negative until examination under considerable magnification. Under the microscope the resulting white or light yellow background caused the formations of the reddish-brown lead dioxide or metallic lead to stand out clearly.

The Mechanism of Formation—Positive Plate

In both the positive and negative plate the conversion to lead dioxide and lead, respectively, invariably began at the grid member. At low magnification the positive plate reaction was observed to proceed outward from the grid as a fairly uniform cylinder of lead dioxide with the exception that reaction appeared to slow down as the surface of the plate was reached, so that the cylinder became ovoid with its greater diameter parallel to the plate surface. There was a thin surface layer in which conversion to lead dioxide did not take place until quite late in the process so that the last portions of the plate to form were at the surface and at points midway between grid members. The material within the cylindrical area of reaction was not uniformly converted to lead dioxide, but in cross section presented a fernlike appearance as if the reaction were proceeding by the formation of branched filaments of lead dioxide. These features are illustrated in Fig. 1.

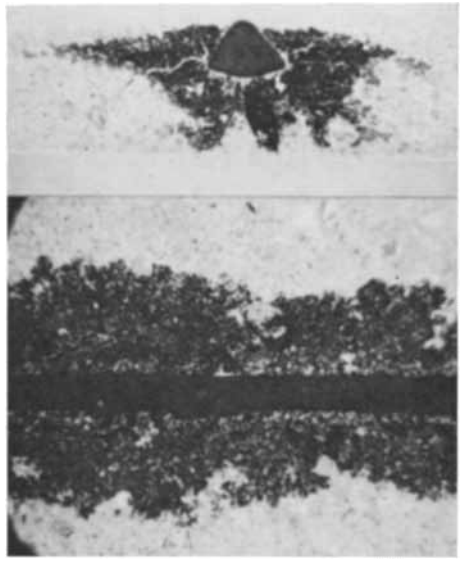

Fig. 1. Upper photograph: Cross section through the positive plate. The light areas represent unformed positive paste, the dark areas result from conversion of paste to reddish-brown PbO_2. Dark triangular area at top center is cross section of small lead alloy horizontal grid member as is also the dark line bisecting the lower photograph horizontally. Lower photograph: Section of same plate parallel to surface. Formation took place at room temperature, in 1.05 sp gr electrolyte, at 0.25 amp/dm^2 current density. Total time of formation was 6 hr. Note that cross section gives less misleading view of total area of formation than does plane section since latter gives widely varying areas at different depths. Magnification approximately 8X.

Examination at higher magnification revealed that the formed portions of the positive plate were made up of at least two varieties of crystal. Most numerous were the polyhedral crystals of nearly equal size, herein designated as type B. These were interspersed with larger crystals of a different configuration, herein designated as type A.

The small, polyhedral crystals, type B, were usually quite regular in form, but so small (2 or 3μ) that the general impression was of a rough sphere. These polyhedral crystals predominated under all of the conditions where formation to lead dioxide had occurred. Crystals identical in size and shape to these but consisting of sulfate were found in the unformed portions of the same plate and in the original dried paste of the plates as received from the manufacturer. These crystals did not vary significantly in size, shape, or number under any of the forming conditions used. It appeared that the polyhedral crystals of sulfate were being converted directly into lead dioxide without external change of form. It was found moreover that this conversion occurred subsequent to and with greater apparent difficulty than that which took place on a second form of sulfate present in the paste.

This second form of crystal (type A) appeared usually in the formed areas of the plate as long needlelike or rectangular crystals of lead dioxide. [The excellent electron micrographs of Buskirk, Boyd, and Smith (3) show thin plates of rectangular form at the surface of formed positive plates. There is a possibility that the crystals herein described may be of a similar form and appear needlelike only as a consequence of having been sectioned edgewise.

While the term needlelike will appear frequently in the subsequent discussion as a description of the actual appearance of the crystal in the section, the above possibility should be retained in mind.] This type A crystal varied in size, shape, uniformity, and quantity depending on the conditions under which forming took place, as will be discussed in a later section. The size of these type A crystals varied with the conditions from a maximum of about 150μ in length when long and needlelike to a minimum of about 10μ when short and rectangular. Crystals similar in size, shape, and frequency of occurrence were always found in the unformed portions of the same plate, indicating that these crystals were being converted directly from a sulfate to type A lead dioxide crystals without change in external form.

In the dried unformed plates as received from the manufacturer, the small, polyhedral crystals of type B predominated. Only a few of the type A crystals were formed and these were all long, slender needles with no hint of the rectangular structure seen in some of the plates after forming under certain conditions. Examination of unformed plates from several manufacturers, however, disclosed that in some of these the rectangular crystals of large size (type A) predominated. Thus it appears that the presence of the type A crystals can be induced either by certain conditions associated with paste composition, temperature, time of drying, specific gravity of the acid, etc., during pasting, or by the control of similar conditions in the forming process. In the present experiment it was certain that crystal structure of the crystals of type A was modified (and, in some instances, the number of crystals was changed) either during the soaking prior to passage of current or in that period at the beginning of current flow when no conversion to lead dioxide could be detected.

Fig. 2. Large needlelike crystals of what is presumed to be a basic sulfate overlaid with hard PbO_2. Each needlelike crystal is surrounded by a slightly less dark area of soft PbO_2 that formed on crystals of a much smaller type and at a later time than the overlay on the needlelike crystals. The white or very light areas represent unformed paste. Compare with Fig. 3. Formed at 4°C, in 1.25 sp gr electrolyte and 0.25 amp/dm^2 current density. Photographed by polarized light. Magnification approximately 650X.

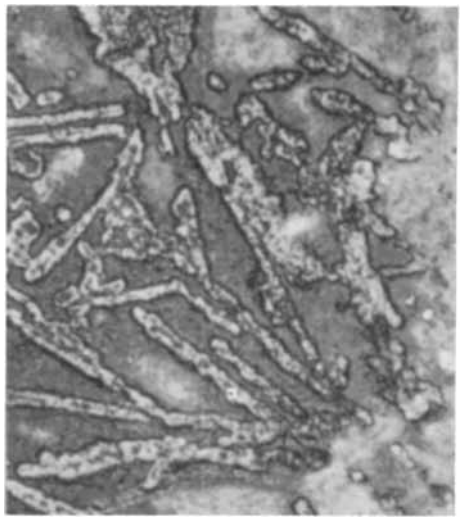

Fig. 3. More detailed view, of crystals similar to those shown in Fig. 2, obtained by relief polishing. The hard dense PbO_2 stands in relief, outlining the original crystal of basic sulfate, and because of its hardness is brightly reflecting. The softer PbO_2 surrounding these needles is featureless and dark in color while some as yet unformed paste may be seen as a featured, light colored material at upper and lower right margin. Photograph represents the type of crystal obtained when positive plate was formed at 30°C, in 1.05 sp gr electrolyte and 0.25 amp/dm^2 current density. Magnification approximately 650X.

It was also found that the initial oxidation always began on the surface of the larger crystals of type A, forming a hard dense layer of lead dioxide that caused these crystals to appear much darker than the small polyhedrons when illuminated by polarized light and to stand outlined in relief when subjected to relief polishing and oblique illumination with unpolarized light, Fig. 2 and 3. The reaction spread promptly and rapidly from one to another of this type A crystal wherever there were points of contact either with the grid or other crystals on which this lead dioxide layer had already formed. At a later stage in the forming reaction, and much more slowly, the small polyhedral sulfate crystals (type B) were converted to a softer, lighter hued lead dioxide. The fernlike appearance of the conversion boundary observed at lower magnification was a result of the initial stage of the reaction rapidly spreading through a thinly dispersed mass of the large crystals to cover a fairly large area while some of the small polyhedral grains in the spaces between these larger crystals remained unchanged at this stage. As a consequence an area of small polyhedrons adjacent to each large crystal was converted to lead dioxide which was sufficient in extent both to mask the outline of the original large crystal and to make the area visible at low magnification, but insufficient to completely fill the area between the points of primary reaction. (Since the conversion of both the large needlelike, and the small polyhedral crystals of lead sulfate to lead dioxide appeared to take place without change in external form of the crystal, the terms type A and type B will be used to identify the corresponding crystal shape in both its sulfate and dioxide form.)

It was also established that the presence of the large type A crystals was not absolutely essential for the conversion of the small polyhedral sulfate crys-

tals to lead dioxide crystals of type B. However, in the absence of the former, the process was extremely slow and required a much greater total quantity of electricity to convert a given area of plate than when they were present. For reasons that will be outlined later in the paper it is assumed that the initial formation process that resulted in the production of hard, dense lead dioxide on the surface of the large crystals produced the rhombic form of lead dioxide, α-PbO_2, whereas the later conversion of the small polyhedral crystals to a softer, lighter colored lead dioxide produced the tetragonal form, β-PbO_2.

Effect of Changing the Forming Conditions— Positive Plate

As to the second part of the experiment, that of studying the effect of changes in forming conditions, very definite and significant changes were noted, especially in the positive plate. In the first place, although all of the samples received the same total quantity of electricity, there was a decided difference in the amount of lead dioxide formed. It would be better, perhaps, to say that the area of lead dioxide in comparable sections varied rather than the amount since some doubt remains whether those plates that exhibited the greatest apparent coverage by lead dioxide would have indeed had the greatest capacity. This is because unformed material remained in all reacted areas, and in some cases reacted areas of small extent had also a noticeably lesser amount of unreacted material within this area or, in other words, a much higher density of reacted particles per unit area. Nevertheless, the size of the area converted to lead dioxide appears to be a good means of judging the efficiency of the process for several reasons. In order to reach the plate interior where reaction begins the electrolyte must diffuse through a relatively nonporous paste, consisting largely of lead sulfate which is a very poor conductor of electricity as well. Those particles that are converted to lead dioxide immediately become a much better conductor, and because the lead dioxide has a lesser specific volume than the lead sulfate the plate becomes more porous to the flow of electrolyte. The greater the area of formation for a given total current, the more easily should the balance of the unformed material be converted to lead dioxide because of the more extended circuit paths and greater porosity under these conditions. A careful study at higher magnification indicated that even with more reacted particles per unit area those plates with a small total area of reaction could not be as completely formed as those with a larger area of reaction.

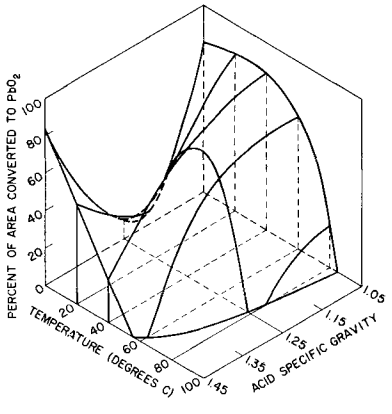

Fig. 4. This graph shows how the area of formed material in the positive plate varied as the specific gravity and temperature were changed although all samples received the same total quantity of electricity, using a current density of 0.025 amp/dm².

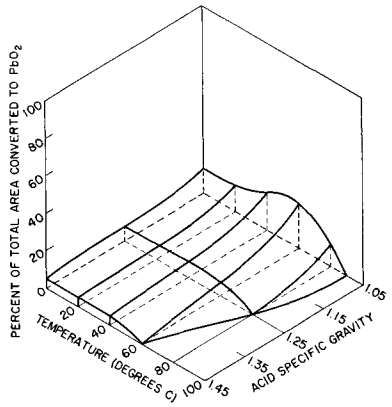

Fig. 5. As for Fig. 4, this graph shows variation of area of formed material in the positive plate with variation of temperature and specific gravity, but at a higher current density. The total quantity of electricity that these samples received was the same as in Fig. 4, but the much lower average area of formation was apparently caused by the use of the higher current density of 0.25 amp/dm².

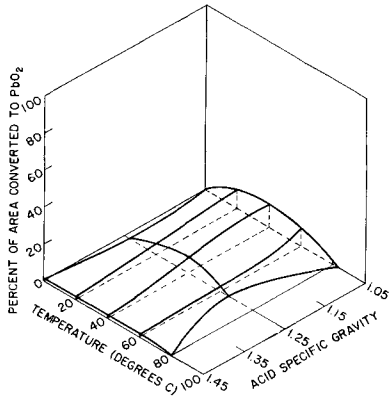

Fig. 6. Graph similar to Fig. 4 and 5 but showing the lowered area of forming in the positive plate when a current density of 2.5 amp/dm² was used. Comparison of Fig. 4, 5, and 6 indicates a maximum in area of formation at temperatures in the region of 40°-60°C, at the lowest specific gravity of 1.05 and at the lowest current density used, 0.025 amp/dm².

For the purpose of evaluating results, therefore, an estimate was made of the area of the plates involved in the forming reaction, ignoring the actual density of formed particles within this area. From these estimates, based on an averaged value of the plate surface, the sections parallel to the surface and cross sections, the graphs shown in Fig. 4, 5, and 6 were prepared. Each graph represents the variation in the total area of formed material with changes in acid specific gravity and temperature when the current density and total current are maintained constant. The successive graphs show the change in area, at a given acid specific gravity and temperature, with change in current density. The results indicate that the area of formation continuously increased with decreasing specific gravity of electrolyte and with

decreasing current density. In general the maximum area of formed lead dioxide, for a given specific gravity and current density, appeared between 40° and 60°C.

The microstructure of the positive plate was also found to vary with the conditions used in forming. This was not true of the small polyhedral crystals previously referred to as type B which apparently retained the same size and shape regardless of conditions, but applied to the larger crystals of type A on which the forming process appeared to initiate and which changed shape, size, and frequency of occurrence with changes in conditions. The subsequent description of the changes in crystal form is incomplete. There were not only variations in form that are not included, but variations in size and frequency of occurrence for a given type that would be superfluous to describe. The main point to be made is that change from one form to another of the type A crystal was reproducibly obtained and that definite correlation could be drawn between experimental conditions and the obtained microstructure. It might be wise to reiterate that the subsequent description refers only to the changes that occurred in the larger crystals of type A that produce the initial and harder form of lead dioxide, and not to the small polyhedral crystals that produced the subsequent softer form of lead dioxide, and which apparently were not influenced by the forming conditions.

The large crystals of lead dioxide fell into several main categories, and as has been mentioned, varied in size from 10 to 150μ. At the lowest current density, temperature, and specific gravity, Fig. 4, the area of formed lead dioxide was near the maximum. Yet under these conditions the lead dioxide so formed did not seem to be much harder than the original lead sulfate, because relief polishing produced only a uniformly smooth section in which the unformed areas could not be distinguished from those where formation to lead dioxide had occurred. (Relief polishing, done on a very soft lap with light pressure, tends to preferentially remove the softer material, leaving the harder exposed in relief on the surface. Any such irregularity in surface can be easily detected by using oblique illumination for the microscope.) It was found, however, that this apparently soft material contained large numbers of extremely long and thin needlelike crystals of lead dioxide, Fig. 7. These only became visible when the section was examined by polarized light. It is believed that these long crystals consisted of the hard, dense modification of lead dioxide, but that because of their thinness they could not be resolved in the relief polishing process. It is significant that in the as yet unformed portions of the same plate there were found sulfate crystals of similar shape and size.

When samples were compared in which the temperature and current density used in the forming had been the same, but in which the specific gravities of electrolyte had differed, the area of formation was found to decrease with each increase in specific gravity. At the same time the crystals of type A in the microstructure were found to become increasingly shorter, thicker, and more rectangular in outline as the specific gravity increased to about 1.25. As the crystals became shorter and more rectangular in shape they also increased in thickness, and it was found that a harder layer of lead dioxide had formed on the surface of the crystal than on the interior and that this hard material outlined the boundaries of the original crystal, Fig. 8. Thus, each increase in specific gravity of electrolyte produced structures that were more clearly outlined and had a more definite demarcation between the outer coating and the interior. Above a specific gravity of 1.25 this demarcation became increasingly less distinct, and at the highest value of specific gravity the formed area was small

Fig. 7. Illustrating the very long and thin needlelike crystals produced at low specific gravity of electrolyte, 1.05, and low temperature, 4°C. Such crystals were visible only by polarized light. These were produced at a current density of 2.5 amp/dm^2. At lower current densities they are even longer, but more difficult to see. Dark line at left is a portion of the grid. Compare these crystals with those of Fig. 2. Magnification approximately 650X.

Fig. 8. Illustrating the more rectangular type of crystal obtained with increasing specific gravity of electrolyte. Compare this figure where forming was at a specific gravity of 1.25 with Fig. 3, where the specific gravity was 1.05. Current density and temperature were as in Fig. 3. A portion of the grid metal alloy with segregated light-colored particles of antimony appears as a dark material at the left side of the photograph. Magnification approximately 650X.

and appeared to be uniformly soft. In this case no large crystals could be found with either relief polishing or polarized light, and it must be concluded that conditions were unfavorable to their formation. Under these conditions only the small polyhedrons were detected in either the formed or unformed portions of the plate.

It was found that for a given specific gravity of electrolyte and current density that the area of formation was at a maximum between 40°-60°C and decreased at both higher and lower temperatures. Temperature also influenced the microstructure. Thus, if at the lowest temperature there were present only the long needlelike crystals similar to those shown in Fig. 7, these were replaced at a higher temperature by the shorter, harder, more rectangular forms shown in Fig. 8, but usually of larger size. This latter form was almost invariably found at those temperatures where the area of formation was at a maximum. At still higher temperatures the open rectangular forms were replaced by large rough, irregularly shaped particles that had a uniform hardness throughout their cross section, Fig. 9, but which were not very numerous. In general, the effect of a temperature increase was to produce shorter, thicker crystals, with a more irregular outline than those formed under otherwise equivalent conditions but at a lower temperature.

Comparison of Fig. 4, 5, and 6 shows that with a given temperature and specific gravity there was an increasingly large area of formation as the current density was decreased. The microcrystals formed at the three current densities employed had roughly the same shape when compared at equivalent temperature and specific gravity of electrolyte except that the individual crystals were much smaller and more numerous for each increase in current density.

Mechanism of Formation—Negative Plate

The process of formation in the negative plate followed a quite different course from that in the positive. Initially reduction took place at the negative grid just as oxidation also originated at the grid of the positive plate. But whereas the lead dioxide formed a more or less uniform cylinder of reaction around the grid the negative plate reaction proceeded at once to the surface by the most direct route. This route was usually along both sides of any cracks that opened to the surface. Wherever the reaction reached the surface it spread rapidly to cover it, so that the two surfaces of the plate were quickly converted to crystals of lead although the interior of the plate remained unformed until long afterward, Fig. 10. This was quite the opposite to what occurred in the positive plate, and erroneous conclusions would have been obtained if the plate had not been sectioned.

In the original dried, unformed, negative plates used for these experiments only the small polyhedral lead sulfate crystals were found. In the formed or partially formed plates this also appeared to be the case. During the forming these crystals were observed to become translucent and finally to dissolve in the immediate vicinity of lead crystals already formed or at the grid. Under the conditions used for the first part of the experiment, where a study was made of sections removed at various stages of the forming process, the lead crystals that formed at the grid or on other lead crystals in contact with the grid were observed to have long needlelike structure and to be so densely intermingled as to make difficult individual examination, Fig. 11.

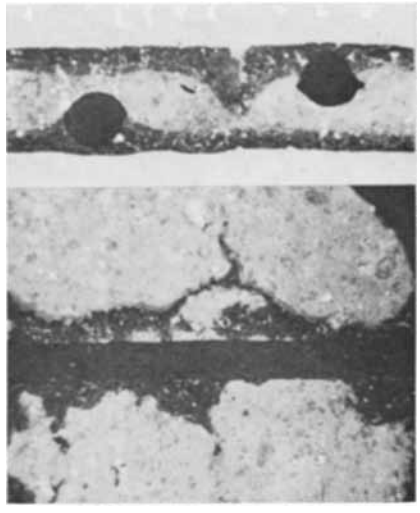

Fig. 9. The large irregular crystals that appear at high temperature. Note that these are hard and dense throughout and are surrounded by an area of the softer lead dioxide, which is shown as the dark featureless material surrounding the large grains. Do not confuse this with the dark appearing grid at the left of the picture. Unformed paste also appears at the right. Formed at 80°C, specific gravity and current density were as in Fig. 8. Magnification approximately 650X.

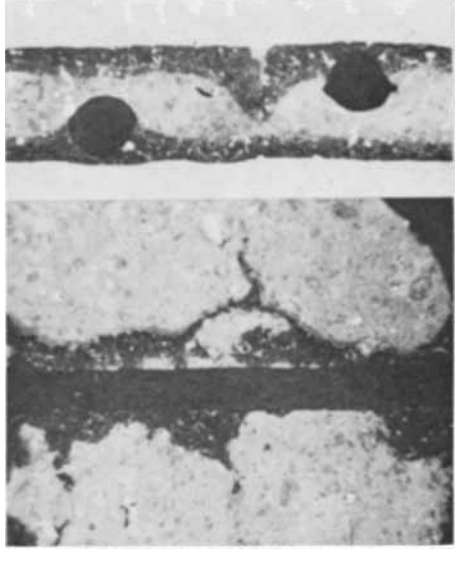

Fig. 10. Upper photograph: Cross section through negative plate after 6 hr forming time, showing how surface is formed prior to the interior. The two oval dark areas are cross sections through grid members as is the dark line that bisects the lower photograph horizontally. Lower photograph: Plane section of negative plate with 2 hr forming time. Note that formation does not proceed uniformly from the grid, but preferentially along the sides of cracks that allow entrance of electrolyte. Conditions of formation the same as for Fig. 1. Magnification approximately 8X.

Effect of Changing the Forming Conditions—Negative Plate

In the negative plate it was found that the greatest area of formed material was at a specific gravity of electrolyte of about 1.25, between 30° and 60°C and

Fig. 11. Appearance of lead crystals in the negative plate. Such crystals are scattered fairly uniformly throughout the area where formotion has occurred. The area containing such crystals increased with the time of forming rather than the number of crystals per unit area. As a result the material in the area between crystals, as shown here, would not be converted until quite late in the process. Toward the end of the forming period, however, the number of crystals of lead would enormously increase and would no longer be individually distinguishable. Magnification approximately 200X.

that current density did not have very much effect when the temperature and specific gravity was as stated above, Fig. 12, 13, and 14. As can be seen from Fig. 12 the lowest current density did cause an increase of the area of formed material when forming took place in low specific gravity electrolyte, but the amount does not appear to be significant. The combination of high temperature and high acid gravity not only produced no forming but caused actual shedding of plate material.

When the negative plates were examined at high magnification it was found that considerable change occurred in the structure of the lead crystals when the conditions of forming were varied. Since the lead crystals were definitely formed by deposition from solution after the dissolution of the necessary amount of lead sulfate their structure did not depend on the presence of any particular kind of crystal but only on the availability of lead ion.

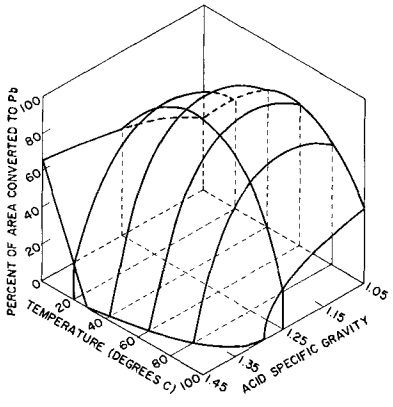

Fig. 12. Graph showing that a maximum occurred in the area of formed material of the negative plate when the electrolyte had a specific gravity of between 1.15 and 1.25 and was used at about 40°C. The same total quantity of electricity was employed for all samples and the current density was 0.025 amp/dm².

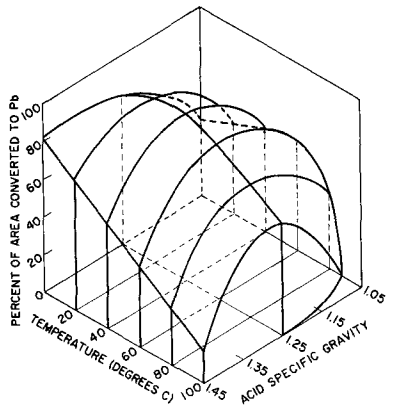

Fig. 13. Graph showing a very slight increase in area of formed material over the previous figure, but here the current density was increased to 0.25 amp/dm².

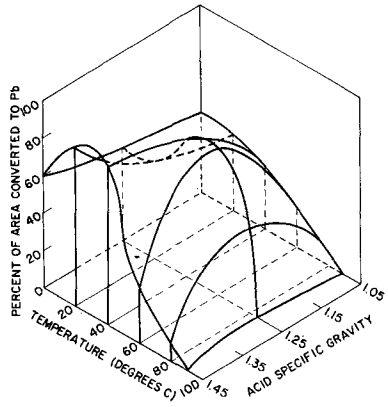

Fig. 14. Graph showing the somewhat lower area of formed material obtained when the current density was further increased to 2.5 amp/dm². Comparison of Fig. 12, 13, and 14 with Fig. 4, 5, and 6 indicates that current density had a more pronounced effect on positive plate formation than on that of the negative plate.

Two main types of structure were observed. Depending on the conditions employed the lead crystals were either long and needlelike or roughly spherical. It was suspected that the needlelike crystals at times had a branched structure, but they were usually so closely intermingled that it was difficult to determine this, Fig. 15. For the same reason there was a possibility that the so-called spherical crystal, since it showed no clearly defined faces, might in reality be a mass of needlelike filaments radiating from a common nucleus but with each needle so fine as to be below the limit of optical microscope resolution thus giving the impression of a solid spherical object, Fig. 16.

The major change in crystal appearance produced by varying the forming conditions was to alter the size of these crystals and to convert one type into the other. The largest crystals of the needlelike appearance were produced when temperature, specific gravity, and current density were all at the minimum of the series. The crystals did not appear very sensitive to changes in temperature within the range investigated. There was a slight tendency, however, for the average crystal size to become smaller as the temperature was increased. Change in the specific gravity of electrolyte had the most effect on crystal appearance. When the specific gravity was increased

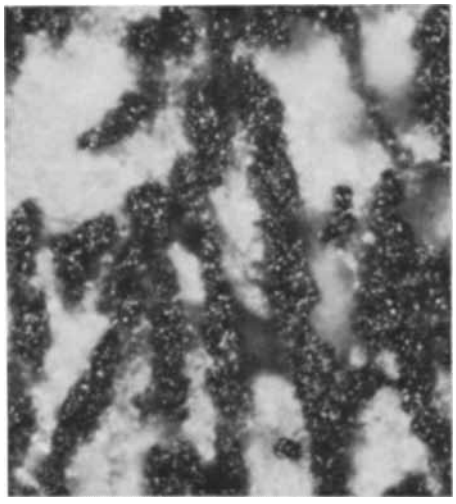

Fig. 15. View of the unusually large dendritic type crystals of lead formed in the negative plate at 4°C, an electrolyte specific gravity of 1.05 and at a current density of 0.025 amp/dm^2. The long lead filaments appear to have an irregular and porous surface that may possibly consist of much smaller secondary filaments. Magnification approximately 650X.

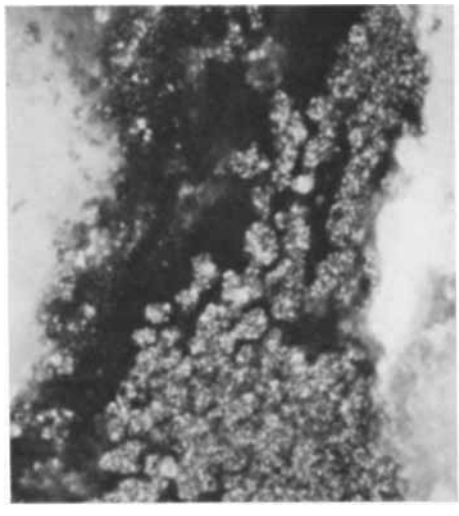

Fig. 16. View of the spherical type of lead crystals formed in the negative plate when the specific gravity of electrolyte was 1.45, the temperature 4°C, and the current density 2.5 amp/dm^2. Magnification approximately 650X.

the crystals were found to become coarser, that is, the needlelike forms became short and thick and appeared in dense groups. At the higher specific gravities these groups appeared to be replaced by the spherical particles of lead which, as has been said, might possibly be composed of many extremely small needlelike forms.

At a constant temperature and specific gravity, forming at an increased current density produced smaller crystals in the same manner as that caused by increasing the temperature when specific gravity and current density were held constant.

The most extensive area of formation occurred in the samples with the needlelike crystals and the minimum area of formation in those plates containing the spherical particles of lead. The area of formation was more extensive when the needlelike crystals were of small size than when they were large.

Discussion

The data obtained are insufficient to arrive at any definite conclusions, but some very interesting suppositions can be made, particularly in the case of the positive plate. There was definite evidence that a particular large type of crystal was the first to undergo reaction to form the lead dioxide. At the same time it was found that forming could take place in the absence of this type of crystal but apparently at a much slower rate.

It therefore appears obvious that this type of crystal which produces a crystal structure and affinity for oxygen so different from that of the far more numerous small regular polyhedrons must represent a different chemical compound. While determination of the identity of these compounds was not attempted in the present experiment it is possible to make a tentative identification based on previously published work.

Lander (4) established the composition of three compounds obtained by boiling water suspensions of lead monoxide, PbO, and lead sulfate, $PbSO_4$, in the proper ratios. Two of these compounds were found to be basic sulfates: tetrabasic lead sulfate, $PbSO_4 \cdot 4PbO$ and monobasic lead sulfate, $PbSO_4$ PbO. The third compound appeared to be a hydrate and was tentatively identified as the monohydrate of tribasic lead sulfate, $PbSO_4 \cdot 3PbO \cdot H_2O$. Ikari (5) studied the preparation of the monohydrate of tribasic lead sulfate and concluded that its formation was modified by the particle size of the PbO used and by whether the red or yellow modification was employed. The method of drying and the amount of CO_2 in the drying atmosphere also influenced the yield. Takagaki (6-8) and Ikari, Yoshizawa and Okada (9, 10) studied the basic oxides that were found in pasted plates made from various ratios of PbO and $PbSO_4$. They found variations in the amount of basic oxides and the points of maxima depending on whether they used the red or yellow form of PbO and on the size of the lead monoxide particles. They agreed on the additional significant observation that the tetrabasic lead sulfate was entirely absent from those pastes that were dried at temperatures below 60°C and was found in pastes that were dried above 80°C or steam dried, apparently formed at the higher temperature by the decomposition of the hydrated tribasic salt into the tetrabasic and monobasic forms.

The theoretical points of maxima in the PbO, $PbSO_4$ mixtures should occur at approximately 25 weight percent of the lead sulfate for the formation of tetrabasic lead sulfate, $PbSO_4 \cdot 4PbO$; at approximately 31% of lead sulfate for the formation of the monohydrate of tribasic lead sulfate, $PbSO_4 \cdot 3PbO \cdot H_2O$; and at approximately 58% of lead sulfate for the formation of monobasic lead sulfate, $PbSO_4 \cdot PbO$. None of the authors cited above reported agreement with the theoretical percentages under all of the conditions investigated, but Ikari, Yoshizawa, and Okada (9) appeared to attain agreement with these values when using steam dried pastes made from either modification of the lead monoxide with mean particle size of 0.9μ or

less. Takagaki (6) apparently reached agreement only when using the yellow modification and steam drying, but particle size was not specified.

In summarizing the work of these various authors it would appear that in mixtures containing from 0 to 25% $PbSO_4$ the unreacted PbO will diminish to insignificant amounts and the $PbSO_4 \cdot 3PbO \cdot H_2O$ will increase to a maximum at 25% $PbSO_4$. Provided the temperature of mixing has been maintained below 60°C no crystals of $PbSO_4 \cdot 4PbO$ would be expected. If the temperature has exceeded this value the amount of $PbSO_4 \cdot 3PbO \cdot H_2O$ found in this region will decrease greatly and be replaced by increasingly large amounts of $PbSO_4 \cdot 4H_2O$ as the amount of $PbSO_4$ in the original mixture increases toward 25%. Paste mixtures with from 25 to 60% will contain increasingly large amounts of $PbSO_4 \cdot PbO$ while $PbSO_4 \cdot 3PbO \cdot H_2O$ in significant amounts will disappear at about 45-50% and $PbSO_4 \cdot 4PbO$ will likewise become insignificant at about 31%. Paste mixtures above 60% $PbSO_4$ will contain increasing amounts of unreacted lead sulfate and decreasing amounts of $PbSO_4 \cdot PbO$ as the $PbSO_4$ content in the original mixture increases toward 100%.

Ikari, Yoshizawa, and Okada (9) and Dodson (11) found that the amount of α-PbO_2 found in a formed pasted plate increased as the specific gravity of the electrolyte used in forming decreased and as the density of the original paste used in forming increased. They also found that the amount of α-PbO_2 increased as the temperature used in formation was increased, but the temperatures used in their experiments apparently did not exceed 60°C. The Japanese authors also showed that an incubation period, after electroformation began, was required before PbO_2 could be detected in the paste. Both Dodson and the Japanese workers reported that α-PbO_2 was formed first, followed at a later stage in the electroforming by increasing amounts of β-PbO_2. Comparing these observations with those in the present paper that the first conversion to PbO_2 is at the surface of a particular species of crystal, that these crystals increase in number, length and regular habit with decreasing electrolyte specific gravity, current density, and temperature, and that these crystals apparently form as a first step in electrolysis, develops a strong suspicion that the hard dense surface layer on these crystals must be the α-PbO_2 observed by the earlier workers employing x-ray analysis. Further data from the cited papers indicate that maximum formation of α-PbO_2 occurred under conditions that would cause maximum formation of $PbSO_4 \cdot 3PbO \cdot H_2O$. This indicates that the observed crystals on which the PbO_2 formation first occurred were probably the monohydrate of the tribasic lead sulfate. Doubt is cast on this conclusion by Takagaki's photomicrographs (7) which show crystals similar in size and shape to those reported in the present paper but which he identified as the tetrabasic lead sulfate, $PbSO_4 \cdot 4PbO$. However, since the formation of α-PbO_2 is generally observed as a surface layer on the underlying crystal it is probable that in this layer of the crystal there has occurred some change prior to PbO_2 formation. This might be caused by the transformation of $PbSO_4 \cdot 3PbO \cdot H_2O$ into $PbSO_4 \cdot 4PbO$ and $PbSO_4 \cdot PbO$, as reported by Lander (4) or the formation of some as yet unidentified, relatively unstable, intermediate compound on the crystal surface. It is evident that further investigation will be required to settle this.

On the basis of the foregoing some very interesting speculation is in order concerning the ever present problem of increasing the efficiency and longevity of battery plates. For if a continuous film of hard dense lead dioxide is being formed on the surface of a particular crystal, the presence of a sufficient number of such crystals of the proper size and shape should ensure a continuous network of such hard structure throughout the plate and the separation of the softer material into small cells held together by the hard film, somewhat as shown in Fig. 17. This hard lead dioxide film should have a greater density than the surrounding softer material and therefore greater electrical conductivity. If it does consist of α-PbO_2 then this would assuredly be true because of the greater oxygen deficiency. Less electrical resistance would therefore be encountered between the grid and the more distant portions of the active material and the electron flow would be expedited.

Perhaps an even more important point would be the possibility of prolonging plate life by the retention of active material. Ikari, Yoshizawa, and Okada (13, 14) and Dodson (12) showed that the discharge capacity of the α-PbO_2 was not as great as that of the β-PbO_2. In experiments with solid electrodes of the two forms of lead dioxide (13) the Japanese workers showed that the dischargeable thickness when the porosity of the material was zero was between 0.3 and 0.4μ on α-PbO_2 and about 1μ on β-PbO_2. Provided a sufficiently thick film of

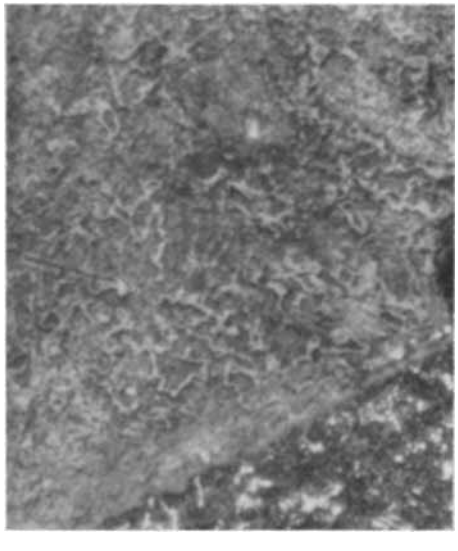

Fig. 17. Photomicrograph illustrating a type of structure that might assist in active-material retention and electrical conductance for the positive plate. Here the original crystals have been overlaid by a hard, dense surface layer of what is presumably α-PbO_2. These crystals are sufficiently interlaced so that this surface layer of PbO_2 when envisioned in three dimensions could act as a cellular network throughout the paste. Crystals were formed at 40°C, 0.23 amp/dm^2 current density, and 1.05 sp gr of electrolyte. Magnification approximately 650X.

α-PbO_2 was present initially on the appropriate crystal forms, it can be seen that the surface layer of lead sulfate formed by the initial discharge would be converted to β-PbO_2 on the next charge cycle and that subsequent charge-discharge cycles would tend to take place in this surface layer and that penetration into the underlying α-PbO_2 would occur very slowly or not at all. It has been reported by Ikari, Yoshizawa, and Okada (13) that when layers of α-PbO_2 were present under the β-PbO_2 that discharge of the β-PbO_2 occurred first, followed by the discharge of the α-PbO_2. These experimenters have also reported the interior of plates to be strongly alkaline even after long immersion in acid, and it is likely that the interior of a two-layer coating such as has been proposed would remain permanently in a state of low hydrogen ion concentration. The present authors in the light of the foregoing reports see no real obstacle to the formation of a network of α-PbO_2 throughout the mass of active material that would serve simultaneously as a continuous current path and a binder to retain and support the balance of the paste made up of small polyhedrons of β-PbO_2. By the mechanism previously outlined this network, provided it had sufficient thickness, would be covered by an outer layer of β-PbO_2 which would protect the underlying structure and alternate from PbO_2 to $PbSO_4$ with each cycle of charge and discharge. The underlying α-PbO_2 would not cycle at all or conversion would be at such a slow rate that many cycles would be required to destroy it.

In an attempt to confirm this line of reasoning an examination was made of a limited number of plates that were available with known performance data. It was found that in all cases of successful performance a type of structure such as has been anticipated and described above was present and still visible, for example, in plates that had been on open circuit for four years, or on float for nine. For the cases of unsuccessful operation it was found that a hard network was completely lacking although hard isolated particles were occasionally present. It was reported by Burbank (15), who studied the x-ray diffraction pattern of some of these plates, that those plates having the type of structure described above also gave evidence of large amounts of α-PbO_2 whereas those in which it was absent did not. The absence of the above described network of hard material and the simultaneous absence of α-PbO_2 in plates with unsatisfactory performance appears significant.

Further confirmation is supplied by the work of Dodson (12) in which he reported that on SAE Overcharge Life Tests the batteries containing α-PbO_2 outlasted production batteries, and the same appeared to be true of SAE Cycle Life Tests although the test results were not as conclusive as in the former case.

Since the reports of Dodson and of the various Japanese workers previously cited indicate the steps necessary to produce a paste with these characteristics it should prove to be a relatively simple matter to produce a positive paste of good retention and long life should these suppositions prove to be correct.

In the case of the negative plate the basic cause of failure is not loss of active material, but appears to be through the formation of large sulfate crystals that block the pores of the plate and through a gradual conversion of the needlelike lead crystals to polyhedral forms with much less reactive surface. There was no indication from the foregoing experiment that any solution to this problem could be found in the method used for the forming process. Here the mechanics of the process require the solution and reprecipitation of the crystals alternately either as lead or as lead sulfate according to whether the cell is charging or discharging. It does not appear likely that the form of crystal produced by the forming process could exist long enough to have any prolonged effect on performance.

The Behavior of the Metal-Oxide Interface During the Early Stages of the High-Temperature Corrosion of Aluminum

J. H. Greenblatt and J. T. N. Atkinson

Department of National Defense, Defense Research Board, Naval Research Establishment, Dartmouth, Nova Scotia, Canada

ABSTRACT

The oxide-metal interface of samples of two iron- and nickel-containing aluminum alloys and commercial aluminum was examined by optical microscopy after short exposures to high-temperature pure water. The initial attack proceeds faster on the second phase particles in the aluminum than on the surrounding matrix, but with time a reversal in relative corrosion rates occurs. The time at which this reversal occurs varies with temperature, and after it occurs the aluminum matrix surface recedes past the second phase particles leaving them isolated and not further corroded. The method of preparing the sample for examination is described briefly.

Draley *et al.* (1-3) have shown that aluminum can be made very much more resistant to corrosion in high-temperature water by alloying with cathodic metals, such as iron and nickel. Krenz and Biefer (4, 5) have reported considerable testing of two such alloys (alloy 10155 and alloy 10157) developed at Atomic Energy of Canada Ltd., and have correlated the enhanced properties of these alloys with presence of second phase particles in the metal and their size and distribution. This requirement for a uniform fine distribution of second phase particles had also been put forward by Draley and Ruther (6), Coriou *et al.* (7), and Brown *et al.* (8). Carlsen (9) has made observations on the behavior of second phase material when segregated in grain boundaries of cast alloys and showed that attack occurred more rapidly in these regions. However, in the previous work no specific information was obtained as to how the second phase particles themselves behaved.

The program of investigation at the Naval Research Establishment has concentrated on the initial period of film formation, and films from specimens exposed for periods varying from 1 min to 7 hr have been examined by electron and optical microscopy. Some of the results of this work, as reported previously (10-12), had revealed the behavior of second phase particles at the metal-oxide interface after 7 hr of exposure and the relation between these particles and topological features of the innermost and outermost surface of the oxide film. More recently, complete sets of exposures were completed on commercial aluminum and two special iron- and nickel-containing alloys over the time range 1 min to 7 hr at 5 different temperatures. Each metal-oxide interface was examined in detail on cross-sectioned samples using specially developed metallographic techniques (13-15). By following the condition of the oxide-metal interface during the initial stages of corrosion, this work has yielded new information on the behavior of second phase particles.

Experimental

The techniques and apparatus used in obtaining corroded samples are standard and have been used by the authors already cited as well as numerous others. As the focus in this work was on short exposure times, slight modifications were made in the more usual apparatus and these have been described previously in detail (10). In brief, a tandem autoclave system was used so that heated water at the proper temperature could be brought in contact with an annealed metal specimen, held at test temperature in argon, by turning a valve connecting both autoclaves. The exposure period was terminated by opening an exit valve and allowing the water to escape as steam.

The nominal composition of the alloys used is shown in Table I. This material was originally supplied by Atomic Energy of Canada Ltd. as ½ in. extruded rod and later material was obtained from the Aluminum Company of Canada as cast 100-lb ingots which were subsequently given the same physical treatment as the earlier material and finally extruded as ½ in. diameter rod. In the cast material the second phase particles were segregated in grain boundaries, but in the extruded rod the second phase material was dispersed. In alloy 10155 the second phase particles were larger and more irregularly distributed than in 10157. Such observations had also been made earlier by Biefer (4) in his work with these alloys.

Specimens 3/8 in. in diameter and 5/16 in. long were cut and machined from the extruded 1/2 in. rod, and then one end was polished metallographically to 0.25μ diamond in batches of 14 in a special jig. Following this the samples were degreased in refluxed trichlorethylene for 2 hr. The specimens were mounted on stainless steel racks

Table I. Nominal composition of alloys

Alloy	% Ni	% Fe	% Si
10155	0.5	0.5	0.2
10157	2.0	0.5	0.2
2S			

(Commercial) Fe + Si 0.4% total for typical material.

while in the autoclave and subsequently annealed for 2 hr in argon at 344°C in the dry autoclave. After this procedure, the samples were then brought to the test temperature while in argon, and water at the proper temperature admitted to the autoclave. Samples were exposed at 5 temperatures over the range 150°-350°C and for 8 times varying from 1 min to 7 hr.

After exposure, the samples were examined in cross section. To reveal greater detail at the oxide-metal interface the following technique was used. The specimens were coated with a thin film of aluminum by vacuum evaporation, mounted in diallyl phthalate plastic, and cross-sectioned by grinding on the sample preparation wheel. This procedure has been described in detail previously (13-15) and leads to mounted specimens, with excellent edge preservation, clearly revealing the detail at the interface.

After mounting and cross sectioning, the specimens were polished down to 0.25μ diamond on waxed Pellon[1] disks given a final polish to 0.1μ using Gamal.[2] Following polishing, specimens were etched for approximately 3 sec in dilute HF (10 drops of 28% HF in 100 ml water). The etching time was governed by the thickness of the evaporated aluminum film, and when this was thin, the samples were given a lighter etch. The specimens were then washed in water and alcohol, hot air dried, and examined. All grinding and polishing down to 0.25μ was done with kerosene as a lubricant, while polishing with Gamal was done in water. The specimens were photographed at a magnification of 800 using 35 mm film to record the data. The polishing technique is currently undergoing further refinement and will be described in detail elsewhere when fully developed. For each exposure condition at least one representative photograph was taken, and for thicker corrosion films at longer exposure times and higher temperatures more than one photograph was taken.

Results

In general the results for very short exposures, *i.e.*, 1-30 min, revealed considerable difference from the behavior at the interface previously observed for the 7-hr samples. The difference was a reversal in the electrochemical behavior of the second phase particles. Whereas in the previously described 7-hr work, the second phase particles of the alloys were observed to be uncorroded and standing proud of the surface, at 1 min they were more rapidly corroded than the surrounding aluminum, and pitting initiated in the second phase particles. Blanks that had gone through the cleaning and annealing cycle, but had not been exposed to high-temperature water showed no attack of the second phase particles. With 10155 the second phase particles were larger than with 10157, and the pits in them were correspondingly larger.

Examples of conditions at the metal-oxide interface for these alloys are shown in Fig. 1-4. Figure 1 shows the metal-oxide interface of 10155 after 1 min of exposure at 150°C, and the more rapid attack on the second phase particles is clearly seen. Such behavior also occurred at the highest temperature of exposure as can be seen in Fig. 2 at 350°C. By 10 min of exposure at this higher temperature the reversal in relative rates had occurred and the aluminum matrix was receding faster. Figure 3,

taken after 2 hr exposure at 350°C, shows small second phase particles just isolated within the oxide and in the process of being isolated at the oxide-metal interface, as the aluminum matrix recedes past them. In Fig. 4 the interface of 10157 after 1 min exposure at 250°C is shown. Again with this alloy it is seen that the initial corrosion attack proceeds rapidly on the second phase particles. The empty pits in the aluminum are presumably the sites of small second phase particles that have been completely corroded. A summary of the behavior of the particles at the corroding interface is given in Table II.

The behavior of 2S, although analogous, does not follow such clearly defined trends. With this material, several types of behavior can be distinguished in the second phase particles. The very small ones that always appeared blue under the microscope were invariably uncorroded and remained so and were usually eventually isolated from the surrounding aluminum matrix. The larger particles were initially more rapidly corroded; some appeared to maintain the more rapid corrosion over the entire range of times and temperatures investigated, while others appeared to change, since with time the aluminum around them corroded faster than the particles. The latter tendency results in an evening out of the surface over some sections and the partial or complete isolation of the remnants of the second phase particles in the oxide. The particles that did not change continued to corrode faster than the surrounding aluminum, leading to deep irregular pits. Grain boundary attack leading in from the surface was observed at higher temperatures and appeared consistently at 350°C. With 2S at longer exposure times there were also a few examples of slower corroding second phase particles protruding through the metal-oxide interface, and the corrosion of the aluminum for regions immediately sur-

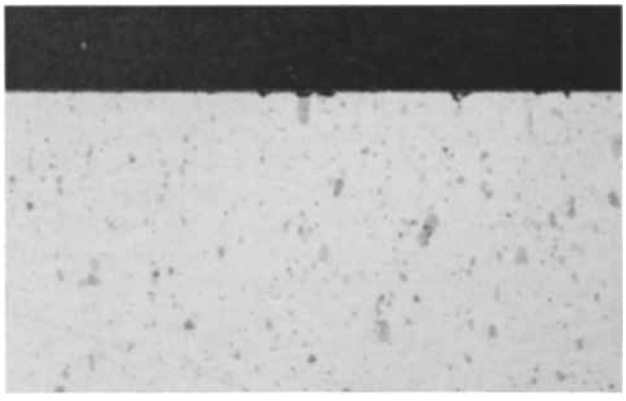

Fig. 5. Cross section of 2S alloy at 1000X after exposure to water at 150°C for 1 min.

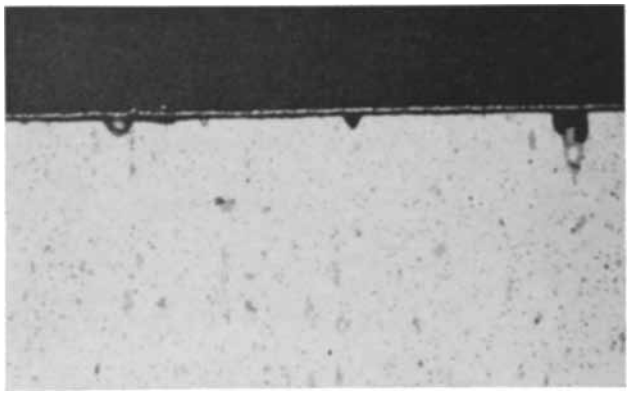

Fig. 6. Cross section of 2S at 1000X after exposure to water at 250°C for 2 hr.

rounding these particles resembled that of the special alloys.

Typical behavior for 2S is shown in Fig. 5 and 6. In Fig. 5 after 1 min of corrosion at 150°C it can be seen that a large second phase particle has corroded faster than the matrix. In Fig. 6 the interface after 2 hr exposure at 250°C is seen. At the extreme left of the figure is an oxide filled cavity with pieces of second phase particles isolated in the oxide. To the right of this can be seen one of the small blue second phase particles that were always observed to be slower corroding than the surrounding aluminum, and on the extreme right a large second phase particle becoming isolated in a pit formed in the now more rapidly corroding surrounding aluminum.

The vacuum evaporated film of aluminum on all samples varied in thickness, and when thin, a limitation was imposed on the time a specimen could be etched to bring up microstructure, lest this aluminum boundary be etched off. For this reason the contrast of the photographs presented varies to some extent, with the microstructure etched up more clearly in the case of thick aluminum covering films than thin ones. This difference can be seen by comparing Fig. 4 and 7.

Observations on the whole of the sample interface rather than on the fields of view selected for photography show that the conclusions as to the behavior of second phase particles are generally correct and that the summary in Table II is a valid one for their behavior.

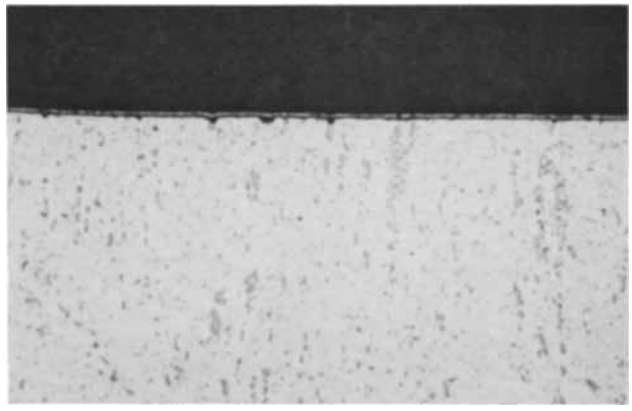

Fig. 7. Cross section of 10157 at 1000X after exposure to water at 150°C for 10 min.

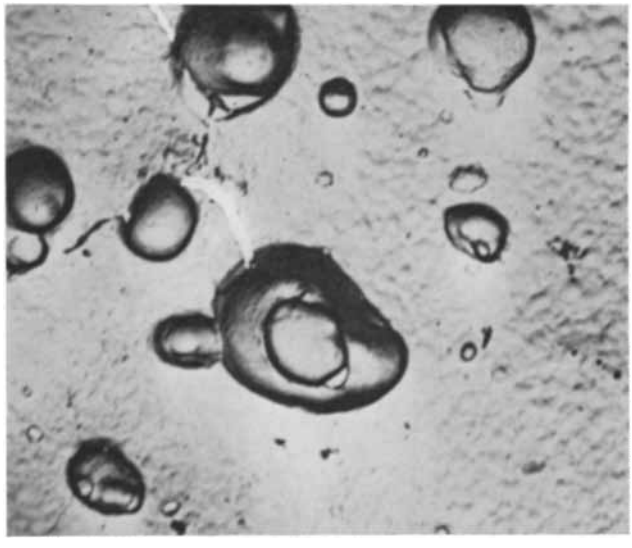

Fig. 8. Electron micrograph of the inner surface corrosion film on 10155 alloy at 6000X after exposure to water at 300°C for 1 min.

Electron micrographs of the surface of the oxide film give corroborating evidence of the pitting of the second phase particles. Electron micrographs of the oxide-metal interface of 1 and 5 min samples, which were previously reported (10, 12), showed that the film protrudes into cavities in the metal. In the earlier reports, it was presumed that these mounds on the underside of the film were due to excessive corrosion of aluminum around the second phase particles, and the depressions observed in the mounds corresponded to the already isolated second phase particles. The cross sections of samples exposed 1 min show that this is not the case, but that the pitting to which the mounds correspond is in the second phase particles themselves. Figure 8 shows an electron micrograph of the inner surface (oxide-metal interface) of the oxide film on 10155 alloy at 6000X after 1 min exposure to water at 300°C showing typical mounds.

Discussion and Results

The results of the present study show that, in the early stages of corrosion, the second phase particles in the alloys tested, with the exceptions noted for 2S, corrode faster initially than the surrounding aluminum, but subsequently a reversal of behavior

occurs. Stimulation of a preferential attack, by cathodic current densities of the order of 0.1 ma/cm^2 at 100°C, has been observed by Carlsen (9, 16) in the eutectic precipitated in the grain boundaries of cast iron and nickel containing aluminum alloys. One possible explanation of our observations of more rapid initial corrosion of second phase particles could be based on Carlsen's concept of cathodic stimulation. However, other work done by us on the effects of cathodic polarization on the corrosion of the alloys described in this paper has shown no effect of current densities of up to 0.1 ma/cm^2 and greater over a 24 hr period at 300°C. Thus Carlsen's observations may not be extrapolated unequivocally to our operating conditions. Figure 2 shows that the preferential attack is still occurring at the much higher temperatures. An alternate explanation is that the second phase particles are initially anodic, but that once a film forms over the specimen the rate of attack on the particles slows down while that on the aluminum continues. The information on hand at present does not allow an unequivocal choice of either alternate, but the authors prefer the latter.

Regardless of which possible explanation is correct the initial, more rapid attack on the second phase particles must produce an oxide film enriched in dissolved iron and nickel which may affect the subsequent corrosion behavior of the alloys. Thus Draley *et al.* (6) have found marked influence of such variables as start up time on the corrosion resistance of aluminum alloys, the nickel- and iron-containing alloys showing better resistance to steam with a slow start up than with a fast one. Our data indicate more corrosion of the second phase particles at low temperature than at high, and thus a slow start up would yield an initial film more enriched in iron and nickel than those with fast start up. In addition, polarization measurements made *in situ* in autoclaves have indicated that the resistance of the films on iron and nickel containing alloys is considerably less than that of 2S. Current-voltage curves obtained on specimens with preformed films indicate that the films on the alloys have many different properties than those on 2S, *e.g.*, they do not show the same rectifying properties and they require less energy to promote additional conducting electrons from the valence bands of the oxide. Such properties must be related to the dissolved iron and nickel ions in the aluminum oxide.

With the passage of time, the noncorroding second phase particles protrude and eventually become isolated in the oxide where they can act to decrease further its resistance by providing a metallic path through an otherwise insulating medium. The effects of decreased oxide resistance by this mechanism, in causing the hydrogen discharge to occur at the oxide water interface, have been discussed by Brown (8) as one alternate explanation to Draley's original hypothesis that the iron and nickel alloying elements function as cathodes for the discharge of hydrogen (1-3).

The data presented in this paper show that the role of the second phase particles is not as simple as originally conceived and that ideas on what actually occurs must be modified in the light of the information presented.

On The Defect Structure of Ta_2O_5

Per Kofstad

Central Institute for Industrial Research, Blindern, Oslo, Norway

ABSTRACT

The defect structure of Ta_2O_5 has been studied by measurements of the electrical conductivity and the weight change of Ta_2O_5 as a function of the partial pressure of oxygen. Ta_2O_5 exhibits p-type conductivity at pressures close to 1 atm oxygen and n-type conductivity at lower oxygen pressures. The defect structure is interpreted in terms of interstitial oxygen ions (p-type) and oxygen vacancies (n-type). Ta_2O_5 has been found to have a small homogeneity range. The heat of formation of oxygen vacancies is $\Delta H_v \geqq 150$ kcal/mole.

Tantalum is receiving considerable attention as a material for high-temperature applications. A major shortcoming of tantalum under such conditions is, however, its great reactivity with oxygen and other gases.

Above 800°C and during initial stages tantalum shows a parabolic oxidation behavior (1). This is interpreted in terms of a rate-determining transport of oxygen ions through a growing oxide scale consisting of Ta_2O_5. For a better understanding of the oxidation mechanism it was desirable to study the defect structure of Ta_2O_5. For this purpose the electrical conductivity of Ta_2O_5 has been studied as a function of oxygen pressure at high temperatures. In addition, attempts have been made to study the weight change of Ta_2O_5 under corresponding conditions. The work also constitutes part of a more general study of defect structures and diffusion in metal oxides (2-5).

According to Lagergren and Magneli (6) and Wasilewski (7) Ta_2O_5 exists in two modifications with a transition temperature of 1320° ± 20°C. The low-temperature modification, β-Ta_2O_5, is isostructural with the low-temperature modification of Nb_2O_5, γ-Nb_2O_5 (8-10). In disagreement with the above results Schönberg (11) found no high-temperature modification of Ta_2O_5. The melting point of Ta_2O_5 is approximately 1470°C.

Attempts to reduce Ta_2O_5 with tantalum metal have mostly proved unsuccessful (6, 7, 12). However, Lapitsky, Simanov, and Artamonova (13) report having produced TaO by reduction of Ta_2O_5 with tantalum metal, magnesium, carbon monoxide, or carbon.

There does not appear to have been any previous investigations of the defect structure of Ta_2O_5.

Material and Methods

The studies on Ta_2O_5 were carried out in conjunction with investigations of the oxidation behavior of tantalum. The oxide was therefore prepared by oxidizing tantalum metal powder in air. The tantalum powder was supplied by National Research Corporation. The amount of impurities in the metal powder was as follows: Fe, Cr, Ni, and Nb, each 0.01%; Si and Al, each <0.025%; Mg, Ti, Zr, Cu, and Co, each <0.005%. Specimens were prepared by sintering cold-pressed oxide powder in air at 1400°C. After this treatment the specimens had a density of approximately 65% of theoretical density (8.73 g/cm³).

The thermogravimetric measurements were carried out with a quartz helix-type apparatus. Measurements were carried out in 1 atm O_2 and in mixtures of CO + CO_2 with a total gas pressure of 1 atm. Detailed descriptions of both the apparatus and the procedure used have been given elsewhere (2).

In the measurements of electrical conductivity the specimen had a cylindrical shape with a diameter of 1.4 cm and a length of 1.3 cm. Two Pt-10% Rh plates served as electrodes. In the measurements of thermoelectric force a small platinum wound furnace was placed in contact with one of the electrodes. The temperature of the specimens was measured with two Pt-Pt 10% Rh thermocouples melted to the electrodes. The resistance of the specimen was measured with a Wheatstone bridge.

Measurements were carried out in pure oxygen and in mixtures of CO + CO_2. During measurements at low oxygen pressures, oxygen was continuously pumped through the system. Measurements were taken at both increasing and decreasing partial pressures of oxygen. A more detailed description of the apparatus and the procedure has been given elsewhere (4).

Results and Discussion

Thermogravimetric studies.—By comparing with thermogravimetric studies on α-Nb_2O_5 (2) it was expected that the defect structure of Ta_2O_5 could be studied by the same technique. Several attempts were therefore made to study the weight change of Ta_2O_5 specimens as a function of oxygen pressure at temperatures of 1200°-1400°C. However, in these studies only very small weight changes were observed when equilibrating the specimens successively in 1 atm O_2, in mixtures of CO + CO_2, and in pure CO. If the formula of the oxide is written as Ta_2O_{5-x}, the maximum weight loss observed in going from 1 atm O_2 to 1 atm CO ($p_{O_2} \sim 10^{-15} - 10^{-16}$ atm) correspond to a change in the value of x of about 0.005-0.006 at the indicated temperatures. Furthermore, because of the small magnitude of the weight

changes it was not possible to evaluate their oxygen pressure dependence.

The small weight changes may of course be due to slow kinetics. However, specimens were held in CO atmospheres for periods up to 2-3 hr without any further weight loss. Furthermore, in the electrical conductivity studies at the same temperatures equilibrium was established as fast as the oxygen pressure could be changed from one value to another. Thus it appears that the small weight losses are not due to slow kinetics; rather, it is concluded that this reflects a very small homogeneity range for Ta_2O_5 and a correspondingly large free energy and heat of formation of defects. As discussed below this conclusion was also confirmed by the electrical conductivity measurements.

From the above values ($x=0.005$ at 10^{-15} atm) a rough estimate may be made of the partial molar free energy of dissociation. This is given by $\Delta\bar{G}_{O_2} = -RT \ln p_{O_2}$, and at $x = 0.005$ and $T = 1500°K$ the value of $\Delta\bar{G}_{O_2}$ is about 100 kcal/mole.

Studies of electrical conductivity.—The results of the studies of electrical conductivity as a function of oxygen pressure are shown in Fig. 1, in which the logarithm of the resistance of the specimen has been plotted as a function of the logarithm of the partial pressure of oxygen at temperatures ranging from 877°-1380°C. The results at 1380°C suggest an anomalous behavior. This may be due to the fact that one is dealing with the high-temperature modification of Ta_2O_5 under these conditions.

From Fig. 1 it is seen that the oxygen pressure dependence is a function of the partial pressure of oxygen. Expressing the resistance as

$$R = \text{const. } p_{O_2}^{\ n} \qquad [1]$$

it is found that the exponent n has a value of 1/6 at the lower oxygen pressures. With increasing partial pressure of oxygen n increases to 1/5-1/4, after which the value of n again decreases and the resistance goes through a maximum. At oxygen pressures higher than that of the maxima n takes on small negative values. The maxima in the resistance become more pronounced and are found to be displaced toward lower oxygen pressures with decreasing temperature.

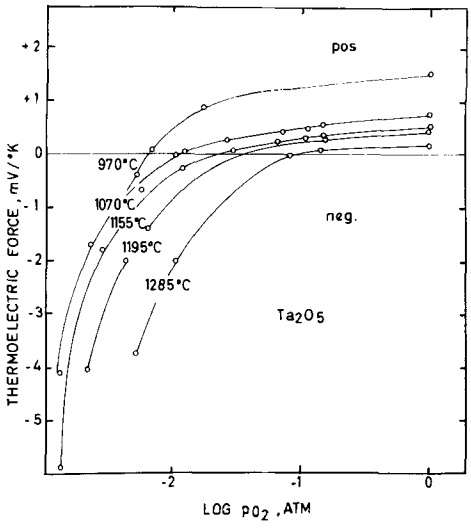

Fig. 2. Thermoelectric force of Ta_2O_5 specimen as a function of the logarithm of the partial pressure of oxygen.

A positive value of n indicates n-type conductivity in the oxide, while a negative value suggests p-type conductivity. The maxima in the resistance *vs.* p_{O_2} curves thus suggest a transition from an n-type to a p-type conductivity.

To study this, measurements of thermoelectric force were carried out. Results are given in Fig. 2. A positive thermoelectric force was found at oxygen pressures higher than those of the maxima, while at lower oxygen pressures a negative thermoelectric force was observed. On this basis it is concluded that the maxima do represent transitions for n- to p-type conductivity.

The p-n transition takes place at lower oxygen pressures with decreasing temperature. This relationship is illustrated in Fig. 3 where the logarithm of the oxygen pressure at the p-n transitions is plotted as a function of the reciprocal absolute temperature.

For an n-conducting oxide with a defect structure involving oxygen vacancies, the defect structure

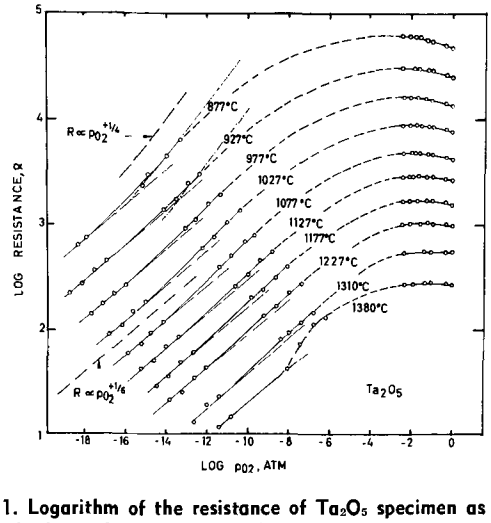

Fig. 1. Logarithm of the resistance of Ta_2O_5 specimen as a function of the logarithm of the partial pressure of oxygen.

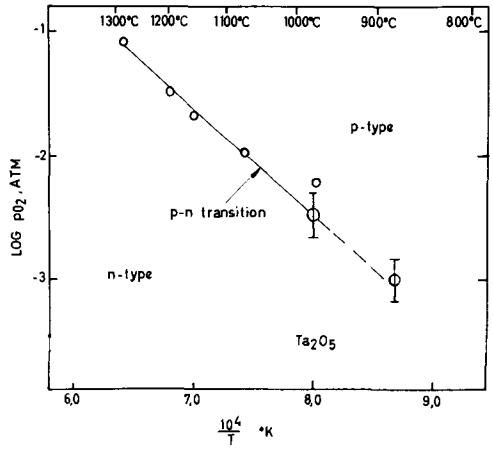

Fig. 3. Logarithm of the oxygen pressure at p-n transitions as a function of the reciprocal absolute temperature. Open circles taken from Fig. 2, values at 877° and 977°C from maxima in Fig. 1.

may be described by the following equations (2, 4)

$$O_i^{=} = Ov + 1/2\ O_2^{(g)} \quad ; \text{Equil. const.} = K_a \quad [2]$$

$$Ov = Ov^{\cdot} + e^{-} \quad ; \text{Equil. const.} = K_b \quad [3]$$

$$Ov^{\cdot} = Ov^{\cdot\cdot} + e^{-} \quad ; \text{Equil. const.} = K_c \quad [4]$$

$$Nil = e^{+} + e^{-} \quad ; \text{Equil. const.} = K_d \quad [5]$$

Ov denotes an oxygen vacancy with two trapped electrons, $Ov^{\cdot}$ and $Ov^{\cdot\cdot}$ represent singly and doubly ionized oxygen vacancies, respectively, e^{+} denotes an electron hole and e^{-} an electron in the conduction band. Equation [5] describes intrinsic ionization.

By applying the condition of electroneutrality and the law of mass action the concentration of electrons, $[e^{-}]$, is given by

$$[e^{-}]^3 = K_a K_b p_{O_2}^{-1/2} (2K_c + [e^{-}]) + K_d [e^{-}] \quad [6]$$

The following limiting conditions may be considered:

i. if intrinsic ionization (Eq. [5]) predominates

$$[e^{-}] = K_d^{1/2} \quad [7]$$

ii. if intrinsic ionization is negligible and if

$$(a)\ 2[Ov^{\cdot}] >> [Ov^{\cdot\cdot}] \ (i.e., [e^{-}] >> 2K_c)$$

$$[e^{-}] = (K_a K_b)^{1/2} p_{O_2}^{-1/4} \quad [8]$$

$$(b)\ 2[Ov^{\cdot}] << [Ov^{\cdot\cdot}] \ (i.e., [e^{-}] << 2K_c)$$

$$[e^{-}] = (2K_a K_b K_c)^{1/3} p_{O_2}^{-1/6} \quad [9]$$

Thus for an oxide with oxygen vacancies the value of the exponent n (Eq. [1]) may vary from $n = 1/4$ to $n = 0$ depending on the relative values of K_a, K_b, K_c, and K_d.

The temperature dependence of the equilibrium constants may be expressed as

$$K = K_o\, e^{-E/RT} \quad [10]$$

where E is equal to ΔH_a (Eq. [2]), E_b (Eq. [3]), E_c (Eq. [4]), and $Ed_{/2}$ (Eq. [5]). ΔH_a represents the heat of formation of an oxygen vacancy with two trapped electrons, E_b and E_c denote the ionization energies of the first and second trapped electrons, respectively, and E_d represents the intrinsic energy gap.

A p-type conductivity in oxides may be ascribed either to cation vacancies or to interstitial oxygen ions. Marker studies in connection with initial parabolic oxidation of tantalum at 1 atm O_2 at temperatures above 800°C suggest that oxygen ions are the most mobile species in Ta_2O_5 (1). It thus seems reasonable to assume that the p-type conductivity in Ta_2O_5 at the higher oxygen pressures may be ascribed to interstitial oxygen.

Defect structures involving interstitial oxygen has been considered unlikely on the grounds of an unfavorable size factor of the O^{-2}-ion (14). However, interstitial oxygen should not be excluded on the basis of size considerations alone; factors such as polarizability of the oxygen ions and the correspondingly better accommodation should also be taken into account. Furthermore, interstitial oxygen may also be present as singly ionized ions, which are more favorable from a size standpoint.

Interstitial oxygen may be described by the equation

$$1/2\ O_2 = O_i^{-2} + 2e^{+}; \text{Equil. const.} = K_e \quad [11]$$

where O_i^{-2} represents an interstitial oxygen ion.

Applying the law of mass action and combining Eq. [5] and [11] the concentration of charge carriers is given by

$$[e^{+}]^3 = 2K_e p_{O_2}^{1/2} + K_d [e^{+}] \quad [12]$$

Equation [11] could of course be considered in more detail, similarly to Eq. [3], [4], [5], and [6].

The present results are interpreted in terms of the above considerations. At the maxima in the resistance *vs.* p_{O_2} curves (Fig. 1), where the conductivity is independent of oxygen pressure, it is concluded that the conductivity is essentially determined by the intrinsic ionization (Eq. [7]). At oxygen pressures higher than those of the maxima the defect structure predominantly involves interstitial oxygen ions (Eq. [12]) and at the lower oxygen pressures predominantly oxygen vacancies (Eq. [6]). At the maxima it is also believed that the oxide has an approximately stoichiometric composition with some anti-Frenkel defect structure (involving both oxygen vacancies and oxygen interstitial ions) of the oxygen lattice. The formula of Ta_2O_5 is consequently considered to be Ta_2O_{5+y-x}, where y represents the fractional amount of interstitial oxygen and x oxygen vacancies.

A plot of the resistance at the maxima as a function of the reciprocal absolute temperature gives a value for the activation energy of the intrinsic conductivity. This is shown in Fig. 4. An approximately straight line relation is obtained with an activation energy of 41.2 kcal/mole or 1.79 ev. This indicates that the intrinsic energy gap in Ta_2O_5 is equal to 3.58 ev. As a comparison it has been found that the intrinsic energy gap in rutile (TiO_2) has a value of 3.04 to 3.12 ev (15-17). It should be emphasized that for Ta_2O_5 the evaluation neglects both the effect of

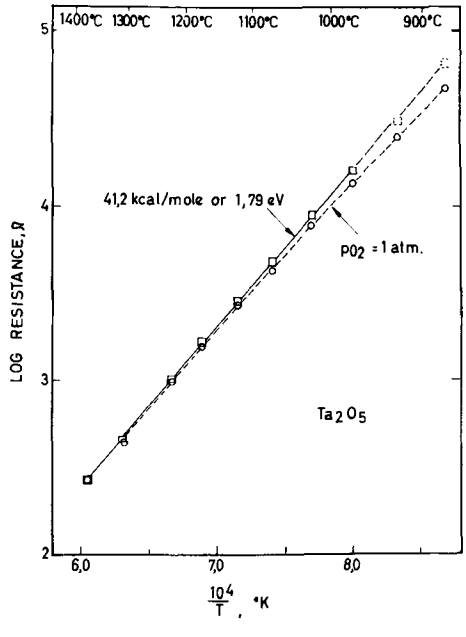

Fig. 4. Logarithm of the resistance of Ta_2O_5 specimen at the maxima in log R *vs.* log p_{O_2} curves (Fig. 1) as a function of the reciprocal absolute temperature.

mobility of the charge carriers which has a negative temperature coefficient (17) and the effect of the proposed anti-Frenkel disorder of the oxygen lattice under these conditions.

At oxygen pressures smaller than those of the maxima the intrinsic ionization becomes of less relative importance. With decreasing oxygen pressure and depending on the temperature the value of n (Eq. [1]) reaches values of 1/4 to 1/5. At the very lowest oxygen pressure n is equal to 1/6.

The latter value of n is concluded to reflect a defect structure predominantly involving doubly ionized oxygen vacancies (Eq. [9]). Correspondingly a value of $n = 1/4$ is concluded to reflect a defect structure in terms of singly ionized oxygen vacancies (Eq. [8]).

In order to explain the change in oxygen pressure dependence from $n = 1/4$ to $n = 1/6$ (*e.g.*, at 877°C) it is necessary to assume that the ionization energies of trapped electrons, *i.e.*, E_b and E_c, decrease with increasing defect concentrations. The same interpretation has been given of changes in the oxygen pressure dependence of the electrical conductivity in α-Nb_2O_5 (4) and of similar changes in thermogravimetric studies on rutile (5). In the latter cases it has been proposed that the ionization energies may be expressed as

$$E_i = E_o - aN^{1/3} \qquad [13]$$

where E_i represents the ionization energy, E_o is the ionization energy for an isolated donor, and N is the number of donors. Equation [13] was originally proposed by Pearson and Bardeen (18) for electron holes in silicon. As discussed by Cronemeyer in connection with studies of infrared absorption of reduced rutile a similar behavior is expected for oxide semiconductors (15).

According to Eq. [13], E_i changes rapidly when degeneracy ($E_i = 0$) is approached. This may in turn explain qualitatively the relatively rapid change in oxygen pressure dependence in going from a value of $n = 1/4$ to $1/6$ (*e.g.*, at 877°C in Fig. 1).

When $n = 1/6$ the temperature dependence of the carrier concentration is given by

$$[e^-] = (2K_{Oa}K_{Ob}K_{Oc})^{1/3}\, p_{O_2}^{-1/6} \exp\left(-\frac{\Delta H_a + E_b + E_c}{3RT}\right) \qquad [14]$$

K_{Oa}, K_{Ob}, and K_{Oc} represent pre-exponential factors according to Eq. [10].

A plot of the logarithm of resistance as a function of the reciprocal absolute temperature when $n = 1/6$ (*e.g.*, at $p_{O_2} = 10^{-12}$ atm) is given in Fig. 5, and as seen the activation energy equals 50 kcal/mole. This experimentally observed activation energy also includes the effect of carrier mobility which has a negative temperature coefficient. Thus depending on the relative importance of the mobility, it may be concluded that 1/3 $(\Delta H_a + E_b + E_c) \geqq 50$ kcal/mole or $(\Delta H_a + E_b + E_c) \geqq 150$ kcal/mole. In terms of the theory of decreasing ionization energy with increasing defect concentrations, E_b and E_c may be considered negligibly small when $n = 1/6$, and thus $(\Delta H_a + E_b + E_c) \approx \Delta H_a$.

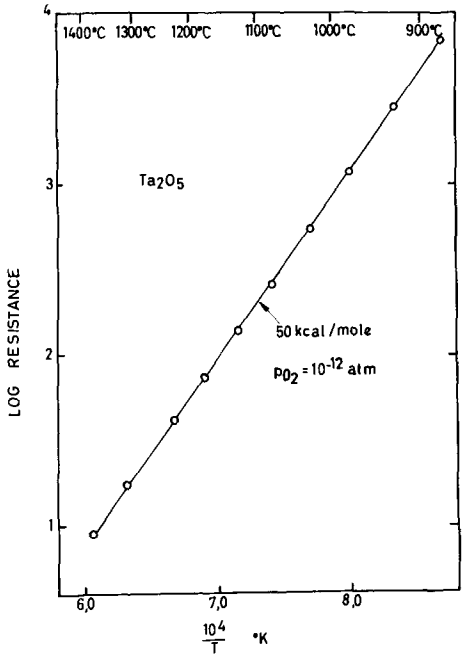

Fig. 5. Logarithm of the resistance of Ta_2O_5 specimen at $p_{O_2} = 10^{-12}$ atm as a function of the reciprocal absolute temperature.

According to Eq. [8] the temperature dependence of the charge carrier concentration when $n = 1/4$ should equal

$$[e^-] = (K_{Oa}K_{Ob})^{1/2}\, p_{O_2}^{-1/4} \exp\left(-\frac{\Delta H_a + E_b}{2RT}\right) \qquad [15]$$

If E_b is assumed small under these conditions the activation energy for the charge carrier concentration should be about $\frac{150}{2} = 75$ kcal/mole.

From the present results it is difficult to evaluate the temperature dependence of the resistance (or conductivity) under these conditions. For the results at 877° and 927°C it has, however, been attempted to draw the curves with values of $n = 1/4$. This is indicated by the stippled lines in Fig. 1. These two curves suggest an activation energy of about 70-75 kcal/mole for the conductivity when $n = 1/4$. Although no great accuracy can be claimed for such evaluation from but two temperatures, the results indicate satisfactory agreement with the above interpretation.

A corresponding treatment for the p-type conductivity does not appear possible because of the lack of knowledge of the exact oxygen pressure dependence under these conditions. From the results it is difficult to resolve the contribution from intrinsic conductivity and that of the p-type conductivity resulting from interstitial oxygen. However, the fact that the maxima become more pronounced at decreasing temperatures suggests that the p-type conductivity has a smaller activation energy than the intrinsic conductivity. This also explains that the maxima are displaced towards lower oxygen pressures at the lower temperatures.

The transition from the low-temperature to high-temperature modification of Ta_2O_5 has been reported to take place at about 1320°C (6, 7). This transition may be expected to influence the electrical conduc-

tivity in Ta_2O_5. The results at 1380°C also show anomalies which may be traced to such effects.

From Fig. 5 it is seen that at $p_{O_2} = 10^{-12}$ atm there is no change in the activation energy at the transition temperature. This may indicate that the transition temperature is a function of the oxygen pressure, and that the *low*-temperature modification is stable even at 1380°C at oxygen pressures smaller than about 10^{-8} atm. An alternative interpretation may also be that the heat of formation of oxygen vacancies are not appreciably different in the two modifications of Ta_2O_5.

Similarly from Fig. 4 it is also seen that no change in the activation energy is observed at the transition temperature. This thus indicates that the intrinsic energy gap is not appreciably different for the two Ta_2O_5 modifications.

As shown above the value of the heat of formation of oxygen vacancies in β-Ta_2O_5 was found to be $(\Delta H_a + E_b + E_c) \geqq 150$ kcal/mole. The corresponding value for α-Nb_2O_5 has been found from thermogravimetric studies to be 103 kcal/mole (2). Thus the heat of formation of oxygen vacancies is 1.5 times larger for β-Ta_2O_5 than for α-Nb_2O_5. For α-Nb_2O_5 the value of x was found to be about 0.01 at 1227°C and at an oxygen pressure of 10^{-14} atm. On the basis of the differences in heat of formation of oxygen vacancies in α-Nb_2O_5 and in β-Ta_2O_5 and assuming the same entropy change for the defect equilibrium in the two oxides, it may be estimated that the value of x in Ta_2O_{5-x} under the same conditions should be about $x \approx 10^{-9}$. This thus explains the very small weight changes observed in the thermogravimetric studies on Ta_2O_5. Considering the experimental errors involved in weight measurements, it also appears impossible on this basis to study the defect structure of Ta_2O_5 by thermogravimetric techniques.

Below about 700°-800°C the defect reactions apparently become sluggish, and several hours (and at lower temperatures even days) were needed to establish an apparent equilibrium. Therefore the oxygen pressure dependence of the conductivity was not studied in detail under these conditions. However, the temperature dependence at 1 atm O_2 was measured down to 450°C. In these measurements equilibration periods of 1 day were used. The results are shown in Fig. 6, which gives the logarithm of the electrical resistance of the specimen as a function of the reciprocal absolute temperature. A change in the activation energy is observed in the temperature range 600°-800°C, and at the lower temperatures the activation energy amounts to about 14 kcal/mole or 0.61 ev. This may reflect conduction due to impurities in the oxide.

In the above discussion of the defect structure of Ta_2O_5 effects of impurities have not been considered. Impurities may of course greatly affect the defect structure and the associated electrical conductivity. In the present work it is not possible to evaluate eventual effects of impurities present in the oxide. When considering impurities it is likely that these have larger effect close to stoichiometry where the defect reactions such as Eq. [2], [3], and [4] are of minor relative importance. In future studies in this

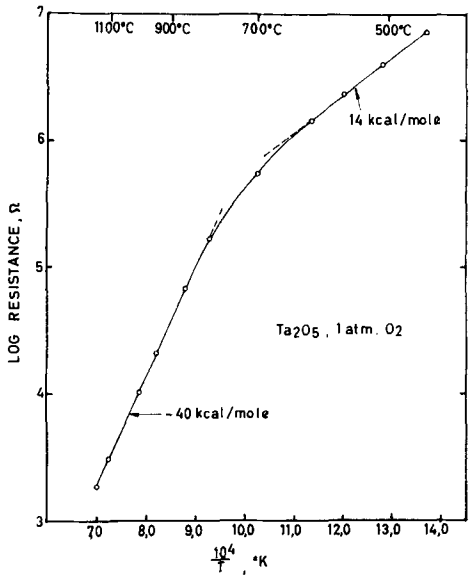

Fig. 6. Logarithm of the resistance of Ta_2O_5 specimen at 1 atm O_2 as a function of the reciprocal absolute temperature.

institute the effect of known amounts of impurities on the defect structure of Ta_2O_5 will be studied.

In this connection it is of interest to note that rutile doped with small amounts of Fe^{+3} (0.02 and 0.2 mole %) exhibits similar transitions from n- to p-type conductivity as observed in the present work (16). The transitions take place at lower oxygen pressures for the more heavily doped sample. Undoped rutile only shows n-type conductivity below 1 atm O_2. This may indicate that an n-type to p-type transition takes place at a higher oxygen pressure than 1 atm for the undoped oxide.

At high temperatures n-conducting rutile has a defect structure involving oxygen vacancies (5). As for Ta_2O_5 it may be proposed that p-conducting rutile at high temperatures also involves interstitial oxygen. In these terms it may be concluded that trivalent iron in rutile has different relative effects on the defect reactions involving interstitial oxygen and oxygen vacancies (Eq. [11] and Eq. [2], [3], and [4]) so as to cause a displacement of the transition of n- to p-type conductivity to lower oxygen pressures. The exact mechanism involved is difficult to elucidate at present and will have to await further studies on this system.

The present work on Ta_2O_5 is of importance for the understanding of the oxidation mechanism of tantalum at high temperatures. A detailed discussion of the effect of the transition from n- to p-type conductivity on the oxidation behavior will, however, be given elsewhere (1).

Acknowledgment

The work has been sponsored by the Aeronautical Systems Division, AFSC, through the European Office, Office of Aerospace Research, United States Air Force.

The author is indebted to Mrs. M.-K. Melsom for carrying out most of the experimental work. Thanks are also due to Mr. P. B. Anderson, Mr. Ö. Kalvenes and other members of the Central Institute for In-

dustrial Research for their assistance and helpful discussions.

Manuscript received March 12, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Anodic Oxidation of Iron in a Neutral Solution

I. The Nature and Composition of the Passive Film

Masa-ichi Nagayama[1] and Morris Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

Iron was anodically oxidized in a borate-boric acid buffer solution of pH 8.4 in the potential range extending from the active region to oxygen evolution. In the active region there appeared to be some Fe_3O_4 on the surface. In the passive region the iron was covered with an oxide film 10-30Å thick, depending on the potential. The structure of the film was studied by its cathodic behavior and electron diffraction and was found to consist of an inner "Fe_3O_4" and an outer "γ-Fe_2O_3" layer. The outermost part of the film had a defect structure of the general formula $Fe_x^{6+} \cdot Fe_{2-2x}^{3+} \cdot \square_x \cdot O_3$. The thicknesses of the layers and the number of defects were found to be functions of the anodic potential. The chemical reactions involved in the anodic passivation and the subsequent cathodic reduction processes are discussed.

The phenomenon of "passivity" of iron was first noted over one hundred years ago by Faraday and Schönbein, and since that time the factors controlling the establishment and maintenance of this state have been investigated by many workers (1-5). There is as yet no commonly accepted view of the nature of the passive film or the role that it plays in passivity. In this investigation the electrochemical quantities involved in the anodic formation and subsequent cathodic reduction of passive films on iron in a neutral borate-boric acid buffer solution were measured and compared. From the results information has been obtained regarding the chemical reactions in the passivation and reduction processes and on the thickness, chemical composition, and structure of the passive film.

Experimental

Materials.—Ferrovac iron sheets of 5 x 1 cm with small handles were used as test specimens.[2] After polishing with 4/0 emery paper, the specimens were electropolished in a mixture of glacial acetic and 70% perchloric acids (20:1) at a c.d. of 0.45 amp/cm^2 (6). Temperature of the bath was kept between 15° and 17°, and polishing was done in 10-sec bursts to avoid overheating. A total thickness of more than 20μ was dissolved so as to remove the deformed layer due to abrasion. The specimen was withdrawn from the bath and immediately washed with a jet stream of anhydrous methyl alcohol, then dried quickly by absorbing the methanol with Fisher lens paper. Electron microscopic observation (Fig. 10(a)) indicated a very smooth surface; the surface roughness factor would be very close to unity (6, 7). This procedure was followed by annealing in a hydrogen atmosphere for about 2 hr at 700°C. The specimens were electropolished again for a short period just before measurement.

A deaerated equivolume mixture of 0.15N sodium borate and 0.15N boric acid solutions was used for both the anodic passivation and the cathodic reduction experiments. The pH of this solution is 8.41. The solution was kept in a storage vessel under a stream of nitrogen which was purified by bubbling through Fieser's solution and then passing through

[1] N.R.C. Postdoctorate Research Fellow. Present address: Faculty of Science, Hokkaido University, Sapporo, Japan.

[2] The composition of the iron was: C 0.007 (%), N 0.0002, O 0.013, P 0.0002, S 0.0017, Si 0.0095, Al 0.001-0.003, Cu 0.001-0.003, Mn 0.002-0.004, Pb none detected <0.01, Sn none detected <0.004.

a column of finely dispersed copper on Kieselguhr, heated to 220°C. The oxygen content of the solution was checked by an electrochemical method with a Pt cathode, and it was found that the concentration was less than 1 x 10^{-7} m/l. The corresponding limiting diffusion current of oxygen, 0.04 μa/cm^2, would not have affected the results of the experiments.

Cell.—The electrolytic cell used was similar to that described by Oswin and Cohen (8). It had a capacity of about 80 ml and was usually filled with 30 ml of the solution. Solution could be transferred from the storage vessel to the cell or removed from the cell for analysis under a nitrogen atmosphere through a three-way solution-lubricated glass stopcock at the bottom. For the purpose of polarizing the specimen two auxiliary Pt electrodes were provided. The one employed for the cathodic reduction of the specimen consisted of a set of two Pt wires sealed at the top of glass side arms. The other was a cylindrical Pt sheet having a large geometrical surface area (80 cm^2) fixed in position so as to surround the specimen, being used only for the anodic passivation experiment. The specimen was suspended on a heavy tungsten wire sealed into the ball-joint on the top of the cell, and the potential of the specimen was measured against a saturated calomel electrode via a salt bridge filled with the electrolytic solution.

Electrical circuit.—A schematic diagram of the electrical circuit used is shown in Fig. 1. The right-hand side is a potentiostatic polarization circuit employed to apply a constant anodic potential to the specimen. The design of the potentiostat is basically that of Gerischer and Staubach (9). It consists of a differential amplifier having an amplification factor of 600 and a band width of about 5 kc/sec. Zero point drift was found to be less than 5 mv/day. The change of current with time after applying a constant potential was followed by recording the ohmic drop across a standard resistance of 100 ohms inserted in the polarizing circuit in the usual way. A recorder of the direct writing oscillograph type (range 0-200 mv) was used for the initial current of several milliamperes, and it was then switched over to a strip chart recorder of higher sensitivity (range 0-10 mv) when the current went down to about 100 μa. The response times of these recorders were about 1/100 sec and 1 sec for the full scale shift of the needle, and chart speeds were 25 mm/sec and 8 mm/min, respectively. As has been pointed out recently by Will (10) and others (11), the time required to attain a constant potential is a function of the total impedance in the polarizing circuit, so that an effort was made to keep the resistance of the cell and of the recorder low so as to obtain a constant potential within 5 sec. The left-hand side of the figure is a galvanostatic polarization circuit consisting of a transistor rectifier of 30v output voltage and variable large resistance. It was used mainly to apply a constant cathodic current to the specimen. The change of potential with time during cathodic reduction was recorded with a Speed-o-Max recorder (range 0-100 mv) through an electron-tube potentiometer having an input impedance of about 10^8 ohms. The direction of polarization could be changed rapidly by means of a multiple switch. All the experiments were conducted at room temperature, which ranged from 24° to 25.5°C, and potential data given here are always referred to the saturated calomel electrode.

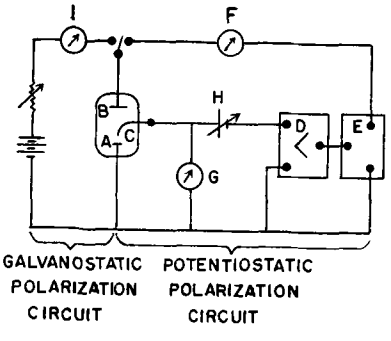

Fig. 1. Schematic representation of circuit. A, specimen; B, auxiliary Pt electrode; C, saturated calomel electrode; D, differential amplifier; E, output tube of the amplifier; F, current-recorder; G, vacuum tube voltmeter with recorder; H, signal voltage; I, microammeter.

Analysis.—Colorimetric analysis of the solution for iron by the orthophenanthroline method could be carried out after any desired period of time of cathodic or anodic polarization by removing the specimen quickly from the solution while the polarization was going on and dumping the solution from the cell. The technique of analysis can be briefly described as follows: The analytical reagent was made up from 200 ml of 0.25% o-phenanthroline, 300 ml of 3% hydroxylamine-hydrochloride and 500 ml of 10% acetic acid, and it was stored in a refrigerator. Ten milliliters of the mixed reagent was transferred to a 50 ml volumetric flask, being followed by the addition of the solution and washings to the mark. The amount of acetic acid in the reagent had been chosen so as to make the *p*H of the final mixture about 4. Measurement of optical density in a 50 mm silica cell was carried out 30 min after mixing with a Beckman Model B spectrophotometer at 508 mμ. Experimental error of the analysis is claimed to be less than ± 1.0%. The limiting sensitivity of this method is 0.05 μg Fe^{++} in the total solution.

Results

Anodic polarization curve.—The nearly stationary anodic polarization curve obtained by means of the potentiostat is shown in Fig. 2. Before the measurement of each point, the specimen was pretreated at a cathodic current of 10 μa/cm^2 until the air-formed or passive oxide film was completely removed. This could be checked by the cathodic potential measurements which will be described later. The solution was changed after the cathodic treatment. The transition from the active and the passive states takes place in the potential region from —650 mv to —550 mv (E_a^1). In the passive potential region from —550 to +850 mv, the magnitude of the current falls to less than 0.01 μa/cm^2 after 10 hr of polarization, and even then it was still tending to decrease with time. Beyond a potential of about +850 mv (E_a^3), the current again begins to increase steeply with potential presumably because of the onset of oxygen evolution.

Potentiostatic measurement of the amount of film.—Each experiment was started from the completely reduced surface condition. The change in the anodic

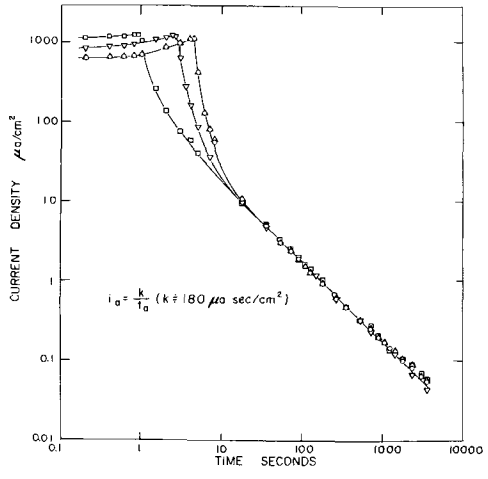

Fig. 3. Change of current with time after applying anodic polarization. Dotted circle, E_a = +600 mv, 20 min additional cathodic treatment after completing the reduction; dotted triangle, E_a = +600 mv, just after completing the reduction; inverted dotted triangle, E_a = +200 mv, just after completing the reduction; dotted square, E_a = —300 mv, just after completing the reduction.

current i_a with time t_a was followed immediately after applying a constant passive potential. Log-log plots of the $i_a - t_a$ relationship obtained at three passive potentials are shown in Fig. 3. The relatively large current of the order of 1 ma/cm² flowing in the initial period of time decreases rapidly, but the change then becomes much slower. While the shape of the initial part of the curve is markedly dependent on the impedance of the polarizing circuit, the succeeding part of the curve is a straight line of slope approximately 45° independent for both applied potentials and practical values of the circuit element; the point of transition between these two parts of the curve is quite dependent on the impedance. The linear relation was ascertained to continue for at least 15 hr. This relationship has been reported by many workers for the passivation of iron and other metals (12). The charge passed can be calculated by graphic integration of the curve. For different values of impedance, and consequently for different shapes and heights of the initial part of the curve, it is still an experimental fact that the total charge passed up to the transition point is a constant for a constant applied potential. Thus, the amount of charge passed during 1 hr of polarization was calculated, and the results obtained for the various anodic potentials E_a ranging over the passive region are shown in Fig. 4. The amount of charge Q_a accumulated in the film was then obtained by subtracting the equivalent coulombs for the amount of iron found in the solution from the total charge passed. The dissolution of iron occurs as ferrous ion below —200 mv, the amount being increased as the potential is lowered. In the potential range between 0 to +850m, the relation between Q_a and E_a is essentially a straight line having a slope of 0.34 mC/cm²/100 mv. This slope is similar to that roughly estimated by Weil (13) for passive iron in phthalate buffer solution at pH 6. A slight negative deviation from the linear relationship is observed in the potential region below about 0 mv (E_a^2). The fact that Q_a commences to increase steeply with potential beyond +850 mv would be explained as being due to the oxygen evolution reaction. Hence, the amount of the oxide film above +850 mv cannot be determined by this method.

The effect of time of polarization t_a on the Q_a — E_a curve is roughly estimated as shown in Fig. 5,

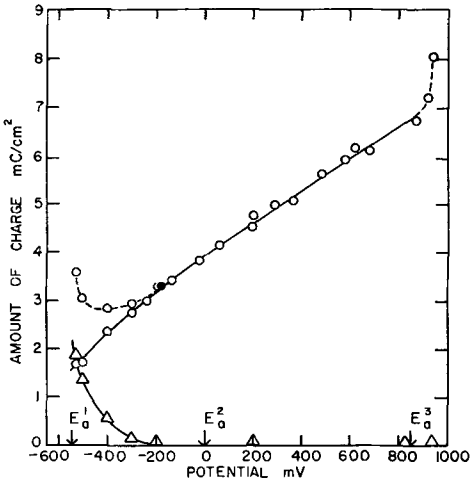

Fig. 4. Effect of potential on the amount of charge passed during 1 hr anodic polarization . . . . ○ . . . , Total amount of charge passed; ——△——, amount of charge corresponding to the Fe^{++} dissolution; ——○——, amount of charge for the formation of passive film; ●, amount of charge for a [112] single crystal specimen.

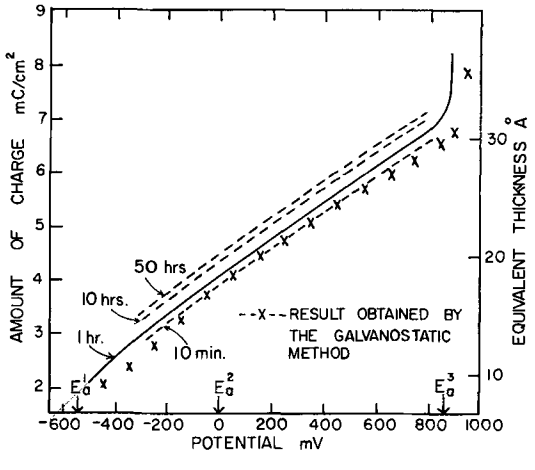

Fig. 5. Effect of time of polarization on the amount of passive film.

assuming that the linear relation between log i_a and log t_a does not depend on the applied potential and that it will also hold for up to 50 hr. It can be seen that the curves do not change very much from the one obtained for one hour's experiment even if the polarization is continued for 50 hr.

Galvanostatic measurement for the amount of film.—The amount of charge required to passivate a specimen, which had been pretreated by cathodic polarization, was estimated by the galvanostatic method for comparison with the result obtained by the potentiostatic method. A current higher than the maximum current which is observed in the active potential region of the polarization curve (Fig. 2) was applied, and the resulting change of potential with time t or charge passed was followed. The result is shown in Fig. 6. Two waves are observed in the initial and middle parts of the curve. The first transition point, A, is in the potential region of E_a^1 where the transition from the active to the passive state takes place in the potentiostatic experiments. The second transition, B, at about 0 mv corresponds to the point E_a^2 on the potentiostatic polarization curve where a negative deviation in the $Q_a - E_a$ curve was observed. Point C corresponds to the oxygen evolution potential E_a^3. A similar type of curve was reported by Heusler and Weil (14) for iron in an amino-acetic acid buffer solution of pH 9.3. The quantity of charge accumulated in the film Q_a was obtained by subtracting the equivalent coulombs for the amount of iron found in solution from the total charge passed, assuming that the corrosion had occurred as $Fe \rightarrow Fe^{++} + 2e$ before the point A was reached. The result is shown in Fig. 5 as crosses. The $Q_a - E_a$ curve obtained by this method is quite similar to that obtained by the potentiostatic method for a very short period of polarization such as several minutes. This method, however, seems to have disadvantages for the purpose of obtaining a reproducible passive condition or for controlling the film thickness of the specimen at a certain passive potential.

Cathodic reduction curve.—The anodic passivation experiments were immediately followed by

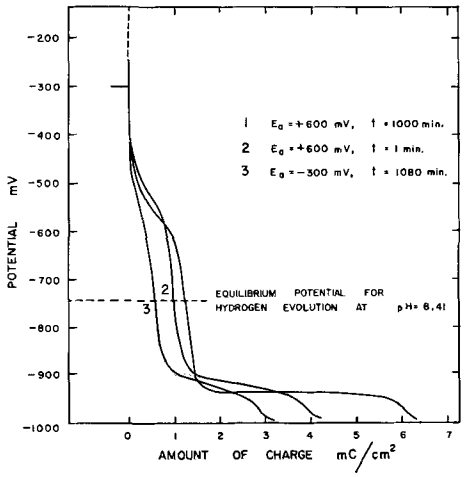

Fig. 7. Effect of anodic polarization and time of polarization on the cathodic reduction curve.

measurement of the cathodic reduction curve; the change of cathodic potential E_c with time or amount of charge Q_c was traced at a constant c.d. of about 10 μa/cm². Typical cathodic reduction curves obtained for various passivating conditions are shown in Fig. 7. Three arrests or two waves can be seen in the curves, and the points of inflection corresponding to these arrests appear around −550 mv, −920 mv, and −1000 mv, respectively. The potential for the first arrest is in the same potential region where the active-passive transition occurs (E_a^1). In general, the change from the first to the second wave becomes much more clearly defined and more charge seems to be associated with both waves, the more positive the anodic potential and the longer the time it is applied. Thus, the amount of charge Q_c^1 and Q_c^2 associated with these two waves is measured as a function of passive potential, and the time of polarization, and the results are shown in Fig. 8 and Fig. 9.[3] It might be interesting to point out here that the slope of the $Q_c^1 - E_a$ curve (Fig. 8) changes at

[3] The intersection of the extrapolated lines of the descending part of the first wave and the second arrest, and the point of inflection between the second arrest and the third plateau are used for calculation of coulombs passed.

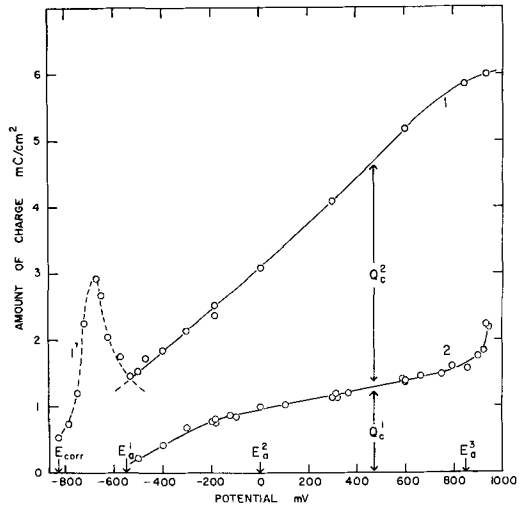

Fig. 8. Effect of anodic polarization on the first and second waves of the cathodic reduction curve (t_a = 1 hr). 1,1', Total amount of charge for the complete cathodic reduction; 2, amount of charge for the first wave of cathodic reduction.

the same characteristic potentials of E_a^2 and E_a^3 as is shown in Fig. 4, and that Q_c^1 approaches zero at the transition potential between the active and the passive states E_a^1.

Cohen and his co-workers (8, 15) have recently obtained the cathodic reduction curve for oxidized iron in a neutral borate-HCl buffer solution at a c.d. similar to ours, and have found by means of electron-diffraction that the composition of the oxide when the first wave appears around −850 mv is α-Fe_2O_3 and unreducible magnetite remains on the second plateau of about −930 mv. Stockbridge, Sewell, and Cohen (16) have further studied the cathodic reduction of thin air-formed oxide films on iron and have ascertained that when the first wave appeared at a much higher potential (−500 mv *vs.* S.C.E. at *p*H 7.6) than that for α-Fe_2O_3, it was mainly due to the existence of γ-Fe_2O_3 as the outer layer of the film. Hence, by referring to these results, the first and the second waves and the third plateau observed here in the cathodic reduction curve are probably related to a structure of a surface of γ-Fe_2O_3, magnetite, and the bare metal, respectively. The magnetite layer seems to be completely reducible in this case. This reducibility of the magnetite is confirmed by the fact that if cathodic reduction is used as the pretreatment for an anodic passivation and if the reduction has been carried on until the third plateau or the bare surface condition is attained, then the $i_a - t_a$ curve or the amount of charge Q_a accumulated during the anodic passivation becomes reproducible and independent of the previous treatment of the specimen (cf. Fig. 3). An electron diffraction examination by reflection was made for the passive film of about 15Å produced at −190 mv on a [112] single crystal specimen (cf. Fig. 4). The pattern shown in Fig. 10 indicates a cubic structure of the film having an average lattice parameter of a = 8.37 ± 0.04Å. This could also be explained by the concept that the outer and the inner layers of passive film are mainly composed of γ-Fe_2O_3 and Fe_3O_4 (17). An attempt to obtain a reflection diffraction pattern for the film of about 30Å obtained at higher passive potential

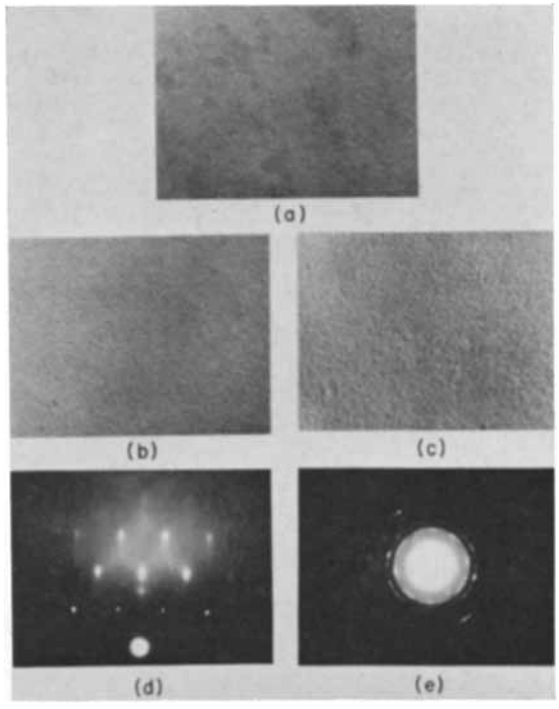

Fig. 10. Electronmicrograph of surface and electron diffraction of passive film. Series treatment of surface, Pt-C replicas, co-evaporated at 45°, magnification 100,000X. (a) Electropolished; (b) anodically passivated for 1 hr at +600 mv; (c) cathodically reduced at 10 μa/cm²; (d) reflection electron diffraction of anodically passivated 112 single crystal, 112 surface from $1\bar{1}1$ azimuth. Specimen was passivated at +190 mv for 1 hr, film thickness ca. 15Å. $d_{(100)}$ = 8.37 ± 0.04Å; (e) transmission electron diffraction of passive film stripped from polycrystalline specimens passivated at +850 mv for 1 hr. $d_{(100)}$ = 8.40 ± 0.04Å.

was also made, but no clear information was obtained. A transmission pattern showing the structure of cubic iron oxide was obtained for a film of similar thickness stripped from a polycrystalline specimen by the iodine-methanol method (Fig. 10).

As a matter of interest, cathodic reduction curves were obtained for specimens which were anodically polarized at nearly steady states in the active potential region. Only the second wave of the curve, which could not be clearly defined, was observed. This would indicate that in the active region no ferric oxide is formed, but that there may be some magnetite present on the surface. The $Q_c - E_a$ curve in Fig. 8 shows a maximum amount of charge of about 3 mC/cm² at E_a = −660 mv which agrees with the potential where maximum anodic current is observed.

Ferrous ion dissolution during cathodic reduction. —The amount of the ferrous iron dissolution $W_{Fe^{++}}$ at various stages of the cathodic reduction was measured for a specimen which was polarized anodically at +600 mv for 1 hr. The results obtained are shown together with the cathodic reduction curve in Fig. 11. The broken line OA indicates the relationship between $W_{Fe^{++}}$ and Q_c which would be expected if the cathodic reduction from ferric oxide to ferrous ion followed the reaction

$$Fe_2O_3 + 6H^+ + 2e \rightarrow 2Fe^{++} + 3H_2O$$

with a current efficiency of 100%. As can be noted, there is a distinct negative deviation from the theo-

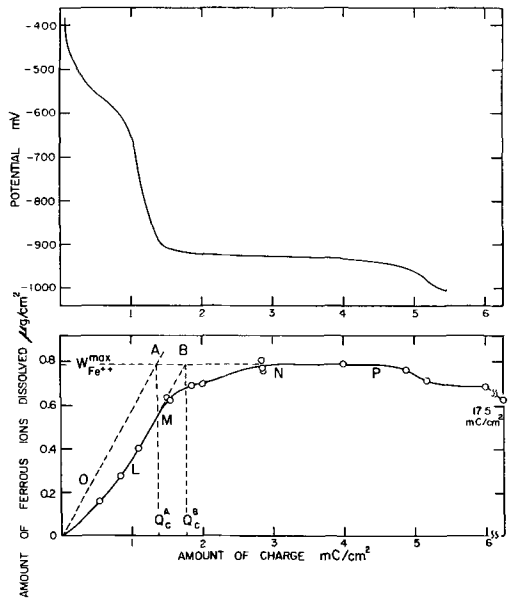

Fig. 11. Amount of ferrous ion found in the solution during cathodic polarization (E_a = +600 mv, t_a = 1 hr).

retical line OA in the early part of the reduction process, followed by a section LM in which cathodic reduction is essentially 100% efficient. The reduction efficiency then begins to drop sharply from the point M onward. This point corresponds to the point of inflection at the second wave of the reduction curve, and the reduction efficiency finally becomes nearly zero at point N. No change in the Fe^{++} ion concentration is observed until the point P that corresponds to the end of the magnetite wave is reached. A drop in Fe^{++} concentration is observed after completing the reduction of the oxide film.

Similar curves for films formed at other potentials are shown in Fig. 12. In all cases these show the negative deviation from 100% current efficiency at low values of Q_c. In every case 100% current efficiency (corresponding to point L in Fig. 11) is reached at a cathodic reduction potential of −700 mv. If we assume that the cathodic processes between M and N on Fig. 11 consist of 100% current

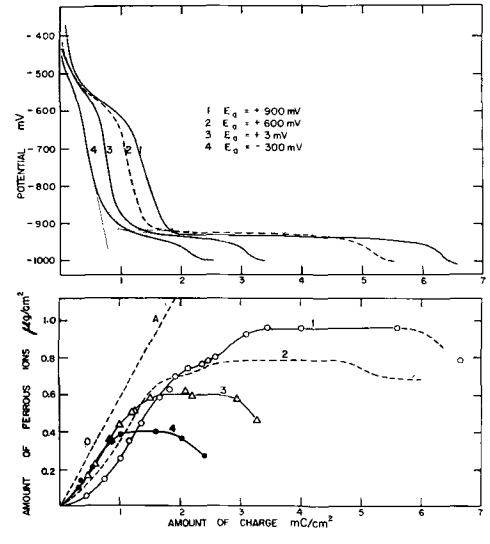

Fig. 12. Effect of anodic polarization for $W_{Fe^{++}}$ — Q_c curve (t_a = 1 hr).

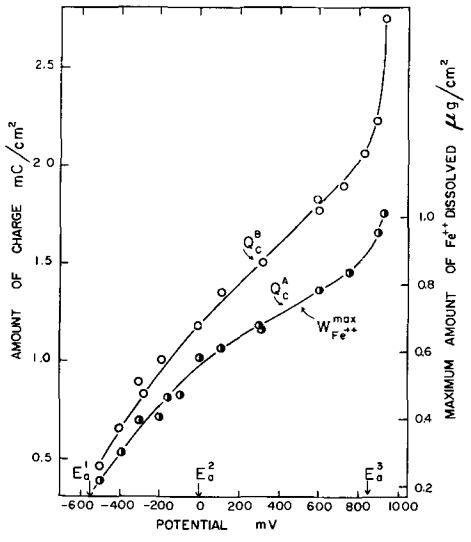

Fig. 13. Effect of anodic polarization on Q_c^A, $W_{Fe^{++}}^{max}$ and Q_c^B (t_a = 1 hr).

efficiency of reduction of γ-Fe_2O_3 to dissolved Fe^{++} ion and low current efficiency reduction of Fe_3O_4 to the metal, then extrapolation of LM to the line at which the maximum amount of dissolved ferrous ion is observed gives the actual amount of charge Q_c^B required to reduce the outer layer.

A series of experiments were then made to determine the number of coulombs required to reach −700 mv and the accompanying amount of iron in solution for specimens which had been anodically treated for 1 hr at various potentials.[4] The maximum amount of dissolved iron $W_{Fe^{++}}^{max}$ which could be produced was also measured by analyzing the solution when cathodic reduction had been carried on to about the middle part of the second wave of the reduction curves. The theoretical number of coulombs for the reduction of stoichiometric ferric oxide Q_c^A was calculated from the experimental value of $W_{Fe^{++}}^{max}$. Q_c^B was obtained as described above. The results are shown in Fig. 13. As can be seen the deviation (Q_c^B — Q_c^A) becomes larger as the applied anodic potential E_a is raised. Inflection points on the curves appear around 0 mv and +850 mv, *i.e.*, in the same potential regions E_a^2 and E_a^3 where the characteristic inflection appears in the Q_a — E_a curve shown in Fig. 4.

Discussion

Anodic Reactions

In the active region the reactions are probably

$$Fe \rightarrow Fe^{++} + 2e \qquad [1]$$

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 8H^+ + 8e \qquad [2]$$

At this stage there always appears to be some magnetite on the surface, as judged from the cathodic reduction potentials.

When the anodic potential is made more positive, *i.e.*, electrochemical conditions are more oxidizing,

[4] Since changing the solution immediately following anodic polarization had been found not to affect the behavior on cathodic reduction, the solution was changed twice just before cathodic reduction for the case where anodic polarization had been at potentials < -200 mv or $> +850$ mv in order to remove ferrous ions or oxygen which had been produced during anodic polarization.

the outer part of the Fe_3O_4 is converted to γ-Fe_2O_3 by reactions such as

$$2Fe + 3H_2O \rightarrow \gamma\text{-}Fe_2O_3 + 6H^+ + 6e \quad [3]$$

$$2Fe_3O_4 + H_2O \rightarrow 3\gamma\text{-}Fe_2O_3 + 2H^+ + 2e \quad [4]$$

It is probable that the oxidation takes place through reaction [4]. The oxidation of magnetite to γ-Fe_2O_3 by air or oxygen at room temperatures has been observed previously (16), and the anodic oxidation was discussed in a previous paper (18). Under the more strongly oxidizing conditions of higher potentials during anodic polarization the outer layer of the γ-Fe_2O_3 may be oxidized even more to form a cation vacancy structure which is still in the cubic system by the reaction

$$(2-x)\gamma - Fe_2O_3 + 3xH_2O \rightarrow$$

$$2Fe_x^{6+} \cdot Fe_{2-2x}^{3+} \square_x \cdot O_3 + 6xH^+ + 6xe \quad [5]$$

Some electron diffraction evidence for this type of vacancy structure leading to a lowered lattice parameter of the cubic oxide has been reported elsewhere for films formed by electropolishing (19).

In essence the above discussion treats the anodic passivation system in a manner similar to the treatment given for air oxidation of iron where the oxide is formed by a re-arrangement of oxygen and iron ions to form a lattice in which the oxygens form a face-centered cubic lattice with iron atoms fitted into octahedral and tetrahedral sites. The oxidation of magnetite to γ-Fe_2O_3 and of γ-Fe_2O_3 to the vacancy structure oxide take place by diffusion of iron ions out of the lattice accompanied by oxidation to a higher valency state.

On the basis of the above considerations the film formed by anodic polarization would have the composition shown in Fig. 14. Because of the close crystallographic resemblance of the oxides and the thinness of the film phase boundaries are probably not sharp. However, in general the phase next to the metal most closely resembles Fe_3O_4 and that next to the solution a cation vacancy cubic oxide containing iron of a valency greater than three, with γ-Fe_2O_3 between them.

Cathodic Reactions

The cathodic reduction curve has three plateaus corresponding to three electrochemical reactions. These can be considered to be

$$Fe_x^{6+} Fe_{2-2x}^{3+} \square_x \cdot O_3 + 3H_2O +$$

$$(2+2x)e \rightarrow (2-x)Fe^{++} + 6\,OH^- \quad [6]$$

$$Fe_3O_4 + 4H_2O + 8e \rightarrow 3Fe + 8\,OH^- \quad [7]$$

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \quad [8]$$

In contrast to the results of Hancock and Mayne (20) which indicated that γ-Fe_2O_3 was reduced to metallic iron, the data obtained here show that the reduction product is always Fe^{++} ion in solution. In the middle part of the first wave of the reduction curve (from −700 mv to −900 mv) where γ-Fe_2O_3 is being reduced to ferrous ion with almost 100% current efficiency, any other side reactions such as

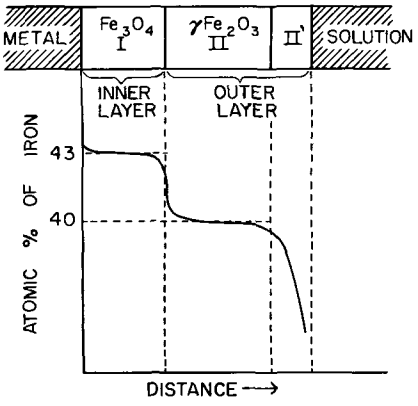

Fig. 14. Postulated change of film composition with the distance outward from metal/oxide interface.

hydrogen evolution or the conversion of γ-Fe_2O_3 to Fe_3O_4 (13, 14) are not likely to occur. Hydrogen evolution, even without polarization, cannot be expected above −750 mv at the *p*H of solution used. The lower current efficiency of reduction observed during the early period (above −700 mv) must therefore be due to a cation vacant (high iron valence) oxide.[5] In Eq. [6] showing the reduction of the outer γ-ferric oxide layer with the cation vacant structure in the outermost part, the value of x may vary from some finite value to zero consistent with stability of the structure and the applied anodic potential. The change of polarization potential E_c with Q_c in the first wave could be interpreted as being due to the gradual decrease of defect concentration at the oxide surface and to the increase of Fe^{++} ion concentration in the solution with the time of cathodic reduction.

In the second wave of the reduction curve except for the initial period of reduction, Fe_3O_4 is the only oxide present, and no ferrous ion is produced in solution. The Fe_3O_4 is reduced directly to iron with a low current efficiency, as is shown in Eq. [7], the accompanying reaction probably being hydrogen evolution on the surface of oxide, which will be further discussed below. After completing the reduction of Fe_3O_4, a potential which is characteristic of hydrogen evolution on iron (the third plateau) is reached. At this stage there appears to be some redeposition of iron from the ferrous ion in the solution. The concept of the complete reduction of the magnetite layer is supported by the fact that the number of coulombs used during anodic oxidation after complete cathodic reduction is independent of the time of cathodic reduction or of the thickness of the previous oxide before cathodic reduction (cf. Fig. 3). If the magnetite layer was not completely reduced, a very marked change was observed in the number of coulombs used during subsequent anodic passivation.

The ferrous ion dissolution observed in the initial period of the second wave (or in the final period of

[5] An interpretation of the low current efficiency of reduction could also be made by assuming either an oxygen rich type of oxide or an absorption of oxygen atoms on the surface of a stoichiometric oxide layer. However, the first idea is discarded because too much energy is needed to insert oxygen ions in the interstitial positions of the crystal lattice. The second possibility did not fit the experimental results on the decay of the passive potential which will be described in a following publication.

the first wave) is probably to be interpreted as due to the reduction of γ-ferric oxide still remaining as isolated areas on the surface of the underlying magnetite layer. This would be expected at the cathodic current density used for the reduction of such thin films. The relatively high c.d. was required in order to avoid self-corrosion or autoreduction of films. Thus in this stage the reduction of γ-Fe_2O_3 to Fe^{++} ion, the reduction of Fe_3O_4 to metallic iron and the evolution of hydrogen on the oxide are all taking place simultaneously. The lack of sharp definition in the transition between the first and the second waves of the cathodic reduction curve is related to the above situation.

Composition of the Film

The thickness and composition of the films formed during anodic passivation have been calculated from the number of coulombs used for anodic treatment and a study of the cathodic reduction data.

In order to calculate the exact number of coulombs associated with the anodic formation of passive film it is necessary to consider the amount of charge for the possible side reactions. Thus, the amount of charge equivalent to the ferrous ion dissolution which was found only in the potential region below −200 mv was subtracted from the total charge passed during the passivation experiment. The second possibility is the oxygen evolution reaction. Although the equilibrium potential for oxygen evolution in this solution is about +480 mv there is no change in the polarization curve until about +900 mv which indicates a high overvoltage for oxygen evolution. The fact that there is no discontinuity in the polarization curve and also in the $Q_a - E$ curve at +480 mv would indicate that oxygen formation plays no part in the passivation process. However, due to oxygen evolution above +900 mv, thicknesses could not be calculated above that potential.[6] The third possible reaction is the oxidation of hydrogen produced during the cathodic pretreatment to hydrogen ions at the early stage of passivation. The possibility of this reaction is discounted for two reasons. First, the number of coulombs required for anodic passivation was independent of the time of cathodic treatment after the magnetite was reduced. Second, any correction for hydrogen oxidation at the low passivation potentials would reduce the amount of magnetite only, and even a small correction would eliminate it. This is contrary to the observation that the potential wave for magnetite is always observed during cathodic reduction. On this basis, the rough estimation of film thickness is first made assuming a roughness factor of 1.2, a density of oxide of 5, and an average film composition of Fe_2O_3. The result is shown in Fig. 5. However, corrections to the thickness are required because of a change of film composition with the distance outward from the metal/oxide interface as described below.

Cathodic reduction of the outer layer of the oxide produces ferrous ion in solution. In that the reduction is done at constant current the time during reduction is a measure of charge passed. Iron in solution may also be formed by autoreduction. To check this point, cathodic reduction was carried out at three different current densities with a negligible effect on the number of coulombs Q_c^1 for the first wave. This is shown in Table I and indicates that there is no autoreduction during the cathodic reduction. An autoreduction reaction would reduce the number of coulombs required for cathodic reduction.

Table I. Effect of current density on the cathodic reduction curve

	$E_a = -182$ mv, $t_a = 1$ hr		$E_a = +850$ mv, $t_a = 1$ hr	
i_c, μa/cm²	Q_c^1, mC/cm²	Δ, %	Q_c^1, mC/cm²	Δ, %
5	0.796	+3.9	1.572	+0.9
10	0.766	—	1.558	—
20	0.762	−0.5	1.548	−0.6

A comparison was therefore made between the coulombs passed during cathodic reduction and the theoretical coulombs required for the production of Fe^{++} from Fe_2O_3 at various points on the cathodic reduction curve (Fig. 13). The excess of experimental to theoretical charge ($Q_c^B - Q_c^A$) before magnetite was uncovered was attributed to the presence of Fe^{6+} ion in the outer layer of the oxide.

If we assume that the vacancy structure is associated with the presence of Fe^{6+} in the outer layer of the film, the number of electrons required to reduce the film will be greater than the number based on a stoichiometric film of γ-Fe_2O_3. The proportion of Fe^{6+} (or vacancies) can be calculated as follows. The charge passed in reducing a ferric oxide film containing Fe^{6+} to ferrous iron in solution is

$$Q_c^B = (W_{Fe^{++}}^{max} - W_{Fe^{6+}}^{(S)})/A + (4W_{Fe^{6+}}^{(S)})/A \quad [9]$$

where $W_{Fe^{++}}^{max}$ [μg/cm²] is the maximum amount of ferrous ion dissolution during the cathodic reduction, $W_{Fe^{6+}}^{(S)}$ [μg/cm²] is the amount of hexavalent iron ion or the amount of vacancy in the outer layer of the film, and A [0.5787 μg/mC] is the electrochemical equivalent of iron for the one-electron reaction $Fe^{3+} + e \rightarrow Fe^{2+}$. Accordingly, the expression for the amount of hexavalent and trivalent ion in the film is

$$W_{Fe^{6+}}^{(S)} = \frac{1}{3}(Q_c^B \cdot A - W_{Fe^{++}}^{max}) \quad [10]$$

and

$$W_{Fe^{3+}}^{(S)} = W_{Fe^{++}}^{max} - W_{Fe^{6+}}^{(S)} = \frac{1}{3}(4W_{Fe^{++}}^{max} - Q_c^B \cdot A) \quad [11]$$

The amount of charge $Q_a^{(O)}$ [mC/cm²] used for the anodic formation of the outer oxide layer from metallic iron is then calculated by referring to Eq. [10] and [11] as

$$Q_a^{(O)} = 6W_{Fe^{6+}}^{(S)}/A + 3W_{Fe^{3+}}^{(S)}/A = 2W_{Fe^{++}}^{max}/A + Q_c^B \quad [12]$$

The difference between this and the total charge Q_a [mC/cm²] passed during anodic passivation would

[6] Estimation of the thickness of the outer ferric oxide layer by means of the cathodic reduction technique is possible even for the specimen prepolarized above +900 mv as will be seen below, if the solution is changed just before the reduction so as to eliminate oxygen produced during the anodic polarization.

give the amount of charge required to form the inner magnetite layer $Q_a^{(M)}$. Thus,

$$Q_a^{(M)} = Q_a - Q_a^{(O)} \qquad [13]$$

The amount of iron in the magnetite $W_{Fe}^{(M)}$ [$\mu g/cm^2$] is

$$W_{Fe}^{(M)} = \frac{3}{8} A \times Q_a^M \qquad [14]$$

so that the total amount of iron in the passive film is

$$W_{Fe}^{(S)} = W_{Fe^{6+}}^{(S)} + W_{Fe^{3+}}^{(S)} + W_{Fe}^{(M)} \qquad [15]$$

Comparison between $Q_a^{(M)}$ and the amount of charge for the second wave of the cathodic reduction curve, which is reasonably expressed as the difference between the total amount of charge for the cathodic reduction Q_c and Q_c^B, would give the average current efficiency of the reduction reaction of magnetite $\eta_c^{(M)}$.

$$\eta_c^{(M)} = \frac{Q_a^{(M)}}{Q_c - Q_c^B} \times 100\ (\%) \qquad [16]$$

The possible side reaction which occurs simultaneously with magnetite reduction would be hydrogen evolution on both the magnetite and bare metal surface. The value of the subscript x in the formula of nonstoichiometric oxide which expresses the average defect concentration in the outer layer is obtained as

$$x = \frac{2W_{Fe^{6+}}^{(S)}}{W_{Fe^{3+}}^{(S)} + 2W_{Fe^{6+}}^{(S)}} = \frac{2(Q_c^B \cdot A - W_{Fe^{++}}^{max})}{2W_{Fe^{++}}^{max} + Q_c^B \cdot A} \qquad [17]$$

By using the equations described above, the composition of the film for various passive potentials was calculated. The experimental data for Q_a, Q_c, $W_{Fe^{++}}^{max}$ and Q_c^B which are shown respectively in Fig. 4, 8, and 13 were used, the results obtained being summarized in Table II and also in Fig. 15 and 16. In these results, the characteristic potentials E_a^1 (−550 mv), E_a^2 (0 mv) and E_a^3 (+850 mv) are again recognized. E_a^1 is related to the transition potential between the passive and the active states observed in the measurement of the anodic polarization curve and also to the first arrest of the cathodic reduction curve. It is clearly seen that "γ-Fe_2O_3" which is the characteristic material for the passive state commences to be produced and reduced above and below this potential. Accordingly, E_a^1 appears

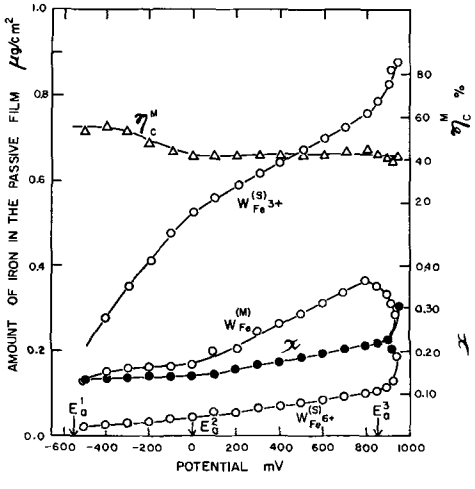

Fig. 15. Change of the composition of passive film with anodic potential (t = 1 hr).

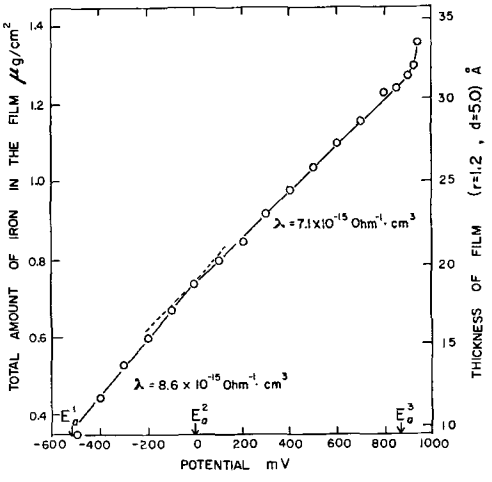

Fig. 16. Effect of anodic polarization on the film thickness

to be the threshhold potential above which γ-Fe_2O_3 is stable. At the characteristic potential E_a^2, a decrease in the slope of $W_{Fe^{3+}}^{(S)} - E_a$ curve and an increase in the slope of both $W_{Fe^{6+}}^{(S)} - E_a$ and $W_{Fe}^{(M)} - E_a$ curve were observed. The average current efficiency of the reduction of Fe_3O_4 ($\eta_c^{(M)}$) decreases with potential up to E_a^2 and stays constant at about 42% above E_a^2. This would suggest that a change in the nature of the Fe_3O_4 layer occurs below this potential. At the oxygen evolution potential E_a^3, a steep increase in both $W_{Fe^{3+}}^{(S)}$ and $W_{Fe^{6+}}^{(S)}$ is observed, while $W_{Fe}^{(M)}$ begins to decrease steeply with potential.[7]

The relation between total film thickness and potential shown in Fig. 16 was estimated according to Eq. [15] by assuming that the average density of both layers is 5 and the roughness factor of the surface is 1.2. A film thickness of about 10Å at the passivation potential E_a^1 corresponds to the order of one unit cell length of an iron oxide of spinel structure. It is not surprising that the individual thickness of γ-Fe_2O_3 or Fe_3O_4 layer at E_1^a is less than the unit cell length, because some continuous change in structure with the distance should be considered for such a thin oxide film, as is emphasized above. The total film thickness ranges from 10 to 30Å over the passive potential region. The apparent field strength in the film was estimated from the results shown in Fig. 5 by dividing the increase in potential by the increase in film thickness for a number of consecutive points on the curve and was found to be 5.8×10^6 v/cm and 7.0×10^6 v/cm below and above E_a^2 so that the apparent specific conductance of the film is 8.6×10^{-15} and 7.1×10^{-15} mho cm^2 for an anodic current density of 0.05 μa/cm^2. These values would be considered to correspond to cationic conductivity of the film which apparently controls the rate of growth of the film in the nonsteady condition of passivity. The significance of the characteristic potential E_a^2 and the role of defects in the mechanism of passivity will be discussed in a following publication.

Relationship between Composition and Anodic Potential

In the active region, that is at potentials below —500 mv, there appears to be a film, not necessarily continuous, of Fe_3O_4 on the metal. Above this potential both Fe_3O_4 and γ-Fe_2O_3 are formed. The major part of the passive film is formed within the first 10 sec of polarization (cf. Fig. 5). However, the composition of the film is very dependent on the potential of formation. Up to +850 mv there is an increase in thickness of the Fe_3O_4, Fe_2O_3 and the per cent vacancies. This is as one would expect if the outer layer of film is formed by anodic oxidation of magnetite and if the thickness of the total film required to decrease the migration rate below 0.01 μa/cm^2 is directly dependent on the potential drop across the film. In that a more positive anodic potential is the equivalent of a more strongly oxidizing environment, the increase in vacancies with increased anodic potential is also reasonable.

[7] The value of $W_{Fe}^{(M)}$ obtained above the oxygen evolution potential is probably not correct because a certain number of coulombs used for oxygen evolution would be included in the total amount of charge Q_a passed during the anodic polarization. However, if a correction were made for the partial amount of charge for oxygen production, the decrease of $W_{Fe}^{(M)}$ with potential would be much steeper.

Acknowledgment

The authors are indebted to Mr. L. Bradley for his help in constructing the electrical apparatus and to Mr. E. Brewer for the electron optical examination.

On the Fundamentals of Etching High-Purity Aluminum Foil for Capacitor Use

R. Bakish

Electronics and Alloys Incorporated, Ridgefield, New Jersey

and E. Z. Borders and R. Kornhaas

Republic Foil Corporation, Danbury, Connecticut

ABSTRACT

Studies on the factors underlying the morphology of etched structures are presented. The importance of coulomb input and current density are evaluated for their contribution to the morphological effects observed. Experimental results on studies conducted both with single crystals and polycrystals are presented.

The fundamental parameters underlying the etching of aluminum foil for capacitor applications are complex. The establishing of the processing variable affecting the morphology and its correlation with electrical properties of etched foils are of great interest.

A number of studies on the etching behavior of aluminum have been reported in the literature (1-5). These studies, however, are only related but not truly pertinent to the work discussed here inasmuch as they deal with chemical and not electrochemical etching processes.

In the work to be reported the authors attempt to establish the role of processing variables in the electrochemical etching process. The morphological parameters revealed as functions of these etching variables are evaluated, in order to establish their correlation to electrical properties of interest. The relative significance of the different variables is discussed.

Experimental Conditions

These studies were conducted on annealed high-purity 0.0035 in. foil meeting the specifications for 99.99% Al and on single crystals of selected orientations. All etching experiments were conducted in a simple cell maintaining a 2 in. cathode-anode spacing throughout the studies; 64.5 cm^2 specimens were used in all etching experiments. The 10% NaCl etching electrolyte used in this study was prepared from deionized water with resistivity better than 10^6 ohm-cm and 99.99% NaCl. All etching was performed under stationary conditions.

Weight loss, capacitance at 6, 75, and 550v, and morphological changes in the etched material were used as indices for the variables investigated.

Capacitance measurements were conducted in accordance with procedure given in Table I for 6v data, Table II for 75v data, and Table III for 550v data; 12.9 cm^2 specimens were used in all electrical tests. A current density range of 0.00698-0.489 amp/cm^2

Table I. Procedure for 6v data

Formation electrolyte	Measuring electrolyte	Forming procedure	Measuring procedure
Ammonium pentaborate 80 g/l. Solution resistivity 30 ohm-cm. Temperature 65°C.	Ammonium pentaborate 80 g/l. Solution resistivity 30 ohm-cm. Temperature 65°C.	1. Apply 23.3 ma/cm^2 until 6v is reached. 2. Hold at 6v for 30 min. 3. Record leakage current.	Record capacity into $\mu F/cm^2$. Record % dissipation factor.

Table II. Procedure for 75v data

Formation electrolyte	Measuring electrolyte	Forming procedure	Measuring procedure
Ammonium dihydrogen phosphate 1 g/l. Demineralized water 10^6 ohm-cm or better. Solution resistivity 400 ohm-cm at 90°C.	Boric acid 27.5g and ammonium pentaborate 20g/final liter of solution. Demineralized water 10^6 ohm-cm or better. Solution resistivity 190 ohm-cm at 25°C.	1. Apply 15.5 ma/cm^2 until 75v is reached and maintain voltage for 30 min. 2. Record leakage current.	Record capacity in $\mu F/cm^2$. Record % dissipation factor.

Table III. Procedure for 550v data

Forming electrolyte	Measuring electrolyte	Forming procedure	Measuring procedure
100g boric acid per final liter of solution.	27.5 g/boric acid 20g of ammonium pentaborate per final liter of solution.	1. Hydrate sample in boiling demineralized water for 5 min.	Measure capacity and record in $\mu F/cm^2$.
Demineralized water 10^6 ohm-cm or better.	Demineralized water 10^{-6} ohm-cm or better. Solution resistivity 190 ohm-cm at 25°C.	2. Apply 38.7 ma/cm² until 400v is reached.	
Solution resistivity 3000 ohm-cm at 90°C.	Temperature 25°C.	3. Decrease current to 25.7 ma/cm² and hold until voltage reaches 550v. Hold voltage at 550v for 30 min.	
Temperature 90°C.		4. Record leakage current.	

was investigated at 38.7, 72.9, and 108.5 coulombs/cm². These values were selected arbitrarily for this study. The single crystal current densities are calculated on basis of square centimeters of projected area.

All capacitance measurements were made with a General Radio 1611-A capacitance bridge with an accuracy of ± 1%. Polarizing current was not utilized in the measurements. Measurements were made at a frequency of 60 cps. The bridge circuit is so arranged that a maximum of 1 v-amp of reactive power is delivered to the sample.

Leakage current and dissipation factors were also measured and fell into a range considered to be good by the capacitor industry. It is hoped that these factors will be the subject of future study in connection with different anodizing electrolytes. All photomicrographs, unless otherwise specified, are at 750X.

Low index planes (100), (110), (111) of single crystals of aluminum grown from the melt of 99.99% Al were also used in these studies. The orientations were determined in accordance with classic Laue back reflection method, and all measurements are accurate within 2°. Current density and amount of charge with which all these single crystal planes were processed were selected on the basis of the polycrystalline etching experiments. After careful cutting, the crystal faces selected for these studies were wet ground through 0, 00, 000, and 0000 corrundum papers prior to final wet diamond abrasive polish on rotating wheel. Surface areas of these faces needed for calculations of current densities were measured by a planimeter. All surfaces, other than the one of interest, were masked with Hysol epoxy resin after making suitable electrical connections.

Experimental Results

Electrical measurements.—Capacitance and weight loss data obtained in the course of these studies for specimens etched at 38.7, 72.9, and 108.5 coulombs/cm² are plotted in Fig. 1. These data give the current density dependence of processing as function of amount of charge passed, weight loss, and capacitance for 6, 75, and 550v. Each point represents the arithmetic average of measurements conducted on 3 independently processed specimens. Capacitance of annealed foil, before etching or cleaning, was measured and gave results of 0.23 μF/6.45 cm² at 550v, 0.91 μF/6.45 cm² at 75v, and 17 μF/6.45 cm² at 6v. Etch ratios can be established from these data. The capacitance appears to vary in a similar fashion as a function of the current density at the different coulomb levels. Some differences in this mode of variation are observed as, for example, the apparent reaching of a plateau value at the high current density for the 72.9 coulomb/cm² measurements, with indications of continual increase, but at a lower rate,

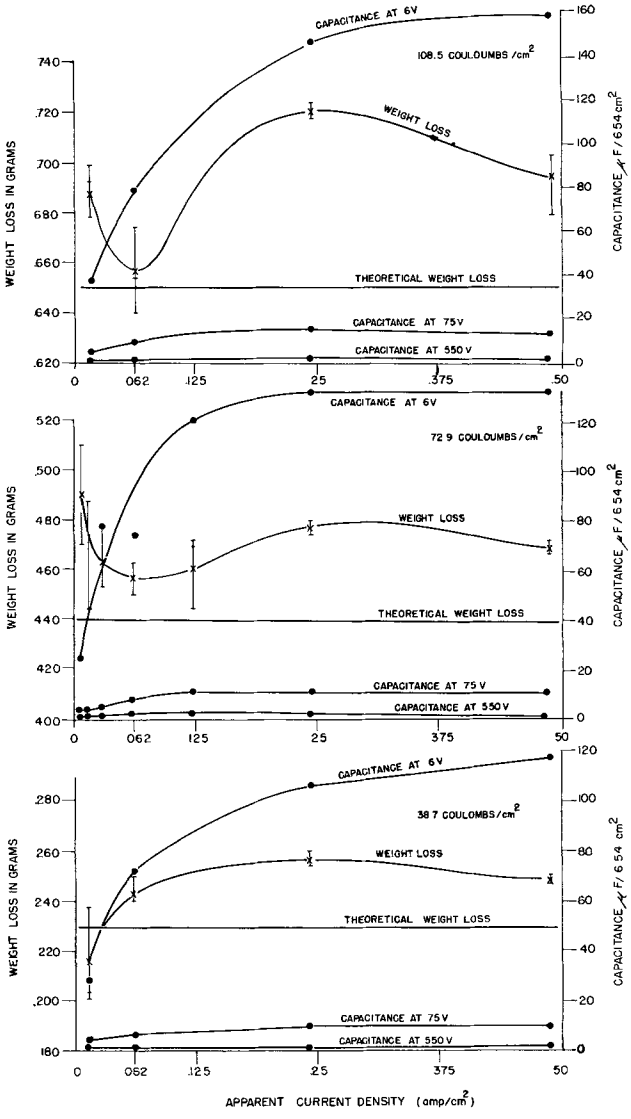

Fig. 1. Data for 99.99% Al processed at 38.7, 72.9, and 108.5 coulombs/cm².

with increase of current density for both the 38.7 and 108.5 coulomb/cm² measurements, this being true for the 6v formation. These trends are interesting, but it is felt that much additional data are needed before quantitative functional relations can be derived. At the present these curves will be considered only as indicative of significant trends.

The weight loss dependence on the current density appears to be different with the different amounts of charge passed. There is some similarity between the 72.9 and 108.5 coulomb/cm² weight loss curves, but this is only as a first order approximation. The curves themselves are extremely interesting because of possible processing significance, but to these authors they are difficult to interpret fully. Weight loss is plotted against current density calculated on the basis of the initial surface area of the samples, ignoring the fact that the real surface area was continually changing and at each measuring level was substantially different from the initial surface area.

The weight loss is basically a function of the amounts of charge passed, the efficiency of the process, and the initial configuration of the surface. The exact nature of this function is not known. The weight loss values obtained in this study are above the (calculated) theoretical weight loss data which are plotted as a straight line in the same figures. It appears that the most likely reason for this discrepancy is the high percentage of edge area relative to the sample size which must contribute to nonuniform current density distributions. In addition the possibility of chemical attack superimposed on the anodic dissolution exists. Loss of grains from the foils is also likely as a consequence of preferential grain boundary attack. It would be desirable to study further the weight loss dependence and to establish the real significance of this factor in the etching process.

Morphology.—Figure 2 shows the structures of foils etched at current densities of 0.489, 0.243, 0.118, 0.061, 0.030, 0.015, and 0.007 amp/cm² with 72.9 coulombs/cm². A clearly manifested systematic increase in the dimension of structural detail within the etched structure is observed as the current density decreased. Fine surface details leading to high capacities of formed foils result from etching with high densities while rather coarse structures are observed in the low range of current densities studied with corresponding decrease of capacities for the formed foils. In passing from the region of extreme fineness of detail to the relatively coarse structures shown there appears to be a range of current density where structure-sensitive details in the foil are revealed.

Fig. 2. Etched structures produced at current densities of 0.489, 0.243, 0.118, 0.061, 0.030, 0.015, and 0.007 amp/cm² and 72.9 coulombs/cm². Magnification 350X.

Fig. 3. Etched configuration associated with poligonized grain boundaries.

Fig. 4. Etched configuration associated with slip elements

Configuration of these indicates the possibility of these being dislocation arrays associated with poligonized sub-boundaries and slip lines. This appears to be true in the middle range of the current densities investigated and in particular at about 0.118 and 0.061 amp/cm². Figure 3 shows configuration believed associated with a poligonized grain boundary while Fig. 4 shows configuration associated with the 3 slip elements of this lattice.

To get additional details on the structures a set of specimens were etched at 38.7 coulomb/cm² and current densities of 0.015, 0.061, 0.243, and 0.489 amp/cm² and examined also by electron microscopy. Figure 5 shows both optical and electron optical detail on these structures. This set of microphotographs as well as morphological details observed with experi-

ments at 108.5 coulomb/cm² level show, quite conclusively, the importance of current density in producing a given structure, with the amount of charge passed having apparently only secondary importance. This is particularly observable when Fig. 2 and 5 are compared. The discussion hereto only considered the size of the structural detail without consideration of the crystallographic parameters involved.

After discussing the experiments conducted with single crystals the authors will come back to the crystallographic parameters involved both in the single and polycrystalline material.

Single crystal experiments.—As already stated, a number of low index planes were cut and polished from single crystals, and Table IV gives the experimental variables under which these crystals were processed as well as a brief indication of results observed. In essence, it is indicated that the 100 directions within each of these planes were delineated. Etching is a result of dissolution along <100> directions both within the plane and normal to it; these manifest themselves as rectilinear grooves (Fig. 6) in addition to much deeper etched structures in which the 90° symmetry elements can also be seen. Etching on the (110) is typified by a series of parallel grooves or only ½ of the symmetry elements shown in the <100>, demonstrating as in the x-ray Laue back reflection photographs, 4-fold and 2-fold symmetry, respectively. Figure 7 shows structure produced by etching at 0.061 and 0.020 amp/cm², respectively. This figure also asserts the trend toward coarser structures as observed with the polycrystalline samples as a consequence of etching at lower current density. Figure 8 shows the appearance of a (111) face after etching under conditions, given in Table IV for crystal NO32. The 3 <100> directions within the (111) plane are delineated, and this type of micro detail leads to the observed etching and gross material removal.

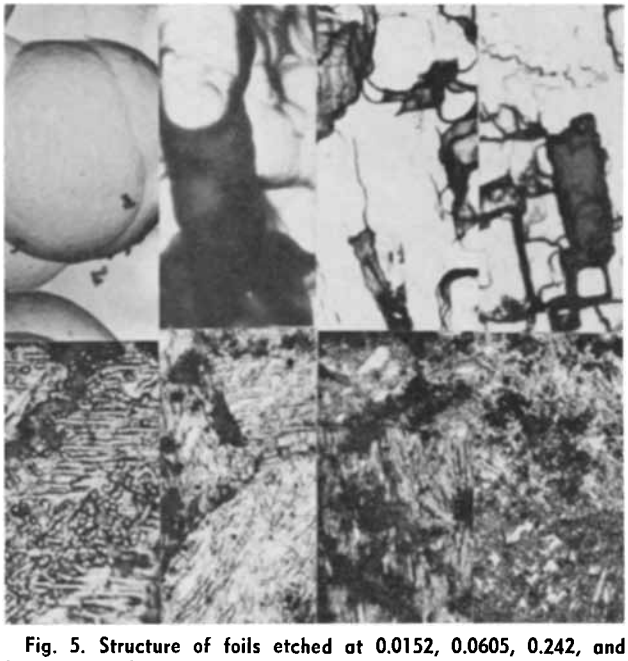

Fig. 5. Structure of foils etched at 0.0152, 0.0605, 0.242, and 0.48 amp/cm² at 38.7 coulombs/cm². Note the conversion from angular to bulbous structural detail with corresponding increase of detail size.

Discussion of Results and Conclusions

Considering the data presented the significant role of current density in the etching process is clearly

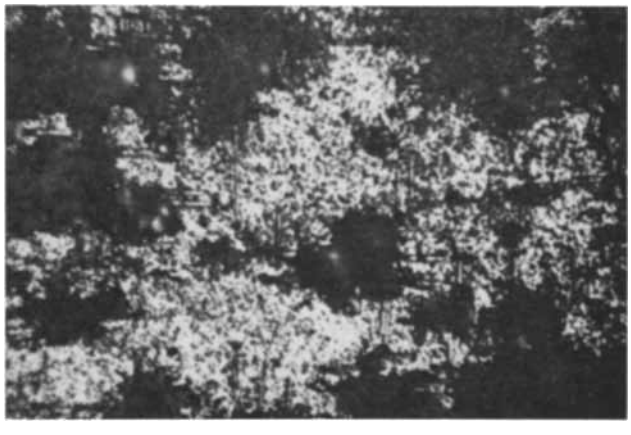

Fig. 6. Characteristic etch on a (100) crystal face processed with 0.0605 amp/cm² and 38.7 coulombs/cm².

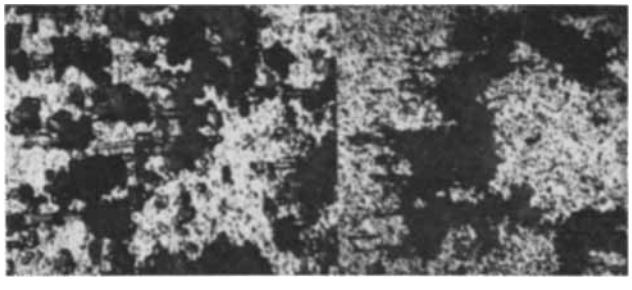

Fig. 7. Characteristic etch on a (110) crystal face processed with 0.0605 amp/cm² and 0.0202 amp/cm² at 38.7 coulombs/cm².

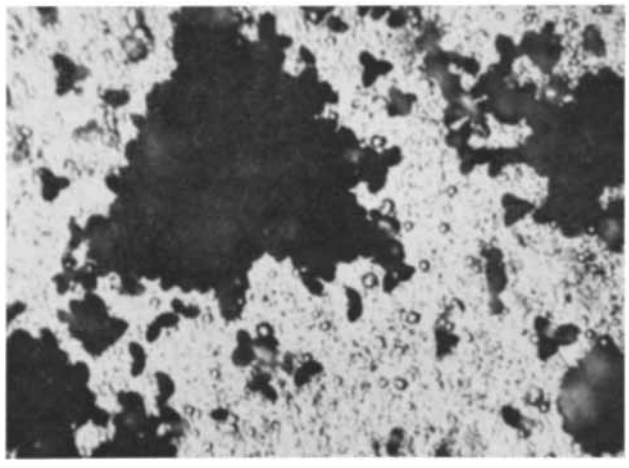

Fig. 8. Characteristic etch on a (111) crystal face processed with 0.0605 amp/cm^2 and 38.7 coulombs/cm^2.

demonstrated. The electrolyte composition and temperature can play an important role, but in this study they have not been investigated. As one increases current density at a given amount of charge passed the etched structure becomes finer, and an increase in the surface area is observed by the increased capacitance of the foil. Within the current density ranges studied it also appears that one tends to reach a limiting value above which capacitance cannot be greatly improved even by significant increase in the amount of charge passed. This capacitance behavior, namely, the increase of capacitance with increase of current density, can well be interpreted by the analysis of the morphology of the etched structures conducted in this study.

The significant crystallographic factors remain constant and are not subject to variation by either coulomb or current density variation. On the basis of observations made on the single crystals it can be stated that the <100> directions appear to play a most important role in the etching process under the experimental conditions of this study. Chemical etching processes with different electrolytes tend to change this behavior (1). A number of grains which are apparently of substantially higher index do not appear to exhibit the 100 crystallographic features, but instead tend to show essentially noncrystallographic, almost spherical, structural details. The mechanism and exact reasons leading to these different morphological manifestations are not fully understood. It is hoped that continuation of the work initiated and reported here with single crystals will lead to the eventual understanding of these observations. The ability to control variation of structural detail through control of current density appears to be a step in the right direction in the quest of manufacturing good custom property etched foil. The full understanding of the phenomenon and the true relationships involved are yet to be established.

Polarization and Inhibition of Steel in the NH_4NO_3-NH_3-H_2O System

J. D. Goodrich[1] and Norman Hackerman

Department of Chemistry, The University of Texas, Austin, Texas

ABSTRACT

Anodic and cathodic polarization for the system steel-NH_4NO_3-NH_3-H_2O were measured with and without added inhibitor. Phenomena typical of passivation were obtained on anodic polarization. Steel deliberately covered with thin oxide showed similar effects and provides the basis for a discussion of the possibilities of bulk oxide as the cause of passivity. Although this is shown to be feasible, it is by no means conclusive since charge needed for active-passive transition is very much less than that equivalent to bulk oxide iron transition. Inhibition by SCN^- operates by replacement of the reduction reaction NO_3^- to NO_2^- by H_2O to H_2.

Dissolution rates have been reported for this system (1) as high as 29,000 mdd at 30°C. The primary cathodic reaction involves reduction of NO_3^- to NO_2^-. Formation of an iron-ammonia complex was offered as the primary effect responsible for the high dissolution rates.[2] The oxidation product was reported

[1] Present address: Department of Chemistry, Louisiana State University at Alexandria, Alexandria, Louisiana.

[2] The possibility of a more stable product such as "ammonium hexanitritoferrate (II)" is being considered at this time.

as being a hydrated or ammoniated form of ferrous hydroxide.

Several interesting facts arose from earlier work (2) on this system. The open-circuit dissolution potential was found to change about 0.2v in an anodic direction when the inhibitor SCN^- was added. Also, an inactive to active transition was observed when the system was subjected to stress. For example, rates changed from near 0 to 29,000 mdd in some cases when small stresses were applied. This investigation attempts to explain these and other phenomena exhibited by this system.

Experimental

Polarization data were taken both potentiostatically and galvanostatically, but unless stated the data were obtained by the former procedure. An electronic "Wenking" potentiostat, modified for use with U.S. tubes, was used in conjunction with a L&N student-type potentiometer. All currents were time dependent as usual. The values given here were constant for at least 5 min. All points on the curves are averages of two or more measurements, and the data were all within ± 3% of the averages. The solution composition in all experiments was as follows: NH_4NO_3, 66.4; NH_3, 14.3; H_2O, 19.3 w/o. The NH_4NO_3 was reagent grade and gave a negative test for nitrite ion. Distilled water and anhydrous NH_3 were used with no further purification. The solutions were held at 25° ± 1°C and were not stirred. An H-type cell was used with the arm containing the steel test electrode having a 50 ml capacity. A reference saturated calomel electrode made contact with the test solution via a KNO_3 salt bridge. No junction potential corrections were applied. The test electrode of type MICO steel (should be designated as D269B) was mounted in paraffin, while the polarizing electrode consisted of a coiled platinum wire 4 cm long. This steel was obtained from the U. S. Steel Company with the composition in w/o given as 0.048 C, 0.32 Mn, 0.006 Si, and 0.028 S.

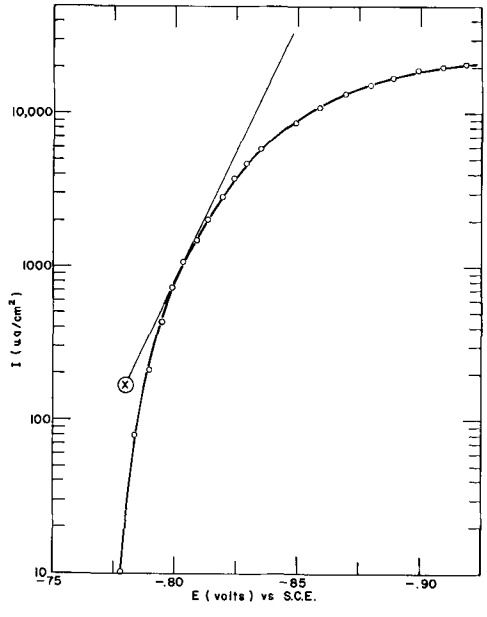

Fig. 1. Cathodic polarization curve (potentiostatically), steel D269B, 25° ± 1°C, *E* vs. Log *i*.

Results

Upon cathodic polarization a curve was obtained (Fig. 1) which exhibited no readily discernible "Tafel" region. Gas was not evolved below 10 ma/cm², but above this hydrogen was produced as shown by gas chromatography. The absence of gas evolution below 10 ma/cm² substantiates the proposition that the reduction reaction was NO_3^- to NO_2^-. Assuming a two-electron change in the over-all reaction, point X (Fig. 1) is obtained from the intercept of the measured steady-state dissolution potential and from the dissolution rates via Faraday's law. If the rate could have been determined in this system from a polarization curve which exhibited a distinct Tafel line, point X should lie on this line. From the slope of the line through this point and tangent to the curve a value of 0.03 ± 0.01v was obtained for the Tafel b. Of course, the method is subject to error if concentration polarization is controlling to any appreciable degree.

Figure 2 gives a typical anodic polarization curve for this system. It is characteristic of passivation of iron or steel in other solutions. There is no distinctly linear portion in the region of active iron dissolution, *i.e.*, −0.6 to −0.8v but again a line was constructed by using point B. It has a slope of 0.07 ± 0.01v, about the same as for iron dissolution generally. Gas evolution occurring in the region of +0.8v was shown to be oxygen by flame tests.

Galvanostatic anodic polarization gave Fig. 3, again typical of such curves for Fe in other solutions. It is similar to Fig. 2 between the open-circuit potential and an apparently critical current density, but discontinuous from there to oxygen evolution. Decreasing the current density once oxygen evolution occurs gives a curve which is similar to all of the curve of Fig. 2. If the applied current is turned off after the oxygen evolution region is reached, the electrode maintains a potential within the region −0.4 to +0.7v unless disturbed. In summary, this is typical passivity behavior.

Effect of inhibitors.—The inhibitor efficiency of SCN^- is quite high as shown by the weight-loss data of Table I for different NH_4SCN concentrations.

The open-circuit potential changed 170-200 mv in the anodic direction when this inhibitor was added.

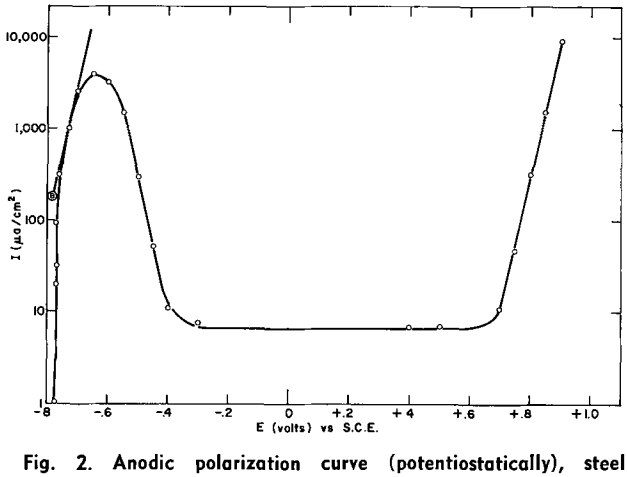

Fig. 2. Anodic polarization curve (potentiostatically), steel D269B, 25° ± 1°C, *E* vs. Log *i*.

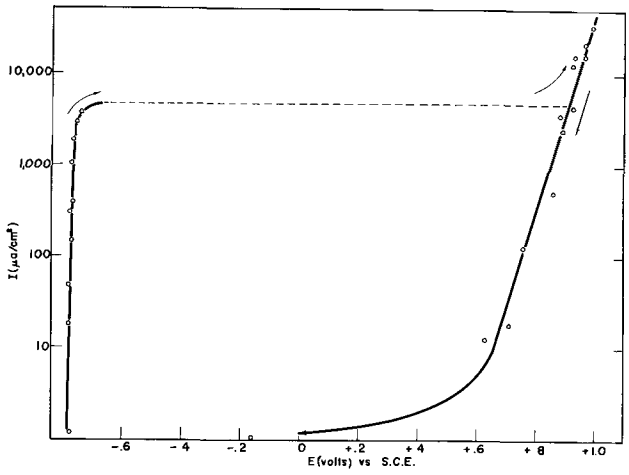

Fig. 3. Anodic polarization curve (galvanostatically), steel D269B, 25° ± 1°C, *E* vs. Log *i*.

Anodic and cathodic polarization curves, such as those in Fig. 4, were obtained for steel inhibited with 0.013M NH_4SCN. Linear plots extending over several log cycles were obtained. The slope of the cathodic curve is 0.11 ± 0.005v and that of the anodic curve is 0.05 ± 0.005v. The effects shown in Fig. 4 are for the steel in the active state. Polarizing anodically to current densities higher than shown on Fig. 4 gives a discontinuous curve (similar to Fig. 3) with galvanostatic measurements while potentiostatic measurements yield a curve similar to Fig. 2. Thus the inhibition has not induced passivity.

In this case, hydrogen evolution occurred immediately upon cathodic polarization. Anodic polarization to positive enough potentials give curves like those of Fig. 2 or 3, depending on the procedure used.

The open-circuit potential of steel in NH_4OH solutions is very near that of the steel in the solutions in this study inhibited with SCN^-, *e.g.*, —0.95v. The dissolution rates are also similar, near 30 mdd at 30°C.

Inhibition by other sulfur-containing compounds, such as thiourea, 2, 3-quinoxalinedithiol, mercaptoacetic acid, and sodium sulfide, was as complete as with SCN^-. In each case, the potential shifted 170-200 mv in the anodic direction.

The dissolution rate of inhibited steel (SCN^-) increased slightly when oxygen was bubbled over its surface.

Active-inactive transitions.—Steels with potentials of the order of —0.78v were always active, and those with potentials more positive than —0.3v were always inactive. Sample activation was accompanied by an increase in rate by as much as 1000 times and a shift of potential of 400-500 mv in an anodic direction. Activation was obtained by application of small stresses, by acid pickling, by pre-exposure to hot dry H_2, among other methods.

Table I. Effect of NH_4SCN on dissolution rate

M × 10^2 NH_4SCN	Rate, mdd, 30°C

3.3	30

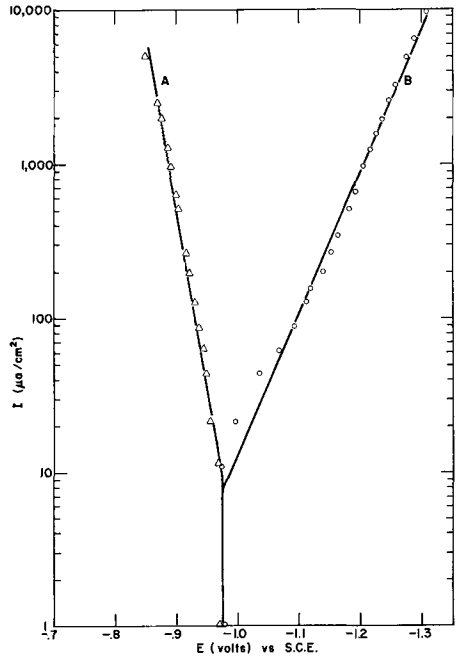

Fig. 4. Anodic (A) and cathodic (B) polarization (potentiostatically), steel D269B, 25° ± 1°C, 0.013M NH_4SCN, *E* vs. Log *i*.

A series of experiments were performed in which the steel samples used throughout this work were heated at 750°C in a stream of dry H_2 for 1 hr and then placed in the NH_4NO_3-NH_3-H_2O solution without coming into contact with air. This was done by closing the heated tube, reducing the pressure, and placing one end in the solution. All samples showed high dissolution rates in the NH_4NO_3-NH_3-H_2O system after being subjected to the high-temperature H_2 treatment. A set of steel samples with preformed thin (blue) oxide on them was kindly provided by John Griess of Oak Ridge National Laboratory. These lay inactive for months in this solution, but were activated by the high temperature H_2 treatment. Oxide covered steel always exhibited open-circuit potentials in the region —0.4 to +0.7v.

Conclusions

Certainly the changes shown in Fig. 2 and 3 indicate that the steel is being passivated. The fact that the anodically treated steels and the oxide covered steel exhibit similar potentials, —0.4 to +0.7v, and equally low rates suggest that an oxide film is involved in both cases. The insolubility of Fe_2O_3 in NH_4NO_3-NH_3 solutions as reported by Leonard (3) would justify this viewpoint. Also, the inactive-active transition resulting in potential changes of 400-500 mv in a cathodic direction when small stresses are applied could be caused by oxide cracking. Certainly it is difficult to explain it on the basis of stress effect alone. Yet the argument is not conclusive because in the anodic polarization the total number of coulombs passed between active dissolution (therefore clean steel surface) and *E* of about —0.4 in Fig. 2 is manifold less than that equivalent to the blue oxide of the deliberately coated samples.

Thus, one is left with the conclusion that the metal uniformly covered by thin film simply lends itself very readily to self-passivation, given that a small amount of dissolution occurred.

Of interest is the fact that oxygen is not needed in this system; and of considerable significance is the fact that the iron appeared to be in the dipositive oxidation state in the solution.

The small differences between the slopes of the inhibited and uninhibited anodic curves, *e.g.*, 0.05 and 0.07v, shows that the anodic reaction is being affected to only a small extent by SCN^-, although they might be affected importantly. However, the slope of the cathodic curves changed considerably (0.03-0.11) even when taking into account the large experimental error in the slope of Fig. 1. This indicates a change of reaction. The formation of hydrogen gas on cathodic polarization of the inhibited system (Fig. 4) confirms the replacement of $NO_3^- \rightarrow NO_2^-$ by $H_2O \rightarrow H_2$. The observed increase of rate by a hydrogen depolarizer such as oxygen further substantiates this. Cessation of the NO_3^- reduction reaction by inhibition results in a system which is essentially $Fe\text{-}NH_3\text{-}H_2O$, and it is a fact that iron in $NH_3\text{-}NH_4NO_3\text{-}H_2O\text{-}NH_4SCN$ exhibits the same potential. —0.95v, and rate as does iron in NH_4OH. Thus, the effect is largely one of alteration of the cathodic reaction.

Although sulfur appears to be the element responsible for inhibition in these experiments, no attempt is made to explain its function at this time.

Acknowledgment

The authors are pleased to acknowledge the financial support of this work by the Robert A. Welch Foundation of Houston and by the Office of Naval Research under Contract NONR 375(02). They also wish to take this opportunity to thank the U. S. Steel Company for some of the steel samples used in this study and J. Griess for the oxide covered steel which he kindly provided to them for this work.

Manuscript received Feb. 7, 1962; revised manuscript received May 15, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Effect of Some Addition Agents on the Kinetics of Copper Electrodeposition from a Sulfate Solution

I. Cathode Potential-Current Density Relation

D. R. Turner and G. R. Johnson[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The mechanism whereby certain organic addition agents modify the crystal growth of copper electrodeposits was studied with the aid of cathode polarization measurements and microscopic examination of the deposit. Thiourea and l(-) cystine refine grain size and brighten the deposit. The effect is attributed to a degradation of the additive at the cathode surface with the formation of sulfide ions and precipitation of CuS. The normal crystal growth habit is modified by the incorporation of copper sulfide into the deposit. Gelatin, a grain refiner and hardener, modifies crystal growth of copper electrodeposits by being adsorbed on growth sites thereby interfering with normal growth. Glycine, a "leveling" agent, affects cathode polarization only between about 0.1 and 1 ma/cm^2. Additions of up to 0.1 g/l dextrin have no effect on the cathode polarization curve for copper plating.

The purpose of this work was to study the mechanism of addition agents in electroplating. An addition agent is defined as any material which is added to an electroplating bath for the specific purpose of modifying the physical properties of the deposit.

Relatively small amounts of addition agents have large effects on physical properties of deposits such as brightness, smoothness, hardness, and ductility. Most addition agents are organic compounds, but occasionally inorganic materials are employed. Organic addition agents are used in concentrations from 10^{-6} to 10^{-1}M, while inorganic materials (usually codepositing metals) may range from 10^{-6}M up to concentrations which give deposits better described as alloys.

Practically all commercial electroplating baths contain one or more addition agents. In spite of this extensive use, however, little is known about how addition agents function. The art of electroplating is still far ahead of the science. This is not because of a lack of effort, but rather it is an indication of the degree of difficulty encountered in conducting significant experiments or in carrying out rigorous theo-

[1] Present address: Sprague Electric Company, North Adams, Mass.

retical analyses of electroplating processes. The difficulty lies in the fact that the process of electroplating contains a large number of variables, and some are not easily controlled. Attempts to control as many variables as possible often lead the experimenter to a large cumbersome piece of apparatus which only gives up data at a painfully slow rate. The theoretician must make a great many assumptions to make any headway, and these often destroy the value of the effort. Addition agents appear to work by somehow interfering with the normal crystal growth of electrodeposits. This interference should modify the kinetics of electrodeposition. One method of studying the kinetics of electrode processes is by means of analyzing electrode potential-current density data (polarization curves). This technique was applied in the work to be described in this paper.

As many of the known variables as possible were controlled without markedly interfering with the process of obtaining data. The simplest plating system is one which deposits metal from uncomplexed ions in solution and where there is only one electron transferred for each metal atom deposited. Strange as it may seem, there is no plating system in practical use which meets the two requirements. As a compromise, we chose to work with copper plated from an acid sulfate solution. This is a simple salt solution, but a two electron transfer is involved.

General theory of electrodeposition.—In order to understand how addition agents work, it is desirable first to have some concept of how metal ions are discharged and built into a crystal lattice in the absence of addition agents. In the discussion to follow, the process of metal ion desolvation or stripping of complex ion ligands prior to metal deposition will not be considered although it certainly is part of the overall mechanism. It has been suggested that metal electrodeposition occurs in three steps: (i) charge transfer to give adatoms (or adions); (ii) surface diffusion of adatoms; and (iii) adatom deposition into kink sites on the cathode. Adatoms may carry some positive charge which is discharged when the adatoms are incorporated into the crystal lattice. The rate of metal deposition is generally considered to be determined by either the initial charge transfer process or the surface diffusion of adatoms (1-4). In copper plating from acid solutions, Mattsson and Bockris (3) have shown that the rate-determining step at low current densities ($< i_o \cong 3$ ma/cm^2) is surface diffusion of adatoms while at high current densities the charge transfer process is controlling. Barnes (5) found a correlation between crystal growth habit and the overpotential above 3 ma/cm^2 which was explained in terms of adion mobility over the crystal surface and supersaturation.

The theoretical rate equation for the charge transfer process is

$$i = i_c + i_a = i_o \left[\exp\left(\frac{-\alpha_c F \eta_A}{RT}\right) - \exp\left(\frac{\alpha_a F \eta_A}{RT}\right) \right] \quad [1]$$

where i is the net plating current density, i_c is the total plating c.d. (cathodic currents taken as +), i_a is the deplating c.d., α_c is the cathodic transfer coefficient (that portion of the activation overpotential, η_A, which lowers the energy barrier for plating); i_o is the exchange c.d., α_a is the anodic transfer coefficient; R, T, and F have their usual meaning. The discharge of cupric ions is a two electron transfer process per ion, thus $\alpha_c + \alpha_a = 2$. If the activation overpotential is more negative than about 50 mv, the second term in the brackets of Eq. [1] can be neglected, *i.e.*, the anodic or deplating current, i_a, is negligible as compared to i_c and

$$i = i_o \left[\exp\left(\frac{-\alpha_c F \eta_A}{RT}\right) \right] \quad [2]$$

On rearranging:

$$\eta_A = \frac{RT}{\alpha_c F} \ln i_o - \frac{RT}{\alpha_c F} \ln i \quad [3]$$

Let

$$a = -\frac{RT}{\alpha_c F} \ln i_o$$

and

$$b = \frac{2.3RT}{\alpha_c F}$$

and we have the Tafel equation

$$-\eta_A = a + b \log i \quad [4]$$

The kinetic parameters α_c and i_o are easily determined from experimental data by plotting η_A against log i. Above ~50 mv, the η_A-log i curve is linear. The slope b is equal to $0.059/\alpha_c$ at 25°C while a straight line extrapolation to the current density axis at $\eta_A = 0$ gives i_o (see Eq. [3]).

Experimental and Apparatus Procedure

Careful consideration was given to the design of the electrolytic cell in order to achieve uniform current distribution over the cathode surface while permitting, at the same time, an accurate measurement of the cathode potential. A cross-section view of the arrangement used is shown in Fig. 1. It is a modified form of a cell devised by Barnartt (6) for anodic studies.

The cathode is OFHC[2] copper machined to a sphere with a cylindrical post for support and electrical contact. A glass sleeve masks the cylindrical portion so only the spherical surface is exposed. The end of the glass sleeve is beveled, as shown in

[2] Oxygen-free high conductivity.

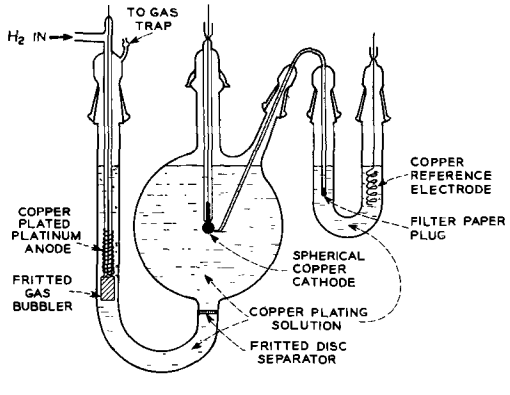

Fig. 1. Cross-section view of electrolytic cell

Fig. 1, to avoid a current masking effect by the sleeve around that portion of the sphere (6). A small hole is drilled into the top of the cylinder to take the OFHC copper wire which conducts current to the cathode. The top of the cylinder is squeezed in a vise to fasten the copper wire without resorting to a contaminating solder. Prior to use, the copper spheres are electropolished in 50% (by volume) orthophosphoric acid and rinsed in 10% (by volume) sulfuric acid. The cathode assembly is mounted to the cell by means of a ball and socket ground glass joint so the electrode can be positioned close to but not touching the capillary tip leading to the reference electrode.

The cell is constructed from a 500 ml round bottom flask which serves as the cathode compartment. It is separated from the side arm anode chamber by a medium porosity sintered glass disk. In addition to the opening for the cathode at the top of the flask, there are three other ports. Only the one to the reference electrode is shown in Fig. 1, to simplify the drawing. The other two are at right angles to the one shown, one projects outward and the other inward from the illustration. Standard taper ground glass joints were used throughout. The joints were protected from freezing by using tapered polyethylene sleeves. One of the ports not shown in Fig. 1 is for a gas bubbler so that oxygen and other gases can be displaced from the plating solution by hydrogen gas. Bubbling hydrogen over the cathode also provided a convenient means of stirring the solution to minimize concentration polarization. The other port not shown was used to add or withdraw material from the cathode chamber.

Initial experiments were carried out using a saturated KCl calomel reference electrode, but it proved to be unsatisfactory since chloride ions diffused into the cathode chamber and gave anomalous results. A copper plated copper reference electrode in the copper plating solution worked very well. The copper reference electrode had an added advantage in that the cathode potentials measured were polarization values. Connecting the reference electrode to the cathode was done with a syphon as shown in Fig. 1. The glass is drawn to a fine capillary tip at one end (~0.4 mm OD) and plugged with rolled-up filter paper at the other end. The IR drop included in the electrode potential measurement was computed to be negligible, < ~1 mv, in the highly conducting plating solution.

The anode for the plating experiments was a copper plated platinum wire wound on a gas bubbling plug. The copper was plated from a purified solution. Hydrogen gas was bubbled over the anode continuously to avoid concentration gradients in the solution and to sweep out any oxygen produced. The hydrogen bubbled through both the anode and cathode chambers was vented through gas traps.

The entire cell up to the solution level was immersed in a water thermostat set at 25.0° ± 0.01°C.

The electrolyte used in this study consisted of 1M $CuSO_4$+1M H_2SO_4. In order to determine the true effect of the addition agents to be studied, the plating solution must be purified of all important impurities, inorganic as well as organic. Our first concern was to determine if it was necessary to purify reagent grade chemicals of trace inorganic impurities. Copper sulfate was recrystallized 3 times using freshly deionized water filtered free of bacteria. Sulfuric acid was purified by distillation and only the middle portion of the distillate was collected. The cathode potential-current density curves obtained in the highly purified solution were not significantly different from the results obtained without improving reagent purity. It was important to remove all surface-active material from the plating solution, however. This was done by passing the plating solution through a carefully prepared "Chromatograph type" column containing about 12 lb of Baker activated alumina and about ½ lb of Darco Red Label activated carbon. A IM H_2SO_4 solution was used to wash the column beforehand and also as the displacing liquid to extract the desired amount of plating solution. It was customary to make up and treat five liters of plating solution at a time. Of this, four liters were collected and stored in a glass-stoppered Pyrex bottle. The material in the purifying column was used to treat only one batch of plating solution.

Thiourea, 1(-)cystine, glycine, gelatin, and dextrin were used as addition agents. Most of these materials are used in the commercial plating of copper from acid sulfate solutions. Thiourea refines the grain size and brightens the deposit. 1(-) Cystine is not commonly used in acid copper plating. However, its chemical structure is similar to thiourea so one would expect a similar behavior as an addition agent. Glycine affects the microdistribution of copper plating and is called a "leveling" agent. Gelatin is a colloidal material which reduces grain size and hardens the deposit. Dextrin is generally used with thiourea and enhances brightening. The structural formulas of the additives are given in Fig. 2 for the purpose of noting the parts of structure they have in common. All contain amine groups except dextrin. The sulfur in thiourea and 1(-) cys-

tine is an active group since the corresponding oxygen substituted compounds such as urea are not effective as addition agents.

The addition agents were dissolved in a sample of plating solution and then added to the bath. The speed of addition agent dissolution in the sample solution was increased markedly by dipping the beaker into an ultrasonic cleaner tank.

Since many polarization measurements were to be made, it was considered worthwhile to develop an apparatus which would automatically plot electrode polarization-log current density curves. A block diagram of the apparatus is given in Fig. 3. The control unit in the center of the diagram is the heart of the arrangement. A 21 contact-6 section step by step relay is actuated at 1-min intervals using a synchronous motor-cam-microswitch pulsing device. Each time the stepping relay is actuated, the current from the power supply to the cell is changed. This is done by changing the resistance in the circuit of a Teletronics Model PS-110 constant current power supply. As the cell current changes with each relay step, another electrical circuit provides a voltage which deflects the pen along the X-axis of a L&N X-Y recorder in proportion to the logarithm of the cathode current density. The voltage between the copper sphere and copper reference electrode is passed through a cathode follower-type amplifier to the recorder to avoid drawing an excessive current from either electrode. Just before the plating current is changed, the X-Y recorder pen makes a dot on the paper as shown in Fig. 3. A direct plot of polarization-log current density speeds data analysis since the apparent exchange current and Tafel slope can be read off immediately.

Results and Discussion

Purified solutions.—Initial experiments were carried out in 1M copper sulfate + 1M sulfuric acid solution free of addition agents. Anodic as well as cathodic polarization curves were obtained and a summary of the results are given in Fig. 4. The rest potential of a copper electrode in the plating solution at 25°C is +0.31v *vs.* H_2 electrode. A Tafel slope of 100 ± 3 mv/current decade was observed when cathodic (copper plating) and 43 ± 3 mv/current decade when anodic (deplating copper). These values were obtained from six cathodic and 5 anodic polarization curves. The corresponding transfer coefficients from $b = 0.059/\alpha$ are $\alpha_c = 0.59 \pm 0.02$ and $\alpha_a = 1.38 \pm 0.10$. The sum of α_c and α_a is 1.97 ± 0.12, close to the theoretical value of 2.

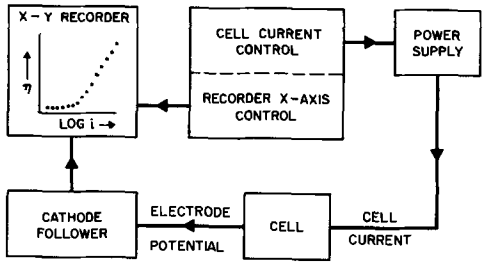

Fig. 3. Block diagram of apparatus for automatically recording electrode potential-log current density curves.

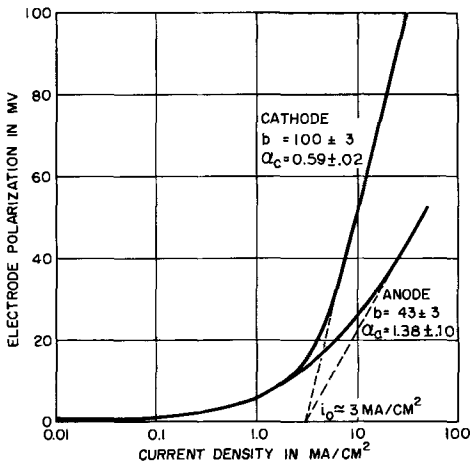

Fig. 4. Anodic and cathodic polarization curves for a copper electrode in purified IM $CuSO_4$ + IM H_2SO_4.

Both the anodic and cathodic Tafel slopes extrapolate to an exchange current density of about 3 ma/cm².

The transfer coefficients and exchange current density obtained in this study agree closely with results obtained by Mattsson and Bockris (3) who used a constant current pulsed plating-deplating technique. They concluded that the rate-determining reaction at high current densities (> 50 mv) for plating and deplating copper in acid sulfate solutions is

$$Cu^{++} + e^- \underset{\longleftarrow}{\overset{\text{SLOW}}{\longrightarrow}} Cu^+ \qquad [5a]$$

while

$$Cu^+ + e^- \underset{\longleftarrow}{\overset{\text{RAPID}}{\longrightarrow}} Cu \qquad [5b]$$

exists in reversible equilibrium with Cu at the electrode surface.

Plating on single crystal copper.—The results of electroplating copper from additive-free solutions on single crystal copper will be mentioned here as background material for the discussion to follow on the effect of gelatin in acid copper plating. Copper was electroplated on the (100) face first at 1 ma/cm² current density and later at 10 ma/cm². Photomicrographs were taken of the same area after a sequence of anodic etching and plating operations. These are given in Fig. 5. The etch pits in Fig. 5A are square shaped as expected for the (100) face. Outlines of the etch pits are barely visible after 1 hr plating at 1 ma/cm² (B); however, a four sided pyramidal crystal has started growing out of the surface. After 2 hr plating at 1 ma/cm² (C), the pyramid has grown and no new ones appeared in the area viewed. Next, the surface was anodically etched in the plating solution for 10 min at 1 ma/cm², Fig. 5D. Square etch pits were again evident which indicated that copper had deposited as a single crystal with the same orientation as the base layer. Large steps appeared on the pyramid faces. When copper plating was resumed at ten times the original current density, 10 ma/cm², the plating time was reduced by a factor of ten in order

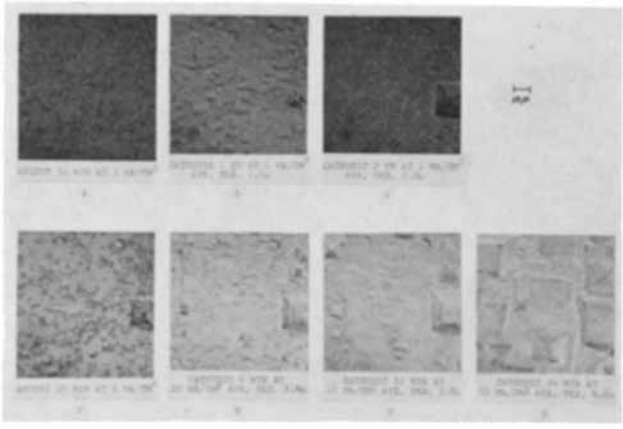

Fig. 5. Photomicrographs of the same area on a single crystal of copper (100) after anodic etching and copper plating at 1 and 10 ma/cm². 750X before reduction.

to compare deposits of the same thickness. In Fig. 5E, two things are immediately evident: (i) the number of pyramids growing has increased markedly, and (ii) the original pyramid appears truncated. All the pyramids growing at 10 ma/cm² plating c.d. eventually become truncated. Previous workers (7, 8), reporting on the crystal growth form in copper plating, have stated that an abrupt transition occurs from pyramidal growth to cubic layer growth at a critical current density (~2 ma/cm²). Our results show that even above the critical c.d., copper crystals begin to grow as pyramids and later develop flat tops and convert to cubic layer growth.

Effect of addition agents.—The effect of thiourea, l(-) cystine, glycine, gelatin, and dextrin in the copper sulfate bath on the cathode potential-current density relation was determined at various addition agent concentrations. Additions of up to 0.1 g/l dextrin had no effect on the η-log i curve for copper plating. All the other additives did influence the polarization curve and each one behaved differently. The reproducibility of the polarization curves varied with the addition agent and experimental conditions. Thus it is possible to give only a qualitative evaluation of the results.

Thiourea in acid copper sulfate solutions displaces the rest potential of a copper electrode in the positive direction. At low thiourea concentrations, 10^{-6}M, the electrode potential requires several hours to reach a steady value. The potential change increases with thiourea concentration and reaches a limiting value of about +15 mv, with respect to a copper reference in additive-free solution, at about 10^{-4}M, thiourea.

The potential of a copper electrode in the acid copper plating solution containing thiourea is a mixed potential between the equilibrium reduction potential of thiourea and the dissolution potential of copper. In effect, thiourea causes copper to corrode in acid copper plating solutions.

When a copper electrode is made cathodic in 1M $CuSO_4$+1M H_2SO_4 with thiourea at low current densities, the electrode potential remains near the rest potential up to about 0.1 ma/cm² where an abrupt change occurs. This is shown in Fig. 6 where cathode potential-current density curves are given for various thiourea concentrations. The current density at the step in potential appears independent of thiourea concentration, but the step height increases with thiourea concentration. The curves for 4 x 10^{-6} and 4 x 10^{-5}M thiourea, show that there is a region between about 5 and 50 ma/cm² plating c.d. where the electrode potential is lower with addition agent than without it. All the curves reach the lower end of the Tafel line at about 20 ma/cm². The transfer coefficient for copper plating, α_c, derived from the Tafel slope, decreases with increasing thiourea concentration and reaches a limiting value of about 0.2 at about 10^{-4}M thiourea. The corresponding exchange current density, i_o, obtained by extrapolating the Tafel line to zero polarization, increased abruptly at low thiourea concentrations to about 10 ma/cm², and then it gradually decreased with increasing thiourea back to the original value of 3 ma/cm² at about 4 x 10^{-4}M thiourea.

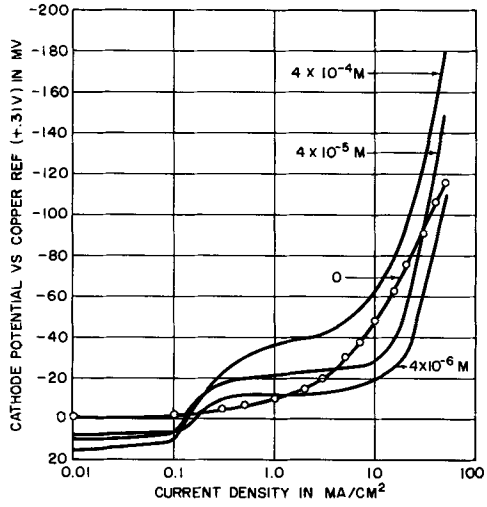

Fig. 6. Effect of thiourea concentration on the cathode potential-current density relation in copper plating.

An interpretation of the effect of thiourea on copper plating from acid sulfate solutions and the polarization curves in Fig. 6 is aided by measurements of the cathodic plating efficiency with and without thiourea over a range of current densities, Fig. 7. These experiments were carried out with cylindrical copper cathodes (5.0 cm² surface area) in unstirred solutions. Cathode efficiencies were determined from the weight gain after plating to a theoretical deposit thickness of 0.005 in. assuming 100% efficiency. Below about 1 ma/cm² current density, the cathode efficiency for copper plating decreases. With the additive-free solution, the de-

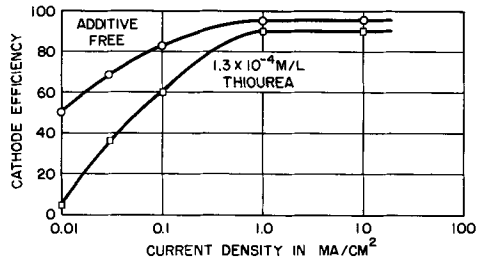

Fig. 7. Effect of current density on the copper plating efficiency with and without thiourea.

crease can be attributed either to the reduction of dissolved oxygen or to the incomplete reduction of some cupric ions. The effect is much greater with thiourea which suggests that either thiourea is reduced at the cathode or it complexes cuprous ions as they form so that a great portion of cupric ions are not completely reduced to copper. Llopis and co-workers (9), using radioactive tracers, found sulfur but not carbon in the copper deposit when the plating bath contained thiourea. This indicates that the thiourea molecule comes apart in the course of electroplating. There are two possibilities: (i) thiourea hydrolyzes to urea and H_2S, or (ii) thiourea is reduced forming perhaps NH_4CN and H_2S. The latter mechanism appears to be the most likely one of the two although there is no proof to offer at this time. The solubility product of CuS in aqueous solutions is very low, 8.5×10^{-45} $(M/L)^2$ in water. Thus, CuS will precipitate at the cathode surface at a relatively low sulfide ion concentration. The potential step in Fig. 6 at 0.1 ma/cm^2 may be the point at which CuS begins to precipitate and interfere with normal crystal growth. Below the exchange current density (~3 ma/cm^2), the rate of crystal growth without addition agent is controlled by surface diffusion of copper adatoms. Therefore CuS may interfere with crystal growth by inhibiting the surface diffusion of copper adatoms to growth sites. Copper sulfide may even block a growth site and force renucleation. The increase in step height with higher thiourea concentrations may be interpreted to mean that the cathode surface reaches the mass transfer limiting condition.

The depolarizing effect of relatively small amounts of thiourea in the plating solution at about 10 ma/cm^2 has also been observed by others (10, 11). Since the Tafel slope increases with thiourea concentration, the apparent "Tafel" exchange current density at 4×10^{-6} and 4×10^{-6}M thiourea is larger with the additive than without it. We have no satisfactory explanation for this anomaly. The result suggests that, as the current increases, thiourea delays the transition of the rate-determining step in copper plating from surface diffusion of adatoms to charge transfer according to Eq. [5a].

As stated earlier, dextrin by itself does not affect the η-log i curve for copper plating. Dextrin does appear to enhance the effect of thiourea. However, the results were erratic, not reproducible, and will not be discussed further.

The effect of the other "active" addition agents at a concentration of about 10^{-4}M on the η-log i relation in acid sulfate copper plating is shown in Fig. 8. The curves obtained with no additive and 4×10^{-4}M thiourea are included for comparison. l(-) Cystine and thiourea have a similar effect on the η-log i curve except that l(-) cystine does not shift the rest potential and a hystersis loop was observed between increasing and decreasing current curves. The same inhibiting effect of precipitated CuS is proposed for the effect of l(-) cystine on copper plating. Sulfide ions are formed by hydrolysis or cathodic reduction of l(-) cystine. l(-) Cysteine may be an intermediate.

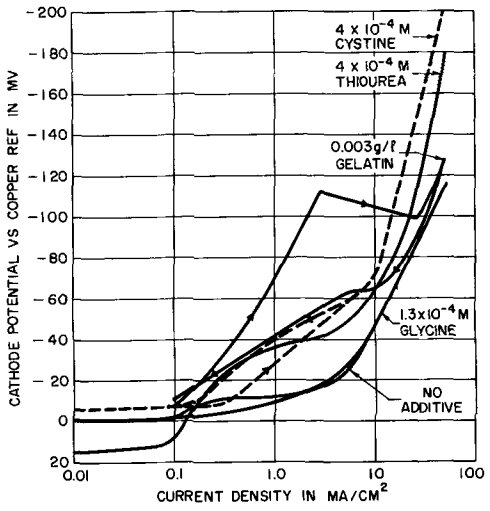

Fig. 8. Cathode potential-current density curves for copper plating with and without the various addition agents.

Glycine affects the η-log i curve only between about 0.1 and 1 ma/cm^2. The remainder of the curve is essentially the same as the no-additive curve. Glycine is noted as a leveling agent in acid-copper plating. The mechanism whereby metal distribution is affected by glycine does not involve an appreciable change in the kinetics of copper electrodeposition.

The largest polarization effect at low current densities was obtained with gelatin as shown in Fig. 8. The η-log i curve with increasing current has the same general form as the no-additive curve except that is is displaced about one order of magnitude lower in current density. At a critical current density of about 3 ma/cm^2, a sharp break occurs in the curve, and the cathode potential decreases up to about 30 ma/cm^2 where it again increases. On decreasing the current from 50 ma/cm^2, the η-log i curve traced is different from the increasing current curve. The sharp break in the η-log i curve for copper plating from acid solutions containing gelatin has been observed before. Lyzlov and co-workers (12) proposed that, below the critical current density, a small portion of the surface is active and gelatin accumulates on these isolated active sites. They suggest that all the cathode surface becomes active when the current density exceeds the critical value.

A significant factor in interpreting the results obtained with gelatin is that the break in the η-log i curve occurs at about the transition current density at which pyramidal crystal growth changes to cubic layer growth in copper plating (7, 8). We propose that below the critical c.d. gelatin molecules inhibit pyramidal growth by adsorbing on the screw dislocations that generate the pyramids as illustrated in Fig. 9. A gelatin molecule adsorbed on one of the steps can be buried by advancing steps whereas a molecule on the initial growth site at the top of the pyramid cannot. The net result is that gelatin blocks pyramidal growth, and cubic layer growth predominates even below 3 ma/cm^2. This is demonstrated in Fig. 10. Copper was plated on the (100) face of a copper single crystal for 1 hr at 1 ma/cm^2

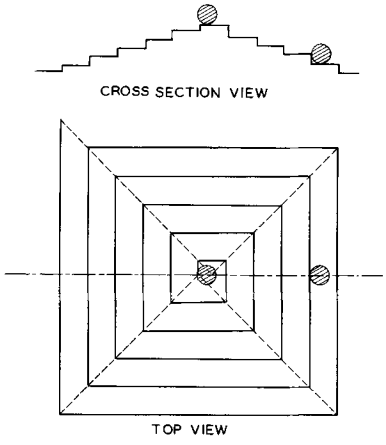

Fig. 9. Mechanism for inhibiting pyramidal crystal growth of copper with gelatin molecules.

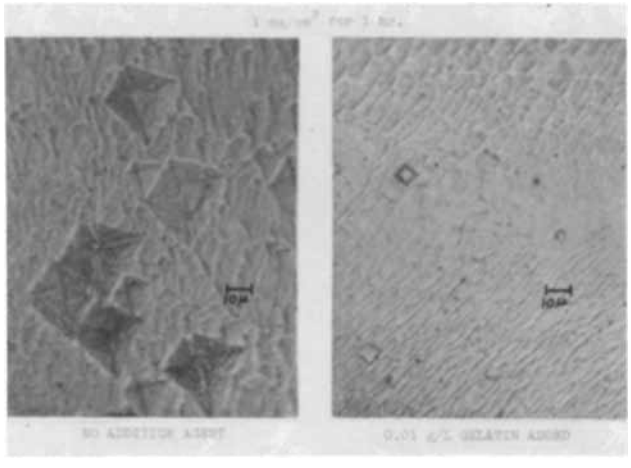

Fig. 10. Copper plating on (100) face of single crystal copper with and without gelatin at 1 ma/cm^2.

first without addition agent and then with 0.01 g/l gelatin. The results are apparent from the photomicrographs (750X). The cubic layer growth predominates throughout when gelatin is added.

At the transition current density, the adatoms or adions reach supersaturation (8), and the natural crystal growth habit becomes cubic layer growth without gelatin. In order to maintain the polarization effect above 3 ma/cm^2, the gelatin would need to inhibit cubic layer growth. The concentration of gelatin available, however, is insufficient, and the cathode potential decreases with increasing current density until the polarization due to charge transfer again increases the cathode potential above 30 ma/cm^2.

The hysteresis effect observed on decreasing the current from 50 ma/cm^2 with gelatin and l(-) cystine was not observed with rotating disk electrodes (13). Both ascending and descending η-log i curves were identical in form with the ascending curve for gelatin shown in Fig. 8. This suggests that the hysteresis effect in these studies, using spherical electrodes, is the result of inefficient stirring.

Conclusions

Thiourea and l(-) cystine have similar behavior as addition agents in acid copper plating. Both addition agents contain sulfur groups, and it is proposed that they are either hydrolyzed or electrochemically reduced during plating to form sulfide ions which precipitate copper as CuS at the cathode surface. The depolarization effect of relatively low thiourea concentrations in the vicinity of 10 ma/cm^2 suggests that the kinetics of copper electrodeposition is limited by surface diffusion of adatoms up to a higher current density with small amounts of thiourea than without it. Higher thiourea concentrations inhibit the surface diffusion of adatoms as expected.

Glycine has only a small effect on the cathode potential-current density relation. Therefore, while glycine has a profound effect on the distribution of copper plating on a microscale, it does not influence the kinetics of copper deposition.

Gelatin appears to affect the crystal growth of copper electrodeposits by a mechanism involving the adsorption of gelatin at growth sites. Relatively few gelatin molecules are needed to inhibit pyramidal crystal growth as compared to cubic layer growth.

Dextrin by itself has no effect on the kinetics of copper electrodeposition. It does appear to enhance the effect of thiourea, but these results are not conclusive.

Manuscript received Feb. 7, 1962; revised manuscript received April 2, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Carrier Injection Electroluminescence in GaP

F. G. Ullman

The National Cash Register Company, Dayton, Ohio

ABSTRACT

Two types of carrier injection electroluminescence can occur in GaP. The luminescence resulting from minority carrier injection at a p-n junction (p-n luminescence) reported here and previously by others peaks near 5650 and 7000Å in Zn-doped GaP. A much lower efficiency luminescence results from majority carrier excitation at electrode barriers in apparently junction-free crystals and does not seem to result from an avalanche breakdown process. The emission spectrum for this form of excitation peaks at 5800 and 6500Å and is the same for n- and p-type material (with the addition of the 7000Å "Zn" emission from Zn-doped, p-type material). The 5800Å emission is attributed to recombination across the band gap, the 6500Å emission to recombination at deep donor levels, and the 7000Å emission to recombination at deep-lying Zn acceptor levels. The 77°K photoluminescence peaking at 6300Å, reported previously by others, is also attributed to recombination at the donor levels. The shift in the peak for the band gap emission to 5800Å, rather than 5650Å as in the corresponding p-n luminescence band, is suggested to be caused by the high field at the electrode barrier. Photoluminescence and photoconduction excitation spectra were also obtained and are consistent with these hypotheses.

Until recently, little information was available on the luminescent properties of GaP. The observed electroluminescence has been attributed to minority carrier injection at p-n junctions (1-3) and to avalanche breakdown at metal contacts or at reverse biased p-n junctions (1, 3). Emission bands peaking at energies less than the band gap were observed and described as resulting from impact excitation of luminescent centers (3), indirect recombination of free electrons with free holes (4), recombination at Cu or Zn impurity centers (1, 3), or recombination at levels resulting from Ga and P vacancies (5). Recently, two detailed studies of electroluminescence at p-n junctions in GaP have been published (6, 7); these also differ on several points of both observation and interpretation.

The luminescence resulting from minority carrier injection at a p-n junction differs significantly from the luminescence resulting from majority carrier excitation at electrode barriers in apparently junction-free crystals. If junctions are present, both processes may occur simultaneously; this could account for some of the disagreement among the observations of others.

The results reported here suggest that there are three major radiative recombination processes active in our crystals, indirect electron-hole recombination across the band gap, recombination of a free hole with an electron in a donor level of unknown origin, and in Zn-doped crystals recombination of free electrons with deep-lying Zn acceptor levels. The observed luminescence depends on which are dominant, and this in turn depends on the excitation process and the conductivity type of the recombination region. Some of the disagreement among earlier observations can be resolved if allowance is made for the type of excitation and the relative probabilities of the various recombination mechanisms possible.

Description of Crystals

All of the crystals studied were prepared by the solution growth method of Wolff, Keck, and Broder (8) in sealed, evacuated, silica tubes. Solutions of the order of 10 at. % of phosphorus in gallium were heated to 1300°C, maintained at this temperature for at least 2 hr, and then cooled to room temperature in 24 hr following a programmed parabolic cooling curve. (Increasing the cooling time to 72 hr had no significant effects on the crystal growth.) The quartz tubes often expanded, indicating that the dissociation pressures were greater than 10 atm at these growth temperatures. Dopants (*e.g.*, Zn metal) were mixed with the gallium prior to evacuation. Starting materials of at least 99.999% purity were used in all cases.

The crystals selected for study are of two types, (i) platelets with (111) major faces, that are 1 mm or less in thickness and range from a few millimeters to a centimeter in the other dimensions, and (ii) <111> axis needles a centimeter or more in length and of triangular cross section with sides of the order of a tenth of a millimeter or less. The needles are found at the opposite end of the growth vessel from the solution and are often intermingled with deposits of mixed oxides of gallium. The vapor phase growth and properties of similar needles have been described by Gershenzon and Mikulyak (9). Some results of x-ray diffraction indicate that the plate-like crystals may not be single but may contain one or more 180° twin planes. The needles, however, are single crystals.

Spectrographic analyses indicate that the only major impurity in the crystals is Si, in the concentration range of 10-100 ppm. The source of the Si impurity is unknown; it is believed to result from a high-temperature reaction between Ga and silica (14). In addition, 1 ppm or less of Fe and Mg are

found in undoped GaP crystals and in the initial phosphorus. Cu and Ag, in about the same concentrations as the Fe and Mg, are found in Zn-doped crystals and in the initial Zn.

The crystals were separated mechanically from the Ga solvent and then boiled in about a 1:1 mixture of concentrated HCl and water. In most cases, this treatment was sufficient to remove all the surface Ga. The samples studied were carefully selected; crystals with occluded gallium or obvious grain boundaries were not used. Electrodes of various metals in the form of point and area contacts were tried. The luminescent properties did not depend on the electrode metal; hence silver paste or ultrasonically applied In were used in most cases.

Hall effect measurements have shown that undoped crystals are n-type with room temperature carrier concentrations in the range of 10^{15}-10^{16} electrons/cc and a donor ionization energy of 0.07 ev. The Zn-doped crystals discussed in this article are p-type with about 2×10^{17} holes/cc at room temperature and an acceptor ionization energy of 0.03 ev; spectrographic analysis indicates 10-100 ppm of Zn in these crystals. Room temperature mobilities for both electrons and holes are in the 50-100 cm^2/v sec range.

Apparatus

Electroluminescence emission spectra were measured with d-c excitation. The sample was mounted at the entrance slit of a Bausch and Lomb grating monochromator (Model 33-86-45). A Photovolt photometer with a 1P21 photomultiplier served as the detector, and its output was recorded on a Moseley X-Y recorder whose X-axis was suitably coupled to the wavelength drive of the monochromator. Photoluminescence emission and excitation spectra were similarly obtained except that a light pipe was used to channel the emitted light to the monochromator or the exciting light to the sample so that the sample could be immersed in liquid nitrogen. The photoluminescence is only observable at low temperature because of temperature quenching (5, 7). The photomultiplier was calibrated against a thermocouple, and all spectra were corrected for the constant incident energy response of the photomultiplier. The spectral range covered was limited to wavelengths shorter than 8000Å by the over-all sensitivity of the system.

The photoconductivity excitation spectrum was obtained with a Perkin-Elmer Model 99 double-pass monochromator. The resulting 13 cps photocurrent was amplified by a 13 cps twin-tee amplifier. The incident energy was measured with a Perkin-Elmer thermocouple and associated Model 107 13 cps amplifier. An isophotonic correction was applied to this spectrum.

Electroluminescence at a p-n Junction

An initial objective of this work was to study the red emission that had been reported to result from doping GaP with Zn (3). Zn-doped crystals were prepared, the "Zn" red emission was observed, and the emission spectrum, which peaks at 7000Å, was determined (10). Light emission was observed only at the negative electrode (3, 10). In some samples with identically prepared electrodes the red emission occurred at only one electrode. Negative bias on the other electrode produced only an emission of much lower intensity and yellow in color. (Its spectrum had a shoulder at about 5900Å and then increased out to 6500Å, the detection limit for that particular measurement.) The similarity to the p-n luminescence reported by others (6, 7) suggests that this asymmetry results from the presence of junctions in the crystal. Crystals containing both p and n regions have been found and discussed (5, 7). Zn-doped crystals prepared with higher purity starting materials and improved growth conditions did not exhibit this anomalous behavior, indicating the absence of junctions.

One Zn-doped crystal was found, however, that had a junction located near the crystal surface. It was characterized by an asymmetrical current-voltage characteristic with a rectification ratio of the order of 100. Emission from the junction, not in contact with the electrode, could be seen clearly as a bright spot. The room temperature emission spectrum for forward bias is shown in Fig. 1; it consists of a narrow band (0.1 ev at half maximum), peaking in the green near 5650Å as reported by others (4, 6, 7) and the previously reported "Zn" band (7, 10) peaking near 7000Å.[1] The effect on the spectrum of absorption by the crystal was determined by measuring only the light escaping through the back side of the crystal; light emitted at the junction had to pass through at least 1 mm of crystal before entering the monochromator. This result is also shown in Fig. 1. It can be seen that the shape of the 7000Å band is unaffected by absorption whereas the 5650Å band is attenuated with the attenuation becoming more severe at shorter wavelengths. There is, however, no shift in the peak.

Since similar results have been presented in detail by others, as indicated above, this discussion has been included only for comparison with the results described in the following sections.

[1] Errors in the correction for the photomultiplier spectral response and in the wavelength measurements prevent the determination of the peak wavelengths to better than ±50Å. Although the peaks in Fig. 1 are at about 5550 and 6900Å, the results of several measurements indicate that 5650 and 7000Å are reasonable choices for the peak wavelengths. Since other workers have reported these to be the peak wavelengths, we have used the same designation throughout this article.

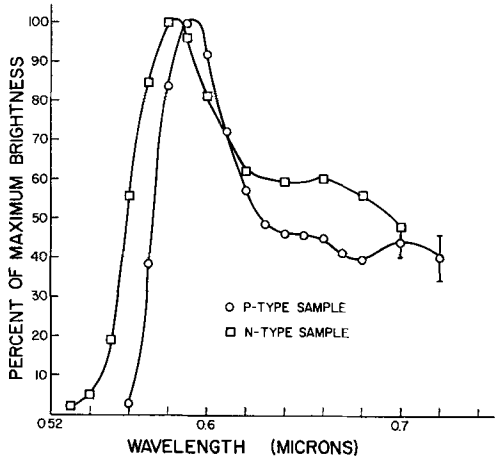

Fig. 2. Emission spectra from metal-crystal contact to n-type crystal and p-type crystal.

Electroluminescence at a Metal-Crystal Contact

There is general agreement that electroluminescence is never observed at ohmic contacts to GaP. Ordinary metal contacts, *e.g.*, Ag paint, ultrasonically applied In, pressure contacts, however, do not make ohmic contact to GaP without special treatment to penetrate the surface oxide (13). Samples with symmetrical contacts behave like two rectifiers opposed in series; breakdown potentials[2] are usually between 1 and 5v. The current-voltage characteristics are often asymmetrical, as shown by Wolff *et al.* (3). Kinks in the characteristics as reported by Gorton *et al.* (11) have also been observed, but are not usual.

The electroluminescence at a metal-crystal contact is at least one or two orders of magnitude lower in efficiency than the p-n luminescence. Since GaP has a high index of refraction, 3.4 (12), the crystals appear to glow uniformly. However, microscopic examination indicates that the emission is actually localized close to one electrode. The emission has been reported to occur only at the negative electrode (3, 10). However, observations of apparently junction-free crystals[3] have shown that the emission is at the negative electrode for n-type crystals but at the positive electrode for p-type crystals, indicating that this process is governed by majority carriers.

The emission spectrum obtained with majority carrier excitation consists of two bands with half widths of about 0.2 ev and peaking at about 5800 and 6500Å; in the crystals made p-type by Zn-doping the peak at 7000Å is also observed. In Fig. 2, two typical spectra are shown, one for an n-type crystal and one for a p-type crystal. In this figure it can also be observed that (i) there is no detectable emission at wavelengths shorter than the absorption edge, (ii) the 5800Å band is shifted to longer wavelengths in the p-type crystal, and (iii) the 6500Å band of the p-type crystal has a smaller relative amplitude than it has in the n-type crystal.

The first observation is general; we have never detected emission wavelengths shorter than the absorption edge for any of our crystals. The second and third effects do not result from the difference in conductivity type, but rather from heating of the sample. For the measurements shown in Fig. 2, the power dissipation in the p-type crystal was 0.37w; in the n-type crystal it was only about 0.05w. Power dissipations greater than 1.5w (as great as 3.0w in some cases) will produce incandescence in crystals of the same size and mounted in the same way. The energy shift of the 5800Å band computed from the peak positions in Fig. 2 is close to 0.05 ev; this is roughly consistent with the thermal shift of the band gap, 5.5×10^{-4} ev/°K (12), for the p-type crystal at about 120°C.

Grimmeiss *et al.* (5, 7) have suggested that both gallium and phosphorus vacancies play an important role in the observed luminescence. This conclusion suggests that the emission spectra of crystals prepared in different environments would differ. Since the vapor phase environment in which the needles are grown would tend to be much less rich in Ga than the solution in which Ga is present in large excess, the emission spectra of needle crystals were determined for comparison with the spectra found for solution-grown crystals. The electroluminescence of the needle crystals is identical to that found for n-type solution-grown crystals, as shown in Fig. 3. These needles have at least an order of magnitude higher resistance than the solution-grown crystals (6) and therefore require higher voltages for observable electroluminescence. The two curves shown in Fig. 3 were taken at about 100v-10 ma and 20v-2 ma, respectively (about 40 ma at 7 or 8v is usual for comparable light emission from solution-grown crystals). The shift of the 5800Å band (to 6000Å) and the quenching of the 6500Å band, for the higher power dissipation, are similar to that for solution-grown crystals. The shift to 6000Å, assuming a band gap transition, indicates a crystal temperature of the order of 200°C for the higher power dissipation.

Photoluminescence and Photoconductivity

At liquid nitrogen temperature, most of the solution-grown GaP exhibits a red fluorescence which is quenched on heating. The emission spectrum for 3650Å excitation peaks at about 6300Å and is almost identical with the photoluminescence spectrum re-

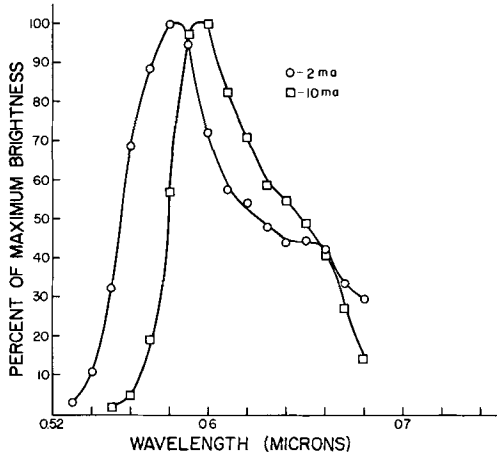

Fig. 3. Emission spectra from metal contact to n-type needle crystal for two currents.

[2] The rectification characteristic is "soft." The applied voltage at which the knee occurs in the current-voltage characteristic is taken to be the breakdown potential.

[3] The basis for this description is given in the Discussion section.

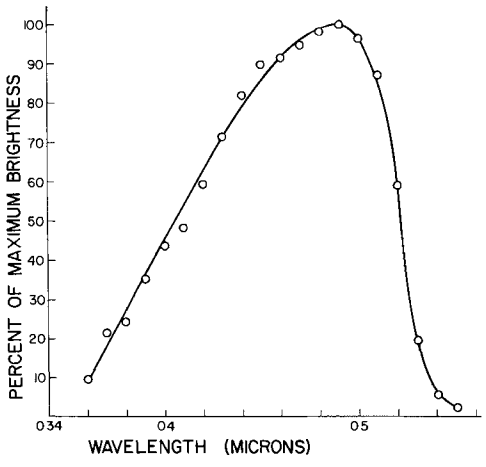

Fig. 4. Excitation spectrum of 77°K fluorescence

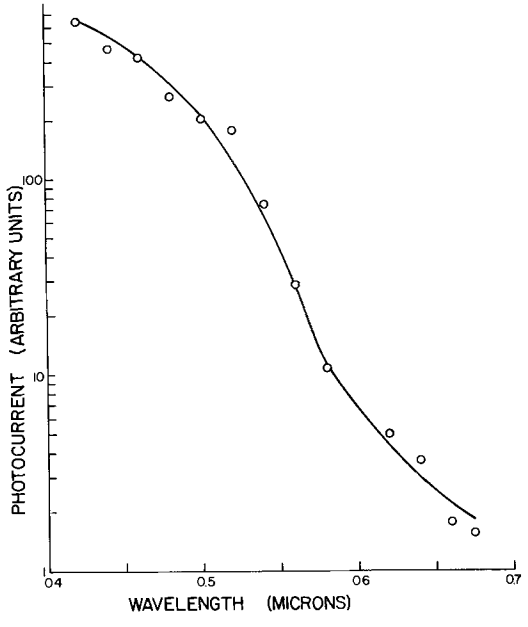

Fig. 5. Excitation spectrum of photocurrent in n-type needle crystal.

ported by Grimmeiss and Koelmans (5). Zn-doped samples gave the same spectrum and appeared to have additional emission near 7000Å, but the difference between the emission at 7000Å and the background of scattered light was not outside of experimental error. The 7000Å "Zn" photoluminescence has, however, been observed by Grimmeiss *et al.* (7). The excitation spectrum (relative photoluminescent brightness *vs.* incident wavelength for constant incident energy) follows the fundamental absorption as shown for powdered, undoped material in Fig. 4. The decrease at short wavelengths is probably caused by the increased absorption and scattering of the exciting light in the powder sample, although a difference in surface *vs.* bulk efficiency may also be involved. No excitation was observable with wavelengths longer than 5500Å.

Photoconductivity can be observed in many of these crystals. It is difficult to measure in the relatively low resistance, solution-grown crystals because of the large dark-current noise. In the high resistance needles, however, photocurrents are easily observed. Since no short circuit photovoltaic effects could be observed, these are believed to be bulk photocurrents rather than barrier layer photoeffects. The photocurrent excitation spectrum for a needle crystal with In electrodes is shown in Fig. 5. The applied voltage was of the order of 45v which was well above the breakdown voltage of these contacts. This spectrum follows the optical absorption, but extends to wavelengths as long as 6800Å. However, no long wavelength maxima were observed. The photocurrent varied linearly with light intensity over the range of light levels used for this measurement.

Discussion of Results

A complete explanation of the observed luminescence of GaP requires an understanding of the mechanisms of both excitation and recombination. In GaP, electroluminescence is excited by injection of either minority or majority carriers. However, the possibilities for their recombination and therefore the possible emission spectra are numerous. Reasonable arguments, supported by experiment, have been given for (i) indirect recombination of free electrons and free holes across the band gap (2, 6), (ii) recombination at levels resulting from both P and Ga vacancies, (iii) recombination at deep-lying Zn acceptor levels (7), (iv) recombination at deep donor levels of unknown origin (6), and (v) recombination at impact-ionized centers associated with excess Ga or Zn (3). If the recombination processes that are operative are competitive, both the conductivity type of the recombination region and the excitation mechanism can be expected to influence the relative magnitudes of the various possible emission bands. A discussion of the excitation and recombination mechanisms indicated by our results and their relation to previous work, follows.

Excitation by majority carrier injection.—It has been pointed out (3, 6) that a contact barrier or p-n junction must be present for electroluminescence to occur in GaP; no luminescence is observed with ohmic contacts. GaP forms a protective oxide layer on its surface (13) which accounts for its stability, in contrast to its cousins, AlP and AlAs, which decompose continuously in moist air (3). This oxide serves as an insulating layer between metal contacts and the GaP bulk unless special means are employed to make ohmic contact by penetration or elimination of the intervening oxide. The rectifying contacts thus obtained break down and luminesce for applied potentials of only a few volts (except for the high resistance needles). This luminescence is excited by majority carrier injection, occurring at the positive contact to p-type material and the negative contact to n-type material.

If p-n junctions are present, however, they could dominate both the electrical characteristics and the light emission. This may account for the observations of essentially only the forward bias p-n luminescence in Zn-doped GaP (3, 5, 7, 10) with nonohmic contacts. The presence of junctions may result from an inhomogeneous distribution of the Zn acceptors in the normally n-type solution-grown GaP, similar to that found in InSb (16).

Gershenzon and Mikulyak (6) have proposed three excitation mechanisms for light emission from reverse biased p-n junctions: an avalanche process for diffused junctions, tunneling through the narrower alloyed junctions, and thermal generation of carriers in the depletion layer for prebreakdown emission. For all three mechanisms the emission spectrum was a broad, essentially structureless band with a significant portion at wavelengths shorter than the absorption edge, similar to the emission spectrum at breakdown of junctions in silicon (17). This indicates that the pair production threshold was exceeded in all three cases. Such reverse bias p-n luminescence cannot account for our observations of the metal-crystal contact luminescence because of the absence of emission at wavelengths shorter than the absorption edge, because of the structure of the emission spectrum, and because only a linear dependence of photocurrent on light intensity was found in samples biased above breakdown.

It is possible that the electrode barrier is lowered sufficiently by the applied electric field for the most energetic carriers to surmount it; their energies, however, are below the pair production threshold. The crystal will still have a higher resistance than with ohmic contacts since only the most energetic carriers contribute to the current; a reduction in resistance by about two orders of magnitude was found when ohmic contacts were made. The resistance should show some dependence on the work function of the metal contact. No systematic variation with electrode metal was found, but low work function metals such as In have been reported to make a low resistance contact to GaP (18, 19).

Recombination processes for p-n luminescence.— Gershenzon and Mikulyak (6) found the room temperature emission spectrum with forward bias to consist of a narrow band (~3kT band width) peaking at 5650Å, and a red band peaking at about 6700Å. No emission bands characteristic of the diffused impurities were found. Both bands were observed to shift to shorter wavelengths on cooling by approximately the band gap shift of 5.5×10^{-4} ev/°K (12). They attributed the 5650Å emission to indirect recombination across the band gap and the 6700Å emission to recombination of an injected hole with the electron in a deep (0.3 ev) donor level known to be present in all their material.

Grimmeiss *et al.* (7) also found the 5650Å band, but observed no shift in emission peak with temperature. They found a second band at 7000Å in both electroluminescence and photoluminescence from Zn-doped samples which also showed little wavelength shift with temperature. They attributed the 5650Å band to recombination of a free hole with the electron in a shallow (0.07 ev) donor level and attributed the donor levels to phosphorus vacancies. The 7000Å band was attributed to recombination at a deep (0.4 ev) Zn acceptor level. A 6200Å emission band was found in undoped n-type material only, although a corresponding photoluminescence emission band was found for both n-and p-type material.

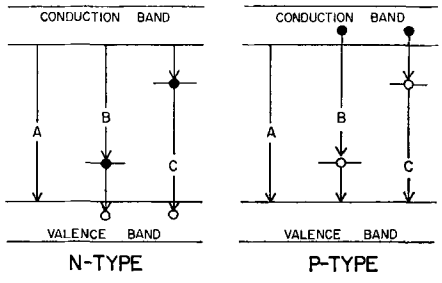

Fig. 6. Simplified energy band model illustrating major radiative recombination mechanisms in GaP; ●—electron, ○—hole.

The p-n luminescence emission spectrum reported here for Zn-doped samples resembles that of Grimmeiss *et al.* rather than that reported by Gershenzon and Mikulyak. However, a plausible explanation can be given for the differences in emission spectra found by different observers if consideration is given to the conductivity type of the recombination region. This is illustrated by the model shown in Fig. 6. Only three recombination processes are considered in this model, (*A*) electron-hole recombination across the band gap, (*B*) recombination of a free electron with the hole in a deep (0.4 ev) Zn acceptor level,[4] and (C) recombination of a free hole with the electron in a deep (0.3 ev) donor level of unknown origin. The shallow donor and acceptor levels responsible for the conductivity are not included. The donor concentration is assumed the same in both n- and p-type material since no donors were deliberately introduced and the undoped material is n-type. The acceptor concentration, however, will vary from greater than the donor concentration in the p-region to less than the donor concentration in the n-region. Free holes injected into the n-region can recombine with either the donor (largely occupied because of its depth) or acceptor electron; these levels will then recapture electrons from the majority carrier population. However, the donor concentration exceeds the acceptor concentration in the n-region and process *C* will dominate the emission. Since Gershenzon and Mikulyak (6) have shown that recombination occurred in the n-region in their diodes, this argument accounts for their inability to observe emission bands characteristic of the Zn and Cd acceptors they introduced.

Let us now consider the recombination of electrons injected into the p-region. The deep acceptor levels are largely un-ionized because of their depth, and the acceptor concentration now exceeds the donor concentration. For this case, process *B* will dominate the emission.

Process *A* will occur in both regions with a probability dependent on its cross-section relative to the probabilities for *B* and *C*. These, in turn, depend on both their cross sections and the relative concentrations of donors and acceptors.

We conclude that the emission spectrum for n-region recombination should consist principally of the 5650Å band and the 6500Å band as observed by

[4] It has been shown previously (7, 10) that the 7000Å band results from Zn-doping. Since the activation energy for Zn acceptors is 0.03 ev (Hall effect), Zn must be at least a double acceptor in GaP similar to Cu in GaAs (15).

Gershenzon and Mikulyak (6). For p-region recombination the spectrum will consist principally of the 5650Å band and an emission characteristic of the acceptor if it gives rise to deep levels (the 7000Å band with Zn-doping) as reported by Grimmeiss *et al.* (7) and here.

In the model, the transition producing the 5650Å band is shown as the suggested band gap recombination (4, 6) rather than the free hole capture at a shallow donor level suggested by Grimmeiss *et al.* (7). Our results for the p-n luminescence are insufficient to make a choice between these two hypotheses, but the arguments just presented deal only with the impurity recombination and are valid in either case. However, the results with majority carrier excitation, discussed below, do indicate a band gap transition.

Recombination with Majority Carrier Excitation. —The model discussed in the previous section must also be consistent with the results found with majority carrier excitation, namely, the emission of the 6500Å band from both n- and p-type material, the emission peak at 5800Å in contrast to the 5650Å peak in the p-n luminescence, and the low radiative efficiency relative to the p-n luminescence.

These spectra are distinctly different from those found for both forward and reverse biased p-n junctions. It is this fact, as well as the different character of the current-voltage characteristics for the metal-crystal contact, on which the designation of these crystals as apparently junction-free is based. In crystals believed to contain junctions, the more efficient p-n luminescence dominates, and the emission resulting from majority carrier excitation appears as a low level background (10).

The recombination level for the 6500Å emission should be situated about 0.3 ev from one of the band edges. If it were near the valence band, effects due to an impurity absorption at about 2.0 ev should be expected in the excitation spectrum of photoluminescence. (The 6350Å photoluminescence and 6500Å electroluminescence may be assumed to result from recombination at the same level.) Since such effects are not observed, we conclude that the low-temperature photoluminescence and 6500Å electroluminescence result from recombination of a free hole with the electron in a 0.3 ev deep donor level as indicated in the energy band model. This could be the same donor level postulated by Gershenzon and Mikulyak.

With majority carrier excitation, the 6500Å emission, attributed to n-type recombination with p-n luminescence, is observed from both n- and p-type crystals. This lack of dependence of emission spectrum on conductivity type, the low efficiency of the majority carrier excitation relative to the p-n luminescence, and the absence of any superlinear dependence of brightness on current as found for p-n luminescence (6, 7), all suggest that the recombination kinetics for majority carrier excitation are controlled by a small free carrier population rather than the recombination center concentrations. Since the results indicate a band gap transition, minority carriers must, somehow, be involved. Approximate calculations indicate that minority carrier densities less than 10^{10}/cc can account for the observed intensities. However, the room temperature np product for GaP is of the order of unity, so there are no minority carriers. We can only suggest that minority carriers are produced in the barrier region by some mechanism such as electric field or impact ionization of impurities. The 6500Å band will then be produced by hole capture at the occupied donor levels in n-type crystals; in p-type crystals the donor is ionized and must first capture a minority electron. As long as the minority carrier density is very much smaller than the donor concentration the 6500Å emission will be observed from crystals of both conductivity types. For larger minority carrier densities, as in p-n luminescence, the 6500Å emission from p-type crystals is obscured by the other, much more efficient emission bands.

We turn now to the 5800Å band. The shift of emission peak with temperature (high current effect) and the sharp cut-off at short wavelengths suggest that this emission is produced by band gap recombination. The fact that the emission peaks at 5800Å rather than 5650Å as in the p-n luminescence could result from the effect of the high field at the electrode barrier on the absorption edge or the band gap. Field-induced strains or possibly the Franz-Keldysch (20, 21) effect could produce such a shift in the emission band edge. Consideration was given to the possibility that the 5800Å emission might be the 5650Å emission shifted by absorption, which might occur if it originated deep in the crystal. The measurements shown in Fig. 1, however, eliminate absorption as a possible explanation.

Grimmeiss *et al.* have attributed some of the luminescent centers to levels resulting from Ga and P vacancies. Since our vapor-grown crystals showed the same luminescence as solution-grown crystals although their growth environments were different, and since the 0.07 ev donor identified as a phosphorus vacancy by Grimmeiss *et al.* is found in crystals prepared in different laboratories and in widely different environments, impurities such as silicon and oxygen [possibly from a high-temperature reaction of gallium with silica (14)] seem more likely suspects than lattice vacancies.

Summary of Results

The emission spectra produced by majority carrier injection from a metal-crystal contact consist of two emission bands peaking at 5800 and 6500Å and additional emission at 7000Å in crystals made p-type by Zn-doping. The 6500Å band and the low-temperature photoluminescence are attributed to recombination at a donor level situated about 0.3 ev below the conduction band. The 5800Å band is suggested to be band gap recombination in the high field region of the electrode barrier where the emission band edge has been shifted to longer wavelengths as a consequence of the high electric field at the electrode barrier. The majority carrier injection is suggested to occur by thermal excitation over the electrode barrier which is lowered by the applied field. The charge carrier energies, however, are less than required for pair production since the emission spectra and dependence of photocurrent on light intensity are not

characteristic of avalanche breakdown processes. The low efficiency for this form of excitation is suggested to be a consequence of a relatively small concentration of minority carriers produced by electric field or impact ionization of impurities, which control the recombination kinetics.

Consideration of competitive recombination processes in a simplified energy band model has been used to demonstrate that the emission spectrum for p-n luminescence will be as reported here and elsewhere (7) for p-region recombination. For n-region recombination, however, the 6500Å band will be dominant, as found by Gershenzon and Mikulyak (6). This is not the case with majority carrier excitation where the relative concentrations of recombination centers do not enter significantly into the recombination kinetics; the emission is controlled by the small minority carrier population produced in the barrier region.

Acknowledgments

The author is indebted to M. S. Hall and S. H. Liebson for critical reading of this manuscript, to W. M. Becker for his contributions to the early part of this work, to E. L. Peirson for preparation of the crystals, and to C. V. Osterday for technical assistance. The author would also like to thank M. Gershenzon for making his results available prior to publication.

Manuscript received Jan. 8, 1962; revised manuscript received April 23, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Effect of Cupric Ion on the Electrical Properties of the Germanium-Aqueous Electrolyte Interface

P. J. Boddy and W. H. Brattain

Bell Telephone Laboratories, Murray Hill, New Jersey

ABSTRACT

The capacity of the germanium-aqueous electrolyte interface measured at high frequency after interaction with cupric ion in concentrations of the order of 10^{-7}M cannot be interpreted as simply that of the semiconductor space charge. Since the deviation is in the direction of larger observed capacity the data can be understood in terms of a capacity in parallel with the semiconductor space charge, *i.e.*, fast surface states in the vicinity of the Fermi level. Conductance measurements allow the extra capacity to be determined as a function of surface potential. From the form of this relationship the data are shown to be consistent with two charge traps, the parameters of which are $\nu = +1.9\ kT/e$, $N_t \sim 1 \times 10^{11}$ cm^{-2} and $\nu' = -1.2\ kT/e$, $N'_t \sim 1.9 \times 10^{10}$ cm^{-2}. Surface recombination, which is not present at a significant level on the freshly anodized surface in the absence of cupric ion, appears as a result of the interaction. These data identify the recombination center as that with $\nu' = -1.2\ kT/e$, the capture cross section for holes being 400 times greater than that for electrons. The phenomena are similar to those on the dry etched surface, and a common origin for the states is indicated.
