The electrical properties of germanium surfaces after anodic etching in carefully purified solutions have been discussed in a previous communication (1). The major conclusion to be drawn from these experiments is the absence of a significant density of fast surface states over a range of about 200 mv each side of the middle of the energy gap. It has been reported that etched germanium surfaces in gaseous ambients are generally n-type, but that the presence of traces of certain impurities, including cupric ion, in the final rinse water results in the surface becoming p-type (2). We have observed a similar phenomenon on a germanium surface in contact with an aqueous solution containing cupric ion and have determined some of the electrical changes occurring at the surface as a result of this interaction.

Experimental Method

The measurement of the differential capacity of the germanium-solution interface by a current pulse method and the bridge electrodes used in these experiments have been previously described (1). The two electrodes were 12.5 ohm-cm n-type and 25.5 ohm-cm p-type with the thin arm oriented to the (100) plane.

The solution was M/10 K_2SO_4, phosphate buffered to *p*H 7.4. Purification was effected by gettering with crushed germanium produced *in situ* by the collision of small pieces agitated by rapid stirring. Solution was introduced into the cell through filter paper that had previously been washed with several portions of purified solution. Nitrogen, which had been passed over hot copper gauze, displaced the air in the cell.

Dilute solutions of cupric nitrate or sulfate were made of sufficient concentration that when a few milliliters were added to the purified solution in the cell (ca. 250 ml) a final concentration of 10^{-8}-10^{-6} M was achieved.

The thin arm of the electrode was etched initially, and between each addition of cupric ion to the solution, in CP-4. Before the CP-4 etch the electrode was dipped for about 10 sec in hydrofluoric acid containing 5% nitric acid, producing a gold-colored stain. The advantage of this procedure was that the "gold film" was instantaneously attacked by CP-4 and even after dissolution of the film (ca. 5 sec) the etching continued uniformly over the whole surface. Without the gold film, CP-4 was initially active only on certain areas of the thin arm, although etching would become uniform after 15-20 sec. However, it was desired to keep the material removed by etching down to a minimum, consistent with a uniformly etched surface, and the gold film technique seemed to afford a method of doing this. After rinsing in germanium-gettered deionized water, the electrodes were put into the cell and anodically etched at about 200 μa cm^{-2} for 5 min (n-type electrodes illuminated). Before each series of experiments the changes of capacity and conductivity with applied bias in solution free from cupric ion were checked for consistency with previous data (1) in purified solutions. All other experimental details and the experimental arrangement were as previously reported (1).

After addition of cupric nitrate to the cell, the electrode potential was followed with time until approximately constant (about 30 min). Measurements of capacity, change in conductivity, and filament lifetime as a function of electrode potential were then made on the thin arm of the bridge. The electrode potential was varied by switching a preset current through the interface for about 1 sec or less. The instantaneous values of electrode potential

and either change in potential at the interface due to the differential current pulse, balance point of the bridge, or decay of photoconductivity were measured, each of the latter three quantities being determined in separate experiments on the identical system. The potential response to the square 5 μsec current pulse is similar to that obtained for the clean surface; the change in potential at the interface being linear with time over 5 μsec. The same equivalent circuit applies and the capacity may be calculated as before (1).

Results

The electrode potential as a function of time for various cupric ion concentrations is shown in Fig. 1. When the potential had reached a steady value the capacity was measured as a function of electrode potential. In Fig. 2 the capacity for a simple block electrode before and after adding cupric ion is shown. When the cupric ion is added, additional capacity appears peaked about a given value of V_E. The immediate inference is that this capacity is due to fast surface states that were not present before the cupric ion was added to the electrolyte. Since it was desirable to determine this added capacity as a function of the surface potential ψ_s (the electrostatic potential across the semiconductor space-charge region) and also to make surface recombination velocity measurements, the subsequent data were taken on a germanium bridge with the thin arm in the electrolyte.

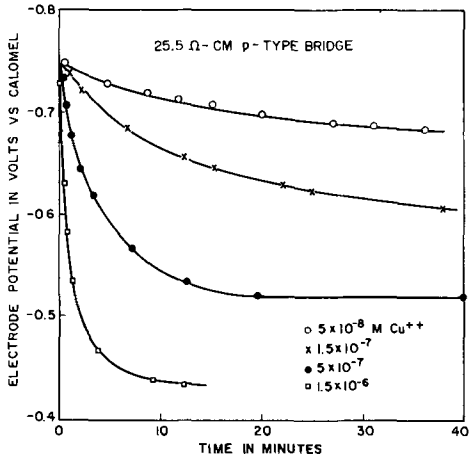

Fig. 1. Electrode potential *vs.* time immediately after CP-4 etching and anodizing.

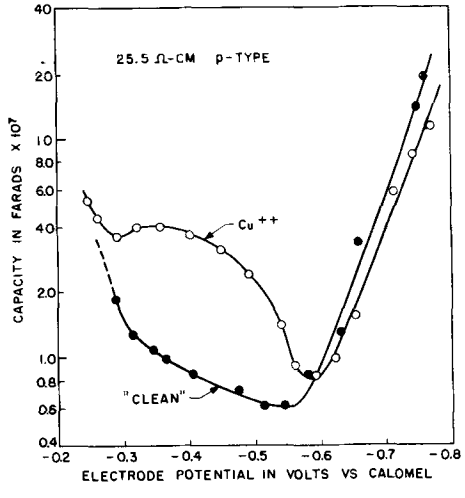

Fig. 2. Interfacial capacity *vs.* electrode potential before and after addition of Cu^{++}.

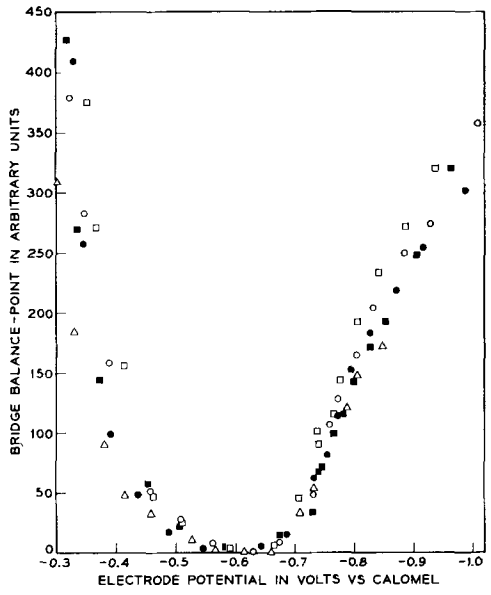

Fig. 3. Bridge balance (normalized to the conductivity minimum and corrected for changes in thickness due to etching) *vs.* electrode potential.

It has been shown previously (1) that analysis of the apparent change in conductivity of a thin slice of germanium in contact with electrolyte gives values of surface potential that do not agree with those derived from capacity and that the values from the capacity are probably correct. However, it was shown that the discrepancy in the conductivity is reproducible, so that in a purified solution of given pH a plot of bridge balance (normalized to the conductivity minimum and corrected for decrease in thickness of the active arm due to etching) *vs.* electrode potential is a constant curve for a given electrode. Figure 3 shows the normalized bridge balance *vs.* electrode potential for the p-type bridge. Further, since from capacity measurements on the uncontaminated surface the surface potential may be deduced as a function of electrode potential, an empirical correlation between surface potential and bridge balance may be derived. Use is made of this relationship to determine surface potential in the present experiments, where the interaction with cupric ion results in additional capacity, and consequently the surface potential cannot be deduced directly from the capacity. It should be noted that surface potential derived from capacity measurements involves no mobility correction. Experimentally, the surface potential-electrode potential relationship in the presence of up to 10^{-6}M cupric ion is similar in form to that derived in purified solutions (*i.e.*, essentially a one-to-one relationship over a range of potential), but with a shift in the curve toward more positive values of electrode potential, the magnitude of the shift depending mainly on the Cu^{++} concentration.

Capacity was determined as a function of surface potential (Fig. 4 and 5), each of these quantities

being determined separately as a function of electrode potential. In addition, the filament lifetime was measured indirectly by first calibrating the photoconductivity due to a 40 cps square light pulse with a measured decay lifetime, then measuring the photoconductivity and deducing the lifetime by simple proportionality. Some typical data for the p-type bridge are shown in Fig. 6. The experiments were repeated at a variety of cupric ion concentrations. Identical data were obtained with both cupric nitrate and cupric sulfate.

Discussion

The additional capacity observed in the presence of cupric ion is determined by subtracting the space-charge capacity from the total observed capacity at each value of ψ_s. The results are shown in Fig. 7 and 8 for n- and p-type electrodes. The implicit assumption here is that the real surface area of the electrode is the same in both cases. The justification for this lies in the fit of the capacity data (in most instances) to the theoretical curve at extreme positive and negative values of ψ_s. The additional capacity can be explained only in terms of fast surface states, distributed in some manner in the energy gap.

For a surface state at a given energy the resulting capacity is

$$C_{ss} = dQ_{ss}/d\psi_s = eAN_t df_t/d\psi_s \qquad [1]$$

where e is electronic charge, A electrode area, N_t number of surface states in cm^{-2}, and f_t the fraction of the states occupied (3). The states are assumed

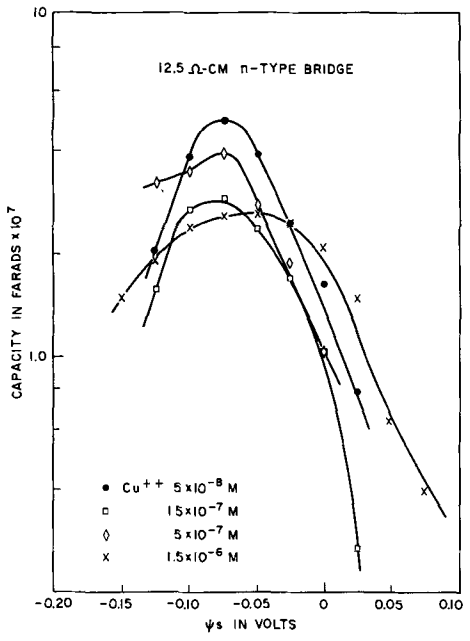

Fig. 8. Additional capacity after interaction with cupric ion vs. ψ_s for the n-type electrode.

to reach equilibrium with the semiconductor in times that are short compared with the duration of the measuring pulse. This may be rewritten

$$C_{ss} = e^2 A N_t k^{-1} T^{-1} (2 \cosh 1/2(Y + \nu - \ln \lambda))^{-2} \quad [2]$$

where $Y = e\psi_s/kT$, ν is the energy of the state in units of kT/e measured positive downwards, *i.e.*, toward the valence band, from the center of the gap, λ is p/n_i, where p is the hole concentration in the sample and n_i is the intrinsic hole or electron concentration in germanium.

The data in Fig. 7 and 8 can be satisfactorily accounted for by assuming surface states at two discrete energies. The nature of the fit that may be obtained is shown in Fig. 9 and 10 for p- and n-type electrodes in one instance. The remaining data have been similarly fitted with two states, a small latitude being allowed in positioning the states on the potential scale in order to obtain average values. In eight sets of data, four for each electrode, the maximum variation in position of either state is less than 10 mv from the arithmetic mean for that state and the particular electrode. The state of higher density, at more negative potentials, has its position and density fixed by the maximum in the additional capacity. The second state accounts for the remaining capacity at more positive potentials. Reference to Fig. 4 and 5 shows that this is the region of minimum space-charge capacity and, hence, of maximum sensitivity for our measurements. These potentials are also close to the steady-state open-circuit value and are accessible with a minimum of polarization of the interface. No attempt has been made to account for extra capacity at more positive potentials, since this is a region of poorer sensitivity due to the relatively large space-charge capacity and high polarization from the open-circuit state.

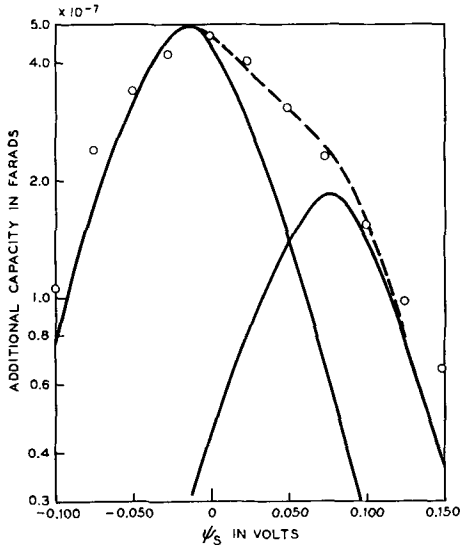

Fig. 9. Theoretical fit of additional capacity for the p-type electrode. Parameters of the states are $N_t = 1.26 \times 10^{11}$ cm^{-2}, $\nu = 2.2$ kT/e and $N_t = 4.4 \times 10^{10}$ cm^{-2}, $\nu = -1.3$ kT/e.

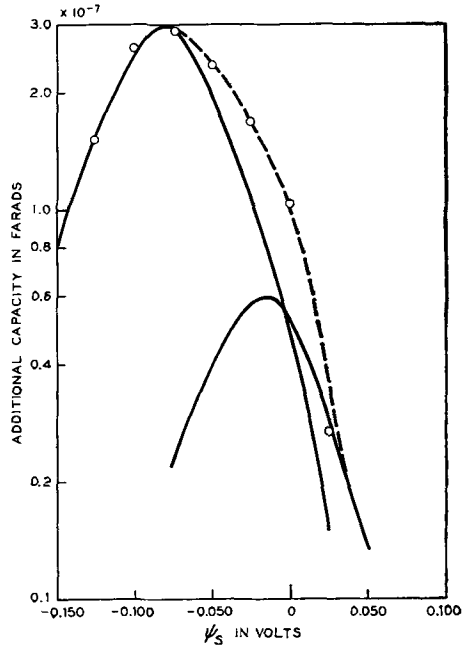

Fig. 10. Theoretical fit of the additional capacity for the n-type electrode. Parameters of the states are $N_t = 0.71 \times 10^{11}$ cm^{-2} $\nu = 1.5$ kT/e and $N_t = 1.47 \times 10^{10}$ cm^{-2}, $\nu = -1.2$ kT/e.

Since, from Eq. [2], at the potential of the maximum in capacity for each state $Y - \ln \lambda + \nu$ must equal zero, the energies of the two states may each be determined, and N_t may be calculated from the magnitudes of the maxima.

From the filament lifetime and dimensions of the thin arm, surface recombination velocity (s) may be calculated by means of the expression

$$\tau^{-1}_{\text{Total}} = \tau^{-1}_{\text{Body}} + (2s/t)(1 + t/w) \quad [3]$$

where w and t are the width and thickness of the thin arm. This equation is valid up to $s = 2D/t$, where D is the diffusion constant for the minority carrier. Surface recombination velocity, normalized to the maximum value, is plotted *vs.* $Y - \ln \lambda - \ln \chi$ for the p-type electrode in Fig. 11. The theo-

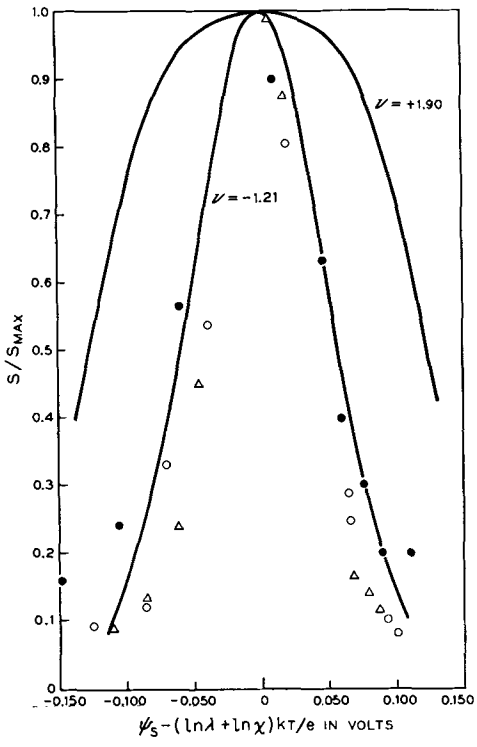

Fig. 11. Surface recombination velocity, normalized to the maximum value, *vs.* ψ_s—(ln λ+ln χ)kT/e for the p-type electrode. The curves are constructed using the experimental values ln χ = 3.0, ln λ = 1.72 and ν' = —1.2 or +1.9kT/e. The various points represent different initial Cu^{++} concentrations.

retical expression for surface recombination velocity at a surface potential Y, due to surface states at an energy ν', is (3)

$$s = (\lambda + \lambda^{-1})(C_n C_p)^{1/2}\{2\cosh(\nu' + \ln\chi) + 2\cosh(Y - \ln\lambda - \ln\lambda)\}^{-1} \quad [4]$$

where C_n and C_p as defined by Shockley and Read (4) are

$$C_p = N_t v_{T,p}\,\sigma_p \quad [5]$$

and

$$C_n = N_t v_{T,n}\,\sigma_n \quad [6]$$

where $v_{T,p}$ and $v_{T,n}$ are the thermal velocities of holes and electrons, σ_p and σ_n the capture cross sections for holes and electrons, and

$$\chi = (C_p/C_n)^{1/2} \quad [7]$$

Equation [4] indicates that at the maximum in surface recombination Y — ln λ — ln χ equals zero, since only this term in the denominator depends on Y, whence ln χ is known and ($C_n \cdot C_p$) may be calculated from Eq. [4].

In experiments on the dry germanium surface it is customary to analyze the surface recombination data by fitting it to a curve, the shape of which is determined essentially by the magnitude of the quantity cosh (ν' + ln χ) and hence, knowing ln χ from the position of the recombination maximum, obtain a value for ν' which is used as a basis for analyzing the field effect data. Since we measure the differential with respect to surface potential of the trapped charge, our field effect data are more sensitive than that on the dry surface and, as has been shown, we are able to fit that data to discrete surface states without recourse to the recombination. As is evident from Fig. 11, our recombination data are not of a high order of reproducibility and are not wholly suitable for a detailed analysis. They are sufficiently good, however, to distinguish which, if either, of the states that we observe by added capacity is effective in recombination. The two curves in Fig. 11 are constructed using the known energies of these states. Clearly, the state at ν' = — 1.2 kT/e is the one involved. A point of interest here lies in the fact that when fitting the hyperbolic cosine to the recombination data two solutions, equal in magnitude but opposite in sign, are obtained. For ln $\chi \neq 0$ this leads to two possible values of ν'. Many and Gerlich (5) in a typical case obtain ln χ = 1.1 and (ν' + ln χ) = ± 3.0, giving values for ν' of +1.9 or —4.1. On the basis of the variation of s/s_{max} with temperature they chose — 4.1 as the proper value, *i.e.*, the negative solution. We obtain, on the other hand, ln χ = 3.0 and are able to show that the state at ν' = —1.2 fits the recombination data, *i.e.*, the positive solution applies. If we were to take the negative solution (ν' + ln χ) = —1.8, then we would obtain ν' = —4.8, in much closer agreement with Many and Gerlich. Wang and Wallis (7) have taken both solutions and interpret their data in terms of a pair of states of equal density.

In our data, in the region of ψ_s corresponding to ν' = —4.8, we lack precision due to the larger value of the space-charge capacity (relative to that at ψ_s corresponding to ν' = —1.2) and also to the fact that at the former potential the space-charge capacity is changing rapidly with surface potential. Hence, we cannot unequivocally state that there is no state located at this energy nor that both signs of the solution do not correspond to recombination centers, only that the evidence is that the positive solution is a proper one.

The data are summarized in Table 1. The state not effective in recombination is designated I, the other II. The analysis indicates a charge trap 1.9 kT/e below and a recombination center 1.2 kT/e above the intrinsic level. In Table II are shown the results of four experiments on the p-type sample illustrating how the values in Table I were obtained. The values of the cross sections were calculated from C_p and C_n by assuming a thermal ve-

Table I. Analysis of data for 12.5 ohm-cm n-type and 25.5 ohm-cm p-type electrodes

	n-type	p-type	Average

Table III. Comparison of surface states at the germanium electrolyte interface with those on the dry surface

	Present data	Many *et al.* (10)
State I		
ν	+1.9	+1.0
N_t	1×10^{11}	0.1 to 1×10^{11}
State II		
ν	−1.2*	−3.0 to −6.0
N_t	1.9×10^{10}	1 to 4×10^{11}
$\ln \chi$	3.0	0.14 to 1.7
σ_p	6.0×10^{-14}	6 to 15×10^{-15}

* This value would be −4.8 taking the negative sign for the argument of the cosh.

locity 1×10^7 cm/sec. The density of state I varied from 0.94 to 1.6×10^{11}, somewhat less than the variation for state II. It will be noted that variation in σ_p is much less, as it should be. The various data in Table II refer to different cupric ion concentrations over the range 5×10^{-8} to 10^{-6}M. There was no obvious correspondence between these concentrations and the parameters N_t and s_{max}.

Data on the dry germanium surface have been obtained by several workers (5-9). In Table III the averages of our data for n- and p-type electrodes are compared with some data summarized by Many (10), which are typical for the dry surface. There is a reasonable similarity between the two sets of data. They agree in that there is a charge trap just below and a recombination center just above the intrinsic level. The densities of states are also quite similar. The only markedly dissimilar feature is the ratio of hole to electron capture cross sections and the shapes of the surface recombination velocity curves.

It is pertinent to compare the magnitudes of surface recombination obtained by various observers. One notes from Eq. [4] that in any recombination mechanism (due to a state or distribution of states of fixed parameters such as density, energy, and trapping cross section) the quantity $s_{max}/(\lambda + \lambda^{-1})$ should be a constant, independent of doping. The various values obtained for this quantity range from about 20 cm sec⁻¹ on a (110) oriented surface (7) to 1000 cm sec⁻¹ on surfaces heat treated in vacuum (8) with considerable evidence that an etched (100) surface in air (5, 9, 11) has values between 100 and 200 cm sec⁻¹. These are to be compared with the values we find on a (100) surface in aqueous solution of 30-100 cm sec⁻¹, depending on the density of state II.

The general agreement between the states observed on the dry surface and those produced by the interaction of cupric ion with the germanium surface in an aqueous electrolyte suggests that they have a common origin. However, it is not possible to state unequivocally that the phenomena we observe are due directly to the presence of copper species *per se;* we may be certain only that the states arise as a consequence of the interaction of cupric ion with the surface. Since copper is a more noble element than germanium, cupric ion will tend to be displaced from solution by an appropriate ion containing germanium in an oxidized state with the production of a lower oxidation state of copper. It has recently been shown that metallic copper may be deposited by the oxidation of germanium monoxide to the dioxide with cupric ion (12). Germanium monoxide may be present on the surface of a germanium electrode under steady-state conditions in aqueous solutions of intermediate pH (13, 14). In our experiments, however, the electrode has been CP-4 etched and subjected to anodic current, and it would seem unlikely that under these highly oxidizing conditions significant amounts of monoxide remain unconverted to the soluble dioxide.

It is more probable that cupric ions interact directly with surface atoms, discharging to metallic copper and either injecting holes (*i.e.*, consuming valence electrons) or consuming conduction electrons

$$Cu^{++} \rightarrow Cu + 2e_o^+$$

or

$$Cu^{++} + 2e_o^- \rightarrow Cu$$

and correspondingly to maintain charge balance

$$Ge + me_o^+ \rightarrow Ge^{+n} + (n-m)e_o^-$$

where n is 2 or 4. If n is 2, then a further oxidation by cupric ion to Ge^{+4} may occur.

It would appear that copper may be present at the surface either as copper atoms deposited directly on germanium atoms or bound in the ionic state in a surface complex. In either case it is not at all apparent why the density of surface states should be essentially independent of cupric ion concentration and should be such a small number relative to the density of surface atoms, since approximately monolayer coverage of copper atoms (or ions) has been demonstrated for germanium in contact with solutions of cupric ion of the order of those used here (12). Taking our data alone, there would seem to be good arguments in favor of a surface state due to neutral or negatively charged copper atoms. (This would permit the state to be negatively charged when occupied by an electron, as indicated by the relatively large capture cross section for holes.) The low density of states could be rationalized by postulating that only those copper atoms in certain select sites (*e.g.*, along dislocations at the surface) are effective.

Copper is electrically active in the bulk of germanium, giving rise to at least three levels (17), the species and approximate energies being Cu^{-} ($+14\ kT/e$), Cu^{--} ($+2.5\ kT/e$), and Cu^{---} ($-5.0\ kT/e$). Our state I is not in serious disagreement with the Cu^{--} state, while the Cu^{---} energy agrees well with the alternative value for state II, although our data indicates that we should strongly prefer the value $\nu' = -1.2\ kT/e$ for state II. On this picture, since state II has the higher negative charge, it would have a relatively higher hole capture cross section and could dominate in the recombination process, as observed.

The close similarity between the parameters we observe and those commonly observed on the dry surface, which are by and large almost independent of the way the dry surface was etched, tend to weaken, although not disprove, the specific relationship between surface states and the presence of cupric ion in solution. It should be recalled in this regard that unless rigorous precautions are taken most etched germanium surfaces are contaminated to some degree with copper. This constitutes the "deathnium" or "thermium" that was observed some years ago to cause most samples of germanium to become p-type if heated to a sufficiently high temperature for diffusion of the surface contamination to occur (15).

The present data are not sufficient to distinguish the chemical nature of the surface state other than to say that since it appears as a consequence of the interaction of cupric ion with the surface, it must be due to some copper containing species or to an oxidation product deposited on the surface as a consequence of the spontaneous reduction of cupric ion. More recent data on surface states produced by ions of silver and gold (14) indicate a similar, although not identical, effect. Experiments on the dry surface pretreated with dilute cupric nitrate solutions (16) indicate that there is a relationship between the parameters of fast surface states and such pretreatment, albeit not a simple one, in that case also. More recently a definite level ($+6\ kT/e$) and value of C_p/C_n (~ 200) have been ascribed to copper on the dry surface (18).

Conclusions

The interaction of cupric ions with the germanium-aqueous electrolyte interface results in capacity and surface recombination which may be interpreted in terms of two surface states, one a charge trap $1.9\ kT/e$ below the intrinsic Fermi level with a density $1 \times 10^{11}\ cm^{-2}$, the second a recombination center $1.2\ kT/e$ above the intrinsic level with a density of $1.9 \times 10^{10}\ cm^{-2}$.

Electrical Properties of Mg_2Sn Crystals Grown from Nonstoichiometric Melts

Barry D. Lichter

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[1]

ABSTRACT

Resistivity and Hall measurements were carried out on Mg_2Sn crystals in the temperature range 300°-60°K. Single crystals were grown by a modified Bridgman technique from stoichiometric melts and from melts containing 1, 2, 10, and 18 at. % excess Sn and 3 at. % excess Mg. In the mixed conduction and extrinsic ranges, it was found possible to describe the calculated temperature dependence of the conduction mobility on the basis of a combination of lattice vibration (acoustic mode) and ionized impurity scattering. A stoichiometry effect is observed. The Mg_2Sn crystals appear to dissolve the excess constituent producing n-type crystals (excess Sn) and p-type crystals (excess Mg). The observed effect corresponds to a solubility of 10^{-5}-10^{-6} atom fraction excess constituent. This result is briefly discussed in terms of bonding in Mg_2Sn.

The intermediate phase Mg_2Sn has been the subject of a number of investigations of electrical properties (1-5) as have been the other "II-IV compounds" Mg_2Si, (2, 6) Mg_2Ge, (2, 7), and Mg_2Pb (1, 2). These investigations have established that Mg_2Si, Mg_2Ge, and Mg_2Sn are semiconductors while Mg_2Pb is metallic.

The width of the forbidden energy gap in Mg_2Sn is reported as 0.33 ev at 0°K with a value of approximately -4×10^{-4} ev °K^{-1} for the temperature dependence (4). The mobility ratio is close to unity, $b = 1.5$ according to Busch and Winkler (2), and $b = 1.23$ according to Blunt *et al.* (4). Theoretical calculations (3) indicate that the intrinsic carrier concentration $n_i = 2.76 \pm 0.51 \times 10^{17}$ cm^{-3} at room temperature and that b remains nearly constant with temperature. The Mg_2Sn crystallizes in the fluorite (CaF_2) structure, magnesium occupying F^- sites, and tin occupying Ca^{++} sites. At present no measurements as to the form of the band structure are available.

It has been noted by previous investigators (4, 6, 7) that crystals of Mg_2Si, Mg_2Ge, and Mg_2Sn are predominantly n-type when grown and can be made p-type by addition of Cu, Ag, or Au to the melt. Since evaporation of Mg from the melt can be considerable, one may inquire whether or not the conductivity type is influenced by stoichiometry. Recently it has been shown that the carrier concentration is markedly changed after annealing in magnesium vapor (5). The present investigation offers evidence tending to confirm the stoichiometric effect in crystals grown from melts whose compositions were controlled during the course of solidification. In addition, some information on carrier mobilities in the mixed conduction range is presented.

[1] Operated for the U. S. Atomic Energy Commission by the Union Carbide Corporation.

Experimental

Growth of Single Crystals

Single crystals of Mg_2Sn were grown under 2 atm pressure of purified argon by a modified Bridgman procedure from high-purity, zone-refined Sn ingots (Varlacoid Company, New York City) and high-purity Mg rods (Varlacoid Company and Johnson, Matthey and Company). Typical results of emission spectroscopic analysis for impurities in Mg, Sn, and Mg_2Sn are given in Table I. In addition, 14 other elements were sought for and not detected. Values in parentheses in Table I were obtained by neutron-activation analysis. Copper, silver, and gold are known acceptors in Mg_2Sn (4, 5), and Sb is a known donor (8).

The furnace was a water-cooled, cylindrical, vacuum chamber used conventionally to pull Ge and Si crystals and modified to operate under 2 atm pressure of argon. A cylindrical, graphite, re-

sistance heater was employed, and the temperature was controlled with a chromel-alumel couple to ± 1°C using a high-speed controller and motor-driven variac.

Cylindrical crucibles (8 × 1.2 cm OD) were machined from high-purity graphite (National Carbon Company, grade CCH). Premachined and etched Sn and Mg rods were inserted into a graphite liner which fit tightly in the crucible. The inside diameter of the top 2-4 cm length of the liner was 0.6 cm, and the remaining section diameter was 1 cm. The crucible was closed with a graphite cap which was threaded to the end of a stainless steel pulling rod. Small holes were drilled through the cap to allow initial evacuation before melting and subsequent access of argon to the melt. In this manner, and by means of partial encapsulation of the crucible in fused silica and stainless steel outer liners, vaporization of magnesium was minimized.

After evacuation and flushing with argon, the furnace was heated to 200°C above the liquidus temperature (650°-778°C) corresponding to the melt composition, and a pressure of 2 atm was established. The furnace was adjusted to obtain a maximum gradient (50°C cm^{-1}) at the liquidus temperature, which coincided roughly with the top of the heater. Directional solidification was effected starting from the top of the crucible. Stoichiometric Mg_2Sn undergoes a 2% volume expansion on solidification, according to the data of Sauerwald (17). The associated strain was presumably taken up either by expansion into the small volume of dead space above the crystal or by compression of the graphite liner and crucible. The pulling rod was rotated at 1 rps. For melt compositions close to stoichiometric (N_{Sn} = 0.33) pulling speeds of 5 mm hr^{-1} or less yielded single crystals. For melts containing excess Sn or Mg, pulling speeds as low as 0.5 mm hr^{-1} were required to obtain single crystals.

Figure 1 shows the orientation of resulting Mg_2Sn crystals with respect to the growth axis. A decided preference for {211} orientation is observed. It is interesting to note that the three orientations obtained constitute three adjacent planes of the five low index planes in the <210> zone. Rotation

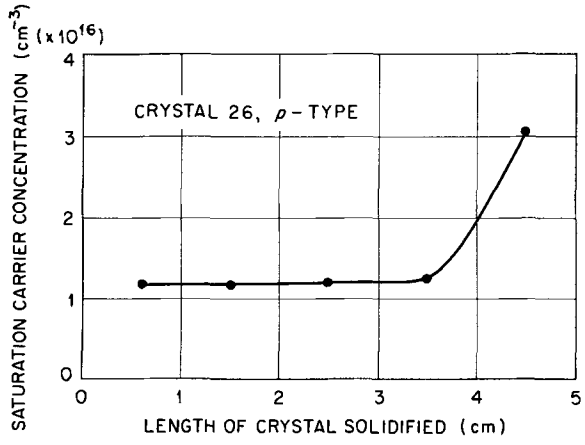

Fig. 2. Variation in saturation carrier concentration for p-type crystal grown from nearly stoichiometric melt.

about a [$\bar{1}$02] zone axis yields in sequence the low index planes (201), (211), (221), (231), and (010).

In order to minimize the effect of concentration changes in the melt during directional solidification, only the first 1.5-cm length of crystal was used for electrical measurements. Since the distribution coefficients for Mg and Sn are very small, the approximate variation in melt compositions can be calculated. The inside dimensions of the graphite liner were adjusted so that the maximum variation in melt composition that occurred after 1.5 cm of solidification was less than 1% of the initial composition in all cases. In Fig. 2, the variation in the direction of solidification of saturation carrier concentration is shown for a nearly stoichiometric melt. For p-type crystals, excess Mg was observed in the final fraction solidified, whereas, for the n-type crystals, a Mg_2Sn-Sn eutectic was observed. Melt compositions are listed in Table II.

Electrical Measurements

Samples were prepared from the top 1.5-cm length of each crystal. The usual sample dimensions were 0.5 × 0.1 cm^2 cross section and from 1.0 to 1.5 cm long. Sample surfaces were sandblasted with 600-grit SiC abrasive, cleaned in a stream of compressed argon, and rinsed in acetone. As noted by previous investigators, it was not possible to employ suitable chemical etchants or electropolishing techniques in the preparation of sample surfaces (1, 4).

Hall and resistivity measurements were carried out over the temperature range 60°-300°K using

conventional d-c techniques. A permanent magnet with 3-in. diameter pole pieces was used to establish a field of 1000 gauss at approximately a 4-in. gap. Tungsten probes ground to conical points were spring-loaded to form pressure contacts. The probes were arranged in a "diamond" pattern (9), and resistivity and Hall voltages were measured with a type K-3 potentiometer. The sample holder was a boron nitride block, advantage being taken of the relatively high thermal conductivity of this insulator.

The sample holder was contained in an evacuated Dewar flask surrounded by a second Dewar flask filled with liquid nitrogen. Relatively slow heat transfer from the inner to the outer flask (approximately 2° min^{-1} initial cooling rate) allowed continuous measurements to be made during cooling. For measurements below 150°K, liquid nitrogen was added directly to the inner flask, and the sample was cooled at 60°K by evacuation of the space over the liquid nitrogen. Measurements were made as the sample temperature increased slowly.

Results

The resistivity (ρ) and Hall coefficient (R) are plotted *vs.* the reciprocal of the absolute temperature in Fig. 3-6 for *n*- and p-type samples. The temperature dependence of the Hall mobility, $\mu_H = R/\rho$, is given in Fig. 7 and 8. For comparison, the high-temperature data of Busch and Winkler (2) and the low-temperature data of Blunt *et al.* (4) are shown in Fig. 7 and 8. The conduction mobility ratio for electrons and holes, $b = \mu_n/\mu_p = 1.21$, was determined from the Hall coefficients of p-type samples according to Breckenridge *et al.* (10) and was assumed to be constant with temperature in the calculation of conduction mobilities presented below.

The equations relating the Hall coefficient and resistivity to the conduction mobility and carrier concentrations may be written

$$R/R_s = (\alpha b^2 - 1)(\alpha - 1)/(\alpha b + 1)^2 \quad [1]$$

$$\mu_H/\mu_p = b\mu_H/\mu_n = -G(\alpha b^2 - 1)/(\alpha b + 1) \quad [2]$$

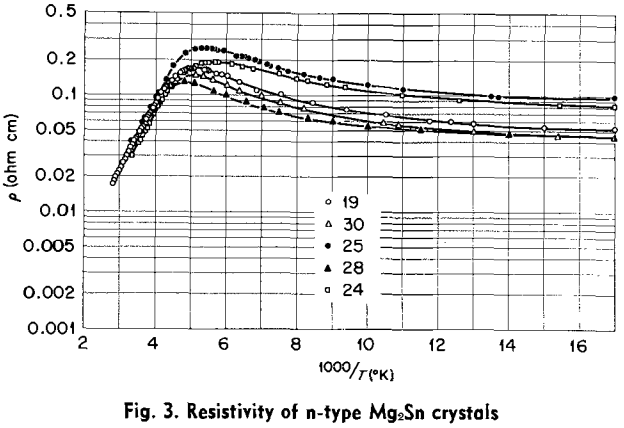

Fig. 3. Resistivity of n-type Mg_2Sn crystals

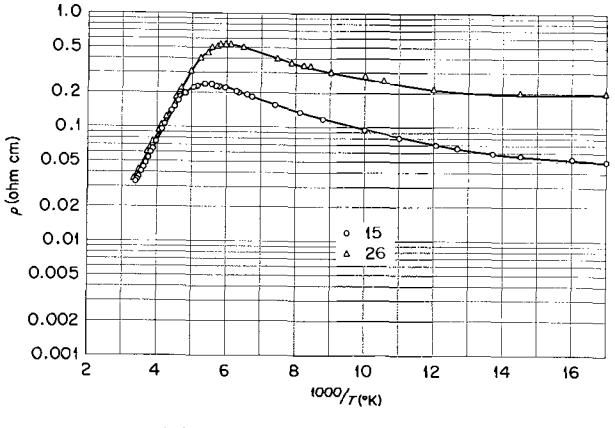

Fig. 4. Resistivity of p-type Mg_2Sn crystals

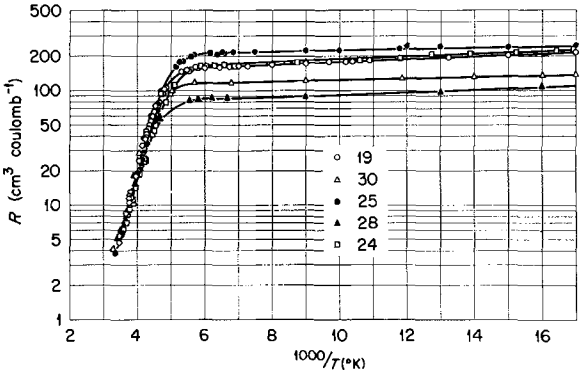

Fig. 5. Hall coefficient of n-type Mg_2Sn crystals

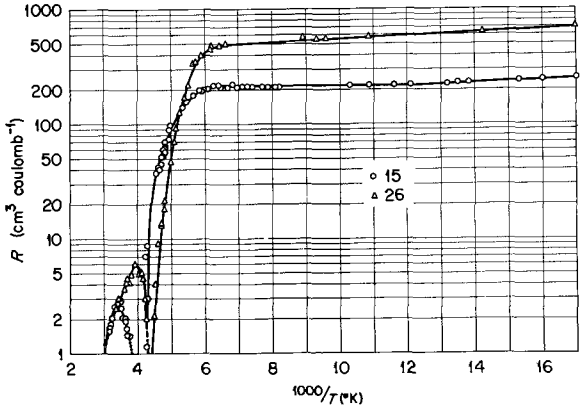

Fig. 6. Hall coefficient of p-type Mg_2Sn crystals

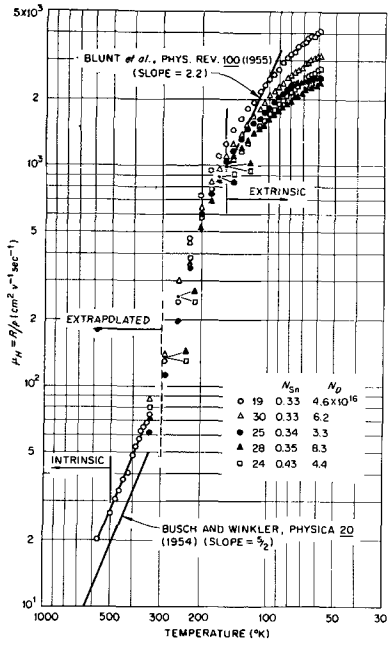

Fig. 7. Hall mobility of n-type crystals

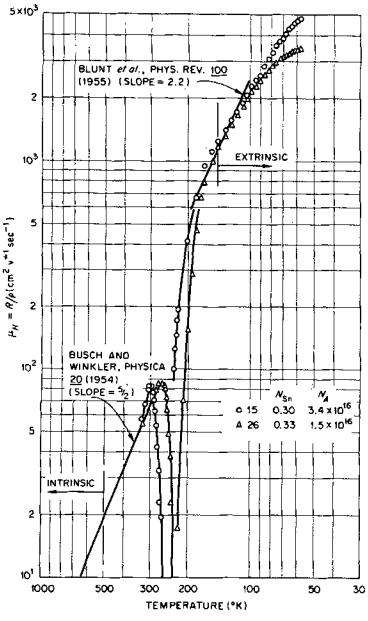

Fig. 8. Hall mobility of p-type crystals

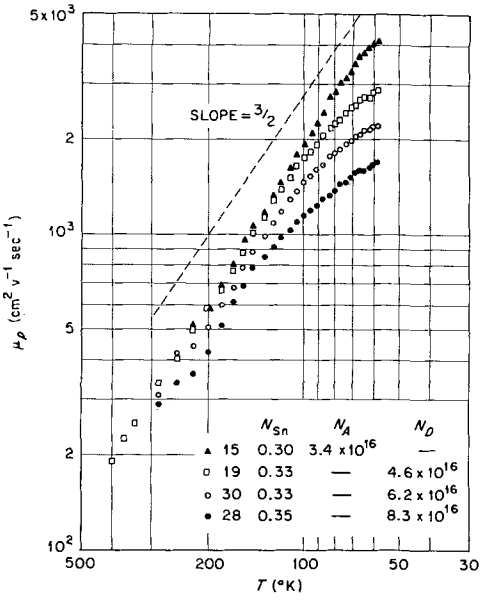

Fig. 9. Hole conduction mobility of n- and p-type crystals

where R_s is the saturation value of the Hall coefficient estimated from Fig. 5 and 6, $\alpha = n/p$ is the carrier concentration ratio for electrons and holes, and $G = 3\pi/8$. Equations [1] and [2] are essentially in the form given by Dunlap (11) except that Eq. [1] assumes complete ionization of uncompensated donors or acceptors. Equations [1] and [2] are therefore especially useful in the mixed conduction range. In the extrinsic range, Eq. [2] becomes

$$\mu_p = -\mu_H/Gb; \ (\alpha \text{ very large, n-type}), \quad [3a]$$

$$\mu_p = \mu_H/G; \ (\alpha \text{ very small, p-type}). \quad [3b]$$

The temperature dependence of μ_p calculated using Eq. [1], [2], and [3] is given in Fig. 9. Values of μ_p at 300°K and 77°K are given in Table II.

Uncompensated donor or acceptor concentrations (N_D or N_A) were determined from the Hall coefficients according to the relation

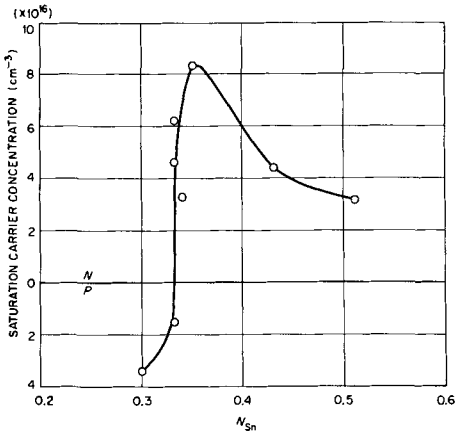

Fig. 10. Saturation carrier concentration vs. melt comopsition

$$N_D \text{ or } N_A = G/e|R_s| = 7.4 \times 10^{18}/|R_s| \quad [4]$$

As shown in Table II, values of 1.5-8.3 x 10^{16} cm^{-3} were obtained for N_D or N_A. These values are plotted in Fig. 10 *vs.* the corresponding melt composition, N_{Sn}. When Sn was added to the melt in excess of the stoichiometric composition ($N_{Sn} = 0.33$) n-type crystals were always obtained, whereas, a p-type crystal was obtained from a melt containing excess Mg.

These results are consistent with results of Guenoc (5) who earlier had observed that Mg acts as a p-type impurity in Mg_2Sn: the carrier concentration of a p-type crystal annealed in Mg vapor was observed to increase from 7 x 10^{16} to 1.5 x 10^{19}. However, similar annealing experiments performed during the present investigation were less conclusive. The carrier concentration of an n-type crystal increased from 7.4 x 10^{16} cm^{-3} to 1.2 x 10^{17} after annealing for 4 hr at 650°C in an argon atmosphere. No change in carrier concentration was observed after annealing for 20 hr at 650°C in the presence of a Mg-Sn melt containing excess Mg($N_{Sn} = 0.24$).

If the observed carrier concentrations are attributed entirely to the presence of the excess constituent, one obtains a solubility of 10^{-5}-10^{-6} atom fraction of excess Sn or Mg in Mg_2Sn.

Discussion

Mobility of Charge Carriers

The sigmoidal shape of the log-log plots of the Hall mobility in Fig. 7 is not present in the corresponding plots of the calculated conduction mobility shown in Fig. 9. Throughout the mixed conduction region, the slopes of log-log plots of μ_p *vs.* $1/T$ are constant, the values lying between 1.4 and 1.7. At lower temperatures, the slopes of curves decrease to lower values. If both lattice scattering and impurity scattering are present, tentatively it may be assumed that the individual cross sections for scattering are additive. Hence,

$$1/\mu = 1/\mu_L + 1/\mu_I \quad [5]$$

where

$$\mu_L \approx A/T^m \quad [6]$$

$$\mu_I \approx BT^{1.5} \quad [7]$$

Combining Eq. [5], [6], and [7], one obtains

$$T^{1.5}/\mu = T^{1.5+m}/A + 1/B \quad [8]$$

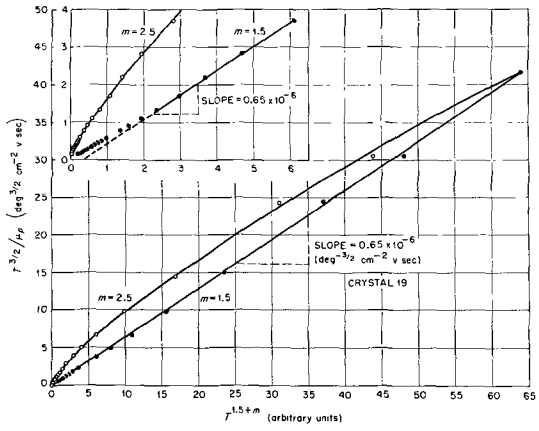

Fig. 11. ($T^{1.5}/\mu_p$) vs. $T^{1.5+m}$ for sample 19

A value of $m = 1.5$ corresponds to lattice scattering according to simple theory. A value of $m = 2.5$ corresponds to the observed high-temperature dependence of the mobility in the intrinsic range according to Busch and Winkler (2). In Fig. 11, the quantity ($T^{1.5}/\mu_p$) is plotted *vs.* $T^{1.5+m}$ for sample 19. A straight line with slight deviations below 125°K is obtained for $m = 1.5$, whereas large deviations from a straight line are obtained for $m = 2.5$. Actually, a straight line is best approximated over the entire temperature range (60°-400°K) for $m = 1.6$, the slope of the log-log plot of μ_p *vs.* $1/T$ in the mixed conduction region for sample 19. Similar results are obtained for other samples.

It is therefore possible to describe the mobility in the mixed conduction and extrinsic regions as a combination of lattice (acoustic mode) and ionized impurity scattering. Such a simplified view, however, neglects the fact that at higher temperature a $1/T^{2.5}$ dependence is observed, and therefore scattering mechanisms associated with optical mode lattice vibrations may be involved. Attempts to explain observed mobilities of Mg_2Ge and Mg_2Si (6, 7) in terms of optical mode scattering mechanisms, while successful in part, involved a large degree of arbitrariness in the selection of critical parameters. Similarly, an explanation of observed mobility behavior in PbS, PbTe, and PbSe in terms of optical mode scattering has not been successful at higher temperatures where approximately a $1/T^{2.5}$ dependence has been observed (12). At present no complete theory exists either involving optical mode scattering or explaining a $1/T^{2.5}$ dependence.

Other scattering mechanisms such as scattering by neutral impurities, dislocations, or atom clusters apparently cannot be neglected in view of the fact that the low-temperature mobilities are not completely consistent with extrinsic carrier concentrations as seen in Fig. 7 and 8. Also, sample 29, which suffered a large decrease in mobility as shown in Table II, is thought to have contained occluded or precipitated Sn as a second phase.

Stoichiometry and Conductivity Type

The effect of departures from the ideal stoichiometric composition on the electrical properties of compound semiconductors depends on the nature of "bonding" in the crystal. Wagner (13) has generalized the situation in predominantly ionic crystals, for which case, interstitials, vacancies, quasi-free electrons, and electron holes are considered. A composition corresponding to a cation/anion atom ratio slightly greater than stoichiometric leads to the creation of donor levels (*e.g.*, Zn interstitials in ZnO), whereas a cation/anion atom ratio slightly less than stoichiometric leads to the creation of acceptor levels (*e.g.*, Cu vacancies in Cu_2O). These effects may occur independent of the nature of the defect responsible for the stoichiometric departure (*i.e.*, interstitials or vacancies on either cation or anion sublattice) and arise chiefly from the requirement of maintaining electrical neutrality. Thus, if $Mg_2^{+2}Sn^{-4}$ (corresponding to transfer of electrons from the less electronegative Mg to the more electronegative Sn) represented the configuration of the crystal, the effects of stoichiometric departures on conductivity type would be opposite to that actually observed.

For predominantly valence crystals, involving only small electronegativity differences between constituent atoms, the normal electron affinities may be reversed in view of the greater stability of possible covalent bond structures (14), *e.g.*, transfer of an electron from Sb to In leading to sp^3 hybridization in InSb (15). Alternatively, no charge transfer takes place, but electrons are shared between bonds by means of "pivoting resonance" (16). In this case, stoichiometric departures may arise from disordering in the constituent sublattices. Replacement of a *B* atom in the *B* sublattice by an excess *A* atom, where *A* has fewer valence electrons than *B*, results in acceptor states and *vice-versa*. The effects of antistructure disorder are analogous to the effects of substitutional impurities in Ge and Si.

The observed results are therefore consistent with antistructure disorder in Mg_2Sn. The following facts suggest that bonding in Mg_2Sn is predominantly covalent: (*A*) Mg_2Sn undergoes a volume contraction on melting (17) similar to the observed behavior in Ge and Si and corresponding to a change from covalent to metallic bonding. (*B*) The electronegativity difference ($\Delta x = 0.6$) between Mg and Sn is relatively small (compare InSb, $\Delta x = 0.2$; SiC, $\Delta x = 0.7$; PbS, $\Delta x = 0.9$; NaCl, $\Delta x = 2.1$). (C) The hard sphere approximation to the fluorite structure, *i.e.*, $r_{Ca^{++}}/r_{F^-} = \sqrt{3} - 1$; $a_o/r_{F^-} = 4$, is most nearly realized by assuming the single bond covalent radius for Sn ($r_{Ca^{++}}^{Sn} = 1.40$Å) and the metallic radius for Mg ($r_{F^-}^{Mg} = 1.62$Å) for the observed lattice parameter ($a_o = 6.76$Å).

Conclusions

1. In the mixed conduction range, the temperature dependence of the electron and hole conduction mobilities may be approximated by a combination of lattice and ionized impurity scattering.

2. Crystals of Mg_2Sn grown from melts containing either constituent in excess of the ideal stoichiometric ratio appear to dissolve the excess constituent producing n-type crystals (excess Sn) and p-type crystals (excess Mg). This result is consistent with antistructure disorder and predominantly covalent bonding in Mg_2Sn.

3. If the observed carrier concentrations are attributed entirely to the presence of the excess constituent, one obtains a solubility of 10^{-5}-10^{-6} atom fraction of excess Sn or Mg in Mg_2Sn.

Molten Metal Etches for the Orientation of Semiconductors by Optical Techniques

J. W. Faust, Jr., A. Sagar, and H. F. John

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Under controlled conditions the dissolution and redeposition of semiconductors in molten metals proceed along the same definite crystallographic planes. It has been found that these planes are {111} for Ge and Si and {111} and {100} for the III-V intermetallic compounds. Conditions are given for producing pits whose facets give good light reflection for accurate orientation by optical techniques.

Several types of semiconductor devices and many fundamental investigations on semiconductors require a specific surface orientation. In some cases the surface need only be oriented to within one degree of a crystallographic plane, while in others accuracies of a few minutes of arc are necessary. Various x-ray techniques are widely used to determine orientation. Since x-rays penetrate the crystal and are reflected from planes of atoms within the crystal, all that is required of an etch in preparing the surface is that it remove the damaged layer caused by abrasive processes. A carefully constructed optical goniometer used on a suitably etched surface can, however, give accuracies comparable to those obtained with x-rays, *i.e.*, within 1-2 min of arc. Optical goniometry (1) is attractive because of the simplicity of the equipment and the fact that intensive training is not necessary for an operator. Since light has a much longer wavelength than x-rays, it is reflected from the surface of the crystal; thus the etch must be capable of producing etch pits whose facets are definite crystallographic planes, preferably of low Miller indices. The accuracy of the orientation determination depends on the accuracy of the goniometric instrument, the size of the revealed planes on the faceted surface, and the flatness of these planes.

Chemical etches have been used exclusively for producing such pits; Faust (2) has tabulated chemical etchants that produce such surfaces for numerous materials. Studies on chemical etches for the III-V intermetallic compounds have produced some useful results (3) although, in general, the results leave much to be desired. Etching silicon with NaOH (2, 4) produces excellent pits that allow orientation to within a few minutes of arc; however, the chemical etches for germanium (2) are not as good, often giving accuracies no better than 10 min (5).

The preferential nature of the dissolution and recrystallization of germanium and silicon from molten metals is well known to those who have

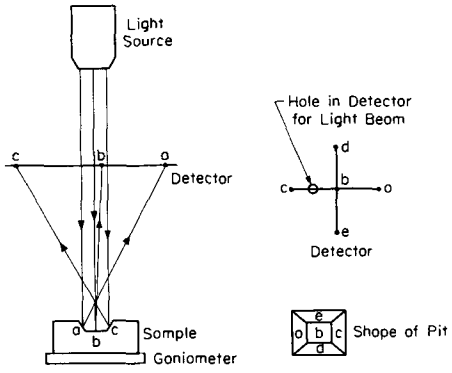

Fig. 1. Essentials of an apparatus for optical goniometry, and details of reflection from a pit.

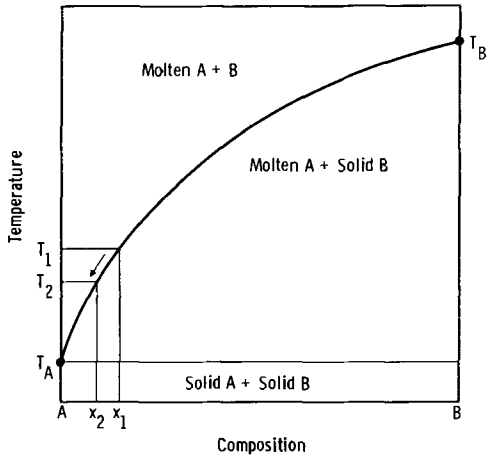

Fig. 2. Phase diagram illustrating molten metal etching

studied the alloy-fusion technique for preparing p-n junctions. This has been discussed by Mueller and Ditrick (6), Pankove (7), John (8), and in an incidental way by others. It was found that the reflected light pattern from pits produced by alloying In onto Ge (8) consisted of very bright sharp points which are necessary for accuracy in orienting surfaces. This paper reports on studies on "alloy etching," *i.e.*, molten metal dissolution and recrystallization, for preparing surfaces of germanium and the III-V intermetallic compounds for accurate orientation by optical methods.

Experimental Procedures

Since the purpose of this paper is to describe a technique for producing good facets for orientation rather than the operation of particular goniometers, the reader is referred to Barrett (1), Hancock and Edelman (9), and Wolff (5) for the detailed operation of goniometers. However, it seems appropriate to sketch the essentials of an optical goniometer apparatus, Fig. 1. The small parallel or slightly convergent beam of light is reflected from facets of the etched specimen back onto the detector, as shown in Fig. 1 for a nearly {100} surface etched to reveal {100} and {111} planes. If the specimen surface is only slightly different from the basal facet, b, the orientation of the specimen can be calculated very accurately from the specimen-detector distance and the displacement of the spot, b, from the light beam. Because of the large angles between the side facets and the basal facet, their angular relationship must be determined from a calibrated goniometer head.

Ingots of the semiconductor were oriented by x-rays or by optical methods using chemical etches to produce the proper surface. Wafers were cut whose large faces were parallel to the {111}, {001}, and {110} planes; in some cases wafers with surfaces parallel to other planes were also used. The surfaces were lapped to remove saw marks and to leave a less deeply damaged surface. The surfaces, or parts of the surfaces, were etched by placing a metal foil or pellet in contact with the wafer and heating to the desired temperature in a quartz tube under vacuum. A particularly convenient technique was to coat the metal "etchant" onto the surface with an ultrasonic soldering iron before heating. This procedure insured more uniform wetting over the entire surface. After the alloying operation, the metal was removed by a suitable reagent, *i.e.*, one that dissolved the metal but did not attack the semiconductor. The planes revealed by the etching were identified by measuring angles between various facets with an optical goniometer and by calculating angles from microscopic measurements.

The molten metal etching process may be understood by referring to Fig. 2. When a metal A is placed on another metal or semiconductor B of higher melting point and the system is heated to temperature T_1, metal A melts and dissolves enough of metal B to give the molten solution its equilibrium concentration X_1. Upon cooling, the dissolved metal B separates out to keep the molten solution at its equilibrium concentration. The concentration follows the arrow on the liquidus curve; for example, at T_2 the molten solution will have a concentration of X_2. Metal B can separate in one or both of the following ways: (i) It will redeposit epitaxially onto the solid along the solid-liquid interface. (ii) Crystallites will nucleate and grow in the molten solution. If the molten solution is caused to cool more slowly than the base, most or all of metal B will separate by (i): thus the observed facets will be those of redeposited material. Metal B can be prevented from redepositing onto the substrate if (*a*) metal B is caused to cool more slowly than the molten solution, particularly if a strong reverse thermal gradient is imposed, (*b*) the molten solution is decanted from the base, or (*c*) metal B is removed so far away from the interface that it cannot diffuse back. In these cases the facets will be those formed by the dissolution process.

Although (*a*) above can be accomplished by the use of large carbon blocks with cooling coils in them, it was found easier to obtain dissolution pits by (c) as follows. A large sphere of alloying metal was placed on the surface of the material to be etched in such a way that there was only a small area of contact. If the system is brought up to temperature rapidly and the heating cycle kept short, the equilibrium concentration in the molten metal will not be attained. Metal B can diffuse easily throughout the volume of metal A. The large area

ratio of melt-gas to melt-solid will discourage redeposition at the melt-solid interface.

Experimental Results

Germanium.—Indium, aluminum, gallium, gold, lead, and tin were studied as alloy "etchants" for germanium, being listed in order of decreasing usefulness. The actual amount of alloying element was not found to be critical; more element merely resulted in a more deeply etched area. For the technique that yields redeposition facets, the time of etching is not too important since the alloying element dissolves only its equilibrium amount of germanium in a few minutes. Leaving the molten metal in contact with a wafer for many hours, however, can result in alloying through a wafer by a thermal gradient transport process if the temperature is not controlled better than ±0.5°C (8). Although the cooling rate did not appear to be too critical, it was found that cooling rates slower than 25°C/min produced more nearly perfect facets. The facets produced at various temperatures were examined under the microscope for size and flatness; the light reflections on the optical goniometer were also checked. It was found that the best facets were produced over the temperature range of 400°-600°C. Higher temperatures tended to produce large but uneven facets, and lower temperatures tended to produce fewer and poorly defined facets.

Faceted pits produced by dissolution were examined as well as the faceted figures produced by redeposition. The results were identical. Microscopic examination of the pits and regrowth figures produced on {111}, {110}, {100}, and {221} surfaces by In, Au, and Al showed their shapes to be truncated triangular pyramidal figures or truncated hexagonal pyramidal pits (only three of whose side facets were visible), "roof"-type figures, four-sided pyramidal figures, and tilted truncated triangular pyramidal figures, respectively. Drawings of the pits and regrowth figures for {111}, {100}, and {110} surfaces are given in Fig. 3. From measurements made on many facets, angles were calculated. Only {111} planes were found. The angles between all facets were also measured with an optical goniometer; these measurements also showed that only {111} planes were revealed. Pits and regrowth figures on {411} and {211} surfaces were also examined and found to give the predicted pattern for {111} facets only. Gallium seems to reveal at least one additional set of planes which were not identified, while tin and lead did not produce satisfactory results. Small dissolution pits with very perfect {111} facets can be obtained on Ge by technique (*c*) described above. Such pits are probably capable of giving somewhat greater accuracy than the regrowth figures obtained by redeposition from molten metals. The latter, however, were found to be more convenient for goniometric measurements because of the larger areas available. Accuracies of 1 min of arc can be obtained; this is much better than that obtainable from chemical etching techniques. Although the molten metal etching techniques are applicable to silicon as shown in Table I, the quality of the facets produced by the NaOH chemical etch are adequate for almost all orientation requirements.

III-V Intermetallic compounds.—Antimony, arsenic, and phosphorus form intermetallic compounds with many metals; some of these compounds are more stable than the III-V intermetallic compounds. If a metal that formed one of the more stable compounds with the group V component were used as the etchant for a III-V intermetallic compound, the dissolution and redeposition processes may proceed along different crystallographic planes or the redeposition may not be epitaxial. To avoid such difficulties, only the group III component of the intermetallic compound was used as the etchant.

In these materials, as in germanium, the amount of metal etchant was not found to be critical. From the examination of the pits produced at various temperatures, the temperature range for producing the best facets was determined. The temperatures chosen for use are summarized in Table I along with the reagent used to remove the metal etchant. Facets formed by dissolution and by redeposition were examined and found to be the same.

* Only 9 at. % of the Si recrystallizes, the remainder being tied up in the eutectic.

Microscopic examination of the regrowth figures showed the redeposition process was the same for all of the III-V intermetallic compounds, but different than germanium. Drawings of the regrowth figures are given in Fig. 3 for comparison with the germanium figures. One can see that the {111} surfaces gave truncated hexagonal pyramidal figures; however, all side facets were visible, as can be seen in Fig. 4. Figure 5 shows the flats obtained on a large area. The {001} surfaces gave square and rectangular figures with one or more corners cut off as shown in Fig. 6 while Fig. 7 shows a figure with some visible side facets. The {110} gave "roof"-type figures, Fig. 8, similar to those found on germanium; however, figures with the shape shown in (*b*) of Fig. 3 were also observed. (These are indicated by arrows in Fig. 8).

The regrowth figures produced on the various surfaces of GaSb and InSb were carefully measured by microscopic and by optical goniometric techniques. The measurements show that not only are {111} planes revealed but also {100}. The identification of the planes that form the facets on the various surfaces are given in Fig. 3. For the {111} and {110} surfaces, the reflected light spot on the viewing plate of the goniometer was strong and sharp from the {111} facets: the reflections from the {100} facets were weaker. From the intensity and small

area of the reflected light spot, it is estimated that accuracies of better than 1 min of arc can be obtained from these surfaces. Figures of the shape b on the {110} surface were not as frequent as those of shape a. No reflections from the four {100} side facets of the figures found on the {001} surface were obtained which is understandable since these planes are perpendicular to the surface. The {111} plane and the $\{\bar{1}\bar{1}\bar{1}\}$ plane gave the same type of pits as did the {001} and the $\{00\bar{1}\}$, indicating that the polarization which is found to give a difference in the attack of chemical etches on these planes (3, 10) does not affect the alloying process. The stability of {100} facets is apparently related to molecular association in the liquid, as discussed elsewhere (11).

Examination of the figures produced on GaAs and InAs gave the same results as those reported above for GaSb and InSb. Only partial results were obtained for AlSb because of difficulties in obtaining complete wetting of the surface by the aluminum; however, the results indicated that the same planes were revealed.

Discussion

The difficulty in devising chemical or electrolytic etchants for revealing low index planes should, by now, be appreciated. Alloy etching, however, affords a convenient method for revealing low index planes. The principle on which it is based is completely general; thus the technique can be used on any material provided the material can meet certain requirements. Certain metal-metal systems have suitable phase diagrams. Bailey and Watkins (12) show photomicrographs of Cu deposited onto Cu from Cu-saturated Pb which indicate the applicability of Pb as an alloy etchant for Cu.

There are two techniques which may be used for this method of etching, namely, the foil method used here and the decanting technique (5). Temperatures and reagents for the foil method are given in Table I along with pertinent data from other work. The success of this method depends on finding a suitable metal etchant and a reagent that will dissolve the metal etchant but not the material being etched. Existing phase diagrams (13) are helpful in deciding on the metal etchant and also in choosing the temperature. Since some of the dissolved material will recrystallize on the surface, it is necessary to choose a metal-material system that does not form intermetallic compounds since such compounds may be of a different crystal system or might not grow epitaxially on the substrate.

The generally greater accuracy obtainable from molten metal etches is the result of the fact that larger and more nearly perfect facets are produced by this technique than by chemical etches. Optimum conditions to produce large and perfect facets often represent a compromise between quantity of alloying material, alloying temperature, and cooling rate.

In Table I we have included the equilibrium concentration of the material in the metals at the alloying temperatures which were chosen for the various materials. One can see that these values fall between 1 and 15 at.%. Concentrations above this value often produce less satisfactory facets; thus in choosing a temperature for a new system the temperature should be chosen so that the equilibrium concentration falls within these limits. Although the planes revealed are generally of low Miller indices, Wolff (5) has reported that certain metals on silicon, for example gold and zinc, reveal other planes in addition to the {111}; thus it is necessary to determine experimentally the planes revealed in a new system.

Perhaps the most stringent requirement for the success of this method lies in finding a suitable reagent for removing the alloying metal; this is particularly troublesome for metal-metal systems. Decanting techniques can, to a certain extent, overcome such difficulties. Broder (14) used a bath of molten metal and dipped the material to be etched in it and then rapidly removed it from the bath (a decanting technique). In this method, however, one may be troubled by the alloying metal adhering to the edges of the pits (12). The time of etching also becomes important since there is a large quantity of alloying metal present. In spite of these difficulties, decanting techniques are attractive for systems that present insurmountable obstacles to the technique used here.

Distribution of Sulfur in InSb Single Crystals

Mario D. Banus and Harry C. Gatos

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The distribution of sulfur impurity in single crystals of InSb pulled from the melt in the <111> direction was studied by high resolution autoradiography, electrical measurements, and analytical techniques. Autoradiography was found to be more suitable for the microdistribution of sulfur than the other techniques employed. A (111) facet present at the solid-melt interface led to the formation of a longitudinal core with a higher sulfur concentration than the rest of the crystal. The ratio of the on-core to off-core concentration of sulfur was greater with rotation than without rotation. It also varied with sulfur concentration in the melt (C_L) going through a broad maximum for values of C_L between 1.5×10^{18} and 4×10^{18} sulfur atoms/cc. The effective distribution coefficient (k_{eff}) of sulfur was found to vary with sulfur concentration in the melt and with orientation. For $C_L = 10^{18}$ sulfur atoms/cc the following values were obtained: on-core $k_{eff} = 0.4$, off-core $k_{eff} = 0.16$. The results are explained on the basis of specific adsorption of sulfur at the solid-melt interface and on the dependence of adsorption on crystallographic orientation.

The distribution of electrically active impurities continues to be of basic interest in semiconductor materials. Although incorporation of impurities in solids under equilibrium solidification conditions is in many respects a straightforward problem, commonly employed crystal growth conditions lead to impurity distributions of a rather complex nature.

In growing semiconductor single crystals from the melt by Czochralski-type techniques heterogeneous distribution of impurities is quite frequently encountered. Thus, it has been found (1) that in germanium single crystals, antimony and other impurities are periodically distributed along the growth axis (striations). In addition, it has been observed (1) by autoradiographic techniques that along the axis of growth a distinct impurity core is formed containing an increased concentration of the impurity elements.

Hall (2) has found that, during growth of germanium single crystals from the melt, the distribution of impurities is a function of the growth rate and orientation. He developed an expression for the variation of the impurity segregation as a function of the growth rate, assuming that the impurity atoms are preferentially adsorbed at the surface of the crystal. Similar observations on germanium (3) and other semiconductors (4) have been reported by many investigators, who have shown that the formation of the core is associated with the presence of an (111) facet on the crystal at the growth interface.

The present study was aimed at the detailed distribution of sulfur in single crystals of InSb. Sulfur was chosen because it is a soft beta-ray emitter (0.167 mev) and lends itself to high resolution autoradiography.

Experimental Techniques

Crystal growth.—InSb single crystals were grown by conventional Czochralski techniques in a purified hydrogen atmosphere. In view of the high vapor pressure of sulfur at the melting point of InSb (523°C), the sulfur impurity was first incorporated into InSb ingots in evacuated and sealed quartz ampules as follows. The radioactive sulfur (2-5 millicuries S^{35}) together with the desired amount of inert sulfur was dissolved in benzene, and the solution was introduced in the quartz ampule whereupon it was evaporated to dryness on a low-temperature airbath. Subsequently, the pure InSb was placed in the ampule which was then evacuated and sealed off. To prepare ingots containing only inert sulfur, elementary sulfur was placed directly in the quartz ampule. On melting, the ampule was manipulated so that the melt was displaced from one end of the ampule to the other to insure an effective incorporation of the sulfur into the melt.

The sulfur-containing ingots prepared as above were etched in CP4 to remove any surface slag formed during preparation. It was found by chemical analysis that about 50% of the sulfur originally employed was incorporated in the polycrystalline ingots. In one instance where detailed mass balance was performed after single crystal growth, it was found that, within experimental error, all of the sulfur present in the ingot was retained in the grown crystal and the residual melt.

Each crystal was grown under a constant pulling rate in the range of 0.3-0.6 in./hr. The principal rotation rate was 8 rpm, but on occasions rotation rates of 0, 4, and 100 rpm were employed.

The single crystals were 20-25 mm in diameter, and growth was continued until each crystal touched the bottom of the crucible. At this point the crystal was suddenly removed from the crucible. Actual growth rate (length per unit time) of the main portion of the crystal was carefully determined and was found to be 1.5 to 1.8 times the pull rate (the diameter of the crystals was rela-

[1] Operated with support of the U.S. Army, Navy, and Air Force.

tively large in comparison with the diameter of the crucible).

After growth, the crystals were sectioned in two halves (excluding the seed portion) along the growth axis. The two longitudinal sections were polished with 1600 grit abrasive and then submitted to electrical measurements, autoradiography, and preferential etching.

Autoradiography.—Because of pronounced self-absorption, autoradiographs obtained with soft β-ray emitters (such as S^{35} with a β-ray of 0.167 mev) essentially reflect the concentration of the radiotracer at the surface of the solid sample. In such instances intimate contact between the sample and the photographic emulsion is most important in obtaining the highest attainable resolution. For this reason stripping films with an emulsion 0.005-0.010 in. thick were employed. These films have a potential resolution of about 1μ. Two types of films were tested: The Kodak Autoradiographic Stripping Film "Experimental" exhibited excellent sensitivity but it presented difficulties in handling. The Kodak AR10 Stripping Film gave very satisfactory results with a minimum of handling difficulties, although its sensitivity is approximately one-fifth of the "Experimental" film. The AR10 film was employed predominately in the present study.

The emulsion bearing layer of the film was stripped from the backing, floated in cold water, and then brought in contact with the sample. The emulsion bearing layer could thus follow even minute irregularities of the sample surface. After suitable exposure, the emulsion was developed while in contact with the sample; then it was removed from the sample and mounted on a glass slide. A resolution of 5-20μ was attained by employing a scanning microdensitometer.

Direct calibration of the stripping films was not attempted since standard S^{35} sources could not be immersed in water. However, duplicate autoradiographs were obtained on plates (Kodak Autoradiographic Plate Type A) which were calibrated with standard S^{35} sources. These plates were employed in determining the concentration ratios of sulfur. Photographic enlargements (approximately 15X) of the autoradiograms on the AR10 film made convenient the visual examination of the impurity distribution over the whole longitudinal section of the crystal.

Determination of sulfur concentration.—A calibration curve was established relating the concentration of sulfur to the room temperature electrical resistivity of sulfur-doped InSb single crystals. The sulfur concentration was determined from Hall measurements at liquid nitrogen temperature. The electrical resistivity was measured with a four-point probe having a spacing of 0.008 in. between points. The calibration curve is shown in Fig. 1. Electrical resistivity measurements were taken only with single crystals.

Radiotracer analysis was employed for determining the sulfur concentration in the starting polycrystalline ingots and the residual melts. It was

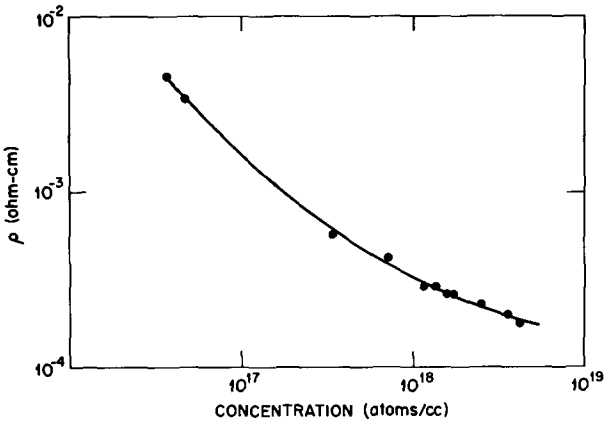

Fig. 1. Correlation between the room temperature resistivity of InSb and the concentration of sulfur impurity as determined from Hall measurements at 78°K.

first established (calibration tests) that the counting rate of InSb powder intimately mixed with elementary sulfur of known specific activity was proportional to the amount of sulfur present. In these calibration tests the sulfur (tagged with S^{35}) was mechanically incorporated in the powder from standardized benzene solutions. The powdered samples were placed on specially designed planchets which fitted into a flow counter. The samples to be analyzed (ingots, single crystals, or residual melts) were ground to a powder, and then their counting rate was determined.

The sulfur concentration was also determined by combustion techniques adopted for InSb by D. Guernsey of the Metallurgy Department, Massachusetts Institute of Technology. Concentrations in the vicinity of 20 ppm represented the lower limit for reasonably accurate determinations. Results obtained by radiotracer analysis and combustion techniques on identical samples, were in good agreement (within 6-20%).

Results

Impurity core and impurity striations.—A distinct core containing an increased amount of sulfur impurity was observed along the length of the InSb crystals grown in the <111> direction as found in germanium (3) and InSb (5) crystals grown with other impurities. The formation of the core was found to take place on the onset of crystal growth on the seed crystal and regardless of growth conditions or size of the seed.

An autoradiograph of the longitudinal section of an InSb crystal is shown in Fig. 2, together with a photograph of the other half of the same crystal which was chemically etched. It is seen that a markedly better definition is obtained by autoradiography than by etching. This result is to be expected since preferential etching initiated by impurities, imperfections, or orientation effects does not in general remain localized with time.

The autoradiograph of Fig. 3 shows the presence of the (111) facet at the bottom of the crystal and illustrates clearly that the size of the core corresponds precisely to the size of the facet. Figures 2 and 3 further show that appreciable changes in the

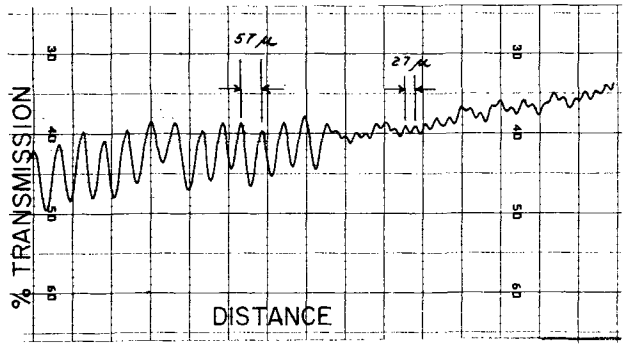

Fig. 4. Microdensitometer tracing of autoradiograph of crystal shown in Fig. 2. A Kodak AR10 Stripping Film was used. Change of rotation from 4 to 8 rpm is clearly reflected in the period of striations. The microdensitometer slit employed was 5μ wide and 0.5 mm high.

size of the core, resulting of course from corresponding changes in the size of the facet, occur during growth, whereas relatively small changes occur in the over-all morphology of the crystal. These changes must be related to temperature variations at the solid-melt interface (shape of the growth isotherm). Consequently, the size of the facet is more sensitive to temperature changes than the over-all size of the crystal. Thus, during growth by the Czochralski method, abrupt changes occur in the shape of the isotherm unless elaborate precautions are taken. If the growth interface (isotherm) is flat, the (111) facet extends the full width of the crystal, as was found in a crystal rotated at 100 rpm during growth.

Periodic variations in impurity concentration (striations) along the growth axis were found in all crystals rotated during growth. The spacing of striations was found to be inversely proportional to the rotation rate (5) as shown in the microdensitometer tracing of Fig. 4. Variations in impurity concentration of approximately 30% were detected. However, the difference between the maximum and minimum impurity concentration in the striations was not found constant in the various crystals even for the same rotation rate.

In the unrotated portions of the crystal striations were not unambiguously present, although in Se-doped InSb crystals, grown without rotation, striations were clearly observed (5). Possible reasons for the absence of striations are discussed below.

On-core to off-core impurity ratio.—The concentration profile of sulfur impurity obtained by electrical measurements and autoradiography along the diameter of the same cross section of an InSb crystal is shown in Fig. 5. A good agreement of the two methods is apparent. The microdensitometer tracing of the autoradiogram, however, represents more precisely the corresponding impurity distribution. In Fig. 5 the on-core to off-core ratio as determined by electrical measurements is in excellent agreement with the value obtained by autoradiography. Such good agreement was not always found, apparently because a much greater thickness of material contributes to the four-point probe measurement than to the autoradiogram. A comparison of the ratios obtained by electrical measurements and autoradiography at various cross sections of this crystal is shown in Table I. Best correlation between the two techniques was obtained when the long axis of the four-point probe was traversed along the traversing path of the slit.

Effect of rotation rate.—It is seen in Table I that there is a distinct increase in the on-core to off-core ratio in going from 8 to 0 rpm and a decrease in

10	8	10.3	2.5	4.1
10	0	10.7	2.3	4.6

the ratio in going from 0 to 8 rpm. The same effect can also be seen in Table II. The observed change in ratio without changing the rotation rate in Table I is discussed below. As shown in Table II, the increase in the concentration ratio associated with the decrease in rotation rate results from a decrease in the off-core concentration and an increase in the on-core concentration. These changes in concentration can often escape detection by electrical resistivity but are always unambiguously observed by autoradiography as shown typically in Fig. 6 (see also Fig. 2).

The above observations are readily understood in terms of changes in the melt concentration at the interface brought about by changes in rotation rate. Stirring of the crystal under the present experimental conditions apparently causes a flow of the melt near the axis of the crystal (facet area) toward the perimeter of the crystal as illustrated

Fig. 6. Effect of stopping rotation on the concentration of sulfur on and off the core (autoradiograph). Note decrease in the off-facet concentration and increase in the on-facet concentration upon stopping rotation. Shifting of the core results from the eccentric position of the crystal in the apparatus.

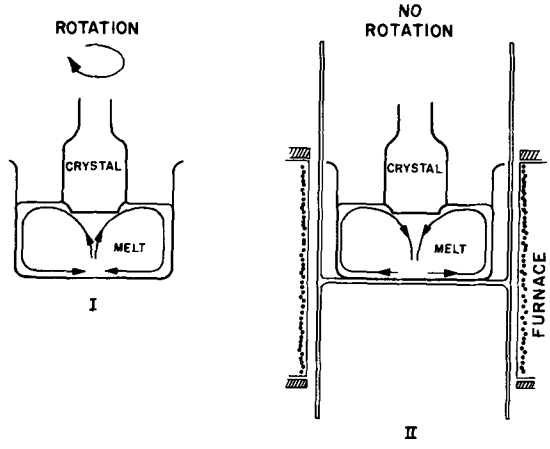

Fig. 7. Schematic representation of flow currents in melt under growth conditions.

schematically in Fig. 7(I). This type of flow was experimentally demonstrated by simulating the growth conditions employing a viscous liquid and a rotating crystal. The direction of flow was observed by employing a dye injected at the interface near the axis of the crystal. As a result of this flow, melt from the facet interface enriched in impurity by rejection from the solid is brought to the off-facet area. It is thus apparent that during rotation the melt at the off-facet interface is more enriched in impurity by rejection from the solid than the facet interface. In the absence of rotation, and owing to the existing thermal gradients, the convection currents are expected to flow in a direction opposite to the direction of flow caused by rotation, as illustrated in Fig. 7(II). Thus, in going from 8 to 0 rpm, the impurity concentration in the melt at the facet interface increases whenever the impurity concentration in the melt at the off-facet interface decreases. Similar effects have been discussed by Goss and Adlington (6).

It is of interest to note that the stirring pattern does not appear to be altered significantly in going from 8 to 100 rpm since, within experimental error, no corresponding change in ratio was observed as shown in Table III. Furthermore, the individual on-core and off-core concentrations decrease only to a small extent in going from 8 to 100 rpm suggesting that under the present experimental conditions rotating at 100 rpm is not appreciably more effective in eliminating the enriched layer than rotating at 8 rpm.

Effect of impurity concentration in the melt.—It has been already pointed out (Table I) that the on-core to off-core ratio of sulfur concentration does

not remain constant during crystal growth even under constant rotation rate. For an impurity with a distribution coefficient less than one, it is, of course, expected that the impurity concentration in the melt will increase, and consequently the on-core and off-core concentrations will increase as crystal growth proceeds. The dependence of the concentration in the crystal on the impurity concentration in the melt is shown in Fig. 8. The sulfur concentration in the solid (C_S) was determined by resistivity measurements and in the residual melt (C_L) by chemical and radiotracer analysis. C_L in the melt during growth was back-calculated by a detailed mass balance of the impurity concentration in the residual melt and in various parts of the crystal.

The on-core to off-core ratio as a function of the impurity concentration in the melt for the three crystals of Fig. 8 is shown in Fig. 9. It is seen that in the crystal grown from the melt with the lowest impurity concentration the ratio increases as crystal growth proceeds; the ratio remains essentially constant in the crystal of intermediate concentration and decreases as crystal growth proceeds in the crystal grown from the melt with the highest impurity concentration.

Effective distribution coefficient of sulfur in InSb.—The effective distribution coefficient of sulfur ($k_{eff} = C_S/C_L$) in InSb as a function of impurity concentration in the melt is shown in Fig. 10. It is seen that k_{eff} on-core increases with increasing C_L until C_L reaches a value of approximately 6×10^{18} sulfur atoms/cc; k_{eff} for the off-core portion of the crystal remains approximately constant at first and then increases with increasing C_L.

The k_{eff} was also determined for several crystals grown in the <100> direction. For $C_L \simeq 2 \times 10^{18}$ sulfur atoms/cc, k_{eff} in the <100> crystals was found to be 0.14 which is in good agreement with the corresponding off-core $k_{eff} = 0.16$. These results are in reasonable agreements with the preliminary data obtained by Harman (7).

Discussion

General observations.—Autoradiography techniques as employed in this study show unambiguously that along the <111> growth axis of sulfur-doped InSb single crystals (pulled from the melt) a core is formed containing more sulfur impurity than the rest of the crystal. A core is present over the whole range of conditions commonly encountered in Czochralski-type techniques. The size of the core was found to vary appreciably more than the over-all morphology of the crystal. Although no effort was made to study the factors affecting the size of the core (size of the (111) facet), it appears that the shape of the isotherm at the interface is changing during growth. It also appears that the degree of supercooling necessary for solidification changes during growth since such supercooling depends on many factors, such as impurity concentration and stirring.

The increased concentration of impurity in the core of the crystals has been considered to be associated with the detailed mechanism of the (111) facet formation (8, 9). Adsorption phenomena alone, however, can account for the observed dependence of impurity concentration on orientation as discussed below. Consequently, the factors responsible for the formation of the facet will not be considered here.

Variations in the distribution coefficient of impurities with crystallographic orientation have been observed and discussed in detail by Hall (2) for germanium single crystals pulled from the melt. He concluded that the incorporation of impurities in the crystal depends on specific adsorption of the liquid solid interface. The transport theory of Burton and others (1) does not account for Hall's observations. This theory is not applicable either to the results described here, since drastic changes in the stirring conditions did not alter the core formation significantly.

Adsorption model.—The results of the present study can be readily understood assuming a difference in the adsorption characteristics of the various crystallographic planes and, in particular, that preferential adsorption is exhibited by the {111} planes. Thus, the impurity adsorption isotherm for the {111} surfaces is significantly different from the adsorption isotherm of the other crystallographic planes. The amount of impurity incorporated into the solid depends directly on the amount of impurity adsorbed. In turn, the amount adsorbed depends on the impurity concentration in the melt at the interface, but this latter dependence is a strong function of orientation. An adsorption model requires, of course, that the concentration of the solute atoms on the solid surface is greater than the concentration near the interface. It requires further that the incorporation of adsorbed solute atoms into the solid takes place faster than the establishment of adsorption equilibrium. Such conditions can be readily realized, particularly if a portion of the adsorbed atoms is rejected, in which case the transport of solute atoms from the interface layer to the solid surface is not exclusively rate determining. Figure 11 illustrates schematically two adsorption isotherms, one for the {111} planes and one for the other crystallographic planes. The assumption that the crystallographic planes, other than the {111}, exhibit similar adsorption isotherms is consistent with the experimental results reported above, whereby the off-facet k_{eff} is, within experimental error, the same as the k_{eff} found for crystals grown in the <100> direction.

The results presented in Fig. 9 are entirely consistent with the two-adsorption isotherm model. It

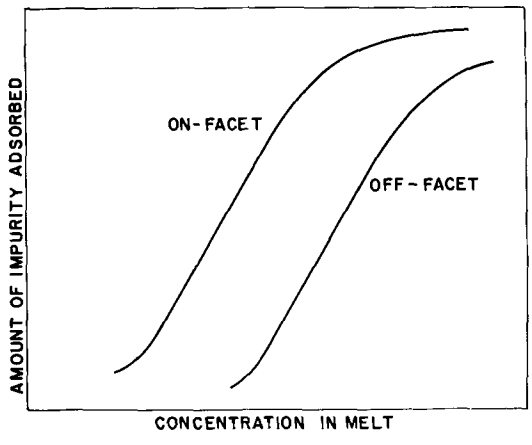

Fig. 11. Schematic representation of two sulfur adsorption isotherms, on and off the {111} facet.

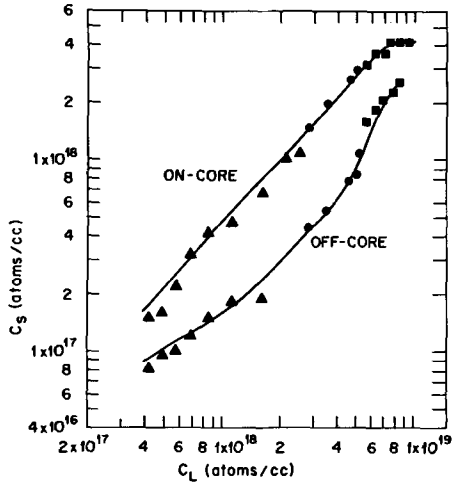

Fig. 12. Logarithmic plot of sulfur concentration in InSb as a function of C_L. The three types of symbols correspond to three different crystals.

is seen that the on-facet/off-facet ratio first increases, then stays constant, and finally decreases with increasing impurity concentration in the melt. In fact, the experimental results as plotted in Fig. 12 reflect two adsorption isotherms.

To the extent that the amount adsorbed is a function of the solute concentration in the melt, the amount of impurity incorporated into the solid depends on the concentration of the impurity in the melt under nonequilibrium conditions of growth. The maximum amount of impurity incorporated into the solid is related to the amount adsorbed at the leveling off point of the isotherms. The leveling off of the on-facet isotherm accounts rather uniquely for the small values of the on-facet/off-facet ratio at high impurity concentrations.

Consistent with an adsorption model are the results reported by Hall (2) and Dikhoff (3) for germanium single crystals. They found that nonmetallic elements (donors) exhibited more pronounced orientation affects than metallic elements (acceptors). It is quite reasonable to expect that nonmetallics exhibit a greater tendency for preferential adsorption than metallic impurities.

Of particular interest is the case of gallium impurities which are more readily incorporated in the off-core than in the on-core region of germanium crystals (3). Adsorption of gallium atoms on the {111} planes must be less pronounced than on the other crystallographic planes. This unusual behavior of gallium impurity is probably associated with the rather complex crystalline structure of gallium. Another relevant aspect of the complex structure of gallium is its low tendency to serve as a nucleation catalyst in solidification processes involving more common crystalline structures (10).

Impurity striations.—The adsorbed impurities undoubtedly influence the nucleation of the solidification process and consequently must affect the degree of supercooling necessary for crystal growth. For given conditions of crystal growth the period of the pulsating growth during no rotation (5) must then depend strongly on the nature of impurities present in the melt. In the present case,

sulfur apparently is more effective in decreasing the degree of supercooling so that it does not allow a pronounced striated growth during no rotation, as does selenium impurity (5).

Acknowledgment

The authors wish to thank W. J. LaFleur, Miss S. Nye, J. A. Kafalas, and Dr. A. J. Strauss for their assistance and profitable discussions during the course of this study.

Manuscript received April 4, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Thermodynamic Properties of VC at High Temperatures

S. Fujishiro

Fuji Iron and Steel Company, Tokyo, Japan

and N. A. Gokcen

Aerospace Corporation, El Segundo, California

ABSTRACT

Equilibrium pressure P_V of V(g) over VC(c) + C(graph.) has been determined in the range of 2346°-2545°K by means of graphite Knudsen cells. The results may be expressed by $\log P_V \text{ (atm)} = \frac{-30{,}700}{T} + 7.63$ in the range of 2400° ± 200°K. Further, $\Delta H°_{298.15} = 145.4 \pm 3$ kcal for VC(c) = V(g) + C(graph.) and $\Delta H°f_{298.15}$ (VC) = −22.7 ± 5 kcal for the standard heat of formation of VC, have been obtained by combining the data with appropriate free energy functions and the heat of sublimation of pure vanadium.

The transition metal carbides of Group IVB, VB, and VIB in the periodic chart have such useful properties as high melting points, great hardness, and chemical stability. Published data on their thermodynamic properties, however, are inadequate as shown in a number of systematic reviews (1-4). The heat of formation of VC(c) has been estimated (3, 4), but not determined experimentally, and its heat capacity has been determined by Shomate and Kelley (5) from 52° to 297°K and by King (6) from 298° to 1611°K. The results, together with the related thermodynamic properties are summarized by Kelley (7, 8). Slade and Higson (9) investigated the equilibrium in VO(c) + VC(c) = 2V(c) + CO(g) by measuring the pressure of CO at a single temperature, but in view of the fact that the stoichiometry of condensed phases is questionable (10, 11), their data cannot be used for reliable thermodynamic calculations.

The purpose of this investigation was to measure the equilibrium pressure of gaseous vanadium over VC(c) by using graphite Knudsen cells, *i.e.*, to investigate equilibrium in the following reaction

$$\text{VC(c)} = \text{C (graph.)} + \text{V(g)} \qquad [1]$$

From the equilibrium constant $K = P_V$ for this reaction, the related thermodynamic properties of VC(c) have been obtained.

Experimental Method

The experimental method has been described elsewhere in detail (12-14); a brief description here is therefore adequate. The apparatus is shown in Fig. 1. A transparent quartz tube A contains a graphite

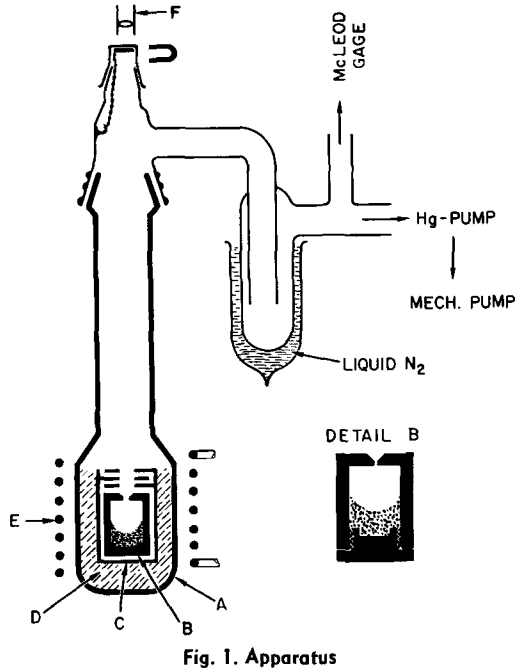

Fig. 1. Apparatus

Knudsen cell B, 25 mm diameter, 40 mm high. The densest, commercially available graphite was used in making the cell in order to minimize the amount of metal diffused through the pores. The cell orifice was drilled and its area was determined with a microscope. A graphite susceptor C with baffles is packed into A with −35+48 mesh insulating graphite powder D. The susceptor was heated by an induction coil E connected to a 20-kc mercury-gap type converter. Temperature measurements were made with a disappearing-filament optical pyrometer F sighted through a window protected with a magnetically closed shutter. The transmissivity corrections for the glass window were made under the prevailing experimental conditions. The accuracy of temperature measurements was better than ± 10°C. The system was kept under a vacuum of better than 5×10^{-6} mm Hg.

Vanadium carbide was prepared by heating the metal of 99.9% purity, from Electro Metallurgical Company, in a graphite crucible and maintaining it at 2400°C for about 10 hr. The combined carbon content of the resulting carbide was 18.89%, free carbon 0.1%, and Fe 0.04%. The lattice parameter of the carbide was found to be 4.160 ± 0.002Å.

Powdered VC was placed in the cell and the bottom plug was screwed on tightly. The cell was placed in the apparatus, degassed for 3-4 hr at 2200°C, and then cooled prior to breaking the vacuum by admitting pure argon. The cell was removed, weighed accurately, and again placed in the apparatus. The cell was quickly heated to the desired temperature and maintained there within ± 5°C for a period of 6-10 hr. The weight loss during this period was determined by reweighing after the termination of experiment. The result represents the weight loss (i) through the orifice and (ii) by vaporization of graphite and diffusion of V through the pores in the cell. The latter loss was determined by making a run by using a cell without orifice and containing VC. Subtraction of weight loss (ii) from (i) yields the loss m due to the effusion of V(g) through the orifice. Substitution of m in the following equation yields the vapor pressure P'_v of V(g) over VC(c) and C(graph.)

$$P' = \frac{m}{W_o a t}\left(\frac{2\pi RT}{M}\right)^{1/2} \qquad [2]$$

Where P' is in dynes per cm², W_o the clausing factor (15) defined by $1/W_o = 1 + 0.5\ h/r$, h and r being the thickness and the radius of orifice, respectively; T is in °K, a the orifice area in cm², t time in seconds, and M the molecular weight of V(g). Experimental runs with empty cells (without a carbide) reported earlier by the authors (12) show that vanadium diffuses out of the cell wall and that a considerably large fraction of weight loss is due to the vaporization of graphite, but this is not essential in the calculation of vapor pressure.

The absence of a gaseous carbide of vanadium, simultaneously effusing with V(g), was ascertained as follows: 155.3 mg of VC, containing 126.0 mg V, was placed in a cell with a large orifice and held at 2400°K for 16 hr. The total loss of weight minus that of graphite was found to be 59.2 mg. The weight of vanadium which remained in the cell was 66.1 mg as determined by chemical analysis of the crushed cell. The total amount of V accounted for in this manner was therefore 125.3 mg of initial V, showing conclusively that the carbide species in the gas phase were absent.

Results

Experimental results are listed in Tables I and II. Table I shows the loss of weight for cells without orifice, from which the loss for temperatures in Table II have been computed by interpolation or short extrapolation. The loss of weight through the orifice was obtained by subtracting this from the total weight loss in the fourth column of Table II.

The effect of orifice area on the observed vapor pressure was investigated by varying a in Eq. [2] from 0.0075 to 0.0212 cm² at two temperatures (Cf. runs 32, 24, 40, 21, 23, 41). The observed preessure, P_{obs} varies with a according to the following equation derived by Motzfeldt (16)

$$\frac{1}{P_{obs}} = \frac{1}{P_{eq}} + \frac{W_o a}{\alpha A P_{eq}} \qquad [3]$$

In this equation P_{eq} is the equilibrium pressure, α the accommodation coefficient; A the surface area of VC,

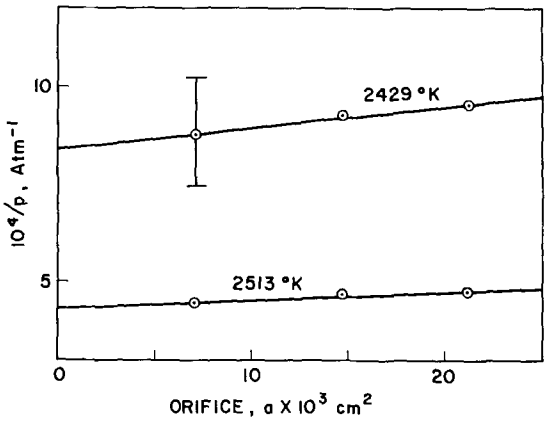

Fig. 2. Effect of orifice size on observed pressure of V(g). Limits shown by ⊖ is obtained from Standard Deviation in $\Delta H°$ for reaction [1].

W_0 and a are the same quantities as before. When the orifice area is plotted *vs.* $1/P_{obs}$ as in Fig. 2, extrapolation to $a = 0$ yields $1/P_{eq}$. The slope is very small and well within experimental errors showing that virtual equilibrium prevailed in all the cells.

Thermodynamic calculations are summarized in Table III. The third column is calculated from P_v in Table II substituted in $\Delta F° = -RT \ln P_v$. The fourth column is obtained by the interpolation of the change in free energy function for reaction [1], $-\Delta[(F° - H°_{298.15})/T]$, whose values are 37.013, 36.931, 36.843, and 36.762 at 2300°, 2400°, 2500°, and 2600°K, respectively. These values are obtained by using $-(F° - H°_{298.15})/T$ for graphite from JANAF Interim Thermochemical Tables (17), for V(g) from Stull and Sinke (18), and for VC(c) computed from

$$\frac{F° - H°_{298.15}}{T} = \frac{H° - H°_{298.15}}{T} - S°_{298.15} - \int_{298.15}^{T} \frac{C_p}{T}\,dT$$

by using $S°_{298.15}$ from Kelley (19) and his recommended equations (20) for $H° - H°_{298.15}$ and C_p and representing King's data (21) within 0.4% in the range of 300-1700°K. The results in the third column are related to those in the fourth by the identity

$$\Delta\left(\frac{F° - H°_{298.15}}{T}\right) \equiv \frac{\Delta F°}{T} - \frac{\Delta H°_{298.15}}{T}$$

from which the last column, the heat of reaction at 25°C, is calculated. The average value of $\Delta H°_{298}$ for reaction [1] is therefore 145,442 cal with a standard deviation of 778 and a maximum deviation of 1746 cal. The probable error in $\Delta H°_{298.15}$ is obtained in the following manner. An unlikely error of 10% in weighing, *i.e.*, nearly 1 mg in most cases, would cause an error of ± 0.5 kcal in $\Delta H°_{298.15}$, but an error of ± 10°K in temperature measurements would cause about ± 2.1 kcal of error. Assuming that the free energy functions contribute an additional error of ± 0.4 kcal, leads to $\Delta H°_{298.15} = 145.4 \pm 3.0$ kcal for reaction [1] or $\Delta H°_0 = 145.0 \pm 3.0$ kcal. Combination of $\Delta H_{298.15}$ with $\Delta H°_{298.15} = 122.72$ cal for the heat of sublimation of pure vanadium, obtained by Edwards, Johnston, and Blackburn (22) yields $\Delta Hf°_{298.15} = -22.7 \pm 5.0$ kcal for the standard heat of formation of vanadium carbide, or $\Delta H°_0 = -22.5 \pm 5.0$ kcal. This value is obtained by subtracting two large values and may be subject to larger unexpected cumulative errors than that indicated arbitrarily as 5 kcal; hence, additional data on $\Delta H°f_{298.15}$ by other methods would be desirable. It may be noted, however, that this is the only value for the heat of formation of VC which is based on experimental data. Estimates from the periodic law correlating $\Delta H°F_{298.15}$ with the atomic numbers of metals agree well with the foregoing result. Thus, if it is assumed that $\Delta H°_{f298.15}$ for TiO_2, VO_2, and CrO_2 follows the same pattern as TiC, VC, and CrC, $\Delta H°_{f298.15}$ for VC is found to be −23.6 kcal, whereas, if the values of $\Delta H°_{f298.15}$ for TiN and VN are assumed to be related to each other in the same way as those for TiC and VC, $\Delta H°f$ for VC becomes −22.2 kcal in agreement with the authors' result. Other such estimates are 15 kcal (4) and 20 kcal (3).

Pressure-Temperature-Composition Relationships of the Yttrium-Hydrogen System

C. E. Lundin and J. P. Blackledge

Denver Research Institute, University of Denver, Denver, Colorado

ABSTRACT

Pressure-temperature-composition studies of the yttrium-hydrogen system were made in the temperature range 900°-1350°C and the pressure range 1-760 mm Hg. The existence of a yttrium-solid-solution phase and a yttrium-hydride phase, which approaches YH_2 in composition, was established. These phases occur over a range of composition and are separated by a two-phase region at intermediate hydrogen compositions. The calculated heat of reaction of the dihydride phase from the saturated solid solution is $\Delta H = -44.42 \pm 0.40$ kcal/mole H_2, and the entropy of reaction is $\Delta S = -27.07 \pm 0.30$ cal/mole $H_2 \cdot$ degree. Partial molal heats and entropies of solution of hydrogen in the single phases are also presented. The nature of the solubility relationships in the yttrium-hydrogen system below 900°C was studied at atmospheric pressure. The existence of a stable trihydride phase was established below approximately 300°C and 1 atm pressure. The solubility relationships of the yttrium-hydrogen system were developed from the pressure-temperature-composition relationships and from x-ray diffraction analysis and metallographic examination. X-ray diffraction structural analysis of yttrium metal, the dihydride and trihydride phases gave the following structures and x-ray densities:

Yttrium metal	YH_2	YH_3
Hexagonal close-packed	Face-centered cubic	Hexagonal
$a_o = 5.750 \pm 0.001$Å	$a_o = 5.201 \pm 0.001$Å	$a_o = 3.674 \pm 0.001$
$c_o = 3.654 \pm 0.001$Å	$\rho = 4.293$ g/cc	$c_o = 6.599 \pm 0.001$Å
$\rho = 4.440$ g/cc		$\rho = 3.958$ g/cc

Yttrium metal is a transition metal in subgroup III-A included with scandium, lanthanum, the lanthanides, and actinium. Because of similar properties and occurrence in nature, yttrium is generally associated with the rare-earth metals. In general, the metals in this subgroup as well as some actinide metals for which hydriding data are available (1-5) form both di- and tri-hydride compositions. Therefore, one would surmise that yttrium forms a similar type of hydride system. Being practically nonexistent in form and purity until recently, very little was known of the various properties of yttrium metal. Therefore, the literature does not provide any information concerning the hydriding characteristics of yttrium metal. The objective of the research program described in this paper is to determine fully the high-temperature phase equilibria presented by the yttrium-hydro-

gen system and to establish some of the associated thermodynamic data of solutions of hydrogen in yttrium.

Experimental Procedure

The apparatus used for the hydriding work is a modified Sieverts' apparatus. Essentially it consists of a source of pure hydrogen, a precision gas-measuring buret, a heated reaction unit, and a mercury manometer for pressure measurement. Pure hydrogen is obtained from the thermal decomposition of uranium hydride. A 100-ml precision gas buret graduated to 0.1 ml divisions is used to measure and admit to the reaction chamber the quantity of hydrogen gas desired to react with the metal sample. The reaction unit consists of a Globar tube furnace surrounding two concentric mullite reaction tubes. The Globar furnace is controlled with a L&N Speedomax G temperature recorder-controller in conjunction with a Claud S. Gordon X-actline. The sample temperature is measured independently with a L&N precision potentiometer and a Pt/Pt-Rh (13%) thermocouple. The temperature was controlled within ± 2°C. The inner reaction chamber contains the specimen to be reacted. The outer chamber is isolated from the inner chamber, but maintained at the same partial pressure of hydrogen to prevent hydrogen loss or air contamination due to permeation through the mullite. A mercury manometer is used to measure the partial pressure of gas in equilibrium with the specimen. Pressures were measured to approximately ± 0.5 mm Hg.

The technique used to study the equilibrium pressure-temperature-composition relationships of the yttrium-hydrogen system was to develop experimentally a family of isothermal curves of composition *vs.* pressure. The range of pressure through which each isotherm was developed was from 1 mm to atmospheric pressure. Isotherms were established at each 50°C interval in the temperature range from 900° to 1350°C.

The yttrium specimens used were from ½ to 1g in weight, cut into rectangular shapes from arc-melted buttons. Analysis of impurities of the yttrium metal showed that zirconium and oxygen were the principal impurities at 0.57% and 0.32%, respectively. The surface of each specimen was prepared by filing with a clean, mill file. The chamber was flushed with hydrogen and evacuated several times prior to each run. The temperature of the initially evacuated chamber was then attained and held constant. Measured quantities of hydrogen gas were repetitively admitted to the chamber. After each admission, time was allowed for equilibrium. Equilibrium was considered complete after the pressure became constant. Calculation of the quantity of gas absorbed in the metal after each admission of gas was done by knowing the system volume which determined the amount of hydrogen in the gas phase. Subtracting this quantity from the total gas admitted gave the quantity of gas in the metal. The individual equilibrium pressures were recorded *vs.* the calculated amount of gas absorbed for each respective pressure. The isotherm was traced until atmospheric pressure was reached. A total of 244 data points was obtained using this procedure.

Additional data on the yttrium-hydrogen system were obtained below 900° down to 100°C. However, these data were not obtained as isotherms of equilibrium partial pressures *vs.* composition. The equilibrium partial pressures below 900°C for compositions less than the ultimate hydrides were less than 1 mm of Hg; therefore measurements could not be made with the manometer (the YH_2-YH_3 region being excepted). The data were obtained in the form of the ultimate equilibrium compositions attained at atmospheric pressure of hydrogen at each of the desired temperature levels: 800°, 700°, 600°. 500°. 400°, 300°, and 200°C.

The x-ray diffraction data were obtained with a Norelco unit in conjunction with a wide-angle diffractometer. All samples for x-ray analysis were prepared in the modified Sieverts' apparatus, allowing the specimen to absorb the quantity of gas required to bring it to the required composition. Samples immediately below YH_2 in composition were easily crushed without causing cold work. Samples between YH_2 and YH_3 were powder as hydrided, and needed no further preparation. The samples in the yttrium-rich region were not amenable to crushing. Therefore, massive fine-grained samples of yttrium metal were used for hydriding to the required composition prior to x-ray diffraction analysis.

Representative structures of metal-gas samples were examined metallographically to verify the solubility relationships determined from the isotherms. Standard metallographic techniques were used with one exception. Cold-mounting plastic was used to mount the specimens to prevent loss of hydrogen. The etchant used was 42 ml H_3PO_4, 47 ml glycerine, and 11 ml 2-ethoxyethanol.

Results and Discussion

The hydriding characteristics of yttrium are similar to the heavy rare earths. In general, a dihydride and trihydride phase are formed, the trihydride phase being stable only at lower temperatures. The dihydride structure is face-centered cubic, and the trihydride is hexagonal close-packed, exhibiting

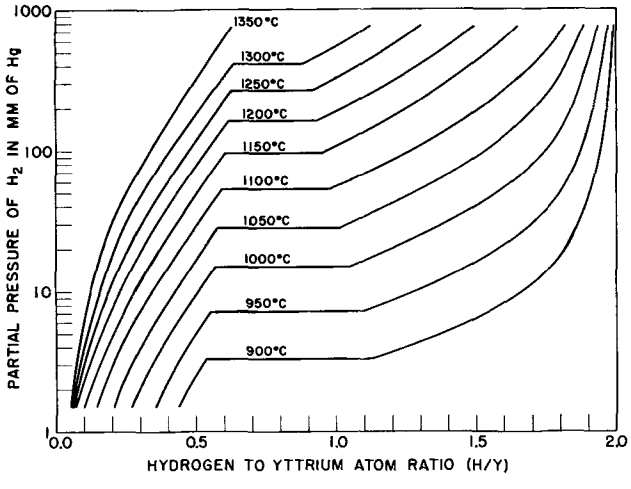

Fig. 1. Isothermal curves of equilibrium partial pressure vs. composition for the yttrium-hydrogen system.

isomorphism with the comparable structures in the heavy rare-earth series.

The region of temperatures from 900° to 1350°C in the yttrium-hydrogen system was of primary concern in this study. To determine the thermal-stability characteristics in this temperature region and at partial pressures up to 1 atm of hydrogen, the pressure-temperature-composition relationships were determined. The data were developed as a series of isotherms at 50°C intervals. The family of isotherms is presented in Fig. 1.

By applying phase rule theory to the series of curves, three distinct regions of partial pressure and hydrogen composition delineate the solubility relationships in the complete range of hydrided yttrium. In the first region, as hydrogen is added to the unreacted metal, the partial pressure and composition both increase up to a certain value. The extent of this rise indicates the limit of solid solubility of interstitial hydrogen in yttrium. Thus, a single homogeneous phase exists in conformity with the phase rule which predicts that only one phase can exist for bivariant conditions.

In the dilute region of hydrogen composition of the yttrium solid solution, a log-log plot of each isotherm yielded straight lines with a slope of essentially 2. This value indicates that Sievert's law is followed, which states that the solubility of hydrogen in yttrium is proportional to the square root of molecular hydrogen pressure. The isotherm slopes were constant up to 0.3 H/Y atom ratio at which point they began to deviate upward.

The second region consists of a series of plateaus of equilibrium partial pressure. Here, the system is reduced to a univariant system with pressure constant. Thus, a two-phase field exists where increasing amounts of the second phase form as the hydrogen content increases.

The third region is similar to the first wherein the pressure and composition rise rather rapidly from each plateau. This end of the plateau represents the metal rich solubility limit for the second phase. Again, bivariant conditions predict a single, homogeneous phase region which exists over a range of composition. In this case the phase is the hydride phase. In the higher temperature regions this phase is comprised of a hydrogen-deficient YH_2 lattice. The ultimate composition approached at 1 atm pressure as the temperature decreases toward 900°C is approximately the stoichiometric ratio, YH_2.

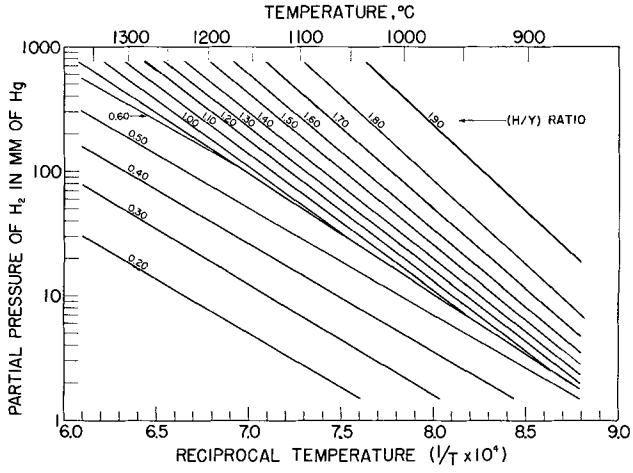

Fig. 2. Family of isopleths of the yttrium-hydrogen system as a function of equilibrium partial pressure and reciprocal temperature.

Table I presents the composition of the solubility boundaries *vs.* temperature between the two single phases and the two-phase region separating them.

From the experimental data, another plot of the logarithm of equilibrium partial pressure *vs.* reciprocal temperature was prepared for a family of isopleths (constant composition). The points of each isopleth fell on a straight line as expressed by the equation,

$$\log_{10} p \text{ (mm Hg)} = -A/T + B$$

Figure 2 presents the family of isopleths. The compositions are presented as the hydrogen-to-yttrium atom ratio, varying in 0.10 increments. The single-phase yttrium solid solution is represented by the isopleths from 0.20 to about 0.60 H/Y atom ratio. The partial pressure plateaus are represented by a series of isopleths which superimpose on one another as one line in the plane of the page wherein the composition ranges from about 0.60 to 1.00 H/Y atom ratio. The hydride phase is represented by the isopleths from about 1.00 to 1.90 H/Y atom ratio. The constants A and B for each isopleth composition level were determined by a least-squares treatment of the data. The standard deviations were also calculated. Table II presents the equilibrium dissociation pres-

sure equations for the yttrium-hydrogen system. From these equations the partial molal entropies can be calculated for each of the isopleths in either single-phase region by employing the Gibbs-Helmholtz and van't Hoff equations. These thermodynamic data are presented in Table III. The values at the plateau of equilibrium partial pressure may be considered the heat of reaction, −44.42 ± 0.40 kcal/mole H_2, and the entropy of reaction, −27.07 ± 0.30 cal/mole H_2 · degree, of the hydride phase from the saturated yttrium solid solution.

Inasmuch as the high-temperature studies indicated the existence of only a dihydride phase, it was felt necessary to survey the low-temperature region for a possible trihydride phase. The approach to the study in the lower temperature region was different from that of the high-temperature region. The study was conducted at atmospheric pressure of hydrogen. Specimens were hydrided to their limiting equilibrium compositions. The formation of the trihydride phase was found to occur between room temperature and slightly above 300°C. When the trihydride is formed from the massive dihydride, the specimen is reduced to a very fine powder. The rate of formation and decomposition of trihydride as the temperature is cycled above and below the critical temperature is rapid.

The range of solubility of the individual dihydride and trihydride phases near room temperature appears to be rather restricted. X-ray diffraction analysis of structures immediately below and above the YH_2 composition were made. Single-phase structures were seen at $YH_{1.95}$ and $YH_{2.00}$. Two-phase structures were seen at $YH_{1.90}$ and $YH_{2.10}$. A two-phase structure was seen at $YH_{2.80}$ with strong lines of YH_2 phase still evident. A single-phase structure was obtained at $YH_{3.00}$.

X-ray diffraction analysis of the line patterns of the yttrium metal, the YH_2 phase, the YH_3 phase, and specimens with intervening compositions confirm the solubility relationships deduced from the thermodynamic data. The x-ray diffraction data are summarized in Table IV.

Table IV. Summary of x-ray diffraction data

Sample	Structure	Lattice parameters	X-ray density, g/cc
Y	Hexagonal-close packed	$a_o = 3.654$Å $c_o = 5.7501$Å	4.440
$YH_{0.63}$	HCP + FCC		
$YH_{1.80}$	HCP + FCC		
$YH_{1.90}$	HCP + FCC		
$YH_{1.95}$	FCC		
$YH_{2.00}$	Face-centered cubic	$a_o = 5.201$Å	4.293
$YH_{2.10}$	FCC + H		
$YH_{2.20}$	FCC + H		
$YH_{2.40}$	FCC + H		
$YH_{2.60}$	FCC + H		
$YH_{2.80}$	FCC + H		
$YH_{3.00}$	Hexagonal	$a_o = 3.674$Å $c_o = 6.599$Å	3.958

Metallographic examinations of structures of representative compositions were made in the yttrium-hydrogen system except in the case of compositions above YH_2, where the material became powdered.

The structures of these samples confirmed the solubility relationships as deduced from the pressure-temperature-composition relationships.

Summary

The yttrium-hydrogen system was studied by determining the pressure-temperature-composition relationships and the resulting solubility relationships. In the high-temperature region of the system, a series of isothermal curves were developed at 50°C intervals between 900° and 1350°C. The ultimate dihydride, YH_2, was approached in composition as the temperature of hydriding decreased toward 900°C.

Thermodynamic data concerning the two single-phase regions and the two-phase region were calculated from the experimental data. In the low-temperature region of the system, the dihydride was stable down to approximately 300°C and 1 atm pressure. At approximately 300°C and below, a stable trihydride phase was found to exist at 1 atm of hydrogen pressure. Metallographic and x-ray diffraction analysis data are also presented to confirm the existence of the solubility relationships as deduced from the thermodynamic data. The x-ray diffraction data of the single phase structures are presented below:

Yttrium metal	YH_2	YH_3
Hexagonal close-packed	Face-centered cubic	Hexagonal
$a_o = 5.750$Å	$a_o = 5.201$Å	$a_o = 3.674$Å
$c_o = 3.654$Å	$\rho = 4.293$ g/cc	$c_o = 6.599$Å
$\rho = 4.440$ g/cc		$\rho = 3.958$ g/cc

Acknowledgment

The authors are grateful to the management of the General Electric Company, Aircraft Nuclear Propulsion Division for granting permission to publish this paper. The authors also wish to thank Dr. V. Calkins, J. McGurty, and E. Funston for their assistance and support in carrying through the research work. The work was conducted under Subcontract

AT-33. Special thanks are due to C. R. Hoggatt for the Sievert's work, R. A. McCune for the x-ray data, R. L. Clark and R. J. McManis for the metallographic work, and to D. Sutton for the arc-melting of the alloys.

Manuscript received Nov. 29, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Mercuric Halides as Molten Electrolytes: Physical Properties, Vibrational Spectra, Constitution, and Electrical Conductance

George J. Janz and James D. E. McIntyre

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

Densities, viscosities, electrical conductances, and Raman spectra for the mercuric halides, $HgCl_2$, $HgBr_2$, and HgI_2, are reported from the melting points to the boiling points. In contrast to ionic fused salts, the energies of activation for electrical conductance are greater than those for viscous flow. Evidence for autocomplex formation is discussed. A model for these molten electrolytes is advanced in which the primary constituents are simple molecules together with the complex ionic species HgX^+ and HgX_3^-. The entropy of fusion is shown to arise, in large part, from an increase of rotational freedom rather than positional randomization, and the cohesive intermolecular forces are of the dispersion and multipole type rather than coulombic as in highly ionic melts. The mechanisms of transport processes for the solid and liquid states of these salts are discussed in the light of concepts current for molten electrolytes.

Current surveys (1-3) show that, whereas very accurate values for the physicochemical properties and electrical conductances are known for the halides of the Group I and Group IIA elements, very little information has been reported for the Group IIB metal halides. The problems of the structure of the molten mercuric halides have been discussed elsewhere (4) in detail. More recently the electrical conductances have been reported with a limited interpretation of the constitution of this class of molten salts (5). The present communication reports the results of investigations on the densities, viscosities, electrical conductances, and Raman spectra for the mercuric halides in the molten state. This broad cross section of properties is discussed to develop the structure and interactions in this class of molten salts.

Experimental

The three mercuric halides, $HgCl_2$ (mp. 277°C), $HgBr_2$ (mp. 238°C), and HgI_2 (mp. 259°C), reagent grade chemicals, were dried under vacuum at 120° and twice sublimed through a Pyrex fritted disk under reduced pressure, using dry argon as a carrier gas, prior to use. Because of the relatively low melting points and relatively small liquid state range (27°, 81°, and 95°C, respectively, for the chloride, bromide, and iodide) the complete range from the melting point to the boiling point could be investigated, and the design of the various apparati was simplified since Pyrex glass could be used throughout. However the high sublimation and vapor pressures dictated the use of experimental assemblies for electrical conductance, density, and viscosity, hermetically sealed under vacuum. The furnace had viewing ports for observation of the melts during measurements; at 300°C a 12 in. flat hot zone (± 0.15°) was gained using a bank of auxiliary shunts and resistors in the heating circuit. Temperatures were monitored with a calibrated Pt-Pt, 10% Rh thermocouple and an electronic recording differential potentiometric circuit (6). There follows a brief description of the salient features of the apparatus and techniques used for the property measurements on these highly volatile salts in the molten state.

Density.—The design of the dilatometer and loading tube assembly is shown in Fig. 1(a); the volumes of the dilatometer were calibrated with mercury at room temperature. Measuring pipettes (0.2 ml capacity) having a 1.6 mm capillary bore were used for the stems; the bulbs were of 3 ml capacity. A suitable quantity of the mercuric halide was weighed into the loading tube containing a fritted disk. This tube was then closed at the top, A, with a torch and sealed to the dilatometer, taking care to avoid moisture condensation at all steps. Residual traces of water vapor were removed by vacuum pumping before the assembly was hermetically sealed at B under vacuum. The unit was heated in an auxiliary furnace until the salt was molten. The vapor pressure of the salt in A served to force the melt through the Pyrex filter disk to

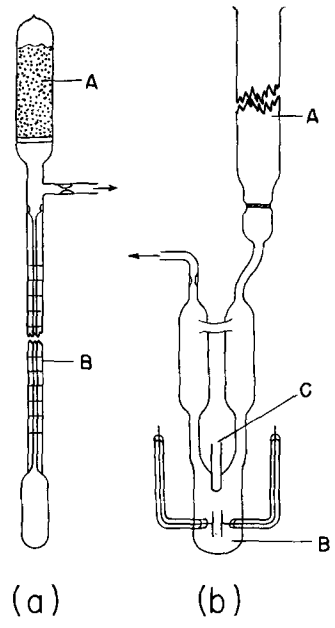

Fig. 1. Details of dilatometer and conductance cell and loading tubes for volatile molten salts. (a) Dilatometer assembly; A, sealed loading tube with salt over fritted disk; B, graduated stem (total vol. 3 ml); (b) conductance cell assembly; A, loading tube and fritted disk; B, platinum disk electrodes below reservoir compartments; C, thermocouple well.

fill the dilatometer; the loading tube was removed after this operation by sealing at C. The dilatometer bulb was seated in a metal block and placed in the furnace with the stem carefully aligned vertically. The menisci were observed through the furnace ports with a cathetometer. On completion of the measurements, the weight of the salt in the dilatometer was determined by direct weighing.

Conductance.—The design of the conductance cell used for molten $HgCl_2$ and $HgBr_2$ is illustrated in Fig. 1(b), the platinum electrodes (1.5 cm diameter) being spaced to give a cell constant of 0.17 cm^{-1}. For the more highly conducting iodide, the cell constant was increased to 17.6 cm^{-1} by use of a U-tube to increase the electrode separation. The procedure for cell filling was similar to that just described for the density measurements. The reservoir chambers provided for thermal expansion of the melt, and after an experiment the cell was inverted to transfer the molten salts from the electrode chamber to the reservoirs before solidification. A high precision conductance bridge of a new design (7) was used for these measurements, test frequencies of 1, 2, 5, and 20 kc being used to gain the value of the polarization-free values for the conductances by extrapolation to infinite frequency.

Measurements of the solid-state electrical conductance were made in a U-tube type cell using a vacuum-tube voltmeter with an 11-megohm impedance. The change of this property during the process of fusion was also studied in this manner.

Viscosity.—The oscillation method (8, 9) is readily adapted for very volatile liquids. For this purpose a Pyrex sphere, 4.6 cm diameter, having a 10-cm tubular stem, was filled with the appropriate mercuric halide using the same technique as for filling the dilatometers; the top of the stem was finally sealed under vacuum. The bulb was chuck-mounted on a stainless steel rod which extended from the furnace to take the inertia bar and the torsion head suspension. The viscosities were determined from the observed logarithmic decrement in the damping of the torsional oscillations of the Pyrex spheres filled with the molten halides. Angular deflections over a range of 0.27-0.068 radians were observed by a telescope-scale-mirror assembly, each determination involving 100 swings of 8-12 sec periods. Corrections for air-damping were made. Typical values for the logarithmic decrements are 0.00848 and 0.05275 for the air-damping and the total damping effects, respectively (HgI_2, 314°). Details for the calculation of absolute viscosities from such data may be found in the work of Andrade and Chiong (9). The absolute value for the internal radius of the sphere was determined by direct weighing with water. The experimental assembly and technique were evaluated using water as the fluid in the sphere at room temperature. The viscosity thus found deviated less than 3% from the accepted value.

Raman spectra.—The spectra for molten $HgCl_2$ and $HgBr_2$ were measured in the high-temperature cell assembly and excitation source for the Hilger Type E612 spectrometer in this laboratory and are described elsewhere in detail (10). The Hg 4358Å and 5461Å lines were used for excitation of the spectra for the colorless $HgCl_2$ and straw-colored $HgBr_2$ melts, respectively. The study of melts such as HgI_2 (red-black) awaits the development of Raman sources for the near infrared region.

Results

Density.—The densities for the three molten mercuric halides were calculated after making corrections for the thermal expansion of the dilatometers (*ca.* 0.026%) and air buoyancy, menisci shapes, and weight of salt vapor above the melt (negligibly small). The complete liquid-state ranges for the three halides ($HgCl_2$, 27°; $HgBr_2$, 81°; HgI_2, 95°C) were investigated in 20-30 uniformly spaced incremental steps. The average deviation from the best straight line of the empirical points was one part in four thousand. The least squares equations for the densities thus found are:

$HgCl_2$: $d_t = 5.1577 - 2.8624 \times 10^{-3}t$ (277°-304°C)

$HgBr_2$: $d_t = 5.8889 - 3.2331 \times 10^{-3}t$ (238°-319°C)

HgI_2: $d_t = 6.0603 - 3.2351 \times 10^{-3}t$ (259°-354°C)

The present values for $HgCl_2$ are 1%-1.5% higher than the values reported by Prideaux (11) in 1910, whereas the results for $HgBr_2$ and HgI_2 are in remarkably close agreement, the average deviation being less than 0.1%. The more recent data for HgI_2 reported by Polyakov (12) (by the Archimedean principle) appear about 1% too high by comparison. The precision attained in the present work is higher than in the studies of Prideaux (11) and Polyakov (12).

Electrical conductance.—The molar conductances for the three mercuric halides are summarized in

Table I. Molar electrical conductance of the molten mercuric halides

(a) $HgCl_2$ t, °C	$\mu \times 10^3$, ohm^{-1} cm^2 mole^{-1}	(c) HgI_2 t, °C	$\mu \times 10^3$, ohm^{-1} cm^2 mole^{-1}

315.4	20.60		

Table I. The much higher conductivity and the negative temperature coefficient of conductance for HgI_2 are in marked contrast to $HgCl_2$ and $HgBr_2$. Comparison with the earlier and limited results by Jander and Broderson (13) and Belyaev and Mironov (14) shows that the earlier values are in good agreement for the bromide near the freezing point, but that the conductivities of the chloride are greater by a factor of 10. Recalculation of the values of electrical conductance for the three mercuric halides reported most recently by Bockris, Crook, Bloom, and Richards (5) to the present density results shows that these are in close agreement (better than 1%) for the bromide and iodide. The conductance values for the chloride thus found are about 10% lower than the results observed at present, most probably due to the use of a more refined sample (triply sublimed) by Bockris, Crook, Bloom, and Richards. The temperature dependence of the solid-state resistance in the process of melting is illustrated in Fig. 2, showing a characteris-

tically large increase in electrical conductance for the three mercuric halides at this point of phase change. The electrical conductances for the liquid state could be expressed by the Arrhenius-type exponential rate equation:

$$(\kappa, \Lambda) = A_{(\kappa, \Lambda)} e^{-\Delta E}(\kappa, \Lambda)/RT$$

within the precision of the results; for $HgBr_2$, ΔE showed a marked temperature dependence. The values thus found for the energies of activation are summarized in Table II(a); two values are listed for $HgBr_2$ at the lower and upper extremes for the liquid state of this salt. The unusual negative temperature coefficient of conductance for HgI_2 is reflected in the negative values for ΔE.

Viscosity.—In Table III are listed the viscosities for $HgCl_2$ and HgI_2 from this work and the results for $HgBr_2$ of Jander and Broderson (13) for consistency. The results fitted a simple Arrhenius-type rate expression well within the precision of the measurements. The activation energies thus found for viscous flow are given in Table II(b), together with the energies of vaporization which were calculated from the heat of vaporization data reported elsewhere (15).

Vibrational spectra.—The Raman shifts found in the present study were:

$HgCl_2$: 313 cm^{-1} (vs) ($\rho = 0.7$);
382 cm^{-1} (w) ($\rho = 0.6$)

$HgBr_2$: 206 cm^{-1} (vs) ; 271 cm^{-1} (w)

where the intensities are indicated as very strong (vs) and weak (w) and the depolarization ratio for the chloride (ρ) was also gained. Polarization

* Present investigation.

measurements were not possible for $HgBr_2$ owing to the much weaker intensity of the 5461 cm^{-1} Hg excitation line. The Raman, infrared, ultraviolet spectra (16-22) and vibrational assignments are summarized in Table IV. Based on a molecular linear triatomic model, it is apparent that of the three fundamental vibrational modes, only ν_1 is Raman active, the remaining two, ν_2 and ν_3, being infrared active. The evidence for a linear triatomic species in the gas phase and solid phase, reviewed elsewhere in detail (4), leaves little doubt that the configuration of the mercuric halides is linear. The assignment of the Raman-active mode, ν_1, for the gas, molten, and solid states (Table IV) leaves nothing to be desired. The two values reported for the gas phase, 310 (16) and 355 cm^{-1} (17), are not in close agreement, and there is need for additional work to resolve this. For nonpolar substances of relatively simple structure it is known that the Raman shifts are relatively insensitive to the change of the state of aggregation, a maximum deviation of 3% having been recently reported by Stammreich and Forneris (23) for gaseous and liquid Br_2. The value of ν_1 for the gaseous state based on the earlier study (17) appears high by this criterion. The weak Raman frequencies, at 377-381 cm^{-1} for the chloride and at 271 cm^{-1} for the bromide, which have been noted by various investigators as well as in the present study, are assigned as an overtone of the Raman forbidden fundamental, ν_2, in the condensed state, although an alternate assignment to the forbidden fundamental, ν_3, assuming a breakdown in the selection rules, has also been advanced (22). In HgClBr, ν_2 is no longer Raman forbidden; this fundamental has been recently observed (24) at 139 cm^{-1} in this molecule in the condensed state. This is strong support for the present assignment of the above weak Raman line in the chloride and bromide as $2\nu_2$. The calculated value for ν_2 based on ultraviolet spectral data in the gas phase seems improbably low. Additional measurements for the gaseous spectra of these inorganic salts are required to resolve the uncertainties in the assignments for the vapor phase spectra of the mercuric halides.

While no visible and ultraviolet absorption spectra have been reported for the molten mercuric halides, some information on the nature of the bonding can be gained (25, 26) from the color changes observed qualitatively. The samples of mercuric chloride remain a clear and colorless liquid when heated in the sealed cells from 279°C (melting point) to 535°C (normal bp 304°C). Mercuric bromide changes from colorless to pale yellow on fusion, and as the temperature is increased, the color intensifies until it is an orange liquid in the sealed cell at 385°C (normal bp 320°C). Mercuric iodide changes from an orange-colored solid to a clear deep red liquid at the melting point and, as the normal boiling point (354°C) is approached, becomes nearly black. All these color changes were reproducible and reversible. The coloration of the solid and liquid mercuric halides undoubtedly relates to the perturbation of the partial covalent bonds, Hg ← X, by nearest neighbors in the condensed states. A quantitative study of the absorption spectra for the molten mercuric halides would contribute to the determination of the mechanism of the exciton transitions and the identity of the perturbed species; the preceding observations nevertheless give additional support to the "molecular" nature of the molten mercuric halides.

Discussion

It is of interest to examine the structure and interactions of the mercuric halides in the molten state in light of the preceding physicochemical properties. It is apparent that the vibrational spectra for these molten salts are understood on a model for the molten salts in which the primary constituents are linear-symmetrical triatomic molecules; no spectral lines corresponding to anionic species such as HgX_3^- and HgX_4^{-2} were found; nevertheless the finite, if but small, electrical conductivities of

these salts indicate that ionic species due to self-ionization in the molten state cannot be ruled out.

The thermal expansion coefficients for the molten mercuric halides $HgCl_2$, $HgBr_2$, and HgI_2 at corresponding temperatures $T(T = 1.10\,Tm)$ are 6.81, 6.52, and 6.40 deg^{-1}, respectively. These values are two to three times greater than those for the ionic halides of the Group IA and Group IIA metal cations, but are less than those for typical nonpolar liquids, *e.g.*, A, O_2, CH_4. The cohesive forces in mercuric halide melts are thus weaker than the coulombic forces in simple ionic melts, but are greater in strength than the London dispersion forces operative in purely nonpolar liquids. Some polar character is thus apparent in the HgX_2 species in the molten state for these salts, and the physical properties would be governed largely by dispersion and multipole forces rather than the coulombic interactions of ionic melts, *viz.*, molten KCl.

Some insight of the constitution of the liquid state can be gained from the entropy of fusion. Ubbelohde (27) has classified the principal mechanisms responsible for the increase of randomization on melting as follows: (i) increase in vibrational entropy due to looser packing and a consequent decrease of characteristic frequencies in the melt; (ii) increase of orientational randomization due to the marked reduction of repulsion barriers accompanying the expansion in volume on melting; (iii) increase in positional disorder, giving rise to the communal entropy term; (iv) randomization of the internal configuration of molecules or ions containing flexible groups; and (v) changes of association or chemical bonding on melting. The entropy of fusion for the mercuric halides, assuming linear triatomic molecules as the predominant species, may be calculated following the statistical thermodynamic treatment of Hirschfelder, Stevenson, and Eyring (28) for the fusion of linear molecules assuming that the molecules can only librate in the solid and that the onset of free rotation occurs at the melting point. It can be readily shown in this treatment that the contribution of the librational motion to the entropy in the solid state is given by

$$\Delta S_{11b} = 2R \left| \ln \left(\frac{kT}{h\nu} + 1 \right) \right|$$

and that of the free molecular rotational term in the molten state by the expression:

$$\Delta S_{rot} = R \left| \ln \frac{8\pi^2 IkT}{\sigma h^2} \right| + 1$$

where the symbols R, I, k, and h have their conventional significance, ν is the librational frequency, and the symmetry number, σ, is introduced to account for the identical molecular configurations. The results of this calculation are summarized in Table V. The lattice oscillations for the mercuric halides have not been determined, but the librational frequencies would be predicted to be somewhat less than the value, 50 cm^{-1}, for Cl_2, Br_2, and I_2 used by Hirschfelder, Stevenson, and Eyring (28) because of the greater coupling interactions among the mercuric halide molecules; an average frequency of 40 cm^{-1} was assumed for the present calculations. Comparison with the observed entropies of fusion (4), also listed in Table V, shows that there is qualitatively good agreement with the theoretically predicted results; it follows that for the mercuric halides the principal contribution to the entropy of fusion thus arises from "rotational melting." If significance may be attached to the fact that $\Delta S_{f_{theor}} > \Delta S_{f_{obs}}$ for each of the three mercuric halides (Table V), it is apparent that a modified form of the rotational partition function, to allow for the fact that, at the melting point, not all molecules are able to rotate simultaneously in the melt, but that groups of molecules undergo a form of hindered rotation in the liquid, should be introduced in this treatment. In the absence of knowledge of the exact values of the librational frequencies, it is not possible to introduce this refinement at present.

Table V. Entropies of fusion of the mercuric halides

Transport properties.—The ratios $n = \Delta E_{vap}/\Delta E_\eta$ [Table II(b)] for the mercuric halides are near 3.5. Ewell and Eyring (29) have noted that there is a relatively sharp separation into two classes of molecular-type liquids with $n = 3$ and $n = 4$. The liquids for which $n = 3$ have approximately spherical fields of force (*e.g.*, A, CH_4, CCl_4, N_2, CO . . .) the other group of liquids with $n = 4$ (*e.g.*, C_6H_6, C_2H_5I, CS_2, C_2H_4 . . .) are not of spherical symmetry and most of them are "polar." For polar or elongated molecules, preferred orientations are possible and a smaller fraction of the energy of vaporization (*i.e.*, the energy required to form a hole of molecular size) is apparently sufficient for the flow process to occur.

The low values of ΔE_η (Table II(b)) are understood if these liquids are not associated or "network" liquids; the units of viscous flow are kinetically free molecular species.

The low electrical conductivities of the molten mercuric halides would indicate that these salts are slightly dissociated to ionic species; the order of decreasing conductance, iodide > bromide > chloride, undoubtedly reflects the relative degrees of dissociation. An estimate of the degree of dissociation, α, of electrolytes which obey Walden's rule ($\Lambda\eta$ = constant) is possible using Greenwood and Martin's (30) equation:

$$\alpha = \frac{\mu\eta}{100}$$

where μ is the molar conductivity and η the viscosity.[1]

[1] For covalent melts, which are only slightly dissociated and for which the viscosity is primarily determined by undissociated molecular species, the simple form of the Walden product should be used even though $\Delta E_\eta/\Delta E_\Lambda \neq 1$; for ionic melts, $\mu \cdot \eta^{1/m}$ as proposed by Greenwood and Martin (30) elsewhere should be used in estimates of α.

Table VI. Degree of dissociation of some molten inorganic salts

‡ Highly ionized molten salts, *i.e.*, the values for these salts indicate that the estimates are more qualitative than quantitative in significance since for a *completely* ionized salt α has a maximum value of of 1.0.

In covalent melts which are only slightly dissociated, viscosity is determined primarily by undissociated molecules rather than by ionic species. The molecules may be considered as constituting a solvent medium in which the ions are dissolved and with which they are in dynamic equilibrium with respect to the process of ionization. These melts may therefore be considered as dilute electrolytic solutions and may be expected to obey Walden's rule to the extent to which the conditions for Stokes' law are applicable. Table VI lists values of α calculated from the Greenwood-Martin equation for the molten mercuric halides at their freezing and boiling points. The value $\alpha = 2 \times 10^{-4}$ for $HgBr_2$ is in good qualitative agreement with the value from emf measurements, $\alpha = 1 \times 10^{-5}$, reported elsewhere (13). The ionic concentrations in the pure molten mercuric halides at the temperatures of their melting points are: 5.5×10^{-4}, 3.3×10^{-3}, and 0.90 g ion l^{-1} for the chloride, bromide, and iodide, respectively. Estimates of α are included as well for some typical ionic salts at corresponding temperatures T ($T = 1.10\ T_m$), where T is in °K.

An interesting feature in the relative values of ΔE_η and ΔE_Λ is that, in direct contrast to ionic fused salts, $\Delta E_\eta < \Delta E_\Lambda$ for the molten mercuric halide melts. An explanation for this apparent "anomaly" is seen on critical examination of the temperature dependence of the degree of ionization, α.

In the absence of excess halide ions, X^-, the most probable entities in these melts are HgX_2 with HgX^+ and HgX_3^- ions at low concentration. The corresponding dissociation scheme is thus

$$2\ HgX_2 \overset{K_i}{\rightleftarrows} HgX^+ + HgX_3^-$$

The temperature dependence of this dissociation is of the form

$$\alpha = K_i^{1/2} = \exp(-\Delta F_i/2RT) = \exp(\Delta S_i/2R)\exp(-\Delta H_i/2RT)$$

If ΔH_i remains constant, α varies exponentially with temperature, and no deviation from linearity of the log Λ *vs.* $1/T$ plot is produced by the changing ionic concentration. The empirical activation energy for conductance, ΔE_Λ, is now seen as a composite quantity

$$\Delta E_\Lambda = \Delta H_i/2 + \Delta H_\Lambda^\ddagger = \Delta H_i/2 + \Delta H_h + \Delta H_j$$

where ΔH_i is the heat of ionization, $\Delta H_\Lambda^\ddagger$ is the enthalpy of activation for the migration process, ΔH_h is the heat of hole formation, and ΔH_j is the energy required to jump over the potential barrier into the adjacent hole. When ΔH_i is very small, ionization is virtually complete, and α is insensitive to temperature change. For salts such as the alkali halides, $\Delta H_i = 0$ since the salts are completely ionic in the crystalline state. A heat of ionization term is thus not observed in the empirical activation energy for conductance for most molten salts of the ionic type. For slightly dissociated molecular melts such as the mercuric halides, however, ΔH_i is appreciable. It can be readily shown that molten salts that are essentially covalent or molecular would be expected to obey the simple Walden rule. It follows that for the mercuric halides $\Delta H_\Lambda^\ddagger \approx H_\eta^\ddagger \equiv \Delta E_\eta$. The difference of the experimental activation energies thus gives an estimate for the heat of ionization, *i.e.*

$$\frac{1}{2}\Delta H_i = (\Delta E_\Lambda - \Delta E_\eta)$$

The measured values of Λ and ΔE_Λ for the poorly conducting $HgCl_2$ are extremely sensitive to trace amounts of ionic impurities, *i.e.*, quite similar to solvents such as water.

The tendency for complex formation in the systems

$$HgX_2 \text{-} MX\ (X = Cl, Br, I;\ M = Na, K, NH_4)$$

in the molten state and the stability of complexes formed have been observed to increase in the order I, Br, Cl (31). This order is the reverse of that found in aqueous solutions. The most characteristic compounds in the halide mixtures were $2MX \cdot HgX_2$ and $MX \cdot HgX_2$, corresponding to the complex anions $HgX_4^=$ and HgX_3^- in the melts.

Values of ΔE_Λ obtained in the present investigation lend support to the existence of autocomplexes in the pure melts. If, as proposed elsewhere (5), the dissociation scheme of the mercuric halides is $HgX_2 \rightarrow HgX^+ + X^-$, a large heat of ionization, ΔH_i, comparable to the energy of an Hg—X bond, should be included in ΔE_Λ. In Table VII are listed values of: the bond dissociation energy, D(X—HgX) (32); the bond energy, E (33); the gas phase dissociation constant, K_p (33); and the heat of ionization, ΔH_i; for

Table VII. Dissociation and ionization parameters for the mercuric halides at their boiling points

Salt	D, kcal mole^{-1}	E, kcal mole^{-1}	ΔH_i, kcal mole^{-1}	K_p, mole
$HgCl_2$	81	54	2.8	2.76×10^{-13}
$HgBr_2$	72	44	1.4	5.50×10^{-11}
HgI_2	60	35	−7.1	3.47×10^{-6}

the mercuric halides at their respective boiling points. Lack of knowledge of ionization potentials, electron affinities, and solvation energies precludes an accurate evaluation of ΔH_i from the Born-Haber cycle. It is evident, however, that ΔH_i is very much less than D and E. This strongly suggests that ionization in the melt occurs with the formation of complex anions, *e.g.*

$$2HgX_2(1.) \rightarrow HgX^+(1.) + HgX_3^-(1.)$$

or

$$3HgX_2(1.) \rightarrow 2HgX^+(1.) + HgX_4^=(1.)$$

Since no net Hg-X bonds are broken in such a process, the heat of complex anion formation should largely cancel the large heat of ionization required to produce free HgX^+ and X^- ions.

The temperature dependence of ΔE_A found in molten $HgBr_2$ and the negative temperature coefficient of electrical conductance for HgI_2 are additional features for consideration. The temperature dependence of ΔE_A ($HgBr_2$) may be attributed, in large part, to a variation of ΔH_i with temperature [cf. H_2O and acetic acid (34)], and to the thermal instability of the autocomplex ionic species. That the effect is due to the decrease in ΔH_j (the part of activation energy associated with the "jump" displacement in the migration process) as has been suggested elsewhere in ionic melts (35) seems much less probable in the molten mercuric halides since intermolecular force fields are much weaker than the interionic force fields of highly ionized molten electrolytes.

The changes of resistance on fusion of the three salts are illustrated in Fig. 2. At their melting points the specific conductivities are strikingly similar for the solids, *ca.* 10^{-6} ohm^{-1} cm^{-1}. These salts, after fusion, have increases in specific electrical conductivity of 10^2-10^4 ohm^{-1} cm^{-1}. Electronic conductors exhibit a decrease in conductivity on fusion owing to the increased lattice scattering of electrons in the conduction band. The molten salts may be regarded as ionic conductors. The marked curvature in the log R — $1/T$ graph which sets in *ca.* 25° below the melting point in HgI_2 is evidence of homophase premelting by onset of ionic conductance. Similar behavior was noted in the dilatometric measurements of the change in volume on fusion of HgI_2. Additional support for this view is found in the value for ΔE obtained near the melting point. The value, 1.11 ev mole^{-1} (25.7 kcal mole^{-1}), well within the limits of experimental error (± 5%), is almost identically one-half the band gap, 2.13 ev, from Bube's optoelectric measurements (36) on solid HgI_2. Ionic conductance in the solid state is thus negligibly small until the melting point is approached. The value of ΔE for solid $HgBr_2$ (0.95 ev) is similar to that of HgI_2, but the value for solid $HgCl_2$ (0.56 ev) is notably less. The former two salts form layer lattices of the same type; the chloride has a somewhat different packing in the solid state.

Both the chloride and bromide have positive temperature coefficients, and in accord with the criterion, it is apparent that ion conductance prevails in these melts. It was observed in the present work that visible amounts of iodine appeared at the anode in an electrolysis of molten HgI_2 at 80 ma for several hours. Belyaev and Mironov (14) have reported, in contrast to aqueous solutions, the iodomercurates are the least stable of the complex anions, HgX_3^- and $HgX_4^=$. The decrease in electrical conductance may thus arise from a retrogression of ionization with increase in temperature. A possible ionization scheme for the iodide is as follows

$$HgI_2 \rightleftarrows HgI^+ + I^- \qquad \Delta H_1$$

and

$$I^- + HgI_2 \rightleftarrows HgI_3^- \qquad \Delta H_2$$

or:

$$2HgI_2 \rightleftarrows HgI^+ + HgI_3^- \qquad \Delta H_3$$

The thermal instability of the species HgI_3^- would repress the primary ionization with increasing temperature. From the temperature dependence of the ionization constant, K_i, *i.e.*, $(\ln K_i/T)_p = \Delta H_3/RT^2$, it is seen that, if ΔH_3 is negative, the electrical conductance would decrease with an increase in temperature. A recent study (37) of the electrical conductance of the interhalogen compound, BrF_3, has shown a negative temperature coefficient. This has been attributed to a repression of the primary ionization due to the thermal instability of the species, BrF_2 and BrF_4, much as advanced for molten mercuric iodide above. Thus while the possibility of some partial electronic conductance is not ruled out for molten HgI_2, there is chemical evidence in strong support for the view that the conductance is predominantly ionic in this molten electrolyte, as in molten $HgCl_2$ and $HgBr_2$.

Acknowledgments

Dr. Y. Mikawa and Dr. D. W. James, of this laboratory, are thanked for helpful discussions and experimental aid in the Raman studies of the molten mercuric halides. This work was made possible in large part by support received from the National Science Foundation, Washington, D. C., (Raman Spectroscopy of Molten Salts) and the U. S. Air Force, Office of Scientific Research, Washington, D. C., (Properties and Constitution of Molten Salts).

Manuscript received Feb. 6, 1962. Abstracted in part from a thesis by one of the authors (J. D. E. McI.) in partial fulfillment of the requirements for the Ph.D. degree, R. P. I., January 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Rates of Electrode Processes by the Rotating Disk Method

D. Jahn and W. Vielstich

Institut für Physikalische Chemie der Universität Bonn, Germany

ABSTRACT

A rotating disk electrode has been applied to the measurement of the kinetics of fast electrode reactions. Standard exchange current densities up to about 10 amp/cm²/mole/liter have been obtained for reversible redox systems by extrapolating the measured current to infinite speed of rotation in order to eliminate diffusion polarization.

In recent years increasing use has been made of the rotating disk electrode in diffusion and kinetic investigations, mainly for determining diffusion coefficients. This electrode has the advantage that there exists a precise theory of convective diffusion at a rotating disk. According to Levich (1) the diffusion layer has the same thickness over the entire area of a rotating disk provided edge effects can be neglected. For laminar flow the diffusion layer thickness is given by the following function

$$\delta = a\, D^{1/3}\, \nu^{1/6}\, \omega^{-1/2} \qquad [1]$$

where D is the diffusion coefficient of the solute species ($cm^2\ sec^{-1}$), ν is the kinematic viscosity of the solution ($cm^2\ sec^{-1}$), ω is the angular velocity of the disk (sec^{-1}), and a is a factor which equals 1.62 according to Levich. A closer approximation (2) yields $a = 1.805\ [0.8934 + 0.316\ (D/\nu)^{0.36}]$.

A diffusion controlled limiting current density is given by

$$j_{lim} = nF\, D\, c/\delta \qquad [2]$$

nF being the number of coulombs per mole transfered at the electrode, c being the bulk concentration of the reacting species. From measurements of limiting diffusion currents thus the quantity $D \times c$ can be obtained with better precision as compared to values obtained with the dropping mercury electrode.

The application of the rotating disk method to the study of chemical kinetics has been proposed by Koutecky and Levich (3). They have derived a formula containing both diffusion and kinetic parameters. Thus, under certain conditions, by measuring currents limited by diffusion and chemical kinetics as a function of the revolution number of the disk and by extrapolating to $\omega \to \infty$, one can determine rates of chemical reactions preceding the electron transfer. This has been demonstrated by the evaluation of the dissociation rates of weak acids (4).

Electrode Kinetics and Mass Transfer

The combined effects of mass transfer and electrode kinetics at a convection electrode which have already been studied by Frumkin and Tedoradse (6) for the chlorine electrode will be described here for the reaction

$$Ox + n\,e^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R$$

with the assumption that no preceding chemical reaction occurs. The general expression for the current density is

$$j = nF\,(k_f\, c_{Ox}^{x=0} - k_b\, c_R^{x=0}) \qquad [3]$$

where k_f and k_b are the formal rate constants (5) for the forward and backward electrode reaction, and x is the distance from the electrode surface. The mass transfer through the diffusion layer for the two reacting species is

$$j = nF\, D_{Ox} \frac{c_{Ox}^{x=\infty} - c_{Ox}^{x=0}}{\delta_{Ox}}$$

and

$$j = -nF\, D_R \frac{c_R^{x=\infty} - c_R^{x=0}}{\delta_R} \qquad [4]$$

δ_{Ox} and δ_R being the diffusion layer thickness for the species Ox and R, respectively.

In the case of a rotating disk electrode using Levich's equation (1) δ can be written in the form

$$\delta = A/\sqrt{\omega}$$

where $A = a\, D^{1/3}\, \nu^{1/6}$ Calculating the concentrations at the electrode surface from the bulk concentrations one gets using the Eq. [4]

$$c_{Ox}^{x=0} = c_{Ox}^{x=\infty} - j \frac{A_{Ox}}{nF\, D_{Ox}} \cdot 1/\sqrt{\omega}$$

$$c_R^{x=0} = c_R^{x=\infty} + j \frac{A_R}{nF\, D_R} \cdot 1/\sqrt{\omega} \qquad [5]$$

Introducing the relations [5] into Eq. [3] one readily obtains

$$j = \frac{nF\,(k_f\, c_{Ox}^{x=\infty} - k_b\, c_R^{x=\infty})}{1 + \dfrac{k_f\, A_{Ox}}{D_{Ox}\sqrt{\omega}} + \dfrac{k_b\, A_R}{D_R\sqrt{\omega}}} \quad \text{or}$$

$$1/j = \frac{1}{nF\,(k_f\, c_{Ox}^{x=\infty} - k_b\, c_R^{x=\infty})}\left[1 + \left(\frac{k_f\, A_{Ox}}{D_{Ox}} + \frac{k_b\, A_R}{D_R}\right)\frac{1}{\sqrt{\omega}}\right] \qquad [6]$$

This equation can be applied to the evaluation of kinetic data (standard exchange current density j_o, transition coefficient α) as follows: Plotting $1/j$ against $1/\sqrt{\omega}$ for constant values of the overvoltage (6) one deduces from the slope and the ordinate at $\omega = \infty$ two equations for k_f and k_b.

From the two rate constants at a given electrode overvoltage one can calculate both j_o and α in the usual way

$$nF\, k_f = j_o \exp\left(-\alpha \frac{nF}{RT}\eta\right)$$

$$nF\, k_b = j_o \exp\left((1-\alpha)\frac{nF}{RT}\eta\right) \qquad [7]$$

We have used Eq. [6] for the determination of kinetic data of several very fast redox systems. We found that in our arrangement standard exchange current densities up to nearly 10 amp/cm²/mole/liter could be measured. This limit is caused by the fact that an evaluation is no longer possible if the ratio of the slope to the ordinate intercept becomes too high. The accuracy of the method can be increased by using a higher speed of rotation. Varying the overvoltage η or the concentrations of the reacting species, however, only yields a small effect.

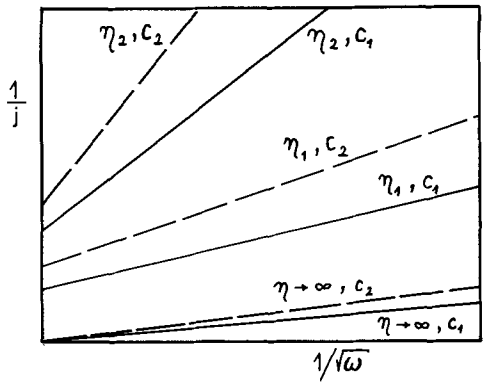

Fig. 1. Schematic $1/j - 1/\sqrt{\omega}$ plot with $c^{x=\infty}$ and η as parameters; $c_1 > c_2$; $\eta_1 > \eta_2$.

The influence of the experimental parameters c and η on the $1/j - 1/\sqrt{\omega}$ diagram can be understood by transforming Eq. [6]

$$1/j = \frac{1}{nF\,(k_f\, c_{Ox}^{x=\infty} - k_b\, c_R^{x=\infty})} + \frac{1}{nF\,(k_f\, c_{Ox}^{x=\infty} - k_b\, c_R^{x=\infty})}\left(\frac{k_f\, A_{Ox}}{D_{Ox}} + \frac{k_b\, A_R}{D_R}\right)\cdot 1/\sqrt{\omega}$$

By lowering the bulk concentrations $c^{x=\infty}$ both the slope $1/j - 1/\sqrt{\omega}$ and the intercept for $\omega = \infty$ increase (see Fig. 1). Therefore the accuracy of the evaluation is not noticeably improved by a change in concentration.

A change of the overvoltage η has a similar effect. In the region $\eta \leq RT/nF$ an increase of η results in a decrease at both the slope and the intercept (Fig. 1, 4, and 5), while for $\eta >> RT/nF$ the slope reaches constant values as is to be expected for purely diffusion controlled polarization (Fig. 1).

Experimental

A platinum wire (diameter 0.1 cm) which was sealed into a glass tube (Fig. 2) served as the disk electrode. The electrode was centered to within 0.002 cm, and the face was mechanically polished using Cr_2O_3 polishing powder. The rod was driven by a synchronous motor which was powered by an audiofrequency generator with an a-c amplifier. This arrangement allowed us to alter very simply the revolution number of the disk electrode in the range from 10 to about 120 cps without the necessity of any control. As we used a very small disk electrode there was no danger of turbulence at the surface of the electrode. At 120 cps a Reynold's number of about 200 is reached, the critical Reynold's number being $> 10^4$. At very low revolution numbers an influence of spherical diffusion at the edge between platinum and glass can become noticeable. The contribution of spherical diffusion can be neg-

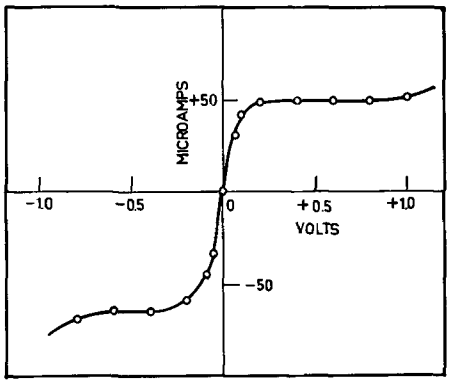

Fig. 3. Current vs. overvoltage at $\omega = 2\pi \times 48.2$ sec^{-1}; 0.5M K_2SO_4, 10^{-2}M $Fe(CN)_6^{3-}$, 10^{-2}M $Fe(CN)_6^{4-}$.

lected, if the condition $r/\delta \geqq 20$ is fulfilled. The radius of our electrode being $r = 0.05$ cm, a frequency of $f \geqq 10$ cps is required.

The experimental cell was thermostated and contained the rotating disk electrode, a platinum counter-electrode, and a second sheet of platinized platinum as a reference electrode. Pure nitrogen was bubbled through the electrolyte. Overvoltages were measured currentless, the currents by means of a microammeter.

The solutions were prepared from reagent grade chemicals. The concentration of each redox component was 10^{-2}M. A large excess of supporting electrolyte was added. The solutions were freed from oxygen by CO_2, and the access of light was excluded when the solutions were stored.

Before the measurements the carefully polished disk electrode was pretreated by alternating cathodic and anodic polarization up to the region of the beginning H_2- and O_2-evolution. Thus a high electrode activity and a relatively good repeatability could be reached.

Results

The method was tested on several reversible redox systems which had already been measured by Randles and Somerton (7) with the a-c method. Prior to the kinetic measurements diffusion coefficients of the reacting species have been determined from the anodic and cathodic limiting currents at a given speed of rotation (Fig. 3). The calculated diffusion coefficients at 25°C for the three systems investigated are listed in Table I.

Table I. Diffusion coefficients and kinetic data at 25°C

Redox system	Supporting electrolyte	$D \cdot 10^6$ R	$D \cdot 10^6$ Ox	α	j_0	j_0 (7)
Fe^{2+}/Fe^{3+}	1M $HClO_4$	5.7	6.5	0.63	0.23	0.5
$Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$	1M KCl	5	7	0.61	5	9
$Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$	0.5M K_2SO_4	4.9	7.2	0.56	7	13

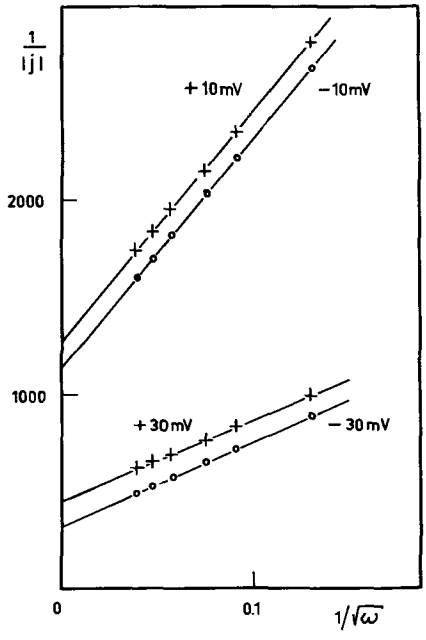

Fig. 4. $1/j - 1/\sqrt{\omega}$ plot for the system 1M $HClO_4$, 10^{-2}M Fe^{2+}, 10^{-2}M Fe^{3+}.

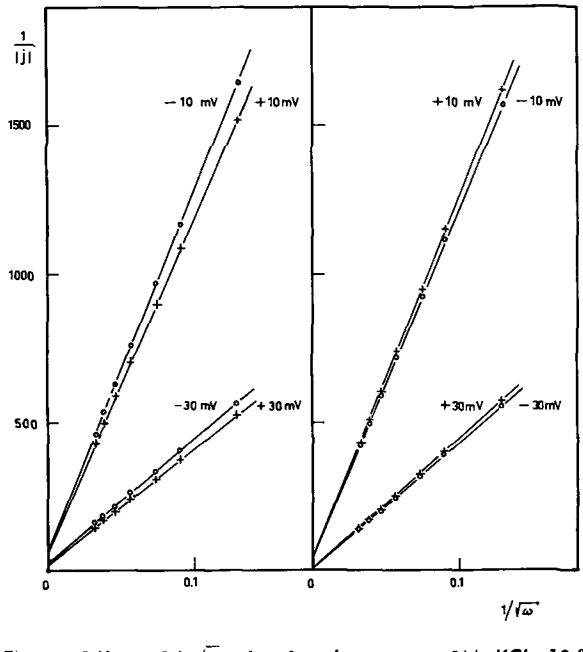

Fig. 5. $1/j - 1/\sqrt{\omega}$ plot for the systems 1M KCl, 10^{-2}M $Fe(CN)_6^{4-}$, 10^{-2}M $Fe(CN)_6^{3-}$ (left) 0.5M K_2SO_4, 10^{-2}M $Fe(CN)_6^{4-}$, 10^{-2}M $Fe(CN)_6^{3-}$ (right).

While in the regions of limiting currents there is no influence of the discharge reaction on the current, the shape of the curve at low overvoltages is determined by both mass transfer and discharge kinetics. Therefore the $j - \omega$ relation has to be studied at constant overvoltages in the ascending part of the current-voltage curve (Fig. 3). In Fig. 4 and 5 values of $1/j$ are plotted vs. $1/\sqrt{\omega}$ for the three systems. The observed dependence can be remarkably well represented by a straight line. The extrapolated kinetic data (for $\omega \to \infty$) are shown in Table I.

Comparing our j_o-values with those obtained by Randles and Somerton one can see that the latter are greater almost by a factor of 2. This may be due to the fact that applying an a-c current induces a continuous activation of the electrode surface. A disagreement of this order is not unusual with measurements on solid electrodes.

The results prove once more the suitability of this method for the investigation of fast electrode processes. With the different relaxation methods the elimination of the influence of the double layer causes considerable difficulties for the experimental procedure as well as for the evaluation and interpretation of the results. The rotating disk method as a steady-state method avoids these obstacles by yielding relationships which are easily explainable in terms of a well founded theory.

Manuscript received Dec. 27, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Effects of Electrostatic Fields on the Surface Tension of Salt Solutions

G. M. Schmid, R. M. Hurd, and E. S. Snavely, Jr.

Texas Research Associates, Austin, Texas

ABSTRACT

The surface tension of air/NaCl solution interfaces with applied electrostatic fields of up to 6700 v/cm was measured using a surface energy balance. The NaCl concentration was 0-3.5%. It was found that fields of either polarity lower the surface tension of all investigated solutions. Maghitude of the surface tension changes and dependence on direction of the field lead to the conclusion that the potential drop at air/water interfaces is smaller than previously thought, that the water dipole orientation is only slight, and that the hydrogen in the oriented water molecule is facing the air. The experiments point out that the effect of the field is predominantly on the sodium ion. It is shown that the difference in the energy for adsorption at the interface between cations and anions cannot be neglected. Calculations on the basis of a modified Gibbs equation on the assumption of a diffuse double layer at the interface leads to unreasonably high surface deficiencies. Neglecting the diffuse double layer and reckoning on the basis of an inner double layer only leads to values of the same order of magnitude as those calculated from the Gibbs equation alone.

For uncharged particles, changes in surface concentration are related to surface tension through the Gibbs adsorption equation (1). For charged particles, this equation has to be modified to take into account the specific properties connected with their strong electrostatic fields. Attempts have been made in this direction by Lewis (2). A more direct approach has been used by Wagner (3) and was further developed by Onsager and Samaras (4) and by Falkenhagen and Schmutzer (5). No direct measurements of surface concentrations are available to check the validity of these theories.

According to Kamienski (6), the potential drop across the air/water interface leads to a field of the order of 10^7 v/cm. If this is true, then it is very unlikely that it would be possible to change the surface concentration of charged particles by externally applying an electrostatic field of, say, 10^4 v/cm. On the other hand, Barnett (7) and Guastalla (8) were able to show that this is not necessarily so. These experiments, however, still did not allow quantitative treatment.

The object of this investigation was to determine the effects of applied electrostatic fields on the surface tension of salt solutions and to try to correlate these to surface concentration changes.

Experimental

Apparatus.—The surface energy balance used in this work is essentially the same as that of Allan and

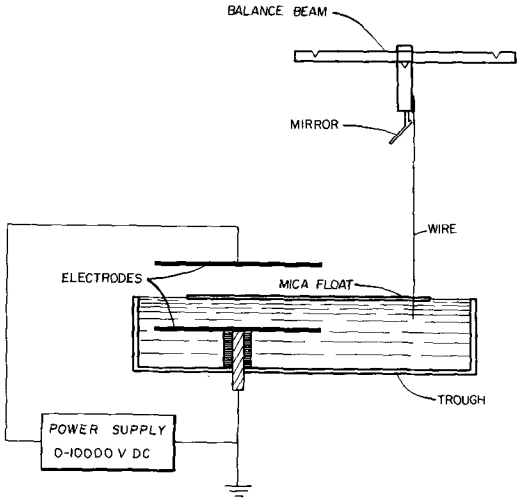

Fig. 1. Schematic of surface energy balance

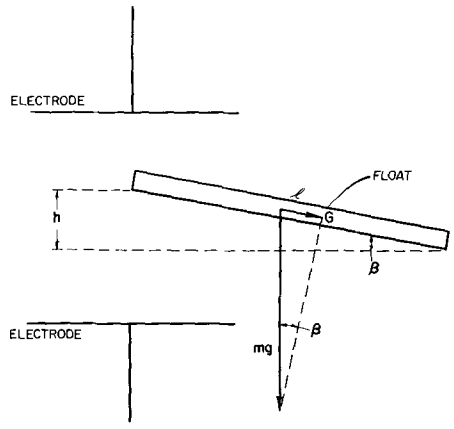

Fig. 2. Schematic of hydrostatic force on float; β, angle of tilt; h, hydrostatic overhead due to the field; mg, force of gravity; l, length of float; force on float.

Alexander (9), slightly modified so that a potential can be applied across the air/solution interface. A rigid, heavy brass frame, resting on three leveling screws, served as support for both a 25 x 15 x 4.5 cm Pyrex glass trough and an aluminum balance beam (Fig. 1). The electrodes, 11 x 9 x 0.1 cm, are made of plate Monel, to resist the corrosive action of the salt water. A hole is drilled into the bottom of the glass trough and the frame to allow mounting of the "water electrode." A water-tight seal is obtained with a Teflon gasket. The "air electrode" is mounted on an insulating Lucite plate directly above the water electrode. The air gap between the solution surface and air electrode was 1.2 cm.

The balance beam is supported 20 cm above water level by two diamond points which pivot on two microscope slides resting on the frame. The slides are replaced frequently to avoid formation of grooves by the cutting action of the diamonds. The beam has two notches to allow calibration of the balance. A rigid wire with a Pt wire prong reaches down into the solution. A small mirror attached to the beam projects a light beam onto a scale, 230 cm away, thus allowing accurate observation of balance deflections.

A thin sheet of mica, generally 7.3 x 12.8 cm, floating on the solution serves as indicator. It has two holes on one end, large enough for the Pt wire prong of the balance body to move in and out freely. The other end of the mica float projects 4.5 cm into the space between the electrodes. Thus a change in surface tension between the electrodes as compared to the area outside the electrodes results in a force on the mica float which is indicated by a deflection of the balance beam.

The voltage applied across the interface was taken from a 0-10,000v d-c power supply. Water electrode, frame, and balance beam were grounded at all times. The balance arrangement had a sensitivity of 0.052 dynes cm^{-1} per cm of deflection, as determined by calibration with small weights (pieces of Pt wire) placed directly on the balance beam.

Application of an electric field leads to an attractive force between the air electrode and balance beam. This force was blocked by separating the two with a mica sheet, perpendicular to the air/solution interface, reaching into the solution to obtain effective grounding and placed as close to the electrodes as possible without arcing. A slot was cut into the shield so as to allow free movement of the mica float.

In measurements of this kind, contamination of the air/solution interface with dust and other foreign substances must be eliminated. This was done by keeping the whole experimental setup covered with a Lucite hood. Float and balance beams were removed frequently and the solution surface cleaned by sweeping with mica barriers several times over the whole surface, including the edges of the trough.

Procedure.—At least two forces other than surface tension changes are indicated by the balance and have to be corrected for to obtain the desired effect of the field on surface tension.

First, application of an electric field across the air/solution interface raises the solution underneath the air electrode. The resultant forces on the mica float are represented schematically in Fig. 2. The mica float, the edge of which lies between the two plates, becomes tilted. This results in a force, G, on the balance body, in addition to the force due to a change in surface tension. G can be calculated to a first approximation as the force of gravity, mg, projected onto the float, *i.e.*,

$$G = mg \sin \beta \qquad [1]$$

with

$$\sin \beta = h/l \qquad [2]$$

where β is the angle of tilt, l the length of float, and h the hydrostatic overhead due to the field. The force, G, can be accounted for by keeping h and l constant (constant field strength, constant length of float) and varying m.

Second, it was observed that the balance deflection caused by a mica sheet, floating on a salt solution with an electric field impressed across the air/solution interface, is dependent on the position of the "working edge" of the float in the field. This is due to electrostatic attraction of the mica float, which must be proportional to the area of the part of the float in the field. Again, this area is proportional to the mass of the float in the field.

The experimental procedure used to make both corrections is based on the following. Consider a rec-

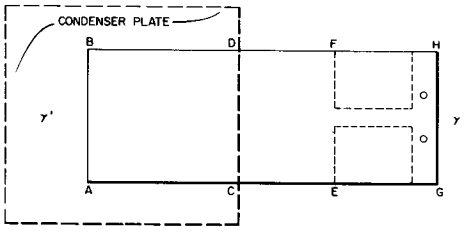

Fig. 3. Geometrical view of float; γ, γ', surface tensions

tangular float of fixed dimensions (Fig. 3) floating on a salt solution with area ABDC inside a perpendicular and constant electric field. There are four forces acting on the float. A surface tension γ' is effective on the "working edge" $\overline{AB}$ and a surface tension γ on the "balance edge" $\overline{GH}$ of the float ($\overline{AB} = \overline{GH}$). The force to be determined is $\gamma' - \gamma = \Delta\gamma$. Due to the hydrostatic head developed in applying the electric field, there is a force of gravity which is proportional to the area of the float between the electrodes. Since the float is of constant thickness, this area is proportional to the mass of that part of the float.

The float is now cut as indicated by the dotted line shown in Fig. 3, leaving a small bridge between the front part of the float, ABFE, and the rear part at GH. We assume that the width of the bridge is small, as compared to the balance edge $\overline{GH}$. The effects of the surface tension difference, $\Delta\gamma$, and the electrostatic force are not changed by this procedure, provided that area ABDC < ABFE. We do, however, change the mass of the float. Making ABFE successively smaller, keeping ABDC < ABFE, and plotting balance deflection *vs.* mass of float shows the dependence of the force due to effects of the hydrostatic head on the mass of the float.

As $\overline{AE}$ is made successively smaller by this process, we finally arrive at $\overline{AE} < \overline{AC}$. Provided that the constant electric field is homogeneous up to $\overline{CD}$, and the width of the bridge is negligible compared to $\overline{AB}$, then the net surface tension forces on the float should disappear at $\overline{AE} < \overline{AC}$. Since now the electrostatic attraction of the float is proportional to the area ABFE and thus also to the mass of the float, we still plot deflection *vs.* mass of float for ABFE < ABDC. This plot shows the electrostatic effect plus the gravity effect due to the remaining mass of the float, but without the surface tension effect.

Thus, we will have two plots of balance deflection *vs.* mass of float (Fig. 4), one of which, for $\overline{AC} < \overline{AE}$, gives the influence of gravity plus a constant electrostatic attraction and surface tension effect; the other, for $\overline{AC} > \overline{AE}$, gives the influence of electrostatic attraction plus the effect of gravity for the remaining mass of the float with no surface tension effect. Extrapolation of the two plots toward each other to a point to the left of which the surface tension effect is zero and to the right of which the surface tension effect as a definite value gives a difference in ordinate which corresponds to the surface tension effect only.

It is seen from Fig. 4 that the slopes of the upper part of the curves become larger with increasing field strength, which is expected for increasing hydrostatic head. The deflection exhibited a slight maximum at the greatest masses, which may be due to forces involved in "lifting" water outside the field by surface tension effects on the rigid float.

Extrapolation of the lower parts of the curves to $m = 0$ should intercept the origin. The small deviations from zero intercept in Fig. 4 occur because the bridge between front and rear part of the float cannot be made infinitely small, and also because a finite rear part is necessary to operate the balance.

The point to the left of which the surface tension effect is zero and to the right of which the surface tension effect has a finite value cannot be determined precisely. The point lies, however, between the abscissae of the highest point of the lower curve and the lowest point of the higher curve (between a and b in Fig. 4). Taking the difference in ordinates at these two points gives a lower and upper limit for the surface tension effects.

The method was checked by using floats having different working edges, different masses, and different areas in the field. The results for a 3.5% NaCl solution at positive air electrode are shown in Fig. 5 and are in satisfactory agreement. Each point in Fig. 5 is the mean of a maximum and minimum value obtained from a plot of mass of float *vs.* balance de-

flection. The curve is the average of the surface tension change thus obtained. Maximum and minimum values are indicated. Positive values of $\Delta\gamma$ correspond to a lowering of surface tension due to the electric field.

It has been pointed out to us (10) that the balance deflections observed on application of the field may be caused by Cl^- adsorption at the float/solution boundary, due to the differences in dielectric constants and induced by the applied field. This adsorption should depend strongly on dielectric constant and material of the float. A run was therefore made with a mica float carefully coated with paraffin. The results did not differ from the ones obtained with plain mica floats, proving that Cl^- adsorption at the float/solution boundary is either absent or does not influence the measurements.

Solutions of 0-3.5% NaCl content have been used for the experiments described here with the air electrode both positive and negative, using fields up to 7000 v/cm.

Results

The $\Delta\gamma$ values measured in the experiments just described were converted into absolute γ's using published data (11). Figures 6 and 7 give a plot of surface tension *vs.* NaCl concentration with field strength as parameter for positive and negative air electrodes, respectively. The surface deficiencies, Γ, have been calculated using the Gibbs adsorption equation and are presented in Fig. 8 and 9.

It is seen from Fig. 6 and 7 that both a positive and a negative air electrode lowers the surface tension of pure water, a negative air electrode more so than a positive one. The surface concentration of NaCl solutions is increased by a negative air electrode (Fig. 8),

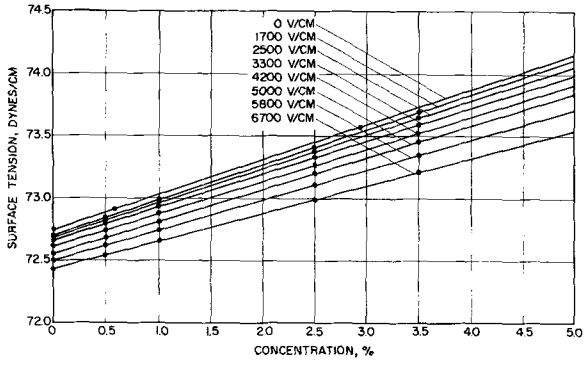

Fig. 6. Surface tension of NaCl solutions, air electrode negative

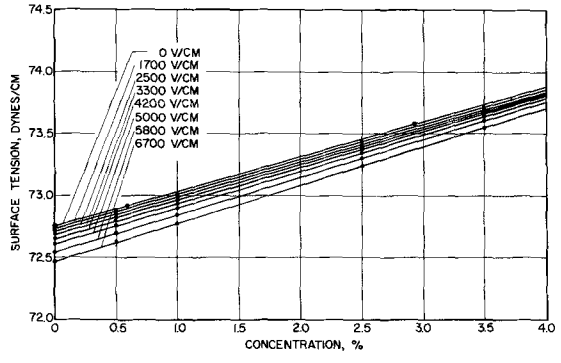

Fig. 7. Surface tension of NaCl solutions, air electrode positive

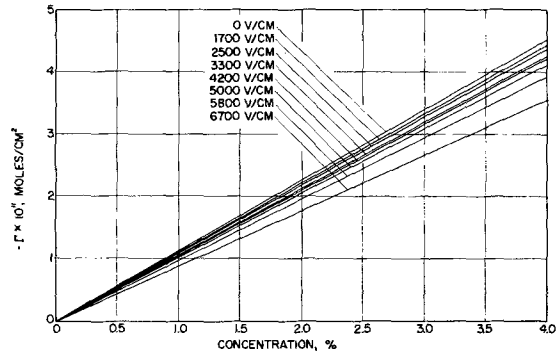

Fig. 8. Surface concentration of NaCl solutions, air electrode negative.

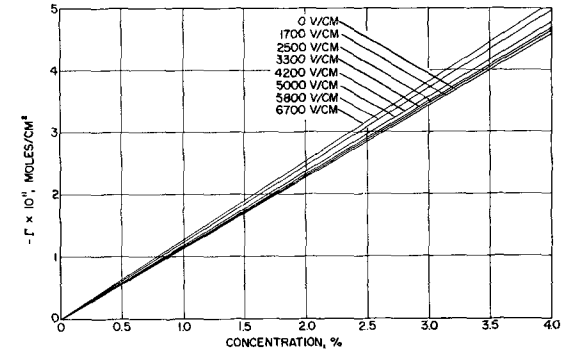

Fig. 9. Surface concentration of NaCl solutions, air electrode positive.

as compared to the surface concentration without a field. A positive air electrode leads, on the contrary, to a lower surface concentration (Fig. 9). The field strength necessary to lower the surface concentration by a given amount at a given bulk concentration is, however, considerably larger than the field strength necessary to raise the surface concentration by a like amount.

Discussion

Dipole orientation.—The potential drop at an air/water interface is, according to Kamienski (6), about 1v, and according to Frumkin (12), 0.1-0.2v. Assuming 10Å for the thickness of the oriented layer of water dipoles at the interface, one obtains a field strength of 10^7-10^8 v/cm. It is unlikely that with such a high field strength already present, application of less than 10^4 v/cm would produce a measurable change in surface tension. Since a measurable change is observed, it appears that either the potential drop across the interface is much smaller than previously thought, or that the thickness of the oriented layer of water dipoles is larger by one to two orders of magnitude.

Both a positive and a negative air electrode lowers the surface tension of pure water. It can be reasonably assumed that this lowering is caused by increased orientation of water dipoles. Equally oriented dipoles repel each other, thus leading to a decrease in surface energy. This leads to the conclusion that the orientation is very slight to start with, since both field directions enhance the orientation, *i.e.*, the surface potential is very close to zero. Pronounced orientation of water dipoles in one direction would

lead, on application of a field, to a lowering of surface tension with one polarity and a raising of surface tension with the other, which may be followed by a lowering in case the field is strong enough to reverse the dipoles. This has not been observed. The fact that a negative air electrode lowers the surface tension more than a positive electrode points to a slight orientation with the hydrogen atoms facing the air.

Surface concentration of NaCl.—The surface deficiency of solutions of strong electrolytes has been shown by Wagner (3) to be due principally to image forces. In his treatment, the concentration $c(x)$ is given as a function of the distance from the surface, x, by the usual Boltzmann expression

$$c(x) = c \exp(-W(x)/kT) \quad [3]$$

where the adsorption potential $W(x)$ is the work required to bring a charged ion from the solution bulk to a point x cm below the surface. For binary electrolytes, Wagner took $W(x)$ as equal for cations and anions, treated them as point charges, and from electrostatic theory obtained

$$W(x) = \frac{D-1}{D+1}\frac{e^2}{4Dx} \quad [4]$$

where D is the dielectric constant of water, and e is the charge on the ion. It is easily seen that integration of Eq. [3] with $W(x)$ as expressed by Eq. [4] would lead to an infinite amount of adsorbed solute. Ions, however, are not point charges, and in ionic solutions, the screening effect of the ion atmosphere limits the effective range of the electrostatic forces to a distance $1/\kappa$, where κ is defined by

$$\kappa^2 = \frac{4\pi}{DkT}\sum_i c_i z_i^2 \quad [5]$$

(13, 14), where c_1, c_2, . . . is the concentration (number of ions/cm^3) of ions with charges z_1, z_2, ... Introducing the mean distance of approach, a, from Debye-Hückel theory, and neglecting variation of κ with x, Eq. [4] is modified to

$$W(x) = \frac{e^{\kappa a}}{1+\kappa a}\frac{e^2}{4Dx}e^{-2\kappa x} \quad [6]$$

This expression, when introduced into Eq. [3], leads to a reasonable solution of c as a function of x. Onsager and Samaras (4) used this treatment to solve for a theoretical value of the surface excess, Γ:

$$\Gamma = -c_{bulk}\int_0^\infty [\exp(-W(x)/kT) - 1]\,dx \quad [7]$$

Values of Γ obtained from this integration were shown to agree satisfactorily with values of Γ obtained from the usual form of the Gibbs equation and surface tension measurements.

Application of an external field across the interface changes the value of the adsorption potential, $W(x)$, through a change in κ (assuming constant a and D) which in turn is a function only of the ionic strength (Eq. [5] and [6]). The changes in Γ with applied field, as indicated by our experiments, are a direct measure of these changes in ionic strength and could theoretically be used to calculate back to the change in adsorption potential induced by the field. This would, however, be a rather tedious procedure, and the uncertainties involved in many of the assumptions made by Wagner and by Onsager and Samaras are probably of greater magnitude than the influence of the field on this potential.

One conclusion which seems to be clear from the experiments, however, is that the difference in $W(x)$ between cations and anions must be taken into account in any refined treatment of the theory. No dependence of Γ on the direction of the applied field would be expected from the derivations above, yet a negative air electrode increases the surface concentration while a positive electrode decreases it, and the magnitude of the effects is different, being greater for the negative electrode (Fig. 8 and 9). From this dependence of Γ of the field direction, it appears that the main influence is centered on the sodium ion, although the reason for this behavior is not immediately clear. The explanation may lie in the difference in the screening effect $1/\kappa$ of the cations and anions as influenced by the electric field, which may be explained by the smaller radius (and resultant higher charge density) of the cation.

An alternative treatment of the concentration gradient at the surface of solutions of strong electrolytes has been given by Lewis (2). This treatment assumes an electrical double layer, made up of positive and negative ions, at the surface, and leads very simply to a modified form of the Gibbs equation

$$\Gamma = -\frac{a}{RT}\left(\frac{\partial\gamma}{\partial a}\right) - (\epsilon_1 + \epsilon_2)\frac{\partial\gamma}{\partial\psi} \quad [8]$$

where ϵ_1, ϵ_2 is the electrochemical equivalent of cations and anions, respectively, and ψ is the potential drop across the double layer.

The dependence of ψ on the externally applied potential, E, is not known. We assume, as a first approximation, a linear dependence of the interface potential on the applied potential, *i.e.*,

$$\Delta\psi = \beta\Delta E \quad [9]$$

where β is a dimensionless factor.

The charge, σ, for a diffuse double layer is given by the Gouy Chapman theory (13, 15) as

$$\sigma = \sqrt{\frac{DRTc}{2\pi}}\,(e^{F\psi/2RT} - e^{-F\psi/2RT}) \quad [10]$$

with c is the concentration of the electrolyte. On the other hand, σ is given by

$$\sigma = EC \quad [11]$$

where C is the capacity of the condenser formed between air-electrode and air/solution interface, per unit area,

$$C = \frac{D'}{4\pi d} \quad [12]$$

where D' is the dielectric constant of air and d the distance between air-electrode and air/solution interface. Combination of Eq. [10] and [11] gives

$$CE = \sqrt{\frac{DRTc}{2\pi}}\,(e^{F\psi/2RT} - e^{-F\psi/2RT}) \qquad [13]$$

and one can obtain

$$\frac{d\psi}{dE} = \beta = \frac{2RTC}{F}\sqrt{\frac{2\pi}{DRTc}}\,(e^{F\psi/2RT} + e^{-F\psi/2RT})^{-1} \qquad [14]$$

Using hyperbolic functions one obtains β as a function of E from Eq. [13] and [14]

$$\beta = \frac{2RTC}{F}\sqrt{\frac{\pi}{2DRTc + \pi E^2C^2}} \qquad [15]$$

For all practical purposes, $2DRTc >> \pi E^2C^2$ and one gets

$$\beta = \sqrt{\frac{2\pi RTC^2}{F^2Dc}}$$

$$= k\sqrt{\frac{1}{c}} \qquad [16]$$

with $k = \dfrac{2\pi RTC^2}{F^2D}$, and C as given by Eq. [12].

With D, the dielectric constant of the electric double layer, assumed to be about 4, and $C = 0.1$ e.s.u./cm^2, we obtain $k = 6.5 \times 10^{-11}$ (mole/cm^3)$^{1/2}$. For $c = 0.5$ mole/l and $\Delta\gamma/\Delta E = 10^{-4}$ dynes/v cm, one calculates (Eq. [8], [9], and [16])

$$(\epsilon_1 + \epsilon_2)\,\frac{1}{k}\sqrt{c}\,\frac{\Delta\gamma}{\Delta E} \approx 10^{-9}\ \text{moles/cm}^2$$

a number which seems unreasonably high.

In the preceding calculations, we have assumed the electrical double layer at the air-solution interface to be of a diffuse nature. This assumption was prompted by the experimental results showing that the effect of the field is mainly on cations, which are usually not thought of as being adsorbed in the inner double layer.

Grahame (16) found that the potential drop ψ_u across the inner double layer is a linear function of the adsorbed charge, σ. Using Grahame's equation for ψ_u

$$\psi_u = 2\pi\sigma\delta/D \qquad [17]$$

where σ is given by Eq. [11], δ is the radius of the hydrated ions; one obtains from Eq. [9], with ψ_u instead of ψ

$$\Delta\psi_u = \frac{2\pi\delta C}{D}\,\Delta E \qquad [18]$$

$$\beta' = \frac{2\pi\delta C}{D} \qquad [19]$$

Now, with $\delta = 10^{-7}$ cm, $C = 0.1$ e.s.u./cm^2, $D = 4$ e.s.u./cm, one obtains $\beta' \approx 10^{-5}$. This leads to a value of $\approx 10^{-11}$ moles/cm^2 for the correction term in the modified Gibbs equation (8), comparable to the order of magnitude given by the standard form of the equation and in good agreement with values of Γ obtained in our experiments with the field. There are too many assumptions involved, however, to warrant systematic calculations of Γ using Eq. [8].

Summary

Electrostatic fields of up to 6700 v/cm, positive and negative, have been applied to air/NaCl-solution interfaces and the surface tension changes measured with a surface energy balance. The NaCl solution concentration ranged from 0 to 3.5%.

It was found that either field direction lowers the surface tension of all investigated solutions. A positive air electrode lowers the surface tension of pure water less than a negative air electrode. This is taken as evidence that the field at the air-water interface is considerably smaller than the 10^7 v/cm previously assumed, that the orientation of the water dipoles at the interface is only slight, and that the predominant small orientation present is with the hydrogen facing the air.

The Gibbs equation has been used to calculate the surface deficiency of NaCl solutions under applied electric fields. The data show that a positive air electrode increases the surface deficiency and a negative air electrode decreases it. This behavior can be explained by assuming the electric field to be either exclusively or predominantly effective on the Na^+ ions alone, due to their smaller diameter. The conclusion is drawn that the difference in the adsorption energy, $W(x)$, of the Onsager-Samaras treatment for cations and anions cannot be neglected.

It is shown that the assumption of a diffuse double layer in the Lewis equation leads to a surface deficiency which is about two orders of magnitude too high. One obtains the right order of magnitude, however, by neglecting the diffuse layer and making the calculations on the basis of an inner double layer only. Most of the experience, which has led to the conclusion that cations are not usually adsorbed in the inner layer, has been obtained from studies of solid/solution interfaces. It is shown that this conclusion does not necessarily hold for air/solution interfaces.

Acknowledgment

This work was performed as part of Contract No. 14-01-001-200 with the Office of Saline Water/Department of the Interior. The authors wish to thank Dr. Norman Hackerman for many helpful discussions.

Manuscript received Jan. 25, 1962. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Rest Potentials in the Platinum-Oxygen-Acid System

James P. Hoare

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

The rest potential of a platinum bead electrode in oxygen-stirred acid solution was investigated as a function of the pH, the partial pressure of oxygen, and the history of electrode preparation. It is believed that the theoretical equilibrium oxygen potential, +1.229v *vs.* N.H.E., cannot be obtained in any known system because all known electronic conductors interact with oxygen. One observes, then, a mixed potential. Such systems are not at equilibrium but in a steady-state condition. Evidence for the understanding of the nature of the potential-determining reactions in this system are presented.

Although a considerable amount of work has been done on the oxidation and reduction of oxygen on a platinum electrode, certain areas still require close examination. Some investigators (1-3) have detected the presence of peroxide intermediates in this system while others have not (4). From the work of Bockris and Huq (2) it appears that the presence of impurities may alter the behavior of this system. It is interesting to note that a platinum oxide electrode prepared by an anodizing process differs in electrochemical properties from one made in air (4-6).

A sizable barrier in the determination of the metal-metal oxide equilibrium potentials is the difficulty with which these relatively unstable oxides can be prepared (7). The dry oxides have different compositions than the hydrated ones (8). If one prepared a given platinum oxide, mounted it on a platinum gauze, and immersed it in an acid solution, the final state would most likely be quite different from the initial. As a result, the recorded potentials are quite uncertain (9-11).

It is the purpose of this work to study the rest potential of a platinum electrode immersed in an oxygen-saturated sulfuric acid solution as a function of the partial pressure of oxygen, pH, and previous history of the electrode preparation in order to present evidence for the understanding of the nature of the potential-determining reactions in this system.

Experimental

The test electrodes were small beads (0.1-0.2 cm in diameter) of platinum (99.9+% pure) melted on the end of the metal wire in an oxygen torch. Platinum wire leads were spot-welded to the test electrode.

The test cell, shown in Fig. 1, was made of Teflon and is composed of two compartments connected through a fritted disk and held together with a clamp made of Lucite. Leakage of solution around the frit is prevented by the use of a polyethylene gasket. In physical appearance this cell is similar to one described before (12). The right-side compartment, in which the test electrodes are placed, contains a large platinum gauze counterelectrode held in place against the cell wall with a Teflon ring. In the left-side compartment, in which the reference electrode is placed, a large platinum gauze, which may be used as a counterelectrode, and a small platinum gauze, which may be used as a hydrogen reference electrode, are held against the cell wall by a Teflon ring. Through the tops of both sides of the cell pass gas-inlet and -outlet tubes made of Teflon. Also, Teflon tubes passing through each top are available through which the test and reference electrodes may be inserted into the cell. At the

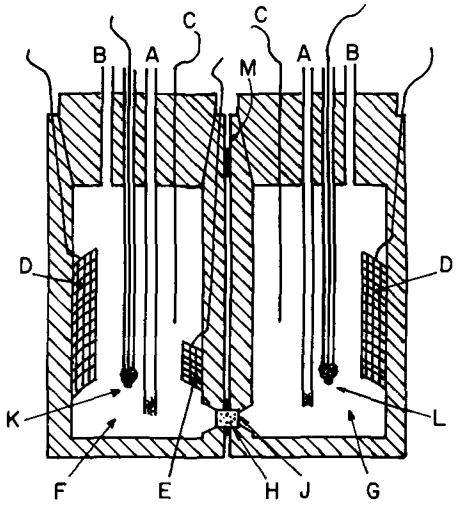

Fig. 1. Teflon dual cell. AA, gas inlet tubes; BB, gas outlet tubes; CC, pre-electrolysis electrodes, DD, large Pt-gauze counterelectrodes, E, small Pt-gauze electrode; F, left-side compartment; G, right-side compartment; H, polyethylene gasket; J, glass frit; K, α-palladium reference electrode; L, test electrode; M, spacer.

bottom of each inlet tube is placed a ball of platinum gauze to break the gas stream into fine bubbles. Finally, a small hole, through which a thin platinum wire may be inserted as a pre-electrolysis electrode, is made in each top.

The choice of a reference electrode system is a very important step in this investigation. The α-palladium-hydrogen (13, 14) reference electrode was chosen for the following reasons. Unfortunately, platinum-oxygen electrodes are neither reversible nor reproducible so that a Pt/O_2 electrode cannot be used in a manner similar to the Pt/H_2 electrode in the hydrogen overvoltage studies. Reference electrode systems such as the calomel and mercurous sulfate electrodes are undesirable because of the possibility of introducing chloride or mercury ions into the system. Another disadvantage with the calomel system is the presence of a junction potential. Finally, a platinum-hydrogen reference electrode is unsuitable because the dissolved hydrogen can pass through the frit and depolarize the oxygen electrode in the right-side compartment. The α-palladium reference electrode avoids these problems since it is reversible to hydrogen ions but independent of the partial pressure of hydrogen gas (14). Therefore, hydrogen gas need not be bubbled in the left-side compartment.

To make an α-palladium reference electrode, one proceeds as follows. A small bead (0.1-0.2 cm in diameter) is melted on the end of a palladium wire and a platinum lead wire is spot-welded to it. The bead is cleaned by heating it red-hot in a burning hydrogen jet and plunging the hot bead into concentrated nitric acid. This procedure is repeated about twenty times. Then the lead-wire and the bead are imbedded in virgin polyethylene so that the weld area is covered and only a hemisphere of the bead is exposed. After inserting the electrode through the Teflon tube in the cell top, it is sealed to the tube with molten polyethylene. The cell and the electrode are soaked in triply distilled water for 48 hr with frequent changes of water. After the test solution is added and after pre-electrolyzing against the auxiliary electrode for about 24 hr, purified hydrogen is bubbled through the solution until the potential of the bead has remained steady for 30 min at 50 mv against a Pt/H_2 electrode in the same solution. Then the hydrogen flow is stopped and the cell is sealed off to the atmosphere. In the absence of oxidizing agents, it has been shown that such an electrode will exhibit +50 mv *vs.* Pt/H_2 in the same solution for a week in a hydrogen atmosphere (15) and indefinitely in a helium atmosphere (16). It is very important that all three-phase contact between palladium, platinum, and solution be avoided, otherwise a local cell will be set up and a steady potential of 50 mv will not be observed (17).

All solutions were made from reagent grade chemicals and from triply distilled water obtained from an all-quartz still. The gases, H_2, N_2, and O_2, were purified in a standard multistage purification train containing heated copper turnings or copper oxide, silica gel, ascarite, heated palladium-on-asbestos, liquid nitrogen trap, and rotameter to monitor the gas flow. The partial pressure of oxygen was varied by diluting with nitrogen since the molecular weights are similar and the mixing of the gases would be facilitated thereby. The mixing was accomplished by connecting the outlets of the nitrogen and the oxygen trains by a "Y" tube and passing the gas through a coil of about 30 ft of tubing before entering the cell. The partial pressure was determined from the rotameter readings according to

$$(O_2 \text{ reading})/(O_2 + N_2 \text{ readings}) = P_{O_2}$$

Although this procedure involves a certain amount of error, consistent results have been obtained.

All electrodes were cleaned in the same manner as that just described for the palladium bead. The Teflon cell and the fritted disks were cleaned by soaking for 24 hr in concentrated HNO_3 and then rinsing in triply distilled water. After the cell had been assembled with the test electrodes mounted in the right side and the palladium bead in the left side, the cell was soaked in triply distilled water with frequent changes of water for at least 48 hr. Then the cell was filled half full (about 25 cc, total) with the test solution and the cell tops sealed in place with molten polyethylene. All the electrodes were tied together and pre-electrolyzed for at least 24 hr against the auxiliary platinum wire pre-electrolysis cathodes. Pre-electrolysis was stopped by removing the platinum wire cathodes and thus breaking the electrical circuit. Hydrogen gas was bubbled into the left side until the palladium bead showed a potential of +50 mv against a Pt/H_2 electrode in the same solution for at least 30 min. Then this side was sealed off to the atmosphere, and potential measurements on the oxygen electrode in the right side were made against the α-palladium electrode in the left side. It was found that the reference potential was invariant frequently for 48 hr and always so up to 24 hr. The reference potential decayed due to the diffusion of dissolved oxygen from the right side to the left side which depolarized the α-palladium electrode.

The pH of the solutions was varied by diluting the 2*N* H_2SO_4 solution with 2*N* Na_2SO_4 solution. At the end of an experiment, a saturated calomel electrode (S.C.E.) was placed in the cell, and the potential against at Pt/H_2 electrode in the same solution was determined. This value was compared to that for the stock solution which had been determined by a separate experiment, and the values agreed within 5 mv. By this measurement, the potentials can be recorded on the normal hydrogen scale (N.H.E.). *All potentials will be referred to N.H.E. unless otherwise noted.*

The temperature of all these experiments was 24° ± 1°C. Samples of solution can be removed from the cell by inserting the 4-in. needle of a hypodermic syringe into the gas exit tube. The potential was measured with a General Radio Electrometer, model number 1230-A, having a variable input impedance from 10^{14} to 10^{4} ohms.

Results and Discussion

Dependence of rest potential on presence of peroxide.—The potential of a platinum bead that was being anodized at about + 1.9v (*vs.* N.H.E.) in O_2-saturated 2*N* H_2SO_4 solution fell rapidly to about 1.5v after the circuit had been broken. Then the potential fell more or less slowly and regularly through a potential of 1.23v to a minimum value of about 850 mv in less than an hour, after which the potential became more noble again. Within three or four hours, the potential became steady at a value between +920 and +970 mv. A sample of the solution in the cell gave a positive test for peroxide with the $TiSO_4$ reagent (18).

Next, hydrogen gas was bubbled over the platinum bead for about 30 min so that the solution would become saturated with hydrogen. The potential fell to the hydrogen potential (—50 mv with respect to α-palladium). Then the H_2-stirring was replaced with O_2-stirring, and the potential rose rapidly to about +700 mv and more slowly afterwards. Within about 2 hr the potential had reached 1000 mv, and after about 20 hr the potential had become steady at a value between 1050 and 1080 mv. This potential remained steady for at least 24 more hours (further observation could not be made because the α-palladium potential began to decay due to O_2-diffusion into the left-side compartment). When the solution was tested with $TiSO_4$ reagent a negative test for peroxide was obtained.

With a hypodermic syringe, H_2O_2 solution was added to the cell until the sulfuric acid solution was about 4×10^{-6}M in H_2O_2. The potential dropped quickly to a steady value of about 825 mv.

These experiments indicate that the anodization of platinum in O_2-saturated solutions builds up the concentration of hydrogen peroxide which depresses the potential of the system as noted by Berl (19). If, however, the peroxide is removed by reaction with dissolved H_2, the potential can more nearly approach the reversible oxygen potential of 1.229v (11).

Dependence of rest potential on partial pressure of O_2.—In another set of experiments, the partial pressure of oxygen was varied in a system containing a platinum bead in oxygen-stirred acid solution which did not contain a detectable amount of peroxide. The data at three different mixed potentials corresponding to different stages of surface development are presented in Table IA in the sequence with which the experiments were performed. Each reading had been time independent for a duration of 10-20 min before being recorded. The data in rows 9, 10, and 11 show that the potential is independent of stirring which indicates that a potential-determining reaction free from diffusion control has been established. Since the potential is the same for various rotameter settings giving the same partial pressure of oxygen, *e.g.*, rows 2, 4, and 7, it seems that the method gives fairly consistent results.

Consider a general over-all apparent, potential-determining reaction involving oxygen, such as

$$O_2 + xX + ne^- = yYO \qquad [1]$$

where X is a substance such as H^+, n is the number of electrons transferred in the over-all reaction, YO is a substance such as H_2O, and x and y are stoichiometric coefficients. The Nernst relationship for this reaction is

$$E = E_o' + (RT/n\mathbf{F}) \ln [a_X^x P_{O_2}/a_{YO}^y] \qquad [2]$$

If only P_{O_2} is varied, then the activity terms may be combined with E_o' to give an expression for E as a function of P_{O_2}

$$E = E_o + (0.059/n) \log P_{O_2} \text{ (at 25°C)} \qquad [3]$$

E_o is the value of E when $P_{O_2} = 1$ so that n may be estimated from the data in Table I and is given in the last column of Table I. From the data in Table

Table I. Dependence of the rest potential of a platinum bead electrode on the partial pressure of oxygen gas in 2*N* sulfuric acid

$n = 0.059 \log P_{O_2}/(E - E_o)$

* The rotameter calibration curves are fairly linear from a reading of 3.0 corresponding to 95 cc/min to a reading of 13.0 corresponding to 600 cc/min.

IA, it seems that the apparent potential-determining reaction is one involving the transfer of 4 electrons. Because the values of n average about 16% higher, it would indicate that the method is more precise than accurate due to the errors in determining P_{O_2} and the inability to read the potential to better than one part in a thousand. Furthermore an uncertainty of $\pm$ 1 mv in $E - E_o$ indicates an uncertainty of 25%-10% in n. However, these data certainly favor the suggestion that the potential-determining reaction is one such as

$$O_2 + 4H^+ + 4e^- = 2H_2O \qquad [4]$$

In Table IB are recorded the potential-oxygen pressure data obtained on the system in which a detectable amount of H_2O_2 had accumulated in the electrolyte due to the anodization of the electrodes. By treating these data as before the estimated value for n is much lower than that in Table IA. The data in Table IC were found for the system in which the electrolyte was made 4×10^{-6}M in H_2O_2. Here the value for n is very close to 2 and leads to the suggestion that, as the H_2O_2 concentration increases the rest potential becomes increasingly determined by a 2-electron reaction such as

$$O_2 + 2H^+ + 2e^- = H_2O_2 \qquad [5]$$

It is to be noted that the potential falls as the H_2O_2 concentration increases towards the E_o value for Eq. [5] of + 682 mv (referred to N.H.E.).

The platinum-platinum oxide couples.—Another series of experiments was carried out in which purified nitrogen was used to stir the system after the potential had become steady in oxygen-stirred 2N sulfuric acid at 1045 mv. After about 2 hr of N_2-stirring, the potential became quite constant at 875 mv. As soon as O_2-stirring replaced the N_2 the potential returned to 1027 mv in about 2 hr. This procedure was repeated many times on different samples of platinum; the potential always came to a steady value between 870 and 890 mv with N_2-stirring.

El Wakkad (20) reports that the potential of a Pt/PtO couple is about 0.88v in acid solution. This corresponds to the point on the potential-time curves where oxide-formation first appears when a previously cathodized platinum electrode is anodized in acid solution (21-23). However, Latimer (11) and others (24) report a value of 0.98v for a $Pt/Pt(OH)_2$ couple in acid solution which is based on thermochemical data obtained from a chemically prepared compound. Since the chemically prepared $Pt(OH)_2$ may very likely be different from the hydrated PtO on the platinum electrode surface, the value of 0.98v for the Pt/PtO couple may be questionable. Coulometric determinations (4, 21, 22) of the quantity of oxygen existing on a platinum electrode anodized to the point of oxygen evolution in acid solution show that the platinum surface is covered with an oxide monolayer corresponding to PtO (23). Since this oxide layer is an electronic conductor (22), additional layers can be formed only under extreme conditions (25).

It is suggested, then, that the potential-determining reaction established at the platinum electrode in N_2-stirred 2N H_2SO_4 solution is most likely

$$PtO^* + 2H^+ + 2e^- = Pt + H_2O \qquad [6]$$

where the symbols PtO* and H^+ refer to the hydrated oxide on the platinum surface and to the hydrated proton in solution, respectively. In view of the data presented here, a potential value of 0.88v is favored for the equilibrium potential of Eq. [6]. It is believed that PtO* is not a formal oxide but is more akin to an adsorbed layer of oxygen, Pt-O. Platinum atoms do not seem to be pulled out of the lattice since the anodized Pt-bead is still bright and smooth. It may be, then, that there is really only one true oxide of platinum, PtO_2.

It has been reported (4) that the oxide film on anodized platinum electrodes contains a high percentage of PtO_2 and that the equilibrium potential for a $PtO_2/Pt(OH)_2$ is about 1.1v (11). When a platinum electrode is anodized, peroxide is accumulated in the electrolyte which interferes with the potential measurements, and, when the solution is stirred with hydrogen to remove the peroxide, the oxides on the platinum surfaces are removed as well.

To investigate the influence of PtO_2 on the potential the following experiment was devised. Two identical Teflon cells were used. In the first cell only the 2N H_2SO_4 solution was pre-electrolyzed, and in the second the test electrodes were pre-electrolyzed in the same solution. After the pre-electrolysis procedure was finished, hydrogen was bubbled into the first cell for 30 min to destroy any peroxide present. Afterward, the hydrogen was replaced with oxygen. When the electrolyte was saturated with O_2 (after 30 min), the electrodes were transferred from the second cell to the first. Potential measurements were taken. The potential fell from an initial value of about 1500 mv to about 935 mv in about 15 min and then became more noble again. Finally, it came to a value of 987 mv which remained steady for an observed 3-hr period. When the O_2-stirring was replaced by H_2 for 15 min and then resumed, the potential rose rapidly from the hydrogen potential (—50 mv *vs.* α-palladium) to + 1016 mv in about 45 min. These data indicate that the presence of PtO_2 causes a significant depression of the rest potential of a platinum bead in O_2-stirred acid solution.

The reason why a potential of 1.229v cannot be reached in the platinum-oxygen-acid system is the fact that the 4-electron reaction, Eq. [4], does not take place on a pure platinum surface but on a PtO surface. One can visualize the 4-electron process occurring at certain sites on the oxide covered platinum surface while at other sites the Pt/PtO couple, Eq. [6], occurs. Since the surface is an electronic conductor and therefore is an equipotential surface, these processes will proceed at the same mixed potential (26) due to the flow of the local cell current. The value of the mixed potential will be between about 0.88 and 1.23v; its exact position will depend on the relative polarization of the two

reactions. The flow of the local-cell current would be such that Eq. [4] would be cathodized and Eq. [6] would be anodized. From the experimental data, it appears that the 4-electron reaction proceeds on oxygen covered sites at a much faster rate than on bare sites, probably due to the relative strengths of the platinum-oxygen and platinum oxide-oxygen bonds. This may be seen from the following analysis.

Initially, after a platinum bead had been treated with hydrogen and then the H_2-stirring replaced by O_2-stirring, the surface had relatively few sites covered with oxygen. In this case, for a given local cell current, the current density for the 4-electron reaction occurring at covered sites is much higher than that for the Pt/PtO reaction occurring at uncovered sites and so the 4-electron reaction will be polarized to a greater extent. As a result, the mixed potential will have a value closer to 0.88v, as shown in Fig. 2(a). Because the local cell reaction is such that the Pt/PtO reaction is anodized, PtO will accumulate on the surface, providing more sites on which the 4-electron reaction can occur. Then the current density and, consequently, the polarization for this reaction decreases while the current density and polarization will increase for the Pt/PtO reaction. The mixed potential becomes more noble as shown in Fig. 2(b). If this process continued, eventually the surface would be completely covered with PtO and now only the 4-electron reaction would occur. A potential of 1.23v would be observed since the PtO layer is an electronic conductor and inert to oxygen.

The fact that the 1.23-v potential is not observed suggests that the cathodic reaction of Eq. [6] continuously provides a supply of bare platinum sites. The system then comes to a steady state involving the anodic and cathodic reactions of Eq. [4] and [6] to a point where the relative steady-state current densities produce a steady-state mixed potential value between 1.05 and 1.08v as shown in Fig. 2(c).

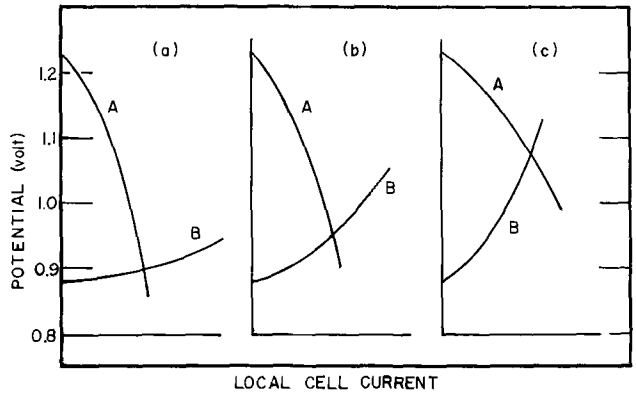

Fig. 2. Sketch of the polarization curves for the two component reactions of a local cell. The potential at the point where the curves cross is the mixed potential, and the current at that point is the total local cell current. Curve A is the polarization curve for the cathodic reaction, $O_2 + 4H^+ + 4e^- = 2H_2O$; curve B, that for the anodic reaction $Pt + H_2O = PtO + 2H^+ + 2e$. Vetter and Berndt (21) have estimated the local action current to be about 0.2×10^{-5} amp/cm^2 except that they attributed this current entirely to impurities. See text for (*a*), (*b*), and (*c*). Potential *vs.* N. H. E.

This means that under open-circuit conditions a certain number of platinum sites that are not covered with oxygen are always present.

The results of the following experiment support the suggestions presented in Fig. 2. Two platinum beads whose exposed geometric areas were nearly the same (0.019 and 0.022 cm^2) were placed side by side in oxygen-stirred acid solution after having been anodized previously. By chance the potentials were different, the one being 1066 mv and the other 911 mv. Then the system was stirred with hydrogen (240 cc/min) and by means of a Honeywell-Brown recorder the time required to reach the hydrogen potential (−50 mv *vs.* α-palladium) was determined for each bead simultaneously. The platinum bead, registering 1066 mv initially, required 450 sec while that registering 911 mv required 200 sec. This indicates that the more nearly the surface is covered with oxygen the more closely will the potential approach the equilibrium value of 1.229v.

A platinum wire was cleaned in a hydrogen flame, allowed to cool in air for 5 min, and then plunged into O_2-stirred acid solution with peroxide absent. The potential was initially 996 mv, but came to a steady value of 1060 mv within 15 min. This shows that the same type of oxide film is formed on platinum in air as by the adsorption of oxygen from acid solution. Also, the film must be nearly a complete monolayer thick because it required only 15 min to set up the steady state. This rapid establishment of a steady rest potential is to be compared with the slow rates observed in solution.

It seems strange that the mixed potential should become less noble when PtO_2 is present if the PtO_2/$Pt(OH)_2$ potential is 1.1v. Again one is justified in mistrusting a potential value derived from the data for chemically prepared $Pt(OH)_2$. In fact, it has been suggested (25) that the equilibrium potential of the PtO_2 electrode is closer to 0.8v. The experimental data seem to support this contention.

Attainment of the theoretical equilibrium-oxygen potential.—It seems, then, that the procedure including anodic pre-electrolysis followed by saturation of the electrolyte with hydrogen will produce a fairly reproducible platinum-oxygen electrode with a rest potential of 1.06 ± 0.01v. It appears, also, that the 1.23-v potential can never be observed because there are not any electronic conductors known that are inert to oxygen and, consequently, a mixed potential is always observed for practical oxygen systems.

Bockris and Huq (2) have reported that a rest potential with a value of 1.24v was established at a platinum electrode in oxygen-saturated acid solution after carrying out a careful purification procedure. However, they report further that this potential remained steady at the 1.24-v value for only 1 hr, after which the potential decayed rapidly to less noble values. It is interesting to note that the potential returned to a value of 1.24v for an additional hour after the purification procedure had been repeated. On consideration of these findings and in view of the work presented in this report,

it seems possible that the Bockris and Huq experimental procedure may have introduced a peroxide, a persulfate, or some other transitory substance that set up a fortuitous steady-state potential value close to the 1.229-v value.

Although the procedure of extrapolating the anodic and cathodic Tafel plots of oxygen overvoltage which have different slopes over such a long distance to the point of their crossing is dangerous, the value of 1.229v obtained (2, 27) at the crossing where the anodic and cathodic current densities are the same may not be as fortuitous as one may think. First of all, under pre-anodic polarization the surface is covered by a conducting monolayer of oxygen (22), and it seems that the over-all 4-electron reaction can proceed on this surface. It is noted that the Tafel lines were obtained at very low current densities, so that even on cathodic polarization the oxide layer would still be intact and any effect of Eq. [6] would not be present. Second, different Tafel slopes may mean that different steps of the same over-all reaction are rate-determining and not necessarily that different over-all reactions are operative. Therefore, by extrapolating the Tafel lines to their crossing point, it is possible to simulate a situation not possible to attain in practice, *i.e.*, the 4-electron reaction proceeding on a platinum electrode whose surface is covered by a stable, complete monolayer of oxygen. As mentioned above, this system should exhibit a potential of 1.229v because such a surface would be an electronic conductor inert to oxygen.

Dependence of rest potential on pH.—In a series of experiments in which a platinum bead was prepared as described above by using hydrogen stirring prior to oxygen stirring, the potential was determined as a function of pH. The data from three typical runs are presented in Table II. The composition of the solutions is given in the first column. The pH values recorded in Table II were obtained from tables in Lange's Handbook for Pt/H_2 *vs.* S.C.E. The potential values against both the α-palladium and N.H.E. for the case of O_2-stirring and for the case of N_2-stirring are presented. Since for all these reactions one electron is transferred for every H^+ ion involved, there should not be any difference in the potential with respect to α-palladium with changes in pH. As shown in Table II this was observed. However, the potentials *vs.* the N.H.E. should show a change of 59 mv per pH unit according to the Nernst relationship. In the last column of Table II for the N_2-stirred case, the ratio of the change in potential from that found in 2*N* H_2SO_4 to the corresponding change in pH is recorded. The agreement is quite good. Similar values are obtained in O_2-stirred solutions.

Table II. Dependence of the potential of a platinum bead electrode on pH

Solution composition	Potential of Pt/H_2 *vs.* S.C.E., mv	pH	Potential, mv O_2-stirred *vs.* α-Pd	O_2-stirred *vs.* N.H.E.	N_2-stirred *vs.* α-Pd	N_2-stirred *vs.* N.H.E.	ΔE/ΔpH
2*N* H_2SO_4	−246	0	1000	1046	830	876	—
0.1*N* H_2SO_4 + 2*N* Na_2SO_4	−345	1.7	1010	957	840	787	52
0.1*N* H_2SO_4 + 2*N* N_2SO_4	−408	2.7	1005	889	830	714	60

Polarization at low current densities.—By using the variable input impedance control on the General Radio electrometer, minute currents could be passed between the α-palladium reference electrode and the test electrode. Since the α-palladium electrode is quite reversible (13), since the electrolytes are highly conducting, and since the stirring-gas flow was between 200 and 300 cc/min, it is safe to assume that the measured polarization is due to that on the test electrode. The test electrode was cathodized in this setup. From the measured potential, the given input impedance, and the measured, exposed geometric area of the bead electrode, an apparent current density was estimated. These data are plotted in Fig. 3 with the difference between the open-circuit potential and the polarized potential, $E_{oc} - E$, as ordinate and the logarithm of the apparent current density as abscissa. Curve A shows the polarization of a platinum bead in O_2-stirred 2*N* H_2SO_4 solution in the absence of a detectable amount of peroxide; curve B, that in the presence of a detectable amount of peroxide; curve D, that for an anodized bead in O_2-stirred solution in the absence of peroxide; and curve C, that for the platinum bead in N_2-stirred solution in the absence of peroxide. The arrows on the curves show that these points could be reproduced within 2 mv going either up or down in current density. Curve C could not be reproduced in either direction due to an extremely large hysteresis, indicating that Eq. [6] proceeds with great difficulty. If this reaction is the main contributor to the formation of the surface film of PtO under open-circuit conditions rather than direct adsorption of dissolved O_2 molecules, it could explain the very great lengths of time (~10 or 12 hr) required to set up the steady state in O_2-stirred acid solutions.

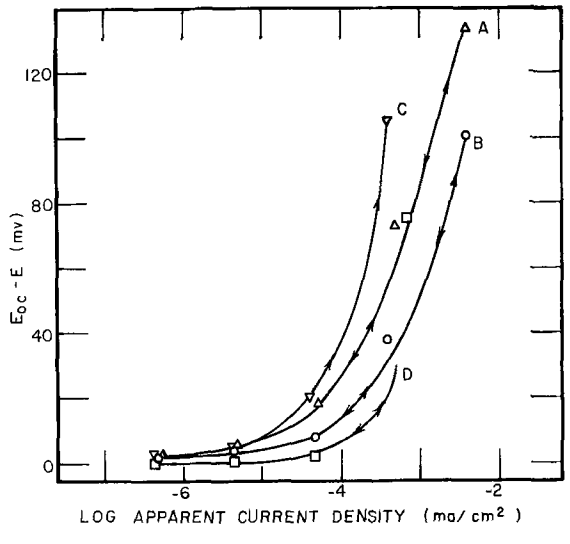

Fig. 3. Cathodic polarization data for Pt-O_2 system in absence of H_2O_2 (A), in presence of H_2O_2 (B), in N_2-stirring (C), and in presence of PtO_2 (D).

It will be noted that the polarization when peroxide is present is much less than when it is absent which agrees with the observations of Berl (19) that a good reversible oxygen electrode can be set up in peroxide solutions. This suggests that the O-O bond must be a very stable bond, so much so that if enough peroxide is present the 2-electron reaction, Eq. [5], becomes potential-determining as shown by the data in Table IC. In fact, this bond appears to be so strong that in the anodic process a certain concentration of peroxide must be built before oxygen can be evolved efficiently, since peroxide is always detected (1, 2, 23) in these cases. This may provide some justification for suggesting that direct adsorption of dissolved oxygen from solution under open-circuit conditions plays a minor role in forming the PtO film. It may be that the O-O bond is so strong that only adsorption at special high energy sites (the nature of which will not be defined) can provide energy enough to break it. The number of such sites would, of course, be few, indeed.

Apparently, from curve D, the presence of PtO_2 in the oxide film decreases the polarization. This may explain why some workers (4-6) find that a platinum electrode that has been anodized provides a more stable electrode in electroanalytical systems than one which has not. Besides, a certain amount of peroxide is formed under these conditions, and this will produce a much more reversible system also.

Effect of poisoning.—In order to test the effect of poisons on the platinum-oxygen-acid system, the following series of experiments was performed. In each case, a clean platinum bead in O_2-stirred 2*N* H_2SO_4 solution was the initial state. The cleanliness of the system was checked by observing the high pseudocapacitance (28) exhibited by a clean hydrogen electrode (29, 30) when H_2-stirring was used. This was done by cathodically polarizing the test electrode with an electronic current interrupter before the H_2-stirring was replaced by O_2-stirring. After the potential had come to a fairly steady value of 980 mv with O_2-stirring, it was polarized with a cathodic current density of about 0.5 μa/cm^2 by setting the input impedance of the electrometer at 10^8 ohms. This depressed the potential by 33 mv to 947 mv. Next, the platinum bead was removed from the cell, and only the bead was dipped in a weak solution of sodium arsenate. When it was replaced in the cell, it exhibited the same potential of 980 mv as before, even after about 45 min. Then the platinum bead was cathodized at 0.5 μa/cm^2 for about 15 min which caused a potential drop of 75 mv. After the polarizing circuit was broken, the potential returned directly to the original value of 980 mv. In a similar experiment, the platinum bead was poisoned by dipping it in a solution of carbon disulfide. In this case, the open-circuit potential dropped from the clean value of 985 mv to 855 mv. When this poisoned electrode was cathodized at 0.5 μa/cm^2, the potential was depressed 120 mv to 735 mv, but the potential returned to 853 mv when the circuit was broken. In a third experiment the bead was poisoned by touching the platinum bead with a finger. Here, the open-circuit potential rose to 1085 mv, and cathodic polarization at 0.5 μa/cm^2 dropped the potential by 202 mv. After opening the circuit the potential returned to 1085 mv. At the end of these experiments H_2-stirring was used, and the pseudocapacitance was observed again with the current interrupter. The pseudocapacitance, of course, was very low now in each case (29, 30).

As pointed out by Bockris and Huq (2) and as shown here, the presence of impurities can affect profoundly the kinetics and potentials in the platinum-oxygen-acid system. In the case of arsenic poisoning, it appears that the open-circuit potential is not significantly altered because arsenic is an electronic conductor. However, the kinetics are affected because As-O sites are poorer catalysts for the oxygen reaction than Pt-O sites. With carbon disulfide poisoning, apparently another electrochemical reaction is set up, and both rest potential and kinetics are affected. As for poisoning with grease, the system is completely changed, and coherent results are not obtained.

Summary and Conclusions

A platinum oxygen electrode in sulfuric acid with a reproducible potential of 1060 ± 15 mv *vs.* N.H.E. may be obtained by rigorous removal of impurities from the system and by anodic pre-electrolysis followed by saturation of the system with bubbling H_2 before the system is stirred with O_2. This procedure removed peroxides and higher oxides of platinum which depress the potential of the system. This final rest potential is reached very slowly (~10 to 12 hr) because atoms must be transferred across the double layer, *i.e.*, adsorption processes are involved. For these reasons this system is quite irreversible.

It is suggested that this rest potential is a mixed potential arising from the local cell composed of the reactions [4] and [6]. It is for this reason that the rest potential may never reach the theoretical equilibrium value of 1.229v for the 4-electron oxygen reaction. It seems that a value of 0.88v is a more realistic one than 0.98v for the potential of the Pt/PtO couple.

It appears that the O-O bond is so strong that the evolution of oxygen on anodic polarization of the platinum-oxygen-acid system is accompanied by an accumulation of H_2O_2 in the electrolyte. If enough peroxide is present the 2-electron oxygen reaction [5] becomes the potential-determining reaction. This system makes a good reversible oxygen electrode.

It is also suggested that the poor reproducibility of the rest potentials in the platinum-oxygen-acid system, noted in the literature, is due to the presence of uncontrolled amounts of H_2O_2, higher oxides of platinum, and organic and inorganic impurities. It may be the case that pre-anodized Pt/O_2 electrodes are more suitable in electroanalytical systems than those that are not pre-anodized because H_2O_2 and higher oxides of platinum are present.

When these substances are present the system becomes more reversible.

Acknowledgments

The author is indebted to Mr. C. F. Nixon, Head of the Electrochemistry Department, for his many helpful comments and for his continued interest in this work. He is also grateful to Dr. Paul Delahay, Dr. Raymond Thacker, and Dr. John L. Griffin for many interesting and fruitful discussions. The author is indebted to Mr. Sigmund Schuldiner of the Naval Research Laboratory, Washington, D. C., for his helpful suggestions in the preparation of the final manuscript.

Manuscript received Jan. 8, 1962; revised manuscript received May 14, 1962. This paper was prepared for delivery before the Los Angeles Meeting, May 6-10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Electrochemical Evidence for Diatomicity of Tellurium

S. A. Awad

Chemistry Department, University College of Cairo, Ain-Shams University, Heliopolis, Cairo, Egypt

ABSTRACT

Overpotential on tellurium cathodes was studied at 25°C in 0.005-0.5*N* $Ba(OH)_2$ and in 0.5*N* NH_4OH solutions. Results were explained on the basis of tellurium dissolution, giving Te_2^{--} ions. In 0.5*N* NH_4OH and in 0.005-0.01*N* $Ba(OH)_2$ solutions the discharge of cations governs the rate of dissolution. At higher concentrations of $Ba(OH)_2$, the electrochemical reaction, with two slopes in the linear logarithmic section, becomes rate determining. Unexpected values for the electron number, amounting to 2 and 4 for the discharge and electrochemical mechanisms, respectively, were obtained. A modified mechanism, based on the assumption that tellurium exists as diatomic molecules, Te_2, was proposed. The mechanism accounted satisfactorily for both Tafel slopes and the electron number values.

The overpotential phenomena on tellurium cathodes in HCl solutions (1) indicated that the reaction taking place at the cathode is hydrogen evolution. On the other hand, work in NaOH solutions (2) showed that tellurium dissolves cathodically giving telluride ions, Te_2^{--}. The results obtained in concentrated solutions indicated that the dissolution is controlled by a rate-determining simple electrochemical mechanism, with two Tafel slopes in the linear-logarithmic section. In dilute solutions the discharge reaction becomes rate determining, and Tafel lines with only one slope were obtained. From the *p*H effect on overpotential, it was found that the discharge reaction involves sodium ions.

The aim of the present investigation was to study the overpotential characteristics for tellurium in $Ba(OH)_2$ and NH_4OH solutions and compare the results with those obtained in NaOH solutions.

Experimental

The experimental technique was essentially the same as that of Bockris and co-workers (3). The electrolytic cell was constructed of arsenic-free glass and was similar to that used by Ammar and Awad (1). In order to minimize the diffusion of gaseous anodic products toward the cathode, a sin-

tered glass disk was inserted between the cathode compartment and the compartment used for electrolytic purification of solutions. Water-sealed taps and ground glass joints were used to retard the diffusion of atmospheric oxygen into the cell. Before each run the cell was cleaned with a mixture of A.R. nitric acid and A.R. sulfuric acid. This was followed by thorough washing with conductance water.

The electrode was prepared from tellurium rods[1] (7 mm diameter) containing no impurities as shown by a spectroscopic analysis. A thin tungsten wire was wrapped around one end of the rod. This end was squeezed inside a clean glass tube, and the glass was sealed over the tungsten wire. The electrode was then washed with conductance water and fitted in its position in the cell. Although the physical appearance of the electrode does not change during the course of the experiment, each electrode was used to trace one Tafel line only.

Barium and ammonium hydroxide solutions were prepared from A.R. grade chemicals. The solution was pre-electrolyzed at 10^{-3} — 10^{-2} amp/cm^2 for 24 hr on a platinum electrode. With these precautions, reproducible results (within ±5 mv) were obtained in all the solutions studied.

Cylinder hydrogen was purified from oxygen, carbon monoxide, and other impurities by passing it over hot copper (450°C), then over a mixture of MnO_2 and CuO (technically known as "Hopcalite") to oxidize CO to CO_2. CO_2 was removed by soda lime.

A saturated calomel electrode with a saturated KCl bridge was used as a reference electrode. The potential of the hydrogen electrode, in the same solution and at the same temperature as the test cathode, was measured against the calomel electrode making use of a salt bridge.

Both a direct method of measurement and the rapid technique described by Bockris (3) were used. The current density was calculated from the apparent surface areas. The current was measured with a multirange micromilliammeter and the potential by a valve potentiometer. The temperature was kept constant with the aid of an air thermostat controlled to ± 0.5°C.

Results

All results included in this investigation are the mean of six individual results which are reproducible among themselves to within ± 5 mv.

Figures 1 and 2 show the mean Tafel lines at 25°C, in 0.005, 0.01, 0.05, 0.1, and 0.5*N* aqueous barium hydroxide solutions and in 0.5*N* ammonium hydroxide solution. It is clear from these figures that in the ammonium hydroxide solution as well as in 0.005 and 0.01N barium hydroxide solutions Tafel lines with only one slope are obtained. In higher concentrations of barium hydroxide the Tafel lines indicate two slopes in the linear-logarithmic section. At comparatively low current densities, a region of stationary potential is observed in all solutions. It is to be observed that the overpotential values in these figures are referred to the reversible hydrogen electrode in order to exclude the possibility of a hydrogen evolution reaction (see below).

[1] Prepared by Johnson and Matthey, Ltd., London, England.

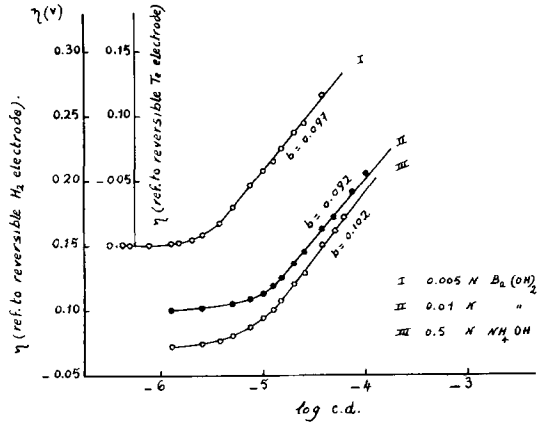

Fig. 1. Tafel lines for tellurium in 0.005 and 0.01*N* $Ba(OH)_2$ and 0.5*N* NH_4OH solutions.

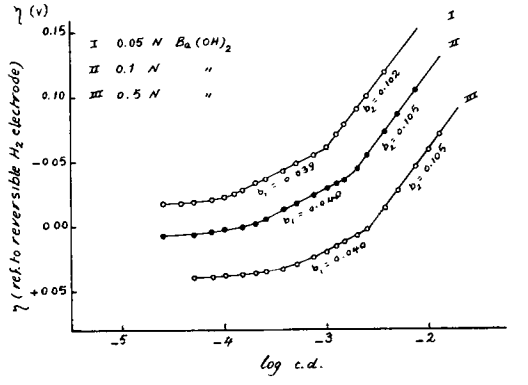

Fig. 2. Tafel lines for tellurium in 0.05, 0.1, and 0.5*N* $Ba(OH)_2$ solutions.

Table I contains the mean values of the slopes b_1 (at the low current density range) and b_2 (at the high current density range). The values of the stationary potentials, referred to the normal hydrogen electrode, for the various solutions studied are also included.

The values of the stationary potentials in the various solutions are considered as the reversible tellurium electrode potentials. To clarify this idea, an additional axis for overpotential in 0.005*N* $Ba(OH)_2$ is drawn in Fig. 1. The zero of this axis corresponds to the stationary potential in that solution. Treating similarly the other Tafel lines, overpotentials referred to the reversible tellurium electrode were calculated at 3.2 x 10^{-5}, 10^{-3}, and 3.2 x 10^{-3} amp/cm^2, and the values are given in Table II. This table contains also the values of $(\partial\eta/\partial\,\mathrm{pH})_i$, calculated for various solutions.

Table I. Slopes (b_1 and b_2) of the linear-logarithmic regions during cathodic polarization of tellurium

Solution	b_1	b_2	Stationary potential v *vs.* N.H.E.
0.005*N* $Ba(OH)_2$	—	97	—0.819
0.01*N* $Ba(OH)_2$	—	92	—0.800
0.05*N* $Ba(OH)_2$	39	102	—0.764
0.1*N* $Ba(OH)_2$	40	105	—0.748
0.5*N* $Ba(OH)_2$	40	105	—0.752
0.5*N* NH_4OH	—	102	—0.737

Table II. Overpotentials on tellurium electrodes and variation with solution pH

Solution	pH	Overpotential, mv *vs.* tellurium electrode at current densities: 3.2×10^{-5} amp/cm²	10^{-3} amp/cm²	3.2×10^{-3} amp/cm²	$(\partial\eta/\partial pH)_i$
0.005*N* $Ba(OH)_2$	11.38	110			
0.01*N* $Ba(OH)_2$	11.82	52	190*		132
0.05*N* $Ba(OH)_2$	12.68		46		167
0.1*N* $Ba(OH)_2$	12.78			68	
0.5*N* $Ba(OH)_2$	13.42			47	33

* This value was obtained by extrapolation.

The electron number λ, defined as the number of electrons necessary to complete one act of the rate-determining step, is calculated using

$$\lambda = -\frac{RT}{i_o F}\left(\partial i/\partial \eta\right)_{\eta \to 0} \qquad [1]$$

where i_o is the exchange current. For comparison, the calculation was extended to the results obtained previously in NaOH solutions (2). Figure 3 shows the relations between η and the current density at very low cathodic polarizations in 0.01 and 0.5*N* $Ba(OH)_2$, as well as in 0.5*N* NH_4OH solutions. The corresponding relations for 0.01 and 0.5*N* NaOH are shown in Fig. 4. The slopes of these linear relations, the exchange currents, and the values of λ in NH_4OH and $Ba(OH)_2$ solutions are given in Table III, whereas those for NaOH solutions are given in Table IV.

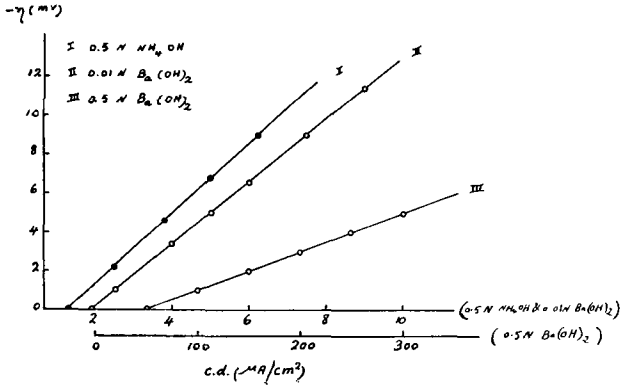

Fig. 3. Relation between overpotential and current density at low cathodic polarization in $Ba(OH)_2$ and NH_4OH solutions.

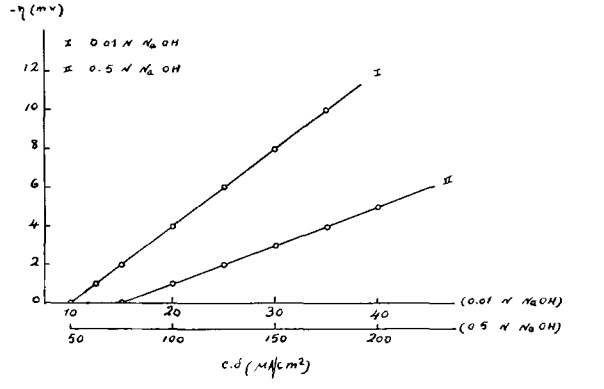

Fig. 4. Relation between overpotential and current density at low cathodic polarization in NaOH solutions.

Table III. Electrochemical parameters for cathodic polarization of tellurium in NH_4OH and $Ba(OH)_2$ solutions

Solution	i_o, amp/cm²	$-(\partial\eta/\partial i)_{\eta \to 0}$, v/amp/cm²	λ*
0.5*N* NH_4OH	6.8×10^{-6}	18×10^2	2.1

* Values of λ are given to the nearest first decimal figure.

Discussion[2]

The overpotential results on tellurium in barium hydroxide solutions are similar to those obtained in the corresponding solutions of sodium hydroxide (2). Thus, in 0.005-0.01*N* solutions, the Tafel lines exhibit one slope in a linear-logarithmic section covering a range of about 100 mv. In concentrations above 0.01*N*, the Tafel lines show two slopes, and they are shifted toward the reversible hydrogen electrode potential. The results in the ammonium hydroxide solution show only one slope covering about 100 mv, although the solution was 0.5*N*. This is because NH_4OH solution contains but a slight amount of NH_4^+ ions (4), with the result that this solution has a pH value (11.3) comparable with that of the 0.005*N* $Ba(OH)_2$, with a pH of 11.38. Similar to the behavior in NaOH solutions (2), Tafel lines lying in the opposite side with respect to the reversible hydrogen electrode were observed (cf. Fig. 2). This phenomenon indicates that the cathode reaction is not hydrogen evolution, and actual evolution of hydrogen has not been observed even at the higher current densities. The cathodic reaction is, therefore, considered to be the dissolution of the electrode material.

The dissolution of tellurium in $Ba(OH)_2$ and NH_4OH solutions takes place according to

$$2Te + 2e \longrightarrow Te_2^{--} \qquad [2]$$

This suggestion is based on the following evidences: (i) The standard potential of the above reaction is −0.84v, while the values for the other possible reactions

$$2Te + 2e \longrightarrow Te^{--} \qquad [3]$$

and

$$Te + 2H_2O + 2e \longrightarrow H_2Te + 2\,OH^- \qquad [4]$$

[2] The European convention of sign of potential is used.

are −1.14 and −1.57, respectively (5). It is, therefore, easier for tellurium to dissolve as Te_2^{--}, since this reaction takes place at the least negative potential. (ii) The stationary potentials at which the Tafel lines become parallel to the log c.d. axis are within the range −0.737 to −0.819v (cf. Table I). These values represent the reversible potentials for the tellurium electrode and are within the order of magnitude of the Te/Te_2^{--} potential. (iii) The solutions of $Ba(OH)_2$ and NH_4OH turn red during polarization. This color is not due to simple telluride Te^{--} ions, but to polytellurides (6), the simplest of which is Te_2^{--}.

The overpotential results in $Ba(OH)_2$ and NH_4OH solutions cannot be attributed to a direct charge reaction as represented by Eq. [2], since the relation between current and potential ($\Delta\phi$) would be

$$i = 2FV = 2Fk \exp\left(-\frac{F\Delta\phi}{RT}\right) \qquad [5]$$

The Tafel line slope according to the above equation is 0.06v at 30°C, a value which was not observed in the present investigation. The cathodic dissolution of tellurium may, therefore, involve the discharge of the cations or water molecules with the result that intermediate tellurides are formed. According to the entities discharged, the following mechanisms are formulated

(*A*) $$Ba^{++} + Te + e \rightarrow BaTe^{+} \qquad [6]$$

$$BaTe^{+} + Te + e \rightarrow Te_2^{--} + Ba^{++} \qquad [7]$$

In case of NH_4OH the reaction is represented by

$$NH_4^{+} + Te + e \rightarrow HTe + NH_3 \qquad [8]$$

$$HTe + Te + e \rightarrow Te_2^{--} + H^{+} \qquad [9]$$

Concerning the case of $Ba(OH)_2$, the mechanism requires the permanent persistence of the positively charged intermediate telluride, $BaTe^{+}$. It may be improbable that this compound remains without discharge, whereas other Ba^{++} ions are being discharged. Therefore, the following modification is suggested

(*B*) $$Ba^{++} + Te + 2e \rightarrow BaTe \qquad [10]$$

$$BaTe + 3Te + 2e \rightarrow 2Te^{--} + Ba^{++} \qquad [11]$$

(*C*) If water molecules are involved in the discharge reaction, the mechanism is represented by

$$Te + H_2O + e \rightarrow HTe + HO^{-} \qquad [12]$$

$$HTe + Te + e \rightarrow Te_2^{--} + H^{+} \qquad [13]$$

The Tafel slope and the *p*H effect associated with a rate-determining discharge step or a rate-determining electrochemical reaction are calculated for the different mechanisms. The values obtained, together with the corresponding electron numbers, are given in Table V. In case of the electrochemical reaction the *pH* effect corresponds to the higher slope.

It is clear that the Tafel slopes associated with modification (*B*) are half the values obtained experimentally, and accordingly, this mechanism is excluded. Table II shows that in concentrated solutions

Table V. Parameters for proposed mechanisms of cathodic dissolution of tellurium

	Mechanism	Slope, mv	Electron No.	*p*H effect, mv
(*A*)	discharge	120	1	120
	electrochemical	40 & 120	2	0
(*B*)	discharge	60	2	60
	electrochemical	20 & 60	4	0
(*C*)	discharge	120	1	0
	electrochemical	40 & 120	2	0

of $Ba(OH)_2$ the overpotential increases but slightly with *p*H, perhaps due to slight variations in ξ with concentration. Below 0.05*N*, η increases appreciably with *p*H. These findings are consistent with mechanism (*A*) involving the discharge of Ba^{++} ions. From the Tafel slopes given in Table I, it is clear that the rate of dissolution of tellurium in 0.5-0.05*N* $Ba(OH)_2$ is governed by the rate of the electrochemical reaction. Below 0.05*N* $Ba(OH)_2$, as well as in the 0.5*N* NH_4OH solution, the discharge reaction becomes rate-determining.

Calculation of the electron number λ, with the hope of providing support for the above-accepted mechanism, was carried out from the relation between current and overpotential at low cathodic polarization. It was expected that a value of λ equal to unity would be obtained in dilute $Ba(OH)_2$ solutions, whereas the value "two," required by the electrochemical mechanism, would be obtained in concentrated solutions. However, Table III shows that λ is equal to 2 in 0.005-0.01*N* $Ba(OH)_2$, and in higher concentrations it is equal to 4. These values satisfy mechanism (*B*), which is refused since it requires lower Tafel slopes. Such contradiction between Tafel slopes and the electron number values made it necessary to calculate λ from the results in NaOH solutions (2). Table IV shows that, even when the cations are monovalent, similar values for λ are obtained in the corresponding concentration ranges; consequently the simple mechanism (as mechanism *A*) suggested for NaOH solutions is also not valid. It is obvious, therefore, that tellurium dissolves according to a certain general mechanism, independent of the nature of the alkaline solution, and involving 2 electrons in the discharge reaction and 2 more in the electrochemical step.

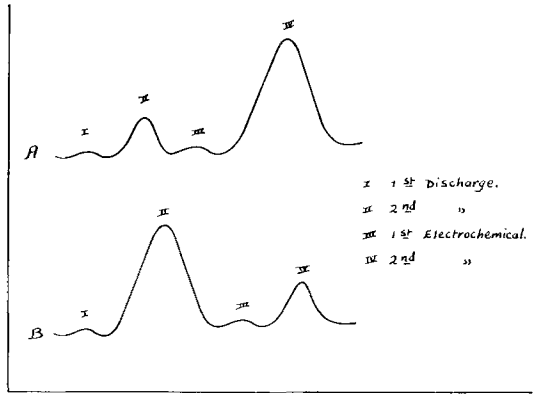

Fig. 5A. Energy barriers for the electrochemical mechanism; B, energy barriers for the discharge mechanism.

The observation that two electrons are involved in the discharge reaction, although the cations discharged are monovalent, necessitates the existence of tellurium in diatomic molecules, Te_2. Since the Tafel slope corresponds to one electron only, one has to assume that the discharge process takes place in two successive steps, the first of which is nearly potential independent and relatively faster than the second. This latter step governs, therefore, the rate of the over-all discharge reaction. Argument of the same type can be applied to the electrochemical reaction. The rate of dissolution of tellurium is, thus, controlled by either the second discharge step or the second electrochemical one. Figure 5 represents diagrammatically the energy barriers for the two mechanisms. Very low energy barriers are assigned to the first discharge and first electrochemical steps to indicate the assumption that these processes are not activation limited. In NaOH and NH_4OH solutions the new mechanism is represented by

Discharge reaction
$$M^+ + Te_2 + e \rightarrow M\,Te_2 \quad [14]$$
$$M^+ + M\,Te_2 + e \rightarrow M_2\,Te_2 \quad [15]$$

Ionization reaction
$$M_2\,Te_2 \rightarrow M\,Te_2 + M^+ + e \quad [16]$$
$$M\,Te_2 \rightarrow Te_2 + M^+ + e \quad [17]$$

Electrochemical reaction
$$M_2\,Te_2 + Te_2 + e \rightarrow M_2\,Te_4^- \quad [18]$$
$$M_2\,Te_4^- + e \rightarrow 2M^+ + 2Te_2^{--} \quad [19]$$

Another fundamental assumption is made that reactions [14] and [18] are reversible, with the result that the areas covered with $M\,Te_2$ and $M_2\,Te_4^-$ always remain small. Accordingly, the surface coverage x is due essentially to the persistence of $M_2\,Te_2$ formed according to Eq. [15].

The velocity of reaction [15] is given by

$$V_1 = k_1\,(a_{MTe_2})(a_{M^+})_{d.l.}\exp\left(-\frac{F\Delta\phi}{2RT}\right) \quad [20]$$

where (a_{MTe_2}) is the activity of $M\,Te_2$. Since the rate of formation of this compound is proportional to $(a_{M^+})_{d.l.}\,(1-x)$, then

$$V_1 = k_1'\,(1-x)\,(a_{M^+})^2_{d.l.}\exp\left(-\frac{F\Delta\phi}{2RT}\right) = a_1\,(1-x) \quad [21]$$

The ionization reaction rate, according to Eq. [16], is

$$V_2 = k_2'\,x_{10^{-9}}\exp\left(\frac{F\Delta\phi}{2RT}\right) = a_2\,x \quad [22]$$

The rate of the electrochemical reaction [19] is

$$V_3 = k_3\,(a_{M_2Te_4^-})\exp\left(-\frac{F\Delta\phi}{2RT}\right) \quad [23]$$

where $(a_{M_2Te_4^-})$ is the activity of $M_2Te_4^-$. Since the rate of formation of the latter intermediate is proportional to x, the electrochemical reaction rate is given the value

$$V_3 = k_3'\,x\,10^{-9}\exp\left(-\frac{F\Delta\phi}{2RT}\right) = a_3\,x \quad [24]$$

At the steady state corresponding to a constant coverage, current, and potential

$$V_1 - V_2 - V_3 = 0 \quad [25]$$

If the second electrochemical reaction is the slowest step, (cf. Fig. 5A), then it governs the dissolution of tellurium under the condition (7)

$$(a_1 + a_2) > 10\,a_3 \quad [26]$$

From Eq. [21], [22], [24], [25], and [26], the surface coverage becomes

$$x = \frac{a_1}{a_1 + a_2} \quad [27]$$

At low current densities a_1 is much smaller than a_2 and so x equals a_1/a_2. The net cathodic current is given by

$$i = 4FV_3 = 4F\frac{k_3'\,k_1'}{k_2'}\,(a_{M^+})^2_{d.l.}\exp\left(\frac{3F\Delta\phi}{2RT}\right) \quad [28]$$

With increase of cathodic polarization, x approaches unity since a_2 becomes much smaller than a_1, and accordingly the net cathodic current is given the value

$$i = 4FV_3 = 4Fk_3'\,10^{-9}\exp\left(-\frac{F\Delta\phi}{2RT}\right) \quad [29]$$

The Tafel line slopes at 30°C are, therefore, 0.04 and 0.12v at the low- and high-current density ranges, respectively.

When the dissolution is governed by the second discharge reaction (cf. Fig. 5B), x is equal to a_1/a_3, and the current is represented by:

$$i = 4FV_3 = 4Fa_1 = 4Fk_1'\,(a_{M^+})^2_{d.l.}\exp\left(-\frac{F\Delta\phi}{2RT}\right) \quad [30]$$

indicating that the Tafel line slope is 0.12v at 30°C.

The above discussion shows that this complex mechanism is in good agreement with the experimental Tafel slopes as well as the electron number values. The contradiction between these two parameters is eliminated by assuming that the first discharge and the first electrochemical steps (cf. Eq. [14] and [18]) are potential independent; and so the potential dependent steps involve one electron each.

In case of polyvalent cations, the mechanism is represented by

$$M^{z+} + Te_2 + e \rightarrow MTe_2^{(z-1)+} \quad [31]$$
$$MTe_2^{(z-1)+} + e \rightarrow MTe_2^{(z-2)+} \quad [32]$$
$$MTe_2^{(z-2)+} + Te_2 + e \rightarrow MTe_4^{(z-3)+} \quad [33]$$
$$MTe_4^{(z-3)+} + e \rightarrow M^{z+} + 2Te_2^{--} \quad [34]$$

It is to be mentioned that, instead of Eq. [2], the cathodic dissolution of tellurium can be represented by

$$2Te_2 + 4e \rightarrow 2Te_2^{--} \quad [35]$$

The latter equation satisfies the molecular nature of tellurium concluded from its electrochemical behavior in alkaline solutions.

Technical Notes

Electroluminescence Emission Spectra of ZnS Single Crystals

E. Alexander and I. T. Steinberger

Department of Physics, The Hebrew University of Jerusalem, Israel

According to the Schön-Klasens model (1, 2) for the luminescence centers in Cu-activated zinc sulfide, the "blue" and "green" emission bands are due to recombination at two different hole-traps, the "blue" and "green" centers. Electroluminescence (EL) excitation is usually interpreted in the framework of this model by impact-ionization of the luminescence centers with accelerated conduction-band electrons (3).

In recent papers objections were raised both to the Schön-Klasens model and to the impact-ionization theory of EL excitation (4-6). As a contribution to this discussion, experiments on the voltage dependence of the EL emission spectra of ZnS are reported here.

It is possible to draw conclusions from the voltage dependence of the emission on the possible mechanism of EL excitation only if the voltage dependence of the light intensity is determined mainly by the rate of ionization of luminescence centers and not if it is masked by other voltage-dependent processes (*e.g.*, the sweeping out of liberated electrons by the field, or the supply of free electrons for the recombination process itself). Experimental evidence (7, 8) indicates that for single crystals and high audio frequencies this condition is satisfied. It seems reasonable to assume the same for powders, but an experimental proof is difficult to obtain. For this reason, single crystals were used in this study.

Crystals No. 1 and 2 were obtained through the courtesy of Dr. A. Kremheller (then at Sylvania Laboratories) and they contained 0.04% by weight of Cu and about 0.001% Al. The Mn, Cr, Ni, Fe, and Ag contents, if any, were less than 1 ppm. The other crystals were grown in our laboratory using commercial ZnS powder ("High purity ZnS," obtained from the New Jersey Zinc Company) as a starting material. Crystal No. 3 was grown in an atmosphere of 10 cm Cl_2 in a sealed-off silica tube for 70 hr. The temperature in the region of the charge was kept at 1240°C. The crystals appeared in a region where the temperature was about 1150°C. A similar method was used for the growing of crystal No. 4 with the following differences: 0.1% by weight of $ZnCl_2$ was added to the starting material; the tube was evacuated and sealed; it was kept for 90 hr at a constant temperature (1240°C at the charge and about 1150°C at the region of condensation). Cooling down to room temperature took about 8 hr in both cases.

Crystals No. 3 and 4 were activated by embedding them in electroluminescent powder contained in a quartz tube which was subsequently evacuated, sealed off, and heated to 800°C. The tube with its contents was kept at this temperature for 1 hr. The electroluminescent ZnS powder used had been prepared according to the description of Zalm (9); it contained 0.1-1% copper and 0.01-0.1% aluminum. The activated crystals contained 0.01-0.1% copper, and their aluminum content was about 0.001%. Again, the Mn, Cr, Ni, Fe, and Ag contents, if any, were less than 1 ppm. These impurity contents were determined by semiquantitative spectroscopic analysis.

The crystals were plate-shaped, their thickness ranging from 0.4 to 0.8 mm. The other dimensions of the crystals were of the order of millimeters. Under the polarizing microscope faintly colored high-order birefringent bands were observed. X-ray investigation showed that the crystals were cubic, but contained stacking defects. The (111) cubic axis was parallel to the faces of the platelets. The applied electric field was perpendicular to the face of the platelets. Electrical contacts were established by the application of indium amalgam. Experiments were performed at room temperature.

A Bausch and Lomb grating monochromator type 33-86-40 served as a spectrometer, in conjunction with a photomultiplier (generally E.M.I. type 9502S, but for crystal No. 1 a 1P21 tube was used). The spectral response of the 9502S tube was determined by using the monochromator, a tungsten ribbon lamp, and a calibrated BMV 31 photocell.

The determination of the spectral distribution was least reliable at the long-wavelength tail of the green band, where the sensitivity of the 9502S tube is only about 20% of its maximum. A synchronous motor driving the monochromator drum, a d-c amplifier, and a recorder completed the apparatus. Under alternating voltages, time averages of EL brightness were measured.

The EL emission of each crystal was determined for at least two audio frequencies and a series of voltages for each frequency. When an appreciable d-c EL was found (crystal No. 3), the d-c EL spectrum was also investigated as a function of applied voltage. For a given crystal and frequency the spectral distributions at different voltages were very similar, the main change being a slight displacement of the whole spectrum toward shorter wavelengths with increasing voltage. This displacement was of the order of 10^{-2} mμ/v.

For the quantitative evaluation of the voltage dependence, the following procedure was adopted. The spectra obtained from the photomultiplier-amplifier-recorder combination were corrected for the spectral response of the photomultiplier. Subsequently, $P(\tilde{\nu})$ *vs.* $\tilde{\nu}$ was plotted, where $P(\tilde{\nu})$ represents the radiant flux per unit wave number. In case of crystals No. 1 and 2 the spectral distribution could be represented unambiguously by the sum of two Gaussian bands

$$P(\tilde{\nu}) = P_1 \exp\left[-\frac{(\tilde{\nu}-\tilde{\nu}_1)^2}{1.44\,h_1^2}\right] + P_2 \exp\left[-\frac{(\tilde{\nu}-\tilde{\nu}_2)^2}{1.44\,h_2^2}\right]$$

Here P_1, P_2, h_1, and h_2 are constants and $\tilde{\nu}_1$, $\tilde{\nu}_2$ are the wave numbers of the blue and green band centers, respectively. For a given crystal, $\tilde{\nu}_1$ and $\tilde{\nu}_2$ were found to be almost independent of voltage and frequency. Figure 1 represents log $D(\lambda_1)$ and $D(\lambda_2)$ as a function of $V^{-1/2}$ for crystal No. 1 at 500 cps. (Here $\lambda_1 = \frac{1}{\tilde{\nu}_1}$ $\lambda_2 = \frac{1}{\tilde{\nu}_2}$, and D represents the deflection on the original records.) The graphs are parallel straight lines except at the region of the highest voltages applied, where the blue peak increases somewhat more steeply than the green one.

The EL emission spectra of crystals No. 3 and 4 could not be resolved into two Gaussian bands unambiguously. The corrected spectral distribution $P(\tilde{\nu})$ had a single peak in the blue region; the green band manifested itself by a strong asymmetry of $P(\tilde{\nu})$. $P(\tilde{\nu})$ fitted well a Gaussian for the large wave-number side of the peak. The center $\tilde{\nu}_1$ of this Gaussian was very near to $1/\lambda_1$, where λ_1 is the position of the single peak observed on the original records ($D(\lambda)$ *vs.* λ). On the other hand, the function

$$P^*(\tilde{\nu}) = P(\tilde{\nu}) - P_1 \exp\left[-\frac{(\tilde{\nu}-\tilde{\nu}_1)^2}{1.44\,h_1^2}\right]$$

was not another Gaussian. The voltage dependence of the spectral distribution was therefore evaluated as follows: $\tilde{\nu}_1$ was determined from the Gaussian plot for the blue band; $\tilde{\nu}_2$ was defined as the wave number corresponding to the peak $P^*(\tilde{\nu})$. Since it is not clear whether the value of $\tilde{\nu}_2$ thus chosen does represent the center of a single band, two wavelengths λ' and λ'' were defined as follows: $|\lambda'' - \lambda'| = 20$ mμ, $|\lambda'' - \lambda_2| \approx |\lambda_2 - \lambda'|$; here $\lambda_2 = 1/\tilde{\nu}_2$. For all voltages $\lambda_1 - \lambda'$ was kept constant even if λ_1 and λ_2 seemed to shift somewhat. Log $D(\lambda_1)$, log $D(\lambda')$, and log(λ'') were represented as functions of $V^{-1/2}$ (Fig. 2 for crystal No. 4 at 3 kc). It is seen that the lines are straight and parallel. In fact, the method of least squares yielded in this case the values $B_{\lambda_1} = 97.1$, $B_{\lambda'} = 97.1$, and $B_{\lambda''} = 95.5$v, calculated from $B = c \times \ln 10$, where c is the slope of the lines.

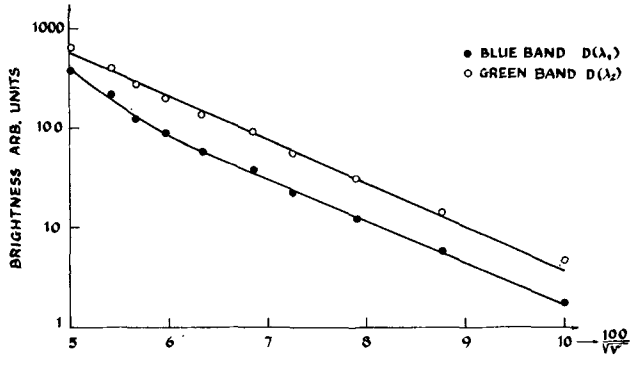

Fig. 1. Dependence of brightness at the band centers ($\lambda_1 = 458$ mμ $\lambda_2 = 521$ mμ) on voltage. Crystal No. 1, 5 kc.

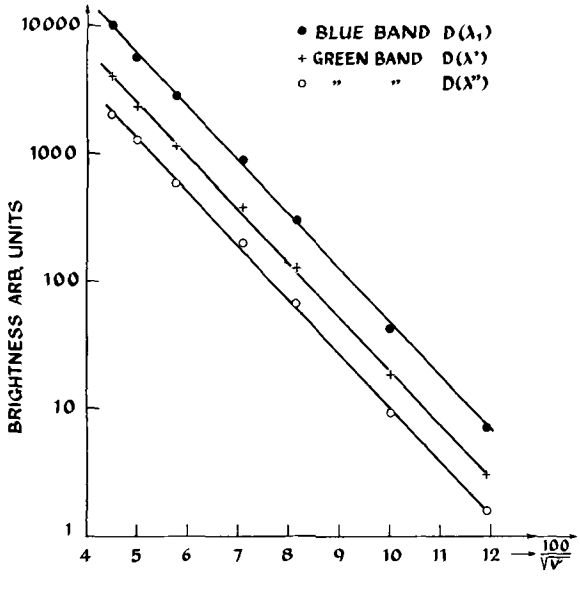

Fig. 2. Dependence of brightness at the center of the blue band ($\lambda_1 = 468$ mμ) and near the center of the green band (λ', λ'') on voltage. Crystal No. 4, 3 kc.

For all the crystals investigated, the spectral distribution was independent of voltage except for the small shift of the whole spectrum mentioned above. The same result was obtained by Mattler and Ceva (10) on electroluminescent ZnS:Cu phosphor powders. These facts have to be taken into account in any theory on EL excitation as they imply that the Schön-Klasens model of luminescence centers, and the theory of direct impact-ionization of the centers by accelerated electrons cannot be correct simultaneously. On these assumptions, the intensity of the blue emission should increase more steeply with voltage than that of the green one. Therefore, on the basis of the Schön-Klasens model one has either to discard impact-ionization altogether, or to assume that the impacts liberate valence-band electrons and not those in the different centers. If, however, future experiments and theory should further substantiate the direct impact-ionization theory, the Schön-Klasens model will have to be modified. Such a modification, which takes into account the results of Mattler and Ceva (10), was proposed by Curie (4).

Acknowledgment

The authors wish to thank Mrs. H. Jaffe, of the Weizmann Institute, Rehovoth, for performing the spectrochemical investigation of the crystals.

Two Unusual Effects in H_2-fired CaO:Mn,Li Phosphors

P. M. Jaffe

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

The stimulating and quenching action of infrared radiation on the luminescence of certain sulfide phosphors is well known (1, 2). Less well known are the stimulating and quenching effects due to higher-energy radiation, *i.e.*, x-rays, gamma rays, cathode rays, and ultraviolet (3-7). The phosphors that show these effects are "normal" phosphors in that no further treatment is necessary after phosphor preparation. That is, it is not necessary for them to be ground, crushed, surface-treated, etc. Kats (8) and Ewles and co-workers (9-11) have reported on luminescence effects in alkali-halide and alkaline-earth oxides due to grinding. The present work reports on two rather unusual effects with H_2-fired CaO:Mn, Li phosphors. The first effect is the production of a new blue emission due to the application of pressure (grinding, etc.). The second effect is a transient stimulation of the Mn emission by 3650Å only after previous excitation by 2537Å. The stimulation apparently only occurs in the phosphor which had previously been subjected to pressure. These two effects will be referred to as the pressure and stimulation effects, respectively. Stimulation is also obtained if ionizing radiation, *i.e.*, x-rays, is used in place of the 2537Å ultraviolet.

The experimental work to be described was obtained with CaO:Mn, Li phosphors, but similar effects were noted if the Li was replaced by Na or K.

Phosphors were prepared from Mallinckrodt's S.L. $CaCO_3$ and A.R. $MnCO_3$. Li, Na, and K were added as the respective carbonates and Al as the hydrated oxide. The Mn concentration was 0.1 atom % and that of Li, Na, K, or Al, 5 atom %. The samples were mixed as a slurry, dried at 110°C, and fired at 1050°C in Pt crucibles in a H_2 or N_2 atmosphere; samples fired in O_2 were similar to those fired in N_2. After firing the samples were well sintered.

The body color of the H_2-fired Mn-containing samples was white while the N_2-fired samples were light tan. This indicates that the valence state of Mn is probably +2 in the former samples and +3 or +4 in the latter.

The luminescent characteristics of the CaO:Mn, Li samples varied depending on the firing atmosphere. After H_2-firing, the samples as removed from the furnace, *i.e.*, no application of pressure (grinding, scratching or rubbing), showed an orange fluorescence and phosphorescence under 2537Å excitation and were dead under 3650Å irradiation. The results were the same regardless of the sequence of excitation. The application of pressure resulted in a new blue emission under 2537Å excitation. Now excitation by 2537Å resulted in a blue-white fluorescence (blue + orange). If, after 2537Å excitation, the sample was exposed to 3650Å radiation, there was a transitory orange emission. The N_2-fired samples, as removed from the furnace, were dead under both 2537Å and 3650Å. The application of pressure resulted only in the blue emission under 2537Å excitation and no stimulation.

In order to ascertain the relationship between the two effects and the presence of Li and/or Mn, samples of CaO:Mn and CaO:Li were prepared by firing in H_2 or N_2. The H_2-fired CaO:Mn samples had a white body color and were dead under 2537Å or 3650Å excitation. No pressure or stimulation effects

Table I. Characteristics of CaO phosphors containing Mn and/or Li

Additions	Firing atmosphere	Body color	Emission characteristics			
			2537Å		3650Å	
			Emission	Pressure effect	Emission	Stimulation effect
Mn	H_2	white	none	none	none	none
Mn, Li	H_2	white	orange	blue	none	orange
Mn	N_2	cream	orange	none	none	none
Mn, Li	N_2	cream	orange	blue	none	none
Li	H_2	white	none	blue	none	orange
Li	N_2	slightly off-white	orange	blue	none	none

were found. The N_2-fired samples had a weak orange fluorescence under 2537Å excitation and were dead under 3650Å. There were no pressure or stimulation effects. H_2-fired CaO:Li was dead under 2537Å or 3650Å excitation; weak pressure and stimulation effects were observed. N_2-fired CaO:Li had a weak orange fluorescence under 2537Å, but was dead under 3650Å. Only the pressure effect was observed. These data are summarized in Table I.

The emission spectra of the orange fluorescence from CaO:Mn with or without Li are the same and are independent of the firing atmosphere. The spectrum of the stimulated emission is the same as that for the fluorescence. The spectra of the blue fluorescence from CaO:Li are also the same independent of the presence or absence of Mn and the firing atmosphere. The orange and blue emission spectra are shown in Fig. 1. The excitation spectra of the two emissions are different as shown in Fig. 2. Figure 3 shows the temperature dependence of both emissions. The temperature breakpoint of the red emission is at 300°-320°C and at or below 20°C for the blue.

Samples similar to those reported in Table I were prepared using Na, K, or Al in place of Li. The results for Na and K were similar to those obtained with Li additions and are reported in Table II. Samples with Al showed only the pressure effect.

The luminescence of SrO phosphors containing Li and Mn were also examined. After O_2 firing the samples had a deep brown body color. Under 2537Å excitation there was a weak white emission and under 3650Å excitation a deep red emission. There was no stimulation effect, but there may have been a weak pressure effect. After H_2-firing the body color was slightly off-white. Excitation by 2537Å or 3650Å resulted in yellow-green fluorescence and phosphorescence. The pressure and stimulation effects were present, but the stimulated emission was yellow-green.

Examination of the data in Tables I and II shows that the 2537Å excited orange emission is due to the presence of Mn. The blue emission induced by the application of pressure is apparently due to the presence of a monovalent or trivalent cation. Spectroscopic analysis of the CaO samples containing only added Li but having the stimulation effect shows the presence of 10-20 ppm Mn so that apparently the stimulation effect requires the presence of both Li and Mn. Further, all the Mn must be in a reduced state (+ 2?) as evidenced by the fact that only H_2-fired CaO:Mn, Li samples show the stimulation effect. From the data listed in Table I and the measurements mentioned above, the orange and blue emissions are apparently unrelated. However, there appears to be some energy transfer from blue to orange centers as shown by the 3650Å stimulated emission only occurring with samples also having the blue emission.

Mn, Al	H_2	white	none	?	none	none
Al	N_2	white	none	none	none	none
Mn, Al	N_2	white	none	none	none	none

A more detailed study of the two effects described here should be made in order to elucidate the nature of the energy levels and transitions responsible for the pressure and stimulation effects. Such a study might shed some light on the reason(s) for the decrease in light output in most phosphors on grinding.

Diffusion Doping of Phosphorus in the Base of Silicon Tunnel Diodes

C. L. Gravel and A. D. Kurtz

Kulite Semiconductor Products, Inc., Ridgefield, New Jersey

and I. Berman

Air Force Cambridge Research Laboratories, Bedford, Massachusetts

One of the problems raised in the process technology of silicon tunnel diodes is the limit of impurity doping obtainable in the crystal as grown, which for phosphorus is approximately $10^{20}/cm^3$. The doping levels attainable using solid-state diffusion techniques to form an n-type layer on the base material are higher, and variation of the thickness of the diffused layer affords a measure of design control over the electrical characteristics of the tunnel diode. This note presents the results of a study of the effect of phosphorus diffused layers into phosphorus doped silicon base material on the tunnel diode peak to valley current ratios and the magnitude of the peak currents obtained under various alloying conditions.

Experimental

To investigate the effect of diffused layers on tunnel diode characteristics, phosphorus doped silicon of resistivity, 0.001 ohm-cm was selected for the base material. Additional diffusion doping was obtained using an open-tube, two-zone furnace with phosphorus pentoxide as the impurity source, and diffusing at 1200°C for times of 4, 16, and 64 hr. Impurity concentration at the surface of the diffused layers was determined as $4 \times 10^{20}/cm^3$ using sheet resistivity measurements and the data of Backenstoss (1). Rectangular bars of length 0.150 in. and width 0.030 in. were cut from the diffused material and also the 0.001 ohm-cm nondiffused base silicon to be fabricated into tunnel diodes. The p-type region was formed by alloying a 0.005 in. aluminum wire containing 1.0% boron into the silicon bars, with a gold wire subsequently being bonded to the bar for an ohmic contact. The alloying range investigated was from 700° to 1000°C and to obtain the steep impurity gradients necessary between degen-

erate n- and degenerate p-materials a short alloying cycle of 2 min at temperature followed by a quench in air was used.

The electrical parameters studied as a function of the two variables, depth of diffused layer and temperature of alloying, were the maximum peak currents obtained and the maximum peak to valley current ratios obtained with progressive etching. To obtain the maximum peak to valley current ratio, each diode was etched for 2-sec intervals in a composition of equal parts hydrofluoric, nitric, and acetic acids until the maximum ratio was passed. Normally, 4-6 such etching intervals were required.

Results

Figure 1 is a plot of the average maximum peak to valley current ratio as a function of alloying temperature with the diffusion time as a running parameter. Each point is the average of data taken on approximately twelve tunnel diodes. The curves exhibit the general tendency of a diffused layer to depress the peak to valley current ratio with increasing depth of the layer. For simplicity the data for the 4-hr diffused layer is not plotted. However, the results fall between the no-diffusion and 16-hr diffusion curves as expected. The effect of the alloying temperature on the peak to valley current ratio indicates that optimum current ratios are obtained in the range 825°-925°C, a range of relative flatness common to all the curves. There is also a tendency for the curves to cross in the vicinity of 1000°C as the material with diffused layers enable the fabrication of tunnel diodes at higher temperatures. The appearance of a negative resistance region persists at higher alloying temperatures the deeper the diffused layer. At an alloying temperature of approximately 1050°C only reverse or backward diodes are obtained.

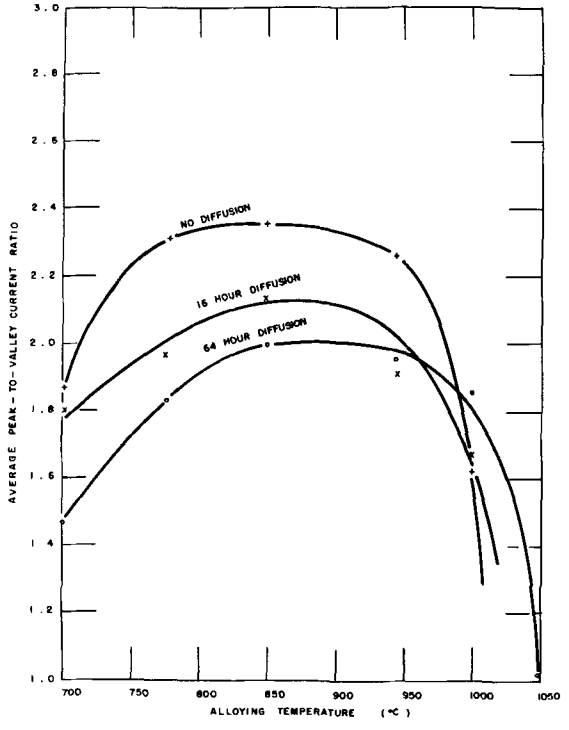

Fig. 1. Average maximum peak to valley current ratio as a function of alloying temperature.

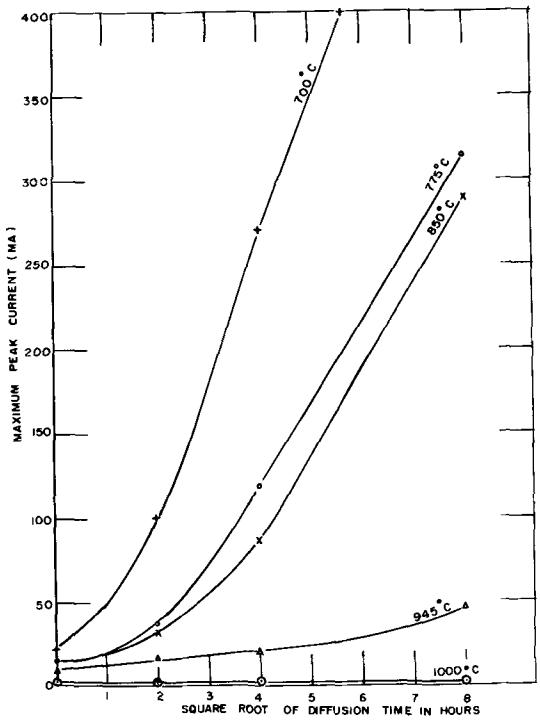

Fig. 2. Average maximum peak current vs. square root of the diffusion time.

Figure 2 is a plot of the average maximum peak current obtained against the square root of the time of diffusion, with the temperature of alloying as a running parameter. Since the increased peak currents resulting from diffused layers are presumed to come from a peripheral region around the alloyed junction, the total current should be proportional to the product of the diffused depth and the peripheral junction area. If it is assumed that the peripheral area remains essentially constant and the diffused depth, characterized by the complementary error function distribution, varies as the square root of the diffusion time, a plot of peak current *vs.* the square root of the diffusion time should be a straight line. The curves of Fig. 2 are reasonably straight lines with curvature appearing near the origin because of the 0.001 ohm-cm n-base material which is degenerate enough itself for tunneling current without having a diffused layer. As can also be seen from this plot the maximum peak current obtained is inversely proportional to the temperature of alloying.

Figure 3 is a plot of the average maximum peak current obtained against the temperature of alloying with the time of diffusion as a running parameter. The curves exhibit the general tendency to drop rapidly at the lower alloying temperatures, level out in the central range of 775°-875° where, incidentally, the maximum peak to valley current ratios are obtained, and then fall rapidly at the higher alloying temperatures. This behavior might be anticipated by considering two of the mechanisms which contribute to the tunneling current, the degree of degeneracy on the p-type side of the junction and the change in barrier width with alloying temperature. Tunneling theory indicates that the current through the barrier is given by the equation

$$I = A \int_{E_c}^{E_v} \{f_c(E) - f_v(E)\}\, Z\, P_c(E)\, P_v(E)\, dE$$

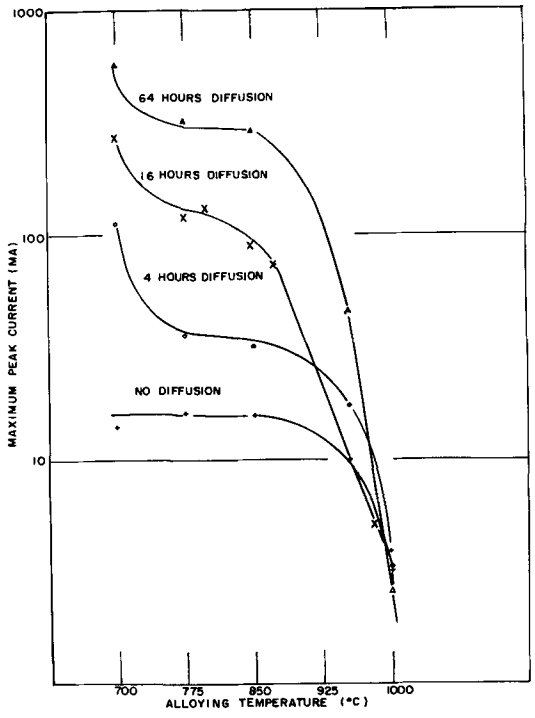

Fig. 3. Average maximum peak current vs. alloying temperature

where, $f_c(E)$ and $f_v(E)$ are the Fermi-Dirac distribution functions, $P_c(E)$ and $P_v(E)$ are the energy level densities in the conduction and valence bands, and Z is the probability of penetrating the barrier. The tunneling probability, Z, decreases exponentially with the width of the junction

$$Z \alpha \exp\{(-\beta m^{*1/2} Eg^{3/2})/F\}$$

where β is a constant, Eg is the energy gap, m^* is an effective mass, and F is the electric field in the junction. The maximum electric field for a step junction is

$$Fm = 2V/w$$

where V is the barrier voltage and w is the width of the junction. The junction width will increase with alloying temperature because of the increased diffusion of the doping impurities going from the liquid phase into the solid. Thus at higher alloying temperatures, 900°-1050°C, the increasing barrier width rapidly reduces the probability of tunneling, and the curves fall steeply to low current levels. At the lower alloying temperatures, 700°-775°C, the barrier width is small enough to permit the large peak currents observed, although the solubility of boron in silicon is smaller at these alloying temperatures. As the alloying temperature is increased to the intermediate range of 775°-900°C, a region of relative flatness in the curves of Fig. 3, the greater boron solubility in silicon increases the degeneracy on the p-type side of the junction. The higher p-type degeneracy increases the energy levels available for tunneling of electrons across the barrier and also decreases the extension of the junction into the p-type side of the junction as this extension is inversely proportional to the square root of the doping level. These two contributions toward an increased tunneling current counteract the reducing effect on the tunneling probability of the barrier width widening with alloying temperature.

Considerable care was taken to obtain reproducibility in the fabrication of the diodes; nevertheless, inhomogeneities in the aluminum-boron wire and the inherent difficulties of reproducibility in an alloying process and the subsequent measurement of structure-sensitive properties introduce scatter in the data. The mean deviation of the data is indicated for each point of Fig. 3.

Summary

Phosphorus diffused layers into phosphorus doped bulk silicon of resistivity 0.001 ohm-cm tend to increase the peak current of alloyed tunnel diodes by as much as an order of magnitude. At a given alloying temperature the maximum peak tunneling current is reasonably proportional to the depth of the diffused layer and decreases inversely with temperature of alloying.

Some negative resistance is observable throughout an alloying temperature range of 675°-1050°C, with the optimum peak to valley current ratios obtained between 825° and 925°C. The optimum temperature range shifts slightly higher with increasing depth of the diffused layer.

The presence of a diffused layer tends to depress the peak to valley current ratios by upwards of 20% when compared with diodes made with the identical nondiffused base material.

Undamaged Germanium Surfaces of High Optical Quality

T. M. Donovan and B. O. Seraphin

Michelson Laboratory, China Lake, California

By established mechanical polishing methods, germanium mirrors of suitable optical quality can be prepared. However, the mechanical action of the abrasive is known to introduce surface damage which affects the electrical properties of the semiconductor (1). Whenever this damage cannot be tolerated, as in most device applications, it is removed by etching. The etching operation removes the disturbed material and restores the electrical properties of the surface. Unfortunately, however, the etching operation degrades the optical finish of the surface at the same time (2).

With the development of epitaxial and other advanced semiconductor devices there is a need for flat and smooth substrate surfaces with unimpaired electrical properties. Sullivan (3, 4) developed an electrochemical technique which yields undamaged surfaces of 2.5 μ/in. flatness and an average roughness of 25Å. Related values for fused quartz optical flats are approximately 0.05 μ/in. and 10Å.

The present paper reports on a modification of Sullivan's technique which yields surfaces of about 0.1 μ/in. flatness and a rms roughness of only 10-13Å, approaching the finish of the best fused quartz optical flats. At the same time it shows by means of electron diffraction, surface recombination velocity, and field-effect measurements that these surfaces approach structurally and electrically surfaces that had been etched in CP-4.

Polishing Procedure

The material used for this study was 30 ohm-cm n- and p-type single crystal germanium. Two faces of the sample were lapped plane parallel, and electrical contact was made to one face using electroless nickel (5). The opposite face was polished[1], diamond paste with an average particle diameter of ¼μ being used for the final stage. The surface obtained at this stage will be referred to as the mechanically polished surface. It appeared scratch free at 30X magnification.

Two types of samples were used. Thick samples (25 x 9 x 9 mm) were mounted in a micarta cage. Thin samples (16 x 9 x 0.25 mm) were fixed to a nylon pressure plate. In both cases provisions were made to bring electrical contact from the samples to the top of the pressure plate. The sample was then made the anode in an electrolytic cell with a cloth covered polishing wheel as rotating cathode. A dilute solution of KOH made by dissolving KOH in polishing fluid was used as electrolyte and was made to flow drop-wise onto the polishing cloth at rates up to 25 ml/min.

[1] The following polishing materials were obtained from Buehler, Ltd., 2120 Greenwood St., Evanston, Ill.: Microcloth, Cat. No. 1576; Metadi Fluid, Cat. No. 1542-2SS; Polishing Compound, Cat. No. 1544-AB.

During the course of the electropolishing experiments it was found that a fresh polishing cloth would not give a scratch-free surface. By dissolving the KOH in polishing fluid so the samples would "ride" on a laminar layer of sufficient viscosity, and by using a cloth that had been broken in during a previous mechanical polishing stage it was possible to obtain a scratch-free surface. It was determined in etching rate experiments that there was no measurable sample weight loss, as determined with an analytical balance, following the above procedure without current flow.

Current densities up to 10 ma/in.^{2} have been used effectively with both n- and p-type germanium. At this current density an etching rate of 0.03 μ/min was obtained. This unusually small current density and the related low etching rate, which are about 50 times smaller than ordinarily used in electropolishing techniques for germanium and silicon, might partially account for the low roughness figure. Current density values up 10 ma/in.^{2} represent the range in the anode potential-current density diagram in which the characteristics for n- and p-type material are still identical (6). Since the removal of only 0.5-1μ of material was necessary to remove the damaged layer (1), an operating time of 20-30 min did not seem unreasonable.

Optical Measurements

The over-all flatness of the samples was checked by a standard interferometric technique using an optical flat and the yellow lines of a sodium lamp. The flatness for the thick samples was found to be better than 0.1 μ/in. The flatness of the thin samples was somewhat less due to the warping of the germanium when it was no longer backed by the pressure plate. No difference in flatness was observed between the last stage mechanical abrasive polish and the electrochemical treatment.

The roughness of the samples was measured according to an interferometric method developed by Koehler and White (7). The test surface is made one plate of a Fabry-Perot interferometer, with a fused quartz optical flat of known roughness as the other plate of the configuration. Using white light, a set of interference fringes of equal chromatic order is displayed behind a spectrograph. By choosing a low order of interference which increases the width of the fringe, and enlargement of the picture, the fine structure of the fringe can be measured, giving a fairly accurate replica of the surface. The precision of the method is given by the authors as 20%. The method is superior to mechanical probing by diamond stylus or brushes, especially in the range below a few microns where the mechanical

probe cannot bottom into the troughs and a value too favorable is usually read.

Figure 1a shows fringes of equal chromatic order from an interferometer consisting of two fused quartz optical flats of 8-10Å rms roughness. The picture represents a sample area of about 0.5 by 0.003 mm. Magnification before reduction for publication was 19. Analyzing the wiggles of the fringes the value for the surface roughness is obtained. Figure 1b shows fringes from an interferometer consisting of an electrochemically polished germanium sample and one of the above quartz flats. The measured rms roughness of the germanium is 10-13Å. Figure 1c shows fringes displayed from a mechanically polished sample and one of the quartz flats. The measured rms roughness is 25-30Å. Figure 1d shows the sample from Fig. 1c again after a 15-sec immersion in CP-4, the minimum time to remove the damaged surface layer of approximately ½ μ thickness. The rough surface obtained with CP-4 was typical of surfaces obtained with a number of chemical etchants, including most of the ones which are recommended for chemical polishing of germanium.

Electron Diffraction Measurements

Electron diffraction studies of the surfaces indicated that the mechanically disturbed layer that existed after the final mechanical polish was removed by the electrochemical treatment. Figure 2a shows the diffraction pattern obtained with the mechanically polished surface. The spot pattern indicates a randomly oriented mosaic structure in the surface. Figure 2b shows the diffraction pattern obtained from the electrochemically polished surface. The spot pattern and the sharp Kikuchi pattern are indicative of a high degree of surface orientation (8). Furthermore, this pattern compares with the pattern obtained by etching a mechanically polished surface in CP-4. This latter pattern is shown in Fig. 2c.

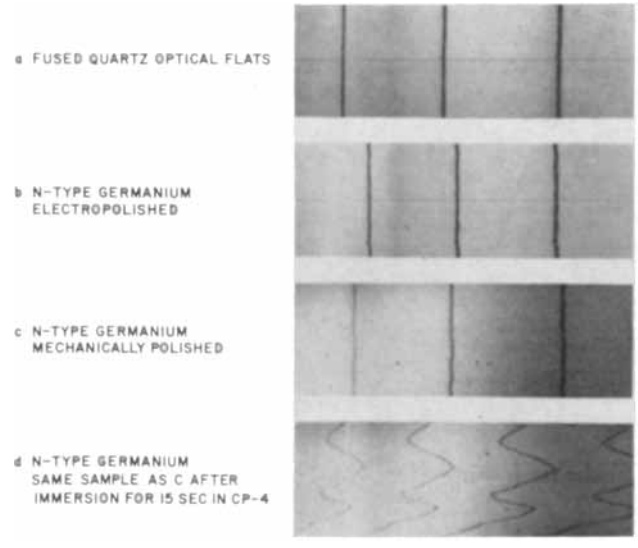

Fig. 1. Fringes of equal chromatic order corresponding to an interferometer made up of (a) two optical flats; (b) an optical flat and an electropolished germanium sample; (c) an optical flat and a mechanically polished germanium sample; and (d) an optical flat and a germanium sample that had been etched in CP-4 for 15 sec.

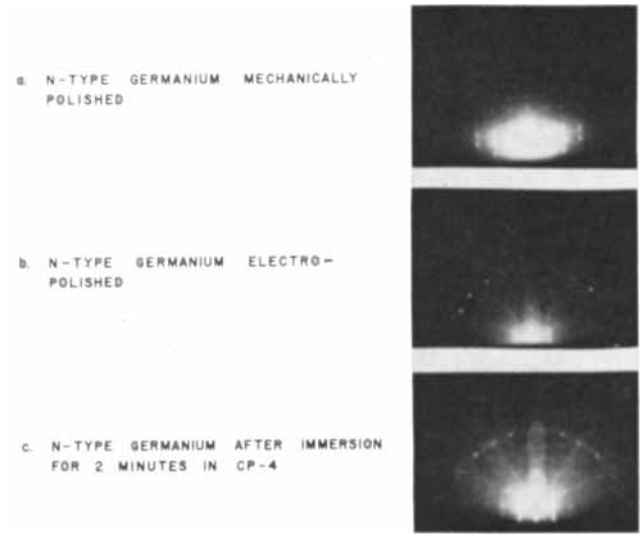

Fig. 2. Electron diffraction patterns corresponding to (111) germanium surfaces with (a) a mechanically polished surface; (b) an electropolished surface; and (c) a CP-4 etched surface.

Electrical Measurements

The surface recombination velocity was determined by measuring the filament lifetime by the photoconductivity decay method. This method which is sensitive to low values of the surface recombination velocity s, gave for mechanically polished samples s-values in excess of 5000 cm/sec. Electropolishing the surfaces of the sample brought this value down to 120 cm/sec. If, on the other hand, mechanically polished samples were immersed in CP-4 for 15 sec, s-values around 100 cm/sec were obtained.

Finally, sets of three thin samples were measured with respect to their field-induced change of the conductivity. The mechanically polished samples did not show any change due to the surface damage which gives rise to a fast state structure of very high density (9). On electrochemically polished surfaces, however, any mechanical damage is removed to the extent where it ceases to dominate the recombination process in the surface. Under otherwise identical conditions these samples showed a field effect which approached (50-75%) the one obtained for samples that had been etched in CP-4.

Acknowledgments

The authors wish to express their appreciation to Dr. Jean M. Bennett for assistance with the optical portion of the paper and to Mr. L. G. LaMarca for making the electrical measurements. Also, the Crystal Physics Branch of this Laboratory should be thanked for the electron diffraction photographs.

Chemical Polish for Lead Telluride

P. H. Schmidt

Bell Telephone Laboratories, Murray Hill, New Jersey

The purpose of this note is to describe a chemical polish which will produce flat, mirror-like, ripple-free and strain-free surfaces on samples of lead telluride. At present there exist only two satisfactory methods for polishing lead telluride (1, 2). Both methods are electrochemical and produce surfaces which are smooth and strain-free but somewhat convex. However, some inherent disadvantages are associated with electropolishing. Some of these are the difficulty of producing flat, ripple-free surfaces, the complex equipment needed, and optimum conditions are sometimes difficult to control. Attempts to polish lead telluride chemically have thus far been unsuccessful (1). Most chemical methods produce an etched surface or an etched surface with an associated film which is difficult or impossible to remove.

Method

Samples are prepared by first abrading surfaces flat with water-lubricated No. 400 grit aluminum oxide paper, removing 0.002-0.004 in. of material with every few strokes on the abrasive paper. Coarse abrasion is then followed by finer abrasion on water-lubricated No. 600 grit silicon carbide paper and finally by abrasion on dry 4/0 grit French emery paper. Care must be exercised during all abrading stages to prevent the specimen from fracturing or cleaving (100 cleavage), and it is therefore recommended that a jig be used for mounting the sample. Quartz type sticky wax[1] (mp 68°C) has been found very satisfactory for mounting samples to metal inserts of jigs. Care must also be exercised not to load the abrasive paper, this being especially true of the No. 600 grit and 4/0 grit papers. Samples must be thoroughly cleaned between all abrading stages.

Using a figure eight 1-2 in. stroke, the sample is rubbed on twill jean cotton cloth that has been stretched over a flat glass plate and saturated with a solution of 50% C. P. hydrogen peroxide (H_2O_2 30%) and 50% glacial acetic acid and Linde A abrasive. Lapping is continued for 2-3 min. Material is removed at a rate of about 0.0002 in./min. The sample surface should appear cloudy-bright with fine scratches.

Finally the sample is twill jean polished (3) for another 2-3 min using the acid mixture without the Linde A abrasive. Material removal rate is about 0.0001 in./3 min. A warm water rinse should immediately follow polishing with a final flush in acetone or ethyl alcohol. The sample surface should appear highly reflective and with no fine grain ripple.

Back-reflection Laue photographs, using tungsten radiation and a film-to-specimen distance of 5 cm, of surfaces polished using the method described above indicate that they are free of strain.

Undesirable films that have formed on polished samples can be removed by immersion of the sample in a solution of equal parts of glacial acetic acid and 30% hydrogen peroxide for 3-4 min followed by swabbing with water. However, it is recommended that the twill jean polish (3) procedure be repeated as it will produce far superior surfaces.

The method described herein is simple and rapid, requiring little or no equipment or setup time. The surfaces so produced appear to be as strain-free as those obtained by electropolishing techniques and are visibly smoother and flatter.

Brief Communication

A Polishing Etchant for III-V Semiconductors

C. S. Fuller and H. W. Allison

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The purpose of this communication is to report a new class of etchant which is capable of producing highly polished surfaces on GaAs and GaP crystals. A more detailed evaluation of this etchant for device purposes is described by Sullivan and Kolb (1). It is applicable to other III-V compounds, but is not as good as other etchants for Ge and Si. The etchant has definite application in removing thin diffusion layers since it is subject to very precise control. It also allows new types of resists to be used as masking materials, *e.g.*, water soluble polymers, and appears to be subject to less undercutting than the usual aqueous etches. Finally, the etchant is useful in the incremental removal of layers of material in order to obtain thin base layers for devices.

The etchant consists basically of an organic liquid in which a halogen, generally Cl_2 or Br_2, is dissolved. The best organic liquids so far found are methyl alcohol or glacial acetic acid. These materials have been "dry" but not intensively dried. Adding water slows the etching reaction. Obviously, organic liquids which react rapidly with halogens cannot be used. The use of perchloro compounds, such as CCl_4, results generally in very slow etching. However, mixtures of CCl_4 with methyl alcohol are quite satisfactory, *e.g.*, 1:1 by volume. Benzene or toluene with methyl alcohol are also useful.

It is well known that the chemical etchants suitable for producing polished surfaces on Ge and Si are not very effective on the III-V compound semiconductors. Mixtures of HF and HNO_3 in various proportions and concentrations can be used (2). However, poor surfaces generally result when used with GaAs even on the smoother etching (111) face. HNO_3 alone results in oxidized surfaces which are unsuitable. Aqua regia is a useful etchant, but does not provide the polish desired. It also attacks and lifts many of the resists employed as masking materials. The situation with GaP is even worse in that aqua regia is about the only etchant which attacks the material. The difficulties of masking are even more severe.

For GaAs the best solution for room temperature use is bromine[1] in methyl alcohol. A wide variety of concentrations may be employed depending on the application. For a high polish 5-20% of bromine by volume is used. For a light etch 0.1-1% by volume is best. Etch rates varied from a few tenths to 4 mils/min on a crystal pulled about 8° off of [111]. The etchant is conveniently removed by mean of methyl alcohol rinses.

[1] Care should be used in handling liquid bromine to avoid burns and breathing fumes.

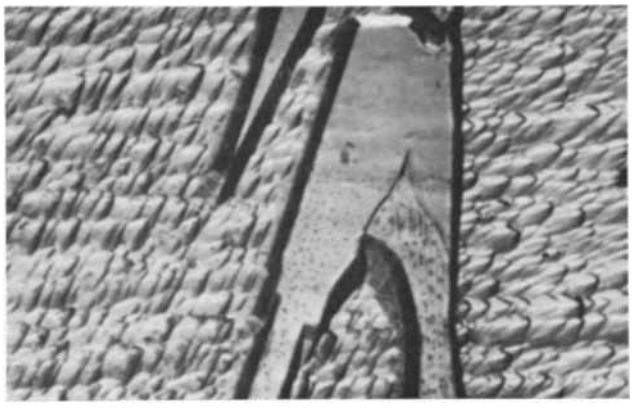

Fig. 1. GaP polycrystal etched for 3 min at 25°C in chlorine-methyl alcohol. Both smoothly etching surfaces and surfaces exhibiting etch pits are shown. Magnification 40X.

For GaP the bromine etch is too slow for most purposes. In this case, the best procedure is to bubble Cl_2 gas slowly through methyl alcohol with the specimen immersed.[2] The solution turns yellow indicating saturation with the gas, and the etching proceeds at a moderate rate at room temperature. Highly polished surfaces are obtained in from 5 to 20 min. Warming slightly will increase the rate. Etch rate is about 0.5 mil/min at 25°C.

Other III-V semiconductors have been etched in the manner described. Iodine in methyl alcohol, for example, has been found useful for etching InSb.

Finally the etchant has application in developing etch pits. The accompanying figure shows a polycrystal of floating-zone GaP. Both smoothly etching faces and faces exhibiting etch pits are shown.

The Transient Impedance of Leclanche Cells

Aladar Tvarusko

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The transient impedance of Leclanché cells was studied on open circuit and during discharge. The transient impedance is defined as the ratio of the Laplace transforms of voltage and current. An equivalent circuit was assumed for the Leclanché cell, and the values of the circuit elements were calculated with the help of the time constant for various electrolytes and manganese dioxides. The influence of the anode, cathode, and discharge on the transient impedance are discussed.

The modern use of Leclanché cells in electronic equipment usually requires cells of low impedance. The present study was undertaken to elucidate the nature of impedance and the parameters influencing it.

The Leclanché cell consists of a zinc anode, MnO_2-C cathode mix, and electrolyte absorbed in a separator and the cathode mix. It is a well-known fact that zinc in contact with an electrolyte forms an electrical double layer at the electrode-solution interface. This double layer together with the bulk of the metal and electrolyte can be represented by an equivalent circuit having a certain impedance.

The phase boundary of semiconducting metal oxides and carbon with electrolyte has been investigated by numerous authors. The cathode mix is composed of MnO_2 and carbon particles surrounded by the electrolyte. Euler (1) described the ionic and electronic resistance, the electrical double layer, and the reaction impedance of an MnO_2 particle by an equivalent circuit. The various MnO_2 and carbon particles are in contact with each other forming a porous electrode. This necessitates the interconnection of the individual equivalent circuits resulting in a 3-dimensional network. The individual equivalent circuits of this network are either in series or in parallel configuration to each other and can be reduced to a simplified equivalent circuit, for instance that of Euler (2). The total impedance will be the sum of the individual impedances or admittances, respectively, be it a-c steady state or a-c transient.

The electrolyte in the separator electrically connects the anode and cathode. Naturally this electrical path (electrolyte, anode, and cathode) is represented by a certain pure resistance. This resistance is the internal resistance of Leclanché cells as reported earlier (3).

Experimental and Discussion

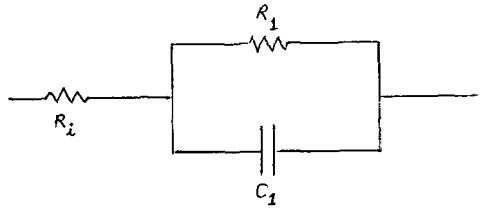
The steady-state form of a time-varying quantity is the same as that of its drive. Thus, a sine voltage produces an a. c. of the same wave-form and frequency. The transient form, in contrast, is independent of the drive and depends only on the circuit investigated. Such a transient response can be achieved by using a unit impulse drive function (delta function). In the case of a square wave drive function the response contains both the transient and steady-state forms.

One can conceive of the transient impedance $Z(p)$ as a generalized impedance concept relating the Laplace transforms of voltage and current in the same manner as the steady-state a-c impedance relates the corresponding phasors (4),

$$\mathcal{L}v(t) = \mathcal{L}I(t) \cdot Z(p) \qquad [1]$$

Assuming the inductance of the leads and Leclanché cell to be negligible, only the pure resistive component and the capacitive reactance have a role in the impedance. The transient impedance will correspond to that of an RC network, *i.e.*, single-energy electrical system because the energy of the circuit is stored in one form only. The "single-energy electrical system" is used here in the sense of the network analysis. When an external voltage step is applied to an RC network, it must all appear across the series resistance (not paralleled by capacitance), since the voltage across a capacitance cannot change instantaneously. This series resistance is the internal resistance, R_i of Leclanché cells as determined by the square wave method (3) or pulse method (5).

Either a series or parallel equivalent circuit can be used to describe the Leclanché cell. The parallel arrangement is preferred here. The simplest possible parallel equivalent circuit is a resistance (R_i) in series with a resistance (R_1) and the capacitance (C_1) in parallel



where R_i is always linear. For an equilibrium condition, R_1 and C_1 are linear; for a nonequilibrium condition, however, they may be nonlinear. A certain nonequilibrium condition within an infinitesimal time interval can be regarded as an equilibrium condition and can be represented by the same equivalent circuit but of differing values for the circuit elements. The capacitance, representing the electrical double layer, is parallel to a resistance and a second capacitance in parallel, representing the faradaic impedance (6). The two parallel capacitances can be added, resulting in C_1. A parallel re-

sistance and capacitance arrangement was considered for Leclanché cells by Euler and Dehmelt (7).

Let us consider the transient voltage response $v(t)$ of the aforesaid equivalent circuit when a constant current step function is applied. The differential equation of this and all single-energy systems is of the first order. Assuming that the circuit (Leclanché cell) is in steady state, the voltage response in one cycle is of the same form as the response in the next cycle. Furthermore, let us assume that the impressed current is $i(t) = Iu_{-1}(t)$, where $u_{-1}(t)$ denotes the unit step source current. The solution for $v(t)$ can be obtained by the classical method of solving differential equations, employing Heaviside operational calculus (8) or Laplace transformation:

$$v(t) = IR_i + IR_1\left(1 - \exp - \frac{1}{R_1C_1}t\right) \quad [2]$$

and the transient impedance, Z_{tr}

$$Z_{tr} = \frac{v(t)}{I} = R_i + R_1\left(1 - \exp - \frac{1}{R_1C_1}t\right) \quad [3]$$

where for

$$t = 0+ \qquad Z(0+) = \frac{v(0+)}{I} = R_i \quad [4]$$

for

$$t = \infty \qquad Z(\infty) = \frac{v(\infty)}{I} = R_i + R_1 \quad [5]$$

In the case of a square wave or pulse signal, the $t = 0+$ condition is practically represented by the leading edge of the signal and the instantaneous voltage drop is due to the internal resistance, R_i of the Leclanché cell. The other extreme ($t = \infty$) corresponds to the steady-state condition, and the parallel resistance can be calculated easily.

All single-energy transients of a d-c nature (square wave or pulse) start at one value and end at another value. In the case of an RC network there is an exp $- t/RC$ term multiplying the magnitude of the change, which describes the course of the voltage response between the two limit values. The exponent's denominator is the product of the values of the parallel resistance and capacitance. This product is called the time constant, τ, and is equal to the time required for a voltage in this circuit and all RC single-energy systems to rise to 63.2% of its steady final value ($t = R_1C_1$). The magnitude of the steady state does not depend on the magnitude of capacitance, since the term containing capacitance is eliminated from the Eq. [5]. Increasing or decreasing the time constant increases or decreases, respectively, the time required to reach the steady state. The time constant is increased or decreased by increasing or decreasing, respectively, either R_1 or C_1, or both.

The time constant can be determined by one of the following three methods: the 63.2% method, the initial-slope method, and the log-plot method. Here, the 63.2% method will be used. Figure 1 shows the oscilloscope traces of a pasted D-size Leclanché cell containing electrolytic MnO_2 of source B and conventional $ZnCl_2$-NH_4Cl electrolyte. The experimental arrangement used for this study is the same

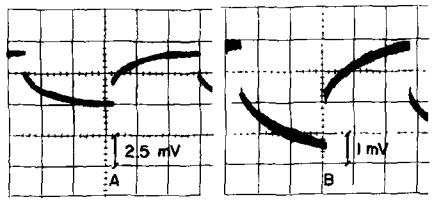


Fig. 1. Oscilloscope traces of the transient voltage responses of undischarged Leclanché cells containing electrolytic MnO_2 of source B and conventional $ZnCl_2$-NH_4Cl electrolyte. A, at 400 cps square wave; B, at 1000 cps square wave.

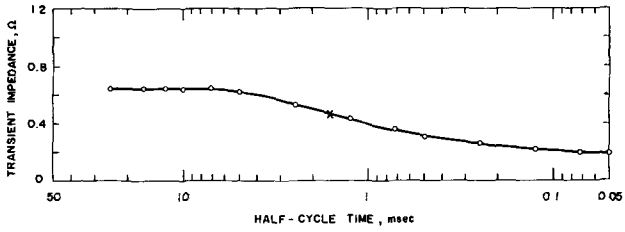

Fig. 2. Transient impedance of an undischarged Leclanché cell (same as Fig. 1) as a function of half-cycle time.

as described previously (3). The 5X attenuation factor is included in the voltage values shown in the figures of oscilloscope traces. Figure 1A shows the oscilloscope trace of $v(t)$ of the undischarged cell at 400 cps square wave. The steady state is already reached and the time constant, τ, can be determined by the 63.2% method. The value of the time constant, however, cannot be determined very accurately, not even on an enlarged picture of the trace.

The time constant, however, can be determined more accurately from the transient impedance-frequency curve since the frequency, by definition, is the number of cycles per second. The oscilloscope trace in Fig. 1B is that of the transient voltage response for the same undischarged Leclanché cell as above, at 1000 cps square wave. Figure 2 is obtained by plotting the $v(T/2)/I$ ratios, *i.e.*, the ratios of the magnitudes of the transient voltage responses at the end of the half-cycles and the magnitude of the constant current square wave, which is the transient impedance (Z_{tr}), as a function of the half-cycle time, $T/2$ (through varying the frequency of the square wave). The curve starts at one value, that of the internal resistance of the Leclanché cell, and increases to the steady-state value. Knowing the internal resistance (0.17 ohm) and the steady-state impedance (0.65 ohm), the parallel resistance is easily obtained and $R_1 = 0.48$ ohm. Taking 63.2% of the difference of the steady-state impedance and internal resistance, and adding it to the internal resistance, the time constant is found where it intersects the curve. In this case, $\tau = 1.59$ msec. Knowing the value of the parallel resistance, R_1 (0.48 ohm) and the time constant, τ(1.59 msec), the parallel capacitance is calculated. It is thus 3310 μF for the aforementioned cell. This value is in excellent agreement with Brodd's results (10) as calculated from his Table II. It is slightly larger than the 2140 μF reported by Euler and Dehmelt (7) for a D-size cell with African (Gold Coast) MnO_2 ore, and is 5 orders of magnitude larger than the 0.43 μF value of Drotschmann (9) for a smaller cell.

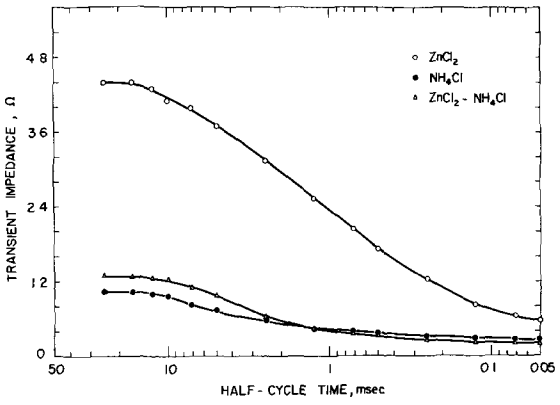

Fig. 3. Transient impedance of undischarged Leclanché cells with African ore and various electrolytes as a function of half-cycle time.

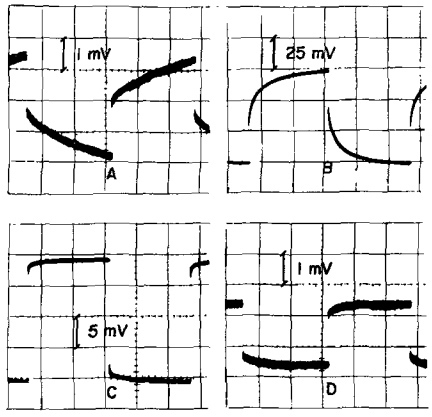

Fig. 4. Oscilloscope traces of transient voltage responses. A, Leclanché cell with African ore and conventional $ZnCl_2$-NH_4Cl electrolyte, 1000 cps square wave; B, two zinc anode portions of the above cell, 100 cps square wave; C, two cores of the above cell, 1000 cps square wave; D, Leclanché cell as above in the beginning of 4-ohm discharge, 1000 cps square wave.

Figure 3 shows the transient impedance of undischarged D-size Leclanché cells containing African ore and $ZnCl_2$, NH_4Cl, and $ZnCl_2$-NH_4Cl electrolytes of constant Cl^- content (225g Cl^-/1000 ml solution), as a function of the half-cycle time, $T/2$. The transient impedance curve of the undischarged cell with $ZnCl_2$ electrolyte is markedly different from the other two. Establishing the R_i and R_1, the time constant is determined by the 63.2% method. These data and the calculated parallel capacitances, C_1, are tabulated in Table I. The NH_4Cl electrolyte yielded a small parallel resistance, R_1, and a large parallel capacitance, C_1. On the other hand, the $ZnCl_2$ electrolyte resulted in a large R_1 and small C_1. The R_1 and C_1 values of a cell with an electrolyte containing both salts were between the values found for each constituent. The same relationship was also found for other natural ores.

The oscilloscope traces of D-size Leclanché cells having African ore and conventional $ZnCl_2$-NH_4Cl electrolyte can be seen in Fig. 4. Figure 4A shows the transient voltage response of an undischarged cell at 1000 cps square wave. It was of interest to see the influence of the zinc anode and MnO_2-C cathode on the transient voltage response. Therefore, four undischarged cells were carefully disassembled so that the paste remained intact on the zinc anodes from two cells and on the mix cores of the other two. Small portions of the zinc anodes were cut out, leads soldered to them, and with the pastes facing each other, pressed together. The trace of this at 100 cps is shown in Fig. 4B. The transient voltage response at 1000 cps of two cores with the original pastes pressed against each other is shown in Fig. 4C. For these two traces the d-c blocking capacitor was not included in the experimental circuit (3). The parallel resistance, R_1, is comparatively large for the zinc anode whereas it is small for the MnO_2-C core, which is in agreement with the findings of Euler and Dehmelt (7) and Brodd (10). The values of the R_1, τ, and C_1 will be calculated from experiments to be performed with more defined geometrical surface areas.

When a cell is being discharged, the magnitude of the transient voltage response (and hence the transient impedance) decreases. The rate of the decrease is a function of the magnitude of the current drain. The larger the current drain, the faster the decrease, and the shorter the time needed for Z_{tr} to reach the steady-state value. This will be reported in detail later in connection with the experiments obtained by a simple indicating instrument using 100 cps constant current square wave.

The oscilloscope trace at 1000 cps square wave of the transient voltage response of the aforementioned cell in the beginning of the discharge through 4 ohms is shown in Fig. 4D. It is evident that the decrease of $v(t)$ is due to the destruction of the interface equilibrium condition at the zinc anode alone and the trace resembles that of the two cores (Fig. 4C). In the measuring circuit (3), the 4-ohm discharging resistor is in parallel with the cell, and the R_i and R_1 is calculated with the help of Kirchoff's law. The value of R_1 is small and remains nearly constant as shown in Fig. 5. This shows the internal resistance R_i and the transient impedance Z_{tr} in ohms at 1000 cps square wave of the aforementioned Leclanché

Table I. Equivalent circuit parameters of undischarged Leclanché cells containing African ore and various electrolytes

cells during 4-ohm continuous discharge as a function of discharge time.

Conclusions

The Leclanché cell can be approximated by an equivalent circuit where the internal resistance is in series with a resistance and capacitance in parallel arrangement. The transient impedance is given by the ratio of the Laplace transforms of voltage and current. From the steady-state value of the transient impedance one can calculate the parallel resistance and through the time constant, the parallel capacitance. A Leclanché cell with NH_4Cl electrolyte yielded a small resistance and large capacitance in parallel, whereas a large resistance and small capacitance in parallel was found for the Leclanché cell containing $ZnCl_2$ electrolyte. The values of the parallel components for a Leclanché cell containing both salts in the electrolyte are between the two limit values. When a cell is being discharged, the magnitude of the transient impedance decreases and the rate of the decrease is a function of the current drain. For high current drains the difference between the transient impedance and internal resistance is small and remains nearly constant during the continuous discharge of the Leclanché cell.

Oxygen Transport and Reaction Rates at an Air-Depolarized Copper Cathode

H. C. Weber, H. P. Meissner, and D. A. Sama[1]

Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Air-depolarized partially submerged electrodes were studied to determine the location of the zones of reaction and the rate-controlling steps in their operation. Reaction was found to occur primarily on that part of the surface of the electrodes covered by the electrolyte meniscus. The rate-controlling step was the diffusion of oxygen through the liquid meniscus to the electrode surface. The mass transport of oxygen as a rate-controlling step was eliminated in a specially constructed wiped, rotating, partially submerged copper electrode. This electrode was used to measure the oxidation rate of copper at room temperature for various partial pressures of oxygen. Oxidation rates were found to be great enough to support far larger current densities than are generally attainable in normal oxygen-electrode operation. The oxidation of copper was found to follow the logarithmic equation

$$w = k_1 \text{ Log } (k_2 t + 1)$$

where k_1 was independent of oxygen partial pressure, and k_2 was proportional to the square root of the oxygen partial pressure.

For a gas diffusion type of electrode to attain a given current output, two requirements must be met: (i) the necessary amount of reacting gas needed to sustain the current must reach the active zone of the electrode surface by transport through the surrounding gas and liquid, and (ii) the electrode surface must be active enough to allow the gas to react at this rate. The purpose here is to indicate which part of the electrode surface actually participates in the electrochemical reaction, and to present evidence on whether mass transport or chemical reaction kinetics is rate limiting. Discussion is limited to the oxygen electrode.

To achieve high current densities per unit of projected surface area, most oxygen or air electrodes are constructed of porous materials. In consequence, their total surface area per unit of cross-sectional area is quite high. However, the area and geometry of the active portions of such porous electrodes cannot be determined accurately, rendering analysis of operating results uncertain. Some clarification be-

[1] Present address: Lowell Technological Institute, Lowell, Massachusetts.

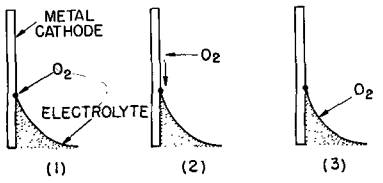

Fig. 1. Possible oxygen transport mechanisms

comes possible, however, if these porous electrodes are considered to be made up of a large number of cylindrical pores, with each pore in turn being made up of partially submerged flat plates. For a flat plate with a lyophilic surface, such as a metal, the electrolyte forms a concave meniscus against the electrode. In order for oxygen to react at such an electrode it must be transported to that part of the electrode area which is active and which is in contact with electrolyte. Three possible mechanisms are shown in Fig. 1. In the first of these, it is assumed that only the oxygen molecules which strike in the immediate vicinity of the boundary line at the intersection of the three phases enter into the electrochemical reaction. In the second, oxygen is first adsorbed on the dry electrode surface projecting above the electrolyte and then migrates along the surface until it enters the electrolyte. In the third, oxygen is first dissolved in the electrolyte and then carried to the submerged electrode surface by diffusion and convection.

The foregoing three alternatives can be tested experimentally. If alternative 1 is correct, then currents obtained would be proportional only to the length of the boundary line between the three phases and independent of the electrode's area above and below the electrolyte surface. If alternative 2 is predominant, then the currents obtained would be a function of the unwetted electrode area and also of the length of the line at the 3-phase intersection. For alternative 3, the current would be some function of the submerged area of the electrode and would be unaffected by the existence of either a 3-phase boundary line or of unwetted electrode area.

These alternative mechanisms were tested in the apparatus shown in Fig. 2. A 2.54 x 1.27 cm (1 x ½ in.) copper plate, about 0.04 cm (1/64 in.) thick, was placed in one leg of a U-tube. A steel wool anode of much larger area was placed in the other leg of the U-tube. The electrolyte was 20% KOH, and the degree of submergence of the copper cathode was varied by removing electrolyte from the anode side of the U-tube. The steel wool anode was so placed that it was completely submerged under all conditions of operation. The over-all reactions during the operation of the cell are:

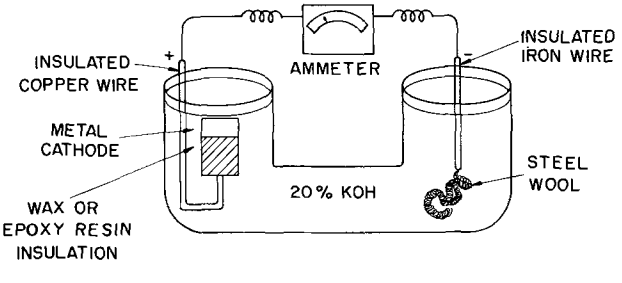

Fig. 2. Cell with air-depolarized electrode

$$\text{Cathode} \quad \tfrac{1}{2}\,O_2 + H_2O \rightarrow 2\,OH^- - 2e \qquad [1]$$

$$\text{Anode} \quad Fe + 2\,OH^- \rightarrow FeO + H_2O + 2e \qquad [2]$$

$$\tfrac{1}{2}\,O_2 + Fe \rightarrow FeO \qquad [3]$$

The experimental procedure was to start with the copper cathode completely submerged. The copper-steel wool couple was short circuited.[2] Under these conditions of large anode area relative to the cathode and of low electrical resistance, the cell current is limited by the operation of the cathode. The electrolyte level was varied, and the current generated was measured as a function of the height to which the electrode projected above the level of the electrolyte. Three separate areas are recognizable on a partly submerged electrode such as shown in Fig. 3, namely, the dry area above the meniscus (height u), the area under the meniscus itself (height m), and the area submerged below the bulk electrolyte. The dry area could be directly observed with copper electrodes, since it became discolored and black by oxidation, whereas the submerged areas retained their brightness during operation.

The following findings were made (see Table I):

1. When the electrode is completely submerged and well below the surface of the electrolyte, as at time zero, the current due to oxygen depolarization is essentially zero. Thus, the oxygen-depolarization current is independent of the area of the electrode which is submerged well below the surface of the electrolyte.

2. When the top of the electrode extends slightly above the level of the bulk electrolyte, and while a

[2] On open circuit, a noticeable blue color due to the solution of copper oxide developed in the electrolyte. No such coloration occurred, regardless of time of operation, when the cell was kept short circuited. This indicates that during short-circuit operation all the oxygen reacting at the active portion of the electrode is either directly or indirectly electrochemically reduced.

Table I. Air-depolarized, partially submerged copper cathode 2.54 x 1.27 x 0.0397 cm (1 x 1/2 x 1/64 in.). Steel wool anode and 20% KOH electrolyte

H, height above electrolyte surface	m, meniscus height	u, height above meniscus	Current, ma	Time, min
0	0	0	0.010	0
Edge at electrolyte surface	—	0	0.067	5
0.04 ~ 0.08 cm (1/64 ~ 1/32")	same as H	0	0.255	9
0.16 cm (1/16")	same as H	0	0.590	15
0.24 cm (3/32")	same as H	0	0.875	20
0.32 cm (1/8")	same as H	0	0.98	26
0.48 cm* (3/16")	same as H	**	1.02	31
0.64 cm (1/4")	~0.32 cm ~(1/8")	~0.32 cm ~(1/8")	0.75	105

* At this value of H, the projecting electrode plate was no longer completely covered by the electrolyte (see Fig. 3). Instead, a thin strip of uncovered area developed along the top of the electrode. This strip became visible as it discolored due to copper oxide formation.

** As the electrode is raised further, resulting in larger values of both H and u, no further changes occur either in the meniscus height m or in the current flowing.

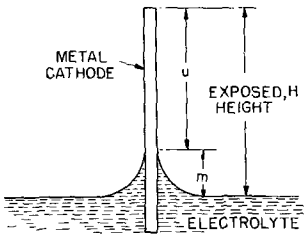

Fig. 3. Measurement of exposed height H and meniscus height m

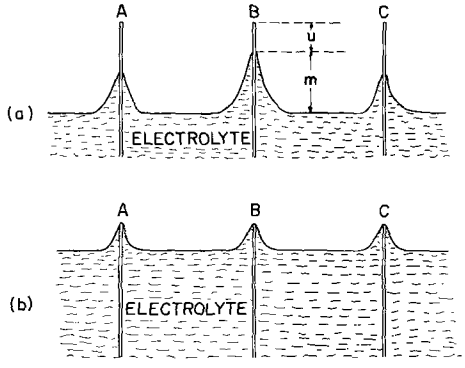

Fig. 4. Electrolyte menisci at different metals

thin electrolyte meniscus still covers the entire electrode as shown in Fig. 4b, a current due to depolarization of oxygen is generated. This is illustrated by the points in Table I up through 26 min.

3. The current increases as the height m is increased, and reaches a maximum when m is at its maximum. At this maximum, a three-phase boundary line between gas, electrolyte, and electrode forms. In the system described here the height m was found to be about 0.32-0.48 cm (1/8-3/16 in.).

4. As the plate is further withdrawn, m remains at its maximum value while u, the height of the unwetted portion of the electrode, increases. The current is found to be independent of u, as is shown by the points in Table I observed after 26 min of operation.

5. A decrease in current and a small contraction of the electrolyte meniscus tend to occur after an hour's time, as is shown by comparing the points at 31 and 105 min. This meniscus contraction may be the result of a change in the contact angle due to further oxide formation, or the slow return of the meniscus to its equilibrium position after being stretched when the electrolyte was lowered.

Rate-Determining Step

The foregoing evidence indicates that the bulk of the electrochemical reaction takes place on the electrode's area under the meniscus (see Fig. 3). This suggests that mass transfer of oxygen through the liquid within the meniscus "controls" the magnitude of the current flowing. Such control by oxygen transfer is compatible with the fact that oxygen diffusivity in the electrolyte is very small, and that the amount of oxygen transported through a unit area per unit time varies inversely with path length (see Eq. [4]). Calculations presented below indicate that significant current densities can be attained only in the electrode area lying under the upper end of the meniscus, where distances from the electrolyte surface to the electrode surface are small. The electrode areas in the lower part of the meniscus, and those electrode areas more deeply submerged, contribute very little to the total current because oxygen diffusion rates are very small for path lengths in excess of a fraction of a centimeter.

The actual quantity of oxygen transported through a liquid by diffusion can be calculated from the familiar equation (1)

$$N_A = \frac{D_L(C_i - C_o)}{z} \qquad [4]$$

where N_A is gram moles oxygen/(sec)(cm^2), D_L is the diffusivity[3] with a value of ~1 x 10^{-6} cm^2/sec, C_i and C_o are oxygen concentrations in the electrolyte at the gas-electrolyte interface and the electrolyte-electrode interface, respectively, and z is the diffusion path length in centimeters. Taking C_o as zero and C_i as 2.77 x 10^{-8} g mole/cm^3, corresponding to saturation with air, then N_A is 2.77 x 10^{-11} g mole/(sec)(cm^2) when z is only 0.001 cm. This corresponds to a current density of only about 0.01 ma/cm^2. When z is 1 cm, then N_A will be only 2.77 x 10^{-14}. It follows that even within the meniscus, current densities must vary, in that more oxygen reaches the electrode area under the top of the meniscus, where the film is thinnest, and less reaches the lower regions of the meniscus, where the film thickens.

Confirming evidence that mass transfer of oxygen to the electrode surface, rather than chemical reaction rate, controls the magnitude of the current generated was obtained by changing the temperature of cell operations. It was found that increasing the temperature resulted in a decrease in the current. This is attributable to lowered oxygen transport rate, which is a result of lowered oxygen solubility, or of changes in the meniscus geometry, or of both. If chemical kinetics had controlled, then a temperature rise would presumably have sharply increased the current flowing.

Further evidence on the nature of the controlling step was obtained from duplicate experiments with electrodes made of copper, nickel, and silver. With meniscus heights less than the maximum wetted height for any of the metals, the meniscus geometries are identical as shown in Fig. 4b. Under these conditions, for any given meniscus height, the current generated was the same for all metals. This again indicates that mass transfer controls, for if kinetics had controlled, then the oxidation rates and the currents obtained therefrom would not have been equal. Due to differences in contact angles, the meniscus shapes and surface areas were no longer the same after raising the electrodes sufficiently so that dry area developed, as shown in Fig. 4a. In consequence, the currents generated were different when the exposed heights were greater than the meniscus heights.

Finally, it is important to note that resistance of the liquid phase to oxygen travel, rather than resistance of the gas phase, will generally be the rate-

[3] This value is for diffusivity of dissolved oxygen in 20% NaOH (2). The diffusivity in 20% KOH was not available in the literature, but should not be appreciably different.

determining step in the operation of gas diffusion type electrodes. It is easily shown that, because of oxygen's very low solubility in strong electrolytes, for a given difference in partial pressure (and concentration) driving forces, a gas layer of given thickness will allow diffusion of 10^7 to 10^8 times as much oxygen as a liquid layer of equal thickness.[4] Thus even relatively long pores in an electrode when filled with gas, generally present less of an obstacle to oxygen diffusion than the liquid film through which this oxygen must travel to reach the electrode surface.

Kinetic Studies

The findings just described indicate that mass transfer limits the rate of operation of these oxygen electrodes. However, these studies yield no information on the kinetics of the reactions occurring at the electrode itself. These reactions involve an oxidation, in which oxygen somehow adsorbs or reacts with the surface, followed by the electrochemical removal of this oxygen. It appeared desirable to obtain information on the oxidation rate in order to determine what current densities might be attainable upon elimination of the liquid phase resistance.

To study kinetics of reactions at the electrode surface, it is first necessary to decrease to a negligible value the oxygen transport resistance through the liquid phase, which normally controls the current developed. This was accomplished by use of the partly submerged rotating electrode described below. The unsubmerged portion of this electrode was wiped free of electrolyte, giving oxygen from the surrounding gas atmosphere direct access to the electrode surface. The consequent oxide layer formation rate was obviously determined by oxidation kinetics, rather than by mass transfer through a liquid film. By suitable adjustment of conditions, this oxide layer was then removed electrochemically upon submergence in the electrolyte. The time and conditions required both to form and remove the oxide layer could be controlled and measured, and the apparent thickness of this layer could be calculated.

Rotating Electrode

The apparatus used, shown in Fig. 5, consisted of a Lucite disk in which a copper ring was embedded so that only the outer surface of this ring came into contact with the electrolyte. This disk assembly served as the oxygen electrode and was partly submerged in the electrolyte, which was 20% KOH. The anode was a zinc wire spiral whose surface area was at least 100 times that of the cathode, thus making the cathode the controlling electrode. The entire assembly was housed in a Lucite box with provisions whereby the oxygen partial pressure in the gas phase could be varied. The partial pressure of water in this gas was kept at equilibrium with the electrolyte at all times to prevent any local changes in electrolyte concentration and the possible consequent development of concentration cell effects. The current was measured under steady-state conditions, and its dependence on the rotational speed and on the partial pressure of oxygen was established. The surface of the copper ring emerging from the electrolyte was of course covered by a thin film of electrolyte, which if not removed acted as a large diffusional resistance to oxygen transport. This liquid film was therefore removed as extensively as possible by use of a rubber wiper, thus giving oxygen free access to the electrode surface. The oxide layer which formed on the electrode surface was then removed by electrochemical reduction when submerged. Thus the copper electrode is not consumed during operation, but instead undergoes alternate oxidation and reduction. In this apparatus, therefore, two things are accomplished: (i) the large liquid phase resistance to oxygen transport encountered in normal oxygen electrodes is reduced to a negligible level, and (ii) the oxidation step is separated from the electrochemical reduction step so that it can be studied separately. By this alternate oxidation and reduction of the rotating electrode, oxygen is removed from the gas phase and transferred as hydroxyl ions into the electrolyte. The resulting cathode reaction is

$$2e + \tfrac{1}{2}\,O_2 + H_2O \rightarrow 2\,OH^- \qquad [5]$$

with the copper alternating between the oxide and the metallic state. The zinc is oxidized to zinc oxide at the anode, which then dissolves in the electrolyte, exposing fresh surface, as follows

$$Zn + 2\,OH^- \rightarrow ZnO + H_2O + 2e \qquad [6]$$

$$ZnO + 2\,OH^- \rightarrow ZnO_2^= + H_2O \qquad [7]$$

making the over-all reaction

$$\tfrac{1}{2}\,O_2 + Zn + 2\,OH^- \rightarrow ZnO_2^= + H_2O \qquad [8]$$

When the rotating electrode is left unwiped, then the resultant liquid film of electrolyte covering the electrode reduces oxygen transport to a very small quantity. This is evident from the low current obtained from the rotating electrode when unwiped, as shown by the lower curve of Fig. 6. The current obtained here is at least partly attributable to the Cu-Zn couple. Removal of the liquid layer from the electrode by wiping results in a large increase in the current, as is evident from the upper curve of Fig. 6. The large resistance of even thin layers of electrolyte to oxygen transport is again evident from these findings.

[4] This assumes bulk diffusion of oxygen in the gas phase. In pores whose diameter is of the order of magnitude of the mean free path of oxygen molecules or less (6×10^{-6} cm, 0.06μ), oxygen transport occurs by Knudsen diffusion and can be considerably less than with bulk diffusion. Thus, in extremely small pores it is possible that oxygen transport through the gas phase may be limiting.

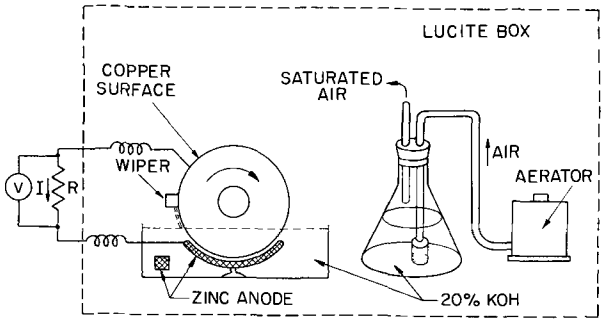

Fig. 5. Apparatus for oxidation studies

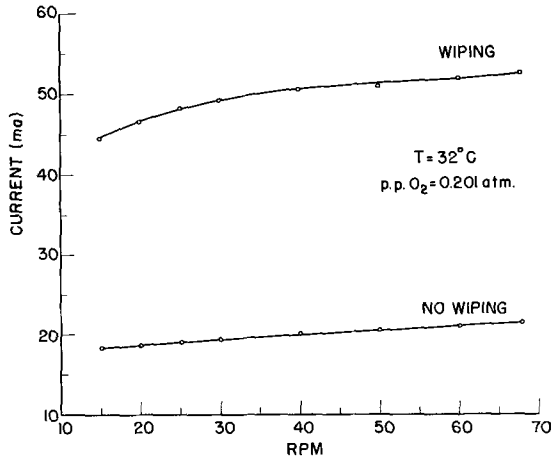

Fig. 6. Effect of wiping on current of rotating copper electrode

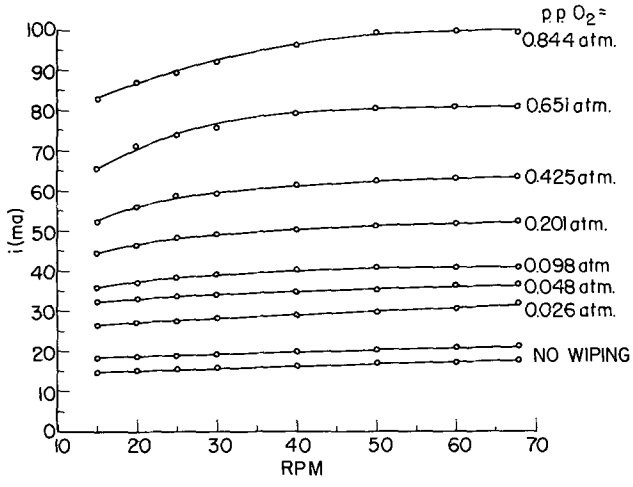

Fig. 8. Data from rotating copper electrode

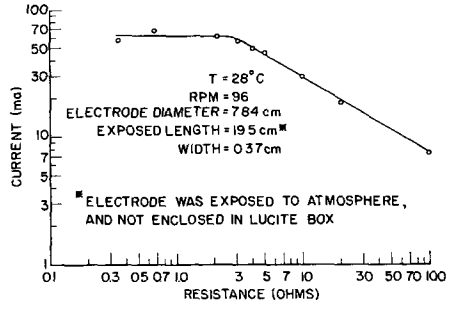

Fig. 7. Effect of resistance on current of rotating copper electrode

Figure 7 is a typical plot showing how the current produced by a cell using a wiped copper electrode rotating at a constant rpm varies with external resistance. Inspection indicates that the current increases with decreasing resistance until the external resistance has been reduced to about 3 ohms, after which the current remains constant. Doubling the zinc anode area does not change the results obtained, indicating that these findings are attributable to the behavior of the cathode. Similarly, decreasing the area of the cathode exposed to the gas phase decreases the magnitude of the maximum obtainable current, indicating that the controlling reaction is the oxidation of the wiped exposed electrode surface, not the electrochemical reduction at the submerged surface. The maximum current obtainable is evidently determined by the amount of oxygen present in the oxide film, which is completely removed upon submergence. The thickness of the film, which varies inversely with rotational speed, can therefore be calculated directly from this maximum current, the rotational speed, and the area of the copper ring on the cathode. At an oxygen partial pressure of 0.844 atm and 32°C, the wiped rotating copper electrode produced a current density of 26 ma/cm^2 of area exposed to the gas phase. It follows that if effective use could be made of the internal area of an air-depolarized porous electrode without being limited by mass transfer problems, then high current densities should be attainable.

The oxide film formed on this rotating electrode is probably thicker and otherwise not the same as that formed in an oxygen electrode operating partially submerged in the usual way. In consequence, the rates measured on the rotating electrode are probably lower than for normal electrodes. It is therefore significant that, even under these conditions, the reaction rates are found to be high. These findings serve to emphasize again the importance of adequate mass transport in gas depolarized electrodes.

Oxidation Studies

The primary purpose of the rotating electrode was to provide information about the relative magnitudes of the mass transport rate and the chemical reaction rate at an air-depolarized copper electrode; it can also be used to investigate the mechanism of metal oxidation.

The current obtained from the wiped, rotating copper electrode was measured as a function of rpm at a number of oxygen partial pressures. The data are presented in part in Fig. 8 and were found to follow the familiar logarithmic relation which often holds for the low-temperature oxidation of metals.[5]

$$w = k_1 \log(k_2 t + 1) \qquad [9]$$

where w is the weight of oxide, t is time, and k_1 and k_2 are constants. For these data k_1 is found to be independent of oxygen partial pressure, while k_2 is proportional to the square root of the oxygen partial pressure. The logarithmic equation has been derived by various workers who proposed a number of different models (4, 5). The finding that k_1 is constant while k_2 is a function of the oxygen partial pressure is consistent with a model proposed by Evans (4) in which it is assumed that the rate-limiting step is the transport of oxygen through the oxide film. The proportionality of k_2 to the square root of the oxygen partial pressure suggests, for the Evans model, that a monatomic form of oxygen is the species transported through the oxide film.

Surface Behavior of Silver Single Crystals in Fused Sodium Chloride

Jerome Kruger and Kurt H. Stern

National Bureau of Standards, Washington, D. C.

ABSTRACT

The effect of immersion in fused NaCl on a silver single crystal has been studied at 900°C. In the presence of a temperature gradient both dissolution and deposition of silver occurred. No effect of crystallographic orientation was noted. Mass-transfer, resulting from dissolution and deposition, occurs from the hot to the cold end of the crystal and is accounted for by shifts of the equilibria $2Ag + \frac{1}{2} O_2 = 2Ag^+ + O^=$ and $Ag + Na^+ = Ag^+ + Na$ to the right with increasing temperature. In the absence of a temperature gradient some effects due to orientation occurred. In the presence of oxygen, subgrain boundaries became delineated by the formation of ridges containing metal impurities, such as iron, whose oxides are insoluble in NaCl.

Recent work (1) on the oxidation of polycrystalline silver in fused NaCl has shown that silver ions appear in the melt by two mechanisms:

$$Ag^\circ + Na^+ = Ag^+ + Na^\circ \quad [1]$$

$$2Ag^\circ + \frac{1}{2} O_2 = 2Ag^+ + O^= \quad [2]$$

The relative contribution of the two reactions to the total silver ion concentration depends on conditions, [2] being most important when the rate of transport of oxygen to the NaCl-Ag interface is high. Metallic sodium formed by [1] may partly vaporize under some conditions; some of it diffuses from the Ag surface, where it is formed, into the metal, forming an Ag-Na alloy.

The microscopic examination of metal surfaces oxidized in fused salts is a neglected area of research. Single crystal surfaces are well suited for such studies since they permit the study of the effect of differences in atomic arrangement on reaction rate. That such differences occur in aqueous media (2) and in the case of thermal etching (3) is well known, but no corresponding study in a fused salt has, to our knowledge, been carried out.

In the present work we have selected a metal whose surface and oxidation behavior in air at high temperature has already been investigated (3) and whose chemical behavior in fused NaCl is known. This investigation is a qualitative study of what happens to a silver surface exposed to a fused salt.

Experimental

Materials.—Reagent grade sodium chloride was dried by heating at 500° under vacuum (~10^{-4} mm Hg) for several days. Most experiments were carried out in alumina crucibles. In a separate experiment the solubility of this container in NaCl was determined to be approximately 0.001%. Some experiments were carried out in Vycor test tubes, others in silver crucibles described elsewhere (1).

Single crystals of silver[1] in the form of spheres ¾ in. in diameter were used. These crystals were grown in a graphite mold of the proper shape by the Bridgman technique at the rate of 1 in./hr in a vacuum of 10^{-4} mm Hg. Flat surfaces parallel to {100}, {110}, and {111} crystallographic planes were ground at the appropriate sites on the sphere. After extensive etching, mechanical polishing, and electropolishing, the back-reflection Laue method of x-ray diffraction showed the flats to be free of cold work and within ±2° of the desired orientation. Four different crystals were used in the experiments. One of these, in addition to the 3 faces described, had one cut randomly. Its orientation was within 2° of the {211} plane. Each crystal was then mounted in a silver holder for convenience of handling.

The temperature in the 12-in. tubular furnace used in most experiments was regulated by a Marshall controller. Under the conditions obtaining in most experiments a temperature gradient undoubtedly existed along the crystal and its silver holder, the hottest region being at the bottom and at the walls of the container.

Runs in an oxygen-poor environment were carried out in an argon-filled drybox (partial pressure of $O_2 = 10^{-4} - 10^{-5}$ atm).

One experiment, to test for differences due to absence of temperature gradients, was carried out in a large muffle furnace.

Procedure.—Prior to an experiment, the flats on the crystals were mechanically polished using a diamond abrasive on canvas, then the same abrasive

[1] 99 98% pure with Cu, Fe, Ca, Al, and Mg as the major impurities.

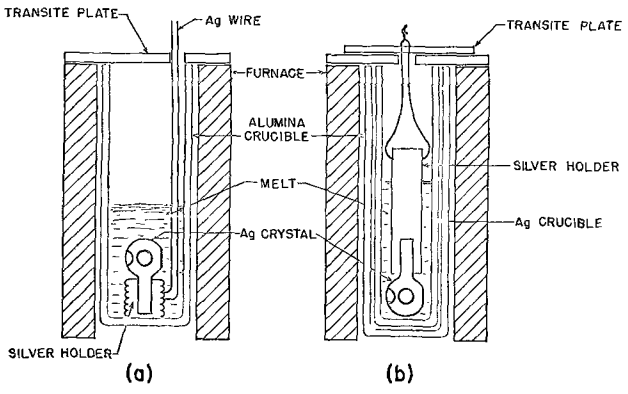

Fig. 1. Experimental arrangements used to immerse silver single crystals in molten sodium chloride.

on velvet. The whole crystal was finally electropolished in the cyanide bath described by Tegart (4). After washing in distilled water, spectroscopically pure methyl alcohol, and drying in a stream of warm air, the crystal was placed into the salt in one of the experimental arrangements shown in Fig. 1. In some experiments the crystal and solid salt were heated together from room temperature. There was no difference in results due to this change in procedure. The crystal was positioned as far away from the container walls as possible, although in some cases this amounted to only a few millimeters.

After removal from the melt the crystal was allowed to cool with a thin layer of solid salt on it. This was removed by quick rinsing in distilled H_2O. The silver surfaces were then examined by optical and electron microscopy, and with an electron probe microanalyzer.

Results

Two surface processes were observed when silver was immersed in molten NaCl at 900°C: (*a*) etching or dissolution as silver ions, and (*b*) deposition of silver onto the single crystal surfaces.

Etching Phenomena

Most of the experiments were carried out in either alumina or silver crucibles in the presence of air. Etching was identical in both kinds of crucibles, indicating that the alumina was essentially inert with respect to its influence on the behavior of silver in molten sodium chloride. Figure 2 shows the main features of etching at 900°C for 2 days in the presence of air. There are no marked differences in etching between the crystallographic orientations

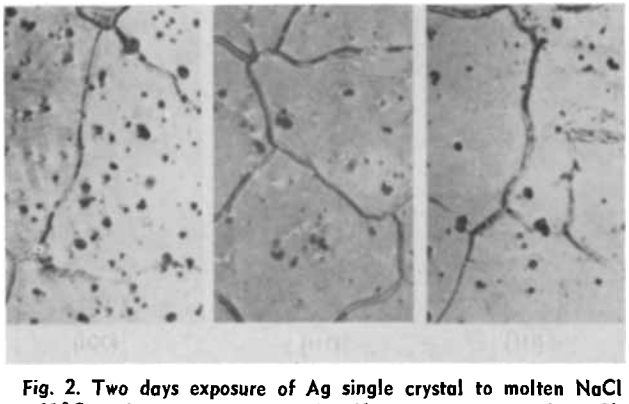

Fig. 2. Two days exposure of Ag single crystal to molten NaCl at 900°C in the presence of air. Magnification approximately 250X.

studied. The most notable feature was the delineation of a cell-like network of material. The boundaries delineating these cells broadened with immersion time. In some instances this substructure exhibited a subgrain boundary appearance (Fig. 3), which was somewhat similar to the structures observed by Rutter and Chalmers (5). The boundaries studied by these authors were formed by segregation of impurities during the solidification of metals, including silver.

An electron probe microanalyzer was used to determine whether impurities were indeed segregated in the boundaries. This instrument, described elsewhere (6), allows one to determine the amount of a selected element in a circular area of 4μ diameter. Two common impurities of silver were studied, iron and copper. The boundaries had an iron content of approximately 0.6 mole % after etching, while the cell interiors contained almost no detectable iron. There was no detectable difference, however, between the copper content in the boundaries and in the cell interiors.

In order to see whether these boundaries were ridges or trenches, negative Parlodion replicas were made of the etched surfaces for study by the electron microscope. Prior to shadowing of the replicas they were sprayed with a suspension of polystyrene spheres. By looking at the positions of the shadows of the spheres one could tell that the boundary areas had a higher elevation than the rest of the etched surfaces. Figure 4 shows that the shadow cast by the boundary is exactly opposite to that cast by the sphere. Thus, since the Parlodion replicas were negative, the boundaries must project from the surface.

Only very short immersion times (as little as 2 min) were necessary to reveal these boundaries. After 10 min they are readily discernible. Thus, this characteristic feature of the etching of silver (of the purity described) in molten NaCl can be observed almost from the very beginning of the process. It is important to note that when other etching treatments were tried on the specimens used they did not bring out this substructure. Beside etching in conventional aqueous etchants, such as dilute HNO_3 or dilute NH_4OH, thermal etching in air at 900°C was also tried. This latter treatment produced grooves similar to those described by Moore (3) and others but with no substructure delineation as Fig. 5 shows. However, if such air etched surfaces were

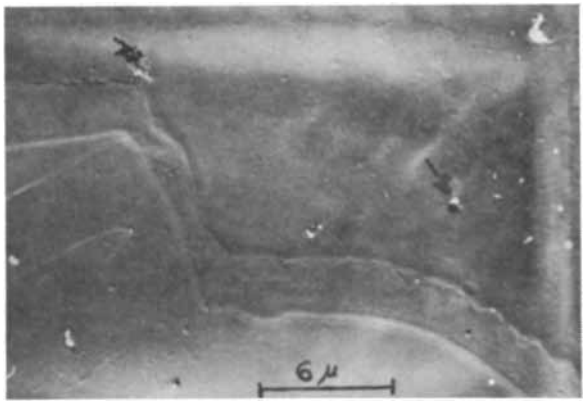

Fig. 4. Negative Parlodion replica (backed with carbon and shadowed by palladium) of raised sub boundary area. Arrow points to shadowed polystyrene sphere whose shadow is opposite to that of the boundary.

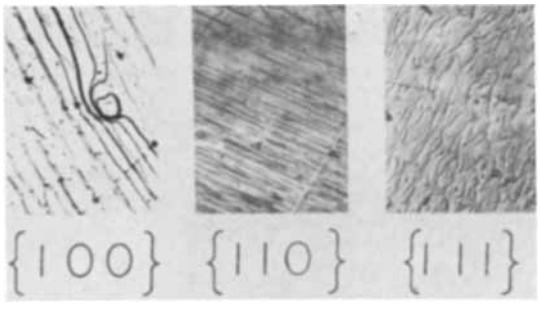

Fig. 5. Thermal etching of Ag single crystal in air at 900°C for 2 days. Magnification 200X.

then placed in molten salt, the grooves were erased and the structures shown in Fig. 2 and 3 were observed.

These structures also were not observed when a Vycor crucible was used or when reaction was carried out in a dry box in an inert atmosphere. Reactions in Vycor were rather irreproducible. Silica introduced by attack of the melt on the crucible has a profound influence on the reaction. A recent investigation by Littlewood and Argent (7) also points out this effect of silica in molten salt reactions.

Beside the delineation of a substructure, Fig. 2 and 3 show many spots which look like either pits or small hillocks sticking up from the surface. The electron microscope technique described above revealed that these spots are hillocks rather than pits. It was at first thought, on the basis of a large number of experiments carried out using one experimental arrangement, that the number of these small hillocks, or nuclei, per unit area depended on the crystallographic orientation of the underlying surface. However, when the geometry of the experimental arrangement (*i.e.*, the position of a given face with respect to the thermal gradient existing between the crucible wall and the specimen) was changed the number of such spots per unit area changed drastically. Figure 6 shows this effect.

In fact, no readily discernible differences in etching behavior or rate could be noticed with respect to crystallographic orientation. If differences in rate of attack did exist, they would produce symmetrical etch patterns on the spherical portion of the specimens used. Such patterns are found on single crystal

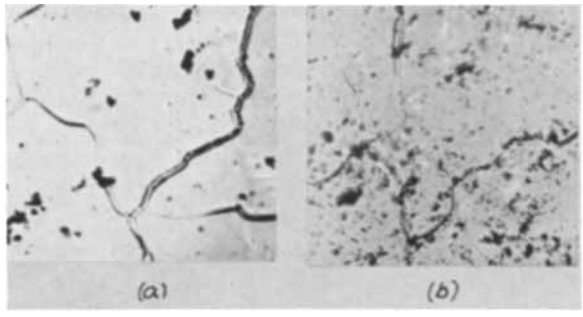

Fig. 6. Effect of position in thermal gradient. {111} surface exposed to molten NaCl at 900°C for 4 days; (a) was closer to the hot end of the thermal gradient than (b). Magnification approximately 250X.

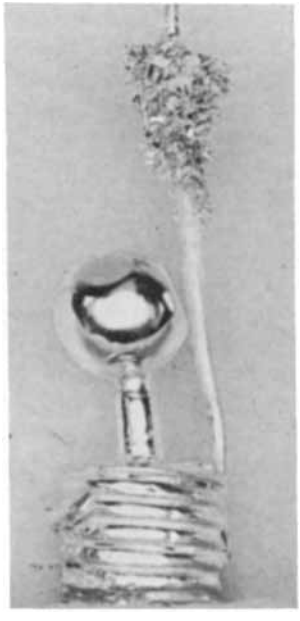

Fig. 7. View of whole crystal and silver wire (experimental arrangement (a)) for handling after 4 days exposure to molten NaCl at 900°C. Some dendritic crystals can be seen growing on the wire at the cold end of the thermal gradient, the molten salt-air interface.

spheres for other etching treatments (8). As Fig. 7 shows, the spherical portion remains quite smooth during the reaction with no evidence of differential attack at the different poles where different crystallographic orientations exist.

Besides the absence of any influence of crystallographic orientation crystal imperfections also do not influence the etching process when a temperature gradient is present. A single crystal disk was bent to a 2 cm radius and then etched in the molten salt for 3 days. At 900°C in this time polygonization probably would have occurred, and if nuclei formed at dislocations, rows of these related to the direction of bending would have been observed. For example, such effects were observed by Henderson and Machlin (9) for silver etched in dilute oxygen. No such effect was found for etching in molten NaCl.

All of the experiments described thus far were carried out under conditions where there existed a thermal gradient. When a silver crucible was used, the gradient was between the crucible wall and the crystal; for an alumina crucible it was between the crystal at the bottom of the crucible and the silver wire near the cooler air-salt interface.

The optical microscope showed no difference in etching when the thermal gradient was eliminated by placing the whole crystal-crucible assembly in a large closed muffle furnace. However, when the surface of silver etched in the absence of a thermal gradient was studied at higher magnifications, pitting and the formation of steps became evident. The formation of square pits and a spiral on the {100} surface, Fig. 8, also indicates that, when there is no thermal gradient, dislocations and crystallographic orientation may effect the etching behavior. These square pits in the interior of subgrains have a concentration of somewhat less than $10^6/cm^2$. This is a reasonable concentration if these pits occur at dislocations (9). An etchant recently described by Robinson and Levinstein (10) as forming pits at dislocations on {100} silver surfaces also gave a pit concentration of $10^6/cm^2$ when tried on the specimens used in this study. Figure 9 shows another area on the surface shown in Fig. 8 where hillocks may be seen occurring along with a pit and some steps. Some pits and steps or terraces were also found on the {111} surface etched in the absence of a thermal gradient, but not on the {110} and {211} surfaces.

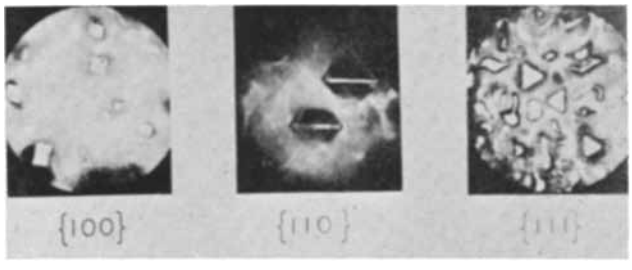

Fig. 11. Silver crystallites deposited on silver single crystal surfaces exposed to molten NaCl in silver crucible at 900°C for 15 hr in the presence of a thermal gradient. Experimental arrangement (b). Magnification approximately 115X.

Deposition Phenomena

Deposition by mass transfer of silver in the molten salt created no problem in the study of the etching phenomena when the experimental arrangement was that shown in Fig. 1a. As can be seen in Fig. 7, deposition occurred at the top of the melt near the air interface. In this case dendritic crystal deposits were formed at the coolest part of the system. When a silver crucible was used, however, (Fig. 1b) and a run was carried out for times greater than 1 hr, deposition occurred over the entire crystal and holder as shown in Fig. 10. In this experimental arrangement the entire crystal and its silver holder was at a lower temperature than the silver crucible wall with no metallic connection between crucible and crystal. The deposits were of two types, dendritic and small faceted crystals. The dendrites grew all over the specimen and holder. The faceted crystals were observed on the crystal itself. Since the crystal was near the bottom of the crucible, it was somewhat warmer than the holder where more dendritic growth was observed. These faceted crystals seemed to bear some epitaxial relationship to the crystallographic planes upon which they grew, as judged by the symmetry of their morphology (Fig. 11).

If the thermal gradient between the crystal and the crucible wall was eliminated by placing the

whole arrangement in a muffle furnace, no growth at all was observed for times as long as 24 hr.

Summary of Results

For the purposes of the discussion that is to follow the more important results obtained are summarized:

1. No faceting nor rate differences due to the crystallographic orientation of the surface are observed in the presence of a temperature gradient.
2. The etching of silver in molten NaCl in the presence of air reveals a cell-like substructure. Small scattered hillocks are also formed on the surface. Iron was found to segregate in the ridges between the cells.
3. This substructure is not revealed by thermal or aqueous etching.
4. In an inert atmosphere this substructure is not delineated.
5. When the crystal is in a thermal gradient no pitting is observed at the hot end. When the gradient is absent pits are observed on {100} and {111} surfaces and some of these seem to be related to dislocations.
6. Dendritic crystals are deposited at the cold end of the thermal gradient by mass transfer of silver. Along with these dendritic growths some faceted growths occur; the orientation of the latter is dependent on the orientation of the surfaces on which they grow.
7. In the absence of a thermal gradient no mass transfer of silver occurs.

Discussion

Etching Phenomena

In the presence of a thermal gradient one of the most notable observations is the absence, in comparison with thermal etching and aqueous etching, of any effect of crystallographic orientation on the production of faceting. This implies that the differences in metal free surface energy used by Moore (3) to explain atomic rearrangement into simple and complex planes at 900° in air must be quite unimportant in the salt. In air etching these planes must develop because of atomic or ionic migration on the surface from planes of high to those of low energies. Moore's observation, that the growth patterns form only in the presence of oxygen but not in an inert atmosphere, suggests that migration occurs because Ag^+ ions formed by reaction [2] are mobile and can thus migrate along the surface, whereas silver atoms are not. In the salt any ions formed are removed from the surface into a very undersaturated melt. When a high temperature gradient exists, the difference in the chemical potential, $\Delta\mu$, between a silver atom, on the one hand, and an electron in the lattice and a silver ion in the melt, on the other, is greater than under isothermal conditions. The high driving force which this implies would swamp out any small differences in surface energies that may exist under equilibrium conditions at high temperatures. Not only was the temperature gradient responsible for the elimination of etching differences between crystallographic orientations, but also for the absence of differences in etching rate between imperfect (dislocations and/or impurities) and perfect sites on the same crystallographic plane. According to Cabrera (11) differences between the rate of removal of an atom at a dislocation and an atom not at a dislocation become insignificant when $\Delta\mu$ is large. Although his treatment is concerned almost exclusively with evaporation of a neutral atom from the metal into the surrounding medium, it can still give some qualitative insight into the case of the dissolution of ions from the metal lattice. Indeed, when $\Delta\mu$ was decreased by the elimination of the thermal gradient some indications of differences in surface free energies, such as the formation of pits with spirals, became evident. Thus, if his theory is applicable to this system, when the thermal gradient was eliminated, $\Delta\mu$ was lowered to a value where the rate of introduction of ions into solution from dislocations, R_d, was greater than that at nondislocation sites, R_p. $\Delta\mu$ was, however, still high enough so that R_d was large enough to produce observable pits.

There remains to be explained why, although an effect of crystallographic orientation on etching is observed in aqueous solution where a reaction similar to [2] operates, no such effect seems to occur in the fused salt. Two possible explanations are as follows: (*A*) Perhaps the most important reason is related to the temperature gradients in the unstirred melt, which are virtually absent in aqueous solutions. (*B*) The differences in surface energy are greater at room temperature than near the melting point (which seems reasonable since at the melting point these differences must disappear) and thus become less important for the oxidation at high temperatures. In the oxidation of copper, for example, Talbot and Benard (12) found that differences in the rate of oxidation disappeared at high temperatures.

Beside the results on the effect of crystallographic orientation, the other most evident feature observed when silver is etched in molten NaCl in the presence of air is the delineation of subgrain boundaries. The results obtained with the electron probe microanalyzer point to an explanation for this. When sufficient oxygen is present, iron in the subgrain boundaries is oxidized to Fe_2O_3, the oxide stable at 900°. This oxide is nearly insoluble in the fused salt (13) and would thus remain in the crystal while the silver between the boundaries dissolved. This interpretation is also consistent with the observation that no such delineation occurs under very low O_2 partial pressures since in this case the oxide will not form. On the other hand, copper, whose oxide (CuO) is relatively soluble in NaCl-0.7 mole percent (13), did not remain in the boundaries since it would presumably dissolve in the melt.

Deposition Phenomena

The presence of a thermal gradient has even greater bearing on deposition than on etching. When deposition occurs mass transfer must be involved. This transfer, *i.e.*, removal of metal from the hottest sites and deposition at the coldest, must occur, not by the differential solubility of atomic silver in the

melt (1), but because equilibria [1] and [2] lie further to the right at higher temperatures. For reaction [2] in NaCl the equilibrium constant $K_2 = [Ag^+]^2 [O^=]/P_{O_2}^{1/2}$ can be calculated (here for $P_{O_2} = 1$) from thermodynamic data.

The activity product of Ag_2O in NaCl can be calculated using free energies of formation compiled by Glassner (13) in

$$\log a^2_{Ag^+} a_{O^=} = \frac{\Delta F^\circ_{Ag_2O} - 2\Delta F_{Ag^+} + -\Delta F_{O^=}}{2.303\,RT}$$

an equation derived by applying the method of Edeleanu and Littlewood (15) for calculating the solubility of metal oxides in fused salts. The dilute solutions are nearly ideal and activities in this equation can be replaced by mole fractions. On the basis of these calculations, assuming a gradient of 50°, K_2 increases from 3.2×10^{-8} to 1×10^{-7} from 850° to 900°, leading to a corresponding Ag^+ ion increase (if [2] is the only reaction occurring) from 4.0×10^{-4} to 5.8×10^{-3}. Such a driving force is quite sufficient to account for mass transfer, *i.e.*, silver dissolves at the higher temperature and precipitates at the lower temperature where such a high Ag^+ concentration cannot be maintained. Corresponding calculations on reaction [1] lead to similar results. For example, K_1 increases from 2×10^{-11} to 1×10^{-10} from 850° to 900°.

At the lower temperature end of the gradient profuse dendritic growth occurs after relatively brief periods of time. In general, such growth usually commences in regions of supersaturation and extends into the concentration gradient (16). This is just what was observed (Fig. 10) when a temperature gradient existed between the silver crucible (high temperature) and the silver crystal (low temperature). Edeleanu and Gibson (17) have reported that mass transfer in fused chloride melts for silver occurs only when there is a metallic connection between the hot and cold ends of the gradient. They suggest a thermocell mechanism for mass transfer. The fact that there was no such metallic connection when the experimental arrangement shown in Fig. 1b was used indicates that mass transfer occurs by the mechanism given by Eq. [1] and [2] rather than by a thermocell mechanism. Faceted growth occurred along with dendritic growth on the crystal near the bottom of the silver crucible because here, since the temperature gradient was minimized, the driving force for dendritic growth was much lower and conditions for such growth became less favorable.

This faceted growth occurring in a small thermal gradient may also be looked at with reference to reactions [1] and [2]. Whenever silver atoms are oxidized, presumably by electron transfer to adsorbed oxygen atoms, (or molecules) and sodium ions, the concentration of Ag^+ and $O^=$ ions and Na° atoms near the surface can be lowered only by diffusion away from reaction sites, a relatively slow process. Thus, even though the bulk concentration of these species in the melt may be low, their concentrations at sites near the surface may exceed those permitted by K_1 and K_2, leading to reversal of reactions [1] and [2], *i.e.*, deposition. Chemical studies (1) of reaction rates in this system also support this mechanism.

When the thermal gradient was completely eliminated, neither dendritic nor faceted growth was observed in a comparable time because the localized supersaturation no longer existed.

Acknowledgments

The authors are greatly indebted to Joan P. Calvert for taking some of the photographs and carrying out some of the replication; to D. Ballard for the electron microscopy; to H. Yakowitz for the electron probe microanalyzer measurements; to Mrs. Martha M. Darr for carrying out the spectrochemical analysis of the silver. We are also grateful to R. L. Parker and A. W. Ruff, Jr., for helpful discussions.

Electron Diffraction Study of the Removal and Formation in Vacuo of Oxide Films on Uranium and Plutonium

James T. Waber, Clayton Olsen, and Dawn D. Whyte[1]

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

Experiments and the development of apparatus relating to the removal of oxide film and the attempts to prepare an oxide-free surface on uranium are described. Polishing the metal in vacua of the order of 10^{-7} torr appears to be the most successful method. UH_3 and UO_2 were observed to form rapidly on the metal in such vacua. PuO_2 was found to form on plutonium in vacua at pressures of less than 1×10^{-8} torr. The possibility that plutonium hydride also formed could not be investigated, because of the similarity in crystal structure and lattice parameter between PuO_2 and PuH_2.

The oxide film that commonly occurs on uranium when it is exposed to aqueous or gaseous media has been identified as UO_2 in electron diffraction studies by Hickman (1), by Hart (2), and by Flint, Polling, and Charlesby (3). The presence of UO_2 in films that are too thin to give rise to interference colors can also be established by standard x-ray technique. Although the detection of thin films by x-ray diffraction is not possible for many metals, it is successful for uranium, because of the high scattering power of the uranium atom.

Hart (2) and Flint *et al.* (3) list additional lines which do not correspond to the diffraction pattern of uranium dioxide. Hart (2) interprets them as due to a mixture of U_2O_5 and U_3O_8. In our work, no evidence for these lines was obtained. Wilman (4) suggested that the lines observed by Flint *et al.* should be attributed to diaspore, which had been embedded in the metal surface during polishing. This explanation, however, is not applicable to Hart's work, because he employed diamond dust as an abrasive.

In the investigations (1-3) cited above, as well as in a number of the experiments described herein, the metal was polished in air before being admitted to the specimen chamber of the electron diffraction unit. Some of the experiments described below show that it is difficult to eliminate traces of UO_2 from the surface. A completely oxide-free surface on uranium (with which to study the formation of the oxide film without the influence of previously existing oxide) was not achieved; our efforts were directed toward improving the ultimate vacuum in which the polishing is conducted, so that the oxide-free portions of the surface would persist long enough to be studied.

Lattice Constants of Some Actinide Oxides and Hydrides

The structure and lattice parameters of most of the known oxides of uranium are cited by Hart (2). The so-called monoxide, UO, has the cubic, NaCl lattice with a parameter of 4.95Å. The dioxide has the face-centered cubic, CaF_2 lattice. The pure compound has a parameter of 5.4706 ± 0.0003Å. Hering and Perio (5) have found that the lattice parameter increases with decreasing oxygen content and shrinks with an increasing oxygen content to a value of 5.4380Å at the boundary of the β phase, where the composition is U_4O_9. Recent data on these and higher oxides of the uranium-oxygen system are reviewed by Gronvold (6).

Mulford, Ellinger, and Zachariasen (7) report that the low-temperature form of UH_3 has a simple cubic unit cell, containing two molecules, with $a_o = 4.160$Å; and the β (or common) form of UH_3 has eight uranium atoms per unit cell with $a_o = 6.63$Å.

Plutonium, like uranium, forms a fluorite-type dioxide, PuO_2, during exposure to air. Also, the oxides Pu_2O_3 and Pu_4O_7, which contain anion vacancies, have been prepared under special conditions. A monoxide similar in properties to UO has also been observed. The available information on the plutonium-oxygen system has been reviewed by Holley, Mulford, and Ellinger (8). The lattice parameter of stoichiometric PuO_2 is 5.396Å.

The two hydrides of plutonium have been investigated by Mulford, Sturdy, and Ellinger (9) and found to have extensive ranges of solid solubility. The compound PuH_x, where x lies between 2.0 and 2.7, has the fluorite structure. The lattice parameter decreases from 5.359 to 5.34 over the range of compounds from $x = 2.0$ to 2.5. The hexagonal hydride PuH_{3-y} is less stable.

Experimental Procedure

All specimens were mechanically polished to free them of the major portion of their overlying oxide films. The final metallographic paper used was 600-grit silicon carbide paper, and petroleum ether was used as a lubricant to reduce the specimen surface temperature during the later stages of polishing. Any SiC particles imbedded in the surface were removed by briefly polishing the specimen on clean

[1] Present address: Commercial Atomic Power Division, Westinghouse Electric Corporation, Forest Hills, Pennsylvania.

billiard cloth that had been moistened with petroleum ether.

In the experiments discussed below, the smooth metal surface was substantially freed of any residual oxide film by polishing *in vacuo*. Ceramic polishing wheels and metallographic polishing papers were both mounted on a shaft, and were used with about equal success for this purpose. ED (electron diffraction) patterns were obtained for the several abrasives used, so that any extra diffraction lines due to abrasive particles imbedded in the metal surface could be identified. The occurrence of such ED lines in individual experiments is not mentioned below; only the patterns of products and the metal are cited.

Apparatus employed.—An electron diffraction unit, available commercially from the General Electric Co., was modified to permit the attainment of vacua of the order of 10^{-7} torr. While such a "hard" vacuum is not required for the operation of the unit, preliminary oxidation experiments demonstrated that it was essential to the preservation of an oxide-free surface on uranium for even a few minutes.

Figure 1 illustrates the mechanical parts of the modified ED apparatus. Two roughing pumps were installed, one for the specimen chamber, F, and the other for the film chamber, J, to increase the pumping speed. By installing the large quarter-swing valve, G, the film and specimen chambers could be separately isolated and the air admitted to one without influencing the vacuum in the other. Fresh film plates could then be inserted without exposing the specimen surface to air. The quarter-swing valve was made of nonmagnetic metals and was mounted with its axis of rotation below the line of flight of the undeflected electrons.

A carefully machined collimator, consisting of two Armco iron disks containing carefully centered 25-mil diameter holes, was inserted between the magnetic lens, D, and the specimen chamber, F. To increase pumping speed, a separate line was added to connect the brass case of the electron gun to the large diameter vacuum line. This vacuum connection increased the beam stability of the electron gun.

In a preliminary modification an abrasive disk was mounted on the front door of the specimen

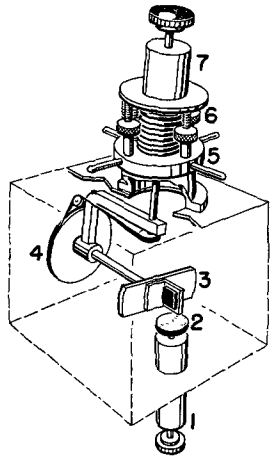

Fig. 2. Perspective sketch of the specimen manipulator used in polishing the specimen and aligning it for grazing incidence: 1, rotary vacuum manipulator; 2, abrasive disk; 3, specimen holder; 4, specimen rotating drive; 5, specimen height adjustment; 6, specimen tilting adjustment; 7, sealed rotating shaft.

chamber and could be rotated in a vertical plane. In the later design, shown in Fig. 2, any electrical charging of the abrasive disk had little influence on the electron beam, because the specimen was electrically shielded by the metal specimen holder when in the normal horizontal position for diffraction.

The specimen was polished by rotating it until its surface became parallel to the surface of the abrasive disk and then turning the shaft of manipulator 1 either by hand or by a motor.

The entire vacuum assembly with the exception of the glass liquid-air traps and the electron gun were wrapped with electrical heating tapes. By this means, the metallic surfaces of the ED unit were baked out for about a week at 100°C. It was observed that the ED unit could be evacuated more rapidly following each insertion of photographic plates, polishing disks, or specimens if dried helium (or argon) was admitted to the system before opening it to the atmosphere.

With the modifications of design and procedure indicated above and with careful attention to various details such as obtaining carefully soldered joints, pressures of 7×10^{-8} torr (or lower) have been obtained repeatedly. If, however, gas was released, due to high local temperatures, from various materials, such as the binder used in the manufacture of polishing wheels, the effective vacuum at the metal surface could be substantially poorer than recorded. The small quantities of gas that may be observed to enter through Wilson seals when their shafts are moved were largely eliminated by using a vacuum tight, nutating rotary shaft[2] sealed with a syphon bellows.

The instrument was frequently calibrated by using transmission patterns from freshly prepared magnesium oxide smoke.

Type of experiments conducted.—This experimental study was divided into two parts. The first was concerned with the examination of uranium and plutonium after exposure to various oxidizing conditions. The second was concerned with preparing an oxide-free surface on uranium.

[2] Marketed by National Research Corporation.

Several uranium oxides were observed during the first part of the work. It is surprising that in the second part one or both of the hydrides were found after almost all of the dioxide film had been removed by polishing. Details of the individual experiments are given below.

Also, experiments were made in which hydrogen was admitted to the specimen chamber. The uranium hydride that was formed on the metal surface was decomposed *in situ* by heating and evacuating the chamber. In connection with these experiments, dried air was subsequently admitted to the ED unit to study the formation of oxide on the hydride. Both gases were used without purification other than the removal of moisture. For these experiments, a simple wire-wound "furnace" was mounted on the specimen holder shaft of the ED unit. The metal specimen was bolted onto the front surface of the heater.

Experiments on Uranium and Plutonium

Uranium polished in air.—Uranium specimens that had been hand-polished in air through 400-grit silicon carbide paper were examined, and only uranium dioxide was observed. In a similar experiment with a uranium alloy containing 6 w/o niobium, uranium dioxide was observed. However, U_3O_8 was detected on the alloy (but not on the pure metal) after it had been polished in air with 240-grit silicon carbide paper attached to a rapidly rotating abrasive wheel.

When uranium is heated in air below 185°C, uranium dioxide is the major product. Above this temperature, the tetragonal U_3O_7 and the orthorhombic U_3O_8 are occasionally observed by x-ray diffraction. This observation suggests that the surface temperature of the 6 w/o niobium alloy rose to at least 185°C during polishing.

Vacuum annealed uranium.—It was observed by Rundle, Baenziger, and Wilson (10), who used x-ray diffraction, that uranium monoxide forms on a uranium surface when powder samples are heat-treated in evacuated silica capillary tubes. These monoxide films are thick enough to be studied readily by x-ray diffraction methods. Hoekstra and Siegel (11) doubt the existence of monoxide and point out that no supporting chemical analyses were made to demonstrate that the diffraction patterns were not due to monocarbide or mononitride films. The latter compounds have crystal structures identical with, and lattice parameters similar to, that of monoxide.

Williams and Westmacott (12) have reported the unusual sequence of products on uranium-monoxide/dioxide/metal and offer x-ray and substantial metallographic evidence to support their conclusion. However, no confirmatory analyses were made. They found that the products occurring in this sequence were thicker when partially oxidized uranium was heated in vacuum. They report, however, that, in initial experiments, dioxide was found by electron diffraction after mechanically polished specimens were heated in a vacuum of 2×10^{-5} torr to temperatures in the range 800°-1100°C. They present an extensive argument concerning the thermodynamic conditions that are necessary to permit the occurrence of this sequence of products. In an additional experiment in which a polished sample was heated in a vacuum at 9×10^{-3} torr they obtained the sequence of layers: dioxide/monoxide/dioxide/metal. Other of their experiments indicate that monoxide can be oxidized on cooling in a poor vacuum.

What appear to be monoxide films, on the basis of x-ray diffraction alone, have been prepared in this Laboratory by heating large specimens at 600°C in vacua of 10^{-6} torr and at 800°C, or higher, in vacua of 6×10^{-5} torr. As far as the x-ray evidence is concerned these films always contain a small amount of UO_2 associated with the monoxide. The electron diffraction method was employed to ascertain whether or not UO_2 was present on the exterior surface of these oxides.

Before discussing the ED results, it seems desirable to review the x-ray evidence obtained on the same specimens. Specimen 1802 was heated in a fused-silica furnace tube for 19 hr at 1000°C in a vacuum of 10^{-5} torr. The x-ray diffraction pattern of 1802 corresponded to α-uranium plus uranium monoxide plus a small amount of strongly oriented uranium dioxide [the (200) line was abnormally strong]. Orientation and pole figure studies reported elsewhere (13) indicate that this cubic orientation texture having the (100) planes of the dioxide lattice parallel to the metal surface is obtained on vacuum heat-treated samples.

Specimen 1804 was heated in a similar furnace tube for 15 hr at 800°C under a vacuum of 10^{-5} torr. Again, uranium metal, monoxide and dioxide were observed by x-ray diffraction.

For comparison purposes, the approximate intensity of the monoxide (111) line was 210 and dioxide (111) line was 36 on specimen 1802. The two (111) line intensities were 720 and 3, respectively, on the lower temperature specimen, 1804. The relative intensities of the metal lines indicated that the film was thicker on 1804 than on 1802. The percentages of UO and UO_2 are not directly related to these relative intensities because the monoxide has a different orientation than the dioxide, and orientation can cause large changes in the relative intensities of two lines of the same pattern.

The electron diffraction study of specimen 1802 gave only a pattern of uranium dioxide. Very broad lines, which made positive identification of the outermost film difficult, were obtained in a similar examination of specimen 1804. These line positions were intermediate between those of the monoxide and dioxide lattices. One cannot conclude from these experiments that the sequence observed by Williams and Westmacott (12) was present in these two tests.

A 5 a/o molybdenum alloy specimen was mounted on the furnace of the electron diffraction unit. The electropolished sample gave only Beilby lines at room temperature. At 100°C in a vacuum of 4×10^{-4} torr, very weak dioxide lines could be seen, and strong dioxide lines were obtained when the alloy specimen reached 400°C. At 600°C, however, in the same vacuum, the dioxide was partially reduced during a few hours, and weak lines corresponding to

uranium monoxide were observed. This is consistent with the experience of Williams and Westmacott (12), who heated a 20 a/o molybdenum alloy specimen for 115 hr at 650°C while maintaining a vacuum of 2 x 10^{-5} torr. Their x-ray and ED patterns were identical and corresponded to monoxide having a lattice parameter of 4.953Å.

Oxide formation of plutonium.—Experiments concerning the vacuum polishing of plutonium were conducted before the vacuum system and specimen chamber were modified. As observed with uranium, some dioxide forms on the metal soon after polishing, and there is evidence that orientation occurs in the PuO_2. With both uranium and plutonium, there is growth in a preferred direction which results in the formation of the dodecahedral or (110) texture in the oxide. Lattice spacings and intensities observed for α-Pu and PuO_2 following polishing and storage in vacuum at a pressure of 1μ or less are presented in Table I. Because of preferred orientation in the metal, line intensities of the α-Pu sheet sample differed from those tabulated, which relate to randomly oriented plutonium powder specimens. Thus, weak diffraction lines occur, but a number of medium ones do not.

Because of the similarity in structure and lattice parameter between PuH_x and PuO_2, it is impossible to ascertain that the hydride is formed *in vacuo*, as has been observed with uranium.

Oxide Removal from A Uranium Surface

Two methods of oxide removal, mechanical and chemical polishing, were studied. In the latter method, an attempt was made to remove the dioxide by first hydriding, brushing, and then decomposing any residual hydride *in vacuo*. However, the mechanical method of polishing was more successful.

Oxide removal by hydriding.—Although UH_3 is known to ignite readily when exposed to air, in many instances it has been found to be reasonably

Table II. Products observed by electron diffraction during a sequence of cleaning operations

Surface preparation	Diffraction lines found
Uranium polished at room temperature through 3/0 paper in air.	UO_2
Heated to 150°C in vacuum, H_2 admitted to a pressure of 116 torr for 10 min, then evacuated.	Strong α-UH_3 + medium β-UH_3 + very weak α-U metal
Sample then polished in vacuum at 150°C with 2/0 paper.	Medium α-metal + UO_2
Residual hydride decomposed by heating 3 hr at 300°C in vacuum of 10^{-5} torr.	Strong UO_2 + weak α-U
Surface then polished at 300°C with 2/0 paper. Vacuum of 10^{-5} torr maintained.	Weak UO_2 + medium α-metal
Rehydrided at 150°C and cooled to room temperature. Evacuated to 10^{-5} torr.	α-UH_3 + β-UH_3
Surface polished *in vacuo* at room temperature.	α-UH_3 + medium α-metal
Held in vacuum of 10^{-5} torr for 12 hr at room temperature.	Strong α- and β-hydrides plus weak metal
Heated to 150°C, 10 torr air pressure admitted.	Weak UO_2 plus medium α-metal
Oxidation continued to blue interference color.	Medium UO_2 plus very weak α-metal

stable at room temperature. In the only ED experiment conducted with the powdered hydride, a sample was prepared from the elements at 150°C and transferred from the vacuum system through air to the specimen chamber of the ED unit. The pattern corresponded to a mixture of α- and β-hydrides plus a slight amount of uranium dioxide. This experiment is cited to show that the hydride is not usually reactive in air at room temperature and to account for the persistence of lines due to the hydrides in many patterns of partially oxidized specimens. This inertness of UH_3 may result because of an overlying dioxide film.

Because of the volume increase attending formation of UH_3 when hydride forms beneath the oxide film on uranium, the adherence of the dioxide to the metal is destroyed. Both UO_2 and some UH_3 can be removed by brushing the surface of a hydrided specimen in vacuum. The residual hydride was decomposed by heating the specimen to about 300°C, holding it at that temperature for several hours, and pumping away the evolved gas. Katz and Rabinowitch (14) report that one hour at this temperature is sufficient to decompose the β-hydride.

The products that were identified by electron diffraction at various stages during one such experiment are listed in Table II. Since, in general, hydride lines were not detected following vacuum heating and the dioxide line intensities increased during the experiment, it is a reasonable conclusion that new dioxide was being formed by reaction between the newly formed uranium and the residual gas in the evacuated ED unit. Evidently the hydrogen released by decomposition is not effective in sweeping away any oxidizing gases.

Oxide removal by vacuum polishing.—As a result of the improvements to the ED unit, vacua of 5×10^{-7} torr could be obtained within 15 min after placing a specimen in the unit. Pressures of the order of 8×10^{-8} torr (equivalent nitrogen pressure) were obtained after a few hours of additional pumping. Almost negligible amounts of dioxide remained on the uranium surface immediately after polishing. The amounts increased rapidly, however, even in such good vacua. Also, appreciable amounts of α- and β-hydride have been detected on the surface, after the uranium was polished in vacua. These give way to oriented dioxide. The diffraction data for one series of experiments on uranium are presented in Table III.

The UO_2 was initially detected on the high-purity uranium sample as it was placed in the ED unit. Three minutes after it was polished with 400 grit emery paper in a vacuum of 5×10^{-7} torr, the pattern corresponded to strong α-metal plus β-hydride plus a very weak pattern of UO_2. After standing 10 min in this vacuum, the lines of UO_2 had increased, but those of β-hydride and α-uranium remained the same. After 120 hr at 5×10^{-7} torr, the pattern corresponded to oriented UO_2 plus one very weak line located in the middle of the triplet of lines corresponding to α metal. This specimen was lightly repolished without breaking the vacuum, and a strong pattern of oriented UO_2 plus a medium weak α-metal pattern was observed. In all of these observations the ratio of intensities indicated a dodecahedral fiber texture of the oxide (13) rather than random texture, and the diffraction patterns were consistent therewith. It is inferred that the texture did change in degree of perfection but not significantly in type as the film grew thicker.

In six separate experiments, at a pressure of 6×10^{-8} torr strong patterns of alpha hydride were found on the surface of vacuum polished uranium. These hydride patterns were stronger than the metal or the dioxide patterns and persisted for as long as 15 min. The slow strengthening of dioxide lines after polishing was noted in each experiment, and lines due to the metal were observed to nearly disappear.

Discussion

The most significant product formed by the oxidation of uranium surfaces is the dioxide. At elevated temperatures some U_3O_8 is formed by reaction with air; in vacuum, however, the partial reduction of the dioxide yields monoxide.

The oxidant in a good vacuum must in all probability be water since both hydride and oxide are eventually formed. It is interesting that water is apparently the major gas pumped by the diffusion pumps when the ED unit is operating at a vacuum of the order of 10^{-7} torr. In one experiment, the ED unit was "blanked-off" from the pumps, and a glass collection bulb was connected to it. The presence of a virtual leak was confirmed with a helium leak detector. When the pressure built up in the unit, the collection bulb was closed off and the gas therein analyzed by mass spectrometry. Water was the ma-

* Approximate relative line intensities taken from various different x-ray spectrometer traces. Those unmarked are for uranium sheet. Data in ( ) are from α-UH_3 and those in [ ] are from β-UH_3 patterns. Intensities for UO_2 are designated by the superscript [z]. Relative intensities are not comparable between different crystal phases.

jor component, amounting to approximately 75%. Small amounts of nitrogen, oxygen, hydrogen, and carbon monoxide were also present. On the basis of other experiments the contaminants may be spurious.

It appears that UH_3 and UO_2 do appear simultaneously in the products from many corrosion experiments involving water (15). It is not clear, however, whether the simultaneous formation represented by the equation

$$7U + 6H_2O \rightarrow 4UH_3 + 3UO_2 \qquad [1]$$

properly describes the reaction mechanism or whether the formation of UH_3 precedes the UO_2 formation. That is, our experiments have not established whether the hydride can form initially by the thermodynamically unlikely reaction

$$4U + 6H_2O \rightarrow 4UH_3 + 3\,O_2 \qquad [2]$$

or whether, as suggested by Draley (16), the UH_3 forms by reaction of the metal with the hydrogen released during the formation of UO_2 as in

$$U + 2H_2O \rightarrow UO_2 + 2H_2 \qquad [3]$$

It has been suggested that the observed hydride could be formed by the outward diffusion of hydrogen contained in the metal (17). It is also possible that the small amounts of hydrogen present in the

residual gas react directly to form UH_3. None of our experiments offered evidence of the nature of the actual reaction mechanism.

The fact that the intensities of the hydride lines decrease as those of the dioxide lines increase suggests that the oriented oxide results from the subsequent oxidation of the hydride by water, or possibly by the oxygen released during reaction [2]. As indicated by [1], 4/3 of a mole of UH_3 is produced per mole of UO_2, if all of the hydrogen yielded by reaction [3] is consumed. The more intense hydride lines could be accounted for if the hydride, after being formed, protrudes from the surface and consequently scatters the electrons of the beam more effectively than does the dioxide film.

A significant feature of this ED study is that the (220) line of UO_2 is stronger, in some cases, than other dioxide lines and is certainly stronger than is normal for a randomly oriented sample of UO_2. This observation is consistent with the preferred orientation observed for uranium oxidized at high temperature by low-pressure water vapor (13). X-ray diffraction studies of uranium following its exposure to moist hydrogen or water vapor have led to the conclusion that the (220) UO_2 planes form parallel to the metal surface with little or no relation to the orientation of the underlying metal.

Recently Sella and Trillat (18) conducted a very interesting electron diffraction study of uranium surfaces that had been prepared in a variety of manners and subsequently treated. They observed that, during bombardment by argon ions, dioxide films were formed by the traces of oxygen in the argon. The films exhibited a strong dodecahedral fiber texture. A similarly oriented film occurred in certain of their anodizing and electropolishing experiments. They concluded that this texture might be associated with slightly anisotropic diffusion in the cubic UO_2 lattice, *i.e.*, with the growth process. They expressed some doubt that the portion of the film next to the metal, which was epitaxially oriented, could be detected. We, however, do not believe that such a region necessarily exists.

Experimental conditions determine which preferred orientation will develop, and the following examples are cited. The observed (220) orientation is not the same as that observed on vacuum annealed uranium. For the vacuum annealed uranium, the (200) planes of UO_2 are oriented parallel to the surface of the metal substrate (13). In other ED experiments it has been shown that UO_2 deposited from the vapor onto glass was oriented with (111) planes parallel to the substrate; when deposited onto a tantalum foil the [111] pole of the oxide was inclined with respect to the substrate and apparently was pointed toward the source of the UO_2 vapor.

These observations indicate that the dodecahedral texture is intimately associated with diffusion and growth processes. The results of Sella and Trillat (18) are consistent with this interpretation. The presence of the dodecahedral fiber orientation (rather than some other orientation or a random texture) in the UO_2 formed at room temperature in the vacuum of the ED unit, as well as at high temperature after exposure to water vapor, suggests that the same or similar mechanism operates and lends support to the conclusion that, in the ED unit, uranium is oxidized by traces of residual moisture.

The relative line intensities observed with an x-ray spectrometer are presented in Tables I and III for a number of substances. The intensities for the different phases are not comparable and are presented only as indicators. For the most part the patterns were obtained with randomly oriented samples, and it is well recognized that when preferred orientation is present in the specimen the relationships between intensities are markedly altered. It is probable that the relative intensities observed by electron diffraction with unalloyed plutonium sheet, which are cited in Table I, suffer from this effect; the x-ray intensities were obtained with a carefully randomized sample. This undoubtedly accounts for the apparent absence of some of the moderately strong lines of the monoclinic cell. It is sometimes difficult even for the x-ray spectrometer to resolve the individual lines of a doublet such as (020) and (211). With the characteristically poor resolution and high background of the electron diffraction instrument, several proximate lines may appear to merge into one broad one. For this reason and also because of the effect of preferred orientation, lines with weak intensities at the low angle region may have been inadvertently overlooked.

A few comments concerning alternative methods of preparing uranium surfaces free of overlying oxide films, are in order. One may (i) deposit the metal from the vapor onto a substrate, (ii) remove the oxide from the metal surface chemically or mechanically, or (iii) create a new surface by cleavage or fracture. Preliminary x-ray diffraction work showed that a substantial amount of oxidation occurred during the deposition of uranium from the vapor. Therefore this method was abandoned. The experiments involving electropolished metal were also disappointing. The removal by undermining with UH_3 has been described above. No other method of chemical attack was tried. Oxide removal by ionic bombardment is only partially effective as shown by Sella and Trillat; even with a beam of hydrogen ions, minute traces of oxygen will result in oxide films. The possibility that ions will be driven into the metal and exist as neutral atoms cannot be excluded. For these reasons, therefore, this method was not investigated. Hayman (19) demonstrated the formation of curious ridges, which appeared to be unrelated to the underlying metal, following bombardment of uranium by argon ions. The development of UO_2 nuclei in patterns on the metal surface following cathodic bombardment (20), due to traces of oxygen and water in the gas, could lead to misinterpretation. Other recent studies on surfaces following this type of ionic attack are cited (21-26).

Without question the uranium surfaces following mechanical polishing are very rough. The metal asperities projecting above the general level of the metal surface are heavily cold worked. Only a relatively few of them are thin enough to be penetrated by the electron beam. It may well be argued that the

diffraction from the oxide, which may occur as patches in the "valleys," is obscured by the high background scattering arising from the very rough surface. Nevertheless most of the observed diffraction pattern apparently results from the diffraction by the asperities, and these appear to be essentially denuded of oxide. The growth of oxide films on these surfaces is then easily detected and followed, although the oxide may be in the "valleys." The growth of UO_2 is surprisingly rapid at such low gas pressures.

Despite their shortcomings, the methods of oxide removal employed seem to be as satisfactory as any available. Although traces of dioxide persisted on the surface after it was polished *in vacuo*, doubtless the dioxide was present as patches, and a substantial portion of the surface was free of oxide. It would seem, then, that the goal of studying oxidation on the denuded uranium surface was achieved in the present study, and there is no compelling evidence that oxide-free surfaces on uranium were obtained in any of the previous investigations. However, the possible influence of the remaining patches of oxide on the nucleation and growth of new oxide was not eliminated in the present study.

Summary

Dioxide films are left on polished uranium and plutonium in the sense that they form so rapidly, even in good vacuum, that a truly oxide-free surface cannot be preserved for more than a few minutes after polishing. Also, the evidence presented suggests that the formation of uranium hydride may precede that of the dioxide.

The bare metal and the hydride react readily in vacua of the order of 10^{-7} torr to form dioxide, and it is necessary to maintain vacua of this quality to observe the reactions of relatively oxide-free uranium.

Some ED work that deals with the sequence of oxide films when both monoxide and dioxide are present is reported. Only the dioxide has been observed by the ED technique although x-ray diffraction work shows that the films formed by vacuum annealing consist mainly of uranium monoxide. From our evidence the sequence of products appears to be dioxide/monoxide/uranium, which is in contradiction to the results of Williams and Westmacott (12).

Acknowledgments

The authors are deeply indebted to Professor Lawrence Brockway for his inspiration, guidance, and interest during the work. A number of members of this Laboratory have assisted the authors from time to time. They should like particularly to mention Miss Gladys Sturdy, Ulrich Merten, Robert Mulford, Virginia Shadden, and Edward Wright. Finally, they should like to thank Gaza Nagy and his group of machinists for their careful work in fabricating the modified system. The assistance of William Miner in revising and of Mrs. J. Zastrow in typing this manuscript is gratefully acknowledged.

Manuscript received Feb. 29, 1960; revised manuscript received May 10, 1962. The work on this paper was done under the auspices of the U.S.A.E.C.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Theory and Design Principles of the Reversible Electroplating Light Modulator

Solomon Zaromb[1]

Research Division, Philco Corporation, Blue Bell, Pennsylvania

ABSTRACT

The potential uses and advantages of adjustable light shutters and reflectors based on reversible electroplating on transparent, chemically inert electrodes are indicated briefly. Over the entire visible light range, the highest ratio of optical density change δ to applied charge density q_d appears to be achievable with Ag, especially when formed in conjunction with I_2 or I_3^- ions. An aqueous plating solution containing 3-3.5M AgI and 7M NaI appears to be most suitable for achieving (*a*) a maximum δ/q_d ratio; (*b*) a satisfactorily uniform plating; (*c*) a maximum plating speed; and (*d*) a maximum rate of unplating. Of several electrode geometries and electrode arrangements capable of yielding essentially uniform plating, those utilizing adjacent subelements composed of parallel, closely spaced, flat, and narrow transparent electrode strips with line-symmetrically situated contacts is preferred, especially for large-area modulators. A series connection between the subelements is especially desirable.

With aqueous electrolyte solutions, the shortest practical plating time must exceed $\rho_e q_d^2/400$ sec, where ρ_e is the electrolyte resistivity in ohm-cm, and q_d is in coul/cm^2. Hence, to achieve both a maximal speed and a high δ, it is necessary to use several plating cells back-to-back. To maintain the desired opacity, a low, continuous plating current may be required, following the initial plating pulse. The time required to clear the cell may vary from less than a msec, in cases where a fast plating pulse is followed instantly by a rapid unplating pulse, to a maximum of $3a^2/\pi^2 D$ (where a is the electrode spacing, and D is the diffusion coefficient of the main oxidizing component, *e.g.*, I_3^-) in cases where the plating is to be maintained for a long period of time prior to the application of the clearing pulse.

In view of the virtual omnipresence of light and its important part in most activities, an electronic method of controlling its transmission and/or reflection should have numerous potential applications ranging from glare and lighting adjustors through flash-blindness preventing goggles and display or information storage devices. An electrochemical color filter based on changes in the transmission of indicator dyes with changes in pH or redox potential of an electrolyte solution is known (1, 2). The main intrinsic limitations of these "reversible dye" devices are that: (i) they do not modulate the reflection of light; (ii) they are limited by relatively low speeds of reaction in solution and of migration of reacting species to and from the electrodes; (iii) the required dyes and electrolyte solutions deteriorate on prolonged exposure to intense light or on passage of an excessively high charge (at voltages above 2v); and (iv) they usually operate only within relatively narrow wavelength regions.

These objections are eliminated or reduced in the reversible electroplating light modulator discussed in the present paper.

Theoretical Considerations

Required Charge Density vs. Desired Opacity (and Wavelength)

Figures of merit.—The absorption coefficient α, as defined by the Lambert equation

$$I_t = I_i e^{-\alpha\theta} \qquad [1]$$

where I_i is the intensity of the incident light, and I_t the intensity transmitted through a thickness θ of a given metal, is related to the wavelength λ, the absorption index κ, and the index of refraction n of the metal (3)

$$\alpha = 4\pi n\,\kappa/\lambda \qquad [2]$$

The thickness θ of electrodeposited metal for a plating charge density q_d (in coul/cm^2) depends on its atomic weight W, density d, oxidation state z of the platable ions, and plating current efficiency ϵ

$$\theta/q_d = \epsilon W/z\mathbf{F}d \qquad [3]$$

where **F** is a faraday. Hence, the optical density change due to plating, δ, as defined by the equation

$$I_t/I_i = 10^{-\delta} \qquad [4]$$

should be, according to Eq. [1] through [4]

$$\delta = \alpha\theta/2.303 = (4\pi/2.303)\,\epsilon\, q_d\, n\,\kappa\, W/(\mathbf{F}\lambda z d) \qquad [5]$$

$$= 5.65 \times 10^{-5}\,\epsilon\, q_d\, n\,\kappa\, W/(\lambda z d) \qquad [5']$$

i.e., for $\epsilon \simeq 100\%$, the expected change in optical density per plating charge density becomes

$$\delta/q_d \simeq 5.65 \times 10^{-5}\, n\,\kappa\, W/(\lambda z d) \qquad [5'']$$

The ratio $n\kappa W/(\lambda z d)$ thus gives a relative figure of merit for comparing the minimum charge density requirements, using various platable metals. As seen in Table I, the highest values of δ/q_d may be ex-

* Data obtained from ref. (4).

pected for Se with $\lambda < 0.490\mu$, for Sn with $\lambda = 0.589\mu$, for Ag with $\lambda > 0.395\mu$, and for Cd with $\lambda = 0.589\mu$. It is also apparent that red light will be transmitted by thin Se films and violet light by Ag films, which should yield at least a limited choice of adjustable color filters.

Variation of absorption coefficient of thin films with thickness.—The values of δ/q_d in Table I are based on the optical constants of thick metal sheets. For thin films of less than 200Å, the optical constants are known to vary with thickness (5-8). Furthermore, the experimental values obtained by several workers are not in sufficiently good agreement to be considered reliable, probably due to differences in the mode of film deposition (8). Hence, the only conclusion which can be drawn from previous thin-film studies is that any quantitative predictions based on Table I may be in error by as much as a factor of 2 or 3 for plated film thicknesses of less than 200Å.

Possible supplementary absorption by a colored oxidation product.—For certain light-shutter applications, the formation of a light-absorbing oxidation product at a transparent anode may complement the absorption by the metal plated on the cathode. Of particular interest is the I_3^- ion formed with plating solutions of AgI in concentrated NaI. The wavelength dependence of the extinction coefficient of

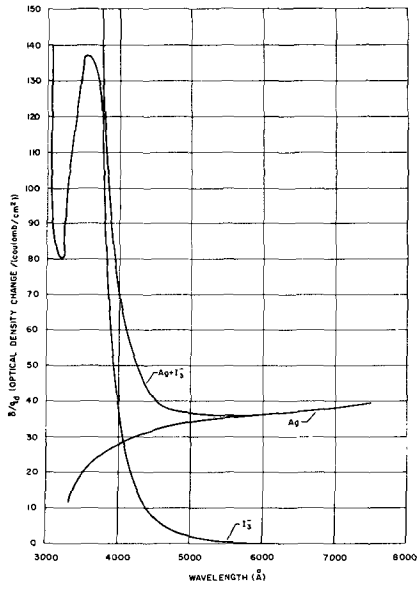

Fig. 1. Optical density change per plating charge density for AgI solutions.

I_3^- was estimated from the literature (9, 10) and the corresponding values of δ/q_d are plotted in Fig. 1 together with those for Ag and for the combined absorption by I_3^- and Ag. It can be seen that the I_3^- drastically reduces the transmission of blue and u.v. light ($\lambda < 4500$Å), and reduces the variation of transmission with wavelength for the remaining visible light region ($4500\text{Å} \leq \lambda \leq 7500\text{Å}$).

Estimated minimum charge requirements vs. desired optical density change.—According to Table I and Fig. 1, Ag gives the highest (or nearly highest) value of δ/q_d in the visible light range, especially in combination with I_3^-. Hence, any estimate of minimum charge requirements based on Fig. 1 should represent the lowest value achievable in practice with white light. Thus, for a desired optical density change of at least 3.0 for all visible wavelengths, the minimum required plating charge density is 0.08 coul/cm^2. Of course, much lower charge densities may be required for selected narrow wavelength regions.

Achievement of Uniform Plating over Large Areas

Effect of plating solution.—For 100% over-all plating current efficiency, the most serious deviations from the minimum charge requirements estimated in the previous section may arise from a nonuniform plating density. This is a common problem in electroplating, and most industrial plating solutions have the property of "smoothing out" the plating density even over somewhat irregularly-shaped substrates. Unfortunately, most industrial plating solutions contain unstable and/or highly toxic agents (*e.g.*, cyanides) which are unsuitable for common light-modulator applications.

The mechanism by which a plating solution tends to counteract the effect of geometric irregularities appears to be associated with an overpotential rapidly increasing with current density (11, 12). Negative complexing ions usually increase the overpotential by transforming readily platable cations into less readily platable anion complexes. Thus, Ag

plating solutions have been recommended based on fluoborate (13), rhodanide (14), thiosulfate (15), and iodide (16) complexes. The last appear especially suitable for reversible light modulators.

The mechanism by which Ag is plated from concentrated iodide solutions cannot occur via the steps:

$$AgI_2^- \rightarrow Ag^+ + 2I^- \qquad (I)$$

followed by

$$Ag^+ + e^- \rightarrow Ag \qquad (II)$$

because the concentration of free Ag^+ ions in 5-10M iodide solutions cannot appreciably exceed 10^{-17}M (the solubility product of AgI being 8.5 x 10^{-17}). Although the concentration of dissolved AgI molecules or AgI-H_2O molecular complexes should be more appreciable in view of the ease of precipitation of AgI from 1M iodide solutions, it still cannot exceed 10^{-6}M. Hence, the most likely mechanism must be of the form

$$AgI_p^{1-p} + e^- \rightarrow Ag + pI^- \qquad (III)$$

where p may be a value (17) between 2 and 4. The negatively charged AgI_p^{1-p} species approaching the cathode must proceed under the influence of a concentration gradient against the direction of the applied electric field. Hence, for continuous plating at high current densities, reaction (III) should be diffusion-controlled, and the current density i_c approaches an asymptotic limiting value i_L with increasing overvoltage η

$$i_c = i_L(1 - e^{zF\eta/RT}) \qquad [6]$$

where i_L depends mainly on the concentration of the platable complex and on the thickness of the stationary layer of electrolyte adjacent to the cathode (12, 18).

Reported polarization curves for a solution of 0.01M AgI_2^- in 1M KI (11) with different stirring rates actually show the asymptotic variation of i_c predicted by Eq. [6]. A similar asymptotic behavior or plateau in the i_c *vs.* η plot appears likely with more concentrated solutions (*e.g.*, 3M AgI in 7M NaI). However, the plateau could hardly extend over a range of more than a few tenths of a volt before the occurrence of H_2 evolution. Although the latter may not affect the uniformity of the plating, it would lower the current efficiency just the same. Thus, the use of a suitable plating solution and of an optimum plating rate may, at best, allow for geometric voltage drop irregularities amounting to no more than a few tenths of a volt.

Geometric considerations.—In view of the expected limited effectiveness of even the best possible plating compositions, special attention must be given to the geometric requirements for uniform plating densities, as discussed in detail in a concurrent paper (19). Of several possible cell geometries [cf. Figs. 1 and 4 of ref. (19)], those based on electrodes perpendicular to the cell walls are of primary interest because of the common availability of plate glass and the ease of aligning a large number of parallel subelement bands to form a large, flat area of any desired dimensions. Thus, if b is the max allowable subelement width, as established by Eq. (68)‡ or (92)‡ [ref. (19)],[2] then for a rectangular area A of width w and length L, *i.e.*

$$A = Lw \qquad [7]$$

the required number n_s of subelements of length L and width b is

$$n_s = w/b \qquad [8]$$

or

$$A = n_s bL \qquad [8']$$

These obvious relations will be used extensively in the following section.

Dependence of cell resistance and required plating charge on geometry and contact connections.—The resistance r_s of any subelement of width b and length L is by definition

$$r_s = (V_{c_1} - V_{c_2})/I_c \qquad [9]$$

where V_{c_1} and V_{c_2} are the potentials at the contacts C_1 and C_2, *i.e.*

$$V_{c_1} = V_{g'_1} \ (y_1 = b) \qquad [10]$$

for both the mirror-symmetric and line-symmetric electrode arrangement [Eq. (71')‡ and (88)‡, respectively],[2] whereas

$$V_{c_2} = V_{g'_2} \ (y_1 = 0) \qquad [11]$$

for the line-symmetric case [Eq. (72)‡ and (64)‡] or,

$$V_{c_2} = V_{g'_2} (y_1 = b) \qquad [12]$$

for mirror-symmetric contacts [Eq. (89)‡ and (85)‡]. Hence, Eq. [9] to [11], (71')‡, (72)‡, (64)‡, and (65)‡ yield

$$r_{s1} = \frac{\rho_{g'}}{L}\left[\frac{b}{2} + \frac{1}{\gamma}\coth(\gamma b/2)\right] \qquad [13]$$

for the line-symmetric case, which reduces to

$$r_{s1} \simeq \frac{\rho_{g'} b}{2L} + \frac{a\rho_e}{bL} \qquad [13']$$

for $\gamma b/2 << 1$, whereas Eq. [9]-[10], [12], (85)‡ and (65)‡ yield

$$r_{sm} = \frac{2\rho_{g'}}{L}\coth(\gamma b) \qquad [14]$$

for mirror symmetry, which reduces to

$$r_{sm} \simeq a\rho_e/bL \qquad [14']$$

for $\gamma b << 1$.

For a uniformity ratio u better than 0.65, a must be greater than $b^2/2k$ for the line-symmetric case [cf. Eq. (68)‡ and (82)‡], and $a \geqq 2b^2/k$ for mirror symmetry [Eq. (92)‡]. Hence, Eq. (82)‡ and [13'] yield

$$\frac{\rho_{g'} b}{2L} + \frac{2k\rho_e}{5bL} \geqq r_{s1} \geqq \frac{\rho_{g'} b}{L} \qquad [15]$$

whereas Eq. (92)‡ and [14'] lead to

$$r_{sm} \geqq 2\rho_{g'} b/L \qquad [16]$$

Thus, the minimum practical value of r_{s1} can be made half as small as that of r_{sm}, *i.e.*, line-symmetric contacts are preferable to mirror-symmetric ones where a minimum cell resistance is required (with fixed parameters b, L, and $\rho_{g'}$), whereas the mirror-

[2] The sign ‡ following an equation number denotes an equation from ref. (19).

symmetric arrangement may be more useful where a large electrode spacing $a > 2k/5$ is desired [cf. Eq. (82)‡].

For a cell made up of n_s subelements, the over-all resistance R_c and required plating charge Q will depend, of course, on whether these subelements are connected in parallel or in series. For parallel connection

$$R_p = r_s/n_s \qquad [17]$$

and

$$Q_p = n_s q_s \qquad [18]$$

where

$$q_s = A_s q_d \qquad [19]$$

is the required plating charge per subelement of area

$$A_s = bL \qquad [20]$$

i.e.,

$$Q_p = q_d n_s bL = q_d A \qquad [21]$$

For series connection,

$$R_s = n_s r_s \qquad [22]$$

and

$$Q_s = q_s = q_d\, bL = q_d A/n_s \qquad [23]$$

The eight possible multiple-contact arrangements are shown in Fig. 2. The parallel alternating connections, 2 and 5, and nonalternating subelements in series, 4 and 8, appear least practical, especially the last two, which require twice as many sets of contacts (one for each subelement) as the other arrangements. On the other hand, the arrangement most easily achievable by far is that of alternating subelements in series, 7, in which the adjacent contacts C_{1+}-C_{2-}, C_{2+}-C_{3-}, etc., are parts of the conducting glass-surface strips. The following calculations will, therefore, be concerned mainly with arrangement 7 (see also Fig. 3), and also, for purposes of comparison, with the parallel connections 6 of Fig. 2.

For both arrangements 6 and 7, the simplified approximate relation [13′] will be assumed to apply. Hence, Eq. [17] together with Eq. [13′], [15], and [8] yield

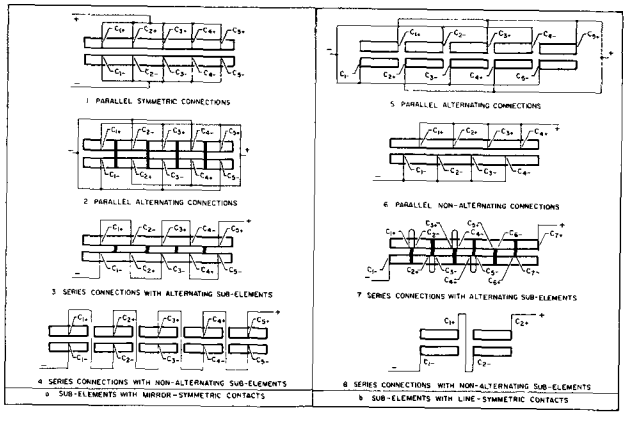

Fig. 2. Possible contact arrangements for a large-area light shutter. a, Subelements with mirror-symmetric contacts: 1, parallel symmetric connections; 2, parallel alternating connections; 3, series connections with alternating subelements; 4, series connections with nonalternating subelements. b, Subelements with line-symmetric contacts: 5, parallel alternating connections; 6, parallel nonalternating connections; 7, alternating subelements in series; 8, nonalternating subelements in series.

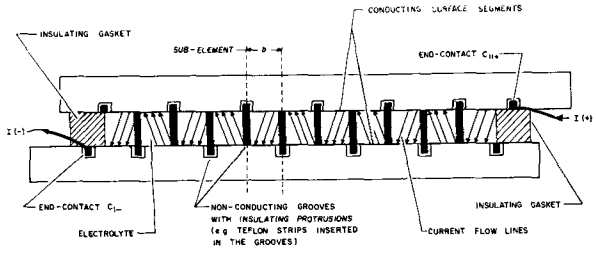

Fig. 3. Detailed drawing of arrangement 7 of Fig. 2

$$R_p = \frac{1}{n_s}\left[\frac{\rho_{g'}b}{2L} + \frac{a\rho_e}{bL}\right] \geqq \rho_{g'}b/(n_s L) \qquad [24]$$

or

$$R_p = [a\rho_e + 0.5\rho_{g'}b^2]/A \geqq \rho_{g'}b^2/A \qquad [24']$$

for arrangement 6, while Eq. [22] yields

$$R_s = n_s\left[\frac{\rho_{g'}b}{2L} + \frac{a\rho_e}{bL}\right] \geqq \rho_{g'}n_s b/L \qquad [25]$$

or

$$R_s = \frac{w}{L}\left[\frac{\rho_{g'}}{2} + \frac{a\rho_e}{b^2}\right] \geqq \rho_{g'}w/L \qquad [25']$$

for arrangement 7.

If the plating is to occur within a time τ_p at a constant value of the current I_c, then the resulting energy dissipation H is

$$H = \tau_p I_c^2 R_c = Q^2 R_c/\tau_p \qquad [26]$$

$$= [a\rho_e + 0.5b^2\rho_{g'}]q_d^2 A/\tau_p \qquad [26']$$

or

$$H \geqq b^2\rho_{g'}q_d^2 A/\tau_p \qquad [26'']$$

Equation [26′] can be derived either from Eq. [21] and [24] for the parallel arrangement 6, or from Eq. [23] and [25] for the series arrangement 7, which serves as a fair check of these relations.

Although no savings in H result from the use of either arrangement for fixed values of the parameters in Eq. [26], much smaller values of b can be achieved in practice with the series arrangement 7 than with 6, which, therefore, allows for lower over-all energy requirements. Besides greater ease of construction, the series arrangement 7 also reduces the over-all plating charge and current requirements (cf. Eq. [23] and [21]), and allows for a better uniformity of plating current distribution than the parallel connections 6.

All these advantages appear to counterbalance for most applications any possible objections to alternate light-reflecting and absorbing strips and to the higher voltages required by arrangement 7 (cf. Eqs. [17], and [21] through [23]).

Although the complete deterioration of a single subelement would render the series arrangement inoperative, such a failure appears much less likely than those tending to result from any imbalance among subelements connected in parallel.

Transient Effects

Plating speed limitations.—A major factor determining the usefulness of the electroplating light shutter for a given application is its maximum achievable speed of operation. One basic speed limitation which can be considered immediately is that

arising from thermal effects. The temperature rise ΔT in the electrolyte due to the passage of a high current pulse must be less than 100°C if boiling is to be avoided. Hence, the energy H rapidly dissipated in the electrolyte has an allowable maximum

$$H \leq v_e h_e \Delta T_{max} \simeq 100\, v_e \text{ (cal)} \simeq 400\, v_e \text{ (joul)} \quad [27]$$

where v_e and h_e are the volume and heat capacity per unit volume of the electrolyte. But, according to Eq. [26']

$$H \geq a\rho_e q_d^2 A/\tau_p = v_e \rho_e q_d^2/\tau_p \quad [28]$$

Eq. [27] and [28] yield

$$1/\tau_p \leq 400/(\rho_e q_d^2) \quad [29]$$

i.e., the maximum satisfactory operating speed is an inverse square function of the plating charge density or desired optical density change. Thus, for $\rho_e = 10$ ohm-cm and $q_d = 0.1$ coul/cm² (corresponding to an optical density change δ of 3 to 4), Eq. [29] yields a minimum τ_p of 250 μsec, whereas for $q_d = 0.02$ coul/cm² (corresponding to $\delta \simeq 2/3$) the minimum τ_p is 10 μsec. Hence, in order to achieve a high optical density change δ of say 3 to 4 in 10 μsec, it would be necessary to use 5 plating cells back-to-back, each yielding a low δ of only 2/3.

A more serious speed limitation, of a purely electrochemical nature, may be associated with the transition time (20)

$$\tau_{trans} = \pi \mathbf{F}^2 D c_p^2/4i^2 \quad [30]$$

corresponding to the time of depletion of platable ions at the electrode-electrolyte interface on application of a constant current density i (in amp/cm²). Setting $\mathbf{F} = 96{,}500$ coul, and assuming a value of $D \simeq 10^{-5}$ cm²/sec for the diffusion coefficient of the platable ions, one obtains

$$\tau_{trans} \simeq 2 \times 10^5\, c_p^2/i^2 \quad [30']$$

where c_p is the concentration of platable ions in moles/cc. On the other hand, for maximum plating speed,

$$i_{max}\, \tau_{trans} \simeq q_d \quad [31]$$

Hence,

$$i_{max} \simeq q_d/\tau_{trans} \simeq q_d\, i^2_{max}/(2 \times 10^5\, c_p^2) \simeq 2 \times 10^5\, c_p^2/q_d \quad [32]$$

and the minimum plating time τ_{min} becomes

$$\tau_{min} \simeq q_d/i_{max} \simeq 5 \times 10^{-6}\, q_d^2/c_p^2 \quad [33]$$

For $c_p = 0.01$ mole/cc (*i.e.*, a 10M solution of platable ions), Eq. [33] yields a τ_{min} of 500 μsec for $q_d = 0.1$ coul/cm², and $\tau_{min} \simeq 20$ μsec for $q_d = 0.02$ coul/cm², which is comparable with the thermal limitation given by Eq. [29]. However, the coefficient of q_d^2 in Eq. [33] may vary drastically with electrolyte composition. Thus, for $c_p = 0.004$ mole/cc, which is the limit of solubility of AgI in iodide solutions, τ_{min} as given in Eq. [33] becomes twelve times higher than that of Eq. [29]. However, the effective value of c_p need not necessarily be limited to that of the ultimately plated cations, but may include that of all the cation species. Thus, for a solution containing 4M AgI plus 8M NaI, the effective value of c_p may be 0.012 mole/cc. The actual plating mechanism would then involve a very rapid deposition of an Ag-Na alloy, followed by a somewhat less rapid displacement of the Na by Ag (and, what is less desirable, by H_2 if the H_3O^+ ion concentration of the solution or the rate of reduction of H_2O is sufficiently high).

It should also be noted that Eq. [30], [32], and [33] are based on the assumption of negligible electromigration of platable ions. In cases where most of the cationic species present are platable, the diffusion coefficient D of Eq. [30] should be replaced by an effective diffusion coefficient (18)

$$D' = D/(1 - t_+) \quad [34]$$

where t_+ is the transport number of the cations. Thus, for $t_+ \simeq 0.5$, the coefficient of Eq. [30] would be doubled, resulting in a reduction of τ_{min} by a factor of 2. Furthermore, at the plated electrode, t_+ should approach unity as the catholyte becomes depleted,[3] which should cause D' to approach ∞. All these considerations suggest that for maximum plating speeds:

i. the concentration c_p of platable ions should be as high as possible;

ii. the concentration of H_3O^+ ions should be kept as low as possible to avoid or minimize the formation of H_2; and

iii. if the solubility of the desired species to be plated is limited, as in the case of AgI in concentrated alkali-metal iodide solutions, the initial plating of alkali metal followed by its displacement by the metal to be plated (*e.g.*, Ag) may allow for increased plating speeds, provided that H_2 formation can be avoided. This last possibility may render Eq. [33] somewhat uncertain. Hence, the safest conclusion is that Eq. [29] imposes a definite limitation on the rate of darkening of a single-layer shutter, whereas, Eq. [30] through [33] may impose a further limitation for some electrolyte solutions. Here again it must be emphasized that these limitations apply only to single-layer shutters. With several shutters placed back-to-back, the limiting darkening speed will depend on the number of allowable layers, depending on required open-state transmission, maximum thickness, cost, etc.

Other transient effects.—Compared with the above-discussed speed limitations, most other effects are relatively unimportant. The "rise time" (or time required for charging the electrode double layer capacitance before plating can occur) is usually much shorter than the transition time, and may be further minimized, if need be, by peaking the applied voltage or current at the start of the plating pulse. The resistivity of the plated surface may decrease on deposition of a sufficiently heavy metal layer, but the resulting decrease in the over-all cell

[3] When all the cations are platable, charge neutrality requires that the depleted catholyte layer contain a low concentration of both cations and anions. The latter then diffuse toward the cathode, against the direction of the applied field. Hence, as the current becomes increasingly diffusion-controlled, it must be carried predominantly by cations, *i.e.*, t_+ must approach unity near the cathode.

resistance could not exceed 30% according to Eq. [13] through [15], and would probably be completely negligible (21) for the extremely thin layers (of 100Å or less) to be deposited in most applications.

Finally, some inductance may be associated with the parallel contact arrangement 6 of Fig. 2, but should be entirely negligible in the preferred series arrangement 7 which happens to be somewhat similar to the "transposed-conductor" configuration used to minimize mutual inductance between telephone lines.

Methods of Clearing (or Unplating)

The obvious method of removing a layer of plated metal from a transparent glass electrode, *i.e.*, that involving application of an unplating current pulse, may be satisfactory only in a limited number of cases, e.g., in modulated light reflectors in which transmissivity is not important, or in small-area shutters with specially shaped or hidden counter-electrodes. In large-area shutters, however, such as those involving arrangements 1 through 8 of Fig. 2, an unplating current pulse at one transparent glass electrode would ordinarily cause plating at the opposite glass electrode with no resulting improvement in transmission. It, therefore, becomes necessary to introduce an oxidizing component Ox in the electrolyte which can participate in the reversible reactions:

$$Ox + e^- \rightleftharpoons Red^- \qquad (IV)$$

and

$$Ox + M \rightarrow Red^- + M^+ \qquad (V)$$

where Red^- is the reduced form of Ox, and M is the plated metal. For example, for AgI-NaI solutions, the Ox component could be $\frac{1}{2}I_3$ (or IO_3 in basic solutions) so that reactions (IV) and (V) would take the form

$$\frac{1}{2}I_3^- + e^- \rightleftharpoons \frac{3}{2}I^- \qquad (IV')$$

and

$$\frac{1}{2}I_3^- + 2Ag\left(+ \frac{3}{2}I^- \right) \rightarrow (3\,I^- + Ag^+) \rightarrow AgI_3^= \qquad (V')$$

The Ox component (I_3^-) can, of course, be either added initially to the electrolyte or formed electrochemically via reaction (IV) or (IV') going from right to left. The following calculations will be concerned with the control of the concentrations $c_{ox}(x, t_p)$ and $c_{ox}(x, t_u)$ of the Ox component (in g-equivalents/cc) as a function of the distance x from the plated surface and of the respective times t_p and t_u after the start of a given plating and unplating operation.

The rate of reaction (V) or (V') may be limited by chemical kinetics or by the rate of flow

$$\vec{J}_{ox}(x \rightarrow 0, t)$$

of the Ox component towards $x = 0$ (the plated electrode).

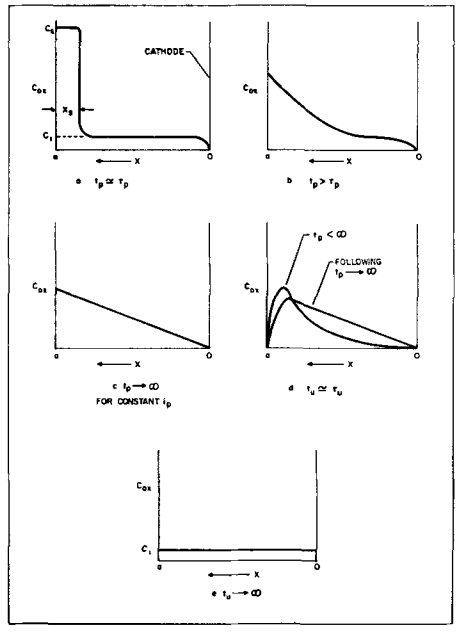

Fig. 4. Distribution of the Ox component at various stages of the plating-unplating cycle.

Now, by Fick's laws

$$\vec{J}_{ox} = -D(\partial c_{ox}/\partial x) \qquad [35]$$

and

$$\partial c_{ox}/\partial t = D\,\partial^2 c_{ox}/\partial x^2 \qquad [36]$$

For good initial plating efficiency and to maintain continued plating with minimal additional energy input, one should aim at minimal $c_{ox}(0, t_p)$ and minimal $\vec{J}_{ox}(0, t_p)$, whereas, for rapid clearing, high values of $c_{ox}(0, t_u)$ and $\vec{J}_{ox}(0, t_u)$ are desirable. The best way of achieving these aims appears to be by electrochemical formation of Ox when clearing is desired, *i.e.*, by application of an unplating current pulse. Plating at the opposite electrode ($x = a$) could then be minimized by the reaction with the Ox formed at $x = a$ during the preceding plating pulse, *i.e.*, by maintaining a high $c_{ox}(a, t_p)$ and a high $\vec{J}_{ox}(a, t_u)$. The full plating-unplating cycle is shown qualitatively in Fig. 4a through e. In Fig. 4a, a highly concentrated layer of Ox^+ is formed within a relatively short plating pulse period τ_p. If c_s is the solubility limit of Ox in the electrolyte, then the thickness of the initially formed layer x_s of Ox-saturated electrolyte is given by the materials balance

$$(c_s - c_i)x_s = q_d/\mathbf{F} \qquad [37]$$

or

$$x_s = q_d/[\mathbf{F}(c_s - c_i)] \qquad [37']$$

where

$$c_i = c_{ox}(x, 0) \qquad [38]$$

is the assumed (relatively low and) uniform initial Ox concentration. Hence, the initial boundary conditions are

$$c_{ox}(x, \tau_p) = c_i \text{ for } 0 < x \leq a - x \qquad [39]$$

$$c_{ox}(x, \tau_p) = c_s \text{ for } a - x_s \leq x \leq a \qquad [40]$$

and

$$c_{ox}(0, t_p) = 0 \text{ for } t_p \geq \tau_p \qquad [41]$$

the last condition [41] arising from an assumed rapid occurrence of reaction (V) at the plated layer $x = 0$.

Since $x_s << a$, the boundary conditions can be rewritten, as follows

$$c_{Ox}(x, \tau_p) = c_i \text{ for } 0 < x < a \qquad [39']$$

and

an amount $q_d/\mu\mathbf{F}$ injected at $x = a$ and $t_p = \tau_p$ [40']

The solution to Eq. [36], [41], [39'], and [40'] is:[4]

$$c_{Ox}(x, t_p') = \frac{2q_d}{z\mathbf{F}a}\sum_{n=0}^{\infty}(-1)^n e^{-(2n+1)^2\pi^2 D t_p'/4a^2}\sin\frac{(2n+1)\pi x}{2a} + \frac{4c_i}{\pi}\sum_{n=0}^{\infty} e^{-(2n+1)^2\pi^2 D t_p'/4a^2}\sin\frac{(2n+1)\pi x}{2a}$$

$$= \sum_{n=0}^{\infty}\left(\frac{2q_d(-1)^n}{\mathbf{F}a} + \frac{4c_i}{\pi}\right) e^{-(2n+1)^2\pi^2 D t_p'/4a^2}\sin\frac{(2n+1)\pi x}{2a} \qquad [42]$$

where

$$t_p' = t_p - \tau_p \qquad [43]$$

For

$$t_p' \geqq a^2/4D \qquad [44]$$

a simplified approximation of Eq. [42] is obtained

$$c_{Ox}(x, t_p' \geqq a^2/4D) \simeq \left[\frac{2q_d}{\mathbf{F}a} + \frac{4c_i}{\pi}\right] e^{-\pi^2 D t_p'/4a^2}\sin\frac{\pi x}{2a} \qquad [42']$$

as shown schematically in Fig. 4b. Equations [42'] and [35] give the rate of spontaneous unplating at $x = 0$

$$-\vec{J}_{Ox}(0, t_p' \geqq a^2/4D) \simeq D\left[\frac{\pi q_d}{\mathbf{F}a^2} + \frac{2c_i}{a}\right] e^{-\pi^2 D t_p'/4a^2} \qquad [45]$$

As seen from Eq. [45], the rate of unplating decreases rapidly with t_p' if the initial plating pulse is not followed by an additional plating current.

In order to maintain a desired opacity for an indefinitely long period ($t_p' \to \infty$), it is necessary to maintain a continuous plating current density i_p to counterbalance the effect of diffusion of Ox toward $x = 0$. The required value of i_p can be readily calculated for the steady-state condition ($t_p' \to \infty$) for which

$$c_{Ox}(x, \infty) = (\Delta c_{Ox}/\Delta x)x \qquad [46]$$

and

$$i_p = -\mathbf{F}\vec{J}_{Ox}(x, \infty) = \mathbf{F}D(\partial c_{Ox}/\partial x) = \mathbf{F}D(\Delta c_{Ox}/\Delta x) \qquad [47]$$

By a materials balance, one obtains

$$ac_i + \frac{q_d}{\mathbf{F}} = \int_0^a c_{Ox}dx = \int_0^a\left(\frac{\Delta c_{Ox}}{\Delta x}\right)x\,dx = \left(\frac{\Delta c_{Ox}}{\Delta x}\right)\frac{a^2}{2} \qquad [48]$$

[4] Cf. ref. (22) pp. 297-8 for our boundary conditions [41] and [40'] setting $x' = a/2$ in C and J's Eq. §132 (2), and p. 83 for boundary conditions [41] and [39'] setting $-c_i$ for V, a for l, and $a - x$ for x in C, and J's Eq. §36 (2), and adding $+ C_i$.

Hence

$$i_p = \frac{2D}{a^2}(q_d + \mathbf{F}\,a\,c_i) \qquad [49]$$

For example, for $D = 10^{-5}$ cm^2/sec, $a = 2 \times 10^{-3}$ cm, $q_d = 0.02$ coul/cm^2, and $c_i = 10^{-5}$ mole/cc, one obtains $i_p \simeq 0.12$ amp/cm^2. Under conditions where a constant current i_p (as given by Eq. [49]) is passed following the initial plating pulse, the boundary condition [40'] must be supplemented by the additional condition that:

a continuous injection of Ox occurs at $x = a$ and $t_p \geqq \tau_p$ at the rate $i_p/\mathbf{F}$

$$= \frac{2D}{a^2}\left(\frac{q_d}{\mathbf{F}} + ac_i\right) \qquad [49']$$

This, together with the conditions leading to Eq. [42], results in a solution of the form

$$c_{Ox}(x, t_p') = \sum_{n=0}^{\infty}\left[\left(\frac{2q_d(-1)^n}{\mathbf{F}a} + \frac{4c_i}{\pi}\right) e^{-(2n+1)^2\pi^2 D t_p'/4a^2}\sin\frac{(2n+1)\pi x}{2a}\right] + \frac{2}{a}\left(\frac{q_d}{\mathbf{F}} + a\,c_i\right)\left[\frac{x}{a} - \sum_{n=0}^{\infty}(-1)^n\frac{8e^{-(2n+1)^2\pi^2 D t_p'/4a^2}}{(2n+1)^2\pi^2}\sin\frac{(2n+1)\pi x}{2a}\right] \qquad [50]$$

which can be simplified under conditions [44] to

$$c_{Ox}(x, t_p') \simeq \left[\frac{2q_d}{\mathbf{F}a} + 2c_i\right]\frac{x}{a} + \left[\frac{2q_d}{\mathbf{F}a}\left(1 - \frac{8}{\pi^2}\right) + \frac{4c_i}{\pi}\left(1 - \frac{4}{\pi}\right)\right] e^{-\pi^2 D t_p'/4a^2}\sin\frac{\pi x}{2a} \qquad [50']$$

which finally reduces for $t_p' \to \infty$ to

$$c_{Ox}(x, \infty) = \frac{2}{a}\left(\frac{q_d}{\mathbf{F}a} + c_i\right)x \qquad [50'']$$

as expected from Eq. [46] through [48].

With the help of Eq. [50''], it becomes relatively easy to estimate the rate of clearing of the light shutter on application of a pulse of charge density $q_d' \leqq q_d$ in the reverse (unplating) direction. It is worth noting first of all that the rate of clearing is lowest if the unplating pulse is applied at $t_p' \simeq \infty$ at which time the average displacement of the Ox particles from $x = a$ is at its maximum (cf. Fig. 4b, c, and d). Hence, the minimum clearing rate can be obtained by solving Eq. [36] with the boundary conditions

$$c_{Ox}(x, 0) = \frac{2}{a}\left(\frac{q_d}{\mathbf{F}a} + c_i\right)x \text{ for } t_u = 0 \qquad [50''']$$

and

$$c_{Ox}(0, t_u) = c_{Ox}(a, t_u) = 0 \text{ for } t_u > 0 \qquad [51]$$

the latter condition presumably remaining valid as long as the plated metal is present at both electrodes

[5] Cf. ref. (22) p. 104 for our boundary conditions [41] and [49'] setting a for l, D for K, and $i_p/\mathbf{F}$ for Q in C and J's Eq. 43 (2).

($x = 0$ and $x = a$). The solution to Eq. [36], [50‴] and [51] is[6]

$$c_{ox}(x, t_u) = \frac{4}{\pi}\left(\frac{q_d}{Fa} + c_i\right)\sum_{n=1}^{\infty}\frac{(-1)^{n-1}}{n} e^{-n^2\pi^2 D t_u/a^2}\sin\frac{n\pi x}{a} \quad [52]$$

which simplifies for $t_u \geq a^2/(\pi^2 D)$ to

$$c_{ox}(x, t_u) \simeq \frac{4}{\pi}\left(\frac{q_d}{Fa} + c_i\right)e^{-\pi^2 D t_u/a^2}\sin\frac{\pi x}{a} \quad [52']$$

The net fraction of metal removed at a time t_u is (by materials balance)

$$f_r(t_u) = [a\,c_i + (q_d/F) - \int_0^a c_{ox}(x, t_u)\,dx]/(q_d/F) \quad [53]$$

Substituting Eq. [19] into [20] one obtains

$$f_r(t_u) = \left(1 + \frac{a\,c_i F}{q_d}\right)\left[1 - \sum_{m=0}^{\infty}\frac{8e^{-(2m+1)^2\pi^2 D t_u/a^2}}{(2m+1)^2\pi^2}\right] \quad [54]$$

which simplifies for $t_u \geq a^2/\pi^2 D$ to

$$f_r(t_u) \simeq [1 - (8/\pi^2)\,e^{-\pi^2 D t_u/a^2}](q_d + a\,c_i F)/q_d \quad [54']$$

For example, for $c_i \simeq 0$, the degree of unplating is approximately 70% for $t_u = a^2/(\pi^2 D)$, 91% for $t_u = 2a^2/(\pi^2 D)$, and 97.3% for $t_u = 3a^2/(\pi^2 D)$. Hence, if the initial plating pulse yielded an optical density change δ between 3 and 4, the reverse pulse should reduce δ by 97.3%, *i.e.*, to $\delta \simeq 0.1$ (corresponding to 90% of the original transmission) within a time $t_u \leq 3a^2/\pi^2 D$. Thus, for $D \simeq 10^{-5}$ cm^2/sec, nearly complete clearing should occur within 30 msec for $a = 0.001$ cm, within 0.5 sec for $a = 0.004$ cm, and within 3 sec for $a = 0.01$ cm.

Equations [52] through [54'] are based on the boundary conditions [51] which are satisfied only as long as plated metal is present at both electrodes. It is, therefore, necessary to calculate the value of the reverse charge density q_d' required to maintain this condition up to the time $t_u \simeq 3a^2/\pi^2 D$ when nearly complete clearing has been achieved. Following integration of the total fluxes of Ox toward $x = 0$ and $x = a$ within the time interval between $t_u' = 0$ and $t_u' = 3a^2/\pi^2 D$, one can make use of the following materials balance requirements at the electrodes $x = a$ and $x = 0$

$$q_d'/F \geq \int_0^{3a^2/\pi^2 D}\vec{J}_{ox}(a, t_u')\,dt_u' \quad [55]$$

and

$$(q_d - q_d')/F \geq -\int_0^{3a^2/\pi^2 D}\vec{J}_{ox}(0, t_u')\,dt_u' \quad [56]$$

Equations [55], [35], and [52] yield

$$q_d'/F \geq \frac{4}{\pi^2}\left(\frac{q_d}{F} + ac_i\right)\sum_{n=1}^{\infty}[(1 - e^{-3n^2})/n^2] \quad [57]$$

which simplifies to

$$q_d'/F \simeq \frac{4}{\pi^2}\left(\frac{q_d}{F} + ac_i\right)\sum_{n=1}^{\infty}(1/n^2)$$

$$= \frac{2}{3}\left(\frac{q_d}{F} + ac_i\right) \quad [57']$$

[7]

Similarly, Eq. [56], [35], and [52] yield

$$(q_d - q_d')/F \geq \frac{4}{\pi^2}\left(\frac{q_d}{F} + ac_i\right)\sum_{n=1}^{\infty}[(-1)^{n-1}(1 - e^{-3n^2})/n^2] \quad [58]$$

which simplifies to

$$(q_d - q_d')/F \simeq \frac{4}{\pi}\left(\frac{q_d}{F} + ac_i\right)\sum_{n=1}^{\infty}\frac{(-1)^{n-1}}{n^2} = \frac{1}{3}\left(\frac{q_d}{F} + ac_i\right) \quad [58']$$

[7]

Conditions [57'] and [58'] are satisfied for

$$c_i << q_d/aF \quad [59]$$

and

$$q_d' \simeq (2/3)\,q_d \quad [60]$$

It should be noted that requirement [60] is based on the boundary condition [50‴] which follows a steady-state opaque shutter condition $t_p' \simeq \infty$. For $t_p' << \infty$, most of the Ox component is located near the $x = a$ electrode, hence q_d' should preferably be higher than (2/3) q_d. For example, for $t_p' = 0$, a value of $q_d' = q_d$ would theoretically yield an instantaneous clearing [assuming no spurious mixing, $\tau_p \simeq 0 \cong \tau_u$, and an infinite rate constant for reaction (V)]. If, in lieu of condition [50‴], a simplified approximation of Eq. [50'] be satisfactory for $t_p' << \infty$

$$C_{ox}(x, 0) \cong \frac{2q_d}{zFa}\left[1 + \frac{1}{2}e^{-\pi^2 D t_p'/4a^2}\right]\frac{x}{a} \text{ for } t_u = 0 \quad [50'''']$$

then condition [60] could be replaced by

$$q_d'/q_d \simeq [2 + e^{-\pi^2 D t_p'/4a^2}]/3 \quad [60']$$

Equation [60'] results in optimum q_d'/q_d ratios of unity for $t_p' = 0$ and of 2/3 for $t_p' \to \infty$, and in nearly optimum ratios for intermediate values of t_p'.

In practice, condition [60'] can be readily met, *e.g.*, by supplying the charge q_d' from two capacitors, one having a permanent charge $Q' = 2Q/3$, and one having an initial charge $Q'' = Q/3$ at $t_p' = 0$, and a parallel leakage resistance R_l such that the leakage time constant is

$$\tau_l = C_l R_l = 4a^2/\pi^2 D \quad [61]$$

where C_l is the capacitance of the leaking condenser.

Summary and Conclusions

1. For a maximum darkening efficiency or ratio of δ/q_d over the entire visible wavelength region, the plating of Ag from AgI solutions appears most suitable.

2. For a maximum plating speed, the concentration of AgI in the electrolyte should be as high as possible (see Eq. [33]). The highest achievable AgI

[6] Cf. ref. (22) pp. 76-89, Eq. 34 (10).

[7] The summations $\sum_{n=1}^{\infty} 1/n^2$ and $\sum_{n=1}^{\infty}(-1)^{n-1}/n^2$ are $\pi^2/6$ and $\pi^2/12$, respectively [cf. ref. (23)].

concentration in aqueous solution appears to be that of 150g AgI to 180g NaI and 100g H_2O (24) corresponding to a volume concentration of approximately 3.7M AgI (based on an approximate specific gravity value of 2.47 g/cc, as measured by the author). To avoid any precipitation due to temperature fluctuations, a slightly undersaturated solution of 3.0-3.5M AgI in 6.9M NaI is recommended.

3. Acidified solutions may tend to evolve H_2 at high plating speeds, whereas alkaline solutions will convert the light-absorbing I_3^- ions into colorless IO_3^- ions. Hence neutral solutions appear to be preferable for best shutter performance.

4. To achieve uniform plating over a large area, the most practical geometry is that consisting of adjacent, narrow-band subelements disposed as in arrangement 6 or, preferably, 7 of Fig. 2, with the spacing a between the electrodes being greater than $b^2/2k$ [Eq. (82)‡] or the width b of each subelement being less than $(2\,ka)^{1/2}$. On the other hand, for fast clearing rates, the spacing a should be as low as feasible (depending largely on achievable electrode surface flatness).

5. The maximum operable plating speed is an inverse square function of the plating charge density q_d and cannot exceed $40/q_d^2$ sec^{-1} for an electrolyte resistivity of 10 ohm-cm (cf. Eq. [29]). Hence to achieve both maximum speed and a high optical density change it is necessary to use several plating cells back-to-back.

6. To maintain a large-area shutter in the opaque state for an indefinitely long period of time and yet be able to achieve rapid clearing when desired, it is necessary to maintain a continuous plating current density i_p as given by Eq. [49], and, when desired, to apply an unplating charge density q_d' as given by Eq. [60']. The time required to revert to 90% of the original transmission should then be less than $3a^2/(\pi^2 D)$.

Acknowledgments

Stimulating and informative discussions with Doctors J. O'M. Bockris and J. Y. Chang and constructive suggestions by Dr. J. Stuart Fordyce have contributed to a general improvement of this paper. SYMBOLS

a	x-component of the distance between the origins O_1 and O_2
A	total area of light shutter
A_s	area of one-cell subelement in a multicell shutter
b	maximum value of y, y_1, or y_2
C_1, C_2, C_{1+}, C_{2-}, C_{2+}	current collecting contacts
C_l	capacitance of condenser having a parallel leakage resistance R_l
c_i	average value of c_{Ox} before the occurrence of plating
c_{Ox}	concentration of Ox component in g-equivalents/cc
c_p	concentration of platable ions in moles/cc
c_s	solubility limit of Ox in the electrolyte
d	density in g/cc
D	diffusion coefficient
D'	effective diffusion coefficient
$f_r(t_u)$	fraction of plated metal removed at time t_u
F	Faraday or 96,500 coul.
g', g_1', g_2'	flat transparent (glass) electrodes
H	energy dissipated upon passage of plating pulse
h_e	heat capacity of the electrolyte per unit volume
i	current density
i_c	continuous cathode current density
i_L	limiting continuous current density
i_{max}	maximum allowable current density
i_p	continuous plating current density required to maintain a desired opacity
I_c	current at the collecting contacts
I_i	intensity of incident light
I_t	intensity of transmitted light
$\vec{J}_{Ox}$	current density of Ox component
k	ρ_e/ρ_g'
L	length of cell in the direction perpendicular to Fig. 2 through 4.
M	plated metal
n	index of refraction
n_s	number of subelements in large-area shutter
Ox	oxidizing component in the electrolyte
p	number of anions in a complex ion
Q	over-all required plating charge
Q_p	value of Q for a cell with subelements con-

	nected in parallel
Q_s	value of Q for a cell with series-connected subelements
q_{pl}	plating charge density in coul/cm²
q_{pl}'	unplating charge density
q_s	plating charge per subelement
r_s	resistance of a single-cell subelement
r_{sm}	resistance of a mirror-symmetric subelement
r_{sl}	resistance of a line-symmetric subelement
R	gas constant
R_c	over-all cell resistance
R_i	resistance connected in parallel with a capacitance C_i
R_p	over-all resistance of cell having subelements connected in parallel
R_s	over-all resistance of cell with series-connected subelements
Red^-	reduced form of Ox
t_+	transport number of the cations
t_p	time after the start of a plating pulse
t_p'	$t_p - \tau_p$
t_u	time after the start of an unplating pulse
t_u'	$t_u - \tau_u$
T	absolute temperature
v_e	volume of electrolyte
V_{c1}, V_{c2}	potentials of contacts C_1, C_2
$V_{g'1}$, $V_{g'2}$	potential at electrode g'_1, g'_2, respectively
w	total width of large-area light shutter
W	atomic weight
x	distance along the direction parallel to the cell walls and the main current flow lines
x_s	thickness of Ox-saturated electrolyte layer
y_1	distance along the direction perpendicular to the cell walls and the x-direction [cf. ref. (19)]
z	oxidation state of platable ions
α	coefficient of light absorption
γ	constant defined by Eq. (59) of ref. (19)
δ	optical density change due to plating
Δc_{Ox}	increment in c_{Ox} corresponding to Δx
ΔT	rise in temperature due to high current pulse
ΔT_{max}	maximum allowable temperature rise
Δx	increment in x
ϵ	plating current efficiency
η	electrode overpotential
θ	thickness of an electrodeposited, light-absorbing metal layer
κ	light absorption index
λ	light wavelength
ρ_e	volume resistivity of the electrolyte solution
$\rho_{g'}$, $\rho_{g'1}$, $\rho_{g'2}$	respective surface resistivities of transparent conductors g', g'_1, g'_2
τ_{min}	minimum allowable plating time
τ_p	duration of plating pulse
τ_{trans}	transition time
τ_u	duration of unplating pulse

Geometric Requirements for Uniform Current Densities at Surface-Conductive Insulators or Resistive Electrodes

Solomon Zaromb[1]

Research Division, Philco Corporation, Blue Bell, Pennsylvania

ABSTRACT

The conditions for practically uniform current densities in the presence of ohmic potential drops along electrode surfaces are established for several configurations. Perfectly uniform current flow lines in the electrolyte can be obtained within limited ranges, with electrodes having cylindrical surfaces traced by Eq. [9], or be closely approximated with electrodes in the form of parabolic cylindrical or paraboloid segments traced by Eq. [11] or [20] or [22]. For practically uniform current densities at either curved or flat electrodes, the areas must be limited to narrow bands, rings, or small circles, as indicated in Fig. 2 or by Eq. [38], [49], [68], or [92]. For identical flat narrow-band electrodes perpendicular to the cell walls, a mirror-symmetric arrangement of external current-collecting contacts is shown to require a fourfold larger minimum electrode spacing than a line-symmetric arrangement.

In the Reversible Electroplating Light Modulator (RELM) (1-3), as well as in other devices or experiments involving reactions at semiconducting or even very thin metallic electrodes, the current density distribution may be seriously affected by ohmic potential drops along the electrode surfaces. The conditions for maintaining essentially uniform current densities in spite of nonuniform surface potentials are established in the following sections for several cell configurations.

Case 1. Perfectly Uniform Parallel Current Flow Lines in the Electrolyte

Let J_x be the current density in the electrolyte along the x-direction perpendicular to the surface of a rectangular (highly conducting) metal electrode M. The shape of a surface-conductive glass electrode g (Fig. 1a) required for J_x to be uniform will now be determined. Let x and y be the horizontal and vertical coordinates of any point P on the curve s_g defining the glass surface. The surface current I_g flowing along the glass surface toward the collector strip C (outside the cell) is then given by

$$I_g = L \int_0^y J_x \, dy \qquad [1]$$

where L is the length of the cell along the direction perpendicular to the plane of Fig. 1a. The difference in potential between points $P_1(x, y)$ and $P_2(x + dx, y + dy)$ on the curve s_g then becomes

$$-dV_g = (I_g/L)\rho_g \, ds_g \qquad [2]$$

$$= \rho_g \left(\int_0^y J_x \, dy\right) ds_g = \rho_g J_x \, y \, ds_g \qquad [2']$$

where ρ_g is the surface resistivity of the glass. On the other hand, assuming no change in overvoltage between the points P_1 and P_2 (*i.e.*, essentially uniform

[1] *Present address:* Research and Advanced Technology Department, Electronic Systems and Products Division, Martin-Marietta Corporation, Baltimore, Maryland.

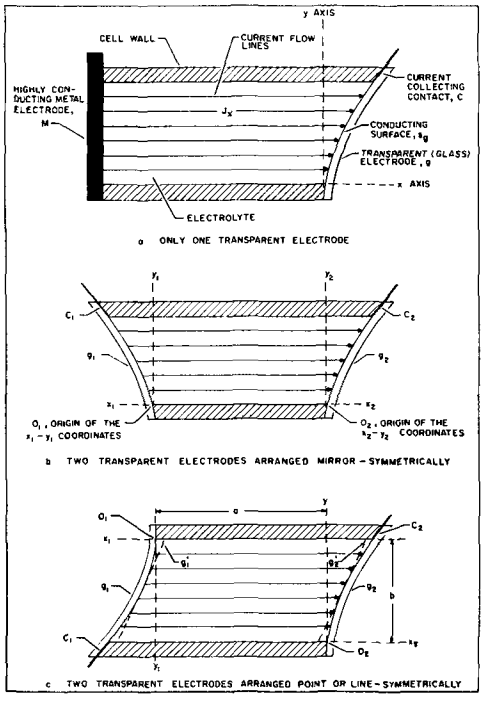

Fig. 1. Plating cells with parallel current flow lines in the electrolyte: (a) only one transparent electrode (b) two transparent electrodes arranged mirror-symmetrically (c) two transparent electrodes arranged point- or line-symmetrically.

current density), dV_g may be readily calculated by following a path through the electrolyte

$$-dV_g = J_x \rho_e dx \qquad [3]$$

where ρ_e is the resistivity of the electrolyte. Equations [2'] and [3] yield

$$ds_g/dx = \rho_e/(\rho_g y) \qquad [4]$$

but for any curve

$$ds_g/dx = [1 + (dy/dx)^2]^{1/2} \qquad [5]$$

Hence,

$$\frac{dy}{dx} = \frac{\rho_e}{\rho_g}\left[\frac{1}{y^2} - \frac{\rho_g^2}{\rho_e^2}\right]^{1/2} \qquad [6]$$

$$= (k^2 - y^2)^{1/2}/y \qquad [6']$$

where

$$k = \rho_e/\rho_g \qquad [7]$$

Rewriting [6']

$$dx = y\,dy/[k^2 - y^2]^{1/2} = -d[k^2 - y^2]^{1/2} \qquad [8]$$

one obtains

$$x = k\{1 - [1 - (y/k)^2]^{1/2}\} \qquad [9]$$

Equation [9] is plotted in Fig. 2. For

$$y << k \qquad [10]$$

one obtains by expansion

$$x \simeq y^2/2k \qquad [11]$$

and

$$x << y \qquad [12]$$

i.e., electrode g is almost parallel to M, and the actual current density on the glass surface

$$i_g = J_x\,dy/ds_g \qquad [13]$$

which, according to Eq [4] and [8], is

$$i_g = J_x[1 - (y/k)^2]^{1/2} \qquad [14]$$

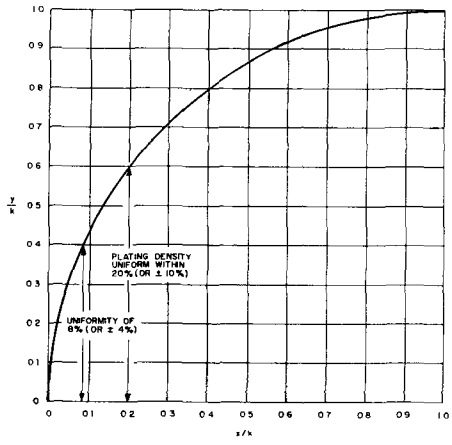

Fig. 2. Plot of Eq. [9]

becomes approximately uniform for condition [10]

$$i_g \simeq J_x \qquad [15]$$

As shown in Table I, Eq. [11] and [15] deviate from Eq. [9] and [14] by less than 10% for values of y/k up to 0.6 and 0.4, respectively.

The range for which J_x can be constant is, therefore, $0 \leq y/k \leq 1$ according to Eq. [9], while the range of fairly uniform electrode current density (Eq. [15]) is $0 \leq y/k \leq 0.4$ for a uniformity of 8% (*i.e.*, ±4%), and $0 < y/k < 0.6$ for a uniformity of 20% (or ±10%).

Similar calculations may be attempted for the cylindrical cell obtained by rotating Fig. 1a around the x-axis. For this case, Eq. [1] must be replaced by

$$I_g = \int J_x 2\pi y dy = 2\pi J_x \int y dy \qquad [16]$$

and Eq. [2] by

$$-dV_g = \frac{\rho_g I_g}{2\pi s_g} ds_g \qquad [17]$$

$$= \rho_g J_x (\int y dy)\, ds_g/s_g \qquad [17']$$

Combining Eq. [17'], [3], and [5], one obtains

$$\rho_e dx = \rho_g (\int y dy)\, ds_g/s_g \qquad [18]$$

$$= \rho_g (\int y dy)\, \frac{[1 + (dy/dx)^2]^{1/2} dx}{\int [1 + (dy/dx)^2]^{1/2} dx} \qquad [18']$$

Table I. Numerical comparisons of Eq. [9], [11], [14], and [15]

$\frac{y}{k}$	[14]/[15] $\sqrt{1-\frac{y^2}{k^2}}$	[9] $x/k = 1-\sqrt{\quad}$	[11] $y^2/2k^2$	$\frac{[9]-[11]}{[9]}$ $\frac{\frac{x}{k} - \frac{y^2}{2k^2}}{x/k}$

$$= \rho_s(\int y dy)\frac{[1 + (dx/dy)^2]^{1/2}dy}{\int[1 + (dx/dy)^2]^{1/2}dy} \quad [18'']$$

There does not appear to exist an analytical solution to Eq. [18]; however, the limiting case

$$(dy/dx) >> 1 \quad [19]$$

yields

$$(\rho_e/\rho_s)\,dx = k dx \simeq d(y^2)/4 \quad [20]$$

or

$$x \simeq y^2/4k \quad [20']$$

Equations [19] and [20'] are obviously equivalent to those obtained for the rectangular cell, Eq. [15] and [11].

Another approximate solution of Eq. [18] may be obtained for a cell comprising the annular space between two concentric cylinders of inner radius r_1 and outer radius r_2. Then, for the case

$$(dy/dx) << 1 \quad [21]$$

Eq. [18'] yields

$$x \simeq (y^2 - r_1^2)/2k \quad [22]$$

which is valid for

$$y/k >> 1 \quad [23]$$

The electrode current density then becomes

$$i_s \simeq J_x dy/dx \quad [24]$$

$$\simeq (k/y)J_x \quad [24']$$

which may be fairly uniform if the maximum radius r_2 is not much larger than r_1.

For either of the three configurations discussed above (rectangular, circular, and annular), the metal electrode M could be replaced by a second conducting glass electrode satisfying one of the appropriate Eq. [9], [11], [20'], or [22], as shown in Fig. 1b and 1c.

In Fig. 1b, the electrodes g_1 and g_2 and their current collectors C_1 and C_2 are arranged symmetrically with respect to a central plane so that the relations between their mirror-symmetric coordinates are

$$dy_1 = dy_2 \quad \text{and} \quad dx_1 = dx_2 \quad [25]$$

In Fig. 1c, the symmetry is with respect to a central point (or line perpendicular to the drawing in the rectangular cell) so that

$$dx_1 = -dx_2 \quad \text{and} \quad dy_1 = -dy_2 \quad [26]$$

Case 2. Flat Electrodes Causing a Minimal Nonuniformity in J_x

The line-symmetric arrangement is of special interest for cells utilizing parallel, flat, conducting glass electrodes, as indicated by the dotted straight lines g'_1 and g'_2 in Fig. 1c. The following calculations will now show under what conditions parallel, flat, glass electrodes can yield essentially uniform plating.

Considering first the rectangular cell, let the origins of x_1, y_1 and x_2, y_2 correspond to that of Eq. [19] or [11], and let the spacing between these origins be a and b along the x- and y-directions, respectively, as shown in Fig. 1c. Then

$$y_2 = b - y_1 \quad [27]$$

and the total spacing X between g_1 and g_2 for any value of y_1 is

$$X = a + x_1 + x_2 \quad [28]$$

Applying Eq. [9] to curves g_1 and g_2 and combining with Eq. [27] and [28], one obtains

$$X = a + k_1\{1 - [1 - (y_1/k_1)^2]^{1/2}\} + k_2\{1 - [1 - (y_2/k_2)^2]^{1/2}\} \quad [29]$$

$$= a + k_1 + k_2 - [k_1^2 - y_1^2]^{1/2} - [k_2^2 + 2by_1 - y_1^2 - b^2]^{1/2} \quad [29']$$

where k_1 and k_2 are the values of ρ_e/ρ_{s1} and ρ_e/ρ_{s2} corresponding to the surface resistivities ρ_{s1} and ρ_{s2} of electrodes g_1 and g_2. Where condition [10] is satisfied, Eq. [29] may be simplified to

$$X \simeq a + \frac{y_1^2}{2k_1} + \frac{y_1^2 - 2y_1b + b^2}{2k_2} \quad [30]$$

Furthermore, for

$$k_1 \simeq k_2 = k \quad [31]$$

one obtains

$$X \simeq a + (2y_1^2 - 2y_1b + b^2)/2k \quad [32]$$

The rate of change of X

$$dX/dy \simeq \frac{y_1}{k_1} + \frac{y_1 - b}{k_2} \quad [33]$$

will be zero for

$$(y_1)_{min} = \frac{bk_1}{k_1 + k_2} \quad [34]$$

resulting in a minimum spacing

$$X_{min} \simeq a + \frac{b^2}{2(k_1 + k_2)} \quad [35]$$

The maximum spacing, on the other hand, corresponds to either $y_1 = 0$ or $y_1 = b$, depending on the ratio of k_1 to k_2

$$X_{max} \simeq a + \frac{b^2}{2k_2} \quad \text{for } k_1 > k_2 \quad [36]$$

$$\simeq a + \frac{b^2}{2k_1} \quad \text{for } k_2 > k_1 \quad [36']$$

Hence, the maximum variation in spacing is

$$X_{max} - X_{min} \simeq \frac{b^2}{2k_2(\text{or } k_1)} - \frac{b^2}{2(k_1 + k_2)} \quad [37]$$

$$\simeq \frac{b^2}{4k} \text{ for } k_1 = k_2 \quad [37']$$

If the curved electrodes g_1 and g_2 in Fig. 1c are now replaced by the parallel, flat electrodes g'_1 and g'_2 separated by the distance a (equal to the actual spacing for all values of y_1), then the maximum resulting nonuniformity in J_x should be, in first approximation, (cf. Eq. [37])

$$u = (J_x)_{max}/(J_x)_{min} \simeq \frac{a + (b^2/8k)}{a - (b^2/8k)} \quad [38]$$

i.e., the plating current density should remain essentially uniform as long as $b^2/4ka << 1$, and should deviate from the average by a maximum of $\pm 25\%$ for $a \simeq b^2/2k$.

Equation [38] is based on the assumptions that (*a*) the potentials corresponding to any value of y are still approximately the same for the flat electrodes g'_1 and g'_2 as for the ideal electrodes g_1 and g_2; and (*b*) the current flow vectors J_x still remain essentially parallel and in the x-direction, *i.e.*, that the y components due to the deviation from the ideal geometry of Fig. 1c are negligible. Hence, any local variations in J_x would be dependent mainly on the deviation of the local resistance or length of path through the electrolyte along the x-direction from the value required by Eq. [32].

In order for assumption (*b*) to be nearly true, the slope $m = dx/dy$ of the parallel plates g'_1 and g'_2 should equal the average slope of the curves g_1 and g_2. Hence, according to Eq. [11], the optimum slope

$$m_{opt} = \frac{\int (dx/dy)\,dy}{\int dy} \simeq \frac{\int_0^b (y/k)\,dy}{b} \simeq \frac{b}{2k} \quad [39]$$

The same result can be obtained by setting

$$x' = my + e \quad [40]$$

as the equation of the line g', and

$$x = y^2/2k \quad [11]$$

as that of curve g, and minimizing the root-mean-square deviation:

$$\int_0^b (x - x')^2\,dy = \text{minimum} \quad [41]$$

Substituting Eq. [40] and [11], integrating the left-hand side, and setting the derivatives of the resulting integral with respect to m and to e equal to zero, one obtains

$$e = -b^2/12k \quad [42]$$

and

$$m_{opt} = b/2k \quad [43]$$

as in Eq. [39].

It may be noted that the optimum slope m_{opt} of Eq. [39] and [43] applies not only to the line-symmetric arrangement discussed in connection with Eq. [26] through [38], but also to cells with only one transparent and one solid metal electrode, or with two mirror-symmetrically arranged transparent conductors as in Fig. 1a and 1b, in which cells, however, the electrodes are not parallel. For cells with one solid metal electrode (Fig. 1a) the total spacing becomes

$$X = a + (y^2/2k) \quad [44]$$

Upon substitution of the curved electrode g by a flat electrode g' with the optimum slope of $b/2k$, the spacing X' becomes

$$X' = a + (by/2k) \quad [45]$$

The deviation

$$X' - X = (by - y^2)/2k \quad [46]$$

is maximum for

$$b - 2y_{max} = 0 \quad [47]$$

which yields

$$(X' - X)_{max} = b^2/8k \quad [48]$$

Since the minimum value of $X' - X$ is 0 for $y = 0$, the resulting nonuniformity ratio u using a similar reasoning as for Eq. [37] and [38] becomes

$$u \simeq \frac{a + (b^2/16k)}{a - (b^2/16k)} \quad [49]$$

Similarly, for a cell with mirror-symmetric flat electrodes of slope $b/2k$, it is easy to show that the nonuniformity ratio u is also given by Eq. [38].

Case 3. Parallel, Flat, Transparent Electrodes

A more general calculation can be made of the current-density distribution between two flat, transparent conductors having any slope m.

Let

$$\Delta V_{g'} = (V_{g'_1} - V_{g'_2})_{y_1} \quad [50]$$

and

$$\Delta I_{g'} = (I_{g'_1} - I_{g'_2})_{y_1} \quad [51]$$

be the difference between the surface potentials and currents at the flat electrodes g'_1 and g'_2 for a given value of y_1. Then by Eq. [1], and the above assumption (*b*) (current flow lines essentially parallel to J_x) one can write

$$dI_{g'_1}/dy_1 = LJ_x = -dI_{g'_2}/dy_1 \quad [52]$$

and

$$d\Delta I'_g/dy_1 = 2LJ_x \quad [53]$$

Also, by Ohm's law,

$$J_x = -\Delta V_{g'}/(a\rho_e) \quad [54]$$

and

$$d\Delta V_{g'}/dy_1 = (I_{g'_2}\rho_{g'_2} - I_{g'_1}\rho_{g'_1})(1 + m^2)^{1/2}/L \quad [55]$$

(cf. also Eq. [2] and [5], which become for identical electrodes ($\rho_{g'_1} = \rho_{g'_2} = \rho_{g'}$)

$$d\Delta V_{g'}/dy_1 = \rho_{g'}\Delta I_{g'}(1 + m^2)^{1/2}/L \quad [55']$$

Equations [53] and [54] yield

$$-d\Delta I_{g'}/dy_1 = 2L\Delta V_{g'}/(a\rho_e) \quad [56]$$

Differentiating Eq. [55'] and [56] and cross-substituting, one obtains

$$d^2\Delta V_{g'}/dy_1^2 = 2\Delta V_{g'}(1 + m^2)^{1/2}\rho_{g'}/a\rho_e = \gamma^2\Delta V_{g'} \quad [57]$$

and

$$d^2\Delta I_{g'}/dy_1^2 = \gamma^2\Delta I_{g'} \quad [58]$$

where

$$\gamma^2 = 2(1 + m^2)^{1/2}\rho'_g/(a\rho_e) = 2(1 + m^2)^{1/2}/(ak) \quad [59]$$

If I_c is the total current at the external line-symmetrically arranged contacts C_1 and C_2, then the boundary conditions are

$$\Delta I_{g'} = I_{g'_2} = -I_c \text{ for } y_1 = 0 \quad [60]$$

$$\Delta I_{g'} = I_{g'_1} = I_c \text{ for } y_1 = b \quad [61]$$

and finally, by symmetry

$$\Delta I_{g'} = 0 \text{ for } y_1 = b/2 \quad [62]$$

The solution to Eq. [55'] through [62] is

$$\Delta I_{g'} = I_c \sinh[\gamma(b/2 - y_1)]/\sinh(\gamma b/2) \quad [63]$$

and

$$\Delta V_{g'} = -K_o \cosh[\gamma(b/2 - y_1)]/\sinh(\gamma b/2) \quad [64]$$

where

$$K_o = \gamma a\rho_e I_c/2L = \rho_{g'} I_c(1 + m^2)^{1/2}/(\gamma L) \quad [65]$$

The minimum value of $|\Delta V_{g'}|$ corresponds to $y_1 = b/2$ (cf. Eq. [55'] and [62])

$$|\Delta V_{g'}|_{min} = -K_o/\sinh(\gamma b/2) \quad [66]$$

while the maximum value, corresponding to $y_1 = 0$ or $y_1 = b$, is

$$|\Delta V_{g'}|_{max} = -K_o \coth(\gamma b/2) \quad [67]$$

Hence, according to Eq. [54], [66], and [67]

$$u = (J_x)_{max}/(J_x)_{min} = \cosh(\gamma b/2) \quad [68]$$

For $m \simeq 0$, the uniformity ratio exceeds 0.98 for $\gamma b \leq 0.4$, or $b^2/4ka \leq 0.02$ (cf. Eq. [59]). Similarly, $u > 0.88$ for $\gamma b \leq 1.0$, and $u \geq 0.65$ for $\gamma b \leq 2.0$ or $a \geq b^2/2k$, which agrees with the results of Eq. [38].

The currents $I_{g'1}$ and $I_{g'2}$, and potentials $V_{g'1}$ and $V_{g'2}$ at the two electrodes can now be obtained. From Eq. [1], [54], and [63] through [65] one obtains

$$I_{g'1} = L\int_o^y J_x dy = \frac{-L}{a\rho_e}\int_o^y \Delta V'_g dy \quad [69]$$

$$= (I_c - \Delta I'_g)/2 \quad [69']$$

similarly,

$$I_{g'2} = (I_c + \Delta I'_g)/2 \quad [70]$$

Also, from Eq. [2], [5], [59], and [63] through [65]

$$V_{g'1} = \int dV_{g'1} = \frac{-\rho_g(1+m^2)^{1/2}}{L}\int I_{g'1}dy_1 \quad [71]$$

$$= [\Delta V_{g'} - \gamma K_o y_1 + 2V_o]/2 \quad [71']$$

where the constant V_o depends on the chosen reference potential. Similarly,

$$V_{g'2} = [-\Delta V_{g'} - \gamma K_o y_1 + 2V_o]/2 \quad [72]$$

The variation of $V_{g'1}/K_o$ and $V_{g'2}/K_o$ with γy_1 is shown in Fig. 3a for $\gamma b = 1.0$. The dotted line in Fig. 3a gives the potential in the midplane between the two electrodes, which is

$$(V_{g'1} + V_{g'2})/2 = -\gamma K_o y_1/2 \quad [73]$$

according to Eq. [71'] and [72].

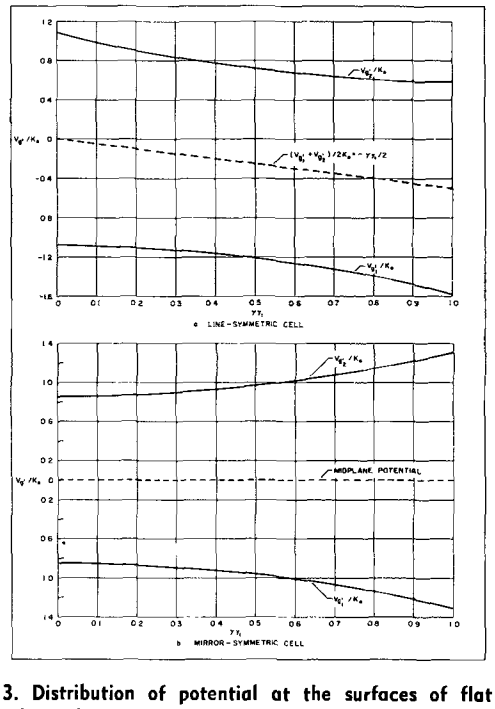

Fig. 3. Distribution of potential at the surfaces of flat transparent electrodes g'1 and g'2 (solid lines) and their midplane (dashed lines): (a) line-symmetric cell (b) mirror-symmetric cell.

Now, in order to have no flow in the electrolyte along the y_1-direction, the slope m of the electrodes g'_1 and g'_2 and their midplane should be such that

$$-\rho_e J_x dx = -\gamma K_o dy_1/2 \quad [74]$$

(cf. Eq. [3] and [73]) or

$$m_{opt} = \gamma K_o/(2\rho_e J_x) \quad [75]$$

But the average value of J_x is

$$(J_x)_{av} = I_c/bL \quad [76]$$

Hence,

$$m_{opt} = \gamma K_o bL/2\rho_e I_c \quad [77]$$

$$\simeq b/2k \quad [77']$$

(cf. Eq. [65] and [7] which confirms the above-derived Eq. [39], and also the approximate validity of the above assumption (b) under condition [77'].

Equation [73] also yields an estimate of the deviation from assumption (b) in cases where the slope m differs from that of Eq. [77]. Especially, for $m = 0$ (*i.e.*, electrodes perpendicular to the x-direction), the perpendicular component of the current flow J_y, in the central plane is by Ohm's law and Eq. [73]

$$J_y = \gamma K_o/(2\rho_e) \quad [78]$$

$$= I_c/(2kL) \text{ (cf. Eq. [7] and [65])} \quad [78']$$

and by Eq. [76] and [77]

$$J_y/(J_x)_{av} = b/2k \simeq m_{opt} \quad [79]$$

which means that the use of a slope differing from m_{opt} is equivalent to the introduction of spurious edge effects at $y_1 = 0$ and $y_1 = b$, resulting in distorted current flow lines, as shown in Fig. 4. To estimate the effect of these distortions on the current density distribution, one may calculate the respective spreading and compression of the flow lines at the lower and upper halves of electrode g'_1. From Eq. [79] one obtains

$$\Delta s/(a/2) = b/(2k) \quad [80]$$

Hence, the fractional spreading or compression of flow lines is of the order of

$$\Delta s/(b/2) \simeq a/(2k) \quad [81]$$

For the resulting nonuniformity to be below ±20%, it is necessary that $a \leq 2k/5$. But Eq. [68] requires that $a \geq b^2/2k$. **Hence,**

$$\text{for } m = 0,\ 2k/5 \geq a \geq b^2/2k \quad [82]$$

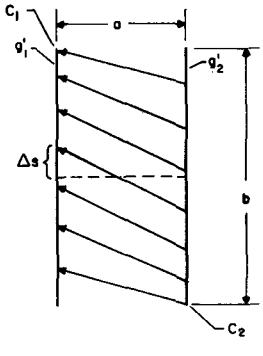

Fig. 4. Compression and spreading of current flow lines for m = 0

In cases where the a dimension may have to be larger than $2k/5$, the perpendicular flow component J_y may be eliminated by using a mirror-symmetric electrode and contact arrangement. The boundary conditions then become

$$\Delta I_{g'} = I_{g'_1} = I_{g'_2} = 0 \quad \text{for } y = 0 \qquad [83]$$

and

$$\Delta I_{g'} = 2I_c \quad \text{for } y = b \qquad [84]$$

Equations [55'] through [59], together with [83] and [84], yield

$$\Delta V_{g'} = 2K_o \cosh(\gamma y)/\sinh(\gamma b) \qquad [85]$$

$$\Delta I_{g'} = 2I_o \sinh(\gamma y)/\sinh(\gamma b) \qquad [86]$$

$$I_{g'_1} = I_{g'_2} = \Delta I_{g'}/2 \text{ (by symmetry)} \qquad [87]$$

$$V_{g'_1} = (\Delta V_{g'}/2) + V_o \qquad [88]$$

$$V_{g'_2} = -(\Delta V'_g/2) + V_o \qquad [89]$$

as shown in Fig. 3b. Finally,

$$|\Delta V_{g'}|_{max} = -2K_o \coth(\gamma b) \qquad [90]$$

$$|\Delta V_{g'}|_{min} = -2K_o \operatorname{csch}(\gamma b) \qquad [91]$$

and

$$u = |J_{mg'}|_{min}/|J_{mg'}|_{max} = |\Delta V_{g'}|_{min}/|\Delta V_{g'}|_{max} = \operatorname{sech}(\gamma b) \qquad [92]$$

For $m = 0$, $u \geq 0.89$ for $\gamma b \leq 0.5$ or $b^2/4ka \leq 0.03$ (cf. Eq. [59]), and $u \geq 0.65$ for $\gamma b \leq 1.0$ or $a \geq 2b^2/k$. Comparison of these results with those of Eq. [68] shows that the mirror-symmetric arrangement with flat electrodes perpendicular to the cell walls requires a minimum electrode spacing 4 times larger than the line-symmetric arrangement for the same electrode widths b.

Conclusions

The problem of current distribution may be extremely complex even for flat, parallel, metallic conductors (4, 5), and becomes further complicated by necessarily uneven voltage drops along the surface of poorly conducting electrodes, as shown in the preceding calculations. For the cell of Fig. 1a, the requirement for uniform, parallel current flow lines is that the conducting surface g be traced by the curve s defined by Eq. [9] or [11]. For $0 < y/k < 0.6$, the plating uniformity is then 20% (or ± 10%), as shown in Table I and Fig. 2.

The surface g may be either a cylindrical segment of length L perpendicular to the plane of Fig. 1a, or a surface of revolution obtained by revolving Fig. 1a around the x-axis. In the latter case, the curve s should approximate Eq [20']. Fair plating uniformity can also occur in an annular cell obtained by revolving the curve of Eq. [22] provided that $k << r_1 \leq r_2 \leq 1.5\, r_1$.

The above equations obviously remain unchanged when the highly conducting solid metal electrode M of Fig. 1a is replaced by a second surface-conductor arranged mirror-symmetrically as in Fig. 1b or center-or line-symmetrically as in Fig. 1c.

On replacing the curved electrodes g, g_1, g_2 of Fig. 1 by flat surface-conductors a minimal distortion in current flow lines will occur if the slope m of Eq. [40] satisfies Eq. [43]. The nonuniformity ratio u of maximum-to-minimum plating current density is then given approximately by Eq. [38] for the arrangements of Fig. 1b and 1c. Hence, for a plating uniformity better than ± 20%, it is necessary that $a \geq b^2/2k$. Similarly, for the arrangement of Fig. 1a, the same uniformity requires a minimum spacing $a \geq b^2/4k$ (cf. Eq. [49]).

A clearer and more complete analysis of the potential and current density distributions at the surfaces of flat, transparent conductors having any slope m is afforded by Fig. 3 (Eq. [50] through [92]). For $m = 0$ (electrodes perpendicular to the cell walls), the required minimum spacing is again shown to be $a \geq b^2/2k$ for the line-symmetric cells (Eq. [68]), but four times larger, $a \geq 2b^2/k$, for mirror-symmetric cells (Eq. [92]). On the other hand, with large electrode spacings, the line-symmetric cells may be subject to the distortions in current flow lines shown in Fig. 4. Hence, for satisfactory uniformity, the spacing in such cells must be in the range

$$b^2/2k \leq a \leq 2k/5 \qquad [82]$$

No such upper limit appears to exist for the spacing of mirror-symmetric electrodes, but a large spacing is usually not compatible with high efficiency and operating speed (1, 2).

The Effect of Some Addition Agents on the Kinetics of Copper Electrodeposition from a Sulfate Solution

II. Rotating Disk Electrode Experiments

G. R. Johnson[1] **and D. R. Turner**

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The manner in which certain organic addition agents affect the crystal growth of copper electrodeposits was investigated with the aid of the rotating disk electrode technique. The results indicate that thiourea and l (-) cystine are cathodically reduced during copper plating. It is proposed that thiourea and l (-) cystine, or their reduction products, decompose to form sulfide ions which combine with cupric ions and precipitate as CuS on the cathode. Gelatin inhibits pyramidal crystal growth at low current densities by adsorbing on the apex of the pyramids. Above a transition current density, cubic layer crystal growth predominates, and much larger quantities of gelatin are required to inhibit crystal growth. Glycine and dextrin have little or no effect on the polarization curve for copper plating. Therefore, the rotating disk electrode technique was not useful in studying the mechanism whereby they act as addition agents.

The rotating disk electrode technique was employed in an effort to extend our understanding of the behavior of various addition agents used in the electroplating of copper from acid sulfate solutions. Stirring is one of the more difficult variables to control in studying electrode processes. The rotating disk electrode technique is one means of varying the rate of stirring at an electrode in a controlled and reproducible manner. The technique also enables one to separate the diffusion controlled current from the total current flowing during the course of metal electrodeposition.

Levich (1) has shown that the magnitude of a diffusion limited current at a rotated flat disk electrode is directly proportional to the square root of the angular rotational velocity of the disk. If there are two simultaneous electrode processes, one of which is diffusion controlled, the current due to the diffusion controlled process may be separated from the total current using a method described by Pleskov (2). The total current at a constant electrode potential is plotted against the square root of the disk angular rotational velocity and the straight line is extrapolated to zero angular velocity. The ordinate intercept yields the current at the constant potential due to the process which is not diffusion controlled. If this is done at a series of electrode potentials over the range of interest, current-potential data are obtained for the nondiffusion controlled process. The current-potential curve for the diffusion controlled process is found by difference.

The rotating disk electrode technique was used in this study to re-evaluate the effect of some organic addition agents on the kinetics of copper electrodeposition from a sulfate solution described in an earlier paper (3).

Experimental

The copper plating solution used in this study was 1M in copper sulfate and 1M in sulfuric acid. As reported in the earlier study (3), the solution was purified of surface-active material by treatment with Al_2O_3 followed by an activated carbon treatment.

A cross-section view of the cell used for these rotating disk studies is shown in Fig. 1. Water from a thermostat set at 25.0°C was circulated through a water jacket around the cell.

[1] Present address: Sprague Electric Company, North Adams, Mass.

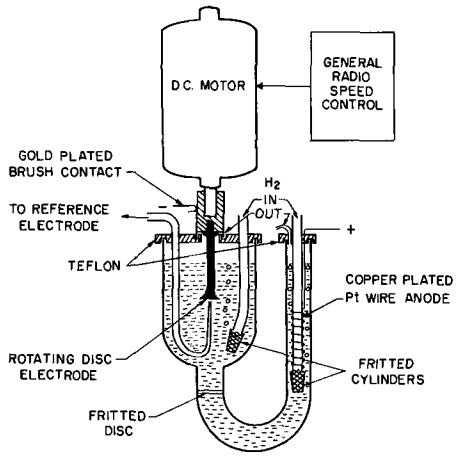

Fig. 1. Cross-section view of rotating disk electrode cell

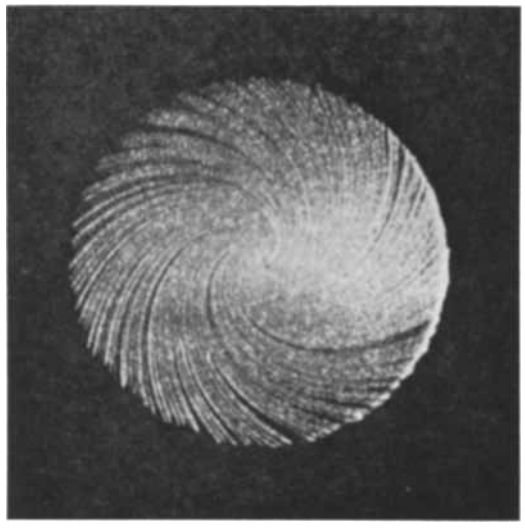

Fig. 2. Flow pattern on a rotating disk electrode

Disk electrodes with an exposed area of 1 cm^2 were machined from brass to the shape shown in Fig. 1. A 0.12 mm thick platinum foil disk was attached to the bottom of the brass mandrel with lead-tin solder. The platinum disk was in turn preplated with copper from the purified solution mentioned earlier. All but the bottom surface of the electrode was masked either with a neoprene coating prepared by "Gaco," or with "Apiexon" wax dissolved in toluene. Both materials were satisfactory insulators.

The simple disk electrode used in this work has the disadvantage in that the current distribution for copper plating is nonuniform even though current distribution for a simultaneous diffusion limited process is uniform (1). A guard ring around the disk electrode would improve metal plating current distribution.

The electrode was mounted close to the end of the motor shaft by means of a short gold-plated brass sleeve to minimize the eccentric motion of the rotating disk. A General Radio Variac speed control unit varied the speed of the d-c motor and a General Radio Strobotac measured the rotational speed in revolutions per minute (rpm). Rotational speeds of 100, 400, 900, and 1600 rpm were used in these studies since their square roots were 10, 20, 30, and 40, respectively. This simplified data plotting and provided uniformly spaced points.

Experiments were carried out at constant current densities using a regulated power supply. Cell currents were measured with a Sensitive Research multirange milliammeter. Electrical contact to the rotating disk was made by means of a gold-plated phosphor bronze spring pressing against the gold-plated sleeve.

The cathode potential was measured with a Millivac Type 17C vacuum tube voltmeter. Pure copper plated on a platinum wire coil dipped in the additive-free solution was used as the reference electrode. This reference electrode was connected to the main cell through a syphon filled with acid copper solution as shown in Fig. 1. The syphon had a long, fine capillary tip which projected up close to the center of the rotating disk electrode. This arrangement did not affect the solution flow pattern over the disk electrode significantly.

The flow pattern of solution over the surface of a rotating disk electrode is illustrated in Fig. 2. The spiral pattern was obtained by plating a heavy copper deposit on a rotating disk (~ 0.12 mm thick) from an acid sulfate bath containing 1 x 10^{-4} moles/l thiourea. Plating conditions and the addition agent produced a ridged deposit which outlined the flow of solution over the surface. The spiral is almost an Archimedes spiral, *i.e.*, displacement away from the center is almost proportional to the angular displacement. Another interesting feature is that the pattern does not change with rotational speeds.

All of these experiments were conducted using the 1M $CuSO_4$ + 1M H_2SO_4 solution described earlier. Oxygen-free hydrogen was bubbled through the electrolyte continuously. Measurements were made first in electrolyte free of addition agent and then with solutions containing one of the following additives: 1.3 x 10^{-4} moles/l thiourea, 4.2 x 10^{-5} moles/l l(−) cystine, 6.2 x 10^{-5} moles/l dextrin, 1.3 x 10^{-4} moles/l glycine, and 0.010 g/l gelatin.

Results and Discussion

Cathode potential-current density curves were obtained with and without the various addition agents in the copper plating solution at the several rotational speeds of the disk electrode. The results were similar to those reported in a previous paper (3), but they differ in some important respects.

In the purified solution without addition agent, disk rotational speeds from 100 to 1600 rpm had no effect on the cathode potential-current density relationship up to 50 ma/cm^2. The curve was the same as that obtained using a spherical cathode (3) and in good agreement with the results of other investigators (4-6).

Of the five addition agents studied, all but dextrin had an effect on the polarization curve, and the results were similar to those obtained in the earlier paper (3). Stirring, by means of the rotating disk electrode, gave some very interesting results which proved helpful in interpreting these and other data in terms of a mechanism whereby some addition agents modify crystal growth of electrodeposits.

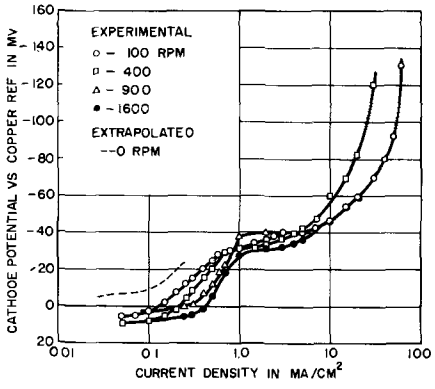

Fig. 3. Effect of disk rotation speed on the cathode potential-current density curve in 1M $CuSO_4$ + 1M H_2SO_4 solution containing 1.3 x 10^{-4} M/L thiourea.

The cathode potential-current density curves obtained with 1.3 x 10^{-4} M/L thiourea as the additive are shown in Fig. 3. When the disk rotation speed increases, the "step" in the curve is displaced toward higher current densities without being changed in form. The data for the $E - \log i$ curve at 400 rpm were obtained on a different day from the other curves. The higher polarization curve for 400 rpm above 10 ma/cm² was an anomaly and was not reproducible. This result illustrates the difficulties that are encountered occasionally in the study of addition agents. The cathode potential-current density relation at the "step," in the unstirred condition, was obtained by plotting i *vs.* $(\text{rpm})^{1/2}$ at various potentials in the "step" region and extrapolating to zero rpm. The results with thiourea will be discussed after the experiments with l(—) cystine are described.

l(—) Cystine is similar in chemical structure to both thiourea and glycine. It has an exposed sulfur group like thiourea, but the amine group is on the second carbon atom away from the sulfur group. A carboxyl group is attached also to the second carbon atom so that the molecule is similar to glycine (NH_2CH_2COOH). As an addition agent in copper plating from acid sulfate solutions, l(—) cystine behaves more like thiourea than glycine. The effect of disk rotational speed on the E-i curves in a copper plating solution containing 4.2 x 10^{-5} M/L l(—) cystine is shown in Fig. 4. There is the same shift in the potential step between 0.1 and 1 ma/

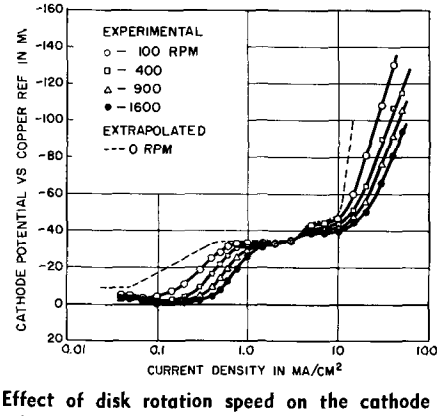

Fig. 4. Effect of disk rotation speed on the cathode potential-current density curve in 1M $CuSO_4$ + 1M H_2SO_4 solution containing 4.2 x 10^{-5} M/L l (—) cystine.

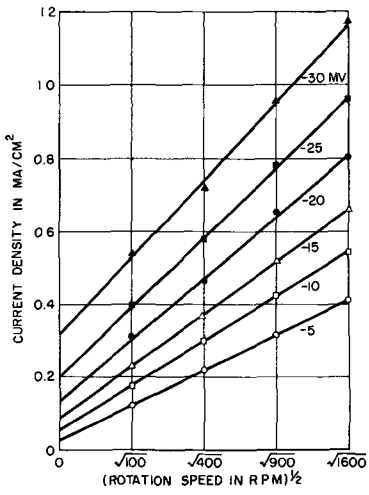

Fig. 5. Current density-(rotation speed)$^{1/2}$ relation between 5 and 30 mv cathode potential in 1M $CuSO_4$ + 1M H_2SO_4 solution containing 4.2 x 10^{-5} M/L l(—) cystine.

cm² toward higher current density as observed in Fig. 3. An additional effect was observed with l(—) cystine. After all the curves passed through a common point at 3 ma/cm², they again split into separate curves at higher current densities. The slope of the curve in the Tafel region (linear E — log i) decreases with increasing speed of disk rotation.

The unstirred (0 rpm) cathode potential-current density curve was obtained above and below 3 ma/cm² by plotting current density *vs.* $(\text{rpm})^{1/2}$ at a series of potentials and extrapolating to zero rpm. The intercept is the current density, at a given electrode potential, of cathodic processes which are not controlled by the mass transfer of a reacting species to the cathode surface. The method is illustrated in Fig. 5 for the low current density region. A similar plot and extrapolation was made for the high current density region.

If the rate of an electrochemical process is determined by the mass transfer of the reacting species,

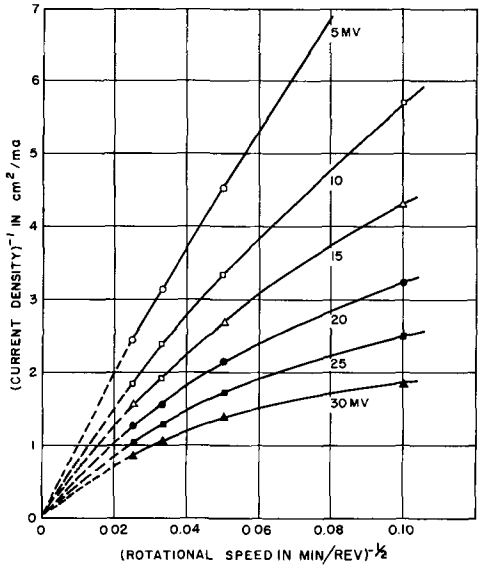

Fig. 6. Curves of (current density)$^{-1}$-(rotation speed)$^{1/2}$ at cathode potentials between 5 and 30 mv in 1M $CuSO_4$ + 1M H_2SO_4 containing 4.2 x 10^{-5} M/L l(—) cystine.

then the limiting current density should approach infinity as the stirring rate becomes infinitely large. When the inverse of the experimental points in Fig. 5 are plotted, that is, (current density)$^{-1}$ *vs.* (disk rotational speed)$^{-1/2}$, a series of curves is obtained as shown in Fig. 6. All the curves appear to extrapolate to, or close to, infinite current density at infinite rotational speed. This result confirms the earlier assumption that the rate of the electrode reaction is determined by the mass transfer of the reacting species. Since the potential step does not occur without addition agents, it must be concluded that the reacting species is some form of or involves the addition agent.

The polarization curves with thiourea or l(—) cystine as the addition agent, Fig. 3 and 4, may be considered to be the result of two effects. First, at the potential step between about 0 and 30 mv, the addition agent is electrolytically reduced, with the formation of H_2S; and second, cupric sulfide is precipitated at very low H_2S concentrations $\sim 1 \times 10^{-44}$ moles/l. The CuS interferes with normal crystal growth; thus the potential for copper deposition becomes more negative than normal (without addition agent). Increasing the disk rotational speed increases the supply of addition agent to the electrode and the current increases. An attempt to confirm this mechanism by measuring the copper plating efficiency at various disk rotational speeds was only partially successful. The trend was to lower plating efficiencies with increasing disk speeds as it should be, but a few of the results did not fall into the pattern.

Above about 30 mv cathode potential, the current density increases markedly with a slight potential rise. This is the potential region where it is believed control of the rate of copper deposition changes from a surface diffusion of adatoms to a charge transfer mechanism (4). The transition is also in the region where the crystal growth habit changes (3, 7). Whatever the mechanism, it is evident that the relative inhibiting effect of both thiourea and l(—) cystine decreases in the vicinity of 30 mv.

l(—) Cystine has an unusual effect on the polarization curves in the Tafel region as shown in Fig. 4. Increasing disk rotation speed has a depolarizing effect. The increase in current density is too great to be attributed entirely to reduction of the addition agent. One interpretation is that l(—) cystine changes the rate-determining step in the charge transfer process for copper deposition. Mattsson and Bockris (4) have presented evidence which tends to support the suggestion that copper deposition from purified acid sulfate solutions is a two step reaction

$$Cu^{++} + e^- \rightarrow Cu^+ \qquad [1]$$

and

$$Cu^+ + e^- \rightarrow Cu \qquad [2]$$

with reaction [1] being rate determining. If l(—) cystine causes reaction [2] to be the slow step, stirring by means of the rotating disk electrode will sweep away some cuprous ions before they can be cathodically reduced. The potential of the electrode is determined by the cuprous ion concentration at the electrode. Therefore, at a given current density, when stirring reduces the cuprous ion concentration at the electrode, the electrode potential becomes less negative.

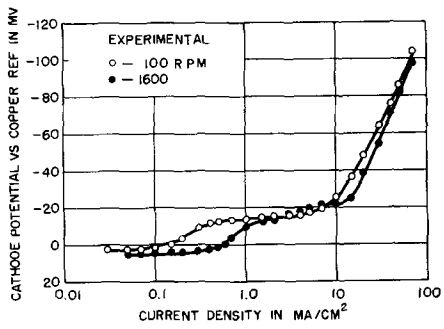

Fig. 7. Effect of disk rotation speed on the cathode potential-current density curve in 1M $CuSO_4$ + 1M H_2SO_4 solution containing 1.3×10^{-4} M/L glycine.

One of the reviewers of this paper has suggested that some study of the effects of temperature variation on E — log i curves might lead to a better understanding of the reaction processes, particularly with l(—) cystine, where a change in the charge transfer rate-determining reaction is proposed.

Glycine affects the polarization curve for copper plating only in the region between 0.1 to 1.0 ma/cm^2. The effect of disk rotational speed on the polarization curve is shown in Fig. 7. The potential step at low current densities is shifted toward higher current densities with increasing rotation speed as it is with thiourea and l(—) cystine. The results do not appear to contribute to our understanding of how glycine in an acid copper sulfate plating solution improves the microdistribution of plated copper.

In the previous paper (3), it was noted that gelatin produced a large polarization effect in copper plating in the low current density region, and that there was a sharp break in the E — log i curve at about 3 ma/cm^2. On decreasing the current, a hysteresis was always observed. These results were duplicated with a rotating disk electrode except for the hysteresis effect which was absent, *i.e.*, ascending and descending curves were identical. The rotational speed of the disk electrode affects the E — log i curve only beyond the break point as shown in Fig. 8; and the slope of the curve in this region decreases with increasing rotation speed. If the inverse of the slope, $(\Delta E/\Delta \log i)^{-1}$, is plotted against disk rotation speed and the data are extrapolated to 0 rpm, the slope appears to become infinite as illustrated in curve 1. The horizontal line, curve 2, for infinite rotation speed was obtained by extrapolating a plot of $\Delta E/\Delta \log i$ *vs.* (rpm)$^{-1}$. Zero rpm and infinite rpm correspond to the completely unstirred and infinitely stirred conditions, respectively. Both conditions are impossible to achieve experimentally but the information is important in understanding the behavior of gelatin as an addition agent.

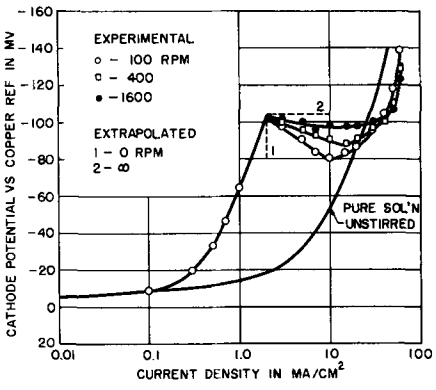

Fig. 8. Effect of disk rotation speed on the cathode potential-current density curve in 1M $CuSO_4$ + H_2SO_4 solution containing 0.010 g/l gelatin.

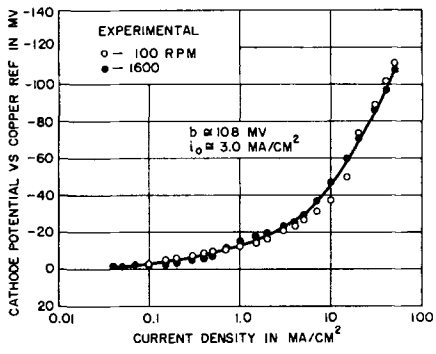

Fig. 9. Effect of disk rotation speed on the cathode potential-current density curve in 1M $CuSO_4$ + 1M H_2SO_4 solution containing 6.2 x 10^{-5} moles/l dextrin.

These results for gelatin using the rotating disk electrode support the mechanism proposed in the earlier paper (3). In the low current density region, the E — log i results clearly indicate a lack of dependence on the cathode angular rotational speed. This is interpreted to mean that even at the lowest stirring rate (rotational speed) employed, sufficient quantities of gelatin are provided to interfere with the normal crystal growth on the cathode. On a (100) oriented face, the crystal growth is pyramidal below the transition current density (~2 ma/cm²), and relatively small amounts of gelatin are needed to block crystal growth. Above the transition current density, it has been shown that cubic layer-type growth of the copper deposit predominates on the (100) face (3). With this growth pattern one would expect that a much greater amount of gelatin would be required to interfere with the lateral extensions of the steps generated from the original pyramid sides. The experimental results in Fig. 8 beyond the transition current density are in agreement with the previous suggestion. At zero rpm, the extrapolated E — log i curve drops almost vertically because the amount of gelatin available to inhibit crystal growth is very small as compared to the amount required for complete inhibition. Stirring by disk rotation mechanically conveys gelatin up to the cathode and the amount increases with rotation speed. Thus the negative slope of the polarization curve beyond the transition point decreases with increased disk rotation speed. The horizontal E — log i curve for infinite stirring may be interpreted to mean that the maximum inhibiting effect of gelatin in copper plating is never greater than that observed at the transition current density. The cathode potential increases again in Fig. 8 above 10 ma/cm² when the rate of copper plating becomes limited by the charge transfer process.

It was observed in the earlier study (3), that up to 0.1 g/l dextrin had no effect on the cathodic polarization curve for copper plating. This result was confirmed with the rotating disk electrode. It was also found that variable stirring rates did not change the result, as demonstrated in Fig. 9. The Tafel slope, b, and exchange current density, i_o, were identical to the values obtained in additive-free solutions.

Summary and Conclusions

Structurally, l(—) cystine is similar to both thiourea and glycine but, as an addition agent in acid sulfate copper plating solutions, it behaves more like thiourea than glycine. The polarization curves for copper plating with thiourea and l(—) cystine as addition agents are interpreted to mean that the additive is electrolytically reduced with the formation of H_2S and subsequent precipitation at the interface of CuS which is incorporated into the deposit. Copper sulfide markedly increases the copper electrodeposition potential at a given current density when crystal growth is pyramidal, but not when it becomes laminar. Stirring has a depolarizing effect above 3 ma/cm² with l(—) cystine. One interpretation is that l(—) cystine changes the rate-determining step in the charge transfer process for copper plating.

Gelatin inhibits pyramidal crystal growth during copper plating at low current densities by adsorbing on the apex of the pyramids. Above the transition current density, gelatin must be supplied in much larger quantities to interfere effectively with cubic layer type growth.

Glycine and dextrin in acid copper plating solutions have little or no effect on the polarization curve for copper plating. Therefore, the rotating disk electrode technique was not useful in studying the mechanism whereby they act as addition agents.

Electrophoretic Deposition: A Versatile Coating Method

Conrado P. Gutierrez, John R. Mosley, and Terry C. Wallace

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

Electrophoretic deposition is shown to be a useful coating method for the deposition of metal, oxide, and carbide coats on metal or graphite. The time-current-voltage relationship on the rate of deposition is discussed, and factors important to preparation of suitable plating suspensions and to the formation of adherent deposits, with and without binders, are described. The method has been applied to the plating of coats of B, Dy, Zr, Au, Nb, Mo, W, Re, Nb_3Sn, ZrH_2, ThC, UC, NpC, PuC, (ZrU)C, UWC_2, UO_2, $UMoC_2$, Ta_2O_5, and both W-UO_2 and Mo-UO_2 composites.

The phenomenon of electrophoresis has been observed and investigated for at least 150 years, but only very limited use has been made of electrophoresis as a method of applying coatings to materials. Yet electrophoresis offers a very general and useful method of coating conducting materials such as metals and graphite with a wide variety of conductors and nonconductors.

The stability of a plating suspension has been explained in terms of an electrical layer (1-10). Various theories on the formation of an adherent deposit have been advanced (11-16); however, this feature of electrodeposition is the least understood and the most difficult to control.

This paper describes ways of preparing stable plating suspensions, and lists the important parameters for plating by electrophoretic deposition.

Experimental Procedure

Selection and purification of the suspension medium.—Polar organic liquids are most commonly used as suspension media for electrophoretic deposition since stable suspensions can be formed in these liquids, and the low electrical conductivity of these liquids minimizes electrolysis of the liquid and attendant gassing at the electrodes. The liquids used in this investigation were isopropyl alcohol (IPA) and nitromethane. These were selected on the basis of their proved utility as suspension media as shown by the important applications of electrophoretic deposition developed by Reichard *et al.* (17).

The IPA (Bakers Analyzed Reagent Grade) was untreated before use. The nitromethane (Eastman Kodak's No. 189) was dried by shaking for a few minutes with calcium sulfate (Drierite) and was then filtered through a "fine" fritted glass filter before use. The drying procedure also appeared to remove ionic impurities from the nitromethane.

Comminution of powders.—The suspensions used for electrophoretic deposition usually had a particle size ranging from 1-20μ. This range of particle size was chosen because colloidal size particles gave low plating rates, and particles coarser than 25μ led to uneven deposits. The optimum size was found to be about 6μ, and grinding times were selected to give a large fraction of the powder close to this size.

All powders were comminuted by jar milling in IPA. The niobium suspensions were prepared by milling −325 mesh Fansteel Metallurgical Corporation niobium for 8 to 12 hr with steel balls and jars. Suspensions of other materials were milled for 1 to 10 hr in Teflon or polyethylene containers with tungsten rods or tungsten carbide balls. The latter powders were separated by centrifugation, resuspended in IPA several times, then resuspended several times in dried nitromethane to remove the IPA. Finally, the desired particle size range was obtained by elutriation of the suspension in a vertical column of the solvent. A haemocytometer was used occasionally to confirm the particle size.

Use of additives.—Early in the investigation of Nb suspensions in IPA, it was observed that some suspensions gave adherent electrophoretic deposits, others gave only a partially adherent deposit, and many gave no deposit, all under the same plating conditions. The suspensions all had approximately the same sedimentation time and exhibited similar electrophoretic migration velocities as determined in a straight tube cell.

By the use of additives, suspensions could be made to form an adherent deposit. Of the additives investigated (ammonium and sodium hydroxides, hydrochloric, nitric and citric acids), a dilute solution of ammonium hydroxide was found to be the most effective. The ammonium hydroxide was added as a 0.15*M* solution prepared from concentrated aqueous ammonium hydroxide and IPA. The small amount of water added in this way was shown to be without effect. The amount of additive required is discussed later.

The use of zein, a corn protein, as an additive was first reported by Reichard *et al.* (17). It is an excellent binder, and deposits containing zein exhibit a "green strength" such that mechanical scraping is required to remove them from the substrate. However, it was not used in the Nb-IPA suspensions since it caused immediate flocculation. It was added to the nitromethane suspensions as a 60-40 vol % IPA-nitromethane solution containing 10 mg zein/cc. Although some suspensoids deposited

at the anode, all suspensoids, on the addition of zein, deposited at the cathode. The further addition of small amounts of benzoic acid, added as a saturated solution in nitromethane to these suspensions improved the smoothness of the deposit.

The zein could be removed from the deposit by heating the sample to 600°C *in vacuo*.

The electrophoretic deposition rate was much faster from nitromethane suspensions containing zein and benzoic acid than from IPA suspensions containing ammonium hydroxide.

Preparation of suspensions.—In the case of the Nb-IPA suspensions, samples of the jar-milled suspension were diluted with IPA to a concentration of 10 mg/cc or less and tested for plating characteristics using various concentrations of ammonium hydroxide additive and various voltages on the plating cell. A suspension that would plate to depletion in 10 sec or less, with formation of an adherent deposit, was considered a satisfactory plating suspension.

When nitromethane was the suspending medium, the ground powders were washed several times with IPA as described above. The number of washings in this step was often important in determining the plating characteristics of the suspension. After subsequent centrifuging and washing of the powder with nitromethane to remove the alcohol, the powder was ground again in nitromethane for a short period (10 min) to redisperse the powder. The suspension was then diluted to a dispersoid concentration of 10 mg/cc or less, and sufficient zein solution was added so that the weight of zein amounted to about 1% of the weight of dispersoid in the suspension. Often benzoic acid was added to improve the quality and adherence of the deposits. The amount of benzoic acid needed was determined in the same manner described above for ammonium hydroxide.

Plating cell.—The electrophoretic deposition experiments were performed by using the cell shown in Fig. 1. This design allowed: (i) the use of small samples of suspensions (6.4 ml), (ii) easy removal or substitution of small, easily weighable electrodes, and (iii) visibility of the suspension during plating. The glass portion of the cell was made from a 25 ml graduated cylinder. A micarta cap centered the electrode in the cell. The suspensions were magnetically stirred by means of a Teflon-covered bar.

Results

The Nb-IPA suspensions were particularly interesting due to their sensitivity to various experimental parameters. In particular, the rate of electrophoretic deposition of Nb on the anode was studied as a function of the following: (a) concentration of dispersoid, (b) plating time, (c) nature of cell electrodes, (d) cell voltage or current density, and (e) concentration of additive.

Dispersoid concentration.—The effect of the concentration of Nb on electrophoretic deposition rates in the Nb-IPA suspensions exhibited no unexpected features. For a given series of suspensions made by various dilutions of a concentrated stock suspension, the deposition rate at constant voltage was proportional to the Nb concentration.

Induction time and electrode studies.—One of the most surprising features of electrophoretic deposition from the Nb-IPA suspensions was the effect of time on the rate of deposition at a fixed voltage. Some of the suspensions exhibited an initial constant rate which then gradually decreased as the suspension became depleted. In contrast, the majority of suspensions, and all those that had been stirred in a Waring Blendor for 5 min, gave an initial "induction period" during which essentially no plating occurred. This was followed first by a gradually increasing rate of deposition and then by a decreasing rate, as before. A comparison of these two typical types of time dependence is shown in Fig. 2. The points of both curves were obtained from aliquots of each of the two types of suspensions which were electrolyzed at constant voltage with selected plating times. After the determination of each point, the cell was drained and cleaned, and a new graphite anode and a new portion of the 3.8 mg Nb/cc suspension were introduced for the next determination.

The induction time appeared to be unrelated to particle mobility since migration experiments indicated that particle mobilities were the same in suspensions with and without an induction period. Also, the anode did not appear to be involved in the induction periods. Figure 3 shows the experimental demonstration of the latter. The solid curve was obtained in the same way as the dotted curve in Fig. 2 (using "blendorized" suspensions), but

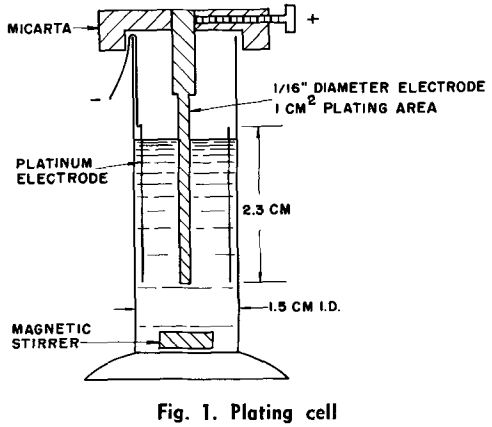

Fig. 1. Plating cell

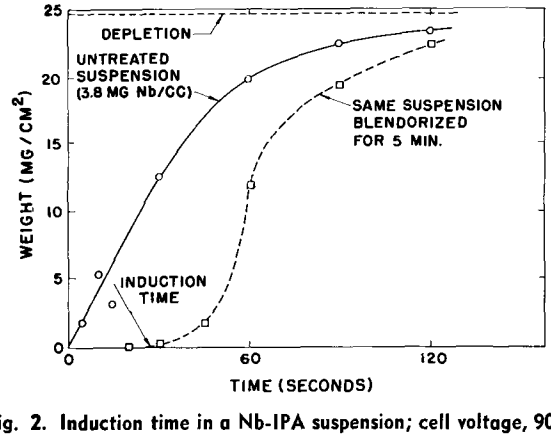

Fig. 2. Induction time in a Nb-IPA suspension; cell voltage, 900v.

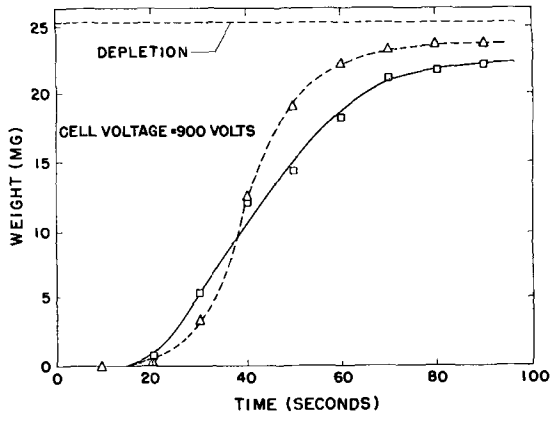

Fig. 3. Effect of the anode on induction time. □, weight obtained at indicated times in identical suspensions (4.0 mg Nb/cc); △, cumulative weight for successive coats on separate anodes in one suspension.

the dotted curve was obtained by the following procedure. Successive graphite anodes were coated at 900v for successive increments of time (10 sec) in the same portion of a blendorized Nb suspension, and the cumulative weight of the coats was plotted against the cumulative time. If an induction time were present with each new anode, no deposit, cumulative or otherwise, would have been obtained. However, the fact that the curves are so similar shows that the anode was not involved in the induction time. In this regard, it is interesting to note that several conductive anode materials were used in various phases of this investigation, and in no case did the anode influence electrophoretic deposition. Anodes of brass, Pt, graphite, Cu, and Mg were tested.

The results of a series of experiments with blendorized suspensions involving the cathode are shown in Fig. 4. When the Pt cathode was removed from the suspension after electrolysis at 900v for 15 sec, which was before the end of the induction period, then washed and dried before being placed back in the same portion of suspension with a new coating anode, the amount of deposit was negligible. The Pt cathode was replaced with successive Al cathodes, and the series was repeated both at 15 and 30 sec increments with essentially the same results: namley, unless the cathode, Al or Pt, was left in place for a plating time longer than

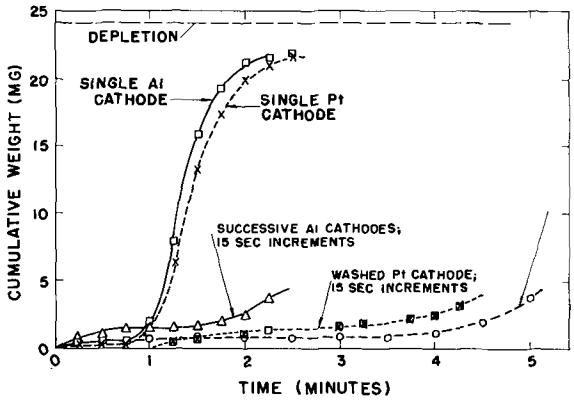

Fig. 4. Effect of the cathode on induction time; cell voltage, 900v, successive Al cathodes, 30 sec increments.

the induction time, no appreciable deposit was obtained. The cathode, therefore, was directly involved in the phenomenon causing the induction time. No plausible explanation of the nature of the cathode reaction which occurs during the induction period has been found. In general, suspensions that exhibited this phenomenon had rather high conductivities, and blendorized suspensions had conductivities two or three times as high as the untreated suspensions, probably due to the presence of impurity ions.

Current and voltage effects.—The initial deposition rate of Nb from straight Nb-IPA suspensions was also studied as a function of cell voltage and current density. The times selected for these studies were sufficiently short to cause only a third or less of the Nb to plate out. At low voltages (less than 1000v) and low current densities, the current density was proportional to the voltage during the short time intervals used. However, at high voltages (2000-4000v), the current quickly dropped (at constant voltage) to values that were sometimes one-half or one-third the initial current. This effect was probably caused by the depletion of impurity ions from the suspensions and led to a final conductance of the suspension that was constant but lower than the initial conductance. Since it was not possible to eliminate this effect, deposition rates were usually plotted as a function of voltage.

This drop in conductance has also been reported in the literature in the plating of nonconductors, and the authors (4, 12, 16) have explained this drop as a result of the resistance of the deposited layer. A different mechanism must account for the rapid drop in current when a conductive coating is being deposited. Since the conductance of the pure solvent, IPA, also falls quite rapidly when electrolyzed, it is probable that the decrease in conductance in the suspensions is caused by the depletion of ions and other current-carrying particles rather than by the electrical properties of the deposit.

The deposition rate increased with voltage at low voltages and decreased with voltage at high voltage. A typical deposition rate *vs.* voltage curve is shown in Fig. 5. The remarkable drop in deposition rate with voltage has not been explained, and only one paper in the literature on electrophoretic deposition (18) presented data which, when plotted, showed a similar decrease.

The initial increase in deposition rate is a result of the induction time of these suspensions since the induction time was found to decrease as the voltage

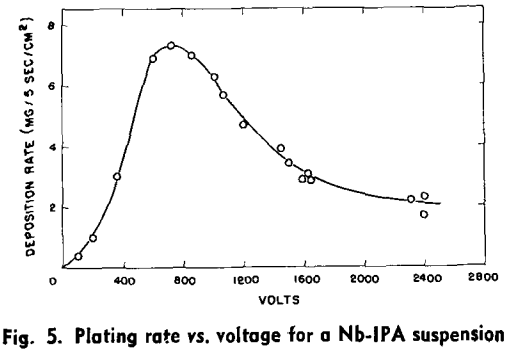

Fig. 5. Plating rate vs. voltage for a Nb-IPA suspension

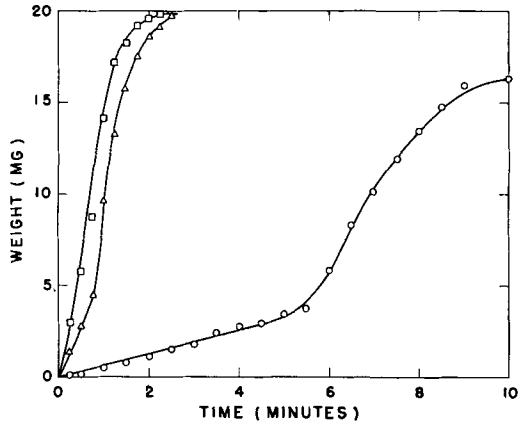

Fig. 6. Effect of voltage on induction time; ○, 100v; □, 250v; △, 450v.

was increased. This is shown in Fig. 6 for a series of experiments on blendorized Nb-IPA suspensions.

Additives.—One of the most important features in the use of electrophoretic deposition to obtain adherent deposits is the use of additives. In the case of Nb-IPA suspensions, ammonium hydroxide was found to be a useful additive that converted nonplating suspensions to ones that gave short induction times and adherent electrophoretic deposits. The effect of ammonium hydroxide as an additive or "activator" on the plating characteristics of a Nb suspension is shown in Fig. 7 which shows the weight of Nb deposited in unit times as a function of initial current density for the suspension as prepared, and for several concentrations of ammonium hydroxide. Such addition caused the peaks to shift to higher current densities with increasing concentration of additive. A similar plot against voltage, shown in Fig. 8, exhibited very little horizontal shift in the peak with concentration of additive. The results indicated that there is an optimum concentration of additive if only the deposition rate at the peak is considered.

Indeed, when the deposition rate at the peak was plotted against the initial conductance (in micromhos) of the suspension, a maximum rate of deposition was observed, as shown in Fig. 9. The

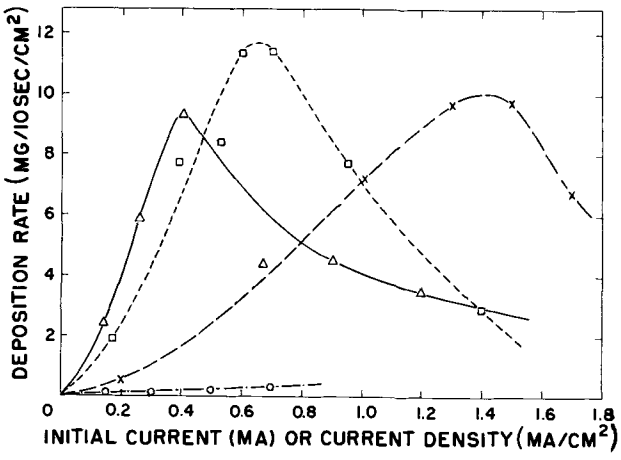

Fig. 7. Effect of additive on plating rate vs. current for a Nb-IPA suspension. Molarity of NH_4OH: ○, 0; △, 1.8×10^{-4}; □, 1.2×10^{-3}; x, 5.2×10^{-3}.

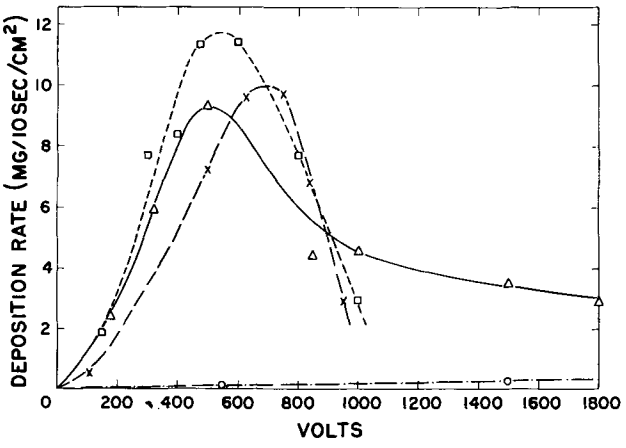

Fig. 8. Effect of additive on plating rate vs. voltage for a Nb-IPA suspension. Molarity of NH_4OH: ○, 0; △, 1.8×10^{-4}; □, 1.2×10^{-3}; x, 5.2×10^{-3}.

conductance at which this maximum occurred was shown in a separate experiment to correspond to a molarity of ammonia of about 1.3×10^{-3}M. The initial conductance of the suspension rather than the molarity was chosen as a variable because the conductance of the original suspension was lower than that of the starting IPA, showing that the powder adsorbs most of the foreign ions in the alcohol. Other experiments showed that the conductance of a suspension increases with further addition of ammonium hydroxide, although the relationship is not linear.

Applications.—The remarkable versatility of electrophoretic deposition has led to its use in a number of applications connected with other laboratory research problems. As discussed above, nitromethane suspensions containing zein and benzoic acid were used instead of IPA since codeposited zein gave strongly adherent deposits and since zein could not be used in the alcohol suspensions because of flocculation. Accordingly, results obtained in the Nb-IPA studies were applied qualitatively to the determination of plating conditions for various nitromethane suspensions. The technique was very effective, and adherent uniform deposits were obtained eventually with every material tested. Thus, although no systematic investigation was

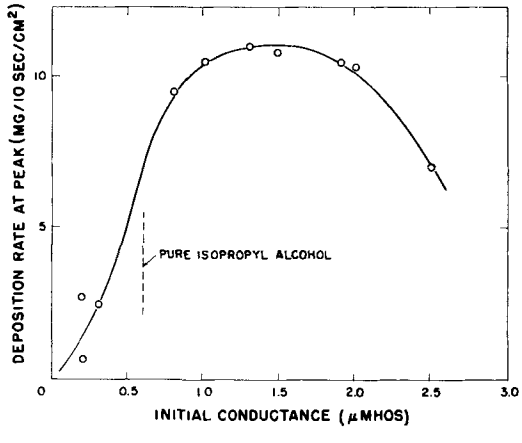

Fig. 9. Plating rate of Nb suspensions at the peak vs. initial conductance.

made of the general applicability of electrophoretic deposition to the coating of solids onto conductors in the nitromethane system, no limitation was found in those materials that were tried.

The following materials have been deposited as coatings by this method: B, Dy, Au, Nb, Mo, W, Re, Nb_3Sn, ZrH_2, ThC, UC, NpC, PuC, (ZrU)C, UWC_2, $UMoC_2$, UO_2, Ta_2O_5, and both W-UO_2 and Mo-UO_2 composites. Of particular interest were the simultaneous plating of W and UO_2 and of Mo and UO_2 powder mixtures of varying compositions. In both cases, the metal and oxide were uniformly distributed in the deposit in the same ratio as in the suspension.

Often, the coat was sintered in place by heating in vacuum to a temperature in the neighborhood of 2000°C. After such treatment, the coats were then used successfully in applications such as: (i) protective coatings to protect reactive materials from gaseous corrosion, (ii) bombardment targets for nuclear reaction studies, and (iii) samples for the determination of work functions.

Conclusions

The method can be adapted to coat any surface regardless of size or shape with surprisingly uniform deposits of preselected thickness. The latter can be accomplished by plating a suspension of known concentration to depletion.

Several factors have been found to be important in this type of plating. (i) The ability to obtain reproducible suspensions that will result in strong, adherent deposits depends, to a large extent, on the ionic impurities present in the suspending medium. (ii) Induction time and rate of deposition also appear to be related to the ionic impurities present. (iii) The effect of additives or "activators" is not clearly understood, but the amount needed for different materials can be determined by time-current-voltage experiments. (iv) These suspensions are sensitive to impurities; therefore grinding materials should be chosen to minimize the amount of impurities introduced. For instance, the use of steel balls and mills introduced as much as 1 w/o Fe in the Nb-IPA system. Also, when nitromethane was used for comminution in steel jars, the suspensions invariably flocculated.

Acknowledgments

The authors would like to thank Dr. R. D. Baker for suggesting this investigation initially, and Dr. M. G. Bowman, Dr. D. T. Vier, Dr. W. J. McCreary, and Dr. J. D. Farr, all of this laboratory, for their help during the course of this work.

Manuscript received March 6, 1961; revised manuscript received June 23, 1962. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960. This work was performed under the auspices of the U.S.A.E.C.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Dependence of Charge Transfer and Surface Diffusion Rates on the Structure and Stability of an Electrode Surface: Copper

J. O'M. Bockris and Hideaki Kita[1]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

Experiments have been carried out to ascertain the effect on the parameters of the Cu deposition reaction of varying the surface configuration, of the substrate. Electrodeposited, He-quenched, H_2-quenched, dissolved, oxide film and chemically reduced surfaces were used. The observations were made by means of cathodic transients. An examination was also made of the change of activity of an electrode surface for times in the range 10^{-3} sec-10 min after production *in situ* of a fresh surface.

The charge transfer process per real sq. cm., is about ten times higher on electrodes prepared by quenching from the liquid than from those of other methods. The velocity of surface diffusion is about ten times lower on the quenched electrodes than on other electrodes. The concentration of adions on the quenched electrodes is much smaller than those on other substrates. The double layer capacity is approximately the same on He-quenched and electrodeposited electrode but much higher on oxide film and chemically reduced surfaces. There is a rapid fall of the velocity of surface diffusion on exposure of a fresh surface produced by anodic dissolution to a solution and no fall for oxide film electrodes. When the He-quenched electrodes were submitted to a successive series of cathodic pulses, such that Cu deposition was succeeded by H_2 evolution in each pulse, i_o, $C_{d\,l.}$ and τ all increased *linearly* with number of pulses. τ increased about ¼ the common rate of increase of i_o and $C_{d\,l}$.

The rate-determining step on electrodeposited, oxide film, dissolved and chemically reduced surfaces is shared at low current density by surface diffusion and transfer process: at high current density, it is predominantly by transfer process. On He- and H_2-quenched electrodes, surface diffusion control is predominant at low current density and transfer process at high current density. The change of rate constant for surface diffusion with time on exposure of a fresh surface to the solution is inconsistent with adsorption of impurities from solution and consistent with an equilibration of the adion concentration among the different planes on the surface. The dependence of i_o on substrate is probably a secondary effect of a larger concentration of adions on electrodeposited surfaces. Oxide film, chemically reduced, dissolved, and H_2-evolved electrodes all have similar surface configuration to that of the electrodeposited electrodes. The surface adion concentration arises from the dominance of 100 planes in the surfaces of these substrates. The remarkable effects of successive cathodic pulses arise from the increase in surface area attendant on the production of Cu in fine particle form by a secondary mechanism. The anomalous linear dependence of τ on the number of pulses is consistent with a horn-like shape of the pores.

Major attention during the recent development of electrode kinetics has been given to liquid-metal solution interfaces, *i.e.*, the charge transfer reaction has been the focus of attention. In advancing toward adequate models for the interpretation of the complex facts of the electrodeposition of solids, it is necessary to design experiments which manifest differences arising only from a change in the configuration of the metal surface.

Considerable differences have been reported in the rate constants for metal-solution exchange reactions depending on whether the metal is prepared by electrodeposition or by flash cooling of the liquid (1, 2). Consequently, systems involving Cu, prepared in various ways, have been subjected to electric pulses which modify the surface, and galvanostatic transient techniques have been applied to evaluate the effect of the modification of the surface on the rate constants.

Such work is intended to throw light not only on the mechanism of electrodeposition but also to indicate the molecular mechanisms which determine the empirical 'activity' of an electrically active catalyst.

Experimental

The apparatus, cell, and purification units were as reported earlier (1, 2). Solutions were purified by pre-electrolysis.

The electric device.—To apply a cathodic pulse at various times after switching off the anodic (or cathodic) polarizing current, an arrangement was devised analogous to that of Mehl, Devanathan, and Bockris (3) (Fig. 1). When switch S was closed, a

[1] On leave from the Research Institute for Catalysis, Hokkaido University, Sapporo, Japan.

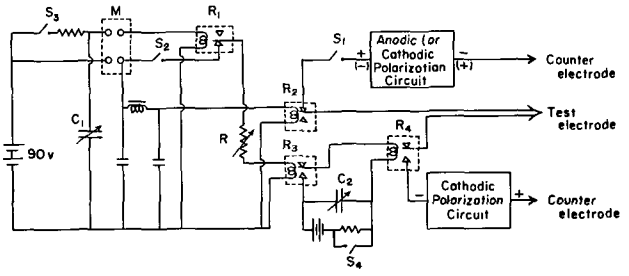

Fig. 1. Electrical arrangement: R_1, delay relay; R_2, anodic circuit relay; R_3, cathodic circuit relay; R_4, pulse relay; M, microswitch; C_1 and C_2, variable condenser; R, variable resistance; and S, switches.

constant anodic current began to pass through the test electrode. After the dissolution of a certain number (10^3-10^4) layers, a cathodic pulse was initiated by closing the microswitch M (S_2, S_3 in 'on' position and S_4 in 'off' position). This affects the circuit in Fig. 1 in such a way that the anodic current ceases and the cathodic current is switched on at a controlled time after the termination of the anodic current, *i.e.*, the fresh electrode surface is allowed to exist for a controlled (short) time in contact with the solution, before the kinetics of deposition on it are measured. The delay time between the two currents is controlled by C (Fig. 1). In this way, delay times between 9 msec and 1 sec were obtained. Delay times shorter than 9 msec could be obtained by controlling the variable resistance, R, when both terminals of the cathode circuit relay, R_3, were directly connected to the cathodic polarization circuit and to the test electrode (S_3 in 'off' position). The shortest time was a few μsec. The length of the cathodic pulse (msec-sec) was controlled by the variable condenser, C_2 (Fig. 1).

The electrodes.—The 'He-quenched' and 'electrodeposited' electrodes were prepared as reported earlier (1, 2). The 'H_2-quenched electrode' was prepared in a stream of prepurified hydrogen, and the 'oxide film electrode' was prepared by heating the He-quenched electrode in a stream of pre-purified oxygen at 600° ~ 650°C for 1 min. The oxidized electrode was sealed into a small glass bulb under an atmosphere of He, as were the other electrodes.

Concentrations of sulfuric acid and cupric sulfate were kept at 1.0 ± 0.03*N* and 0.05 ± 0.005M l^{-1}, respectively, except in specified cases.

Evaluation of Rate Constants

The most important parameters, the variation of which with surface state it was desired to determine, are: (i) the double layer capacity, $C_{d.l.}$ (and hence the roughness factor of the surface); (ii) the concentration of surface adions, c_o; (iii) the surface diffusion flux at the reversible potential, v_o; (iv) the exchange c.d. for the transfer process, i_o; (v) the transfer coefficients for anodic and cathodic reactions, α_a and α_c, respectively. These parameters were evaluated as follows.

Double layer capacity, $C_{d.l.}$.—This can be evaluated from $\left(\frac{d\eta}{dt}\right)_{t\to 0}$ by the equation

$$C_{d.l.} = i\left(\frac{d\eta}{dt}\right)^{-1}_{t\to 0} \qquad [1]$$

where η is the overpotential and i the current density. Equation [1] is valid (95% accuracy) under conditions (4)

$$\left.\begin{aligned} |\eta| &< 0.05\,\frac{RT}{(\alpha_c+\alpha_a)\mathbf{F}}\,\frac{i}{i_o} = 6.5\times 10^{-4}\,\frac{i}{i_o} \\ t &< \frac{C_{d.l.}}{0.95}\,0.05\cdot\frac{RT}{(\alpha_c+\alpha_a)\mathbf{F}} = 6.8\times 10^{-4}\,\frac{C_{d.l.}}{i_o} \end{aligned}\right\} \qquad [2]$$

where α_c and α_a are the Tafel constants for cathodic and anodic processes, i_o the exchange current density for the transfer process, and R, T, and $\mathbf{F}$ have their usual meaning. If conditions [2] are not satisfied, a contribution of the transfer reaction to the charging curve becomes appreciable and hence the validity of Eq. [1] decreases. Conditions [2] are only valid if charge transfer is rate controlling. Consequently, the c.d. for the measurement of $C_{d.l.}$ was always in a region such that this was so.

Surface concentration of adions, c_o, and the surface diffusion flux at the reversible potential, v_o.—These can be calculated using following equations (5) ($|\eta| < 10$ mv).

(*a*) c_o and v_o from the analysis of transient (at low current density) by

$$\ln(\eta_t - \eta_\infty) = \ln\frac{RT}{z\mathbf{F}}\,\frac{i}{z\mathbf{F}v_o} - \frac{v_o}{c_o}t \qquad [3]$$

where i is the Faradaic current density.

(*b*) v_o can be calculated from the steady-state value (at low current density) by

$$\eta_\infty = \frac{RTi}{z\mathbf{F}}\left(\frac{i}{i_o} + \frac{1}{z\mathbf{F}v_o}\right) \qquad [4]$$

utilizing i_o from the linear Tafel line.

The thus obtained v_o varies anomalously depending on the current density of measurement [cf. an interpretation discussed earlier (6)]. Hence, $(v_o)_{i=1\ ma\ cm^{-2}}$ will be quoted for the sake of comparison.

Equation [4] can be rewritten as

$$\eta_\infty = \eta_{\text{transfer}} + \eta_{\text{surface diff.}}$$

where $\eta_{\text{transfer}} = RTi/z\mathbf{F}i_o$ and $\eta_{\text{surface diff.}} = RTi/z^2\mathbf{F}^2v_o$, and hence

$$\frac{\eta_\infty}{\eta_{\text{transfer}}} = 1 + \frac{i_o}{z\mathbf{F}v_o}$$

which shows that when $\eta_\infty/\eta_{\text{transfer}}$ is close to unity (*e.g.*, < 1.3), estimation of v_o becomes inaccurate because i_o is known only to ±30%.

Exchange current density, i_o.—In systems in which the linear η — log i relations was observed, i_o was calculated in the usual way by extrapolation of log i to $\eta = 0$. In systems in which the effect of change of surface activity, *e.g.*, with time of contact of a fresh surface with the solution, was measured by means of a single transient at a given c.d., the i_o value was obtained assuming that the Tafel equation applied in the region concerned, if a Tafel time had been established for a similar state of the surface and similar overpotential range ($\eta_\infty = RT/\alpha\mathbf{F}\ln i_o/i$).

Transfer coefficients.—These were determined in the normal way.

Transition time, τ.—When the current density exceeds the limiting current for diffusion of Cu^{++}, one finds a polarization curve with two steps. Thus, the first inflection point of the curve was taken as the transition time for $Cu^{2+} + 2e_o^- \rightarrow Cu$.

Results

Electrodeposited Electrode

(i) *Values of parameters.*—Values of α_c, α_a, i_o's, $C_{d.l.}$, c_o, and v_o on the electrodeposited electrode are shown in Table I.

The values of α_c, α_a, i_o, and $C_{d.l.}$ agree with those previously reported (1, 2). Values of c_o were analyzed as $\doteq 8.10^{-9}$ mole cm^{-2}. Values of i_o and zFv_o are approximately equal.

A typical Tafel line is shown in Fig. 2. Slight deviations from the ideal line at low current densities can be noticed.

(ii) *Change with time of the surface of the electrodeposited electrode after exposing to a solution, following anodic preparation of a fresh surface.*—In these experiments, the dependence on time of contact with solution of the rate constants for deposition at a surface prepared by anodic dissolution (16 ma cm^{-2}, $\sim 10^4$ layers) was studied. Results are shown in Fig. 3. $(\eta_\infty)_t$ changes roughly linearly with log t in the region observed. $\partial\eta_t/\partial \ln t \simeq 0.5$ mv (cf., the He-quenched electrode).

(iii) *Surface diffusion flux and exchange current density as a function of anodic current density by which a fresh surface is produced.*—The i_o and v_o for cathodic deposition were determined as a function of the anodic current density at which the 'fresh' copper surface had been formed, maintaining (al-

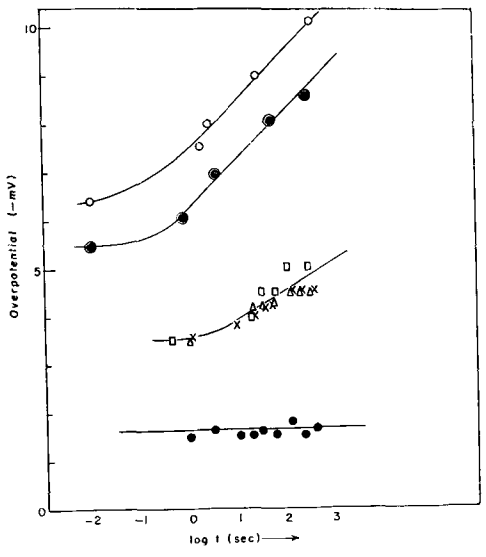

Fig. 3. Change of overpotential at $i = 8.7 \times 10^{-4}$ amp cm^{-2} with time of contact with solution after anodic dissolution. Open circle, circle with dot; He-quenched electrode square box; triangle, x, electrodeposited electrode; dark circle, oxide film electrode.

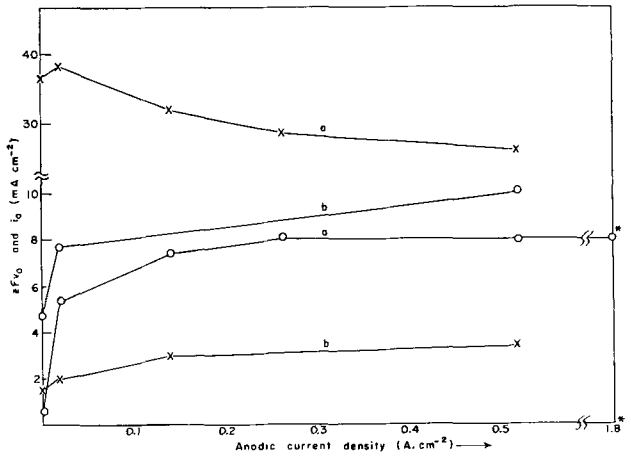

Fig. 4. Change of i_o and zFv_o as a function of anodic dissolution current by which a fresh surface was produced. x = i_o, o = zFv_o; curve a, He-quenched electrode; curve b, electrodeposited electrode. At the current density marked with *, O_2 evolution was observed during dissolution.

most) constant the time between the termination of dissolution and the commencement of deposition, *i.e.*, the age of the surface (20 sec). Measurements were carried out successively from low anodic current density to high ones, and the amount of dissolution was kept constant (10^4 layers) in each treatment.

Changes of i_o and v_o (obtained using Eq. [3] are shown in Fig. 4. They increase by approximately twice times and approach constant values.

(iv) *Surface diffusion flux and exchange current density as a function of cathodic current density by which a fresh surface is produced.*—(*a*) v_o: He-quenched electrodes were subjected to cathodic polarization with a current of $10^{-3} \sim 1$ amp cm^{-2} and a time sufficient for the deposition of 10^4 layers.

Results of v_o as a function of mode of preparation of the surface are shown in Table II. In the c.d. region 0.3 ~ 1 amp, after the transition time for the deposition of Cu is reached, v_o is increased by about 2 powers of 10 compared with that on He electrodes and becomes independent of the time of contact of

Table II. Effect on surface diffusion flux of formation of fresh surface by cathodic deposition

the surface with the solution, over a time of 9×10^{-3} sec to 1 hr. In the region of cathodic current density in which only copper deposits, v_o is increased by 5-10 times only.

(*b*) i_o: The effect of cathodic current density with which the equivalent of ~10^4 layers are deposited in the preparation of a new surface is shown in Fig. 5. (Each measurement was carried out on a fresh electrode.) It is seen that, for (i_o), the electrodeposited surface is a much less active one than is a He-quenched surface. However, after H_2 is codeposited, a considerable increase of i_o occurs.

After treatment at high cathodic polarization, where hydrogen codeposits 10^5 layers of copper was electrodeposited at various current densities. No decrease in i_o was observed (Fig. 6). This experimental result establishes that impurity adsorption from solution during electrodeposition of copper does not cause the decrease of surface activity which takes place on depositing Cu on He-prepared electrodes.

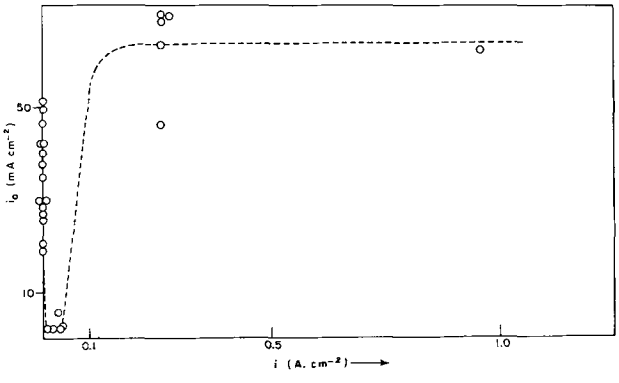

Fig. 5. Change of i_o as a function of cathodic deposition current by which a fresh surface was produced.

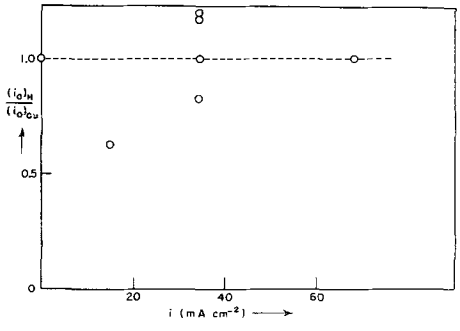

Fig. 6. Change of i_o with electrodeposition of Cu on the electrode which was previously subjected to the high cathodic polarization where hydrogen codeposited (2.6×10^{-1} amp cm^{-2}). $(i_o)_H$; i_o observed on the previously treated electrode with high cathodic polarization. $(i_o)_{Cu}$, after electrodeposition of Cu.

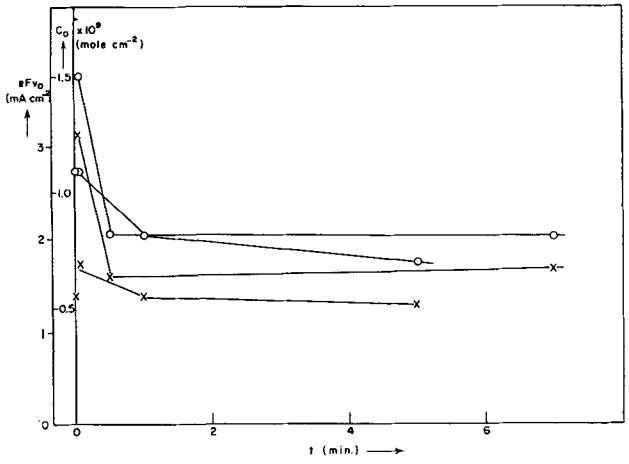

Fig. 7. Change of zFv_o and c_o with time of contact with solution after anodic dissolution. Calculated results from open circle, circle with dot in Fig. 3 using Eq. [3]. 0 = zFv_o, x = c_o.

He-*quenched Electrodes*

(i) *Values of parameters.*—Values of parameters on the He-quenched electrode are shown in Table I. Thus, (*a*) α_c and α_a are about the same as for electrodeposited electrodes; (*b*) the exchange c.d. is increased by about 10 times; (*c*) $C_{d.l.}$ is unchanged; (*d*) c_o is about 10 times less than on electrodeposited electrodes; (*e*) the parameter zFv_o is about five times less than on electrodeposited electrodes.

Comparison of i_o and zFv_o for the He-quenched electrodes indicates that the surface diffusion of adions is rate determining at low current densities.

A typical Tafel line is shown in Fig. 2. One sees a marked deviation at low current density from the expected line obtained assuming transfer to be rate controlling at all current densities.

Parameters were also evaluated after dissolution of the He-quenched electrode (Table I). Thus, c_o is nearly the same as that on an electrodeposited electrode (*i.e.*, it increases more than 10 times) and zFv_o increases more than 10 times. α_c, α_a, and $C_{d.l.}$ remain constant. The exchange current density becomes a little smaller (cf. Fig. 4).

(ii) *Change with time of the surface of the* He-*quenched electrode after exposing it to a solution, following anodic preparation of a fresh surface.*—The dependence of the rate constant for a surface prepared by anodic dissolution upon time of contact with the solution was studied. Results are shown in Fig. 3 for a current density of preparation of 8 ma cm^{-2} ~ 10^3 layers dissolved. In this c.d. region surface diffusion is rate controlling.

In Fig. 3 the section above 1 sec is linear. η_t, (or v_o) changes little during the first second. $\partial\eta_t/\partial \ln t \simeq 1$ mv. In Fig. 7, v_o and c_o calculated from Eq. [3] are shown as a function of time.

(iii) *Surface diffusion flux and exchange current density as a function of anodic current density by which a fresh surface was produced.*—(*a*) v_o increases considerably with the anodic current density and then becomes independent of it (Fig. 4). Contact of the surface with oxygen during dissolution does not effect the v_o value. (At the current densities marked with * in Fig. 4, oxygen evolution commenced.)

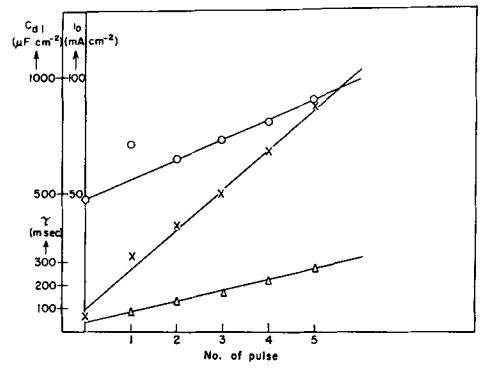

Fig. 8. Effects of the high cathodic polarization pulses (2.6 x 10^{-1} amp cm^{-2}, 20 sec) on i_o, $C_{d.l.}$, and τ (He-quenched electrode). Electrode was kept 30 min in solution after an application of each pulse and then measurements were carried out. ○, i_o; x, $C_{d.l.}$; and Δ, τ.

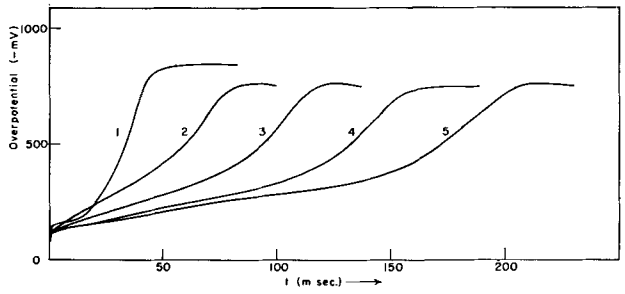

Fig. 9. Cathodic polarization curve at 2.6 x 10^{-1} amp cm^{-2}. Curve 1, on the He-quenched electrode, curves 2, 3, 4, and 5, after successive application of cathodic polarization pulse (2.6 x 10^{-1} amp cm^{-2} 20 sec).

(*b*) i_o: i_o decreases somewhat with increasing c.d. of dissolution (Fig. 4).

(iv) *Effects of repetitive application of high cathodic polarization pulses in which hydrogen co-deposits, on i_o, capacity, and transition time.*—He-quenched electrodes were subjected to a successive application of high cathodic pulse (2.6 x 10^{-1} amp cm^{-2}, 20 sec). Thus i_o, $C_{d.l.}$, and τ were observed, respectively, leaving the electrode 30 min in solution after the application of each pulse. Results are shown in Fig. 8. Changes of these quantities are linear with the number of pulse.

Figure 9 shows the change of the $\eta - t$ relation at constant current of 2.6 x 10^{-1} amp cm^{-2} after the application of successive cathodic pulses. When the current density of the pulses was kept sufficiently low (*e.g.*, if it was <2.6 x 10^{-2} amp cm^{-2}), the transition time did not increase with the number of pulses. Successive anodic dissolution similarly does not affect the transition time (Fig. 10). In Fig. 11, an increase of the transition time with the number of cathode polarization is shown under various conditions. The increase of transition time with the pulse depends sensitively on the concentration of cupric ions and not upon the concentration of protons. A powdery deposit of copper during the high cathodic polarization treatment was observed.

H_2-*treated Electrode*

(i) H_2-*quenched electrode.*—Values of parameters are shown in Table I. These values are almost the same with those of the He-quenched electrode.

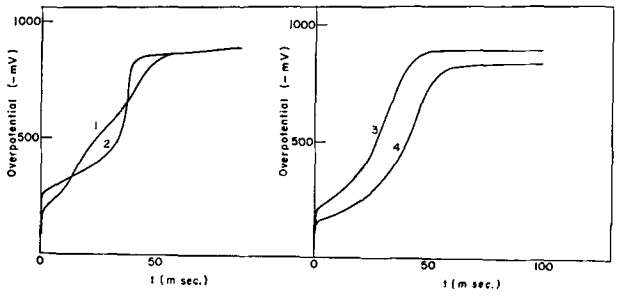

Fig. 10. Cathodic polarization curve at 2.6 x 10^{-1} amp cm^{-2}, as a function of surface state. Curves 1, 3; on the He-quenched electrode; curve 2, after electrodeposition of Cu (5 x 10^{-4} layers); curve 4, after dissolution of Cu (3 x 10^{4} layers).

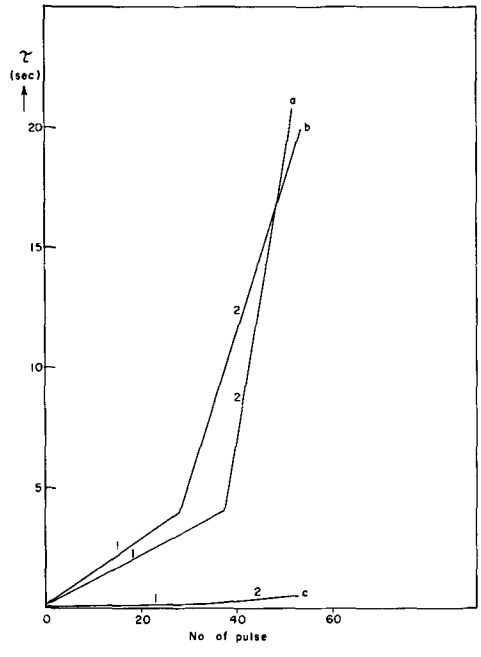

Fig. 11. Change of τ with number of successive high cathodic polarization pulses at various conditions. a, 0.055 mole l^{-1} $CuSO_4$, 1.1N H_2SO_4; b, 0.050 mole l^{-1} $CuSO_4$, 0.41N H_2SO_4; c, 0.013 mole l^{-1} $CuSO_4$, 1.1N H_2SO_4. Section 1; observed after 20 sec of the cathodic polarization pulse (2.6 x 10^{-1} amp cm^{-2} 20 sec); section 2, observed after 2 min of the cathodic polarization pulse (2.6 x 10^{-1} amp cm^{-2} 1 min).

Hence, the surface structure of He and H_2 quenched electrodes are the same.

(ii) H_2-*evolved electrode.*—A He-quenched electrode was polarized cathodically in 1N-H_2SO_4 solution for a certain time (~10^5 layers deposited). Thereafter, cupric sulfate solution was introduced and transient techniques were applied. Results are shown in Table I. No effect of the H_2-evolution treatment was observed. Consequently, there is no reducible surface complex (oxide) on the He-quenched electrode (cf. Section 4; oxide film electrode).

Oxide-film Electrode

(i) *Values of parameters.*—Values of parameters are shown in Table I. (*a*) α_c and α_a are essentially the same as on electrodeposited electrode. (*b*) i_o's are higher than those of the He-quenched electrodes. (*c*) $C_{d.l.}$ is larger (2 ~ 3 times) than on He-quenched electrodes. (*d*) c_o and $z\mathbf{F}v_o$ are slightly larger than those of the electrodeposited electrode.

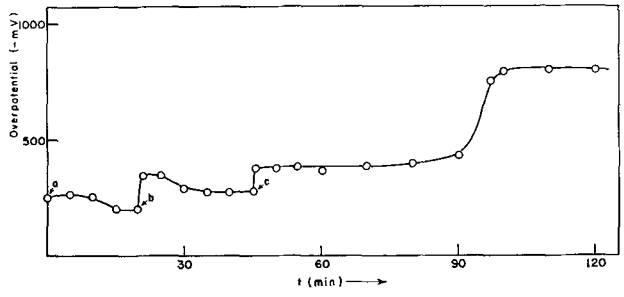

Fig. 12. 'Coulometry' on the oxide film electrode: a, i = 2.6 x 10^{-4} amp cm^{-2}; b, i = 8.7 x 10^{-4} amp cm^{-2}; i = 2.6 x 10^{-3} amp cm^{-2}; electrolyte, 0.2 mole l^{-1} N H_4Cl.

(ii) *Stability of the surface of the oxide film electrode after exposing the surface to the solution, following anodic dissolution.*—No change of the rate constant with time after dissolution of ~10^4 (15 ma cm^{-2}) layers was observed on the oxide film electrode. Results are shown in Fig. 3.

(iii) *Coulometry on the oxide film and He-quenched electrode.*—The thickness of the oxide film was measured by coulometry (4). Using aqueous NH_4Cl (0.2 M/L), a constant cathodic current was applied and the overpotential followed with time. Results on the oxide film electrode and the He-quenched electrode are shown in Fig. 12 and 13, respectively. The thickness of the oxide film electrode was determined as about 10^5Å according to the equation (7), $T = itA$, where T is the thickness in Å, i is the constant current in ma cm^{-2}, t is the time in seconds to the end point, and $A = 10^5 M/N\mathbf{F}\rho$, where M is the gram molecular weight of the compound composing the film, N is the number of Faradays required for the reduction of one-gram-molecular weight of film, $\mathbf{F}$ is Faraday's number, and ρ is the density of the film (for Cu_2O, taking $\rho = 6.0$, A = 12.4). It is seen from Fig. 14 that there is no oxide film on He-quenched electrode (Table III).

Discussion

Reaction Mechanisms

(i) *High current densities.*—The reaction mechanism on the electrodeposited electrode has been studied in detail and is concluded to be (1, 2)

$$Cu^{++} + e \rightarrow Cu^{+} \qquad [5]$$

$$Cu^{+} + e \rightleftharpoons Cu \qquad [6]$$

where reaction [5] is rate controlling. As can be seen from Fig. 2 and Table I, values of parameters, *i.e.*, α_c, α_a, and i_o, are reproduced on the electrodeposited

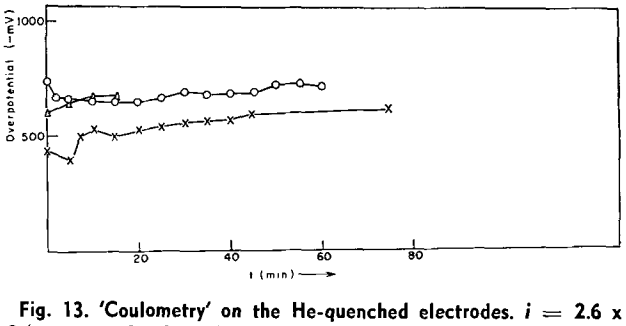

Fig. 13. 'Coulometry' on the He-quenched electrodes. i = 2.6 x 10^{-4} amp cm^{-2}; electrolyte; 0.2 mole l^{-1} N H_4Cl.

Table III. Relative effects of substrates on the kinetics of the copper deposition reaction

Quantity	Electrode: Quenched	Electrodeposited	Oxide film	Chemically deposited Cu
i_o	High	Low	Low	Very high increases with number of high cathodic pulses.
v_o	Low	High	High	Very high
c_o	Low	High	High	Very high

electrodes, and values of α_c and α_a on the other electrodes are also close to those of the electrodeposited electrodes. Hence, the reaction mechanism on the electrodes investigated, including He-quenched and oxide film electrodes, can be considered as [5]-[6] in the region where the linear Tafel line was observed.

(ii) *Low current densities.*—Were the mechanism [5]-[6] to be applicable, the η-i relationship at low current densities could be calculated from

$$i = i_o\left[e^{-\frac{\alpha_c F\eta}{RT}} - e^{\frac{\alpha_a F\eta}{RT}}\right] \qquad [7]$$

using i_o-values obtained by the extrapolation of the Tafel line in its linear region. From Fig. 2, it can be seen that the experimental results on the electrodeposited electrode at low current densities deviate only slightly from those calculated from [7], but on the He-quenched electrodes considerable deviations from the η-log i according to [7] occur. These deviations have been explained by assuming that the surface diffusion of adions is rate controlling at low current densities (1, 2, 6). As can be seen from the ratio of i_o to $z\mathbf{F}v_o$ in Table I, the rate constant of the transfer process is 15 ~ 17 times larger than that of the surface diffusion on the He- or H_2-quenched electrode, whereas on the other electrodes it is nearly unity.

On the H_2-evolved electrode, $z\mathbf{F}v_o$ and c_o could not be estimated because of superpolarization in the transient. However, η_∞ at low current densities was the same with that of the He-quenched electrode, *i.e.*, the surface diffusion is also rate controlling on this electrode surface. In Table IV, reaction mechanisms are summarized.

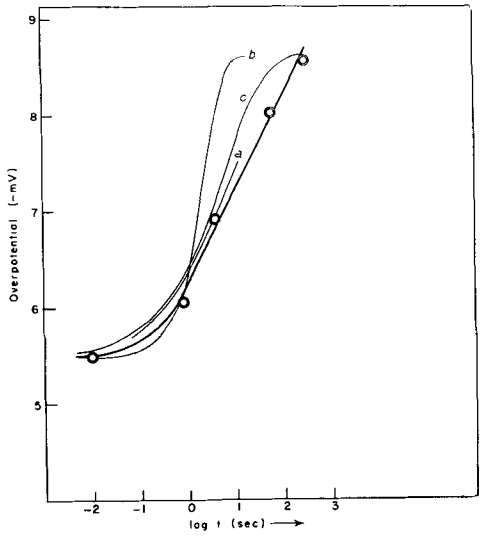

Fig. 14. Change of overpotential with time of contact with solution after dissolution. —circle with inner circle—; observed (circle with dot in Fig. 3); ———, calculated: a, from eq. [13] where D'/K^2 and $N_{t=\infty}'/N_o$ were taken as 1 and 0.7; b, from Eq. [16]; and c, from Eq. [19] where $c_{A,\,t=0}/c_B$, f_A, and zFD/x_o^2 were taken as 5, 0.2, and 10^6 (Table V).

Change of Parameters of Surface of He-Quenched Electrodes with Time after Cessation of Anodic Dissolution

The following models are considered.

(i) During anodic dissolution, spirals unwind, i at points of low radius of curvature being greater than that on the planes. Pits may develop. On cessation of the net dissolution current, dissolution or deposition occurs locally at peaks or pits, respectively, so that the surface tends to become smoother, *i.e.*, its real area less with increase of time. The rate constant per apparent square centimeter would then tend to decrease with time. However, such effects would be reflected in the capacitance measurements, and these show values independent of time after cessation of dissolution.

(ii) After cessation of the anodic current, impurities from the solution (*e.g.*, any dissolved from the electrode surface) may diffuse back to the surface and adsorb thereon, migrating to growth steps. Thus, assuming surface diffusion control and with a model in which the variation of adion concentration

Table IV. Reaction mechanisms as a function of type of electrode surface

Type of electrode surface	Low current density	High current density

H_2-evolved	Surface diffusion control	Transfer control

between the growth steps is assumed linear with distance (5)

$$\frac{i}{z\mathbf{F}} = \frac{Dc_o}{x_o^2}\frac{c - c_o}{c_o} \qquad [8]$$

for steady state, where x_o is half distance between growth steps, D the diffusion constant, and c the concentration of adions at specified potentials (c_o at the reversible potential), respectively.

Or

$$\frac{i}{z\mathbf{F}} = \frac{Dc_o}{x_o^2}\left[e^{-\frac{z\mathbf{F}\eta}{RT}} - 1\right] \qquad [9]$$

x_o is related to the number of growth steps, N, arising from a pair of screw dislocations, by (6)

$$\frac{1}{(2x_o)^2} = 2N \qquad [9a]$$

Hence

$$\frac{i}{z\mathbf{F}} = 8Dc_oN_t\left[e^{-\frac{z\mathbf{F}\eta}{RT}} - 1\right] \qquad [10]$$

The number of growth steps at time t, N_t diminishes with time, after cessation of dissolution, as the impurities adsorb on them.

Now

$$N_t = N_o\left(1 - \frac{N_{t=\infty}'}{N_o}\frac{N_t'}{N_{t=\infty}'}\right) \qquad [11]$$

where N_t' is the number of 'poisoned' growth steps. But (8)

$$\frac{N_t'}{N_{t=\infty}'} = 1 - e^{\frac{D't}{K^2}}\operatorname{erfc}\left(\frac{D't}{K^2}\right)^{1/2\,2} \qquad [12]$$

if the rate of aggregation of impurities to growth steps is controlled by diffusion from solution (D' is the diffusion coefficient of the impurity in solution, and K is a constant characteristic of the corresponding adsorption isotherm).

From [11], substituted into [12] and [10], one obtains for $|\eta| << RT/z\mathbf{F}$

$$\eta_t = \eta_{t=0}\left[\left(1 - \frac{N_{t=\infty}'}{N_{t=0}}\right) + \frac{N_{t=\infty}'}{N_{t=0}}e^{\frac{D't}{K^2}}\operatorname{erfc}\left(\frac{D't}{K^2}\right)^{1/2}\right]^{-1} \qquad [13]$$

where $\eta_{t=0} = RT/8(z\mathbf{F})^2Dc_oN_o$, and c_o is constant with time.

This equation is consistent with experiment, as shown in Fig. 14. However, it is seen that the model involves c_o = constant, and in Fig. 7 it is seen that c_o decreases with time in a way parallel to v_o. The model is hence untenable.

(iii) During dissolution, crystal faces of various indices may be produced, some having higher bond strength to the adions than others. After the current is switched off, the planes on which the adions are present in the highest concentration may dissolve and metal ions deposit on those with a smaller adion concentration.

Assuming for simplicity an equal area of planes A and B, where $c_A >> c_B$, the change of c_A with time can be expressed by

$$-\frac{dc_{A,t}}{dt} = \frac{i_of_A}{z\mathbf{F}}\frac{c_{A,t} - c_{B,o}}{c_{B,o}} \qquad [14]$$

where f_A is the fraction of surface A/cm^2 of surfaces A and B.

Integration gives

$$c_{A,t} = c_{B,o} + (c_{A,t=0} - c_{B,o})\,e^{-\frac{i_of_A}{z\mathbf{F}c_{B,o}}t} \qquad [15]$$

From Eq. [9], [15], and the relationship $c_o = f_Ac_{A,t} + f_Bc_{B,t}$ one obtains

$$-\eta_t = \frac{RT}{z\mathbf{F}}\ln\left[1 + \frac{\left[1 + \left(\frac{c_{A,t=0}}{c_{B,o}} - 1\right)f_A\right]\left[e^{-\frac{z\mathbf{F}\eta_{t=0}}{RT}} - 1\right]}{1 + \left(\frac{c_{A,t=0}}{c_{B,o}} - 1\right)f_Ae^{-\frac{i_of_A}{z\mathbf{F}c_{B,o}}t}}\right] \qquad [16]$$

where

$$-\eta_{t=0} = \frac{RT}{z\mathbf{F}}\ln\left[1 + \frac{ix_o^2}{z\mathbf{F}D}\frac{1}{c_{B,o} + (c_{A,t=0} - c_{B,o}) + A}\right] \qquad [16a]$$

This model is compared with experiment in Fig. 14. It is qualitatively consistent with experiment, but the gradient of the η_t-log t relation is badly reproduced.

(iv) The same concept as that expressed in (iii), but the equilibration of adion concentration occurs by means of surface diffusion.

Hence

$$-\frac{dc_{A,t}}{dt} = \frac{f_A}{x_o}\sqrt{\frac{D}{\pi t}}(c_{A,t} - c_{B,o}) \qquad [17]$$

Integration gives

$$c_{A,t} = c_{B,o} + (c_{A,t=0} - c_{B,o})\,e^{-\frac{2f_A}{x_o}\sqrt{\frac{D}{\pi}}t^{1/2}} \qquad [18]$$

From Eq. [9], [18], and the relationship $c_o = f_Ac_A + f_Bc_B$

$$-\eta_t = \frac{RT}{z\mathbf{F}}\ln\left[1 + \frac{\left[1 + \left(\frac{c_{A,t=0}}{c_{B\,o}} - 1\right)f_A\right]\left[e^{-\frac{z\mathbf{F}\eta_{t=0}}{RT}} - 1\right]}{1 + \left(\frac{c_{A,t=0}}{c_{B,o}} - 1\right)f_Ae^{-\frac{2f_A}{x_o}\sqrt{\frac{D}{\pi}}t^{1/2}}}\right] \qquad [19]$$

The model agrees reasonably with experiment (Fig. 14). The slope of the η_t-log t relation may be

[3] It is assumed in the derivation of [12] that (a) $c' = c_o'$, $x \geq 0$ at $t = 0$; $c' = c_o'$, when $x \to \infty$ at $t \geq 0$; (b) $N_t' = Kc'$, where c' and c_o' are the concentrations of impurities at the Helmholtz double layer and in the bulk, and x is the distance from the electrode to the solution.

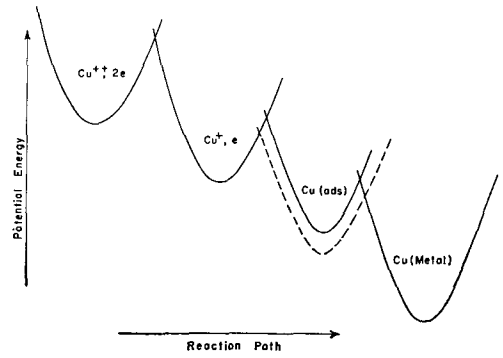

Fig. 15. Schematic expression of potential energy profile for Cu electrode reaction. Change of adsorption energy of Cu(ads) does not effect primarily reaction rate, since the rate determining step is $Cu^{++} + e \rightarrow Cu^{+}$.

qualitatively brought into better agreement with experiment if the formation of further adions from the growth steps on face A is taken into account, the effect being to slow down the equilibration of adion concentration among the crystal faces. It is not unplausible that the rearrangement occurs by surface diffusion, for the i_o value on electrode surfaces in which c_o is high, is small compared with the i_o values on He-prepared electrodes, *i.e.*, adions on the more populated surfaces go into solution less well than those on the less populated surfaces.

Dependence of Rate Constant of Transfer Reaction on Substrate of Metal Surface

For the transfer reaction, two factors may change when the surface of the metal is altered.

(i) The heat of adsorption of Cu adions is larger on the electrodeposited electrodes, as evidenced by the larger value of c_o on such electrodes than on He-quenched surfaces. Consideration of potential energy profile diagrams, however, indicates that the heat of activation for the transfer reaction [5] would not be effected by change of the bond strength between metal and adions (Fig. 15).

A secondary effect may, however, arise from the larger heat of adsorption on the electrodeposited electrode. When $\theta < 1$, where θ is the coverage of the surface with adions, and taking the rate constant for transfer for an electrodeposited and a quenched electrode as the same, the observed value of i_o on an electrodeposited electrode would be $i_o(1-\theta)$.

Thus, i_o can be defined as

$$i_o = \vec{k}_o\,[Cu^{++}]\,e^{-\frac{\beta F V_R}{RT}}\,e^{-\frac{\vec{\Delta H}^*}{RT}}\,(1-\theta) = \overleftarrow{k}_o\,[Cu^{+}]\,e^{\frac{(1-\beta) F V_R}{RT}}\,e^{-\frac{\overleftarrow{\Delta H}^*}{RT}}\,(1-\theta) \quad [20]$$

where $\vec{k}_o$, and $\overleftarrow{k}_o$ are rate constants, $[Cu^{++}]$ and $[Cu^{+}]$ the concentrations of the indicated ions in the Helmholtz layer, V_R the potential of the electrode at equilibrium, β the symmetry factor, and $\vec{\Delta H}^*$ and $\overleftarrow{\Delta H}^*$ are the activation energies of [5] in the forward and backward directions, respectively.

Then

$$\frac{(i_o)_{He}}{(i_o)_E} = \frac{e^{-\frac{\beta F V_{R,He}}{RT}}\,e^{-\frac{\vec{\Delta H}^*_{He}}{RT}}\,(1-\theta_{He})}{e^{-\frac{\beta F V_{R.E}}{RT}}\,e^{-\frac{\vec{\Delta H}^*_{E}}{RT}}\,(1-\theta_E)} = \frac{[Cu^{+}]_{He}\,e^{\frac{(1-\beta) F V_{R,He}}{RT}}\,e^{-\frac{\overleftarrow{\Delta H}^*_{He}}{RT}}\,(1-\theta_{He})}{[Cu^{+}]_{E}\,e^{\frac{(1-\beta) F V_{R.E}}{RT}}\,e^{-\frac{\overleftarrow{\Delta H}^*_{He}}{RT}}\,(1-\theta_E)} \quad [21]$$

Also

$$\vec{\Delta H}^* = H^* - H^{Cu^{++}} + e_o^- \quad [22a]$$

$$\overleftarrow{\Delta H}^* = H^* - H^{Cu^{+}} \quad [22b]$$

$$H_{He}{}^{Cu^{++}+e} = H_E{}^{Cu^{++}} + e \quad [22c]$$

Hence

$$H^*_{He} - H^*_E = \beta(H_{He}{}^{Cu^{+}} - H_E{}^{Cu^{+}}) \quad [22d]$$

where H^* and H's are the potential energies of the activated complex and the chemical species specified, respectively.

From Eq. [21] and [22], and the experimental result that $V_{R,He} = V_{R.E}$, and $(i_o)_{He}/(i_o)_E \simeq 10$

$$10 = e^{-\frac{\beta(H_{He}{}^{Cu^{+}} - H_E{}^{Cu^{+}})}{RT}}\,\frac{(1-\theta_{He})}{(1-\theta_E)} \quad [23]$$

It can be assumed that the potential energy of Cu^{+} will not change with change of surface configuration, and hence the difference in i_o between the two substrates can be attributed to a change of θ. Using $\theta_{He} \simeq 0.07$ (Table I), Eq. [23] gives 0.86 for θ_E which is in good agreement with the experimental result of $\theta_E \simeq 0.8$ (Table I).

However, the theory of the determination of θ involves the assumption that $\theta << 1$, so that the determined θ values cannot be numerically accurate for the electrodeposited electrodes. Thus, only qualitative significance attaches to the result that high adion coverage may cause the comparatively low i_o value of the electrodeposited surfaces (see Appendix).

(ii) The work function may change with the surface state, for electrodeposition determines the predominant crystal planes, which in turn influence the work function. Thus, the work function is less in the vicinity of defects (9). However, predominant transfer at local growth steps is not acceptable because of the observed surface diffusion control at low overpotential. Direct transfer to growth steps was concluded as an unlikely process for metal ions by Conway and Bockris (10) from consideration of potential energy profile diagrams.

On the oxide electrodes, the i_o values are higher than those on the electrodeposited electrodes (Table I), but if the values are divided by the ratio of $(C_{d.l.})$oxide/$(C_{d.l.})$electrodeposited, the values of i_o

for the oxide are of the same order as those on electrodeposited electrodes. This result is surprising. It could be consistent with two models of the surface.

(*a*) The oxide is relatively nonporous. On contact with an acid solution, the oxide film will be completely dissolved (the color of the surface is observed to change from black to dark brown), and a Cu surface is therefore exposed to the solution. The dissolution follows a certain preferred crystal plane in the oxide, and hence a roughening of the surface is caused, in consistence with the larger capacities observed for the (so-called) oxide electrodes.

(*b*) Alternatively, the oxide may be regarded as porous and the reaction to occur on the surface of the substrate. However, if this were so, the transition time should be greatly reduced because of the small fraction of available surface area (transition time is proportional to the square of area, Eq. [28]) and the ohmic overpotential is increased. However, the transition time and ohmic overpotential on the oxide electrodes are roughly equal to those of electrodeposited electrodes. Consequently, model (*a*) is valid and the rate of transfer, per true square centimeter, to the surface which arises from a freshly dissolved oxide is the same as that for electrodeposited electrodes (except for the greater area factor).

The equality of i_o would be explained if θ on the electrodeposited and oxide electrodes were about the same, *i.e.*, the attachment of the adions to the surface the same. On an electrodeposited electrode, a large number of kink sites will arise in the boundary of the growth spirals. At the same time, on oxide electrode, the surface will possess defects, arising from the removal of oxygen atoms in the surface, which will correspond to about half the number of sites. Thus, in both the reduced and electrodeposited electrodes, the number of kink sites is much greater than that on He-quenched electrodes and approaches a limitingly high value. This is consistent with the lower, and approximately equal, i_o value on electrodeposited and reduced electrodes.

The remarkable increases in i_o obtained by the repetition of high cathodic pulses of 20 sec, in which Cu is deposited followed by the evolution of hydrogen, is consistent with the concept that a chemical reduction of Cu^{++} in solution evolved H takes place. The change of standard free energy for $Cu^{++} \rightarrow Cu$ is −61.2 kcal (11), and the reversible potential of atomic hydrogen electrode is −1.98v (12) (hydrogen scale), so that the change of free energy of the reaction $Cu^{++} + 2H \rightarrow Cu + 2H^+$ is −107 kcal [cf. also ref. (13) and (14)].

The relation of i_o to the number of pulses is linear, and the increase per pulse is 8.6 ma. Since the increase of surface area per pulse in 3.6 cm^2, the activity of the surface produced is the same as that of the electrodeposited electrode (see Table I). It is noticed that the i_o value at the commencement of the pulsing increases compared with that on He-quenched electrodes. The i_o/cm^2 on the pulsed electrode is, however, that of an electrodeposited electrode. Hence, as the increase in surface area is only 3.6 times per pulse, an initial decrease of i_o would be expected. Its absence indicates that part of the original He-quenched surface remains active.

Table V. Values of $zFD\,x_o^2$ as a function of electrodes

Electrode	$zFD/x_o^2 (= zFv_o/c_o)$
Electrodeposited	0.7×10^6
He-quenched	2.8×10^6
H_2-quenched	2.2×10^6
Oxide film	0.7×10^6
Dissolved	2.8×10^6

Dependence of v_o and c_o on the Substrate of Metal Surface

Tables I and III show that, per cm^2, v_o and c_o are approximately parallel, *i.e.*, if the model considered is the first approximation model for surface diffusion on electrodes, with a linear concentration gradient, then, as, from this model (5), $v_o = Dc_o(x_o^2)$, the factor $D_{x_o}{}^2$ is roughly constant for quenched and electrodeposited electrodes. (The constancy is only to within about 2-3 times, but the possible variation of x_o are by several orders of magnitude, so that the result v_o/c_o is constant can be regarded as meaning that x_o is approximately constant, for D is unlikely to change for the same metal and adsorbed anion concentration). Results are shown in Table V.

Two models are possible in an interpretation of the variation of c_o with substrate: (*a*) the electrodeposited electrode contains more kink sites than does the quenched surface. Consequently, as $c_o = c_K \exp(-\Delta H/RT)$, where c_K is the concentration of kink sites, and ΔH the energy difference between the atoms at kink site and on the surface, the value of c_o would be greater on the electrodeposited (and oxide) surface than on the quenched electrode. (*b*) Alternatively, the increase of c_o observed on an electrodeposited electrode may arise from a greater bond strength for $M\text{-}M^+$ than on the quenched electrode.

The first model is the less likely, for, if the number of kink sites and hence, number of steps, is substantially larger on the electrodeposited electrode, x_o would be substantially smaller, in contradiction to the results.

The dependence of c_o (hence, v_o) on the surface, therefore, depends on the crystal plane developed in deposition. Let it be supposed, for illustration, that in the deposited surface, a 100 plane predominates (cf. Fig. 16). Then, the coordination number of an

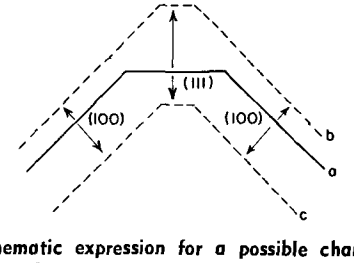

Fig. 16. Schematic expression for a possible change of surface structure during electrodeposition and dissolution. a, original surface; b, after deposition. The facet (111) will grow faster than facet (100) and hence fraction of (111) face in the surface will decrease with deposition. c, after dissolution. The facet (100) will dissolve faster than (111) face and hence fraction of (111) in the surface will decrease with dissolution.

atom in this plane is 8. Let it be correspondingly supposed that (111) planes predominate on the quenched electrode. Then, the coordination number is 9. Hence, the bond strength on the electrodeposited electrode for an adion is $\Delta H_{\text{sublimation}}/12$ greater than that on a quenched and thus 5 kcal mole^{-1} would be the order of increase in bond strength of an adion on an electrodeposited surface, compared with that on a quenched surface. Hence, the c_o value would be (for the same concentration of kink sites) about 60 times larger (experiment shows ten times) for electrodeposited than for He-quenched electrodes.

On oxide electrodes, the i_o and c_o are essentially the same as on electrodeposited electrodes. Thus, according to the model suggested, for these electrodes the metal-adion bond must be about the same as on electrodeposited electrode, *i.e.,* the predominant plane must be the same, and probably the 100 plane. The dominance of the 100 planes on the copper surface formed by reduction, as well as on that formed by deposition, is not surprising, if it is remembered that the atoms in the surface of a 100 plane have a coordination number of 8, compared with those in a 111 plane, where the coordination number is 9. The 100 plane will thus be more readily attacked in a chemical reaction, and in a polycrystalline surface will be preferentially consumed, thus undermining the 100 planes, and reducing the proportion of the other planes associated with the 100 planes in the surface. The 100 planes tend, thus, to be increased in their proportion on the surface (see Fig. 16). In the same consideration, deposition will occur more easily on 111 planes than on 100 planes because an electrodeposited atom can be incorporated into the lattice in a more stable form on a 111 plane than on a 100 plane (difference in coordination number). Hence 111 planes may grow faster than 100 planes as indicated in Fig. 16, and thus the 100 planes tend to be increased in their proportion on the surface.

Mechanism of Effects of Repetitive Application of Cathodic Pulses at High Applied Potential

Cathodic pulses of 20 sec, at a current density of 270 ma cm^{-2}, were applied to He-quenched electrodes for up to 50 consecutive pulses. Experimental results on i_o, $C_{d.l.}$, and τ (cf. Fig. 8 and 11) show that these all increase linearly with the number of pulses.

From Fig. 8, values of di_o/dp, $dC_{d.l.}/dp$, and $d\tau/dp$, where p is the number of pulse, are estimated as 8.6 ma, 180 μ**F** and 48 msec, respectively. Since $C_{d.l.}$ on the He-quenched and the electrodeposited electrode is about 50 **F** cm^{-2}, an increase of 180 μ**F** in $C_{d.l.}$ corresponds to an increase of 3.6 cm^2 in surface area. Dividing the increase of i_o per pulse by the increase of surface area, one obtains 2.4 ma cm^{-2} for i_o on the deposit. Hence, the surface activity of the deposit is the same as that of the electrodeposited electrode.

The suggestion that the extra area is produced, during pulsing, by a chemical reduction of Cu^{++} is supported by the constant increase of i_o and surface area with the number of pulses.

The average increase in thickness of a deposit was observed to be 2 x 10^{-3} cm per pulse. Assuming n layers of particles produced per pulse,

$$2 \cdot 10^{-3} = n \cdot 2r \qquad [24]$$

where r is the radius of the particles. The total number of particles, N, can be expressed as

$$N = \frac{4\pi}{4r^2}[(r_o + r)^2 + (r_o + 3r)^2 + (r_o + 5r)^2 + \ldots + (r_o + (2n-1)r)^2] \qquad [25]$$

However, assuming spherical particles of equal size,

$$4\pi r^2 \cdot N = \frac{dA}{dp} \qquad [26]$$

From Eq. [24], [25], and [26], $r \sim 10^{-4}$ cm, $N \sim 10^6$, and $n \sim 5$. Hence the rate of chemical reduction, i_c, is given by:

$$\frac{i_c \cdot 20 \cdot M}{z\mathbf{F}d} = N \cdot \frac{4}{3}\pi r^3 \qquad [27]$$

as $i_c \sim 10$ ma per apparent surface area.

The transition time, t, can be given by

$$t = \frac{[Cu^{++}]^2 z^2 \mathbf{F}^2 \pi D_{Cu^{++}}}{4i^2} f^2 = t^o f^2 \qquad [28]$$

where f is the effective roughness factor for diffusion (15) of cupric ions. Using numerical values of 7.2 x 10^{-6} cm^2 sec^{-1}, 5 x 10^{-5} mole cm^{-3}, and 2.6 x 10^{-1} amp cm^{-2} for $D_{Cu^{++}}$, $[Cu^{++}]$, and i, respectively, t^o is calculated as 8.4 msec. Figure 9, curve 1, and Figure 10, curves 1 and 3, indicate an observed transition time on the He-quenched, electrodeposited, and dissolved electrodes is about 35 msec. The discrepancy between the calculated and observed transition times may be attributed to f. The thus derived f is 2.0 which can be compared with 3.5, estimated from $C_{d.l.}$.

According to Eq. [28], when the surface area becomes larger, one can expect an increase of t proportional to the square of the surface area. However, the experimental results (Fig. 8 and 11) show a linear increase with the number of pulses, *i.e.,* a linear increase with the surface area, since $C_{d.l.}$ increases linearly with the number of pulses. This contradiction arises from the difference of the surface areas effective for the charging up of double layer and for diffusion. The deposit formed from chemically reduced Cu^{++} would be porous and co-deposited hydrogen escapes through pores in it. Let it be assumed that the hole shown in Fig. 17 is the relevant deposit shape. Thus, the linear relationships in Fig. 8 mean that some part of the original electrode surface is still active for the deposition of Cu,

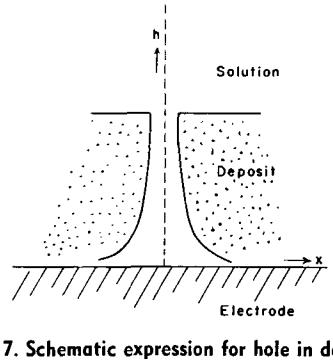

Fig. 17. Schematic expression for hole in deposit

after the application of many cathodic pulses. Similarly, such a shape may be regarded as expectedly arising from the pressure of H_2 evolved on the original substrate. As a rough approximation, let it be assumed that

$$h = \frac{a}{x^2} \qquad [29]$$

where h is the height of the hole, x the radius of the hole at h, and a is the constant, respectively. The total surface area of the holes can be given by

$$N_h \int_0^h 2\pi x \, dh = N_h 4\pi \sqrt{ah} \qquad [30]$$

where N_h is the number of holes.

Hence, t is given by Eq. [28] and [30] as

$$t = t^\circ f^2 \cdot (N_h 4\pi)^2 ah \qquad [31]$$

On the other hand

$$h = n \cdot 2r \cdot p \qquad [32]$$

when n is the number of layers per pulse and p the number of pulses. Hence, from Eq. [31] and [32]

$$t = t^\circ f^2 \cdot (N_h 4\pi)^2 a \cdot n \cdot 2r \cdot p \qquad [33]$$

Equation [33] indicates the linear increase of t with p which is observed experimentally. Taking 10^{-8} cm for x at $h = 10^{-1}$ cm and using $dt/dp = 40$ msec, one obtains N_h as $\sim 10^8$ holes per electrode, or $\sim 10^5/\text{cm}^2$, a plausible value.

Acknowledgments

The authors are indebted to the American Electroplaters' Society's Committee for their Project 16 for stimulating discussion, and to the Society for financial support. One of them (H. K.) wishes to thank Professor J. Horiuti for permission to take study leave.

Manuscript received March 26, 1962.

APPENDIX

When $\theta < 1$, an effect of $(1 - 0)$ term in Eq. [20] on the Tafel slope at high current density is discussed below.

The reaction mechanism is:

$$Cu^{++} + e \rightarrow Cu^+ \qquad [5]$$

$$Cu^+ + e \rightleftharpoons Cu(ads) \qquad [6]$$

$$Cu(ads) \rightleftharpoons Cu \qquad [34]$$

where reaction [5] is rate-determining step.

For the steady state, the net rate, i is expressed for reactions [5], [6], and [34] as follows:

$$i = i_o \frac{1-\theta}{1-\theta_0}\left[e^{-\frac{\beta F\eta}{RT}} - \frac{[Cu^+]}{[Cu^+]_0} e^{\frac{(1-\beta)F\eta}{RT}}\right] \qquad [35]$$

where $[Cu^+]$ is the steady-state concentration of Cu^+ and $[Cu^+]_0$ is the equilibrium concentration of Cu^+.

$$i = i_o'\left[\frac{[Cu^+]}{[Cu^+]_0} e^{-\frac{\beta F\eta}{RT}} - \frac{\theta}{\theta_0} e^{\frac{\beta F\eta}{RT}}\right] \qquad [36]$$

$$i = zFv_o\left[\frac{\theta - \theta_0}{\theta_0}\right] \qquad [37]$$

where i_o' is the exchange current density for reaction [6]. Since reaction [5] is the rate-determining step, $i_o' >> i_o$. Hence, from Eq. [36]

$$\frac{[Cu^+]}{[Cu^+]_0} \simeq \frac{\theta}{\theta_0} e^{\frac{F\eta}{RT}} \qquad [38]$$

From Eq. [35] and [38], one obtains

$$i = i_o \frac{1-\theta}{1-\theta_0}\left[e^{-\frac{\beta F\eta}{RT}} - \frac{\theta}{\theta_0} e^{\frac{(1+\beta)F\eta}{RT}}\right] \qquad [39]$$

At high cathodic polarization:

$$i = i_o \frac{1-\theta}{1-\theta_0} e^{-\frac{\beta F\eta}{RT}} \qquad [40]$$

From Eq. [37], [40], and [8], one gets

$$i = i_o\left[1 - \frac{i}{zF\frac{GD}{x_o^2}(1-\theta_0)}\right] e^{-\frac{\beta F\eta}{RT}} \qquad [41]$$

where $G\theta_0 = c_o$. One can expect a deviation from the Tafel line at the condition

$$i > 0.1 \cdot zF\frac{GD}{x_o^2}(1-\theta_0)$$

Taking values for zFD/x_o^2 and D as 2×10^6 (Table V) and 10^{-7} cm^2 sec^{-1}, respectively, one gets: $i > 20\ (1-\theta_0)$ ma cm^{-2}. However, no deviation in the Tafel linearity was observed up to 800 ma cm^{-2} (Fig. 2). A possible explanation for this contradiction is that: (*a*) x_o decreases with i (2, 6); and (*b*) at high current density, another process, *e.g.*, nucleation, becomes predominant and displaces [37].

On the Emission of Electrons from Solids in Gas Discharges

I. Emission in the Vicinity of "Zero Field"

D. M. Speros and P. R. Buccilli

Lamp Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

ABSTRACT

In the study of the electron emitting behavior of cathodes in practical gas discharge devices, a method for the determination and measurement of emission in the vicinity of zero field was found and is described.

The performance of cathodes is determined by their thermodynamic stability and their ability to emit electrons. Therefore, a general examination of materials intended for cathode use involves the study of both their thermochemical and electron emitting behavior. Factors involved in the thermochemistry of cathode components were examined previously (1). This paper begins the description of work concerned with their electron emitting behavior.

The conditions under which a cathode functions in a gas discharge may conveniently be classified as those involving an accelerating, a retarding, or a zero field in front of the cathode. When a condition of zero field prevails, in front of a uniform cathode, the discharge current equals the "discharge thermionic emission," J_θ, from the cathode.[1] Then the influence of an electron accelerating or retarding field on the cathode is removed and a measure, J_θ, of the thermionic capability of the cathode can be obtained. Methods for measuring the emission in the vicinity of zero field have been developed (2-8), but their use has been limited by the probes, auxiliary electrodes, or special structures that they involve. Because of the utilitarian need to perform measurements on normal standard production discharge devices such as phosphor coated fluorescent lamps, a new method was found and is described below. Since the first results of this investigation were reported (10), Forster-Brown and Cayless (11) and Waymouth (12) have published their work for measurements on normal lamps. Their procedures have assisted the task of interconnection between this work and the above probe techniques.

[1] As "distinguished" from the temperature-limited zero field thermionic emission in vacuum diodes determined by the Schottky and Richardson-Dushman plots. The interrelation between this and the thermionic emission J_θ above is not yet clarified (8, 9).

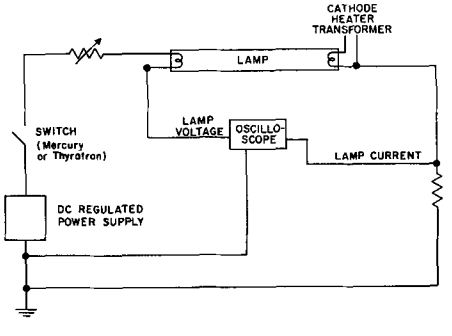

Fig. 1. Schematic diagram of apparatus

Preliminary Experiments

The determinants of cathode emission were sought in the starting or electrical breakdown behavior of the discharge. This behavior was investigated using the arrangement shown in Fig. 1. With the supply voltage set above the breakdown voltage of the discharge, closing of the switch produces oscilloscopic traces shown in Fig. 2 in their most general form. These are characterized by three plateaus termed, from left to right, A, B, and C. For purposes of subsequent reference, the quantities involved in the voltage *vs.* time trace are as follows: V_A is the height of plateau A in volts; this is the supply voltage; Δt_A is the length of plateau A in milliseconds; V_B is the height of plateau B in volts; Δt_B is the length of plateau B in milliseconds; and V_C is the height of plateau C in volts.

The corresponding quantities in the trace of current *vs.* time are in the same order, as follows: J_A, Δt_A, J_B, Δt_B, J_C.

During plateau B, the discharge has the appearance of a generalized glow engulfing the cathode. Immediately after the transition to plateau C, the glow is about as generalized, but has a different

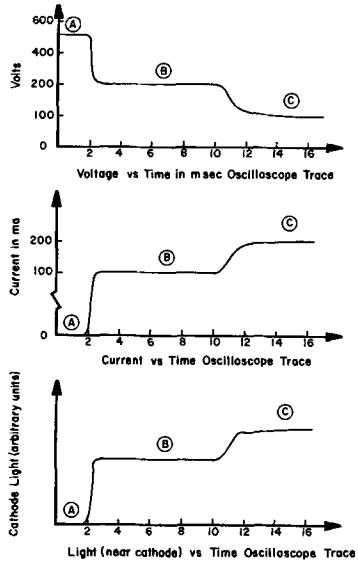

Fig. 2. Oscilloscopic traces of breakdown behavior: top, voltage *vs.* time; middle, current *vs.* time; bottom, light in cathode vicinity *vs.* time.

appearance with respect to both shape and color. After some time at this state, the discharge constricts to a "hot spot."

If a high tension spark of a few microseconds' duration is applied to the discharge during the interval Δt_A, the trace falls immediately to level V_B. If the spark is applied simultaneously with the application of the supply voltage, plateau A disappears while plateaus B and C remain unaffected. These facts and further evidence (13), indicate that plateau A corresponds to a type of formative time lag.

With respect to plateaus B and C, two stable and one transient states are recognized as follows:

(*A*) If the cathode is held at some high temperature before the application of the supply voltage, plateau B disappears, the trace falling directly from V_A, after a Δt_A, to level V_C. This level, V_C, is then the stable operating discharge voltage.

(*B*) If the cathode is at some low temperature, plateau C disappears, Δt_B becoming infinite. V_B under this condition is then the stable operating discharge voltage.

(*C*) If the discharge current is sufficiently high for the discharge to heat the cathode directly, then the temporal sequence seen in Fig. 2 is obtained as the state described in paragraph (*B*) above is made to revert to the state described in (*A*). The extent to which this can occur or, in other words, the height and the length of plateau B, depend on the relative magnitudes of discharge current and initial cathode temperature, as will be seen.

This general breakdown behavior is exhibited by all kinds of discharge devices tried thus far, including a number containing a few mm Hg of noble gas and having anode-cathode spacings of from 1 to 10 mm. As a result, this behavior does not seem attributable to some peculiarity of the positive column. Likewise, this behavior is discernible in some distorted shape if alternating current, square pulses or some sawtooth wave is used instead of direct current.

Correlation with Electron Emission Constants

Long gap discharges.—The bulk of this work was done using standard phosphor coated 40w fluorescent lamps, 48 in. in length and 1½ in. in diameter. In addition to a drop of mercury, they contained a mixture of 70% argon and 30% neon by volume at a pressure of 2.5 mm Hg. The cathodes consisted of a structure incorporating a coiled-coil filament originally coated, unless otherwise stated, with the standard production triple alkaline earth carbonates. The experimental procedure is illustrated by means of Fig. 3. At each setting of cathode heating current, the discharge current is read on the oscilloscope immediately after its rise from plateau A. Therefore, in order to obtain each experimental point, the lamp need be lighted for only a fraction of a second.

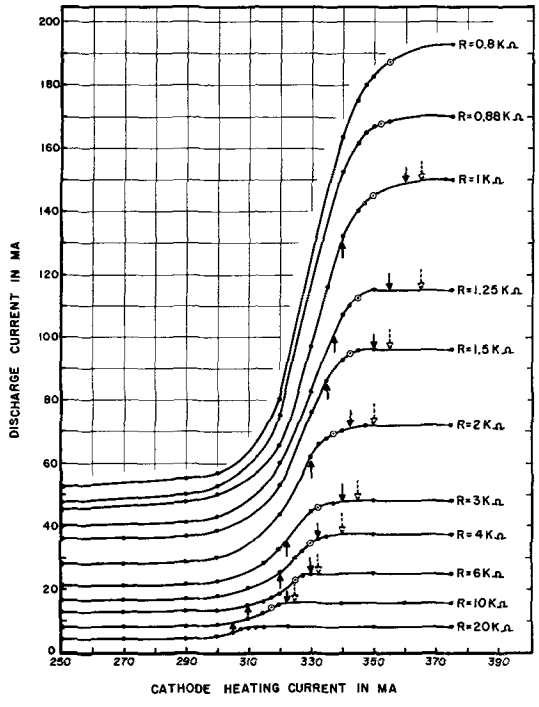

Fig. 3. Discharge current *vs.* cathode filament heating current for 40w standard fluorescent lamp. External resistance, *R*, values shown; supply voltage 300v. At circled points, $V_B = V_C$, $\Delta t_B = 0$. Full arrows show the limits for zero field identification according to Forster-Brown and Cayless (11); dotted arrows, the upper limit for zero field identification according to Waymouth (12).

At constant external resistance and supply voltage,[2] little change is observed in the discharge current as the cathode heating current is increased from zero up to a certain value. Beyond this value, the discharge current increases rapidly and reaches a new level within a narrow range of cathode heating current. Thereafter, the discharge current becomes quite constant again. At a new setting of external resistance, this general behavior is reproduced, and the family of curves shown in Fig. 3 is obtained.

At the low current branch of each curve, Δt_B can be of the order of several minutes, and the discharge has the appearance of a glow discharge. At low temperature and high external resistance values, the glow often covers the entire electrode structure, but as the cathode temperature is raised, the glow becomes localized on the coated portion of the filament.

In the cathode heating current ranges in which J_B increases rapidly, Δt_B decreases until, near the upper elbow of each curve, plateau B completely disappears, and the oscilloscope trace reverts directly from plateau A to plateau C.

In this range, first the appearance of the glow changes and then the discharge acquires the appearance of a "hot spot" mode of discharge. During a number of experiments in this and the subsequent series, the cathode heating current was changed from a.c. to a square wave. The behavior observed during the "off" (up to 8 msec) and "on"

[2] Usually 300v; it is often necessary to use a short duration ($\leq \Delta t_A$) high tension spark to light certain types of lamps at this voltage. V_B and Δt_B are not affected by the spark.

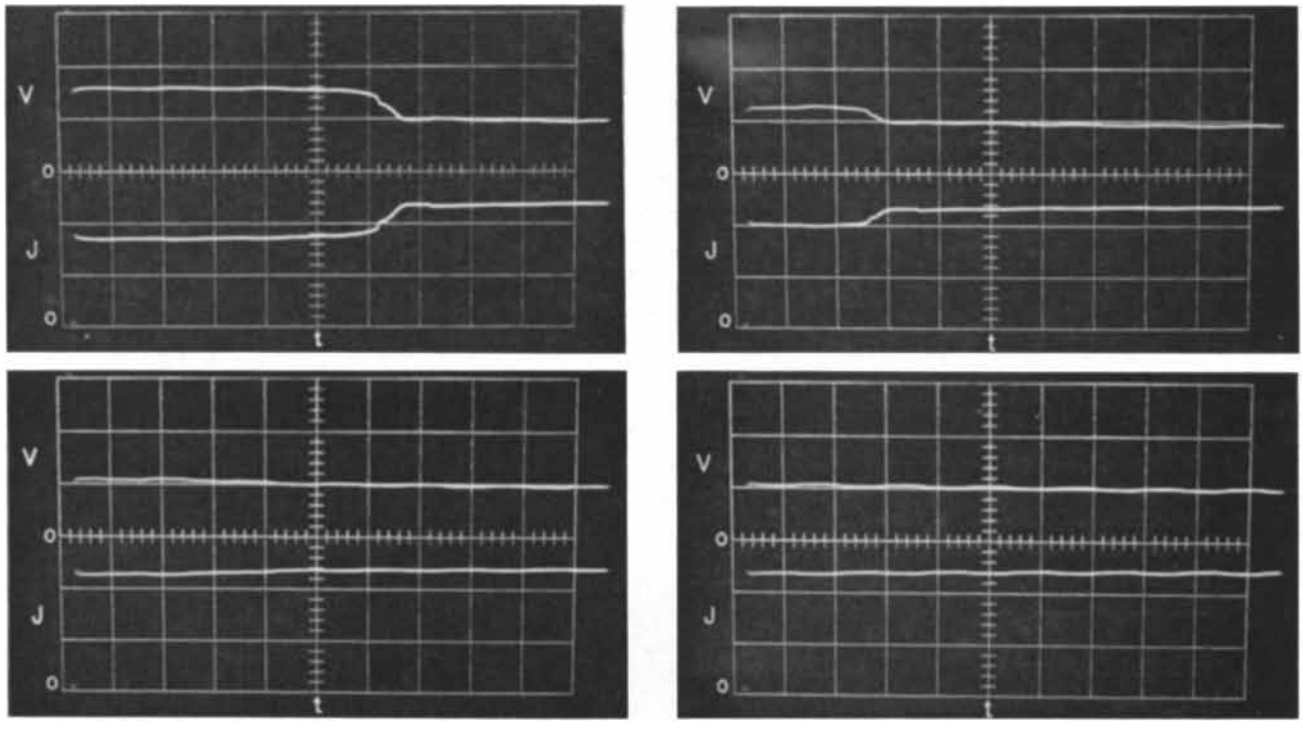

Fig. 4. Variation of V_B, upper trace, and J_B, lower trace, with cathode heating current. Supply voltage 500v; external resistance 3000 ohms. Cathode heating current progressively at 300, 320, 325 and 330 ma. Oscilloscope set at: ordinates, 167 v/cm, and 50 ma/cm; abscissa, 10 msec/cm.

periods indicated that the nature of the results described are not due to some interaction between the cathode heating and discharge circuits.

The possibility is considered that plateau B indicates that an accelerating field exists in front of the cathode. Consequently the cathode temperature at which plateau B disappears, that is, when

$$J_B = J_C;\ \Delta t_B = 0$$

is the lowest cathode temperature at which the state of zero field can possibly (but not necessarily) occur. This happens at the upper elbow of each curve as described above and shown on Fig. 3 by the circled points. Figure 4 shows the appearance of the oscilloscopic trace as the above condition is approached and attained with increasing cathode temperature. Often plateau B slopes smoothly into plateau C; then $\Delta t_B = 0$ is found by comparing the level of the tail end of the trace with the level of the trace immediately after the rise from plateau A. When these levels are first equal, $\Delta t_B = 0$. The level J_C rises slightly after this point is reached. For very high values of external resistance (bottom curve of Fig. 3) J_B rises very gradually and Δt_B is indefinite.

One of the prerequisites for the correctness of this assumption is that the cathode temperature and discharge currents as specified above should obey the Richardson-Dushman relation

$$J_\theta = AT^2 e^{-\frac{e\phi}{kT}}$$

A plot of $\ln J_\theta/T^2$ *vs.* $1/T$ in Fig. 5, line A, using the data (circled points) of Fig. 3 shows that this is the case.[3]

[3] The temperatures were computed from hot-to-cold resistance ratios; these were periodically checked with a micropyrometer. It is to be emphasized that J_θ is plotted in all cases as obtained without concern or correction for the amount of cathode area.

Further experimental evidence that the disappearance of plateau B is related to zero field emission can come from probe measurement methods such as that of Found (2, 13). Cayless and Waymouth also took pains to compare their respective methods to probe measurements. As a result their techniques are used to check this method.

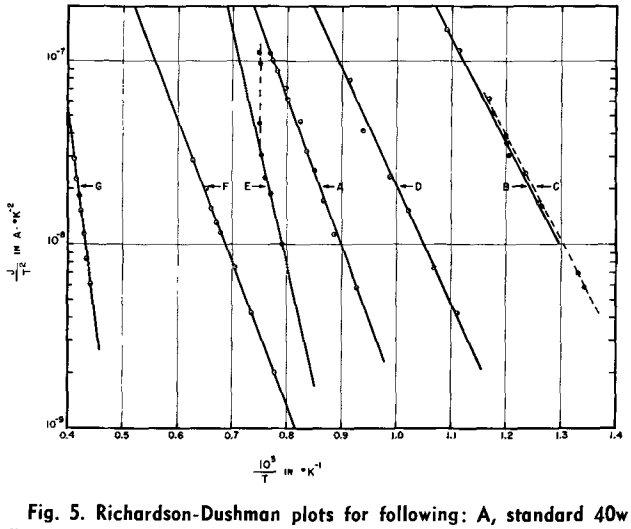

Fig. 5. Richardson-Dushman plots for following: A, standard 40w fluorescent lamp, data from Fig. 3, slope = 1.59 ev; B, standard triple oxide cathode; cathode-anode distance, 2 mm; Supply voltage 36v; data from Fig. 8; slope = 1.13 ev; C, same as B above but measured at 300v; discharge current *vs.* cathode heating current relationship qualitatively same as in Fig. 3; slope = 1.13 ev; D, average behavior for 40w fluorescent lamps; slope = 1.27 ev; E, 40w fluorescent lamp with cathode coated with LaB_6 (14), showing effect of attack on tungsten filament by boron at higher temperatures, initial slope = 2.54 ev; F, 40w fluorescent lamp with cathode coated with Ba_2ThO_3 (1), slope = 1.54 ev; G, 40w fluorescent lamp with uncoated tungsten filament as cathode, slope = 4.5 ev. The coated portion of the filament and coating uniformity in cases A-F vary greatly. J_θ is plotted without correction for the amount of cathode area.

Correlation with other methods.—The Forster-Brown and Cayless method (11) determines the zero field condition by the shrinking of the negative glow around the cathode filament and the sudden motion of the positive column away from the cathode as zero field is approached from retarding to accelerating field conditions. These phenomena are reversed when zero field is approached from accelerating to retarding field conditions.

For phosphor-coated fluorescent lamps, the details of the negative glow are not visible, and therefore the motion of the positive column and the resulting change in phosphor brightness near the cathode are used, according to (11), as the criterion for zero field. The solid arrows in Fig. 3 indicate the beginning and end of the motion of the positive column as visually observed. It is seen that the circled points are consistently within this range.

In order to obtain a definite correlation with the present work, a high speed photoelectric cell pick-up normally used for electronic flashtube work was employed. The 3 x 4 cm aperture of the instrument was placed against the wall of standard lamps, with its long dimension beginning at the cathode and extending in a direction parallel to that of the motion of the positive column at zero field, which amounted to about 3 cm. As a result, this motion was registered by the instrument, the output of which was fed to a dual trace oscilloscope. The second input of the oscilloscope was used for the simultaneous observation of J (see Fig. 2). A small "window" clear of phosphor on the side of the lamp wall away from the photocell allowed the observation of the negative glow.

Figure 6 gives an example of the results over a range of discharge current.

It is seen that the shrinking of the negative glow (or the disappearance of the cathode dark space) and the condition $J_B = J_C$, $\Delta t_B = 0$ bracket closely the beginning of the appearance and disappearance respectively of the Faraday dark space for this particular set of conditions at least. This connection of

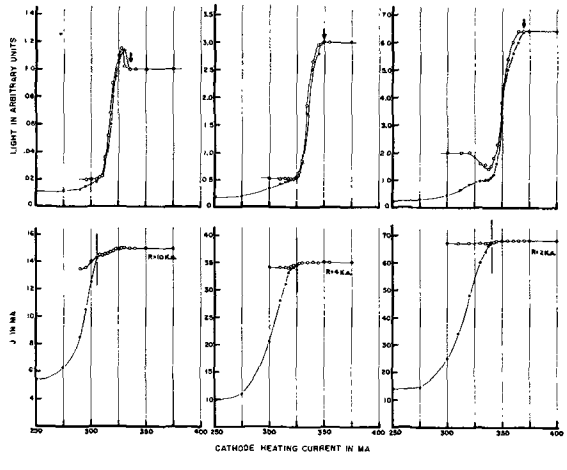

Fig. 6. Variation with cathode heating current of J_B (solid points) and J_C (circles), and corresponding light output in the vicinity of the cathode. Because of the experimental arrangement (see text) the light output increases as the head of the positive column advances toward the cathode. The arrows indicate the regions at which the cathode dark space first appears.

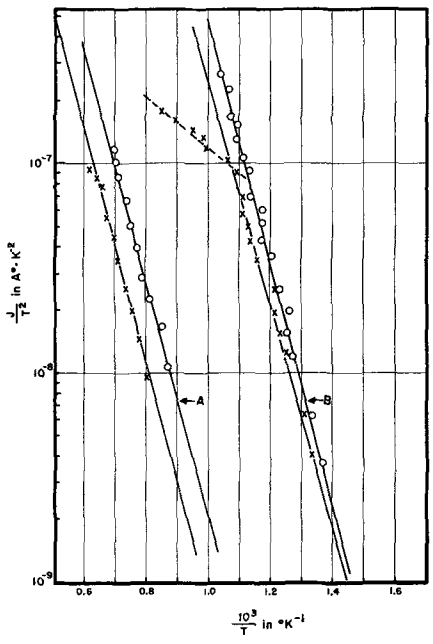

Fig. 7. A. Richardson-Dushman plot of data obtained as indicated in Fig. 6 and described in text, slope = 1.10 ev; B, Richardson-Dushman plot of data for short gap (2 mm) discharge; slopes = 1.05 ev; 1.13 ev. In both A and B circles are points obtained by this method, crosses are points obtained by method of ref. (11).

the disappearance of plateau B with the beginning of the rapid motion of the positive column toward the cathode was found valid for a variety of standard lamps with different cathode structures and tube diameters.

A Richardson-Dushman plot of data obtained as described above is given in Fig. 7A. It is seen that the apparent work functions correspond well within the experimental error of both methods and the intercepts are close enough as to make little practical difference.

The logical consequence of the above was experimentation involving discharges (3 mm Hg of argon plus a drop of mercury) with electrode gaps sufficiently small so as to avoid the formation of a positive column and therefore of a Faraday dark space. In order also to avoid possible electrode effects (see below) the arrangement used for this series involved a titanium anode in the shape of a semicylinder approximately 4 mm in diameter positioned with the cathode filament along its longitudinal axis. A supply voltage of 36v proved sufficiently high for this series. The cathode temperatures and discharge currents at which plateau B and the cathode sheath disappeared were measured, and Fig. 7B gives an example of the results. It is seen that the difference between the conditions at which these two phenomena occur is now smaller. The deviation from the straight line at higher discharge currents of the points determined by the shrinking of the negative glow reproduces the findings in references (8) and (11). This deviation begins to occur as the discharge current approaches 100 ma, also in agreement with reference (11).

The Waymouth method (12) detects the zero field condition by the onset of radio frequency noise as one proceeds from accelerating to retarding field

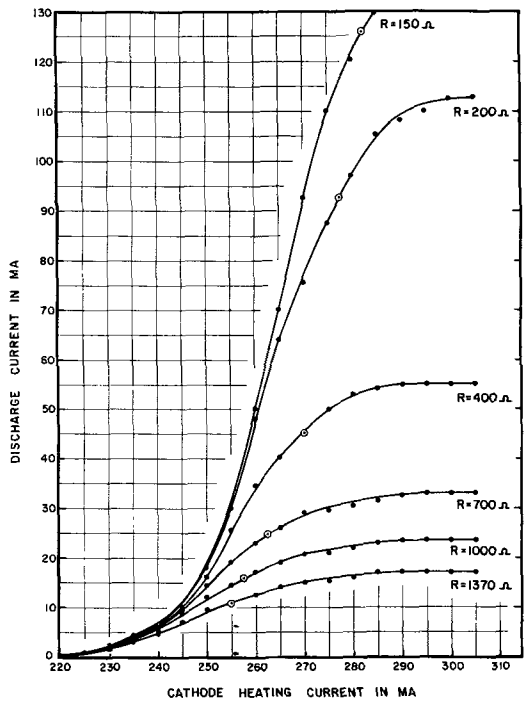

Fig. 8. Discharge current vs. cathode filament heating current for short gap (2 mm) discharge measured at supply voltage of 36v. Circled points indicate the $V_B = V_C = V_\theta$, $\Delta t_B = 0$ condition. The Richardson-Dushman plot using these data is shown in Fig. 5, line B.

conditions. Difficulty probably of instrumental nature, was experienced in obtaining consistent behavior utilizing this intriguing method. In a number of successful experiments, radio noise of the characteristics described in reference (12) was obtained during plateau C, while during Δt_B the noise was absent. The dashed arrows in Fig. 3 indicate the regions at which the radio frequency noise had become appreciable, but no sharp onset of noise was found in this particular instance.

Accelerating field phenomena.—Certain phenomena pertaining to the accelerating field mode appear relevant to the present subject.

It will be recalled that at lower cathode temperatures the cathode glow is not necessarily localized on the part of the cathode which is coated with the emission material. This happens regardless of electrode structure or cathode-anode spacing. In these cases the behavior obtained corresponds closely to that of Fig. 3 even for short gap (1-10 mm) discharges. However in the case of short gap discharges, by reducing the supply voltage from the 100 or more volts which is the "normal" range for fluorescent lamps to a few tens, the glow is made to envelop only the coated portion of the cathode filament even at room temperature. Then, the more anticipated behavior seen in Fig. 8 is obtained. The corresponding Richardson plot is seen in Fig. 5 line B. Line C in Fig. 5 shows the Richardson plot for the same lamp at 300v. It is seen that the two plots correspond quite well. Therefore the different behavior in the accelerating field region (*i.e.*, Fig. 3 *vs.* Fig. 8) does not affect the behavior in the vicinity of zero field, and the evaluation of a cathode either way is quite valid.

The above seem to apply to simple cathode structures as well as to structures incorporating parts variously of metallic and nonmetallic nature such as shields, ceramic supports, screens, wire structures, etc. It is also observed that the bulkier the electrode structure the more the Richardson plot result corresponds to that of Fig. 7A rather than that of Fig. 7B.

It is of pertinent interest to note that a Richardson plot of all the experimental points of Fig. 8 would give straight line portions for discharge current and cathode heating temperature conditions that are far into the accelerating field region (13). This can be readily seen from the exponential nature of the low-temperature portions of the curves of Fig. 8. This illustrates the fact that a straight line Richardson plot is a necessary but insufficient condition for the definition of zero field.

Substances other than triple oxides in standard lamps.—Figure 5, line E, gives an example of the results obtained with cathode filaments coated with LaB_6 (14).[4] At higher temperatures the interstitial attack by boron on the tungsten filament (14) proceeds at such a rate that the measurement of cathode temperature becomes uncertain. Figure 5, line F, gives the results from coatings of an interoxide, Ba_2ThO_4 (1). The above two coatings were not uniform with respect to thickness and filament coverage (see below).

Figures 9 and 5, line G, show the results obtained with uncoated tungsten filaments, the electrode structure being otherwise identical to the above. These filaments are ill-defined physicochemically but of interest because they are the cathode filaments used as base for all of the coatings of this work. It is noted that in this case even at 300v the

[4] Indebtedness is acknowledged to Dr. J. M. Lafferty for making this sample of LaB_6 available for this work.

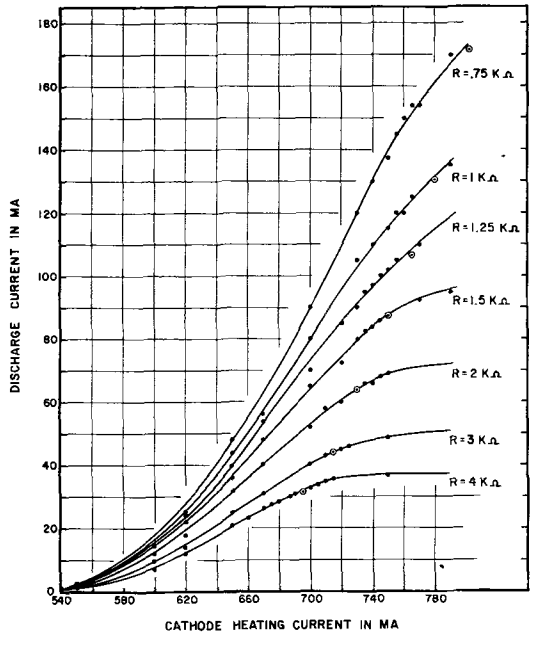

Fig. 9. Discharge current vs. cathode filament heating current for standard 40w fluorescent lamp with uncoated tungsten filament cathode; conditions of measurement same as for Fig. 3. The Richardson-Dushman plot using these data is shown in Fig. 5, line G.

behavior seen in Fig. 8 rather than that in Fig. 3 is obtained.

The above are compared with line D in Fig. 5 which appears thus far to be an average behavior for triple oxide cathodes.

Experimental Pitfalls

Measurements of cathodes in gas discharges are subject to all of the complicating factors of vacuum diode investigations plus some of their own. A number of these factors are pointed out below.

Progressive emission hysteresis.—Figure 10 shows curves of J_B *vs.* cathode heating current for a standard triple oxide cathode like those shown in Fig. 3. The arrows show the order in which the measurements were taken. The figure illustrates the effect of ionic bombardment at the lower level of J_B and the effect of heating at the upper level of discharge current. A reversal in the direction of the phenomenon is also observed. The insert in Fig. 10 gives an example of this. It should be recalled that the cathode operates for only a fraction of a second per experimental point.

To compensate, at least to some extent, for this rapid change in cathode characteristics, the experimental work was planned so that all points were obtained in consecutive ascending (or descending) order within each curve and from one curve to the next. The difference in the results obtained in an ascending or descending procedure involves small differences in the factors A and ϕ of Eq. [1], because this effect is more pronounced at higher than at lower discharge currents.

Temperature.—The cathode temperature is determined not only by the cathode heating current but also by the heating effect of the discharge. At high discharge currents, the latter can predominate to the extent that plateau B reverts to plateau C in a matter of milliseconds even if the cathode heating current is zero. This is the situation depicted in Fig. 2, where the discharge current is of the order of 200 ma. For lower discharge currents, the heating effect of the discharge manifests itself only near the zero field temperature ranges where a slight increase in heating rate, whether contributed by the cathode heating current or by the discharge, causes plateau B to disappear.

Because of these considerations, J_B is read immediately after the rise from plateau A when the heating action of the discharge has been in effect for only a few microseconds.

Temperature and coating uniformity.—Figure 11, from which the data for line F, Fig. 5 was obtained, shows an example of measurements identical to those of Fig. 3 but performed on nonuniformly coated filaments. As a result, these cathodes show rather severe temperature gradients along their length. This condition also affects the extent and uniformity of the activation of the cathode during manufacture.

It is seen that the rise of plateau B occurs over a wider range of cathode heating current as the various parts of the cathode tend to contribute to the total J_B to a different extent at each setting of cathode heating current.

In cases of this kind, the Cayless upper limits, indicated by the arrows in Fig. 11, tend to move further up the high current branch of the curves than in the case of uniformly coated cathodes. It was observed that at temperatures above those indicated by the arrows the brightness of the phosphor near the cathode and therefore the position of the head of the positive column were fairly constant with time. In the region between the arrows and

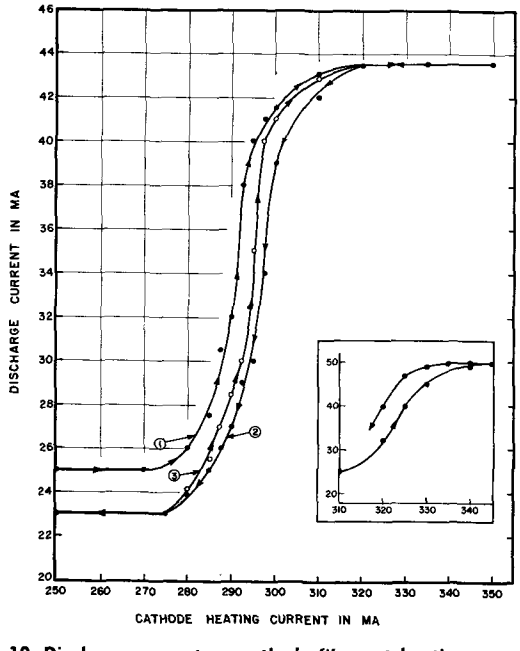

Fig. 10. Discharge current *vs.* cathode filament heating current for standard triple oxide cathode. Measurements followed the sequence shown by the numbers for each branch and the arrows within each branch, in order to illustrate the phenomenon of progressive emission hysteresis (see text). The reverse phenomenon is shown in the insert.

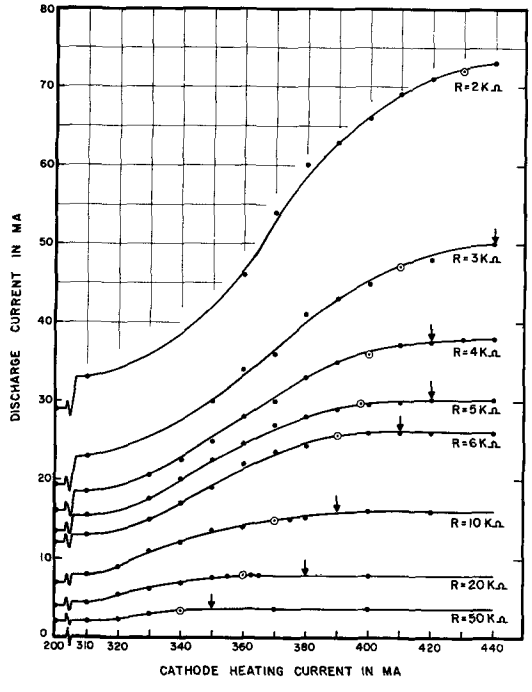

Fig. 11. Discharge current *vs.* filament heating current for standard 40w fluorescent lamp with cathode filament coated nonuniformly with Ba_2ThO_4. The Richardson-Dushman plot using these data is shown in Fig. 5, line F.

the $J_B = J_C$, $\Delta t_B = 0$ points however the position of the positive column was variable for nearly 1 min after the lamp was lighted. This indicated that the cathode activity was changing considerably because of the action of the discharge, causing a large difference between the "instantaneous" procedure described here and the "steady-state" procedure described in ref. (11). This difference is smaller in well activated, stable cathodes like that of Fig. 3 than in the nonuniform cathode of Fig. 11.

Impurities in discharge atmosphere.—The discharge in vessels of tubular shape interacts with the walls especially during Δt_A (13). The surface area of these walls can be large as in the case of a phosphor-coated fluorescent lamp. As a result, desorption or decomposition products can find their way from the walls into the gas atmosphere and to the cathode which in general is the most active getter available to them.

Species that become physically adsorbed on the cathode surface tend to give a sawtooth or "hashy" appearance to the J and V *vs.* time trace the first time the lamp is lighted after standing for some time.

The effect of species that combine with the cathode in a more intimate fashion is more pronounced and can be permanent. Usually those tend to change the cathode behavior from that of Fig. 3 to that shown in Fig. 11. Not infrequently this change can occur in the middle of a series of measurements and even reverse itself to the original behavior later on as the discharge cleans the cathode surface by sputtering or as these species diffuse into the bulk of the cathode.

Variable cathode composition.—A cathode involves a delicate balance between the processes producing the activating species such as "free" barium (1, 15) or lanthanum (14) and those that cause their loss from the cathode. Especially in a gas discharge, a precise balance is rarely if ever attainable. Therefore for each measurement the discharge is left operating for a fraction of a second, and an attempt is made to obtain each set of data uninterruptedly. This procedure can of course be altered to suit different purposes, as for instance the determination of an "equilibrium" state. Then the discharge is interrupted for the desired length of time.

The above factors tend to make the cathode an ever-changing system whether the discharge device is operating or not. However, if these factors are recognized and the experimental work planned accordingly, clear-cut results can be obtained.

Discussion and Conclusions

The purpose of the work described here was to obtain a measure of the thermionic capability of cathodes in gas discharges. The evidence is fairly convincing that there is little practical difference in the results obtained by the procedure described here and that described in ref. (8) and (11).[5] The "instantaneous" nature of the measurements described above offer advantages similar to these of pulsed, over d-c measurements in vacuum diodes. Especially in gas discharge cathode studies, this permits the resolution and hence the study of short duration effects such as the phenomenon of emission hysteresis described above. That this can also be done by a minor alteration of the method of ref. (11) has been demonstrated.

Fundamentally, there is little doubt that the condition $V_B = V_C$ and $\Delta t_B = 0$ occurs on the accelerating field side of the conditions at which the cathode dark space disappears. Evidence derived from spectroscopic[6] an probe (2) work[7] indicates that indeed plateau B disappears while an accelerating field still prevails (13). It is therefore of fundamental interest that the disappearance of the glow condition associated with plateau B is dependent on the behavior of the cathode at zero field and on the behavior of fundamental gas discharge phenomena such as of the Faraday dark space.

Minute Resistivity Variations in Germanium Crystals and Their Effect on Devices

Gurion Meltzer[1]

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

Minute variations of resistivity in germanium crystals were studied by the use of two methods of detection: selective copper plating and micropotential scanning. Results show that horizontal zone-leveled crystals have, in general, much larger minute resistivity variations than vertically grown crystals. Furthermore, n-type crystals have much larger resistivity variations than p-type crystals. These results, when applied to study of breakdown voltage in semiconductor devices, show that the range of breakdown voltage in p-n-p alloyed-junction transistors is much wider than the range in n-p-n devices.

Resistivity variations resulting from nonhomogeneous distribution of impurities have been observed in germanium crystals grown horizontally and by the Czochralski (1) technique. The nonuniform solute distribution appears to be caused by variations in growth conditions, such as rate of pulling, temperature gradients, furnace vibrations, and stirring (2). The variations of resistivity which result from these conditions can be categorized as follows: (*a*) resistivity difference between the seed and the base of the crystal (2); (*b*) nonuniformity across a wafer cut perpendicular to the direction of growth (3, 4); and (*c*) minute variations in the direction of growth (5).

The minute resistivity variations have often been referred to in the literature as resistivity striations (5).

The first type of variation mentioned above can be measured easily by conventional methods using four-point and two-point probes. The other types require methods of measurements providing much better resolution. One such method is the photovoltaic method (4), which is limited, however, to resistivity variations with periods which are long compared with the diffusion length of the minority carriers. Other methods employ radiographs (2) and copper plating (4). The use of radiographs to detect minute resistivity variations is very involved and is inherently restricted to general qualitative results only. The copper plating method, despite its simplicity, also yields only qualitative results.

Methods of measurement were sought because existing methods did not enable full qualitative and quantitative study of minute resistivity variations and their effect on devices. However employing two well-known methods and correlating the results of both provided satisfactory data.

This paper describes how two methods of measuring resistivity variations, copper plating and micropotential scanning, are correlated to give both qualitative and quantitative results with very good resolution. Results obtained by the use of these methods are discussed in terms of the effect of resistivity variations on the manufacturing yield of devices.

The experimental procedures outlined in this paper should act only as a guide to the performance of similar experiments in that the variables involved were not optimized unless so specified.

Experimental Procedures

Copper plating.—The detection of resistivity variations by the use of selective copper plating was suggested by Camp (5). In this method, the electrolytic cell consists of a copper sulfate solution as an electrolyte, a copper anode, and the sample to be plated as a cathode. An electrolyte which resulted in satisfactory selective plating in most cases consisted of 210g of copper sulfate pentahydrate and 52 cm^3 of concentrated sulfuric acid, diluted to a volume of 1000 cm^3 with water.

A pulsed voltage was applied to the electrodes by means of an automatic electromechanical switch. Very good selective plating was obtained with samples from 2 to 8 mm thick, which were covered on the back with solder and cast in an epoxy resin so that only the surface to be plated was exposed. The face to be plated was etched to obtain a clean smooth surface. Current densities ranged from as low as 1½ amp/cm^2 to approximately 30 amp/cm^2.

Both n- and p-type germanium in resistivity ranges of from 0.03 to 40 ohm-cm were satisfactorily plated. Although no exact rules for variations of parameters of the plating bath could be derived from the experiment, certain general rules can be given.

For p-type samples, the applied voltage ranged from 300 to 1700v, depending on the resistivity of the sample; *i.e.*, higher resistivities required higher voltages. The pulse rate was 3 cps. Selectivity of plating was improved in some cases by an increase in the conductivity and, therefore, the current density, of the solution through the addition of sulfuric acid. In other cases, an increase in the copper-ion concentration in the solution by the addition of copper sulfate resulted in better plating.

In plating n-type samples, especially those samples having higher resistivity, the best results were

Pulse rate: about 3/sec.

obtained when high pulsed voltage (above 1500v) was applied for a few seconds, followed by relatively low voltage for a longer time. For some n-type samples, the selectivity was improved when the copper-ion concentration in the solution was reduced. Table I lists typical plating conditions for a few n- and p-type crystals. The plated surfaces of these samples were either in the direction of growth or perpendicular to the direction of growth as shown in Fig. 1.

Micropotential scanning.—Micropotential probing is essentially a two-point probe method except that the space between the probes is very small and the manipulation of the probes is mechanized. A pair of probes is arranged in a jig. One of the probes is coated with a 1-mil thickness of Teflon. The two probes are placed in a groove as wide as the sum of the diameters of the two probes, so that the probes are separated only by the Teflon film, *i.e.*, distance between the two probes is 1 mil. Various tests made with the aid of a high magnification microscope assure that the probe spacing does not change while the pair of probes is moving across the sample. This technique permits the measurement of relative resistivity as a function of distance. Although the conditions of the test make absolute resistivity very inaccurate, the main purpose of the tests is to investigate resistivity variations. Wires welded at right angles to the probes act as both an electrical contact and a pressure spring. After the jig is assembled, the probes are machined to chisel points. The jig is then mounted on a micromanipulator, which has the horizontal-movement control coupled to a very-slow-speed motor (a fraction of an rpm).

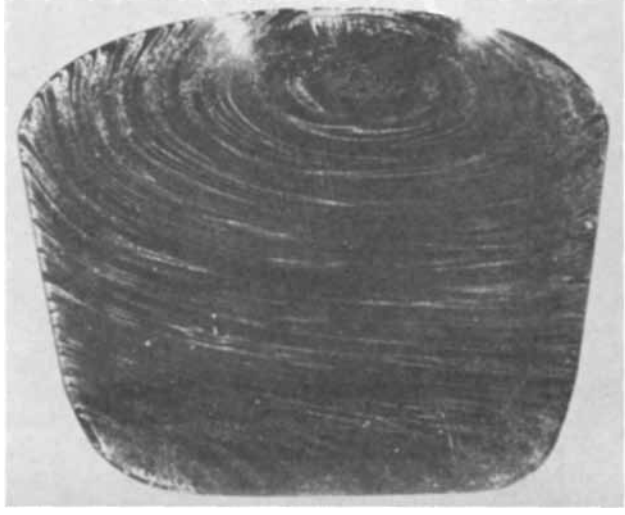

Fig. 1. Horizontal-zone-leveled p-type crystal 0.03 ohm-cm. Face shown is perpendicular to the direction of growth.

A d-c voltage is applied across the sample to be scanned. The voltage across the probes is either amplified or fed directly into a recorder, and the resistivity is plotted as a function of distance directly on the recorder chart. Adjustment of the chart and motor speeds permits the resistivity curve to be plotted to any degree of detail. The resolution of this method is obviously limited by the spacing between the two probes.

The sample to be scanned should be in the form of a bar having any desired length and a cross section of from 1 to 9 mm^2. The cross section of the bar should be chosen so that the current is sufficiently high to give a detectable voltage across the probes but low enough so that conductivity modulation does not affect the reading. The bar should be cut so that the long dimension, which is in the direction of scanning, is perpendicular to the direction of equiresistivity planes (planes represented by copper lines of selectivity plated samples).

Surface preparation is of extreme importance in the micropotential method. The surface to be scanned must be sufficiently smooth to prevent errors due to noise generated by the dragging probes. However, the surface must be sufficiently rough to reduce the metal-to-semiconductor contact resistance to a minimum (at least much smaller than the input impedance of the recorder amplifier). A surface which is lapped on a 600-grit emery paper with the lapping grooves in the direction of scanning provides a satisfactory balance between the two requirements.

Correlation of the methods.—Neither of the two methods outlined in this paper can independently give full information about resistivity variations of the crystal. For example, variations of voltage in the plating process can vary the selectivity of the plating and, consequently, the number of striations revealed; therefore, the exact period of striations cannot always be detected by the plating method alone. Furthermore, the copper-plating method does not yield any information about the magnitude of the variations. On the other hand, for a current which is uniform with respect to the cross section in a germanium bar, the resistivity variations must be perpendicular to the direction of the current; therefore, the bar must be cut accordingly.

It is important to detect the shape and general directions of the changes in resistivity and then cut the crystal so that the copper lines are perpendicular to the long dimension of the bar. A potential scan of the bar then indicates the magnitude and the exact periods of the variations. At this point it is important to emphasize that repeatability of shapes of curves was tested during the experiments; the method used was as follows:

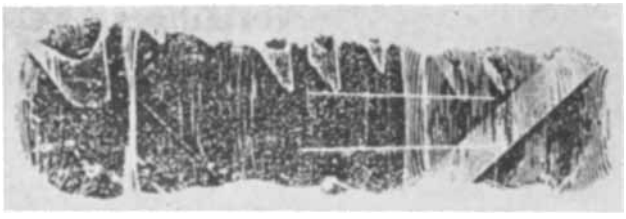

Fig. 2. Copper plating of a p-type crystal. Resistivity variations were purposely introduced in the top (striated) portion.

A specimen was copper-plated, a bar was cut according to the method mentioned above, the copper removed using nitric acid, and the surface of the sample prepared by lapping as explained. A resistivity scan was lapped again and another scan was taken once more. The two scans were to be identical for any conclusions to be drawn, and such was the case.

A comparison of the results obtained by the two methods was made on a crystal specially grown for the purpose of studying the nature of minute resistivity variations. The large resistivity variations were introduced by use of an off-on cycle which varied the pulling speed every 30 sec from 0 to 5 mm/min while the crystal rotated slowly at about 8 rpm. The more uniform section was pulled continuously at 1.5 mm/min and rotated at 70 rpm. Figure 2 shows the copper plating on a sample taken from the center of the crystal and Fig. 3 shows a magnified portion of Fig. 2. Lines were scribed on the sample for the purpose of indexing. Figure 4 shows the result of the micropotential scan parallel to and mid-way between the index line in Fig. 3. The comparison shows that there is complete agreement between measured results of the two methods. The five copper stripes inside the scribed rectangle correspond to the five low-resistivity regions indicated in Fig. 4. The region scanned was purposely chosen to be the one joining the striated and nonstriated region. Reproducibility was checked for both methods by means of plating and scanning a sample, lapping it further, and repeating the steps. Results showed very satisfactory reproducibility.

Experimental Results

Vertically grown crystals vs. horizontally grown crystals.—In general, crystals which are grown by vertical pulling have smaller resistivity variations than crystals grown by the zone-leveling method. In the samples measured, horizontally grown crystals exhibited a 25-50% resistivity variation as compared with about 10% for vertically grown crystals. The degree of variation depends, of course, on the particular growth conditions and may itself vary widely, as shown by a comparison of the resistivity curves of Fig. 5. Figure 5A is a plot of a section from an n-type zone-leveled crystal having a resistivity of about 0.8 ohm-cm. Figure 5B is a typical plot of a vertically grown n-type crystal having a resistivity of about 8 ohm-cm. The resistivity of the horizontally grown crystal varies by about 25%; the variation in the vertically grown crystal is less than 10%. It was extremely difficult to plate the crystal from which the section of Fig. 5B was taken. In some vertically grown crystals the variations were so small that they could hardly be detected by the copper-plating method.

It was found that horizontally grown crystals also differ from vertically grown crystals with respect to striations in the cross-sectional direction. Although the equiresistivity surfaces in all the horizontally grown crystals tested had a concave shape, many of the vertically grown crystals had flat equiresistivity surfaces. The equiresistivity plane in the zone-leveled crystal is not perpendicular to the direction of the growth due to the nonuniformity of the temperature gradient in the direction perpendicular to the direction of growth. Figure 6 shows a copper-plated sample of a crystal in which resistivity variations were purposely introduced and the pattern of the equiresistivity

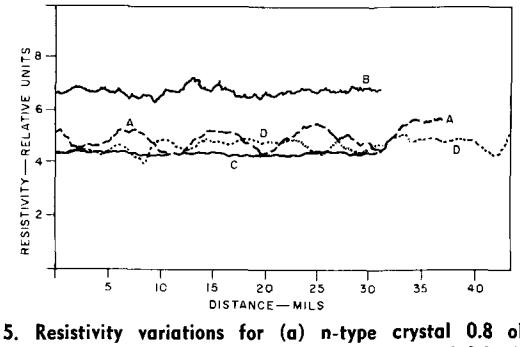

Fig. 5. Resistivity variations for (a) n-type crystal 0.8 ohm-cm horizontally grown, (b) vertically pulled n-type crystal 0.8 ohm-cm, (c) vertically pulled p-type crystal, (d) zone-leveled p-type crystal 2.0 ohm-cm.

plane was changed. At present, the temperature gradients are controlled more closely in the vertical furnace than in the zone-leveling furnaces.

It should be emphasized that no attempt was made during this work to suggest that vertical growing is superior to horizontal growing of crystals as far as minute variations of resistivity are concerned. However, it is to be stressed that, regarding methods used at present, vertical growing crystals do seem to have much smaller resistivity variations as explained above.

A further evidence of the relation between growth conditions and the resistivity variations is demonstrated by the potential scan made on a sample from the crystal of Fig. 6. Figure 7 shows that the distance between two adjacent peaks or valleys is constant and corresponds exactly to the length pulled during one revolution.

P-type crystals vs. n-type crystals.—Measurements made on crystals grown by the zone-leveling method show that variations from the average resistivity value are larger in n-type than in p-type germanium for crystals grown under similar conditions. This difference in resistivity variation can be explained as follows: such growth variables as pulling speed, mechanical vibrations, temperature variations, and variations in temperature gradients result in an effective change in growth rate (6). The segregation coefficient of the common n-type impurities varies very radically with any change in the rate of growth; however, most of the p-type impurities show much smaller changes (7, 8). For example, a comparison of Fig. 5A and 5D shows that the p-type crystals exhibit a 5-10% variation from average resistivity as compared to 30-50% for the n-type crystals. The variations between n- and p-type germanium are smaller in the vertically grown crystals, as shown by a comparison of Fig. 5B and 5C.

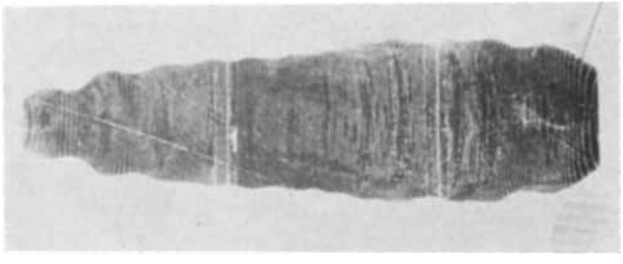

Fig. 6. Copper plating of a crystal in which resistivity variations were purposely introduced and equiresistivity plane was purposely changed.

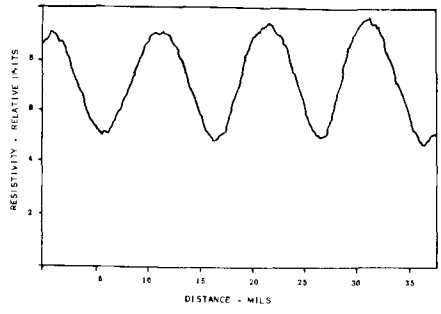

Fig. 7. A scan from a crystal in which resistivity was purposely varied (crystal of Fig. 6).

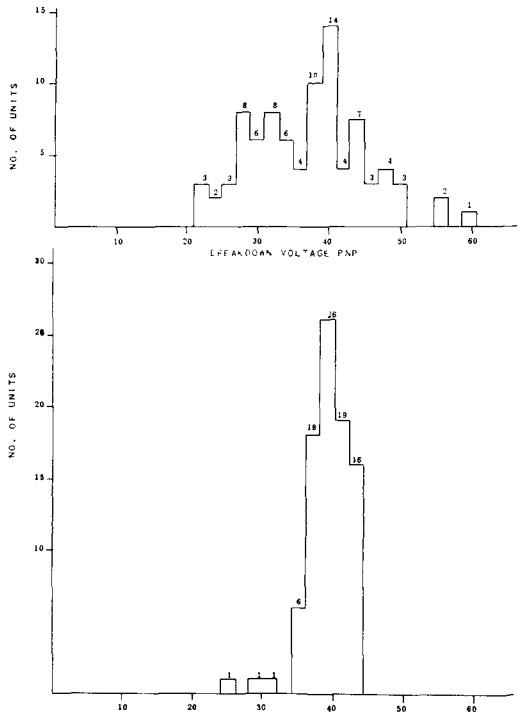

Fig. 8. Collector-to-base breakdown-voltage distribution of n-p-n and p-n-p transistors.

Comparison of breakdown voltage between n-p-n and p-n-p transistors.—Because breakdown voltage in p-n junctions depends mainly on the resistivity of the material at the depletion layer of the junction, large resistivity variations in a crystal result in a wide distribution of breakdown voltages in both alloyed and diffused junctions made from this material, provided production precautions are taken to assure that the breakdown is a bulk breakdown rather than a surface breakdown.

As mentioned previously, resistivity fluctuations are found, in general, to be larger in n-type than in p-type germanium. Thus, the collector-to-base and emitter-to-base breakdown voltages in normal production devices[2] have a much wider range in p-n-p alloyed-junction or diffused-junction transistors than in n-p-n transistors. Figure 8 shows the collector-to-base breakdown voltage distribution of two arbitrarily chosen lots of alloyed-junction. The base material used was with impurity concentration of about 1.8 x 10/15. The resistivity range of the material used was the same for all the lots, and both lots were manufactured by the same general processes. The final etch used was a peroxide etch because it was found to affect breakdown voltage of units much less than electrolytic etch.

A comparison of the two plots shows that the peaks of the distributions are at the same voltage, 40v. The width of the distribution range for the p-n-p transistors (n-type base material) was about 30v, which corresponds to a variation in resistivity of about 30-40% (8). The width of the distribution range for the n-p-n transistors was 10v, which corresponds to a variation in resistivity of about 10-

[2] Data provided by R. Pinto of the Computer Devices Group, RCA Semiconductor and Materials Division, Somerville, N. J.

15%. These values of resistivity variations agree in general with the values mentioned previously. It should be emphasized that the crystals from which the transistors were made did not have variations across the wafers (the so-called "top-to-bottom" variations) that could be detected by the four-point-probe method.

Effect of annealing.—Diffusion of impurities occurs when a crystal having resistivity variations is subjected to long annealing at high temperature. Because the impurities tend to diffuse in the region where an impurity gradient exists, the variations of impurities tend to be suppressed.

The effect of the annealing was determined by means of measurements of a section from an n-type 0.8-ohm-cm zone-leveled crystal which was divided into two parts. One of the portions was annealed for 130 hr at about 850°C; the other served as a control. Figure 5A shows typical resistivity variations in the nonannealed crystal of more than 25% with respect to the average resistivity as measured by the four-point-probe method. The period of the variations is about 9 mils. The annealed sample shows less than 10% variations with a very long period, the length of which is difficult to determine.

The breakdown voltages of alloyed-junction diodes made from the two parts of the crystal were also compared . The processes of the diode preparation were chosen to have as little effect as possible on breakdown voltage. The distribution range of the breakdown voltages of the units made of the annealed portion was narrower than that of the nonannealed portion.

Other processes occurred in addition to the smoothing out of the resistivity. An "out"-diffusion which apparently took place caused resistivity on the surface to increase from 8 to 27 ohm-cm. The resistivity of samples taken from the interior of the annealed portion were in the range of 1.4 to 1.8 ohm-cm. This behavior may possibly be attributed to an "in"-diffusion of impurities introduced into the systems either from the quartz container or by the acids and solvents used to etch and clean the crystals (18). The introduction of impurities from the acids and solvents used in crystal processing may also explain why the bulk lifetime of the material was reduced from about 60 μsec to a fraction of a microsecond as a result of the annealing process. Thus, it is unlikely that annealing can be used to remedy undesired resistivity variations.

Discussion

Explanation of selective copper plating

Camp (4) and Silverman and Benn (11) mention a possible explanation of the selective-plating mechanisms. These explanations, together with Uhlir's (12), and Brattain and Garrett's (13) discussions of the electrolyte-germanium interfaces, explain the initial phase of the plating, *i.e.*, why lower-resistivity sites plate preferentially. As to the subsequent plating phase, the following explanation is suggested. The sites which become copper plated first have a greater tendency to relinquish electrons to copper ions. Once the initial sites become activated and a small amount of copper is deposited on them, they become small copper cathodes in the copper sulfate bath. The measured activation voltage for copper deposition on germanium was found to be appreciable (several tenths of a volt), whereas copper deposition on a copper cathode requires no overvoltage (14). By use of a high-voltage pulse of short duration, the selectivity of copper deposition on copper is enhanced much more than on germanium because activation is time dependent as well as potential dependent (15). The thickness of the coating therefore does not indicate the magnitude of resistivity differences between the sites.

Effects of Variations on Devices

Breakdown voltage is only one of the parameters in a device which depends on the impurity concentration in the material used for the device. Others are, for example, saturation current in the p-n junction and current ratios in a tunnel diode. Impurity gradient in the base material may result in undesired built-in fields which can change the characteristics of a device.

Because uniformity of impurity concentration is a very desirable property for many devices, an effort should be made to provide proper growth conditions to minimize minute resistivity variations.

Acknowledgment

The author wishes to acknowledge the help of many associates. He is specially indebted to H. P. Kleinknecht for advice and fruitful discussions, to E. Jordan who worked on the initial phase of the experiments, to P. Lintz for growing special crystal material, and to A. Frey for assistance in the experimental work.

Manuscript received Feb. 16, 1961; revised manuscript received May 28, 1962. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Epitaxial Growth of Silicon

C. H. Li[1]

General Instrument Corporation, Newark, New Jersey

ABSTRACT

An improved and reproducible method for epitaxial growth of silicon is described. The equipment is compact, simple, reproducible, and has an improved gas-mixing system. The process allows shorter time for preparing the first run and making each subsequent run. The layers produced are planar and uniform from center to edge. Under 500X magnification, they show no pits, oxides, pyramids, waviness, growth scales, or crystal structures. A description is given of the characteristics of diodes and transistors made from this material. Some results of statistically designed experiments on the growth parameters and their interactions are given.

An improved epitaxial process for silicon growth is presented here. The equipment, the process, and the products are discussed in some detail.

We shall first compare two vertical systems and show how some common problems are approached, such as temperature uniformity, gas flow, and gas mixing. Reproducibility of thickness and resistivity of grown layers are next considered. Finally visual defects and some device characteristics are examined.

The control of silicon epitaxial growth has generally been considered difficult. The growth parameters are known to interact in a complex manner. Systematic and reliable results on the significance of various parameters and their interactions are not frequently published.

This paper also gives some results of statistically designed and controlled experiments. The experimental errors or measuring precisions for layer thickness and resistivity were first determined, each from over 50 tests. The growth parameters then could be compared both qualitatively and quantitatively, as shown in the paper. Each conclusion for these comparisons was arrived at from the average of several controlled tests.

The method to be described is similar to the one originated at Bell Telephone Laboratories (1). Basically, the method consists of the reduction of silicon tetrachloride by purified hydrogen on heated silicon wafer substrates. More details of the process, and its modifications in our case, are described later in this paper.

The Two Systems

Figure 1 shows the comparison of two vertical systems. Figure 1a is an early model and is similar to the one described by Theuerer; Fig. 1b is the improved model.

With reference to Fig. 1a, the hydrogen enters at the left side through a flexible stainless steel tubing, passes through a Deoxo unit, a valve, and a first glass trap filled with molecular sieves and immersed in liquid nitrogen contained in a first Dewar flask. The purified hydrogen then bubbles through liquid silicon tetrachloride in a second glass trap kept at −30°C by a mixture of dry ice and alcohol in a second Dewar flask. The second trap has, on its top, a valve system consisting of a three-way valve and a two-way valve to allow switching the hydrogen gas either directly into the cylindrical reaction chamber or indirectly through the liquid silicon tetrachloride first and then into the reaction chamber. In the reaction chamber there is a silicon pedestal to be heated to 1150°C by an induction coil outside the reaction chamber. The heating is started by a molybdenum coil on the pedestal. The spent gases are exhausted from the reaction chamber through another liquid nitrogen trap to catch

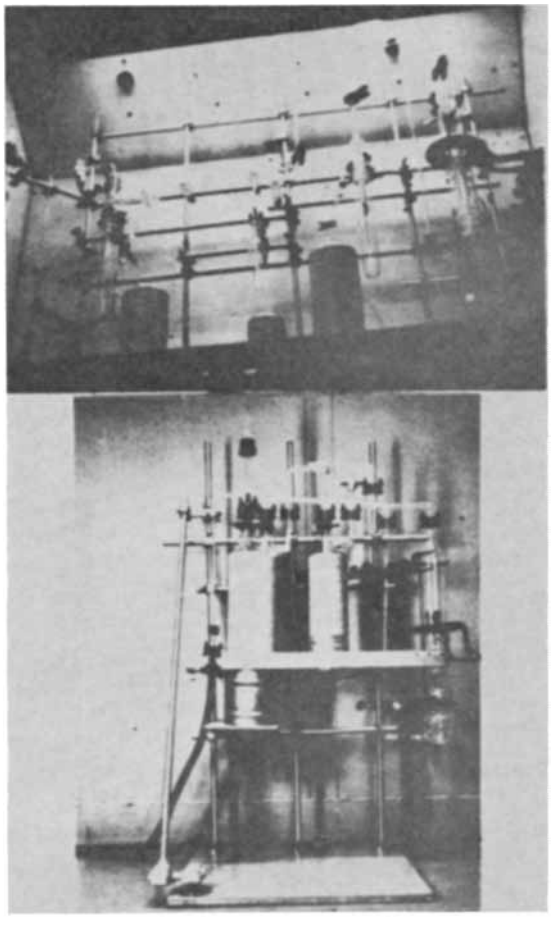

Fig. 1. The two small epitaxial systems: (a, top), an early model, (b, bottom), the improved model.

[1]Present address: Grumman Aircraft Engineering Corporation, Bethpage, N. Y.

any unused silicon tetrachloride. The remaining hydrogen then passes to an exit where it is burned off.

A normal run for transistor-grade wafers consists of a flushing period of 20 min, a deposition period of 10 min, and a cooling period of 20 min. The average thickness of the deposited layer is about 0.8 mils.

Figure 1b shows the later or improved model. It contains all the essential parts, but is more compact and rugged. The glass parts contain three interchangeable traps, a valve system, a flowmeter, five connecting tubes, and a reaction chamber. The total number of glass parts is 11, compared to 17 for the earlier model. Except for the quartz reaction chamber, all these parts are made of Pyrex glass. The total internal volume of the improved system is about 1450 cc compared with 1840 cc for the earlier model.

The smaller volume, internal area, number of parts, and number of ball and socket joints appreciably reduce the system contamination. This condition leads to more reproducible products.

All the parts of the improved system are mounted approximately in a single plane, with all the joints at convenient eye level for improved visibility. The whole system is mounted on an 18 x 18 in. board, occupying less than one third of the hood space required by the earlier system.

The improved system is unitized. To change a system, a single operator merely has to disconnect two clamps, one at the gas flowmeter and one at the reaction chamber. He can then lift the whole system out, replace a precleaned system, make the two clamp connections, and resume operation in a few minutes' time. The system downtime is therefore negligible.

The set-up and running time for the improved system is relatively short because of the small number of parts, compact arrangement, and reduced internal volume. An ice-water mixture is used rather than the alcohol-dry ice mixture, to control the temperature of liquid silicon tetrachloride. This ice-water mixture yields 0°C without adjustment.

Material Preparation

The substrate wafers for this work were normally N^+ type with resistivities ranging from 0.001 to 0.003 ohm-cm. They were prepared from 12-mil slices cut from ⅞ in. diameter, arsenic-doped Czochralski crystals, which were grown at the General Instrument Laboratory or bought from outside vendors, such as Merck or Texas Instrument. The cut slices had <111> orientations to within ½°, as determined by x-ray diffraction methods. The dislocation density of these slices were less than 1000 pits/cm^2, as revealed by a modified Dash etch.

Lapping of cut slices was carried out on a Lapmaster machine with silicon carbide particles. Mechanical polishing was finished on a Shuron polisher with Linde type 0.05B alumina, which has particle sizes of 0.05μ. The finished wafers, about eight mils thick, were visually inspected at 10X and 100X under vertical and inclined illumination. No scratches, pits, or other defects should be visible. Defective wafers may have to be repolished.

Chemical etching was not used to reduce wafer thickness or to remove damaged surface layers, except on some special test runs such as are described in connection with Table II. These wafers were chemically etched with a CP4 etching mixture. Instead of chemical etching, the mechanically polished wafers were steam-oxidized at 1200°C for 15 min with humidified oxygen gas. The oxidized wafers were stored in clean dishes until ready for use, when the oxide skin was removed by a brief HF etch. This oxidation step was designed to remove (or anneal) deformed silicon and other surface impurities of irregularities. This step also helped keep the wafer surface clean and uniform, and therefore give more reproducible results.

The silicon tetrachloride, from Anderson Chemical Company of Weston, Michigan, was used without purification. The volume of the liquid consumed for each filling of the Pyrex vacuum traps (38 mm diameter and 250 mm long) was either 16 ml (for no-bubbling type of gas mixing as described below) or 32 ml (for bubbling type of gas mixing).

Temperature Distribution

A uniform temperature across the substrate is desirable for uniform deposits. In general, a water-cooled reaction chamber gives steep temperature gradients. For this and other reasons, the reaction chambers are not water-cooled.

Even with an air-cooled reaction chamber, nonuniform temperatures still exist across the substrate wafer. The difference between the center and edge of the wafer has been variously reported to be between 10° and 35°C. It has been suggested that the use of metal supports would equalize the temperature. This problem has been approached from a different angle.

Tests were run to determine this temperature difference at various flow rates and induction coil positions. The silicon pedestal used here was about ⅞ in. in diameter and 2 in. long. The induction coil was of a pancake type placed either flush with the bottom or top surface, or in the middle, of the pedestal. Twelve temperature readings were taken at each combination of flow rate and coil position. Of these twelve readings, five were at the top pedestal surface, giving an average temperature difference, ΔT, or the temperature at center minus that at the edge on the top pedestal surface.

To optimize the temperature distribution, two criteria were used: (*a*) the temperature difference $\Delta T = Tc - Te$ should be nil, and; (*b*) the highest temperature should occur at the top pedestal surface.

In general, a higher gas flow rate reduced the temperature difference and the over-all temperature of the top pedestal surface. Coil position had, however, a much greater effect on temperature than gas flow rates. Average temperature differences at various coil positions are shown in Table I.

These averages suggested that if the pancake induction coil was put at the bottom plane of the

Table I. Temperature differences vs. coil position

Coil position	Temperature difference, $\Delta T = I_c - I_e$, °C
Bottom	+8.5
Middle	+2.1
Top	−17.5

pedestal, the top pedestal center was hotter than the edge, since in this case heat was generated at the bottom portion of the pedestal and there was appreciable cooling at the pedestal surface. If the induction coil was located at the top plane of the pedestal, the pedestal edge was overly heated by the RF energy; the center was therefore colder. A better coil position would be somewhere near the middle of the pedestal. To be more specific, by interpolation of the averages, it was found best to put the coil about ¾ in. below the top surface of the 2 in. pedestal, so that practically uniform temperature distribution across the top pedestal surface could be achieved. This coil position had the added advantage that the top portion of the pedestal was kept relatively hot, thereby reducing silicon deposition at unwanted areas.

Gas Flow

Some growth defects are found to relate to the gas flow. Therefore gas flow pattern was studied. The General Instrument Research Laboratory devised a method by which artificial fogs were produced in the reaction chamber. This was done by replacing the connecting tube between the silicon tetrachloride trap and the reaction chamber with another tube having an identical shape but also having a tiny water reservoir. The evaporating water then reacts with silicon tetrachloride to form a fog. Figure 2 shows the results of fog formation, taken over a time interval of 15 min. The build-up of fog could be watched progressively from the top left toward the bottom right.

Figure 3 is a sketch of the fog seen in detail. A cloud was observed to build up directly above the hot pedestal. This cloud was lens-shaped, being thicker at the center and thinner at the edge, possibly because of the gas flow in the annular space between the pedestal and reaction chamber. Further, this cloud was relatively stable in position and shape, but thickened with increasing gas flow rates. A moving eddy and isolated solid particles also were seen above this cloud. Both the eddy and the isolated particles settled down and disappeared in the same cloud. This gas dynamics approach aids in the study of the reaction mechanism and is the subject of a paper to be published elsewhere.

Layer Thickness

Next, thickness measurement and reproducibility are discussed. Layer thickness is measured simply be scribing and breaking the deposited wafer, staining with a mixture of nitric, acetic, and hydrofluoric acids (5:24:3 by volume), and measuring the thicknesses on the broken sections at 100X. This method of thickness measurement has been correlated with one using infrared interference methods.

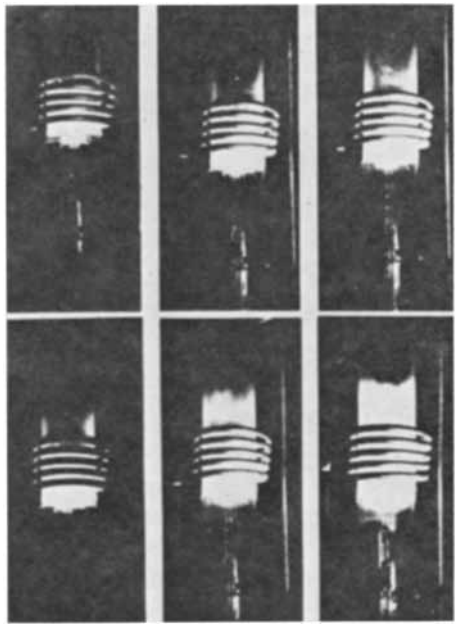

Fig. 2. Pictures of fog formation

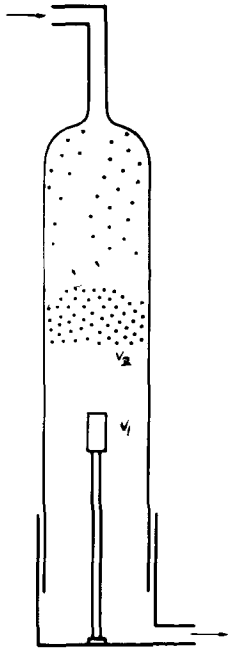

Fig. 3. Sketch of fog formation

To further check the precision of measurement, a number of deposited wafers were broken into quarters and thicknesses measured at ten fixed locations on each quarter, five on each of the two perpendicular edges. The two readings on the same location but different sides of the broken edge gave the desired precision, *i.e.*, 6.5%. Readings between different edges measured thickness reproducibility across the wafer. It was found that the wafers broke evenly except at the extreme outer edges, where complex fracture patterns unfavorably changed the precision to 10.4%. The practice was therefore not to read these edge thickness values. Any two readings on the broken section, except at the edges, checked within the reading error. Their

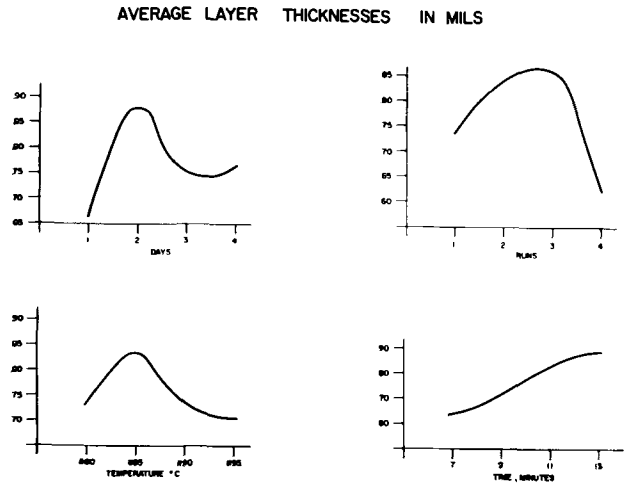

Fig. 4. Experiment on layer thickness

average thus gave an estimate of the layer thickness. Unless the two readings differed appreciably, no additional readings on layer thickness were taken.

Within the measuring precision, no significant thickness variation across the deposited wafer was detected. Temperature uniformity contributes to this desirable condition.

In an early experiment, four epitaxial wafers were made on each of four consecutive days at four different temperatures and times. The first run started with a thoroughly cleaned system on the first day, and with a cleaned reaction chamber and pedestal for the first run of each day. Figure 4 gives a summary of the results. Deposition time, among the four variables, appeared to have the greatest effect. The layer thickness increased nearly proportionately with the deposition time, with a slight leveling off of average rates at long deposition times. Deposition temperature (uncorrected) was next in importance, the deposition rate reaching its maximum at a medium temperature. Further, the layer thickness reached maximum on the second and third run of each day, and also on the second of the four days. This last conclusion seems to suggest that the system, the reaction chamber, and the silicon pedestal needed some decontamination period to operate at peak efficiency.

Table II shows the results of another experiment in which layer thickness was measured on the front side (facing gas) t_f, and at the edge of the back side (contacting pedestal), t_b. Each figure given represents the average of four (on specimen preparation and flow rate) or two (on temperature) readings. From these two thicknesses, the thickness ratios t_b/t_f were calculated. The specimen preparation, gas flow rates, and deposition temperatures were changed in this experiment. The (CP4) etched wafers had smaller layer thicknesses than lapped wafers, the difference being 24% in t_f and 16% in t_b. High flow rates increased the t_f by 61%, decreased the t_b/t_f ratio by 41%, but did not appreciably affect the t_b. The back side thickness also increased regularly with deposition temperature, while t_f reached a maximum, and the thickness ratio a minimum, at an intermediate temperature. These results, in view of the measuring precision of about 6.5%, suggest that the mechanisms of silicon deposition on the front and back side are different.

The data in Table II would also discourage the determination of layer thickness by weighing or the micrometer before and after the deposition, because the deposited thickness on the unwanted backside edge (which occupies large areas) may be close to four times the frontside thickness. The error of thickness measurement by weighing or the micrometer may, under unfavorable conditions, reach several hundred percent and become unsatisfactory.

Gas Mixing

Two types of gas mixing or silicon tetrachloride pick-up methods have been used: the bubbling method, and the nonbubbling method. In the bubbling method, purified hydrogen is bubbled through the liquid silicon tetrachloride. In the nonbubbling method, the purified hydrogen is merely passed over the liquid surface. The same stock glass traps could be used in either method, depending on how much liquid was added to the trap.

Table III shows the results of calculations of the number of moles of silicon tetrachloride available per minute at different flow rates for the theoretical or equilibrium cases and the two actual cases with the bubbling and nonbubbling methods. The nonbubbling method gives a fairly constant number of moles of silicon tetrachloride per minute, whereas the bubbling method does not.

There are other advantages of the nonbubbling method over the bubbling method. In the nonbub-

Table IV. Gas mixing and flow rates vs. layer thickness in mils

Flow rate, cc/min	Thickness deposited, mils Bubbling	Nonbubbling
950	0.95 ± 16%	0.42 ± 17%
1740	1.30 ± 7%	0.42 ± 7%
2450	1.11 ± 2%	0.41 ± 9%

bling method, the evaporating surface of the liquid tetrachloride is always flat and smooth and has a constant area and fairly constant surface temperature. In the bubbling method, the same surface is turbulent and bubbling and has no defined or stable surface area or evaporating temperature. There is always a large and unknown variable temperature gradient across the insulating bubbling layer. This condition makes the trap temperature almost meaningless. There is also an erratic bursting of bubbles giving rise to liquid droplets that are carried downstream to strike and re-evaporate at variable points along the walls at unpredictable temperatures. These droplets of liquid silicon tetrachloride are known sources of growth defects.

Table IV gives the summarized results on the effect of gas mixing and flow rates on layer thickness and thickness reproducibility. These results suggest that increasing gas flow increases thickness reproducibility. Also, in the nonbubbling method, the layer thickness is independent of the flow rate; whereas in the bubbling system, maximum deposition rate is reached at medium flow rates.

It has been suggested that in the bubbling method a system could be designed to trap all liquid droplets. Such a system would, according to our experience, suffer from some disadvantages such as:

1. It requires elaborate traps and filters.
2. It introduces contaminants through the extra filters, traps, joints, and internal surfaces.
3. The efficiency and operation of, and contamination from, these traps or filters are variable and strongly time-dependent.
4. Trapping wastes source liquid and requires more frequent filling of source containers and disturbing of the stable growth conditions.
5. It requires exact temperature controls on the source containers, traps, filters, and various connecting tubes. Still, the boundary layers near the walls of the containers or tubes may have temperatures, velocities, and concentrations entirely different from the inner layers, even at a given instant.
6. It complicates the systems, which are liable to be more variable from one to the other. The product reproducibility also suffers as a result.

Resistivity

Table V shows the typical resistivity variation within wafers. Here, the resistivity of each wafer is measured at six fixed positions, using the four-point probe method. From each set of six readings is obtained the average resistivity, the standard deviation, and the coefficient of variation (or the ratio of standard deviation to average resistivity). Within the wafer, these coefficients varied from 2 to 11%, with an average of 8%. These variations can be reduced by improved growth conditions, as shown below.

Table VI shows that the coefficient of variation in thickness and resistivity could be as high as 46% and 25% respectively on days when the gas valves or glass joints were leaking. Pedestal x was notably worse than the other three. Such variations were significantly greater than the average variations of 6.5 and 8%, respectively.

Designed experiments on resistivity (average 3.5 ohm-cm) have yielded the following lists of critical variables in order of decreasing importance:

To increase resistivity: 1. Increase flow rate; 2. nonbubbling method of gas mixing; 3. optimum deposition temperature; 4. clean substrate surface; 5. increased preheat time.

To decrease resistivity variation within wafers: 1. clean substrate surface; 2. nonbubbling method of gas mixing; 3. increased flow rate; 4. optimum deposition temperature.

Growth Defects

Figure 5 shows the magnified surface of a number of typical wafers after deposition. The wafer in Fig. 5a had a smooth surface. Figure 5b shows a wafer with triangular pits. A higher magnification of such pits is shown in Fig. 5d. These pits are caused by a dirty pedestal or reaction chamber.

Figure 5c shows a wafer having a polycrystalline growth of silicon, purposely deposited on an oxidized surface.

Figure 5e shows silicon deposition on a scratched surface. The gas flow in this case was directional, so that flow lines appeared only on the downstream side of the scratch.

Figure 5f shows the pyramidal silicon growth produced at relatively low deposition temperatures.

Another type of defect appears as a wavy surface

on the wafer. This can be eliminated by proper substrate preparation and controlled gas flow rates.

Device Characteristics

On some of the wafers with n type layers deposited on n^+ substrates, 16 x 32 mil aluminum rectangles have been evaporated through metal masks. The aluminum was later alloyed in at 800°C for different periods of time to form alloyed diodes. The capacitance of these diodes has been measured at different reverse voltages. Within certain ranges, change of alloying time by even a factor of four did not appreciably change the capacitance. The slope of the capacitance *vs.* voltage plotted on a log-log scale had a typical value of −1/2.5, suggesting that these alloyed junctions have characteristics somewhere between step and graded junctions.

These epitaxially grown materials have been used to make small and large-area planar and mesa diodes and transistors. Both the forward and reverse characteristics of the devices are generally excellent. Figure 6 shows a typical planar epitaxial microdiode. This diode was a gold-diffused fast-switching type. It had a junction only 5 mils in diameter. The left side of the figure shows the forward characteristics. The scale is 100 ma per vertical division and 0.2v per horizontal division. The diode thus carries 60 ma at 1v of forward voltage.

The right side of Fig. 6 shows the reverse characteristics. The diode is shown to break down very sharply at 100v. Detailed measurements showed that under 60v reverse bias, the leakage current was only 5 x 10^{-10} amp. Further, this leakage current was maintained after the diode was subjected to thermal cycling and humidity tests. The switching time of the diode was less than two nanoseconds.

Epitaxial Growth of Silicon by Hydrogen Reduction of $SiHCl_3$ onto Silicon Substrates

J. M. Charig and B. A. Joyce

Caswell Research Laboratories, Plessey Company, Limited, Towcester, Northants, England

ABSTRACT

Epitaxial films of silicon have been grown on silicon substrates by hydrogen reduction of $SiHCl_3$. Reaction kinetics have been investigated and an over-all reaction mechanism suggested, assuming reduction to occur on the substrate surface. Electron micrographs and diffractograms of growing layers have been obtained in an attempt to determine the nature of the growth process. Preliminary results indicate that this occurs initially by the formation of individual nuclei rather than by continuous film formation, but the nucleation process is apparently not propagated continuously.

Experimental methods for the epitaxial growth of silicon by the hydrogen reduction of silicon halides have been described by several authors (1-3), and quantitative results have been presented by Theuerer (2) and Wajda and Glang (3) for $SiCl_4$ and $SiHCl_3$, respectively. The results of the two sets of authors show many differences, and only the former attempts to interpret them in terms of

a reaction mechanism which, he suggests, involves the adsorption of $SiCl_3$• onto the silicon substrate, followed by reduction and desorption of HCl, with an over-all activation energy of 37 kcal/mole.

The purpose of this paper is to present some kinetic data for the hydrogen reduction of $SiHCl_3$ on a silicon substrate, from which a reaction mechanism is postulated, and also some preliminary observations on experiments carried out to determine the growth mechanism. Electron micrographs and electron diffractograms of the grown layers have been obtained after various time intervals in the very early stages of growth and have revealed what are apparently individual nuclei distributed on the surface before complete coverage has occurred.

Experimental

The apparatus used was essentially similar to that employed by Sangster *et al.* (1). Hydrogen at a flow rate of 30 ml/min was passed over refluxing $SiHCl_3$ to ensure saturation, and the resulting gas mixture was stripped down to a known concentration in a thermostatted condenser, after which it was further diluted with hydrogen to give the required partial pressure of $SiHCl_3$ in the reactor, and a total flow rate of approximately 1.5 l/min. Partial pressure values calculated from vapor pressure and flow rate data were checked experimentally by determining the gas phase $SiHCl_3$ concentration and were found to be correct to within ± 5%. The hydrogen was purified by passing through a catalytic deoxygenating unit, and a 5A molecular sieve to remove water vapor and other condensable gases. The substrate was supported vertically from its ends with tantalum tapes and heated by a direct resistance method so that it was the hottest part of the system and silicon was not deposited preferentially on the walls (Fig. 1).

The substrates used were bars 2 mm x 7 mm x 4 cm long, and in all of the kinetic experiments the 7 mm face was the {110}, but both {100} and {111} faced substrates were also used in the growth mechanism work. Before growth the substrates were lapped on 15μ alumina and chemically polished to a mirror finish in an etch containing nominally 3 parts 40% HF, 6 parts 70% HNO_3, and 2 parts 60% acetic acid. Final oxide removal was carried out in the reactor by treating in hydrogen for 15 min at a temperature in excess of 1260°C.

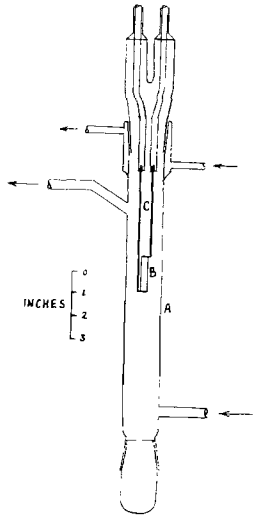

Fig. 1. $SiHCl_3$ reactor: A, quartz tube; B, silicon substrate; C, tantalum power leads.

Since it has been indicated (2) that boron compounds may influence the rate of this reaction, kinetic measurements were confined to n-type layers grown on n-type substrates. The substrate resistivity was 0.1 ohm-cm in each case, and the layers were all approximately 1 ohm-cm. In order to measure the layer thickness the specimen was cleaved or bevelled and the layer delineated by a pulse staining technique reported elsewhere (4).

The procedure for each run was as follows: the apparatus was evacuated and then flushed with hydrogen, the stream containing $SiHCl_3$ vapor initially bypassing the reactor. The substrate was heated for 15 min at a temperature in excess of 1260°C to ensure oxide removal, after which, with the stripping condenser set to the appropriate temperature, the $SiHCl_3$ stream was diverted into the reactor and at the same time the substrate temperature set to the required value as measured with an optical pyrometer calibrated at the melting point of silicon. The duration of the run was timed with a stopclock and terminated by again diverting the $SiHCl_3$ and allowing the substrate to cool in hydrogen.

Kinetic Measurements

The two factors which have been investigated are (*a*) influence of substrate temperature on growth rate of the epitaxial layer for a constant partial pressure of $SiHCl_3$ in the reactor and (*b*) the effect of varying the partial pressure of $SiHCl_3$ for a constant substrate temperature. In both cases the flow rates of hydrogen were held constant, and partial pressure was controlled by the temperature of the stripping condenser.

The rate of the reaction was measured as the growth rate of the epitaxial film, and in a system of this type reaction rates cannot of course be considered as absolute, but for a constant set of conditions experimental values were reproducible to within ± 10% and the general shapes of the curves were also reproducible. Errors in thickness measurement of the film and temperature control of the substrate probably accounted for most of the deviations found.

Wajda and Glang (4) report differences in growth rate along the length of the substrate depending on the geometry of the reactor. This was not observed in the system employed in the work reported here, but some small differences were observed on opposite (parallel) faces of the substrate when it was not positioned centrally in the reactor. Measurements were therefore made on both faces, and the mean thickness determined.

Deposition temperature.—The dependence of deposition rate on substrate temperature for a constant flow rate of hydrogen and partial pressure of $SiHCl_3$ is shown in Fig. 2. Over the temperature range 1110°-1220°C a normal Arrhenius plot is obtained, giving an over-all activation energy for the process of 22 kcal/mole, but above this, growth rate falls

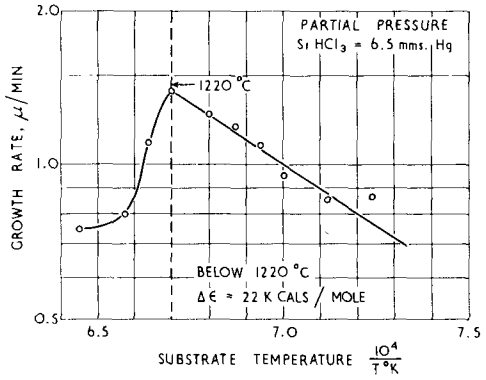

Fig. 2. Temperature dependence of layer growth rate

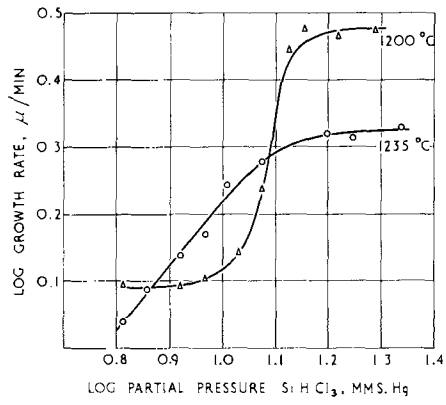

Fig. 3. Effect of $SiHCl_3$ partial pressure on layer growth rate

with increasing temperature. This is contrary to results obtained on $SiHCl_3$ by Wajda and on $SiCl_4$ by Theuerer. The latter followed a normal Arrhenius relationship over the whole temperature range considered (900°-1300°C) with an over-all activation energy of 37 kcal/mole, while the former showed little variation with temperature between 1100° and 1200°C, but this was attributed to the particular design of the substrate heater and gas flow pattern in the reactor.

Assuming the reduction reaction to occur by a heterogeneous mechanism on the substrate surface, then, of the steps which could be rate controlling, gaseous diffusion of the reactants or products is ruled out, since it is not an activated process. This leaves adsorption of the reactants, surface reaction followed by desorption of gaseous products, or in this case, the surface diffusion of silicon formed on the substrate as the possible slow steps in the over-all reaction. If it is assumed, however, that the equilibrium density of this self-adsorbed layer remains sensibly constant, surface diffusion cannot be the rate-determining step since under these conditions it is an equilibrium process. From the available data it is not possible to decide between adsorption and reaction with desorption as the slow step. A possible explanation of the maximum is that the total amount of chemisorption possible on the {110} surface decreases above a temperature of approximately 1220°C. This may be due either to a reduction in the length of time an adsorbed radical is retained on the surface before re-evaporation or reaction can occur, or to a reduction in the actual number of available surface sites.

$SiHCl_3$ *partial pressure.*—The influence of $SiHCl_3$ partial pressure on growth rate was investigated at substrate temperatures above and below the maximum in the growth rate-temperature curve. Results obtained are shown in Fig. 3, and it may be seen that in each case the growth rate reached a limiting value as the partial pressure of $SiHCl_3$ was increased. Since for the same flow conditions the process was found to be activated, it may be concluded that it was a reaction rate and not a mass flow effect which was measured. There are two main possibilities concerning the over-all nature of the reaction. (i) Reaction occurs between an absorbed $SiHCl_3$ molecule or radical and an adsorbed hydrogen molecule or atom (Langmuir-Hinshelwood mechanism), and (ii) reaction occurs between an adsorbed molecule and a molecule coming directly from the gas phase (Rideal mechanism). This gives rise to two alternatives depending on whether a $SiHCl_3$ radical is adsorbed and reaction occurs with a hydrogen molecule from the gas phase, or a hydrogen atom is adsorbed which reacts with a gaseous $SiHCl_3$ molecule.

If a Langmuir-Hinshelwood mechanism is followed, the rate will pass through a maximum as the pressure of either reactant is varied, while the rate will reach a limiting value if a Rideal mechanism applies. The results obtained therefore indicate one or other of the Rideal mechanisms to be the most probable over-all course of the reaction. At the start of the process, hydrogen alone is present over the substrate, and even during the course of growth it is present in considerable excess, but from the measured rate dependence on the partial pressure of $SiHCl_3$ it appears that, if the hydrogen is initially present as a chemisorbed layer on the surface, it is rapidly displaced as soon as a partial pressure of $SiHCl_3$ exists, particularly at the higher temperature (1235°C). At the lower temperature (1200°C) however, hydrogen chemisorption may be responsible for the small rate of change of reaction rate at low $SiHCl_3$ concentrations. Thus the rate curves indicate that essentially $SiHCl_3$ radicals are chemisorbed and react with gaseous hydrogen molecules.

Since it is not possible to measure reaction rates and reactant concentrations in terms of the same variable it is not possible to measure absolute orders of reaction (other than zero order). However Fig. 3 shows that at both temperatures the order becomes zero with respect to $SiHCl_3$ as its partial pressure increases and presumably a monolayer is formed. The relative variations of order with increasing initial concentrations of $SiHCl_3$ at the two temperatures are also evident, and over the linear portions the order at 1200°C is 2.8 times greater than at 1235°C. This difference presumably arises either because of the relative extent of hydrogen chemisorption, or because of the over-all amount of chemisorption possible at the two temperatures.

Influence of Kinetic Parameters on Layer Perfection

We have observed that at substrate temperatures above 1175°C film perfection is, macroscopically,

very high, irrespective of the partial pressure of $SiHCl_3$. As the temperature is reduced, however, imperfections of the type seen in Fig. 10 begin to appear. (This optical micrograph also shows the development of a {112} edge facet.) These imperfections eventually lead to regions of polycrystalline growth, but their onset and concentration with respect to temperature can be lowered by a reduction in trichlorosilane concentration. Below 1000°C it is very difficult to obtain even an imperfect single crystal layer, although the partial pressure of $SiHCl_3$ may be considerably less than 1 mm Hg. This of course suggests that it is the surface mobility of silicon atoms which is essentially responsible for single crystal layers, even when growth involves a chemical reaction.

Growth Phenomena

Epitaxial overgrowths of various metals and compounds evaporated onto an assortment of substrates such as other metals, the alkali halides, and mica have been studied for a number of years (5). Direct observations of the nucleation and growth have been made by evaporating and condensing thin layers actually in the electron diffraction camera and electron microscope (6).

Growth resulting from chemical reactions of mixed gases at solid substrate surfaces at high temperatures has received comparatively little attention.

Observations and Discussion

By using the resistive heating technique already described anomalous growth behavior can be observed at magnifications up to 100X by stereoscopic microscope using long working distance objectives focussed through the clear quartz walls of the reaction tube.

Platinum-carbon replicas (7) of substrate surfaces after chemical polishing and hydrogen etching have been compared with those from surfaces exposed to known growth conditions for different lengths of time (10 sec or more). Each surface so treated has been examined by glancing angle electron diffraction beam to assist in interpretation of the replica observations. The overgrowths prepared for electron microscopy (10 and 30 sec growth) were essentially featureless when examined in the optical microscope. They were grown at 1250°C under conditions equivalent to steady-state growth rates of 0.6-1.2μ/min. Preliminary treatment of the substrate was confined to exposure to dry hydrogen (2 liters/min) for 10 min at 1250°C.

All the layers cooled rapidly when the power supply to the specimen was switched off.

The smooth, featureless surface of a chemically polished {110} silicon substrate is shown in the electron micrograph, Fig. 4. Exposure of a similar substrate to dry hydrogen for 10 min at 1250° or 1300°C produced no detectable change in appearance. The diffraction pattern, Fig. 5 from the surface of the specimen illustrated in Fig. 4 consists of clearly defined Kikuchi lines only, indicating a high degree of crystal perfection and confirming the

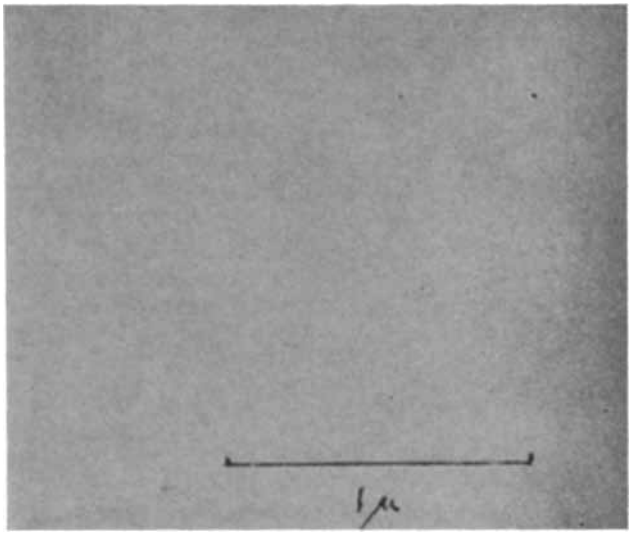

Fig. 4. Electron micrograph of Pt-C replica of chemically polished silicon substrate. {110} surfaces. Magnification 40,000X.

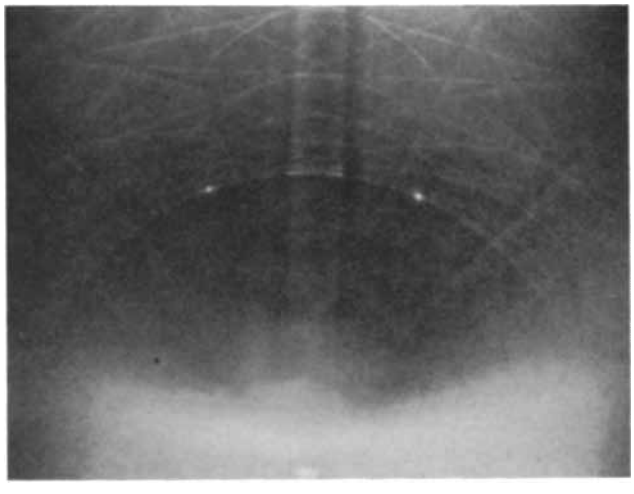

Fig. 5. Diffractogram corresponding to Fig. 4

essentially flat surface revealed in the electron micrograph.

Electron micrographs of replicas of the {110} surfaces of grown layers are shown in Fig. 6-8. After 10 sec growth (Fig. 6) the surface has become covered with a layer of discrete islands typically about 500Å across. After 30 sec, Fig. 7, the islands are still apparent but less clearly defined, the surface having a generally wavy appearance. Electron micrographs from the surfaces of thicker layers (>5μ) do not show the small islands but reveal very fine channels or ridges of a somewhat wavy nature (Fig. 8). Examination of {111} and {100} surfaces after 10 sec growth revealed islands similar to those on the {110} surfaces.

It would seem probable that growth commences by a nucleation process which leads to formation of the small islands observed. (Fig. 6). These islands gradually coalesce to form a relatively rough surface as illustrated in Fig. 8. The roughness of the surface is not, however, the only significant feature relevant to the growth morphology. A specimen with a 30μ deposit was removed from the reaction chamber and fractured. Half was then returned to the reactor for regrowth; 10 sec further growth

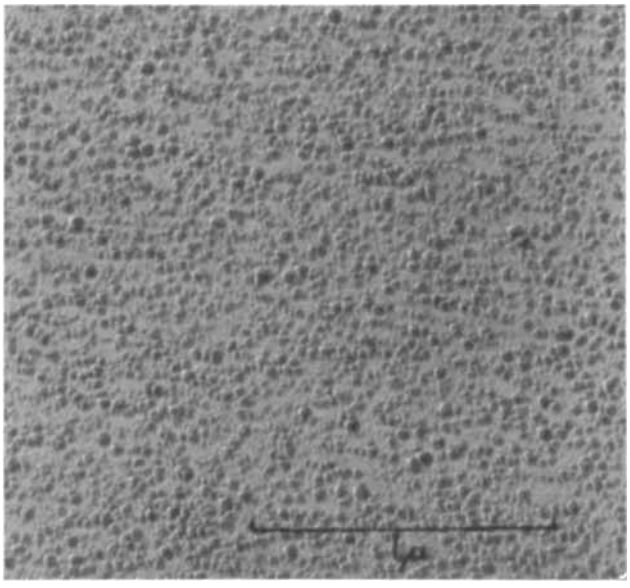

Fig. 6. Electron micrograph of Pt-C replica of epitaxial silicon layer on {110} surface after 10 sec growth at 1250°C. Magnification 40,000X.

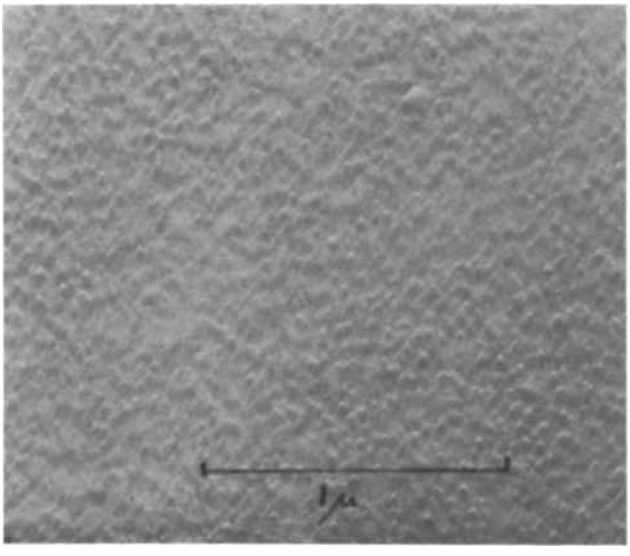

Fig. 7. As Fig. 6 but for 30 sec. Magnification 40,000X.

again resulted in the occurrence of the random islands. This suggests that the formation of individual nuclei when growth commences may be influenced by some residual surface contamination such as an incomplete oxide network. Any such contamination will be on a small scale, none having been detected by electron microscopy or diffraction.

Precise interpretation of the glancing angle electron diffraction patterns has not been attempted. The pattern shown in Fig. 9 is typical of that obtained from any of the grown surfaces in that it shows both Kikuchi lines and diffraction spots. There are, however, differences in the nature and configuration of the spot patterns which depend on the layer thickness.

The spot patterns from the short duration growths may be associated with the presence of the islands, but the occurrence of spot patterns from thick layers ($>5\mu$) indicates the possibility of alternative explanations. For example there is evidence for

the existence of twin bands or regions of stacking faults, the origins of which are currently under investigation. The electron micrographs, Fig. 11 and 12, show examples of such structural defects in the unetched and etched conditions, respectively. The

results of this work will be published in the near future (8).

Summary and Conclusions

The results of the kinetic measurements indicate that the most probable over-all course of the reaction involves the chemisorption of a trichlorosilane radical on the substrate, which is reduced to silicon by a hydrogen molecule impinging directly from the vapor phase with subsequent desorption of HCl. A possible interpretation of the evidence from the electron micrographs and diffractograms is that initially the silicon produced on the substrate does not grow as a continuous monolayer, but rather by formation of individual nuclei which are considerably thicker than one atomic layer. Since chemisorption as such can only occur to monolayer depth, the nuclei must arise either by surface diffusion of silicon from unfavorable sites, or by preferential chemisorption. The former hypothesis seems much more probable, however, since layer perfection decreases with decreasing temperature, which would be expected to reduce surface mobility, not initiate nonpreferential chemisorption. The nucleation process does not appear to continue however, when a layer of the order of 1μ has been obtained.

Vapor Phase Equilibria for the Systems: GaAs-GaI_x-As_y and Ga-GaI_x

V. J. Silvestri and V. J. Lyons

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

Analysis of pressure measurements has led to the determination of the vapor species resulting from the reaction of GaAs with I. The reaction determined from the analysis is $2GaAs(s) + GaI_3(v) \rightleftarrows 3GaI(v) + \frac{1}{2}As_4(v)$ in the range 560°-850°C. The equilibrium constant is given by the equation, $\log Kp = -23{,}650/T + 19.4$. The enthalpy calculated for the reaction is 54.1 kcal/mole of GaAs. A similar analysis for the system Ga-GaI_x resulted in the determination of the reaction $2Ga(l) + GaI_3(v) \leftarrow 3GaI(v)$ in the range 420°-650°C. The equilibrium constant for this reaction is given by $\log Kp = 11{,}000/T + 12.4$. The enthalpy for the reaction is 25.2 kcal/mole of Ga. By combining the two equilibria in the region of overlapping temperatures, the arsenic pressures in equilibrium with GaAs along the three-phase line are obtained. In the range 560°-640°C the predominant reaction is $GaAs(s) \rightleftarrows Ga(l) + \frac{1}{2}As_2(v)$. The enthalpy calculated for this reaction is 44.4 kcal/mole of GaAs. The dissociation pressures are in good agreement with extrapolations from two previous measurements made at higher temperatures.

The growth of crystals of binary compounds from a vapor phase composed of the species resulting from reactions of the compounds with a halogen element has become of significant importance in its application to the fabrication of solid-state device structures. In order to gain some insight into the nature of crystal growth by this method, it is first necessary to identify the reacting vapor species and determine equilibria between these species and the growing crystal. It was felt that this information could be obtained through analysis of pressure measurements.

Because of the current widespread interest in the semiconducting compound GaAs, and the demonstrated ability to grow crystals of the compound at low temperatures through reaction of the compound and certain halogens (1-3), pressure measurements were carried out to determine the equilibrium between solid GaAs and the vapor species resulting from reaction of the compound with iodine.

Of the possible iodide vapor species that might result from the reaction of iodine with GaAs, calculations based on published thermodynamic data (4) reasonably excluded all but GaI_3 and GaI. The excluded species were GaI_2 and the arsenic iodides. The calculations further indicated that GaI_3 would be more stable at lower temperatures and hence would be the predominant iodide species resulting from initial low-temperature reaction of iodine with GaAs. Preliminary experiments showed that iodine reacts completely with GaAs at temperatures below 200°C to form, at equilibrium, arsenic and a gallium iodide species presumed to be GaI_3. The presence of arsenic was verified by x-ray diffraction analysis of the condensed phases. GaI_3 was identified primarily by its melting point (5) and the color of the crystals. Positive identification by x-ray diffraction analysis was not obtained due to rapid hydrolysis of the compound and inadequate x-ray diffraction data for the gallium iodides. At higher temperatures, in the presence of excess GaAs, the vapor species GaI would become important according to Brewer (4).

From this information it was possible to postulate, as a model, a disproportionation reaction for the transport and crystal growth of GaAs from a vapor phase. The proposed reaction was

$$2GaAs(s) + GaI_3(v) \rightleftarrows 3GaI(v) + \tfrac{1}{2}As_4(v) \quad [1]$$

An additional equilibrium which must be considered is the dissociation of tetrameric arsenic according to the reaction

$$2As_2(v) \rightleftarrows As_4(v) \quad [2]$$

The system would be at least bivariant and therefore would require at least two sets of pressure measurements at different initial iodine concentrations in order to test the postulated model. The test of the model would be in a comparison of equilibrium constants calculated from each set of pressure measurements. Because of the invariance of the equilibrium constant, coincidence of the calculated Kp values would be considered a reasonable verification of the proposed equations. Variation of the initial iodine concentration would serve also to establish a possible univariant portion of the system, e.g., GaI_3 (condensed) $\rightleftarrows$ GaI_3 (vapor), and further corroborate the model.

In order to calculate values of the equilibrium constant it is necessary to calculate first the partial pressures of each vapor species. Since the model assumes four vapor species, four independent equations are needed for the determination of their partial pressures. The total pressure measurements need only to be carried out under conditions of known volume and known iodine concentration in order to provide the necessary information for solution of the four equations which are given below.

I. *Total pressure*

$$P_T = P_{GaI_3} + P_{GaI} + P_{As_4} + P_{As_2} \quad [I]$$

II. *Conservation of iodine*

n_I = moles of iodine added to each tube calculated as monatomic iodine

$$n_I = 3n_{GaI_3} + n_{GaI}$$

Multiplying both sides of the equation by RT/V, an equation in terms of pressure is obtained

$$\frac{n_I RT}{V} = 3P_{GaI_3} + P_{GaI} \qquad [II]$$

R is the gas constant; V the reaction tube volume.

III. *Conservation of* Ga *and* As.—For each GaI_x molecule resulting from the reaction of I with GaAs, an arsenic atom is present in the system. Therefore, in the vapor phase

$$n_{Ga} = n_{As}$$

$$\frac{n_{Ga}RT}{V} = P_{GaI} + P_{GaI_3}$$

$$\frac{n_{As}RT}{V} = 4P_{As_4} + 2P_{As_2}$$

hence

$$P_{GaI} + P_{GaI_3} = 4P_{As_4} + 2P_{As_2} \qquad [III]$$

IV. *Arsenic vapor equilibrium.*—$2As_2(v) \rightleftarrows As_4(v)$

$$P_{As_4} = Kp(P_{As_2})^2 \qquad [IV]$$

The values of Kp for Eq. [IV] are tabulated in Stull and Sinke (6). Since the values of n_I, P_T, R, and V would be known the partial pressures of the four vapor species could be calculated and hence Kp for reaction [1] may be calculated from

$$Kp(1) = \frac{(P_{GaI})^3 (P_{As_4})^{1/2}}{P_{GaI_3}}$$

In order to test the proposed model, three sets of pressure measurements were made each at a different initial iodine concentration. The measurements were carried out in sealed quartz tubes employing Bourdon gauges.

Pressure measurements also were carried out on the system resulting from the reaction of iodine with an excess of gallium. From the considerations cited above (4), the reaction proposed for this system was

$$2Ga(l) + GaI_3(v) \rightleftarrows 3GaI(v) \qquad [3]$$

$$Kp = \frac{(P_{GaI})^3}{P_{GaI_3}}$$

The two equations needed to calculate the gallium iodide partial pressures for this system are given below

$$P_T = P_{GaI_3} + P_{GaI}$$

$$\frac{n_I RT}{V} = 3P_{GaI_3} + P_{GaI}$$

The validity of the proposed reaction was tested through a comparison of values of the equilibrium constants calculated from the results of two sets of pressure measurements.

From the equilibria determined for the two systems, it was possible to derive the three-phase line dissociation pressures of GaAs in a temperature range wherein the arsenic pressures are below 1 x 10^{-7} mm. The arsenic pressures determined from this work are in good agreement with extrapolations of direct measurements made at higher temperatures and pressures.

Experimental Procedure

Iodine weighing procedure.—The iodine used in runs 1 and 2 was weighed in the following manner. An 8 mm OD quartz tube 5 in. long was fitted with a 10/30 male joint at one end and a break-off tip at the opposite end. The tube was cleaned with CH_3OH and CCl_4 to remove grease and then weighed on an analytical balance which had an accuracy of ± 0.2 mg. A quantity of 99.95% iodine (Gallard-Schlessinger) somewhat greater than that desired was then loaded into the tube. After evacuating the tube at a pressure of 0.1μ for 30 min, the tube was sealed by fusion of the quartz. The tube plus iodine was then reweighed to give the net weight of iodine. A correction was made for the air displaced from the iodine capsule. The iodine used in run 3 was weighed in the same manner but in Pyrex tubes. It was subsequently determined through control experiments that in the sealing process significant quantities of quartz and Pyrex were vaporized. The weighing results for the I-GaAs experiments are summarized in Table I.

Pressure measurements.—Figure 1 illustrates the apparatus used for the vapor pressure measurements and the loading procedure. For the system I-GaAs, high purity monocrystalline GaAs[1] was broken into 1-2 mm diameter pieces and loaded into the tube. The quantity of GaAs used in each run was approximately ten times greater than the quantity of iodine. This insured an excess of GaAs throughout each experiment thereby approximating the condition prevalent during vapor growth of the compound. The iodine capsule was contained in a separate tube connected to the reaction chamber. Both

sides of the spoon gauge were evacuated simultaneously to 1 x 10^{-6} mm Hg, and the apparatus was then heated for 6 hr at 190°-210°C to remove adsorbed water and other vapors. The tube was then sealed at point B. After breaking open the iodine capsule, the iodine was pumped into the reaction tube by cooling a region of the reaction tube with dry ice. The apparatus was then sealed at point C. A detailed description of the technique used in making the pressure measurements was given in an earlier publication (7). The furnace used in the measurements was found to have a 10°C temperature gradient over the length of the tube. The sample was situated at the lowest temperature in the reaction tube. The furnace was provided with a viewing slit so that visual observations could be made during the course of the measurements. Temperatures were measured with a Pt-Pt, 10% Rh thermocouple which was calibrated against a NBS standardized Pt-Pt, 10% Rh thermocouple. The thermocouple voltages were read with a Rubicon Potentiometer, Model 2732. Pressure measurements were made during both heating and cooling cycles. At each temperature where a measurement was taken, equilibrium times of 0.5 to 1 hr were allowed.

Reaction tube volumes were measured both before and after each run by filling the tubes with water from a buret. The volumes determined appear in Table I.

The procedure outlined above also was employed for measurements on the system I-Ga. The weight of Ga used in each run was approximately ten times the weight of iodine so that liquid Ga was present throughout the measurements. The gallium (99.999% pure) was obtained from Eagle-Picher. Reaction tube volumes for the two measurements were 33.6 cc for run 1 and 58.2 cc for run 2.

Several Bourdon gauges were used during the course of the experiments. In general, the gauges were insensitive to pressures below 4 mm.

Discussion

The reaction I-GaAs.—As the reaction tubes were heated iodine vapor was observed and the vapor pressure of the element was measured. At about 100°C, reaction of the iodine with GaAs was observed both as a color change in the vapor and as a rapid decrease in vapor pressure. After the initial reaction a condensed iodide phase was observed on the wall of the reaction tube. The vapor pressure at this point was below the limit of detectability of the gauges. After the initial reactions, the purple color of iodine vapor was not observed.

The pressure curves corresponding to the three different initial iodine concentrations are shown in Fig. 2. The initial rise in pressure for each set of data falls along a univariant curve which is coincident with that for the system $GaI_3(c) \rightleftarrows GaI_3(v)$ (5). The experimental curves break away from the univariant curve at different temperatures depending on the initial iodine concentration. In run 1 for example, the break-point occurs at approximately 285°C. At this temperature the liquid phase was observed to disappear thereby establishing a dew-point for that material. The number of moles of vapor at this temperature corresponds to one-third the number of moles of monatomic iodine added to the system. From this calculation and the coincidence of the curve with the vapor pressure of GaI_3 it was concluded that the predominant vapor species at this temperature was GaI_3.

The increase in pressure from 285°C to approximately 500°C (run 1) can be approximated by a perfect gas law expansion for the pressure of GaI_3 plus the equilibrium vapor pressure of elemental arsenic. Above approximately 500°C the curve again resumes a lower slope indicating that all of the solid arsenic resulting from the initial reaction was in the vapor phase. The analysis presented above relating to run 1 was also applied to runs 2 and 3. The GaI_3 and arsenic dew-points are consistent with values calculated from the initial iodine concentrations.

Above the arsenic dew-point temperatures it was observed that the only condensed phase remaining in the reaction tubes was GaAs. Since the objective of this work is to describe the equilibrium under conditions wherein the only known condensed phase

is GaAs, the data above 560°C are those which are pertinent to the model presented in the introduction. Reactions [1] and [2] were therefore assumed to represent the predominant equilibria in the temperature range 560°-890°C. The procedure outlined earlier was used to calculate values of the partial pressures of each species using the total pressure data from the three experimental runs. The equilibrium constant values for reaction [1] then were calculated in the following manner. A smooth curve was drawn between the vapor pressure points on each of the three experimental curves. Using n_I values calculated from the recorded iodine weights, the average values of P_T and Eq. [I-IV], values of the equilibrium constant were calculated using an IBM 7090 computer. A test of the assumed model was then to compare Kp values from run to run. The values are plotted as log Kp *vs.* reciprocal temperature in Fig. 3. (For convenience, the values were plotted only to $Kp = 1 \times 10^{-7}$). At higher temperatures the Kp values are in excellent agreement, and they describe a linear relationship between log Kp and reciprocal temperature. The deviations from the linear curve at lower temperatures were found to be well within experimental error. It was noted above that the iodine quantities used in runs 1 and 2 were weighed in quartz ampoules. Subsequent control experiments showed that during sealing of the ampoules, quantities of quartz were vaporized. The weight losses varied between 1.5 and 4.0 mg. These results indicated that weighing errors existed in runs 1 and 2; however the exact magnitude of the errors could not be determined experimentally. Further calculations of Kp were carried out using slightly higher values of n_I for both runs. At n_I values corresponding to iodine weights of 102.7 and 54.2 mg the calculated values of Kp formed a linear relationship of log Kp *vs.* $1000/T$ over the entire temperature range. The correction corresponded to an increase in iodine weight of 2.2 mg for run 1 and 2.5 mg for run 2. The increases agree quite well in magnitude with the expected error. The corrected data are plotted in Fig. 4. The slope is identical with that given for Fig. 3, since the correction shifted the higher temperature points only slightly. The large deviation in the calculated values of Kp at lower temperatures results from the value of P_{GaI} being smaller or comparable to the value of $(\Delta n_I RT)/V$ wherein Δn_I is representative of the iodine weighing error.

Similar control experiments were carried out to determine the loss in weight due to sealing a Pyrex ampoule similar to that used in run 3. The results showed an average weight loss of 0.2 mg. This correction was applied to the n_I value for run 3 and the results are also plotted in Fig. 4. This small correction obviously caused very little change in the Kp values. The values of n_I used for the determination of Kp are summarized in Table I. Thus, the good agreement, over the entire temperature range, of the Kp values calculated from the three sets of experimental data is considered a confirmation of the proposed model. The relationship between Kp and temperature for reaction [1] can be expressed as

$$\log Kp(1) = -\frac{23{,}650}{T°\mathrm{K}} + 19.4$$

From the slope of the curve of Fig. 4, the enthalpy calculated for reaction [1] is 54.1 kcal/mole of GaAs.

Above 930°C, the slope of curve 3 decreases gradually. In this region, the predominant vapor species are GaI, As_4, and As_2. Thus these data may be approximated by a perfect gas law expansion for the GaI pressure plus continued dissociation of As_4 to As_2.

Further evidence for the formation of GaI and arsenic vapors at high temperatures was gained from the results of two simple weight loss experiments. Weighed quantities of GaAs and I were reacted in sealed tubes of known volume. The initial iodine concentrations were approximately the same as used in run 3. The tubes were heated to 1050°C and then quenched. The original pieces of GaAs were then reweighed and the weight losses corresponded to the formation of GaI and arsenic vapor species. During the quenching, GaAs was crystal-

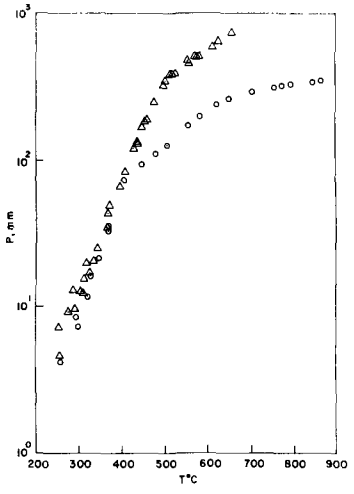

Fig. 5. Vapor pressures for two experimental runs on system Ga-GaI_2. Triangle with dot, Run 1, $n_I = 5.5 \times 10^{-4}$ mole; circle with dot, run 2, $n_I = 2.8 \times 10^{-4}$ mole.

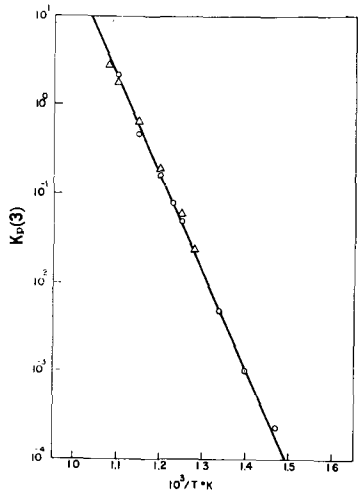

Fig. 6. Equilibrium constants for reaction [4]. Triangle with dot, Run 1; circle with dot, run 2.

lized from the vapor phase in the form of dendritic ribbons and whiskers.

The reaction I-Ga.—During the initial heating of the reaction tubes, iodine vapor was observed and the vapor pressure of iodine was measured. At approximately 80°C reaction of iodine with Ga occurred and the iodine vapor disappeared rapidly. An iodide condensed phase was observed at this point. The vapor pressure curves resulting from two experiments at different iodine concentrations are plotted in Fig. 5. There also appears to be a univariant curve for this system. Although the univariant curve is not coincident with the vapor pressure of GaI_3, calculations of the number of moles of vapor existing at the condensed phase dew-points indicate that the vapor species at the dew-points is GaI_3. The deviation of the univariant curve from the vapor pressure of GaI_3 is in the direction expected if gallium dissolved to an appreciable extent in liquid GaI_3 to form a liquid approximating the composition GaI_2. Since this paper is concerned primarily with vapor phase equilibria, a further investigation of the univariant part of the system was not carried out. In run 2, the slope of the pressure curve decreases above 650°C. Calculations show that the data above 650°C can be approximated by a perfect gas law expansion in pressure for the species GaI. This information, plus the dew-point calculations, experimentally support the assumed model (reaction [3]).

An analysis of the experimental data similar to that presented for the I-GaAs system was carried out for the temperature range 430°-650°C. Values of the equilibrium constant for each set of experimental pressures were calculated.

The values are plotted in Fig. 6. The agreement in slope and magnitude of the calculated *Kp* values shows the validity of the proposed model. The data can be represented by the equation

$$\log Kp\,(3) = -\frac{11{,}000}{T°K} + 12.4$$

The enthalpy for reaction [3] calculated from the slope is 25.2 kcal/mole of Ga.

Dissociation pressure of GaAs.—Through algebraic combination of reactions [1], [2], and [3], the following equilibria are obtained

$$GaAs(s) \rightleftarrows Ga(l) + \frac{1}{4}As_4(v) \qquad [4]$$

$$GaAs(s) \rightleftarrows Ga(l) + \frac{1}{2}As_2(v) \qquad [5]$$

The reactions describe the dissociation of solid GaAs along the three phase line. From the equilibrium constants for reactions [1], [2], and [3], the vapor pressures of the two arsenic species were calculated in the region 560°-636°C, the temperature range in which experimental results were obtained for both the I-GaAs reaction and the I-Ga reaction. The values of P_{As_4} and P_{As_2} are given in Table II. The dissociation pressure of GaAs from this calculation agrees reasonably well with extrapolations of two previous measurements made at higher temperatures (8, 9). Figure 7 is a plot of the dissociation pressure of GaAs showing the results

of four investigations. The values given in the plot are total arsenic pressures. The calculated values from this work have extended the curve to a region wherein direct pressure measurements would be difficult to obtain.

The enthalpies calculated for Eq. [4] and [5] are given below

$$\Delta H = 28.9 \text{ kcal/mole of GaAs}$$
$$\Delta H = 44.4 \text{ kcal/mole of GaAs}$$

The value of the enthalpy for reaction [5] is slightly higher but in agreement with the value of 39.67 kcal reported earlier by Goldfinger and Drowart (8).

Acknowledgments

The authors wish to acknowledge the many helpful discussions of the work with Mr. R. F. Lever and Drs. A. Reisman and K. Weiser of this laboratory. We wish also to thank Miss Agnes Kuhlke for her assistance in programming the calculations on the IBM 7090 computer.

Manuscript received March 12, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Kinetics of the Tantalum-Hydrogen Reaction

M. W. Mallett and B. G. Koehl

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Kinetics of reaction of hydrogen with tantalum was studied for atom fraction compositions, N_H, 0.05 at 500° to 700°C and N_H, 0.10 at 450° to 600°C. The process was one of dissolution and diffusion of hydrogen. The diffusion coefficients obtained are expressed by the following equations:

$$D_{N_{H=0.05}} = 1560 \exp\left[(-32{,}230 \pm 3140)/RT\right] \text{ cm}^2/\text{sec}$$

$$D_{N_{H=0.10}} = 13{,}960 \exp\left[(-33{,}620 \pm 1370)/RT\right] \text{ cm}^2/\text{sec}$$

A single rate was obtained for $N_H = 0.25$ at 450°C. Regardless of composition, N_H 0.05 to N_H 0.33, samples at 300° to 400°C did not achieve surface saturation in the experimental time. The indicated activation energies are higher than the meager literature values for diffusion of hydrogen in most other metals.

The authors have previously reported the vapor pressure equilibria for the tantalum-hydrogen system and the thermodynamic functions derived therefrom (1). In the present study, the kinetics of sorption and diffusion of hydrogen in tantalum was investigated as part of an evaluation of the effects of interstitial elements on the mechanical properties of tantalum. The results of the only previous quantitative study of the kinetics of reaction of hydrogen with tantalum (2) are largely invalidated by inadvertent simultaneous oxidation of specimens.

Experiments were made to obtain kinetic data for the sorption of hydrogen by tantalum to produce compositions having atomic fractions, N_H, 0.05, 0.10, 0.25, and 0.33 in the temperature range of 300°-700°C. Experimental conditions of temperature and pressure were determined from the isopleth of the desired product as determined in the equilibrium studies. It has been shown (3, 4) that kinetic data for reactions producing solid solutions

(e.g., the tantalum-hydrogen reaction) are more readily rationalized when the experiments are designed to produce reaction products of constant composition.

Experimental

Samples were made from the same stock of electron-beam melted tantalum used for the equilibrium studies (1). They consisted of cylinders 0.6-0.7 cm in diameter and 2.5-3.5 cm long cut from rod cold-forged and swaged from the ingot. The cylinders were filed clean and finish dry-abraded through 240-, 400-, and 600-grit silicon carbide papers. Samples were spot welded to the bead of a platinum-platinum plus 10% rhodium thermocouple and suspended by the thermocouple in a Vycor reaction tube of a modified Sieverts apparatus (5). The system was evacuated to a pressure of less than 0.01μ of mercury. The sample was then activated by heating with a resistance-wound furnace at 900°C for 1 hr before adjusting the temperature to that of the run. This treatment served to remove dissolved hydrogen and dissolve invisible surface oxide films thus minimizing times for surface saturation of samples during reaction. Although 11 samples were used in the kinetic studies, 4 of them were reused 3 to 11 times without removal from the reaction tube. Reacted hydrogen was removed between runs by 900°C heating in vacuum. This treatment had no apparent effect on the physical properties of the metal. The sample used for 11 runs showed only moderate pickup of oxygen from a starting level of about 20 ppm to 37 ± 7 ppm after use.

The reaction was initiated by admitting hydrogen through the pressure regulator to the reaction tube. The hydrogen was obtained by thermal decomposition of uranium hydride. The buret was kept balanced at atmospheric pressure at all times. The regulator was set to maintain the pressure selected from a plot of isopleths (1), to correspond to the experimental temperature and composition. Readings of the buret were taken at convenient time intervals depending on the speed of the reaction. The amount of gas reacted with the sample was the difference between the volume added from the buret and the volume remaining in the gas phase in the calibrated dead space of the reaction tube.

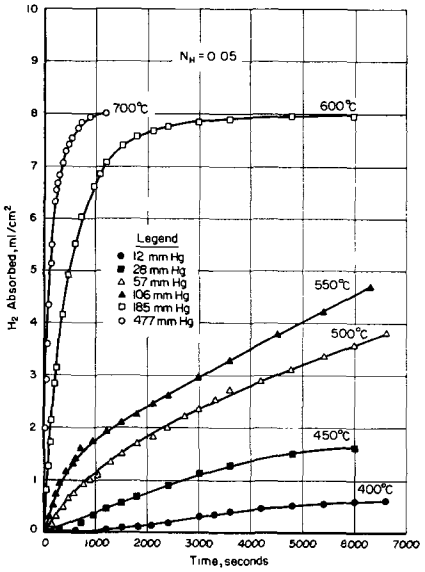

Fig. 1. Representative rate data for the reaction of hydrogen with tantalum (N_H = 0.05).

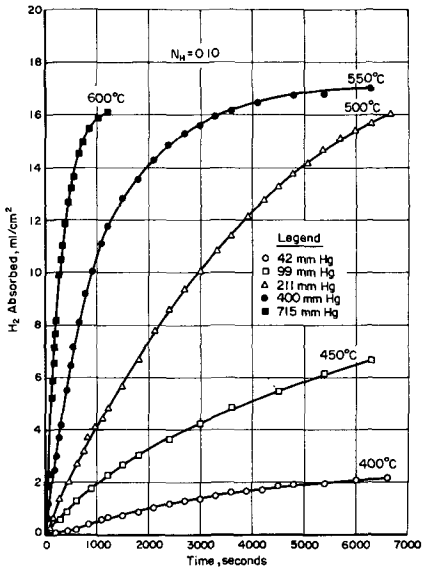

Fig. 2. Representative rate data for the reaction of hydrogen with tantalum (N_H = 0.10).

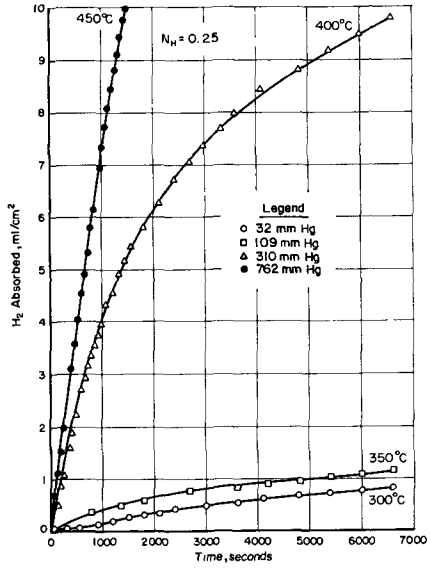

Fig. 3. Representative rate data for the reaction of hydrogen with tantalum (N_H = 0.25).

Results

Representative rate data are shown in Fig. 1-3. The initial parabolic character of the raw data for some of the reactions is apparent for reactions at and above 500°C but becomes obscure at lower temperatures. Since no compound was formed, the reaction was expected to be one of simple dissolution and diffusion of hydrogen in tantalum accompanied by possible secondary interface reactions. Accordingly interpretation of the data was attempted in terms of theoretical diffusion behavior.

Fick's second law for diffusion in a finite cylinder may be expressed as (4)

$$\frac{c}{c_o} = 1 - \frac{32}{\pi^2} \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} \frac{1}{\beta_m^2 (2n+1)^2} \times \exp\left\{ -\frac{Dt}{a^2} \left[\frac{(2n+1)^2 \pi^2}{\left(\frac{l}{a}\right)^2} + \beta_m^2 \right] \right\} \quad [1]$$

where a is radius of sample; l, length of sample; D, diffusion coefficient; C, average hydrogen concentration; t, time; C_o, the final equilibrium concentration; β_m, the m^{th} root of the Bessel function $J_o(\beta)$ and the indices m and n range through integral values as desired.

Since the length to radius ratio, l/a, of the experimental cylindrical samples varied from about 5 to 12, theoretical curves were calculated from Eq. [1] to permit analysis of data for the sorption of gas by any cylinder. These curves are shown in Fig. 4 where C/C_o is plotted against $\sqrt{DT}/a$ for l/a ratios of 1, 2, 4, 8, 16, and infinity.

The fitting of the experimental data to the theoretical diffusion curves of Fig. 4 becomes quite difficult and impractical when the experimental reaction does not show ideal behavior. However, Demarez, Hock, and Meunier (6) offer a partial solution to this problem. They have shown that for values of t greater than some threshold time, t_o, the series such as appear in Eq. [1] degenerate to their first terms with adequate accuracy for interpretation of the experimental data. Then

$$\frac{C}{C_o} = 1 - \frac{32}{\pi^2 \beta_1^2} \exp\left\{ -\frac{Dt}{a^2} \left[\frac{\pi^2}{\left(\frac{l}{a}\right)^2} + \beta_1^2 \right] \right\} \quad [2]$$

Converting to logarithmic form one obtains

$$\log (1 - C/C_o) = \log \frac{32}{\pi^2 \beta_1^2} -$$

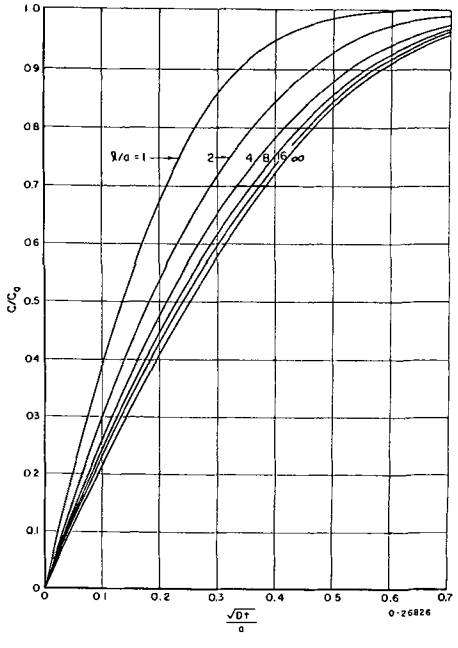

Fig. 4. Theoretical curves for sorption in cylinders

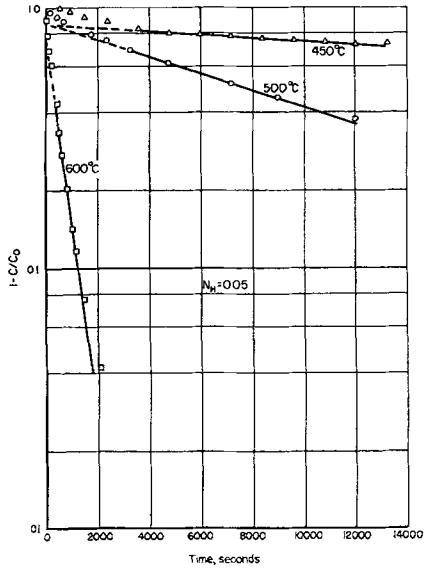

Fig. 5. Hydrogen absorption as a function of time ($N_H = 0.05$)

$$\frac{Dt}{2.303a^2} \left[\frac{\pi^2}{(l/a)^2} + \beta_1^2 \right] \quad [3]$$

Since β_1, l, and a are known, D can be determined from the slope of the straight line plot of log $(1 - C/C_o) = f(t)$. That is, slope $= -$ (const.) D/a^2. Re-examination of the values from the double series from which the curves of Fig. 4 were drawn revealed that they also could be plotted similarly as a function of t to yield lines which were adequately straight over reasonably large ranges. The intercepts of the lines differed from the calculated intercept and decreased with increasing values of l/a. The slopes differed only 2 or 3% from those calculated from Eq. [3]. The more refined values of slopes and intercepts calculated from the data in Fig. 4 were used in our treatment of the experimental data.

Figure 5 shows representative plots of log $1 - C/C_o$ *vs.* time. At 600°C the reaction was quite

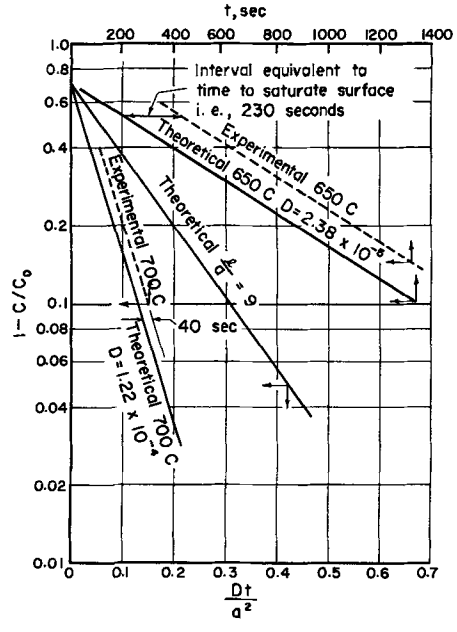

Fig. 6. Comparison of theoretical and experimental absorption rates

rapid and approached complete volume saturation in the experimental time. At 500°C the reaction was much slower and reached only 60% volume saturation in 3 hr. D values were calculated from these curves. In Fig. 6 the theoretical line for $l/a = 9$ is a replot according to the method of Demarez *et al.* (6), of a curve such as shown in Fig. 4. An experimental D value for 650°C was substituted in the Dt/a^2 values for the l/a line and the theoretical time behavior obtained. The theoretical time values were plotted against log $(1 - C/C_0)$ in Fig. 6 along with the experimental line. It is seen that these two lines are parallel and that the interval between them on the time ordinate is equivalent to the time lapse before the sample surface became saturated. This test of surface saturation eliminated use of data for $N_H = 0.05$ below 500°C, $N_H = 0.10$ below 450°C, and all the data for higher N_H values except one rate for $N_H = 0.25$ at 450°C. Except as noted, the lower temperature experiments did not produce surface saturation of the samples within the experimental times. The times for sample surface saturation of the good runs are listed in Table I. The times tend to increase with decreasing temperature from 40 sec at 700°C to about 3000 sec at 450°C for samples of essentially the same size.

Experimental diffusion coefficients for the tantalum-hydrogen systems at compositions of N_H 0.05, 0.10, and 0.25 over a temperature range of 450°-700°C also are given in Table I. Variation of diffusion coefficient as a function of temperature is shown for $N_H = 0.05$ in Fig. 7 and $N_H = 0.10$ in Fig. 8. A single point for $N_H = 0.25$ at 450°C also appears in Fig. 8. There is a trend toward faster diffusion rates at the higher pressures required to form the solutions with larger atom fractions of hydrogen.

The equations for the best straight lines in Fig. 7 and 8 were determined by the method of least squares. The equations are

$$D_{N_{H=0.05}} = 1560 \exp [(-32{,}230 \pm 3140)/RT] \text{cm}^2/\text{sec} \quad [4]$$

and

$$D_{N_{H=0.10}} = 13{,}960 \exp [(-33{,}260 \pm 1370)/RT] \text{cm}^2/\text{sec} \quad [5]$$

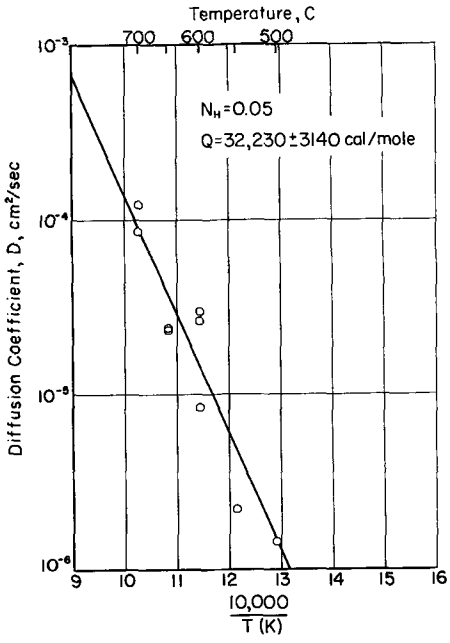

Fig. 7. Temperature dependence of the diffusion coefficient for hydrogen in tantalum ($\Delta_H = 0.05$).

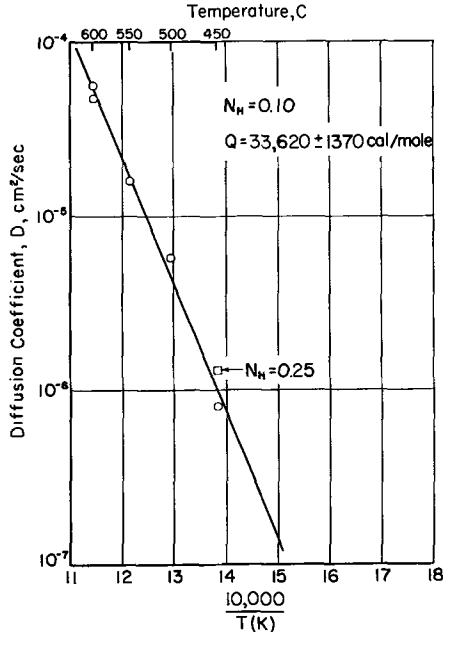

Fig. 8. Temperature dependence of the diffusion coefficient for hydrogen in tantalum ($N_H = 0.10$).

where the activation energy for hydrogen diffusion is 32,230 ± 3140 cal/mole for composition, $N_H = 0.05$, and 33,620 ± 1370 cal/mole for composition, $N_H = 0.10$. It is seen that these values of activation energy agree within the limits of experimental error.

Since Eq. [4] and [5] have the form $D = D_0 \exp(-E/RT)$ the entropy of diffusion can be calculated from D_0 and E by applying the theory of Wert and Zener (7, 8) for interstitial diffusion. For a body-centered-cubic lattice

$$D_0 = 1/6\, a_0^2 \nu \exp(\Delta S/R) \quad [6]$$

where a_0, the lattice constant, is 3.296Å for tanta-

lum. The vibration frequency, ν, of a solute atom in an interstitial position is given by the approximation

$$\nu = (E/2m\lambda^2)^{1/2} \quad [7]$$

where E is assumed approximately equal to the activation energy, m is the mass of the solute atom, and λ, the distance between interstitial positions, is assumed to be $a_o/2$. From Eq. [6] ΔS for diffusion of hydrogen in tantalum was calculated to be 24 cal/mole degree. Theory indicates that a positive ΔS is characteristic of interstitial diffusion and not diffusion through grain boundaries or other short circuiting paths.

Discussion

It was observed that the activation energies for diffusion of hydrogen in tantalum obtained in the present study are considerably higher than the few available literature values for diffusion of hydrogen in metals. Typical values in cal/mole are 12,380 for α-titanium (9), 6640 for β-titanium (9), 7060 for α-zirconium (10), and 9370 for niobium (4). Also the experimental value for D_o is several orders of magnitude higher than those reported for most other hydrogen metal systems. The high D_o value leads to a higher than usual value (24 cal/mole degree) of ΔS, the entropy of diffusion. However, Albrecht and Goode (11) report an equation for diffusion of hydrogen in β-zirconium, $D = 6.14 \times 10^4 \exp(-45{,}900/RT)$, in which all the factors and the calculated ΔS 30.7 cal/mole degree, are of the same magnitude as those of the tantalum study. This is of considerable interest since the diffusion coefficient for zirconium was obtained by a different method, that of permeation. Further data on the diffusion of hydrogen in metals is needed before a critical evaluation is possible. Diffusion in certain systems such as that of hydrogen and niobium requires study over a much wider temperature range.

Initial linear rates were reported for the reaction of hydrogen with niobium (4). Similar apparently linear reactions were noted for tantalum. However, after review of diffusion theory (6) it was concluded that such "linear" portions of the curves are fortuitous and not significant. One tantalum specimen (not activated) showed a linear reaction for 4 hr at 400°C. However, a duplicate run made with a specimen activated by heating in vacuum at 900°C for 1 hr gave the parabolic type curve seen in Fig. 3. It appears that the "linear" rates are the result of interface conditions which delay surface saturation of samples for long times.

Acknowledgments

The authors wish to express their appreciation for the sponsorship of this research by Materials Central, Directorate of Advanced Systems Technology, Wright Air Development Division, Wright-Patterson Air Force Base, Ohio, and for permission to publish this paper. The work was performed under Contract No. AF-33(616)-7604. They also wish to thank Dr. J. C. Bell of Battelle Memorial Institute for calculation of the data for the theoretical sorption curves.

Manuscript received Dec. 22, 1961. This paper was prepared for delivery before the Los Angeles Meeting, May 6-10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Chemical Vapor Deposition of Tungsten at Low Pressure

Arnold Miller and Gordon D. Barnett

Materials Sciences Section, Research and Development Division,

Autonetics, Division of North American Aviation, Downey, California

ABSTRACT

An experimental program utilizing low-pressure chemical vapor deposition techniques for applying thin tungsten films by the hydrogen reduction of tungsten hexafluoride for the ultimate formation of various electronic devices is described. The purpose of this work is to measure deposition rates at various reaction temperatures and pressures which might be accommodated to electron beam heating. Tungsten films formed by chemical vapor deposition are mirrorlike or grainy depending on deposition temperature, reactants, stoichiometry, and film thickness. Mirrorlike, polycrystalline, randomly oriented, alpha tungsten films of high purity with unit resistance values approaching that of single crystal tungsten have been formed in the 10^{-3} torr pressure range and 1000°C at deposition rates of about 3×10^{3} Å/hr. The unit resistance values of these films are considerably lower than those for sputtered tungsten films of comparable thickness. The adhesion between reaction deposited tungsten films and sapphire substrates is much better than that between sputtered tungsten films and Pyrex substrates. Application of tungsten films at 250°C and higher reaction pressures results in the formation of polycrystalline, randomly oriented, beta tungsten films which can be transformed to the alpha material by treatment at 900°C for an extended period.

Chemical vapor deposition processes can be described as the generation of deposits on suitably heated substrates by means of appropriate thermal reactions between volatile compounds directly on the surface to yield the desired product and gaseous by-products. Such processes have been in use for some time to produce massive quantities or thick coherent coatings of both metallic and nonmetallic materials. Their application to the generation of films of controlled structure and composition for electronic purposes has been limited. The work reported here is part of a continuing study of chemical vapor deposition techniques for the formation of thin films of controlled structure of metals, insulators, and semiconductors.

The purpose of this work is to measure deposition rates at various reaction temperatures and reaction pressures which might be accommodated to electron beam heating, and also to determine some of the resultant film properties such as composition, structure, and resistance. The specific model system selected for this study is the flow method for the hydrogen reduction of tungsten hexafluoride (1, 2) to apply a conductive tungsten film on an insulating aluminum oxide surface for several reasons: (i) Tungsten, the principle product, is a realistic refractory conductor for use in combined microelectronic circuits or in field emission devices on the basis of its physical and electrical properties; (ii) Relatively pure gaseous tungsten hexafluoride is commercially available at a reasonable cost; (iii) The reduction reaction occurs below 1500°C, temperatures which can be obtained with conventional resistance or induction heating methods.

Aluminum oxide was chosen as the substrate material because of its stability at the required tungsten deposition temperatures and because of its inertness to hydrogen fluoride, the reaction by-product. In addition, aluminum oxide itself can be formed by chemical vapor deposition from aluminum chloride, hydrogen, and carbon dioxide or by decomposition of the appropriate alkoxide.

Polycrystalline and single crystal tungsten, as well as epitaxially grown tungsten deposits, are of interest. Since an important requirement for epitaxial growth is that the lattice positions of the substrate and the deposit match within a small per cent, the degree of lattice mismatch between tungsten and sapphire for any crystal plane pair must be considered. Assuming the sapphire to be hexagonal in structure with lattice constants $a = 4.75$Å and $c = 12.97$Å and the tungsten to be body-centered cubic with a lattice constant of 3.15Å, it is possible to find sets of matching lattice parameters favorable to epitaxial growth. This compatibility as well as similar thermal coefficients of expansion properties also makes a study of the tungsten-alumina system appealing. In this program, however, the most readily available sapphire substrate surface, not the face providing the best lattice parameter match with tungsten, is used.

While the present program utilizes resistance heating methods or heating by high-frequency induction, the ultimate aim of the program is to determine reaction parameters adaptable to heating the substrates with an electron beam. Consequently, a low-pressure reaction system is suggested.

Experimental

The reaction system used for the deposition of tungsten on alumina, shown schematically in Fig. 1, is capable of an ultimate pressure of 5×10^{-7}. Pumps required by the vacuum system are pro-

Fig. 1. tected from reactant materials or reaction by-products with liquid nitrogen cold traps. Pressures in reactant storage bulbs are measured using calibrated thermocouple gauges. Reaction pressures, determined with an ionization gauge located in the reaction area and using typical hydrogen pressures in the storage bulb during a calibration run, are indicated to be a factor of 10 less than in the reactant bulb. Airco electrolytic hydrogen passed through a DEOXO catalytic purifier and a liquid nitrogen cold trap is used. The tungsten hexafluoride, used as received, is a General Chemical product described as 99.5% pure with the contaminant portion composed of oxygen, carbon, nitrogen, silicon, and nickel.

The sapphire substrates used in these experiments are 1 mm thick single crystals, with a metallographic polish on the deposit side, provided by the Crystal Products Department of the Linde Company; the crystals, produced by means of a flame fusion process, are furnished with the optical axis about 60° from the geometrical axis. The surface preparation includes a potassium dichromate-sulfuric acid etch, a distilled water rinse, a nitric acid-hydrochloric acid (3:1 by volume) etch, and a final double rinse in hot distilled water. In addition, after the substrate is positioned in the reactor, it is baked at a temperature greater than the actual deposition temperature in an atmosphere of hydrogen for about 30 min.

Reactant gas flow rates are established by means of a pressure drop across cylindical metering tubes of known conductance. A molecular conductance equation, applicable in this work where the mean free path of the molecules is of the same order of magnitude or greater than the tube diameters, is used to calculate the relative dimensions of the tubes.

Resistance or induction heating methods are used depending on the temperature range. For lower temperatures a resistively heated tungsten filament located under the substrate is used to elevate the substrate temperature. High-frequency induction methods are required in the higher temperature regions. Deposition temperatures are measured with an optical pyrometer where possible. In other cases, a chromel-alumel thermocouple placed in contact with the substrate is used. Where etching of the walls of the reaction tube occurred, it was very slow and became evident only after a series of runs. Since this usually occurred below the tungsten hexafluoride reduction zone, it did not interfere with the optical method for determining temperatures. Some tungsten deposited on the walls of the tube, and in some experiments it was necessary to view the substrate from above.

Interferometric techniques (3) are used to measure film thicknesses. Resistance values are determined following a method patterned after that of Judd (4). Spectrographic and x-ray diffraction methods are used to determine the composition and structure of the films.

Results and Discussion

Tungsten deposits were formed from the hydrogen reduction of tungsten hexafluoride at a substrate temperature of 250°C using hydrogen reaction pressures ranging from 55 to 175μ and a stoichiometric hydrogen-tungsten hexafluoride pressure ratio. A plot of film thickness versus hydrogen pressure for these experimental conditions is shown in Fig. 2. The plot indicates an increase of deposition rate as a function of pressure over the entire pressure range covered. Deposition rates under these conditions ranged from 100 to 2700 Å/hr. The maximum value in the pressure range examined is determined from the slope of the curve to be about 100 Å/hr/μ.

During the course of these experiments, a great deal of tungsten is deposited in the form of crystals and whiskers on tungsten filaments used as heat sources at temperatures of about 1000°C. Since this filament is located about 0.250 in. beneath the sapphire substrate and behind it in the gas flow stream, it is felt that the stream of reactant materials which reaches the substrate deposition surface is not robbed appreciably of tungsten source material. Probably more important than this is the efficiency of the process due to such factors as the design of the experimental system and the pattern of the gas flow which brings reactants into contact with the heated surface, the total pressure in the reaction zone as a result of incomplete reaction and formation of gaseous by-products, and so forth. No estimation of the effect of these factors on deposition rates has been prepared since it is probable that the same complicating effects exist regardless

of the heating method used, whether resistance heating or heating with high-frequency induction or the dissipated energy of a beam of electrons striking the surface of the substrate.

Films of less than 2000Å produced at 250°C are mirrorlike in appearance. Thicker films prepared at the same temperature appear to be more granular than thinner ones. Tungsten deposits thicker than 40,000Å have been produced.

A glancing angle x-ray diffraction pattern shows the film to be randomly oriented beta tungsten (5, 6), with particle size between 0.03 and 1μ. Because of the diffuseness and broadness of the diffraction lines the particle size is probably at the small end of the range. Treatment of this film for 48 hr at 900°C and 10^{-7} torr resulted in a glancing angle x-ray diffraction pattern typical of randomly oriented alpha tungsten with no evidence of the beta material. The crystallite size is estimated to be between 0.04 and 1.0μ.

Attempts to form thin mirrorlike deposits at 1000° and 1200°C under conditions similar to those used for the 250°C experiments resulted in extremely grainy deposits with infinite resistance. Such temperature effects are not unexpected. Literature information (7) in regard to various other systems shows that amorphous deposits of various materials can be produced at low temperatures, coarse-grained deposits at higher temperatures, and single crystal deposits on single crystal substrates at extemely high temperatures. No single crystal character nor epitaxial growth is in evidence in any of the films so far produced.

Because of the grainy appearance of the high-temperature deposits and because of the severe etching of the sapphire substrate probably as a result of high-temperature reaction of the substrate with the by-product hydrogen fluoride, the ratio of hydrogen to tungsten hexafluoride was increased to 6 to 1. Under these conditions it is possible to form mirrorlike deposits at 1000°C. At 1200°C, however, the deposits remain grainy and have infinite resistance. Tungsten deposition rates as a function of hydrogen pressures at H_2/WF_6 mole ratios of 6 to 1 were determined at these temperatures. Plots of these data are presented in Fig. 3 over a hydrogen pressure range extending from 2 to 14μ. The plots indicate that deposition rates increase with increasing temperature as well as with increasing pressures. At 1200°C and 2-μ hydrogen pressure, a tungsten deposition rate in excess of 400 Å/hr can be realized; at 1000°C and similar pressures, the tungsten deposition rate approaches 100 Å/hr. Maximum values, in angstroms per hour per micron, are determined by the slopes of the curves to be about 4×10^3 at 1200°C and 3×10^2 at 1000°C.

Glancing angle x-ray diffraction examination of a representative tungsten film laid down at 1000°C produces four smooth weak lines of alpha tungsten over a background of a Laue pattern of sapphire. No evidence of preferred orientation in the tungsten film is seen. The crystallite size is less than 1μ and more than 0.03μ.

Spectrographic analyses of selected mirrored films deposited at various temperatures indicate the film material to be very pure tungsten with only trace amounts of silicon and nickel present. This is consistent with the impurities of the tungsten hexafluoride listed by the manufacturer. No analysis of grainy deposits nor of deposits formed where etching of the alumina substrate is evident were performed since these deposits are not filmlike in nature and do not possess electrical properties of thin metallic films.

In general, adhesion between the sapphire and the tungsten film is extremely good with the mirrored deposits showing better adhesive properties than the granular ones. In most cases, it is not possible to remove the film by means of scotch tape. In fact, vigorous rubbing with an abrasive is required. However, instances of flaking have been observed in some early experiments where the surface treatment did not include the nitric acid-hydrochloric acid etch, but only the potassium dichromate-sulfuric acid etch and the distilled water rinse. The intermittent nature of such flaking tends to indicate a problem in surface preparation rather than in lattice mismatch or differences in the coefficient of thermal expansion between sapphire and tungsten. It should be noted here that tungsten films applied to Pyrex substrate surfaces using sputtering techniques are not as adherent as these reaction deposited tungsten films.

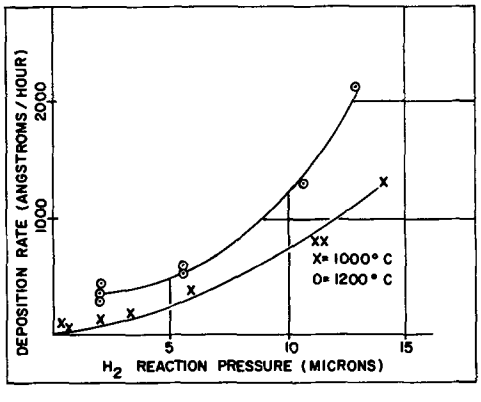

Fig. 3. Tungsten deposition rates at 1000° and 1200°C as a function of hydrogen reaction pressure. The hydrogen to tungsten hexafluoride reaction pressure ratio is 6 to 1.

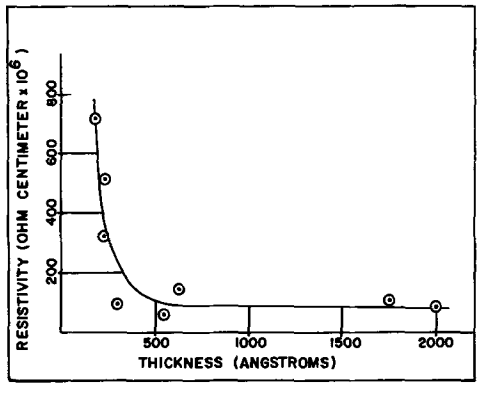

Fig. 4. Normalized resistivity of tungsten films as a function of thickness. These mirrorlike films are deposited at 1000°C with the $H_2 : WF_6$ reaction pressure ratio of 6:1.

Table I. Unit resistance values at various thicknesses for tungsten films applied using high- and low-temperature chemical vapor-deposition techniques and sputtering techniques normalized to the value of single crystal tungsten of 0.015 ohms per square

Reaction deposited* at 1000°C		Reaction deposited** at 250°C			
Thickness (Å)	unit resistance (ohms/square)	Thickness (Å)	unit resistance (ohms/square)	Thickness (Å)	unit resistance (ohms/square)
190	380	150	860	400	2700
300	33	150	860	600	2300
630	23	450	170	3000	100
1750	6.7				

* Mole ratio $H_2/WF_6 = 6$.
** Mole ratio $H_2/WF_6 = 3$.

A plot of resistivity *vs.* thickness for mirrorlike deposits formed at 1000°C is presented in Fig. 4. The data have been normalized to the value for bulk tungsten of 0.015 ohms per square, measured using the Judd method. This normalization process is necessary since the technique and equipment used have not been corrected for edge effects. A typical mirror deposit 190Å thick has a value of 380 ohms per square. For a 1750Å thick film, the unit resistance value is 6.7 ohms per square. Films less than 100Å thick have infinite resistance, while a heavy tungsten film, 5400Å thick, has a unit resistance value of 2.3 ohms per square.

Table I lists normalized unit resistance values for typical films applied using high- and low-temperature deposition methods as well as sputtering techniques. The table indicates that the high-temperature deposition techniques provide films with the best conductivity. Sputtered films have the highest values at comparable thicknesses.

Conclusions

1. Tungsten films resulting from the hydrogen reduction of tungsten hexafluoride deposit at rates in excess of 400 Å/hr/μ for reaction pressures in the 10^{-3} torr range.

2. The appearance of the tungsten deposits ranges from mirrorlike to grainy depending on deposition temperature, reactant pressure ratio, and film thickness.

3. Resistance values of the mirrorlike tungsten films produced by chemical vapor deposition compare favorably with those for sputtered films of comparable thickness. A heavy tungsten film, 5400Å thick, formed at 1000°C has a unit resistance value of 2.3 ohms per square normalized to the value for single crystal tungsten of 0.015 ohms per square. Sputtered tungsten films as thick as 3000Å have normalized unit resistance values as great as 100 ohms per square. The grainy-appearing reaction deposited films have extremely high unit resistance values.

4. Spectrographic analyses indicate that the mirrored deposits formed are high-purity tungsten with only trace impurities of silicon and nickel. X-ray diffraction studies show the low-temperature tungsten deposits to be randomly oriented crystallites with particle size between 0.03 and 1.0μ, probably at the small end of the range.

Treating the beta form over an extended period at 900°C produces the alpha material. X-ray diffraction patterns of mirrored tungsten films formed at the higher temperatures indicate the material to be randomly oriented alpha tungsten with particle size less than 1μ and more than 0.03μ.

5. Adhesion between the deposited tungsten and sapphire substrates is, in general, very good, considerably better than that between sputtered tungsten films and Pyrex substrate material.

Hydrogen Overpotential on Nickel in Alkaline Solution

A. C. Makrides[1]

Metals Research Laboratory, Union Carbide Metals Company, Niagara Falls, New York

ABSTRACT

The exchange current, Tafel slope, stoichiometric number, and limiting anodic current of the hydrogen reaction on nickel in 0.1*N* NaOH depend on the pretreatment and the polarization history of the electrodes. The discharge step of the Volmer-Tafel mechanism is rate-determining on surfaces characterized by high fractional coverage with adsorbed hydrogen. Such surface states are metastable however and are transformed on anodic-cathodic cycling to states which adsorb hydrogen weakly. The exchange currents for the discharge and combination steps are then about equal.

The rate of the hydrogen reaction on nickel shows the familiar exponential dependence on potential; the Tafel slope b is about 0.1v and the exchange current i_o is in the range 10^{-7} to 10^{-5} amp/cm^2. The hydrogen overpotential on nickel is intermediate therefore between the large overpotentials on mercury and lead ($i_o \sim 10^{-13}$ amp/cm^2) and the relatively small overpotentials on metals of the platinum group ($i_o \sim 10^{-3}$ amp/cm^2).

Nickel dissolves slowly in acid and at a negligible rate in alkaline solutions. Side reactions can be neglected in the latter if the solution is free from reducible impurities, mainly oxygen. In spite of the relative simplicity of this electrochemical system the mechanism of the reaction is in doubt. A number of authors (1, 3, 4, 8) concluded from the magnitude of the Tafel slope and from the value of stoichiometric number that the discharge step, $H^+ + e^- \rightarrow H_{ads}$, controls the over-all rate. A simple slow-discharge mechanism does not explain however the frequently observed time-dependence of overpotential, nor does it give correctly the change of overpotential with solution composition.

Lukowzew, Lewina, and Frumkin (1) found that the potential of nickel cathodes which had been heated in H_2 at 400°-420°C and cooled in a water-saturated hydrogen atmosphere drifted for some hours after switching on the current. They attributed the drift of potential to reduction of a nickel oxide film formed during cooling.

Bockris and co-workers (3, 9) also found a potential drift in the first hour of cathodic polarization. Subsequent polarization curves did not follow the Tafel relation. Bockris and Potter (3) attributed the deviations from Tafel behavior to solution of hydrogen into nickel. They obtained satisfactory Tafel lines by making rapid measurements in the direction of increasing current density only and by using fresh electrodes for every run. Their procedure was opposite to that of Lukowzew, Lewina, and Frumkin (1) who carried out measurements after the potential had reached a steady value. Hoare and Schuldiner (10) found Tafel behavior (in acid solutions) with nickel electrodes "saturated" with hydrogen by cathodic polarization.

Ammar and Awad (4) found no time dependence using nickel electrodes electrodeposited from $(NH_4)_2SO_4$ + NH_4OH solutions; the overpotential at a fixed current density reached a constant value in less than a minute.

The reported dependence of overpotential on pH varies from about 0.010 to 0.060v per pH unit (1-4). If the discharge step is rate determining, the cathodic overpotential is given by [ref. (11)]

$$\eta = \psi_1 - 1/\alpha \ln i_c + 1/\alpha \ln a - \ln a_{H^+} + \text{const.} \qquad [1]$$

where η is the overpotential in units of $RT/\mathbf{F}$, ψ_1 is the potential (also in units of $RT/\mathbf{F}$) at a distance of one ionic radius from the electrode, a is the activity at this same distance of the entity discharged, and α is the transfer coefficient ($\alpha \sim 0.5$). Assuming that water is discharged in dilute alkaline solutions and taking its activity as constant, we have from Eq. [1]

$$(\partial\eta/\partial \text{pH})_{i_c} = 2.3 + \partial\psi_1/\partial \text{pH} \qquad [2]$$

In the absence of specific adsorption and in the presence of excess salt (or in concentrated alkaline solutions), $\theta\psi_1/d$ pH = 0 and $\theta\eta/d$ $pH = 0.060$v. In dilute alkaline solutions without salt, $\theta\psi_1/\theta$ pH = 0.060v and $\theta\eta/\theta$ pH = 0.120v. The observed dependence of η on pH (1-4) is generally not in agreement with these predictions. An attempt to remove this discrepancy by assuming that the activity of water molecules in the double layer depends on ψ_1 was not successful (3). In view of these anomalies, further experimental work on the kinetics of the reaction is worthwhile.

Experimental

Two types of cells were used. The solution was pre-electrolyzed in an auxiliary vessel in one series of experiments and then transferred under hydrogen to the cell containing the working electrode. Most runs were made however in the quartz cell shown in Fig. 1. Pre-electrolysis was carried out in the test cell. Nickel electrodes were mounted on the plungers of syringes; they could be immersed or

[1] Present address: Tyco Laboratories, Inc., Waltham, Massachusetts.

Quartz cell: (a) reference electrode, (b) pre-electrolysis electrode, (c) Luggin-Haber capillary, (d) tubes leading to auxiliary compartment (two of four shown), (e) gas inlet, (f) auxiliary compartment, (g) working electrode. The pre-electrolysis and working electrodes (b and g) were mounted on the plungers of syringes. For details of mounting see ref. (5).

withdrawn from the solution without letting air into the cell. The solution was pre-electrolyzed using a nickel cathode. This electrode was then drawn up and the working electrode immersed. There was no difference in results between the two types of cells.

Electrodes were cylindrical and had a projected area of about 1 cm^2. Electrode assemblies were constructed as reported (5). Only quartz and Teflon, besides the electrode, came in contact with solution. To get a uniform current distribution on the working electrode it was placed in the center of a circle defined by the ends of four uniform tubes of equal length which connected the central section of the cell to the anode compartment. The tip of a Luggin capillary, 0.8 mm OD, through which potentials were measured, was placed 1.5 mm from the electrode. Screening effects were negligible (6). The iR correction (6) in any one solution was less than 5 mv at the maximum current density. Constant current was drawn from a 135v source through appropriate resistances ($R_{ext} >> R_{cell}$).

Laboratory distilled water was redistilled with a Pyrex still from dilute, alkaline, potassium permanganate into a two-stage quartz still and from there into quartz flasks. Solutions were prepared from freely boiling distillate. Sodium hydroxide solutions made by electrolysis gave the same results as solutions prepared from sodium hydroxide reagent. These last contained from 10^{-6} to 10^{-7} moles/l of carbonate ion. Solutions were routinely prepared from NaOH reagent.

Electrolytic hydrogen was purified by diffusion through a palladium tube heated to 450°C. Part of the hydrogen was bled off to prevent accumulation of impurities in the tube. Argon, used for sweeping the cell during pre-electrolysis, was passed first over copper at 500°C and then through a dry ice-acetone cold trap. Solutions were saturated with hydrogen for about 2 hr before a run. A stream of hydrogen swept the solution around the electrode during measurements. The resultant stirring minimized changes of hydroxyl concentration in the neighborhood of the electrode and also helped to detach hydrogen bubbles. Light tapping of the electrode assembly was necessary sometimes for removing bubbles formed at current densities higher than 10^{-3} amp/cm^2.

Electrodes were cut from nickel of "spectroscopic purity" (Johnson, Matthey, and Company). They were abraded with 2/0 emery paper and cleaned in chromic + sulfuric acid cleaning solution. They were washed in boiling conductivity water.

The cell was cleaned with chromic + sulfuric acid solution and washed several times in boiling water before each run. Ground joints (also of quartz) were of the mercury-cup type. They were moistened with conductivity water before they were sealed.

Solutions were pre-electrolyzed 18-24 hr at current densities ranging from 10 to 15 $\times$ 10^{-3} amp/cm^2. The sodium hydroxide concentration was determined by analysis at the end of each run.

Results

The rest-potential of nickel electrodes cleaned in chromic + sulfuric acid was + 0.2 to + 0.3v (referred to SHE) in 0.1N NaOH. Electrodes were activated by cathodic polarization. Results were independent of the current density and the number of coulombs in the activating step provided a minimum of the order of 10^{-4} coulombs/cm^2 was exceeded. A cathodic current of 2 $\times$ 10^{-3} amp/cm^2 for 5 min was used generally.

The rest potential after activation was 0 $\pm$ 0.002v *vs.* the hydrogen electrode. After a cathodic run, *i.e.*, after tracing a Tafel curve both in increasing and decreasing order of applied current, the electrode was polarized anodically to a potential greater than + 1.0v. Anodic current densities of 10-100 μa/cm^2 were used. The current was then switched off and the electrode left "passive" until the next cathodic run, whereupon it was activated again as described above. Measurements were taken in most cases over 2 to 4 days. Observations with about 30 different electrodes are reported.

Nickel electrodes gave distinctly different results when they had been polarized anodically once. However, no major change in the hydrogen evolution curve was found after the first cycle of anodic-cathodic polarization. Therefore, we differentiate in our discussion between "initial" Tafel lines and "steady state" Tafel lines measured after one or more anodic-cathodic cycles.

The overpotential with electrodes in the steady state reached its final value within the time needed to read the potentiometer after the current was set at a new value. It stayed constant for long periods. For example, in 0.1N NaOH the overpotential at 2 $\times$ 10^{-4} amp/cm^2 changed 0.4 mv in 30 min. Each current setting was held constant for at least 2 min in tracing polarization curves. A typical curve is shown in Fig. 2. It is obvious from the figure that there was no large change of the Tafel parameters in the 2 hr during which data were taken.

Initial Tafel curves (Fig. 3), *i.e.*, curves obtained with electrodes which had not been polarized anodically, had a definite time dependence. The

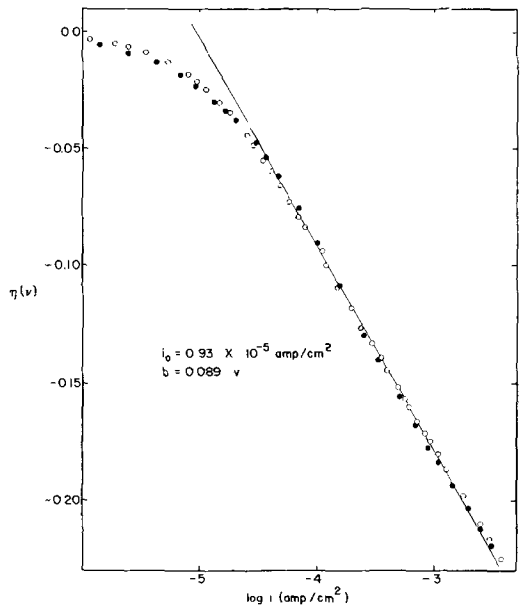

Fig. 2. Cathodic polarization curve with electrode in the steady state. Open circles are for increasing and full circles for decreasing current density. The curve was traced in about 2 hr. Overpotential in volts.

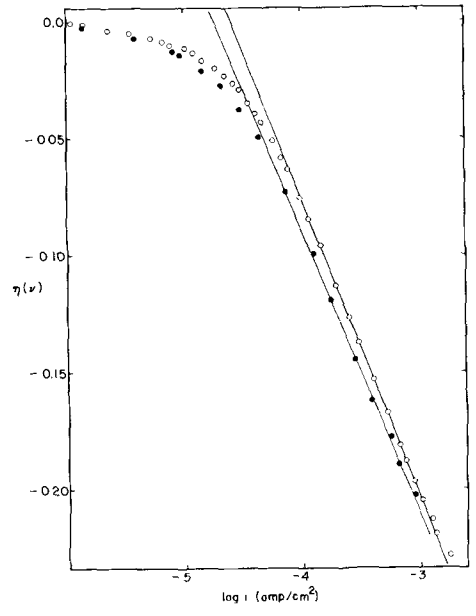

Fig. 3. Cathodic polarization curve with electrode in the "initial" state. Open circles are for increasing and full circles for decreasing current density. The Tafel constants for the open circles are b_c = 0.128v and $(i_o)_{extr}$ = 2.5 × 10^{-5} amp/cm^2; for the full circles overpotential in volts, b_c = 0.120 and $(i_o)_{extr}$ = 1.8 × 10^{-5} amp/cm^2.

drift of potential at a fixed current density was generally about 0.2 mv/min; in some cases it was as much as 0.5 mv/min. Tafel curves traced relatively rapidly (30 sec at each point) showed that both the slope and the exchange current decreased with time. The Tafel slope in a typical case changed from 0.128v to 0.120v and the exchange current decreased from 2.5 × 10^{-5} to 1.8 × 10^{-5} amp/cm^2 in about 30 min.

Table I shows the reproducibility of both initial and steady-state Tafel parameters with different electrodes. The variability of initial Tafel slopes is due, at least in part, to the time dependence noted above. Steady-state results with a given electrode

were reproducible for periods up to 100 hr (Table II).

Statistical treatment of results.—Bockris and coworkers (3, 7) and others after them [see, for example, ref. (4)] treat their results statistically by assuming a normal distribution for i_o and b. These statistical analyses are misleading in some respects. Experimental errors here are not connected with the measurement of either current or potential. For example, the potential is determined routinely with an accuracy of 0.1 mv, while the overpotential cannot be reproduced to better than ± 10 mv (1-4). Reproducibility of overpotential depends entirely on the state of the electrode surface. The mean value of a set of results gives essentially the probability of reproducing some surface condition and extent of surface contamination by some (unknown) impurity provided one follows a specified experimental procedure. It has no direct relation to the most probable value for a "clean" nickel surface. To illustrate, let us assume that a particular set of uniform surface states is produced by a chosen electrode preparation. Let us further assume that a substance Z is present and is adsorbed to an extent $\rho = \rho(C_z)$ where C_z is its concentration. The concentration of Z varies randomly from experiment to experiment. Thus ρ has values ρ_1, ρ_2, ρ_3 . . . in runs 1, 2, 3, ... In the simplest case substance Z decreases the exchange current by an amount proportional to ρ but does not alter the Tafel slope. The exchange current found in a particular run is then $i_o' = (1 - g\rho)i_o$ where g is a constant, probably not far from 1, and i_o is the exchange current for a clean surface ($\rho = 0$). With these assumptions the largest measured exchange current is closest to i_o. The best value therefore is not the average but the maximum observed exchange current.

If the surface is heterogeneous, the relation between i_o' and ρ is not linear. Further, impurities are expected to change both the exchange current

and the Tafel slope. A statistical analysis of a set of overpotential measurements is not justified therefore unless we know in detail the effect of impurities. We chose here to present our results in terms of typical experiments. Their reproducibility is illustrated in Tables I and II. We rejected about 15% of our observations because they appeared to be unreliable. The ground for rejection in most cases was excessive drift of potential.

Discussion

Mechanism of the Hydrogen Reaction on Nickel

There is general agreement (1, 3, 4, 8, 20) that the Volmer-Tafel mechanism is applicable to nickel cathodes. It is a matter of dispute (3, 20) whether discharge

$$H_2O + e^- \underset{v_2}{\overset{v_1}{\rightleftharpoons}} H_{ads} + OH^- \qquad [I]$$

or combination

$$H_{ads} + H_{ads} \underset{v_4}{\overset{v_3}{\rightleftharpoons}} H_2(g) \qquad [II]$$

are rate determining

The simplest kinetic equations for the Volmer-Tafel mechanism are (8, 14-18)

$$d[OH^-]/dt = v_1 = k_1 (1-\theta) = k_1^\circ e^{-a\eta} (1-\theta) \qquad [3a]$$

$$v_2 = k_2 \theta = k_2^\circ e^{\beta\eta} \theta \qquad [3b]$$

$$d[H_2]/dt = v_3 = k_3^\circ \theta^2 \qquad [4a]$$

$$v_4 = k_4^\circ (1-\theta)^2 \qquad [4b]$$

where the k's are rate constants in electrical units (amp/cm^2) and θ is the fractional degree of hydrogen adsorption. In writing Eq. [3] and [4] the electrode surface is assumed to be homogeneous. The ψ_1-potential effect is also neglected.

Equations [3] and [4] can be used to determine θ as a function of η (18). These equations also give the net cathodic current, $(i_c)_{appl}$, as

$$(i_c)_{appl} = k_1^\circ (1-\theta) e^{-a\eta} - k_2^\circ \theta e^{\beta\eta} \qquad [5]$$

At large negative η, Eq. [5] reduces to

$$(i_c)_{appl} = k_1^\circ (1-\theta) e^{-a\eta} = 2k_3^\circ \theta^2 \qquad [5a]$$

The net anodic current is obtained similarly. For large positive η

$$(i_a)_{appl} = 2k_4^\circ (1-\theta)^2 = k_2^\circ \theta e^{\beta\eta} \qquad [6]$$

It is convenient at this point to introduce the exchange currents for steps [I] and [II] which are defined by

$$i_{oI} = k_1^\circ (1-\theta^\circ) = k_2^\circ \theta^\circ \qquad [7a]$$

$$i_{oII} = 2k_3^\circ (\theta^\circ)^2 = 2k_4^\circ (1-\theta^\circ)^2 \qquad [7b]$$

where θ° is the value of θ at $\eta = 0$. The ratio γ of the exchange currents is (see ref. 18)

$$\gamma = \frac{i_{oI}}{i_{oII}} = \frac{k_2^\circ (k_1^\circ + k_2^\circ)}{2k_1^\circ k_3^\circ} \qquad [8]$$

The constant k_4° can be found from the anodic curve provided concentration polarization does not set in before i_a reaches its limiting value. Figure 4 gives typical anodic runs for electrodes in the "initial" and "steady" states. The limiting anodic current with electrodes in the initial state is sensitive to the rate of stirring by hydrogen; it appears therefore to be a diffusion current. However, with electrodes in the steady state and for the same hydrogen flow, the limiting anodic current is an order of magnitude less. Concentration polarization may be neglected in this case; the anodic overpotential is an activation overpotential and is given by Eq. [6]. The limiting anodic current is given by Eq. [6] when we set $\theta = 0$. It is

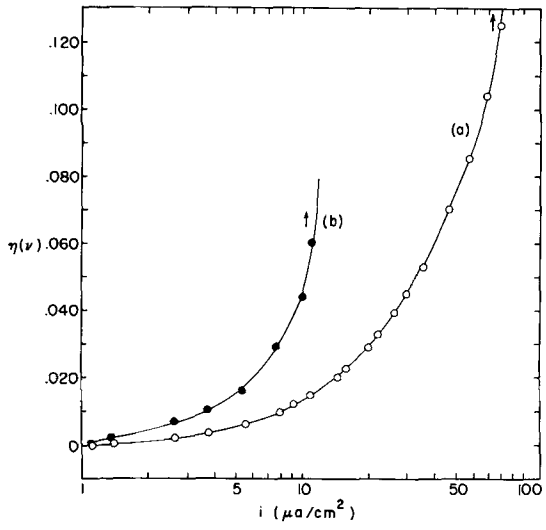

Fig. 4. Anodic polarization curves with electrodes in the initial state (a) and the steady state (b). The arrows indicate that the potential drifts to more positive values at the current densities shown. The limiting current with electrodes in the initial state is sensitive to stirring by hydrogen; it is a diffusion-limited current. The rate of gas flow was the same in (a) and (b). Overpotential in volts.

$$(i_a)_{lim} = 2k_4^\circ \qquad [9]$$

In the particular case shown in Fig. 5, $k_4^\circ = 7 \times 10^{-6}$ amp/cm^2. As shown below, k_4° is useful in determining γ.

Exchange Current

Exchange currents given in Tables I and II are 10 to 50 times those reported by others (1-4). This is attributed to the different electrode pretreatment used here. Electrodes produced by cathodically activating a surface formed under highly oxidizing conditions are less likely to be contaminated than electrodes treated in any of the conventional ways, *e.g.*, by heating in hydrogen at 400°-500°C (1, 3). The large exchange current found here is not caused by a high roughness factor as we have shown already (12).

A recent study of the hydrogen reaction on platinum corroborates our finding that electrode surfaces prepared in this way are to be preferred. The exchange current on platinum cleaned in chromic plus sulfuric acid is time independent and about 2.5 times that for "fresh" electrodes prepared in other ways (13). It should be noted also the Devanathan and Selvaratnam (8) working with nickel in 2*N* NaOH and using anodic-cathodic cycling, a procedure also used here, found an exchange current of 10^{-6} amp/cm^2 and a Tafel slope of 0.095v. These

parameters are in good agreement with our steady state results (Tables I, II).

The surface state of nickel in alkaline solution apparently varies considerably with electrode preparation and pretreatment. The present work shows that at least two states can be differentiated. In the "initial" state hydrogen is extensively adsorbed. Hydrogen is adsorbed to a much smaller extent in the steady state. These inferences are based mainly on anodic polarization studies which are presented and discussed below.

The fractional coverage of nickel cathodes by adsorbed hydrogen in 2N NaOH was determined recently by an anodic pulsing technique (8). The electrodes were subjected to anodic-cathodic cycling in the course of the measurements. These results refer therefore to our steady state polarization runs. According to this study (8) θ^2 is proportional to i_c and log $[i_c/(1-\theta)]$ to η as demanded by Eq. [5a] with $k_1 = 1.0 \times 10^{-5}$ and $k_2 = 3.2 \times 10^{-3}$ amp/cm^2. Using Eq. [7a] and [6] and the experimental value of $\theta^\circ = 0.04$ given in (8), it is found that $k_2^\circ = 2.4 \times 10^{-4}$ and $k_4^\circ = 5.5 \times 10^{-6}$ amp/cm^2. With these values of k's Eq. [3] and [4] give $\theta = \theta(\eta)$ in good agreement with experiment.

On the basis of the above results it was concluded in ref. (8) that discharge of water molecules was the slow step in the hydrogen reaction. This conclusion was based on a comparsion of the k constants and on their determination of a stoichiometric number of 2. However, the relevant quantities are i_{oI} and i_{oII} rather than the rate constants (18). Moreover, the usual way of determining stoichiometric numbers yields ambiguous quantities which are not necessarily diagnostic of the mechanism (18). The data given in ref. (8) actually show that $\gamma = i_{oI}/i_{oII} \simeq 1$, *i.e.*, that the rates of the discharge and combination reactions are the same at equilibrium.[2]

Devanathan and Selvaratnam's (8) Tafel lines are in good agreement with our steady-state results. Further, k_4° determined from the anodic polarization curve agrees well with the value calculated from θ° and k_2° given in ref. (8). Therefore, it may be assumed with some confidence that for electrodes in the steady state θ° is of the order found in (8), *i.e.*, $\theta^\circ \sim 0.05$. If $\theta^\circ << 1$, the exchange currents for steps I and II are

$$i_{oI} = k_1^\circ (1-\theta^\circ) \simeq k_1^\circ \qquad [10a]$$

and

$$i_{oII} = 2k_4^\circ (1-\theta^\circ)^2 \simeq 2k_4^\circ \qquad [10b]$$

The exchange current i_o for the over-all reaction (18) is then

$$i_o = \frac{i_{oI}\, i_{oII}}{i_{oI} + i_{oII}} = \frac{i_{oI}}{\gamma + 1} \simeq \frac{k_1^\circ}{\gamma + 1} \qquad [10c]$$

Stoichiometric Numbers

The two criteria used frequently for identifying the mechanism of the hydrogen reaction are the stoichiometric number ν and the Tafel slope. The stoichiometric number is given by

$$\nu = 2i_o/(\partial i_c/\partial\eta)_{\eta=0} \qquad [11]$$

wher i_o is the exchange current for the over-all reaction, *i.e.*, its total rate in the forward (or reverse) direction at $\eta = 0$. Commonly, i_o is obtained by extrapolating i_c from large $|\eta|$ to $\eta = 0$. An "exchange current" determined in this way may or may not coincide with i_o. To differentiate the two, we denote the extrapolated value by $(i_o)_{extr}$. The apparent stoichiometric number ν' may now be defined (14, 15, 18) by

$$\nu' = 2(i_o)_{extr}/(\partial i_c/\partial\eta)_{\eta=0} \qquad [12]$$

Consequently

$$\nu' = \nu\,(i_o)_{extr}/i_o \qquad [12a]$$

For the Volmer-Tafel mechanism, $\nu = (\gamma + 2)/(\gamma + 1)$ (18). Substituting for i_o from Eq. [10c] into [12a] we have

$$\nu' = (\gamma + 2)\,(i_o)_{extr}/i_{oI} \qquad [13]$$

It has been suggested that a value of 2 (or close to 2) for the stoichiometric number of the hydrogen reaction shows that the discharge step [I] is rate determining in the Volmer-Tafel mechanism (3, 17, 19). Since experimental values of the stoichiometric number are almost always apparent values, this conclusion is not valid frequently. The distinction between ν and ν' is particularly important when γ is of the order of 1.

The apparent stoichiometric number is arbitrary to a certain extent since it depends on the section of the total polarization curve chosen for extrapolation. The significant problem here is to find a γ consistent with the value of ν' and $(i_o)_{extr}$, rather than to use ν' as a criterion for determining the mechanism.

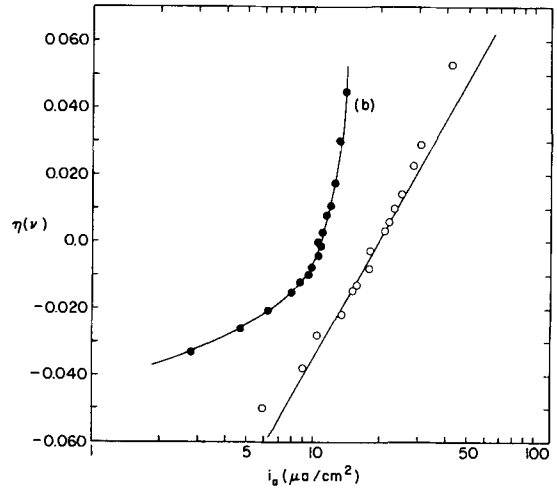

Fig. 5. Overpotential as a function of the total anodic current ($i_a = i_{appl} + i_c$) for electrodes in the initial state (a) and the steady state (b). The Tafel parameters for (a) are $b_a = 0.120$v and $i_o = 1.95 \times 10^{-5}$ amp/cm^2. Points for $\eta<0$ were calculated from the corresponding cathodic curve (Fig. 3) for which $b_c = 0.120$v and $i_o = 1.85 \times 10^{-5}$ amp/cm^2. The anodic curve for electrodes in the steady state (b) is not a Tafel line since θ varies rapidly in this region. The limiting anodic current for electrodes in the steady state is $(i_a)_{lim} = 2k_4^\circ = 1.4 \times 10^{-5}$ amp/cm^2. Overpotential in volts.

[2] The value $\gamma = 1$ is a lower limit. The value of γ depends on θ°. Devanathan and Selvaratnam obtained θ° by a short extrapolation from $\eta \simeq -10$ mv to $\eta = 0$. Any error in the extrapolation is in the direction of large i_{oII}.

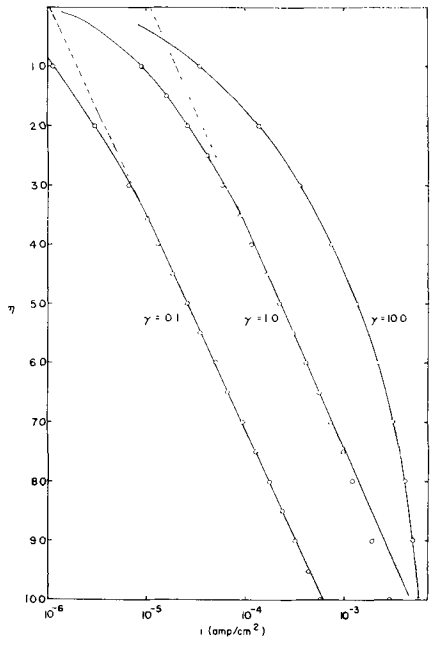

Fig. 6. Tafel plots for a Volmer-Tafel mechanism with $\gamma = 0.1$, 1.0, and 10.0. Surface coverage $\theta^\circ = 0.04$ at $\eta = 0$. The constants $k_3^\circ = 3.2 \times 10^{-3}$ amp/cm² and $k_4^\circ = 5.5 \times 10^{-6}$ amp/cm² are those given in ref. (8). The constant k_1° varies from 1.0×10^{-6} amp/cm² ($\gamma = 0.1$) to 1.0×10^{-4} ($\gamma = 10$) while k_2° varies from 2.4×10^{-5} amp/cm² ($\gamma = 0.1$) to 2.4×10^{-3} amp/cm² ($\gamma = 10$). The overpotential is in units of RT/F (26 mv at 30°C).

We consider first electrodes in the steady state. From Eq. [8] and [10]

$$i_{oI} = (2k_4^\circ)\,\gamma \qquad [14]$$

Substituting Eq. [14] into [13]

$$\nu' = (\gamma + 2)\,(i_o)_{extr}/2\gamma\,k_4^\circ \qquad [15]$$

In a typical case (Fig. 2 and 5), $(\partial i_c/\partial\eta)_{\eta=0}$ obtained from a linear plot of i_c *vs.* η ($|\eta| < 15$ mv), was 3.88×10^2 amp/cm²/v and $(i_o)_{extr}$ was 0.93×10^{-5} amp/cm². The corresponding apparent stoichiometric number was 1.85. From the anodic limiting current we have $2k_4^\circ = 1.4 \times 10^{-5}$ amp/cm². Substituting in Eq. [15] we find $\gamma = 1.1$.

Values of ν' for electrodes in the steady state ranged from 1.50 to 2.25, $i_{oII} = 2k_4^\circ$ ranged from 7×10^{-6} to 1×10^{-5}, amp/cm², and γ from 0.8 to 1.3.

The apparent stoichiometric number for electrodes in the initial state was between 1.8 and 3.0 The value of $2k_4^\circ$ is not known in this case since the anodic limiting current was a diffusion current. However, we can write

$$2k_4^\circ > (i_a)_d$$

where $(i_a)_d$ is the diffusion-limited anodic current density. In a typical case ν' was 2.10, $i_o = 1.85 \times 10^{-5}$ amp/cm², and $2k_4^\circ > 10^{-4}$ amp/cm² (Fig. 4). Using Eq. [15] we find $\gamma < 0.18$. The upper bound of γ calculated according to Eq. [15] for electrodes in the initial state was 0.2.

An extensive discussion of the stoichiometric number of the hydrogen reaction on nickel electrodes was given by Horiuti and Sugawara (20). The distinction made here between ν and ν' amplifies their argument and demonstrates that $\nu' \sim 2$ is consistent with a Volmer-Tafel mechanism for which $\gamma \sim 1$.

Table III. Kinetic parameters of the hydrogen reaction on nickel

O.1*N* NaOH at 30°C

	Initial state	Steady state
$(i_o)_{extr}$, amp/cm²	2.5×10^{-5}	1.0×10^{-5}
b, v	0.125	0.090
ν'	2.0 ± 0.23*	1.8 ± 0.15**
$(i_a)_{lim}$, amp/cm²	$(i_a)_d \sim 1 \times 10^{-4} < 2k_4^\circ$	$2k_4^\circ \sim 10^{-5}$
γ	<0.2	~1.1

* Average of 10 determinations.
** Average of 8 determinations.

Table III summarizes in terms of b, ν', and γ the distinction made previously between the initial and the steady state of nickel electrodes. Typical Tafel slopes and exchange currents are given rather than average values for the reasons discussed previously. However, mean values of ν' may be computed and these are given in Table III.

Tafel Slopes

It is apparent from Table III that the discharge step is rate determining for electrodes in the initial state while for electrodes in the steady state there is no rate-determining step, *i.e.*, the exchange currents for discharge and combination are about equal.

The cathodic polarization curve on electrodes in the initial state is given by Eq. [5a]. If $i_{oII} >> i_{oI}$, the change with η of the pre-exponential term is negligible with respect to $e^{-\alpha\eta}$. The polarization curve approaches

$$i_c \simeq k^1 e^{-\alpha\eta}$$

The Tafel slope gives directly the value of α. With electrodes in the initial state α was between 0.45 and 0.55.

The value of θ° for electrodes in the initial state is not known. If the specific rate of the combination reaction is the same as for electrodes in the steady state, *i.e.*, $k_3^\circ \sim 3 \times 10^{-3}$ amp/cm², then from

$$i_{oII} = 2k_3^\circ\,(\theta^\circ)^2 > 2 \times 10^{-4}\ \text{amp/cm}^2$$

we estimate $\theta^\circ > 0.2$. It is probable that k_3° is less for electrodes in the initial state since the (specific) rate of surface combination of hydrogen atoms is expected to decrease as the energy of adsorption increases. Consequently, the lower limit of θ° is probably considerably higher than 0.2.

The polarization curve for electrodes in the steady state is given also by Eq. [5a]. The variation of the pre-exponential term can be estimated in this case from the data given in ref. (8). We find over the range $2 < |\eta| < 8$

$$(1 - \theta) \sim (\text{const.}) \exp(+0.06\eta)$$

A plot of log i_c *vs.* η should be approximately linear over the range $\eta = -0.050$ to $\eta = -0.200$ mv (see also below) with a slope $-(\alpha - 0.06)$. The transfer coefficient calculated in this way for electrodes in the steady state (Tables I and II) is between 0.69 and 0.73. Devanathan and Selvarat-

nam (8) found $\alpha = 0.67$ (at 27°C) by plotting log $[i_c/(1-\theta)]$ *vs.* η.

Surface States

Since nickel adsorbs hydrogen extensively (21), we expect θ° to approach unity at 1 atm of H_2. The fractional coverage for electrodes in the initial state is at least 0.2 and may be considerably higher. However, θ° is only 0.05 in the steady state. The decrease in hydrogen adsorption implies that water, hydroxyl, or oxygen are adsorbed extensively upon cycling. It is doubtful that water adsorption would be increased significantly at positive potentials. It is also doubtful that water would produce, under any circumstances, a large change in hydrogen adsorption.

It is difficult to say which of the remaining two possibilities is more likely. Hydroxyl ion adsorption probably takes place. The rate and extent of its adsorption must be appreciably increased at positive potentials. However, hydroxyl ion should be desorbed at negative potentials with a return to the "initial" state. This is not observed. A resolution of this contradiction is possible if the free energy of adsorption of hydroxyl ion is larger than about 20 kcal/mole. Its desorption in the negative potential region traversed on cathodic polarization may be relatively small under these circumstances.

An oxide is probably formed during the anodic part of the cycle. Under normal circumstances, one expects this oxide to be reduced on cathodic polarization. The electrode capacity (8) is normal (20 μf/cm^2). Therefore, an oxide of the usual type is not present. However, a thin, conducting nickel oxide may be stable even on cathodic polarization. Its contribution to the total electrode capacity would be negligible if it were an electronic conductor.

In any case, the electrode surface is modified by the first anodic-cathodic cycle so that the energy of adsorption for hydrogen decreases. The increase of the transfer coefficient from about 0.5 to 0.7 is probably a result of the change in the hydrogen adsorption energy.

There are several theoretical interpretations of the coefficient α, none of which is entirely satisfactory (11). In the common representation of electrode reactions in terms of energy-reaction co-ordinate diagrams α is given by the slopes of the potential curves for the initial and final states at their point of intersection (22-24). Although an increase of α can be interpreted in a variety of ways with this theory (24, 25), the most probable interpretation is that the heat of adsorption of hydrogen decreases. For example, in the calculation cited above (25) for discharge of hydrogen ion on nickel, a decrease of the heat of adsorption by about 10 kcal would shift α from 0.5 to 0.7. The calculation (25) assumes that the curve for the final state is displaced vertically without changing its shape and that no displacement takes place along the reaction co-ordinate. Since both assumptions are doubtful, it can only be said that an increase of α is consistent with a decrease of the energy of adsorption of hydrogen.

It should be pointed out that the transition from "initial" to steady state is unrelated to the attainment of any possible equilibrium between adsorbed hydrogen and hydrogen dissolved in the metal. The transition is induced by anodic polarization. Positive potentials certainly do not promote dissolution of hydrogen into nickel.

High Current Densities and the Shape of the Overpotential Curves

The cathodic current is a simple exponential function of the overpotential in the Volmer-Tafel mechanism only if $\gamma >> 1$ or $\gamma << 1$. In both cases, θ is sensibly constant over several hundred millivolts and the Tafel plot is linear. If γ is between approximately 0.1 and 10, the relation between i_c and η is complicated by the term $(1-\theta)$ in Eq. [5a]. The Tafel plot is now linear at large $|\eta|$; it may be linear also at moderate $|\eta|$ (*i.e.*, −50 to −200 mv), but with a smaller slope, if the k's are such that Eq. [4] approximates a simple exponential relation between θ and η. The two linear parts are joined by a curved section.

To make the above remarks specific, let us consider the case $\gamma = 1$ using reported (8) rate constants. A plot of log θ, calculated from Eq. [3] and [4], against η is linear in the interval $\eta = 0$ to $\eta = -7$ (−180 mv); approximately, $\theta = \theta^\circ e^{-0.81\eta}$ in this range of η (18). We find from Eq. [5a] that $i_c = (i_o)_{extr} e^{-0.62\eta}$ which yields a linear Tafel plot with an apparent $\alpha = 0.62$. Deviations from linearity in the direction of larger $|\eta|$ for a given i_c appear at larger overpotentials. Calculated Tafel plots for $\gamma = 0.1$, 1, and 10 are shown in Fig. 6.

There are also experimental sources of deviation from linearity at high current densities which make it impossible frequently to observe the second linear section. The potential measured with the direct method includes a back emf produced by concentration changes in the solution next to the electrode. It includes also an iR potential drop in the solution between electrode and tip of the Luggin capillary. Both errors are in the direction of larger $|\eta|$ and both become appreciable at about 2×10^{-3} amp/cm^2 in 0.1*N* NaOH. Therefore, at high current densities we expect deviations from Tafel behavior in the direction of larger $|\eta|$ both because of the structure of Eq. [3-6] and because of concentration and ohmic overvoltages.

The deviations observed at current densities larger than 1×10^{-3} amp/cm^2 were actually in the opposite direction, *i.e.*, toward smaller $|\eta|$ for given i_c. For electrodes in the initial state, the deviations suggested a transition to another Tafel slope with smaller *b*. Deviations observed with electrodes in the steady state were similar but smaller and appeared at even higher current densities. Because of the experimental errors inherent in the direct method of measurement of η at high current densities, no attempt was made to study this potential region in detail. The results at high current densities suggest nevertheless that the kinetic equations for

hydrogen evolution on these electrodes are modified either by the emergence of an alternative path or by changes in the energy of hydrogen adsorption at high coverages.

Conclusions

The surface state of nickel electrodes in 0.1*N* NaOH depends on their pretreatment and polarization history; it determines the kinetics of the hydrogen reaction. If the fractional coverage with adsorbed (atomic) hydrogen at $\eta = 0$ is high, the discharge step is slow and rate determining. If the fractional coverage is small, the exchange rates for discharge and combination are about equal and there is no single rate-determining step.

Technical Notes

An All-Teflon Electrochemical Cell Assembly

J. L. Weininger and W. R. Grams

Research Laboratory, General Electric Company, Schenectady, New York

In electrochemical studies improved instrumentation and experimental techniques require a corresponding improvement in cell design. This note describes an all-Teflon cell in which the electrolyte saturated with an inert carrier gas is circulated past the electrodes.

It is now recognized that electrodes and electrolyte should only be exposed to each other and to inert container material. Such inert materials are Pyrex glass and fluorinated plastics, *e.g.*, Teflon. Each has distinct advantages. Pyrex glass can be blown easily, and cells made with it are assembled from interchangeable commercial parts. It is transparent and chemically inert to most solutions, concentrated alkali being an important exception. On the other hand, Teflon is readily machined from available stock and is quite inert. It has the disadvantage of flowing under mechanical pressure so that blocks of Teflon, particularly with machined threads, deform on being bolted together. It was found, however, that this could be avoided by using pipe threads instead of machine threads, and by the addition of a simple embossing on Teflon parts that are to be bolted. These two improvements have been incorporated in the construction of the following Teflon cell.

Figure 1 is a schematic of the assembly, which consists of the cell in the center, an impeller and its housing on the left, and a Teflon U-tube to the right. The electrolyte is circulated through this assembly in a counter-clockwise direction. In the drawing the cross-hatched parts are made of Teflon,

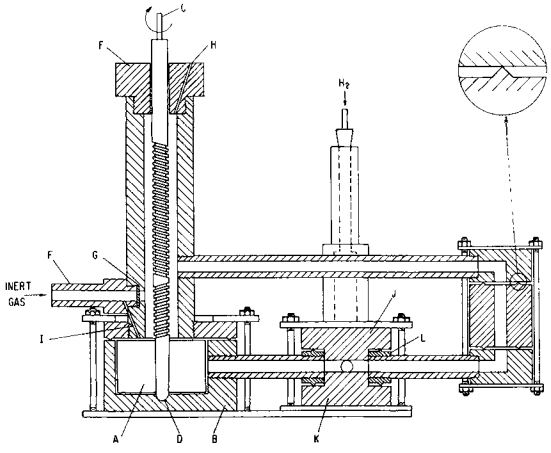

Fig. 1. Schematic of Teflon cell assembly

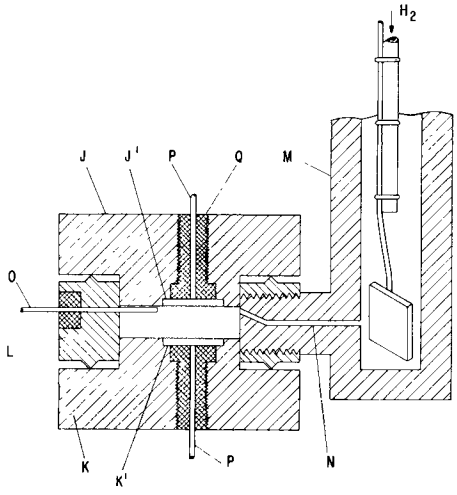

Fig. 2. Teflon cell with reference electrode

as is the rotating impeller, its shaft, and the hydrogen electrode in the background of the cell. The remaining parts are bolted brass plates. All liquid-sealing threads are pipe threads.

The impeller, A, is a flat paddle which rotates with reasonably close tolerance in its housing, B. The outlet tube is off diameter with respect to the impeller so that a pushing or swiping motion of the liquid into the tube leading to the cell is achieved. The impeller shaft is reinforced internally with a steel rod, C. The bottom end of the shaft is seated in the housing like a bearing, D, and in the cylinder at the top it is capped with a Teflon piece, E, thus providing self-lubrication. Opposing threads guide the gas which can be bubbled through the solution. The right-hand thread on the lower part of the shaft introduces fresh gas *e.g.*, inert argon, from tube F through the porous Teflon plug G, into the circulating electrolyte stream. At the end of a single pass gas bubbles are rejected by the left-hand thread of the upper part of the shaft through the hole, H, in the cylinder cap. The plug, G, can also be bypassed by the hole, I.

The U-bend on the right consists of three Teflon pieces bolted between brass plates. They are easily separated in order to make the cell itself readily accessible. The method of embossing these pieces, mentioned above, is shown in an inset. It it also used to make the impeller housing and the cell pressure-tight.

The cell, shown in detail in Fig. 2, also consists of three Teflon pieces, the test electrode J' in J, the counter-electrode K' in K, and the spacer L. The latter defines the cell volume (3.2 cm^3) by separating the electrodes and also provides access to the other electrodes. There is a housing M for a reference electrode connected to the cell by the Luggin capillary N. A hydrogen electrode is shown, but any other standard electrode can be used. Electrode O shows the possibility of introducing other electrodes. Specifically, O is a palladium wire used for capacity measurements. Test and counter electrodes, *e.g.*, a single crystal of nickel and a platinum foil later to be platinized, must be inserted into the Teflon pieces J and K without allowing the electrolyte to come in contact with the leads P. In this respect a simple pressure-fit is not completely satisfactory. Instead, a shoulder is machined into the Teflon piece with close lateral tolerance, and a hole is drilled and tapped through it. While the electrode material rests on this shoulder, the hole is filled with a thermosetting plastic (epoxide at room temperature) to impart rigidity to the electrode assembly. The epoxide Q is not threaded into the Teflon, but the threads are necessary to ensure good adhesion between Teflon and epoxide.

This construction resulted in an electrode-mount without creepage of electrolyte. This was prevented by the design of the shoulder (J' and K' in Fig. 2) as well as the epoxide protection of the lead wire. In an experiment with a nickel electrode under corrosive attack the lead wire did not come in contact with the electrolyte until the electrode was consumed.

The total volume of the assembly is distributed thus: 50 cm^3 in the impeller reservoir, 3.2 cm^3 in the cell itself, and 15 cm^3 in the tubing. The impeller is ordinarily rotated at 400 rpm, which propels the liquid at about 50 cm/sec, but higher speeds of rotation can be used.

In summary, the design of an electrochemical cell is shown which, in addition to the electrode materials, contains only Teflon. All Teflon parts are machined from simple stock and tubes. From the experimental point of view the cell has the advantage of a rapidly circulating electrolyte saturated with any desired gas. The stream of electrolyte is parallel to the electrode surfaces. Only a small volume of electrolyte, isolated from the surrounding, is used. The cell also provides for a symmetrical field between test electrode and counter electrode, and for close proximity to the Luggin capillary. We are using it for the study of electrode reactions at single crystal surfaces, as well as more conventional electrode materials.

Use of a Precious Metal Anode in the Electrowinning of High-Purity Chromium from a Fluoride Bath

J. A. Whittaker

Fulmer Research Institute, Stoke Poges, Bucks, England

In connection with a research program on the ductility of chromium and its development as a high-temperature resistant material (1-3), a pilot plant (4) has been in operation for some years producing high-purity chromium at the rate of approximately 1 kg/day. Various modifications (4) have been made to the plant to improve the purity of the chromium, and this note refers specifically to the introduction of a palladium anode, designed to avoid tin contamination of the chromium, and its subsequent effects on the cathode current efficiency.

When the first palladium anode was received the experimental arrangement was briefly as follows; a high-density polyethylene plating tank (55 liters of solution), a Pb/7% Sn anode and a copper-tube cathode. This anode was first used in a bath which had been operated for some time with the Pb/7% Sn anode; the cathode current efficiencies obtained for a period before and immediately after its introduction are given in Table I.

When, however, the palladium anode was used in a freshly prepared bath, made necessary by the failure of the polyethylene tank, there was a serious decrease in the efficiency after only a few runs, as shown in Table II, the composition and conditions being exactly as described in Table I. Associated with this fall off in efficiency was a pronounced increase in the resistance of the bath and an increase also in its trivalent chromium content. This fall off in efficiency in the new bath may have been due to one or more of the following factors:

Table I. Cathode current efficiencies

Solution composition: 250 g/l CrO_3; 5 g/l HF

Conditions: 90°C; 460 amp/ft²; normal deposition time 24 hr; 55 liters of solution

	Cathode current efficiency, %
High-density polyethylene tank; Pb/7% Sn anode	36, 34, 26, 33, 36, 34, 36, 38, 37.
High-density polyethylene tank; Pd anode	33, 37, 31, 40, 30, 41, 41, 41, 34, 40, 37, 38, 38, 36, 39, 40.

(*a*) the absence of lead salts in the new bath, (*b*) the absence of PbO_2 on the anode, and (*c*) the absence of tin salts.

The results of the investigation of factors (*a*) and (*b*) are given in Table III. These experiments were carried out in a 10-liter polytetrafluoroethylene (P.T.F.E.) beaker, 9 liters of solution, using a second palladium anode of identical construction.

The effect of tin was not investigated fully since one of the main reasons for introducing a palladium anode was to avoid tin contamination of the chromium, and tin salt additions would not have been a practical solution. However, 0.75 g/l of tin, as stannic chromate, was added to the solution in the P.T.F.E. beaker after run 13, and the efficiency of the next run was 29%, indicating no serious effect from tin in solution.

The results in Table III show that the presence of lead salts in the bath and PbO_2 on the anode are definitely associated with a maintained efficiency Despite the fact that the efficiencies in Table III are low compared with those in Table I, these modifications were introduced into the larger, 55 liters, bath, and the first six runs gave efficiencies of 34%, 38%, 37%, 37%, 36%, 38%. Laboratory scale work (5) has since indicated that a correlation exists between solution volume:cathode area ratio and the level of efficiency. The cathode area was here constant for both the 9 liter and 55 liter bath.

Table III. Factors contributing to decline of cathode current efficiency

Solution composition: 250 g/l CrO_3; 5 g/l HF

Spectrographic analysis has failed to detect either lead or palladium in the chromium.

Conclusions

The use of a palladium anode for the electrowinning of chromium from a fluoride bath, made necessary by tin contamination from a Pb/7% Sn anode, resulted in a serious fall off in efficiency of new baths. An increase in the bath resistance and also in the trivalent chromium content accompanied the fall in efficiency. It has been shown that these disadvantages can be overcome by saturating the bath with lead chromate and by preforming PbO_2 anodically on the surface of the anode.[1]

[1] British Patent applications have been filed for these results.

Electroless Ni-Co-P Films with Uniaxial Anisotropy

J. Bagrowski and M. Lauriente

Air Arm Division, Westinghouse Electric Corporation, Baltimore, Maryland

There has been considerable interest in the basic mechanism responsible for the phenomenon of uniaxial anisotropic energy in thin magnetic films as displayed by the rectangular hysteresis loop found in the easy direction and the closed loop in the transverse direction (1). In addition to satisfying the curiosity of the fundamentalist, such information is of engineering importance for solving the reproducibility problems posed by applications such as memories for computers.

In 1959, Heritage and Walker reported anisotropy for thin nickel-cobalt-phosphorous films made by electroless deposition in a magnetic field (2). In a check of this work, uniaxial anisotropy was also found when a magnetic field was not used, thus indicating that another source of anisotropy was present.

Experimental

Chemical deposition (also known as electroless deposition) requires a suitably activated surface to initiate the process. The oblique incidence effect which has been noted for films made by vacuum evaporation (3, 4) thus is impossible to study directly. The experiment was designed to ascertain if oblique incidence effects in a nonmagnetic substrate film would show up in the chemically deposited magnetic film.

The experiment consisted of evaporating one group of 1 x 3 in. glass slides with chromium-gold at oblique incidence and another group at normal incidence. These two groups were then each subdivided so that one group was plated in a magnetic field and the other without the field. The magnetic field was provided by a d-c magnet with a field strength of 200 oe. One set of slides was also mechanically polished in one direction.

Figure 1 indicates the general arrangement used for producing chrome-gold substrates for the oblique incidence study. Slides evaporated at normal incidence had the source distance increased to 16 in. Only two substrates, located directly above the source, were evaporated at any one time to further decrease the oblique incidence effect. The thickness was controlled by means of a resistance monitor. The chromium, used for purposes of adhesion only, was evaporated to 150,000 ohms per square while the gold was evaporated to 3 ohms per square.

The solution found to give the best results was a modification of the one given by Heritage and Walker (2). It consisted of nickel sulfate 7.5g, cobalt sulfate 5.0g, ammonium sulfate 21g, sodium citrate 42.0g, hypophosphorous acid 15.0 ml, and aqueous ammonium hydroxide in sufficient quantity to yield a solution *p*H of 8.5 in a volume of 500 ml. Deposition was at a rate of approximately 1000Å/min. The solution was used at 90° ± 1°C.

The thickness of the films averaged 5000Å as measured by the Tolansky multiple beam interferometry technique (5). This process yields a coercive force which is not too much higher than found for thin Permalloy films. This is very surprising in view of the coercivities of around 1000 oe reported by Sallo and Olsen (6) on films of similar composition which were electrodeposited. A check on the film composition using an electron probe microanalyzer compared favorably with the analysis reported by Heritage and Walker, which

was of equal amounts of nickel and cobalt and 5% of phosphorous.

Measurements.—Magnetic parameters measured were, H_c the wall coercive force, and H_k, the anisotropy field. Measurements were made at 400 cps, using the familiar Crittenden (7) setup. The measurement of H_k is extrapolated from the initial transverse susceptibility to the saturation flux. H_A is the applied field.

Results

For all the films tested, $H_c < H_k$ indicating that the films were normal. The sensitivity of the films to oblique incidence in the substrate is shown in Table I by the consistency of the H_k values found independent of the magnetic field. This point is probably made more dramatically in Fig. 2, where the anisotropy is easier to perceive by the characteristic loop traces.

Now it will be interesting to test the corollary; *i.e.*, will the anisotropy be absent when there is no obliquity. Table II indicates by the absence of the H_k for specimens made without the field that this is the case. Figure 3 illustrates the same point.

Inducing uniaxial anisotropy by directional polishing has been reported (2) and verified experimentally by the authors. Directional polishing, since it offered no significant improvement in magnetic properties, was not pursued further. It did, however, confirm the significant contribution made by the substrate surface to uniaxial anisotropy.

Rotatable anisotropy similar to that reported for Permalloy by Prosen *et al.* (8) were found for some of the thicker films, *i.e.*, in excess of 10,000Å. In these films the easy direction of magnetization can be selected by application of a sufficiently large magnetic field. A closed loop can then be found 90° from this axis. Figure 4 shows typical loops for this phenomenon. This anisotropy could possibly be explained as an antiferromagnetic interaction between cobalt oxide and the cobalt-nickel layers, based on the Permalloy example.

Conclusion

The crystallites which form thin films made by oblique incidence evaporation are known to have a chain-like formation because of the self-shadowing effect. Assuming that the profiles thus exposed in the nonmagnetic film are replicated in detail by plating, the theory proposed by Smith (3) can then be applied. In a like manner, the anisotropy created by polishing scratches strengthens the theory that a shape anisotropy is taking place. This model provides a convenient linkage for relating anisotropy phenomena found for vacuum evaporated films to chemically deposited films.

Electrodeposition of Thorium from Fused Salts into a Molten Zinc Cathode

Ralph E. Johnson

Atomics International, A Division of North American Aviation, Inc., Canoga Park, California

The nuclear industry has been interested in thorium chemistry since this metal constitutes the raw material in the breeding of U^{233}. A breeder reactor of this type may contain thorium in its core, as well as in the blanket. One step in the reprocessing of such a core or blanket could be the anodic solution of the impure thorium and the simultaneous deposition of pure thorium at the cathode. This is certainly not a new idea and has been applied with reasonable success in the past (1-7). Theoretically the electrolysis could take place in either an organic medium or a fused salt medium. The organic system has the advantage of room temperature operation and the disadvantage that complex organic reduction reactions compete with the deposition of the metal ion. The fused salt system operates at an elevated temperature, but the competition for electrons at the cathode is less severe.

Most workers in the field of thorium electrochemistry have selected the fused salt approach to the problem because of the relative simplicity of the electrochemistry (2). Thorium has been deposited from fused salts by a number of workers. Metallic thorium in the form of dendrites has been produced in this country by Gurklis and co-workers (3), and by Raynes and co-workers (4), in Russia by Evstyukhin (5), in Germany by Drossback and Neumayer (6), in Japan by Ogawa (7), and by others. The use of a molten metal cathode has been used previously in fused salt electrochemistry. Izbekov (8) used liquid tin and bismuth cathodes in fused salt electrolyses and Ogawa and his co-workers (9, 10) used a molten zinc cathode into which thorium was deposited. Murbach and Hansen (1) of this laboratory have also electrodeposited thorium into molten zinc. Thorium plated on a solid cathode yields a dendritic deposit which is loosely adherent and losses occur in the process of separation from the salt bath. A molten zinc cathode avoids this difficulty and it has been shown that zinc is easily removed from the thorium-zinc alloy (11).

In the work done to the present time on the electrodeposition of thorium from fused salt media, there has been little success in systematizing or improving the method. Smirov and Yushina (12, 13) have studied the cathode and anode process to some extent, but other works have been concerned only in trying to produce the metal. Gurklis (3) *et al.* report cathode current efficiencies ranging from 3-42%; Raynes (4) and his laboratory obtained 40-45%; and Evstyukhin (5) and co-workers found 75% entrained salt in the solid deposit. With the use of the molten zinc cathode, Ogawa (10) reports 30-60% cathode current efficiencies and Murbach and Hansen (1) were concerned with decontamination rather than efficiency.

In the present work, the technique of electrolytically depositing thorium into molten zinc from a fused salt has been perfected to the point that approximately 100% current efficiencies at the anode and cathode are obtained. The effect of the chlorination of the salt bath prior to electrolysis has been studied. The variation of current efficiency with thorium ion concentration and with current density has been established. In addition, a practical maximum concentration of thorium in zinc obtainable by this method has been established.

Experimental Method

Apparatus

The apparatus is shown in Fig. 1. The electrolysis cell was made from a tall, heavy-wall, Pyrex Dye beaker. The cathode electrical contact which entered from above was a ¼ in. tantalum rod which was threaded on the lower end. A mulite sleeve prevented contact between the salt and the tantalum, and a pin through the tantalum near the bottom retained the sleeve in position throughout the run. The thorium anode was suspended from a ⅛ in. tantalum rod. Care was taken to avoid getting the tantalum in the salt melt. Two short lengths of glass rod which fit into the holes of the stirring platform were fused to the bottom of electrolysis cell. The cell rested on the stainless steel stirring platform which was stirred from below.

The electrolysis cell was positioned in a vacuum furnace (Fig. 1). The main body of the furnace consisted of a 64-mm Vycor tube surrounded by a clamshell heater. The Vycor tube was sealed into water-cooled flanges with Apiezon W wax. The top flange had an exhaust valve leading to a bubbler and contained the rubber stopper through which the electrodes and thermocouple tube were lowered into the melt. The bottom flange was bolted to the vacuum system and sealed by a rubber O-ring. The system had facilities for placing it under vacuum or argon. The argon which was introduced is first passed over uranium chips at 500°C to remove oxygen.

Procedure

The electrolysis cell was prepared by cutting off the top of a 400 mel Dye Pyrex beaker and fusing short lengths of a 9 mm glass rod to the bottom of

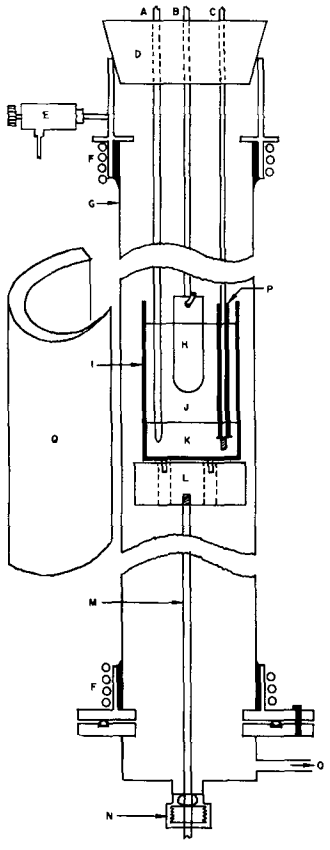

Fig. 1. Apparatus: A, alumina thermocouple well; B, tantalum anode hangar; C, tantalum cathode lead; D, rubber stopper; E, argon outlet valve; F, water-cooled flanges with Apiezon W seal; G, Vycor furnace tube; H, thorium anode; I, Pyrex beaker; J, fused salt; K, molten zinc cathode; L, steel platform; M, steel stirrer; N, O-ring seal for stirrer; P, ceramic insulator on cathode lead; Q, clam shell furnace around Vycor tube.

the beaker about 1½ in. apart. The anode was made by drilling a hole in a rectangular piece of pure thorium which was 6 x ½ x ⅛ in. in dimensions. The ⅛ in. tantalum was passed through the hole and made into a hook which was clamped against the thorium in the vise to insure contact. The cathode was prepared from a zinc ingot which weighed about 200g and the dimensions of which would permit lowering it into the beaker. A hole was drilled and tapped in the zinc to correspond to the threads on the end of the tantalum cathode contact.

The appropriate salt mixture was weighed into the cell. In all experiments, this was 150g LiCl, 150g KCl, and the desired amount of $ThCl_4$. The cell was then placed on the platform in the system, closed with a solid rubber stopper, and a vacuum was drawn overnight to remove most of the adsorbed water. The next morning argon was introduced into the system. The flow or argon was continued throughout the experiment. The uranium trap and the furnace were turned on. After the salt had melted, the solid rubber stopper was exchanged for one which held the electrodes and thermocouple tube. The thermocouple was introduced into the tube, and the zinc electrode was lowered into melt. After the zinc had melted, the tantalum contact was lowered to a point just above the bottom of the cell. This insured that the tantalum was under the surface of the zinc. The stirring motor was turned on so that the cell rotated about 40 rpm. When the temperature had reached 600°C, which was the temperature of all runs, the thorium was lowered into the melt to a depth of about ¾ in. and the current turned on. After a predetermined length of time, electrolysis was discontinued, the melt cooled, and the zinc-thorium ingot dissolved in acid and submitted for analysis.

Results

In the earlier experiments, many variations in apparatus and technique were used. Various crucible materials were used, several salt baths were employed, induction heating of the zinc as a means of heating and stirring the zinc was tried, and compound purification was attempted. High current efficiency was achieved only when a suitable stirring mechanism had been developed.

In a number of experiments, an effort was made to plate a relatively large amount of thorium into zinc. The solubility of thorium in zinc at 600°C is near 1 w/o (14). In this work, alloys with a much higher concentration of thorium were obtained with the highest having 16.2% thorium.

A series of experiments was run to determine the effect of concentration of $ThCl_4$ on the cathode current efficiency. Results are listed in Table I.

Another series was run to determine the effect of current density on the current efficiencies at the electrodes. The 15 w/o $ThCl_4$ salt mixture was chosen as being the optimum concentration based on the previous series of runs. The diameter of the cathode was 6 cm which gives 28.3 cm^2 area, and at the anode there was 1 $in.^2$ or 6.45 cm^2 area. These data are given in Table II. Experiment No. 94 was a blank to determine the weight loss at the anode in the absence of electricity. Each run was made for a duration of time necessary to deposit 19.5g of thorium according to the reaction

$$Th^{++} + 4e \rightarrow Th^{\circ}$$

For each run this was 32,400 coulombs.

The anode and cathode current efficiencies have been given without the correction for the blank run No. 94 since the effect is smaller than the inherent error.

As can be seen from Table I, the highest concentration of thorium in zinc attained was about 16%. It is possible to obtain this high a concentration even though the solubility is of the order of 1% because of the formation of Th_2Zn_{17} which precipitates. About 15% thorium represents a practical limit under the

conditions of this experiment even though the theoretical limit is 29.4% thorium with a cathode of pure Th_2Zn_{17}. At about 15% thorium, the alloy becomes paste-like, and further increases in the thorium concentration would stop the stirring action. Under these conditions of stirring, the zinc-thorium ingot has a smooth surface, and all of the thorium is under the surface. When stirring is omitted, thorium either is deposited as a layer on the zinc or dendritically grows out of the surface of the zinc.

The results of the experiments in which the $ThCl_4$ concentration was varied between 2.5 and 30%, indicate that the optimum concentration was 15 w/o $ThCl_4$ in a LiCl-KCl-$ThCl_4$ bath. It is felt that the 106% current efficiency figure is within the accuracy of the experiments. The difficulty encountered in maintaining a constant current over several hours is considerable. This lack of precision is also characteristic of the results of the series on current efficiency as a function of current density. In this case, the weight loss at the anode was determined simply by weighing before and after, while at the cathode, the solution was analyzed for thorium by first precipitating the thorium away from the zinc as a hydroxide and then reprecipitating the oxalate which was dried and weighed. Higher current densities were not possible with the power supply used in these experiments.

A technique has been established for the electrodeposition of thorium from a fused LiCl-KCl-$ThCl_4$ bath with a molten zinc cathode and thorium anode in which approximately 100% current efficiencies are obtained at both the cathode and anode. The most important condition in the process is the stirring of the zinc. The system developed here requires that the zinc surface be broken by the stirring action. It has been shown that 15% or so of thorium in zinc can be obtained readily by this technique. The concentration of $ThCl_4$ in the bath, which gave the highest current efficiencies, has been found to be 15% and current efficiencies at the electrodes are independent of current densities within the range studied. It was not necessary to purify chemicals or metals in this work in order to obtain maximum efficiencies.

Acknowledgment

The author wishes to acknowledge the efforts of W. D. Turner, who assisted in the laboratory work, and the work of the personnel of the Analytical Unit who performed the thorium analyses.

Inert Electrode Behavior of Tin Oxide-Coated Glass on Repeated Plating-Deplating Cycling in Concentrated NaI-AgI Solutions

J. Mantell and S. Zaromb[1]

Research Laboratory, Philco Corporation, Blue Bell, Pennsylvania

The theory and design principles of the Reversible Electroplating Light Modulator (RELM) are discussed at length in preceding papers (1, 2). The feasibility of RELM is, of course, contingent upon the existence of an electrochemically inert transparent conductor. Evaporated thin films of noble metals such as Pt or Au could not withstand more than a couple of deplating pulses exceeding 2v. Fortunately, however, conductive tin oxide coatings on glass proved much more resistant. The present experiments were performed with the simplest type of RELM, similar to (though not identical with) that shown in Fig. 2a of ref. (2). The actual cell design is shown in Fig. 1.

The electrolyte consisted of 1M AgI plus 1M NaOH in 5M NaI, the OH^- ions serving to convert any colored I_3^- ions into colorless IO_3^- ions. Because of complexing between the AgI and I^- ions, the electrolyte resistivity appeared higher ($\simeq$10 ohm-cm) than expected for 5M NaI solutions.

The cell resistance appeared to be in rough agreement with calculated values, *i.e.*, of the order of 15 ohms, as deduced from RC time constant curves recorded with a Type 545 Tektronix oscilloscope. With applied voltages of 4-22v, the resulting plating and deplating times τ were found to be of the order of 10 msec, in agreement with the calculated times

$$\tau \simeq Q/I = Q/(V/R) \qquad [1]$$

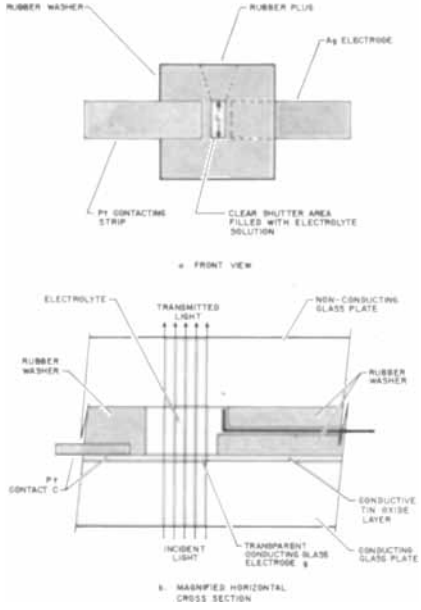

Fig. 1. Design of the reversible electroplating cell used in the present study.

[1] Present address: Research and Advanced Technology Department, Electronic Systems and Products Division, Martin-Marietta Corporation, Baltimore, Maryland

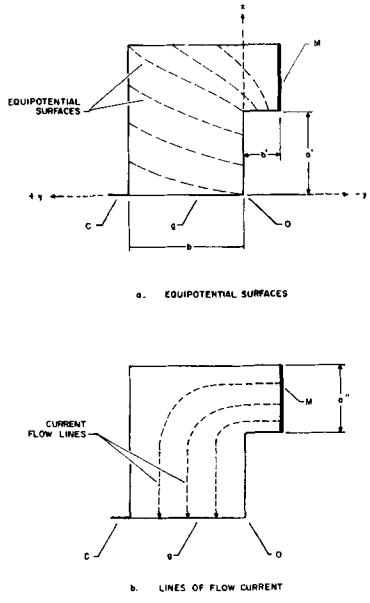

Fig. 2. Schematic representation of equipotential surfaces, current flow lines, and geometric design parameters of the electrode-electrolyte configuration used in Fig. 1b.

for square wave pulses or with the corresponding RC time constant values for condenser discharges. Both of these types of pulses were applied in both directions for a total of more than 1000 plating-deplating cycles without any sign of deterioration of the conductive tin oxide coating. A slow apparent deterioration of the cell was traced to the evaporation of the electrolyte and resulting solute precipitation of the saturated solution after more than 5 days of intermittent cycling.

Extrapolation of the results of ref. (2) shows that for fair plating uniformity, the dimensions of Fig. 2 should satisfy the conditions:

$$a' \geqq b^2/2k \qquad [2]$$

$$a'' \simeq b^2/2k \qquad [3]$$

and

$$b \leqq k \qquad [4]$$

where

$$k = \rho_e/\rho_g \qquad [5]$$

is the ratio of electrolyte resistivity ρ_e to glass surface resistivity ρ_g. The actual cell dimensions and resistivities were approximately $a' \simeq a'' \simeq 0.05$ cm, $b \simeq 0.3$ cm, $b' \leqq 0.1$ cm, $\rho_e \simeq 10$ ohm-cm, and $\rho_g \simeq 40$ ohms/square. These values fall just outside the limits set by Eq. [2] through [5]. Hence, the resulting plating uniformity could be expected to be poor or barely fair. The longer dimension L of the

2000	6.1	12.2	60	0.67	0.96	1.8

* Only those tests are listed here where the charge pulse Q was due to a condenser discharge. The square wave pulses used in most of these tests had serious uncertainties in the value of Q.

plated area was 0.7 cm. Hence, the plated area A was 0.2 cm^2.

According to Fig. 1 of ref. (1), the theoretical ratio of the optical density change δ to plating charge density q_d should be approximately

$$\delta/q_d \simeq 30 \text{ cm}^2/\text{coul} \quad [6]$$

for Ag plating solutions free of I_3^- ions. Hence, for $A \simeq 0.2$ cm^2, a total plating charge of Q coulombs should yield

$$\delta \simeq 150\,Q \quad [6']$$

As shown in Table I, the actual values of δ were usually between 25% and 50% of the theoretical ones. This is attributed partly to poor plating uniformity (related to excessive shutter width b) and partly also to the frequent presence of an appreciable concentration of oxidizing substance (IO_3^- ions formed by application of an excessive deplating charge) near the glass electrode.

In view of the latter factors, these preliminary results seem to be in fair agreement with theoretical expectations. The ability of the tin oxide coating to withstand the numerous relatively drastic plating-deplating pulses without any sign of deterioration renders the RELM promising for practical applications. Of course, the present experiments were performed in alkaline solutions in which the formation of nascent hydrogen (known to reduce the tin oxide) is least likely to occur. In neutral or acidic solutions greater care may have to be taken to operate under conditions of 100% plating current efficiency.

Vapor Growth of Twinned Germanium Platelets

C. Pritchard[1]

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Twinned germanium platelets have been formed from the vapor phase by a mechanism which appears similar to that governing the growth of dendrites from a supercooled melt. Regularly shaped and of {111} habit, the platelets are thin and flat with the twin planes extending parallel to the main faces. This is characteristic of dendrites of the diamond lattice materials, and both Wagner (1) and Hamilton and Seidensticker (2) have pointed out how the twins are essential to this type of growth. At least two closely spaced parallel twin planes are necessary. Together they form a set of self-perpetuating grooves where they reach the surface of the growing crystal. Nucleation takes place at these grooves more easily than elsewhere, and the crystal thus expands predominantly in their plane without appreciably thickening.

Within this preferred plane dendrites grown from the melt also exhibit preferred directions of growth (<211>) and propagate as long flat ribbons. This is partly a consequence of the thermal geometry which becomes set up in the system. Growth is rapid and becomes controlled by the diffusion of the liberated latent heat away from the growing interface. A more isotropic growth resulting in platelet formation has, however, been observed for germanium crystallizing from solution (3). Much slower than growth from the melt, it is governed less by the diffusion of heat from the crystal than by that of solute to it.

[1] Present address: English Electric, Leicester, England.

Platelet formation from the vapor is found to occur when germanium is heated in evacuated quartz capsules which have not been baked out prior to sealing off. The platelets nucleate at the quartz walls and grow there in great profusion, clinging by one edge and projecting into the capsule. They are flat, very thin, and regular in outline. Crystals up to a millimeter across have been obtained not more than 5μ in thickness. Both the main faces and the bounding edge facets are {111} planes and the edges consequently trace out <110> directions around the platelets. Thus, as illustrated by the examples in Fig. 1, their shape is either that of an equilateral triangle or some segment of a hexagon. In Fig. 1a two triangles are shown, one lying on the other. The smaller is tilted slightly and so appears dark under the normal illumination. Figure 1b is typical of the hexagonal type crystals. The longest edge, which is noncrystallographic in most cases, is that from which the growth takes place and by which the crystal is found attached to the quartz walls. Figure 1c is a crystal which points out directly the similarity between platelet and dendrite growth. From one apex of the triangle a tip is protruding in the <211> preferred growth direction much as that of a dendrite growing into a melt.

Twins have been revealed in these platelets by cross sectioning, polishing, and etching, and also by the fracturing technique of Faust and John (4). Etching is possible only on the thicker specimens,

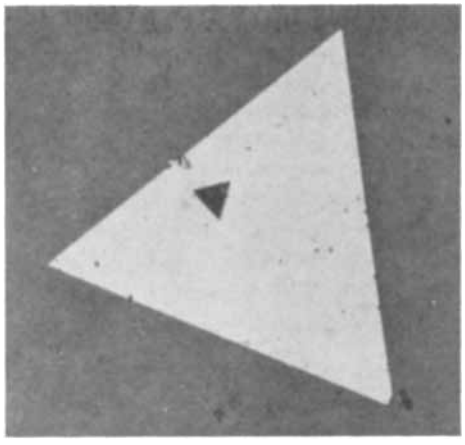

Fig. 1a. Vapor grown germanium. Two triangular platelets. Magnification 100X.

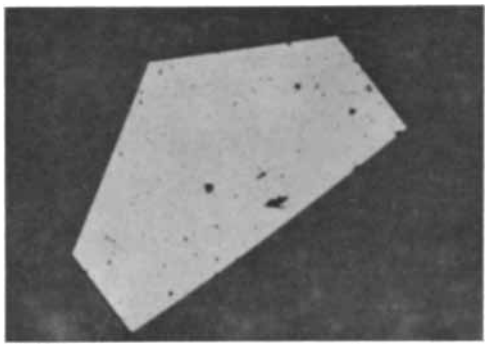

Fig. 1b. Hexagonal type platelet. Magnification 100X

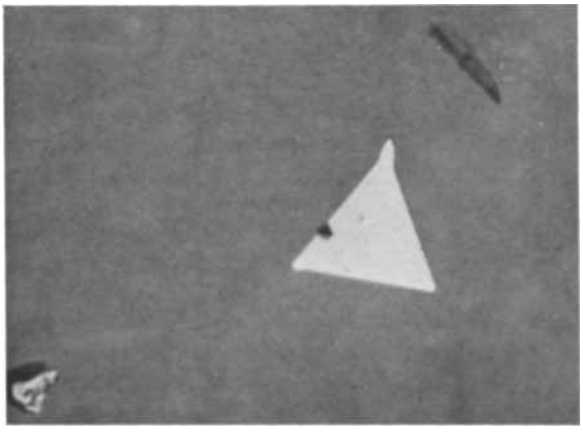

Fig. 1c. Triangular platelet with a "dendrite" growing from one apex. Magnification 200X.

and Fig. 2a shows the twin planes revealed in this way in a platelet about 20μ thick. A twin plane shown up by fracturing is illustrated in Fig. 2b. As revealed by either technique the twins in these crystals are always confined within a lamella which is at most 0.5μ thick. Individual twin planes cannot be resolved and, in particular, it has not been possible to tell from these observations whether there are more than one present or not. When fractured under a razor blade the material does tend to cleave along <110> directions, but the cleavage or fracture surface is invariably at right angles to the main face. This approximates the {211} cleavage discussed by Faust and John (4), and the {111} cleavage by which twins can most easily be resolved and counted was never obtained. However, it can be seen from in-

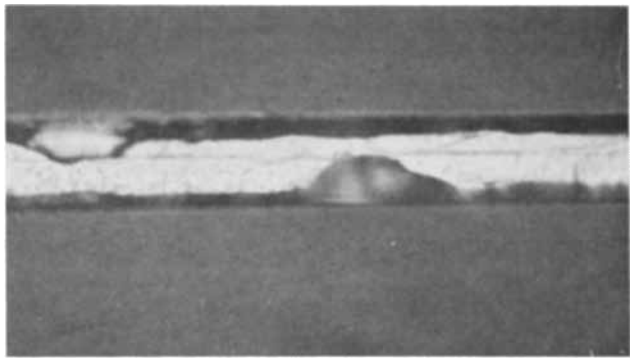

Fig. 2a. Twin planes revealed by etching a polished cross section. Magnification approximately 500X.

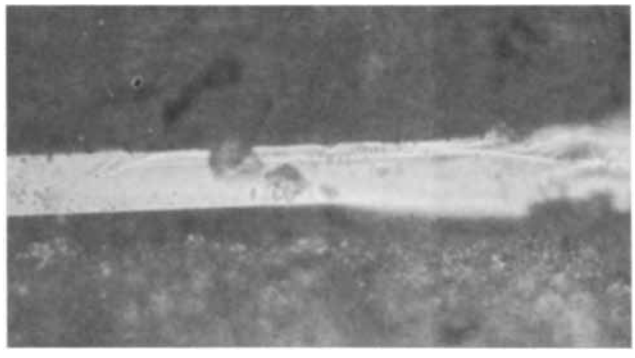

Fig. 2b. Twin planes revealed in a fractured cross section. Magnification approximately 500X.

spection of the edges of the platelets that in most cases there are an even number of twin planes in the crystals. As mentioned above the edges are themselves {111} planes and, were there an odd number of twins, they would be ridged and grooved according to the sense of the twinning operation. Some platelets are indeed ridged in this way, but the great majority have edges which are planar, sloping all in the same sense around the triangular crystals and alternately inwards and outwards around the edges of the hexagons. Thus, except for the few indeterminate examples, we can say that these platelets contain at least two twin planes and that the requirements of the twin plane growth mechanism are met.

About half of the platelets exhibit growth steps which indicate that new growth has nucleated on the main faces themselves at the edges of the fully formed crystal. The steps usually form at the outermost and growing edges and then sweep back toward the edge clinging to the quartz. Similar growth in germanium dendrites has been pointed out by Holmes (5). An early stage is illustrated in Fig. 3a where a rampart has formed round all three sides of a triangle. The rampart is about 1.5μ high, increasing the thickness of the platelet from 3.5 to 5μ. This particular triangle has grown to nearly 0.8 mm on a side before the edge growth has begun. Figure 3b illustrates the later stages typical of most of the overgrowth which has been observed. The growth steps have lost any crystallographic nature they might have had and have taken on the curved character as shown. The edge facets of the crystals retain their {111} orientations throughout and, presumably, nucleation at the twin planes is still going on.

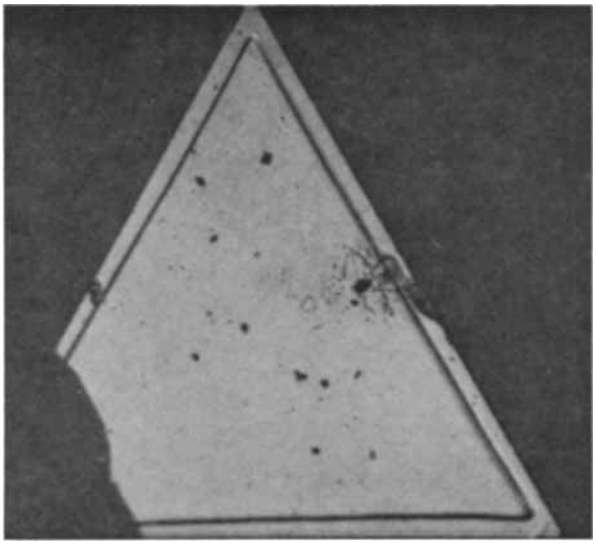

Fig. 3a. Triangular platelet with "rampart" type edge growth. Magnification 100X.

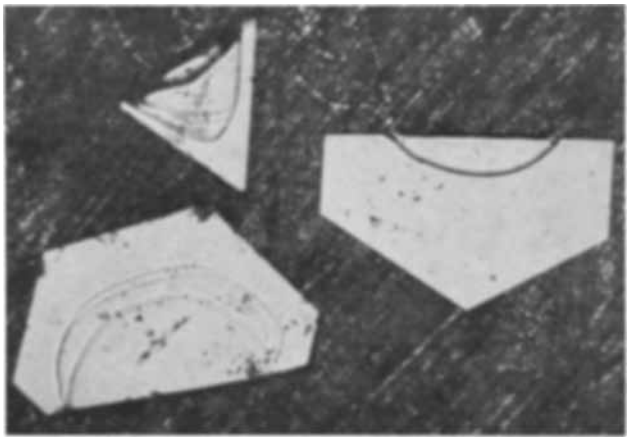

Fig. 3b. Platelets with growth steps arising from edge nucleation. Magnification approximately 100X.

The transport of the germanium to the walls of the capsule from the Czochralski slices sealed off inside must be by means of residual gases left in the system. Halides are known to transport germanium, and traces may remain from the aqua regia used to clean the quartz or from the CP4 used to etch the lapped Czochralski slices. No growth occurs if the system is first thoroughly degassed by baking out under vacuum. The capsules are about 10 cm long by 7 mm ID, and they are heated in a small tubular furnace. The temperatures used are 800° or 900°C, and the largest crystals have been formed in about 80 hr heating. Deposition of the platelets is more or less uniform over the whole length of the capsules except for rather more profuse growth at the two ends. These, in turn, face the ends of the furnace tube which are open to the cold surroundings, but apart from this there is no evidence of any controlling temperature gradient. Instead, it is considered that the transport is governed by the thermal cycling about the control temperature. Control is by an on-off device and the temperature cycle has an amplitude of about 4°C. Germanium which is dissolved into the transporting gas at the higher temperature is then deposited at the lower at any suitable nucleation site. Marinace (6) has discussed a disproportionation reaction between germanium and, in his case, iodine which has just this property of dissolving germanium at one temperature and depositing it at a lower.

Acknowledgments

Open Tube Epitaxial Synthesis of GaAs and GaP

S. W. Ing, Jr., and H. T. Minden[1]

Electronics Components Division, General Electric Company, Syracuse, New York

In 1960 Antell and Effer (1) demonstrated the synthesis of III-V compound semiconductors by the reaction of metal halides in a sealed tube. Since then a great deal of work has been done on the halide transport, synthesis, and epitaxial deposition of these compounds (2-4). Much of this work has involved the use of the synthesized compounds as the source for the epitaxial deposition, and here there are certain disadvantages. The process of melt synthesis (to obtain the source) is fairly difficult, especially in the case of GaP. Moreover, high temperatures must be used to effect these synthesis, so that many impurities are introduced from the furnaces and the containers (5). It has been shown in this laboratory that these impurities will carry over to the deposit in unpredictable ways.

Holonyak *et al.* (4) deposited epitaxial GaP and GaAs from the elements; they used halogen trans-

[1] Present address; Sperry Rand Research Center, Sudbury, Massachusetts.

port in sealed tubes both for epitaxial deposition and for the synthesis of large GaP crystals. Blakeslee (6) has also used the sealed tube halogen transport technique to synthesize GaAs crystals. In this work an open tube system was used to effect the synthesis and epitaxial deposition; results were obtained much more quickly and easily with this system than by the earlier closed tube method.

The chemistry of the system deserves brief mention. HCl gas is passed in an H_2 stream over heated arsenic or phosphorous and over gallium at a higher temperature. An epitaxial deposit is obtained on a seed which is held at a lower temperature than the gallium. A subchloride of gallium is formed at the source

$$Ga + xHCl \rightarrow GaCl + (1/2)\, x\, H_2 \qquad [1]$$

The subchloride disproportionates at the seed

$$3GaCl_x \rightarrow (3 - x)\, Ga + xGaCl_3 \qquad [2]$$

These equations and processes are similar to those described by Williams (2). When the gallium deposits in the presence of arsenic or phosphorous vapor, the compound is formed in an atom for atom manner (4). Epitaxial deposition was obtained over a range of temperature, flow rate, etc., but no concerted effort was made to determine those values of the deposition parameters which would yield optimum growth rate, uniformity, etc. The work was undertaken to demonstrate the feasibility of the method and outline the effective region of operation.

The experimental arrangement is shown in Fig. 1. H_2 was metered through a flowmeter, 2, and passed through a Deoxo unit, 3, and a drying column filled with molecular sieve pellets, 4. HCl gas was metered through another flowmeter, 5, and dried in a trap, 6, which was immersed in dry ice. Teflon tubing and stainless steel fittings were used exclusively in the HCl line and wherever possible in the H_2 system. The argon gas was used as a purge. A 24 in. long two-zone furnace was used, and the temperature of each zone was controlled by a thermocouple (TCA and TCB) located next to the windings. A typical temperature profile is shown in Fig. 1. The reactions were carried out in a 1 in. ID quartz tube. A quartz boat, 7, containing the arsenic or phosphorous was located in the tube outside the upstream mouth of the furnace and was heated by wrapping heating tape, 10, around the exterior of the quartz tube. The quartz boat containing the gallium, 8, was located at the center of the hot zone, A. The seed, 9, was held on a small quartz plate which was sealed to the closed end of a quartz tube. This tube served both as a handle and as a shield for the seed temperature monitoring thermocouple, TCS. The seed holder was supported by a ring stand which could be moved back and forth to position the sample in the desired temperature region of the furnace.

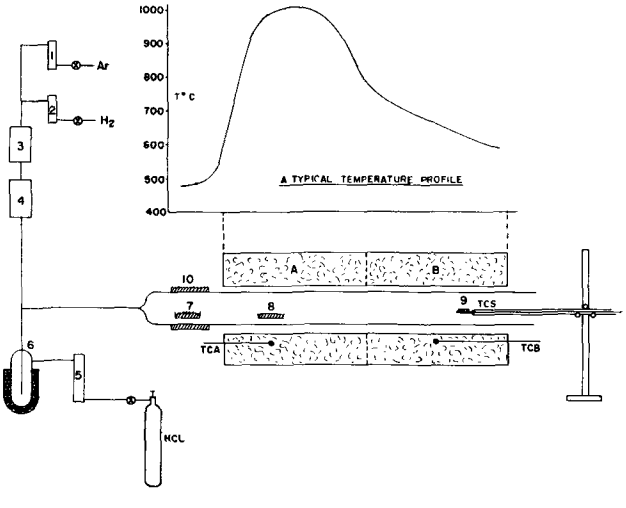

Fig. 1. Furnace and gas flow system for the epitaxial synthesis of GaAs and GaP.

The seed samples were lapped flat and washed in trichloroethylene, acetone and deionized water. The GaAs wafers were treated with a warm 1:1 H_2O_2-H_2SO_4 chemical polish, while the GaP was etched in a warm mixture of 1:1 HCl and HNO_3.

With the furnaces at temperature and Ar flowing, the seed was placed on the holder and introduced into the reaction tube. The H_2 was turned on and the Ar was shut off. The seed was allowed to come to temperature and positioned carefully so as to obtain the desired temperature. The HCl was turned on and the sample repositioned to maintain the required temperature. From time to time during the run the temperature was carefully monitored. At the end of the run the HCl was turned off, the Ar turned on, and the H_2 shut off. When the $GaCl_3$ fumes stopped coming from the mouth of the tube, the sample was moved progressively to cooler zones. The sample was held in the tube until the H_2 was purged. (Often the H_2 burned at the end of the tube during the run, and the dying of this flame was evidence of purge.) The sample was then removed.

In order to determine definitely whether deposition had taken place, the seed was weighed to 0.1 mg before and after the run. In addition, microscopic examination and x-ray measurements were made to determine the nature of the deposited layer. Epitaxial deposition usually gave rise to geometrical surface patterns which had the symmetry of the seed orientation. If the deposit was not epitaxial, *i.e.*, polycrystalline, crystallites were observed which had no symmetrical orientation with respect to each other.

The H_2 flow rate, the HCl flow rate, and the seed temperatures formed a related set of parameters which affected rate of deposition and the nature of the layer. GaAs deposited at a rate of about 0.5 μ/min on (110) oriented GaAs seeds which were held at 750°C; the H_2 flow rate was about 50 cc/min and the HCl flow rate was about 3 cc/min. The deposition rate increased when the HCl flow rate was increased. When the H_2 flow rate was increased to 500 cc/min, etching rather than deposition occurred if the seed temperature was above about 680°; this held true even when the HCl flow rate was increased to as much as 50 cc/min. Below this temperature deposition took place at rates from 0.1 to 1 μ/min.

At the high flow rates deposition occurred both on the seed and on the quartz on which the seed rested. It will be noted from Fig. 1 that there was a temperature gradient in the deposition region. The maximum temperature of deposition was delineated by an abrupt end of the deposit on the quartz sample holder in the high-temperature direction. It should be noted, however, that at the lower flow rates (*e.g.*, 50 cc/min for the H_2) deposition on the sample holder near the seed did not necessarily accompany deposition on the seed.

It will be noted that the effect of increasing the H_2 carrier flow rate was simply to decrease the efficiency of the process. Presumably since the gas mixture was in contact with the Ga source for a shorter length of time at the higher flow rates, the ratio of unreacted HCl to gallium subchloride arriving at the seed was higher. Hence the rate of deposition by disproportionation was lowered relative to the rate of etching the seed by the HCl.

The deposition rate of GaAs appeared to depend on crystallographic orientation of the substrate. When smooth polycrystalline seeds were used, some grains grew faster than others. No detailed study was made, however, on the effect of seed orientation on growth rate. For (110) and (112) oriented seeds the variation in thickness of the deposited layer across the face of the crystal was within ± 10%, while layers on the (111)B surface tended to be nonuniform in thickness at growth rates which exceeded 0.5 μ/min.

The source temperatures were not particularly critical. When the As was below 450°, no deposition of GaAs took place on the seed; when the Ga was below 900° there was no deposition and the seed was etched. Above these temperatures for both the As and the Ga the deposition rate was not observed to be dependent on the source temperature. During some of the runs the Ga melt was observed, and it was instructive to see that there was no skin of solid GaAs. On the other hand, such a skin was always present after the melt cooled; undoubtedly, some As was dissolved in the Ga melt during the run. The point is that for the deposition of GaAs by the disproportionation reaction a solid phase of the compound is not needed at the source.

Two factors affected the nature of the GaAs deposits. When the seed temperature was below about 660°, the deposit was nonepitaxial. Also when air was allowed to diffuse back (at low H_2 flow rates) from the tube exit to the seed, the deposition rate increased, but again the deposit was nonepitaxial.

The Van der Pauw (7) method was used to make Hall coefficient and resistivity measurements on some of the epitaxial layers. These layers were deposited on (111) oriented substrates which had a resistivity of 10^6 ohm-cm. The Hall coefficient was negative and $-1/Re$ ranged from 1×10^{17} to 4×10^{17} cm^{-3} while R/ρ was 2400-2800 cm^2/volt-sec.

For the deposition of GaP very similar results were obtained, although this material was not as extensively studied as GaAs. Here, as with GaAs at H_2 flow rates of about 500 cc/min the maximum seed temperature at which deposition took place was about 680°C. These facts, along with the absence of a solid phase at the gallium source strongly suggested to the authors the hypothesis that the basic deposition reaction involves only the Ga (see for example Eq. [2]). In general, deposition rates were somewhat lower for GaP than for GaAs, although they were of the same order of magnitude. Deposition rates varied from grain to grain on polycrystalline samples, but here again no quantitative study was made of the effect of orientation. The Ga source temperature was about the same as for GaAs, but the phosphorous source temperature was not measured.

GaP was also synthesized by using PCl_3 as the phosphorous source. H_2 was bubbled through the PCl_3 which was at room temperature, and the mixture was passed over Ga at 1000°. No HCl was used in these experiments. Fairly large bright orange needles and small crystallites were formed downstream from the Ga at 850°-890°. Further downstream from 850° to 600° the deposition took the form of fine orange and yellow hair. The formation of similar needles and crystallites were also observed to accompany the epitaxial deposition of GaAs.

Several heteroepitaxy experiments were performed. GaAs was deposited epitaxially on a (111) Ge seed. Both x-ray and electron diffraction measurements showed the deposited layer to be a (111) oriented single crystal. The epitaxial layer was found by chemical etching to have the A (Ga) face up. GaP was also epitaxially deposited on GaAs. In these experiments (110) seeds were used. Although the deposits often appeared gray by reflected light, sectioning revealed that the layers had the characteristic yellow color of GaP. Some of the deposited layers were red, however, even though all the GaP layers which were deposited on GaP were yellow. These results are in accord with those of Holonyak *et al.* (4) who obtained yellow and red deposits of GaP on GaAs in closed tube epitaxial experiments.

Brief Communications

The Effect of Electrolyte Composition on the Anodic Oxidation of Zirconium

N. J. M. Wilkins

Metallurgy Division, United Kingdom Atomic Energy Authority,

Atomic Energy Research Establishment, Harwell, Berkshire, England

In the course of current work on the growth of thin uniform oxide films on zirconium in high-temperature steam and oxygen, the color produced on individual crystals by optical interference is being measured by recording the wavelength of reflection minima at a fixed angle of incidence. To relate color to thickness or weight of thermal films, the color/weight gain relation of anodic films on zirconium has been determined.

Published data offered no reliable basis for this relation. The work of Young (1) showed the danger of attempting to use voltage/thickness and voltage/color data unless all conditions (procedure, current, temperature, electrolyte, concentration, etc.) were closely specified. The color/weight gain relation was therefore obtained by measuring the weight gain and reflection minima of large anodized specimens of annealed and chemically polished Van Arkel zirconium. Films of uniform color were obtained by anodizing at 10 ma/cm^2 and then allowing the current to decay to ~0.2 ma/cm^2 at the required voltage; prolonged oxidation at low current density resulted in the color varying from grain to grain. The films formed in three different electrolytes (0.2*N* H_2SO_4, saturated ammonium borate, 1% wt/v KOH) at room temperature fitted the same series of smooth curves when various orders of reflection minima were plotted against weight gain (Fig. 1). In contrast the voltage/color relation for the different electrolytes indicated a greater difference in the voltage/thickness relation than seems to have been reported previously (2). This is illustrated in Table I, in which the weight gain is derived from color using the relation in Fig. 1, with support from capacity measurements, the reciprocal capacity of a film being taken as a measure of its thickness. Weight/voltage and capacity/voltage relations vary with solution, but the capacity/weight relation is constant.

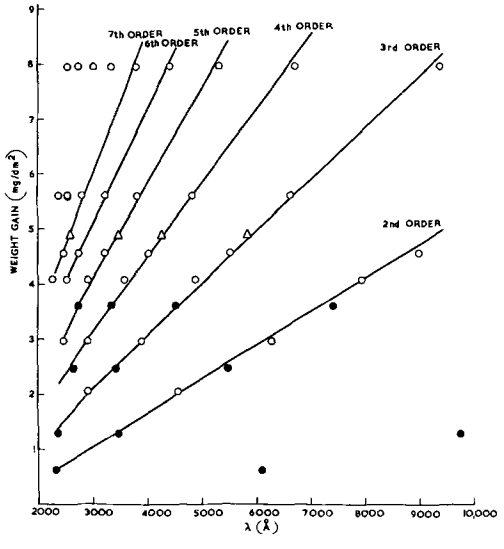

Fig. 1. Weight gain vs. reflection minima for anodized zirconium; ○, 1% KOH; ●, 0.2*N* H_2SO_4; △, saturated ammonium borate.

These results are most readily explained if only the voltage/thickness relation varies with electrolyte. If the density, refractive index, and dielectric constant of the film were to vary, they would have to do so in a most improbable compensating manner to fit the observed weight, optical, and capacity measurements. To determine whether this difference in the thickness/voltage relation resulted from changes within the film or at the film-electrolyte interface, experiments were performed in which specimens were transferred from one electrolyte to another. Results for transfers from 0.2*N* H_2SO_4 to 1% KOH

solutions and *vice versa* are given in Fig. 2. In all transfers, further film growth always began exactly at the voltage at which the film had previously been formed. However, once new growth had started, the incremental voltage/thickness relation approached that of the new electrolyte, but the absolute thickness at a given voltage was not the same as that achieved if the whole film was grown in the second electrolyte. During the adjustment period after transfer from H_2SO_4 to KOH electrolyte, the thickness/voltage ratio was abnormally large, suggesting that once ionic movement occurred, changes were also taking place within the first-formed part of the film.

Assuming a density of 5.7 g/cm³ for the oxide film, a value of refractive index $n = 2.05$ at $\lambda = 5000$Å is obtained from the vertical separation of lines in Fig. 1. This is in good agreement with a value of $n \sim 2.1$ at $\lambda = 5000$Å measured on the stripped oxide by embedding in sulfur/selenium mixtures.

Acknowledgments

The author wishes to thank Mr. D. R. Silvester for the capacity measurements and Mr. J. N. Wanklyn for helpful discussion. Thanks are also due to Dr. J. H. O. Varley for his interest and encouragement.

A Radiotracer Study of Anodic Oxidation

J. A. Davies, J. P. S. Pringle, R. L. Graham, and F. Brown

The Research Chemistry Branch, Atomic Energy of Canada Ltd., Chalk River, Ontario, Canada

The formation of anodic oxide films on metals, particularly aluminum and tantalum, has been extensively studied in recent years, and the results have been summarized by Young (1). While the gross features of the process are well established, some of the details are not; in particular, there is uncertainty as to which atomic species is mobile and carries the current through the oxide.

Attempts have been made in both aluminum (2) and tantalum (3) to tag the oxide film with radioactive $S^{35}O_4^{--}$ and find out whether, on continued anodizing, succeeding oxide layers are formed inside or outside the tagged layer. If the metal moves, fresh oxide will be laid down outside the marked layer; if the oxygen moves, then the new oxide will be formed between the existing tagged film and the metal surface. The experimental results, however, are inconclusive, partly because the mechanism of the oxide dissolution method used to determine the final position of the tagged layer is not established, and partly because the tagged layer itself has different properties from the rest of the oxide film (1). This difference in properties can probably be attributed to the presence of chemically significant amounts of sulfate ion in the tagged layer (4). Furthermore, it has yet to be established that an ionic marker such as SO_4^{--} does not itself move under the high potential gradient of the anodizing field. The present report describes some preliminary experiments in which these difficulties were overcome by injecting trace amounts of the radioactive inert gas, Xe^{135}, as a marker.

Previous investigations (5, 6) in this laboratory have been concerned with the range of accelerated atomic particles in metal targets. As a result of this work, it has been found that a beam of rare gas ions can be injected with a known distribution at various mean depths (15-500 atom layers) beneath the metal surface by using a suitable bombardment energy (1-200 kev), and that these injected atoms remain trapped when the metal lattice surrounding them is converted to oxide. In fact, Kelly and Brown (7) have found that there is no appreciable diffusion of the Xe atoms out of the anodic oxide, even on heating *in vacuo* to 500°C. The anodizing-stripping technique (8) employed to determine the distribution of embedded radioactive atoms in the metal cannot be used to determine the mean depth of the marker in the oxide; consequently, a more general method of determining the location of embedded atoms was sought. This has been found in the "atomic scale micrometer," whose development and calibration will be fully described elsewhere (9).

The principle of the method is as follows. Certain radioisotopes, of which Xe^{135} is one, have low energy γ transitions which are internally converted

with high efficiency; the most intense group of conversion electrons are ejected from the K shell and are essentially monoenergetic. If these electrons are released within a solid, they will lose energy in their passage to the surface, and so their energy spectrum will be modified. With suitable calibrations, these modifications can be related to the amount of matter traversed by the electrons, and hence to the mean depth of their sources, the Xe^{125} atoms, below the surface. Unfortunately, the energy lost by the electrons is not a simple function of the mass of material traversed, but also depends on its atomic number.

Accordingly, calibrations for Al and Ta were performed separately. For Al, a series of electron energy spectra were obtained from Xe^{125} embedded at various known depths within the metal and the spectra from the anodized samples compared. Since Al and O have almost the same atomic number, the presence of the oxygen should have little effect on the calibration (expressed in $\mu g\ cm^{-2}$). The same technique could not be used with Ta, because the Xe^{125} could not be given sufficient bombardment energy to inject it at depths comparable to those found in the anodic tantalum oxide. Instead, known thicknesses of gold were sublimed onto the surface of metal foils containing Xe^{125} at specified depths; the electron energy spectra were then recorded and used for calibrating the anodized specimens of Ta. Gold approximates to Ta in atomic number, but no correction can yet be made for the effect of the oxygen in Ta_2O_5. This calibration is therefore less accurate than that for Al.

Using the Chalk River $\pi\sqrt{2}$ β-spectrometer (10) depths can be estimated to as little as ± 3 atom layers (0.2 $\mu g/cm^2$ for Al) provided the Xe^{125} atoms are less than 3 $\mu g/cm^2$ beneath the surface; with increasing depth, the precision decreases considerably. The method is nondestructive and applicable to any solid; it has been used to measure the depth of the Xe^{125} markers in the growing oxide film.

For these preliminary experiments, aluminum and tantalum targets, each 5.0 x 1.0 x 0.1 cm, were bombarded on the flat face with a beam of 5 kev Xe^{125} ions in an electromagnetic isotope separator. The total integrated beam current striking each target was less than 10^{11} atoms/cm^2; since the number of metal atoms in one atom layer is approximately 2 x 10^{15}/cm^2, it is evident that chemical contamination of the target by the Xe^{125} is negligible. From other work (6) it is known that the mean penetration depth of 5 kev Xe^{125} ions in Al is 3.2 $\mu g/cm^2$, and in Ta 5.5 $\mu g/cm^2$.

After measuring the shape of the K-54.96 (21.79 kev) conversion electron peak, the targets were anodized at constant current, 0.1 ma/cm^2 for Al and 2 ma/cm^2 for Ta, using 3% aqueous ammonium citrate as electrolyte. At 10, 40, and 200v the anodizing was interrupted, and the shape of the conversion peak was measured again. The first step, 10v, converts the metal containing the Xe^{125} to oxide; subsequent steps show what happens to the Xe marker as the oxide film grows thicker. The conversion electron spectra observed are illustrated in Fig. 1

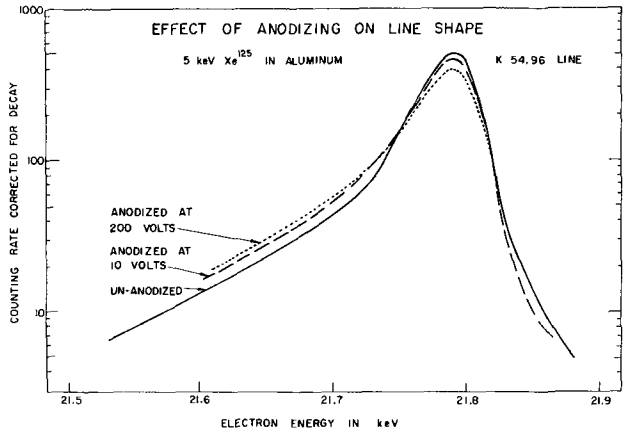

Fig. 1. Effect of anodizing on the shape of the K-54.96 (21.79 kev) conversion line; 5 kev Xe^{125} in aluminum.

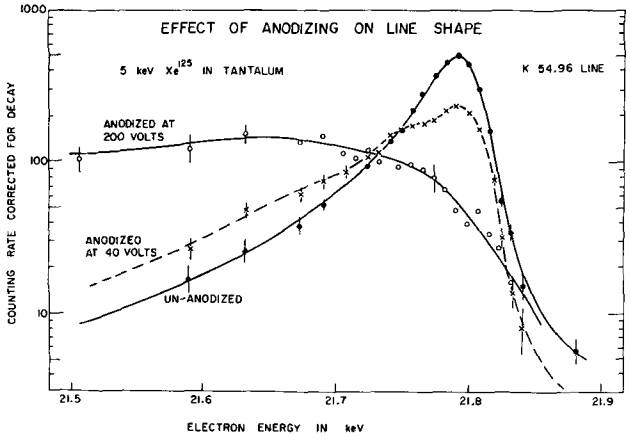

Fig. 2. Effect of anodizing on the shape of the K-54.96 (21.79 kev) conversion line; 5 kev Xe^{125} in tantalum.

and 2. The peak at 21.79 kev represents electrons which have not lost any energy; those electrons which have been scattered at least once before leaving the oxide appear in the low energy tail.

For Al, the line shape changes only slightly on anodizing to 200v, and at least half of the observed change occurs during the first 10-v step. Most of this initial change can be attributed to the conversion of the Al layer (3.0 $\mu g/cm^2$) above the Xe^{125} to a layer of Al_2O_3 (5.7 $\mu g/cm^2$). The results show that the Xe^{125} remains very close to the surface under these anodizing conditions, and therefore, that the fresh oxide layers are being formed under the existing ones. The alternative possibility, that Xe is diffusing toward the surface as fast as fresh oxide layers are laid down, seems very unlikely; Xe, due to its high ionization potential, is almost certainly present in the oxide as a neutral atom and so will not be influenced by the very large voltage gradient across the oxide. Furthermore, were such diffusion of the Xe^{125} occurring, there would probably be an appreciable loss of Xe^{125} to the electrolyte; in fact, the measured loss was less than 4%.

If fresh oxide layers are being formed underneath the old, oxygen must be the mobile species. However, it has been found (8) that, under conditions of constant voltage, about 20% of the aluminum consumed in the anodizing process appears dissolved in the electrolyte. The fraction dissolved

under the constant current conditions used in this work has yet to be measured, but may well be considerable. Consequently, it seems probable that both metal and oxygen migrate, but that at 0.1 ma/cm^2 the film grows mainly by oxygen migration.

In Ta a drastic change in line shape is observed with increasing anodic voltage, as shown in Fig. 2. The Xe^{135} remains at about the middle of the oxide film (Table I), indicating that fresh oxide is being formed on both sides of it. Hence, once again, both metal and oxygen move. However, unlike Al, both types of migration are contributing to the oxide film growth.

These preliminary experiments show that by using Xe^{135} as an inert tracer unique and useful information about the mechanism of oxide film growth can be obtained. Further work is in progress to study the effect of various anodizing conditions, and to extend the technique to other metals.

An Electrode Mount for Electrochemical Studies of Stressed Metal Specimens

N. D. Greene, S. J. Acello,[1] and A. J. Greif[2]

Corrosion Research Laboratory, Interdisciplinary Materials Research Center, Rensselaer Polytechnic Institute, Troy, New York

Electrochemical investigations of stressed metals have been hampered in the past by the lack of a suitable electrode mount. A satisfactory mount for stressed specimens should provide air and liquid tight seals, be noncontaminating, adaptable to varying environments and temperatures, and simple to clean and assemble. The design described here meets all of these requirements and, in addition, permits experimentation under conditions of either static or dynamic tension or torsion.

Figure 1 shows the lower end of the specimen holder in detail; the upper end is essentially the same. Only Teflon, Pyrex glass, and the electrode contact the solution. Wire specimens are used because they are easily stressed, and those not long enough to extend outside the flask are first inserted into a metal rod and held with a set screw. The lower end of the wire and the metal rod are shielded from the solution by a Teflon gasket through which the electrode extends into the solution. A compression seal is obtained by the pressure of a glass bushing on a Teflon gasket. Pressure is applied by screwing together the two halves of a Teflon compression joint.

Figure 2 shows the electrode holder mounted inside a standard polarization flask which has an addi-

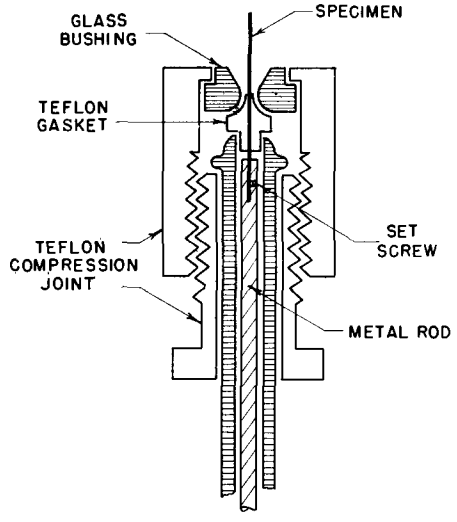

Fig. 1. Specimen holder

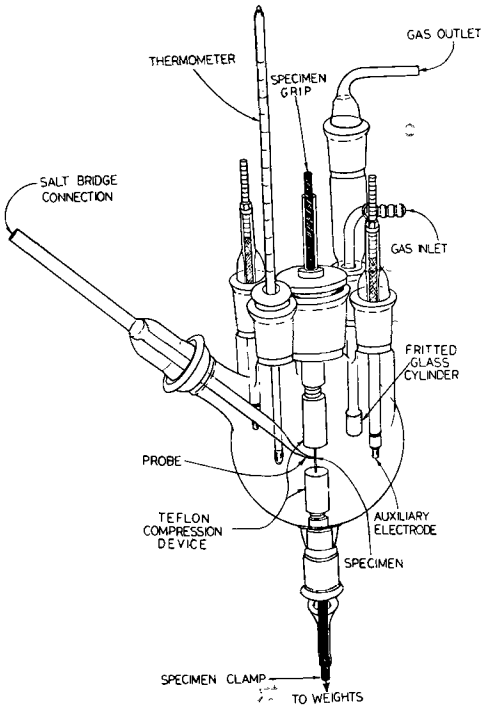

Fig. 2. Polarization cell

tional standard taper joint on the bottom. Vertical adjustment is supplied by passing the upper compression joint through a Teflon stopper. The polarization cell itself has been described in detail elsewhere (1-3).

Tensile or torsional stress can be applied to the electrodes before or after they are inserted into the cell. Tensile stress is applied after insertion by attaching suitable weights to the wire or metal rod. Small synchronous motors are used in a similar manner to apply torsional stress.

The electrode mount has performed satisfactorily in this Laboratory during numerous experiments at temperatures up to 130°C and in widely varying environments.

N^+N Delineation in Silicon

Irvin Berman

Air Force Cambridge Research Laboratories, Office of Aerospace Research, L. G. Hanscom Field, Bedford, Massachusetts

Recently many of the diffusion experiments in the Air Force Cambridge Research Laboratories have been oriented toward increasing the impurity levels in silicon for tunneling effects. Phosphorus pentoxide has been diffused into n-type silicon to give surface concentrations of 6×10^{19} or higher. Because the diffusant impurity is of the same type as the bulk, observation of the depth of penetration has been difficult.

The conventional methods of finding the depth of penetration by a resistivity profile, and by including a control of p-type silicon in the experiment, leave much to be desired. Until recently, this laboratory did not have anything similar to the Fuller Stain (1) for observing this penetration.

Silverman and Benn (2) have shown how excellent delineations of p-n junctions can be obtained through the use of Au chemiplating, good delineation on PP^+, but questionable results for NN^+ delineation. Although in the Air Force Cambridge Research Laboratories the original investigation was on diffused samples, it was extended to N^+ epitaxial layers on n-type bulk and to n-type alloys into n-type bulk material.

In all cases, good results are obtainable under proper control. There is staining by this technique, but also there is some etching. Through proper dilutions, good control of this etching has been established. This experiment was performed under ambient room temperature.

By way of difficulties, there are two conditions that should be mentioned in utilizing the procedure: (i) precaution is necessary in preserving the edges of the silicon, in order to have good reference points for measuring; (ii) the staining reagent should be stored under refrigeration for the maintenance of its potency.

The staining reagent consists of:

40 cc HF (49.2% 20 cc HNO_3 (70.2%)
100 cc H_2O 2g $AgNO_3$

The procedure consists of the following steps: (*a*) prepare sample by mounting in plastic, for angle lapping or for grooving (3); (*b*) lap first with 600 grit to expose desired area; (*c*) lap with successively smaller grits until the desired polish is obtained; (*d*) clean surface and dry; (*e*) use a wooden or plastic applicator to apply a drop of the stain reagent to the exposed silicon. At this point, silver will deposit on the entire surface, but the greatest deposit

2	2.48×10^{-3}	2.48×10^{-3}
3	1.73×10^{-3}	1.54×10^{-3}
4	1.31×10^{-3}	1.4×10^{-3}
5	1.6×10^{-3}	1.42×10^{-3}

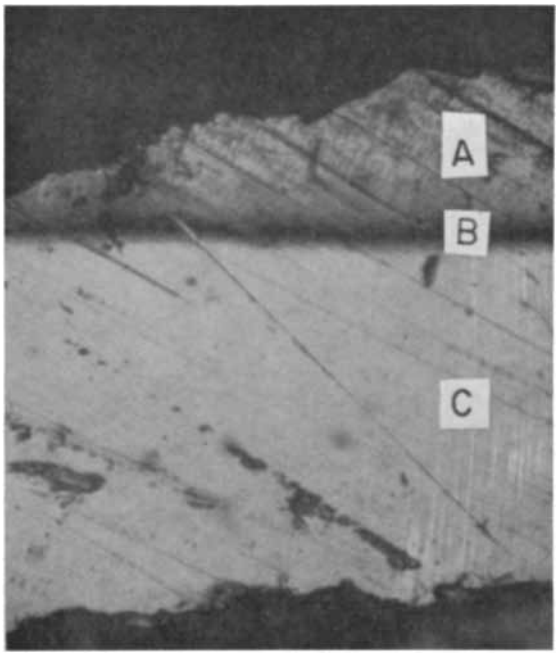

Fig. 1. Epitaxial n-type germanium layer: A, epitaxial layer; B, interface; C, substrate. Magnification 650X.

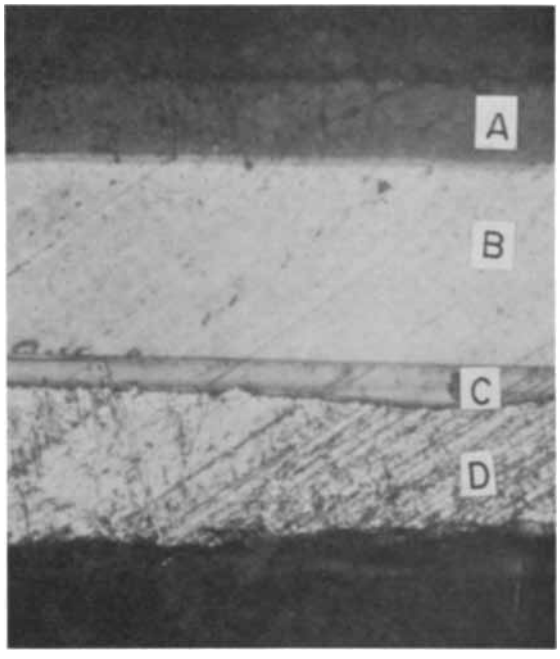

Fig. 2. Cross section of silicon die: A, diffused phosphorus; B, n-type silicon; C, N^+ regrowth; D, gold/antimony. Magnification 650X.

will be at the region of highest resistivity; (*f*) rinse off surface and dry; (*g*) Apply a drop of dilute nitric acid to the surface with a wooden or plastic applicator; (*h*) rinse off sample and dry.

The use of this technique establishes a good correlation between calculated diffusant depth and measured stain depths.

Some of the error can be attributed to the diffusion techniques. The greatest contribution to the error probably comes from the slight etching and subsequent rounding of the edge. This interferes with the point of reference for measuring. To minimize the etching, the solution was varied by diluting with water. As the bulk approaches the degenerate layer in impurity concentration, the delineation becomes more difficult to reproduce. A repetition of the addition of the stain reagent and the nitric acid steps will eventually bring out the delineation. The effect of light on the reaction was also investigated; it did not appear to contribute to the reaction.

The time required for the stain delineation to appear will depend on the impurity concentration and the dilutions of the reagent. By increasing the concentration of the reagent, the time will be reduced. However, the danger of etching will be increased.

Similar techniques employed with N^+N germanium delineation works fairly well, but in germanium the boundaries appear to lack sharpness. Figure 1, a 650X photograph, shows an epitaxial n-type Ge layer deposited by a closed cycle vapor growth process on an n-type Ge substrate. The epitaxial layer is designated as A. The interface labeled B appears so heavily oxidized that it loses its distinction in a photograph. The substrate is designated as C. Figure 2 is a photograph of a cross section (magnification 650X) of a silicon die stained by the techniques described here. Region A is a phosphorus diffusion (8×10^{19} atoms/cm^3) into n-type bulk silicon (region B), with 5×10^{16} impurity atoms/cm^3. On the opposite side, a disk of gold/antimony (1% Sb) has been alloyed. The delineation of the N^+ regrowth region labeled C is quite apparent. The area marked D is the alloy of gold/antimony.

Acknowledgment

The author wishes to thank Mr. Walter McLaughlin and Mr. John Hawley for their assistance in this investigation.

Manuscript received April 9, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

June 1963 Discussion Section

A Discussion Section, covering papers published in the July-December 1962 JOURNALS, is scheduled for publication in the June 1963 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1962 Discussion Section will be included in the June 1963 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 30 East 42 St., New York 17, N. Y., *not later than March 1, 1963*. All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Voltammetric and Chronopotentiometric Study of the Anodic Oxidation of Methanol, Formaldehyde, and Formic Acid

R. P. Buck[1] and L. R. Griffith

California Research Corporation, Richmond, California

ABSTRACT

The anodic oxidation of methanol, formaldehyde, and formic acid on platinized platinum electrodes was studied by the technique of voltammetry at linearly changing potential in 14 aqueous solutions ranging from 10M KOH to 9M H_2SO_4 and over a concentration range of 0.01 to 0.1M. The pH dependences of the current-voltage curves, peak currents, overpotentials, and kinetic parameters were investigated for each of the three compounds where possible. Mechanisms based on these results and the supporting chronopotentiometric and product studies are discussed.

A detailed knowledge of the mechanisms of methanol, formaldehyde, and formic acid oxidations on platinum electrodes is pertinent to consideration of these materials as fuel cell reactants. It may be a prerequisite for the understanding of anodic oxidation of hydrocarbons. Although the anodic oxidation of alcohols on platinum has been previously reported, the kinetics and mechanisms of these processes have not been well established. The work of Müller (1) led to the suggestion that methylate anion may be the oxidizable species in basic aqueous solutions. Tanaka (2) studied the anodic oxidation of methanol in base, but failed to observe formaldehyde as an intermediate. Pavela (3) made extensive use of constant current in his investigation of the oxidation of methanol in basic and acidic solutions. Other voltammetric studies of alcohols and aldehydes have been reported by MacNevin and Sweet (4), Bogdanovskii and Shlygin (5), and Vielstich (6).

In this paper we discuss our experiments designed to elucidate the reaction sequence and the rates of limiting processes in the anodic oxidation of methanol. We obtained electrochemical data from current-potential curves with linearly changing potential and potential-time curves at constant current (7). Comparative data are also given for formaldehyde, formic acid, and formate ion. In the case of voltammetry at linearly changing potential, quantitative descriptions for cases involving rate-determining adsorption processes or preelectrochemical solution reactions are not available. Qualitatively, the effects of preelectrochemical reactions are discussed using arguments similar to those of Koutecky and Brdicka (8). Earlier results of this program have been described (9-11).

Experimental

A versatile instrument, built around commercially available, chopper-stabilized computer amplifiers, was used. The equipment was built after designs by DeFord (12).

Most of the experiments, including all voltammetry in acidic solution, were done with a conventional H-cell using three electrodes. The electrolysis current flowed between a platinum sphere anode and a $Hg\text{-}Hg_2SO_4$, saturated K_2SO_4 auxiliary cathode, separated from the anode by a fritted glass disk and an agar plug saturated with K_2SO_4. Anode potentials were measured and controlled from a Beckman saturated calomel electrode separated from the anode compartment by a similar agar bridge. The anode was platinized from a 0.5 wt % platinic chloride solution to give a black platinum surface.

All solutions were prepared from commercially available C. P. grade chemicals, including: pH 10.0, approximately 0.2M in K_2CO_3 and $KHCO_3$; pH 2.12, approximately 0.1M in KH_2PO_4 and H_3PO_4.

Commercially pure methanol (99.8%), commercially pure sodium formate (100.0%), and Merck formaldehyde (37% in water stabilized with methanol) were used.

Microliter samples were pipetted into the anode compartment; anolyte volume was 50 ml. Samples were stirred into the solvent with a magnetic stirrer. The solvent was deaerated with nitrogen prior to adding the oxidizable sample, and a nitrogen atmosphere was maintained over the unstirred solutions during potential sweeps.

Potential sweeps were done from negative potentials in a positive direction to the beginning of oxygen evolution and then in reverse. Sweep rates were 4.00 and 8.00 mv/sec. Temperature was 23° ±0.5°C.

Early runs showed that electrode pretreatment was essential to the reproducibility of the current observed on successive potential sweeps. A few moments of rapid hydrogen evolution was sufficient to reduce the platinum oxide formed during previous sweeps. However, in solutions more acidic than pH 11.5, a platinized nickel anode had to be both oxi-

dized and reduced, apparently to remove adsorbed materials. This procedure was not always successful.

Results and Discussion

Current-Potential Characteristics

A typical potential sweep of a basic solution containing no oxidizable sample is shown in Fig. 1. A sweep in 1M H_2SO_4 solution is shown in Fig. 2. Three peaks for the oxidation of sorbed hydrogen are clearly seen at the beginning of the latter sweep. Two of these, marked I and II, agree with those observed by Franklin and Cooke (13), who postulated the nature of three forms of sorbed hydrogen. Beyond +0.6v the oxidation of platinum to a platinum oxide layer begins (14). On the reverse sweep, the reduction of the oxide layer appears as a peak between +0.8 and +0.3v. The reduction of hydrogen ions to hydrogen shows two peaks at potentials more positive than hydrogen evolution. It appears that two kinds of sorbed hydrogen form before hydrogen evolution.

Typical cyclic voltammetric sweeps for methanol in four electrolytes are shown in Fig. 3. Data for other acidities are given in the original reports (11). In the basic region, *p*H 10-14, the first part of the ascending anodic current-potential curve obeys the Tafel equation. Toward more positive potentials, the anodic current reaches a maximum value and then decreases either because the surface concentration is depleted or because the surface becomes blocked by oxide formation or because of both. Aside from hydrogen oxidation, there are no other anodic peaks in basic solutions prior to oxygen evolution.

From *p*H 3.75 to low *p*H values, a second, broad peak appears after the main peak but prior to oxygen evolution. We interpret this to be a catalytic current due to regeneration of platinum oxides which are formed electrochemically in this potential region but are reduced chemically by methanol in acidic solutions. The locations of the main oxidation peaks of formaldehyde and formic acid as determined in separate experiments show that the second peak cannot be due to the oxidation of intermediates from the methanol oxidation. This catalytic pattern prevails only in acidic solutions for potentials between +1.0 to +1.3v, depending on the acidity. The height of the second peak for methanol is always about one half that of the first oxidation peak. On the reverse sweep, the second peak does not appear.

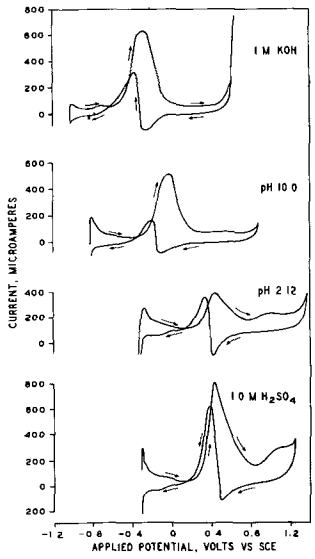

Fig. 3. Voltammetric behavior of methanol; 0.0247M (0.0124M for 1.0M H_2SO_4); sweep rate, 8 mv/sec. All sweeps begin at the most negative potentials; anodic current above zero, cathodic current below.

The direct anodic oxidation of methanol does not occur on platinum oxide in either acidic or basic media at rates comparable to the reaction on oxide-free platinum. This fact is clearly shown in base

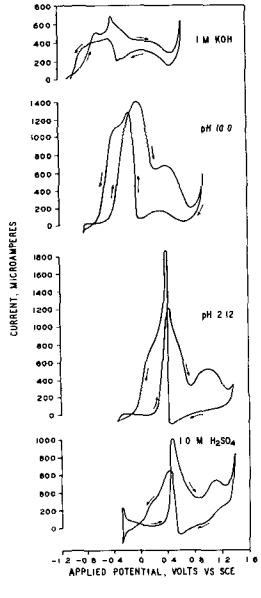

Fig. 4. Voltammetric behavior of formaldehyde; 0.026M (0.013M for 1.0M H_2SO_4); sweep rate, 8 mv/sec. All sweeps begin at the most negative potentials; anodic current above zero, cathodic current below.

where the methanol oxidation current is not observed during the reverse sweep until the oxide layer reduction peak is passed.

Cyclic voltammetric sweeps for formaldehyde in four electrolytes are shown in Fig. 4. In the region 10M KOH to 0.1M NaOH there are reproducible double peaks of remarkably similar fine structure. The peaks move together on decreasing basicity. The second peak, which is the smaller of the two at 10M KOH, becomes larger relative to the first (more negative) peak upon decreasing basicity until, at 0.1M NaOH, the first peak is almost a shoulder on the larger second peak.

The oxidation "peak" of formaldehyde retains a broad aspect in less basic solutions. Evidence of secondary processes giving rise to a shoulder on either the negative or the positive potential side remains until about *p*H 2. Only in solutions more acidic than *p*H 2 does the oxidation peak have a very sharp, spikelike shape. However, the prewave still persists as indicated by the presence of two Tafel slopes.

In all electrolytes, acidic or basic, in addition to the peak, peak and shoulder, or peaks at the negative potential side of the scan, there is a broad peak prior to oxygen evolution in the region where platinum oxide is known to form. In strong base, this third process appears as a mere drawn-out shoulder leading to oxygen evolution. In strong acid, this process appears as a peak of comparable size to, but never more than, the main peak. This third peak is very likely a catalytic current caused by the platinum oxide-catalyzed oxidation of formaldehyde as previously suggested for methanol.

In basic electrolytes, formaldehyde oxidizes on platinum oxide but at a slower rate than on the clean platinum. This reaction can be observed as a considerable anodic current during the reverse potential sweep after reduction of adsorbed oxygen but before platinum oxide is reduced. Greater formaldehyde concentrations produce greater anodic currents in this region. The platinum oxide reduction current subtracts from the anodic current and yields a net current which may be anodic or cathodic, depending on the formaldehyde concentration. When the potential is reached at which the platinum oxide is removed, the anodic current increases greatly. The same effects are observed in acidic solutions of formaldehyde. The region between +0.8 and +0.6v may be one where again both electrochemical oxidation of formaldehyde and electrochemical reduction of platinum oxide occur simultaneously.

Cyclic voltammetric sweeps of formate and formic acid show equally complex shapes. Typical curves are shown in Fig. 5. At all *p*H values, the oxidation peak shows two parts, although in strong base and strong acid it is difficult to tell because of the very small currents. Another peak close to oxygen evolution is observed in the potential sweeps in acidic solutions. This, again, may be a platinum oxide-catalyzed oxidation of formic acid.

Dependence of Peak Currents on Fuel Concentration

Plots of peak current *vs.* concentration of fuel were prepared for 14 aqueous electrolytes ranging from 10M KOH to 9M H_2SO_4. Two or more potential sweep rates were used for each fuel concentration in each electrolyte. These plots are not reproduced here, but are contained in the original progress reports (11).

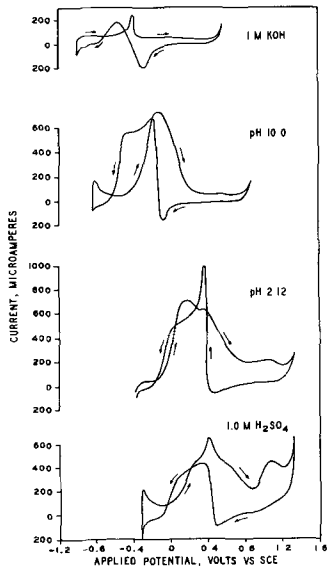

Fig. 5. Voltammetric behavior of formate and formic acid; 0.036M (0.0237M for 1.0M H_2SO_4); sweep rate, 8 mv/sec. All sweeps begin at the most negative potentials; anodic current above zero, cathodic current below.

Generally, peak currents vary linearly with fuel concentration as expected for reactions involving diffusion limitation up to about 0.05M; however, peak currents are much smaller than required for diffusion-limited processes. Two notable exceptions to the linear relationship are formate in basic solutions and methanol in all solutions more acidic than *p*H 11.5. The methanol curves are linear in the region of 0.001M to about 0.03M, but tend to level off at higher concentrations. Formaldehyde shows linearity over a wide concentration range and generally shows greater peak currents. The highest concentration investigated was 0.24M.

Deviations from linearity cannot be explained with the electron-transfer limiting model used by Delahay (15) since the peak currents should be linear in fuel concentration and should increase with the square root of the sweep rate. Methanol peak currents increase with sweep rate but in a proportion less than predicted by the square root relationship. This was also generally true for formaldehyde and formate ion. Only in the acidic range are the formaldehyde peak currents in the proper ratio for sweep rates 8.00 and 4.00 mv/sec.

These features of the variation of peak current with concentration and sweep rate cause us to conclude that the current peak is not diffusion limited. Factors not considered in the theory (15) are slow preelectrochemical solution reactions and dissociative adsorption on the electrode.

Dependence of Peak Current on pH

The slope of the peak current *vs.* fuel concentration curves represent the peak current per unit concentration or "reduced" peak current in microamperes per millimole per liter. These slopes depend on the *p*H of the electrolyte and the potential sweep

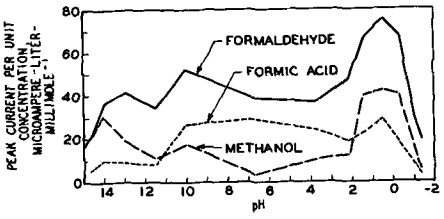

Fig. 6. Reduced peak currents vs. pH for methanol, formaldehyde, and formic acid; sweep rate, 8.0 mv/sec.

rate. When the curves were not linear, the slope chosen was the maximum value obtained at the lowest concentrations. The reduced peak currents are plotted *vs.* pH for methanol, formaldehyde, and formic acid in Fig. 6.

The optimum acidity for the oxidation of these materials is in the range pH 0-1. Decrease in peak currents for still higher acidities may be related to the increased bulk concentration of protonated methanol, formaldehyde, and formic acid (16). Increasing peak heights for methanol and formaldehyde with increasing basicity may be due to the greater concentrations of methylate ion and methylene glycolate ions, respectively. Ultimate decreasing of peak heights with increasing basicity may be due to increased adsorption of OH^- onto the anode.

Formate can be oxidized in base as shown by the small peak in the basic range in Fig. 6. However, it is not oxidized rapidly at the potential of rapid methanol and formaldehyde oxidation, and formate is, therefore, the principal product of the oxidation of methanol and formaldehyde at pH >11. This complication is not clear from Fig. 6, which merely shows the magnitude of the peak current wherever it happens to occur on the potential scale.

Formic acid gives larger reduced peak currents than methanol at intermediate pH values of 2-11. This suggests that formate anion (or formic acid) may not be the principal end product from methanol below pH 11 but merely an intermediate. Product analyses (9, 10) of methanol oxidation, which show buildup of formate in strong base but nearly complete conversion to CO_2 in strong acid, have not been performed for electrolytes in the range pH 2-11. The dropoff of reduced peak currents from pH 10 to about pH 12 for methanol and formaldehyde may reflect the change from six to four electrons for methanol and a change from four to two electrons for formaldehyde if it is true that formate becomes limiting only above pH 11.

At all pH values, formaldehyde gives greater peak currents than either methanol or formic acid. This result may seem puzzling since methanol is intrinsically capable of yielding six electrons while formaldehyde at best can yield only four. This result in basic solutions is consistent with a mechanism for methanol oxidation involving a slower preelectrochemical reaction for methanol than for formaldehyde, *e.g.*, a slow dissociative chemisorption step or a slow solution reaction to produce the electroactive species.

Position of Peak Current on the Potential Scale

The positions of peak current on the potential scale for methanol, formaldehyde, and formic acid or formate are shown in Fig. 7. The values are given as ranges incorporating data from both 4.00 and 8.00 mv/sec sweeps over a wide range of fuel concentrations. The spread in the potential range for each pH is smaller if the data for only one sweep rate are included.

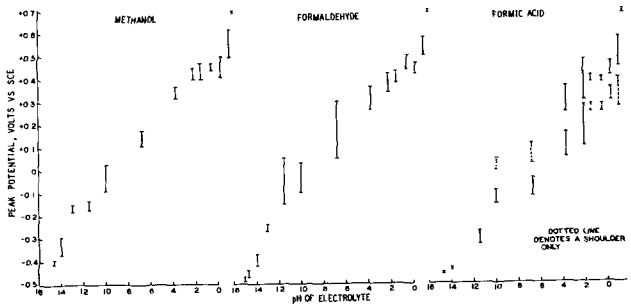

Fig. 7. Position of peak current for two sweep rates and various concentrations to 0.1M.

Rate Constants in Basic Solutions

In the low current region on the negative potential side of a current peak, the following equation is assumed to hold if the reaction rate is limited only by a slow electron transfer step and adsorption of the reactant is absent. The instantaneous current, at a given potential E, is given by the equation:

$$i = n\mathbf{F}C^\circ Ak_{s,h} \exp\left[\frac{(1-\alpha)n_a\mathbf{F}(E-E^\circ_c)}{RT}\right] \quad [1]$$

where n is the number of electrons in the over-all oxidation (n has the value 4 for methanol, 2 for formaldehyde, and 2 for formate in base), $\mathbf{F}$ the Faraday, C° the reactant concentration at the electrode surface and in the bulk, A the electrode area, $k_{s,h}$ the rate constant at a potential E°_c, the reversible potential for the rate-determining step, $(1-\alpha)$ the anodic transfer coefficient, and n_a the number of electrons in the rate-determining step. Applicability of Eq. [1] is restricted to high bulk reactant concentration and very low current drain so that the surface concentration is not depleted during the course of the experiment. If oxidation occurs from an adsorbed state, a constant value of $k_{s,h}$ is not expected with this calculation.

Methanol.—On a 2.6 mm platinized nickel ball anode using current densities in the range 1-500 $\mu a/cm^2$ and methanol of 0.0498M, our value for $b = 0.059/(1-\alpha)n_a$ is 0.21-0.28 at 25°C and b is independent of pH from pH 10 to 14.

Values of $Ak_{s,h}$, the product of electrode area and apparent heterogeneous rate constant for a possible rate-determining step

$$CH_3O^- + 2\,OH^- \rightarrow CH_2(OH)O^- + H_2O + 2e^- \quad [2]$$

were calculated from the following equations and are given in Table I.

$$i = 4\mathbf{F}Ak_{s,h}(CH_3O^-) \exp\left[\frac{(1-\alpha)n_a\mathbf{F}}{RT}(E-E^\circ_c)\right] \quad [3]$$

$$i = 4\mathbf{F}Ak_{s,h}\frac{K_A(OH^-)}{K_w}(CH_3OH) \exp\left[\frac{(1-\alpha)n_a\mathbf{F}}{RT}(E-E^\circ_c)\right] \quad [4]$$

and

Table I. Apparent heterogeneous rate constants for methanol at 25°C

pH	$Ak_{s,h}$, cm³/sec*	$E°_C$ vs. SCE	$Ak'_{s,h}$, cm³/sec**	$E°_C$ vs. SCE
~15 (10M KOH)		−0.972		
~14 (1M KOH)	1.6×10^{-6}	−0.913	8.9×10^{-8}	−0.834
~13 (0.1M NaOH)	5.6×10^{-6}	−0.854	3.3×10^{-8}	−0.775
12.21 (25% K_2CO_3)	5.0×10^{-5}	−0.807	5.0×10^{-8}	−0.728
11.50 ($PO_4^{\equiv}$, $HPO_4^{=}$)	7.9×10^{-5}	−0.765	1.4×10^{-8}	−0.686

* Based on methylate ion.
** Based on formal methanol.

$$i = 4\mathbf{F}Ak'_{s,h}(CH_3OH) \exp\left[\frac{(1-\alpha)n_a\mathbf{F}}{RT}(E - E°_C)\right] \quad [5]$$

$E°_C$ is the formal potential for molal concentrations of reactant and product in the rate-determining step stated by Eq. [2], and

$$E°_C(vs.\ SCE) = 0.913 - 0.059 \log (OH^-)$$

This value was obtained from $E°$ given by Latimer (17) by correcting for the acid dissociation constants of methanol, $pK_A = 15.54$ and methylene glycol, $pK_A \approx 12.8$ (17,19). Apparent formal rate constants based on total methanol concentration referred to $E°$ are given in Table I also.

Since a constant value of neither $k_{s,h}$ nor $k'_{s,h}$ is found, we conclude a preelectrochemical reaction occurs. This preelectrochemical reaction may be a reaction in solution to produce the electroactive species or it may be an adsorption process. Both processes may also occur.

Formaldehyde.—The results shown in Fig. 6, coupled with product analyses, show a two-electron oxidation (to formate) for pH 11.5 or higher and suggest a three- to four-electron oxidation from pH 7 to 10. In addition to this complication, formaldehyde exists in aqueous solution mainly as a hydrate, methylene glycol (19). The increase in peak current is not as extreme with increasing pH beyond pH 11.5 as would be necessary if methylene glycolate anion were the only oxidizable species and the rate of reaction [6] were slow.

$$CH_2(OH)_2 + OH^- \rightleftharpoons CH_2(OH)O^- + H_2O \quad [6]$$

For this reason, we postulate a fast preelectrochemical reaction, [6], is responsible for supplying the electrode with oxidizable methylene glycolate anion in addition to that which diffuses from the bulk. Because of the magnitude of the dissociation constant, methylene glycolate is a predominant species even in 0.1M NaOH.

In basic solutions, formaldehyde decomposes catalytically on the platinum anode to form sorbed hydrogen. The Tafel region is difficult to measure accurately because of the simultaneous oxidation of sorbed hydrogen. Best results have been obtained by sweeping applied potential from −1.0v in a positive direction to about −0.6v, depending on pH. In this region, bound surface hydrogen is removed. The potential is then swept negative to zero current. Upon the subsequent positive sweep, the low current formaldehyde oxidation can be observed without complication by sorbed hydrogen.

Plots of log i *vs.* E for formaldehyde in 0.1M NaOH between −0.8 and −0.5v give slopes corresponding to $(1-\alpha)n_a$ values between 0.3 and 0.4. Our best values for $(1-\alpha)n_a$ were obtained at the highest concentrations used, 0.078M and 0.13M formaldehyde; values of $(1-\alpha)n_a$ are approximately 0.35. A sweep rate of 4 mv/sec was used. The apparent heterogeneous rate constant at the reversible potential (−1.253 *vs.* SCE for 0.1M NaOH) multiplied by the surface area is approximately 10^{-9} cm³/sec.

Formate ion.—Very few observations suitable for quantitative description of formate oxidation in base have been obtained. The reversible potential for formate oxidation to carbonate follows the equation

$$E°_C = -1.252 - 0.059 \log (OH^-) \quad [7]$$

Qualitatively, the rate constant multiplied by the electrode area, at the reversible potential, will be smaller than that of formaldehyde by approximately a factor of 10.

Quantitative Behavior in Acidic Electrolytes

For methanol in 1 and 5M H_2SO_4, plots of log i *vs.* E are not so comparable from one run to another as had been observed for methanol oxidations in basic solutions. Rather than the normal positive deviations from the Tafel slope, due to the onset of concentration polarization at high current drain, methanol shows smaller than normal Tafel slopes at currents greater than 100 μa. This corresponds to the striking sharpness of the current-voltage peaks and is an indication of adsorption limitation.

For 0.0494M methanol in 1M sulfuric acid, $(1-\alpha)n_a$ values averaged 0.5 at currents less than 100 μa and reached 0.6 at higher currents. In 5M H_2SO_4, values for $(1-\alpha)n_a$ averaged 0.4 at the lower currents and increased to 0.7 at higher currents. Two sweep rates, 4.0 and 8.0 mv/sec, were used.

Analysis of formaldehyde data is complicated by the presence of shoulders or double peaks, indicating two electrode processes, one of which is probably adsorption limited. The $(1-\alpha)n_a$ values in 1M H_2SO_4 were 1.3-1.5 while in 5M H_2SO_4 the values ranged from 1.5 to 2.2 at two sweep rates and 0.05M formaldehyde. We have not attempted to analyze the formic acid peaks.

Consistency of Voltammetric Results with Product Studies

The apparent heterogeneous electron-transfer rate constants reported above for methanol, formaldehyde, and formate in base refer to the reversible potential for a given pH. This is, of course, different

for each species. From the point of view of fuel cell operation, it is more informative to compare formal rates at a specific potential. Formal rate constants at a potential E in the Tafel region can be computed from $k_{s,h}$ by correcting to the desired potential. At an arbitrary potential in the Tafel region of both methanol and formaldehyde in 1M hydroxide:

$$\frac{k_{f,h}(\text{Formaldehyde})}{k_{f,h}(\text{Methanol})} = \frac{10^{-9}}{10^{-7}} \times \frac{10^{6.06(E+1.312)}}{10^{4.67(E+0.834)}} \quad [8]$$

where $Ak_{s,h}$(formaldehyde) $= 10^{-9}$ cm³/sec, $Ak_{s,h}$ (methanol) $= 10^{-7}$ cm³/sec, and an average Tafel slope referred to base 10 of 0.16 for formaldehyde and 0.21 for methanol.

In fuel cell product studies by Schlatter (10) using 1.56M methanol in 4.5M NaOH, the cell was operated at constant current. However, because of the high concentration of methanol and the very low current drain, the cell potential remained approximately constant at −0.65v *vs.* SCE. Applying Eq. [8], it can be shown that the rate of oxidation of formaldehyde at −0.65v is much greater than the methanol oxidation rate. The over-all process yielding formate is analogous to a consecutive reaction of the type

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \quad [9]$$

where the concentration of methanol is (A), formaldehyde is (B), and formate is (C). Formaldehyde concentration should approach a steady state given by k_1/k_2 $(A°)$, where $(A°)$ is the initial concentration of methanol. At −0.65v, the ratio of formal rates given by

$$k_2/k_1 = \frac{k_{f,h}(\text{Formaldehyde})}{k_{f,h}(\text{Methanol})} = 1.4 \times 10^5 \quad [10]$$

Thus, we would predict a steady-state formaldehyde concentration of 11 x 10^{-4}M. Experimentally, the steady-state concentration reached by formaldehyde was 2.5 x 10^{-4}M after approximately 90 hr at 50 ma. Only order-of-magnitude values of the heterogeneous rate constants were used so that the prediction is in good agreement with the experimental value.

In acidic solutions, methanol and formaldehyde are irreversibly oxidized to yield peaks in nearly the same potential region. It is not surprising that formaldehyde steady-state concentration during methanol oxidations is much greater than in base as shown by Schlatter. Formic acid in acidic solutions is rapidly oxidized also, and product analyses show that formic acid is indeed an intermediate, and its steady-state concentration is comparable to that of formaldehyde.

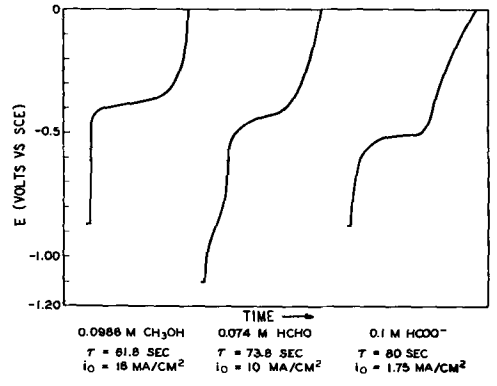

Fig. 8. Experimental potential-time curves for methanol formaldehyde, and formate ion in 1M KOH.

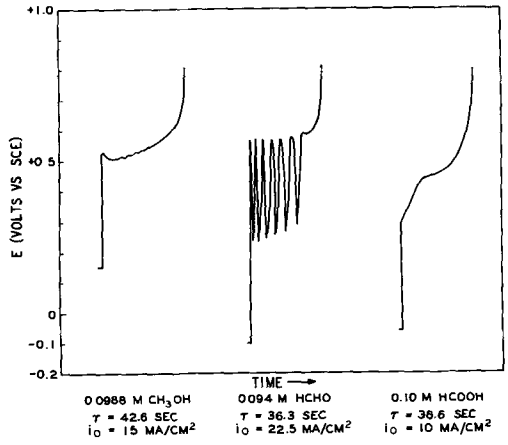

Fig. 9. Experimental potential-time curves for methanol, formaldehyde, and formic acid in 2.5M H_2SO_4.

Chronopotentiometry in Basic Solutions

We have obtained chronopotentiograms for the oxidation of methanol, formaldehyde, and formic acid in both basic and acidic solutions. Representative curves are shown in Fig. 8 and 9. Transition times were measured from recorder plots of anode potential *vs.* time. In general, these curves are not simple shapes associated with (i) reversible oxidations, (ii) irreversible oxidations, or (iii) irreversible oxidations with preelectrochemical solution reactions. The sole exception is methanol in base where the data can be fitted by equations for E *vs.* t for either case (ii) or (iii). Results from experiments using platinized platinum foil electrodes are given in Table II for comparison with voltammetric results.

In the potential sweep experiments at 8M NaOH and with 0.0988M methanol, the average value of $(1-\alpha)n_a$ for six experiments was 0.35 with a range of values between 0.31 and 0.41.

Values of the product $i_o\tau^{1/2}$ for the anodic oxidation of methanol in basic solution decrease with increasing current. For the reaction

$$CH_3OH + OH^- \underset{k_b}{\overset{k_f(OH^-)}{\rightleftharpoons}} CH_3O^- + H_2O \quad [11]$$

the relationship between $i_o\tau^{1/2}$ and i_o is given by:

$$i_o\tau^{1/2} = \frac{\pi^{1/2}nFC°D_o^{1/2}}{2} - \frac{\pi^{1/2}i_o}{2K[k_f(OH^-) + k_b]^{1/2}} \quad [12]$$

Table II. Electrochemical oxidation of methanol in 10M KOH on a platinized platinum electrode

$C°$, mole/liter	i_o, amp/cm²	$(1-\alpha)n_a$	$k°_{b,h}$, cm/sec	$k'_{s,h}$, cm/sec
0.0494	0.0075	0.30	1.6×10^{-2}	3.4×10^{-6}
0.0988	0.015	0.36	1.3×10^{-2}	5.9×10^{-7}

where

$$K = \frac{(CH_3O^-)}{(CH_3OH)} = \frac{k_f(OH^-)}{k_b}$$

and $k_f(OH^-)$ and k_b are the rate constants for the forward and reverse processes, respectively. From 10M KOH to pH 10, application of Eq. [12] gives $k_f \sim 10^3$ cm^3 mole^{-1} sec^{-1}. This value is much lower than is normal for a proton transfer of the type assumed; Luz, Gill, and Meiboom (20) reported a value of $k_f = 10^9$ cm^3 mole^{-1} sec^{-1} which they determined from NMR data. Since $i_o\tau^{1/2}$ varies with i_o when adsorption processes occur in the course of the reaction, we conclude that the rate-limiting process is not solely the formation of methylate ion, but also involves chemisorption of the methylate ion or methanol, itself.

Values of $i_o\tau^{1/2}$ for formaldehyde oxidation in base are not constant. The data were not treated because of the complexity of the chronopotentiograms caused, in part, by the formation of hydrogen on the electrode.

Values of $i_o\tau^{1/2}$ for formate oxidation in base are very nearly constant as shown in Table III. The usual plot of E *vs.* log $[1-(t/\tau)^{1/2}]$ is not a straight line in the region of small values of t. This fact and the shape of the chronopotentiogram indicate that the oxidation may be complicated by other reactions occurring on the electrode.

Chronopotentiometry in Acidic Solutions

In Fig. 9 chronopotentiograms for the oxidation of methanol, formaldehyde, and formic acid in 2.5M H_2SO_4 show variations from the form expected for totally irreversible processes with one rate-determining step. Similar variations are seen in 1M H_2SO_4. In extreme cases, potential oscillations occur in the oxidation of methanol and formaldehyde; however, in both of these cases, it is possible to oxidize the materials without potential oscillations. Although we did not observe oscillations in the case of formic acid, they have been reported by Pavela (3).

Methanol.—Potential oscillations are observed in the current density range of 10-15 ma/cm^2 with 0.0988M methanol in 1M H_2SO_4 at 25°C. At greater current densities where practically no oscillations occur, the measured transition times approach the calculated values neglecting corrections for surface roughness and kinetic complications due to preelectrode reactions.

Formaldehyde.—Typical chronopotentiograms for the oxidation of formaldehyde in acid solutions are shown in Fig. 9 and 10. The first 30-sec period from each of 8 chronopotentiograms at 8 current densities is shown in Fig. 10. The oscillations do not occur at current densities below 7.5 ma/cm^2. As current density is raised, the amplitude of the oscillation increases; the frequency does not change appreciably. We have also observed that the frequency increases with increasing acid concentration, the amplitude decreases with increasing acid concentrations, the frequency decreases with time, and the amplitude sometimes increases and sometimes decreases with time.

Table III. 0.1M formate in 1M KOH

i_o, amp/cm^2	$i_o\tau^{1/2}$, amp-sec$^{1/2}$
0.00175	0.0124
0.0020	0.0117
0.0025	0.011
0.0030	0.0115

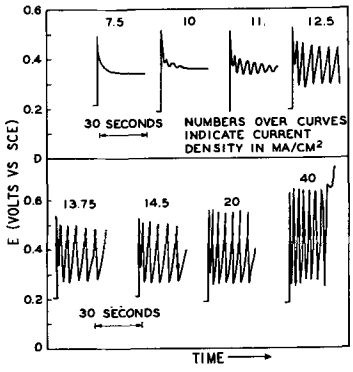

Fig. 10. Potential-time curves for the electrochemical oxidation of 0.1M formaldehyde in 1M H_2SO_4.

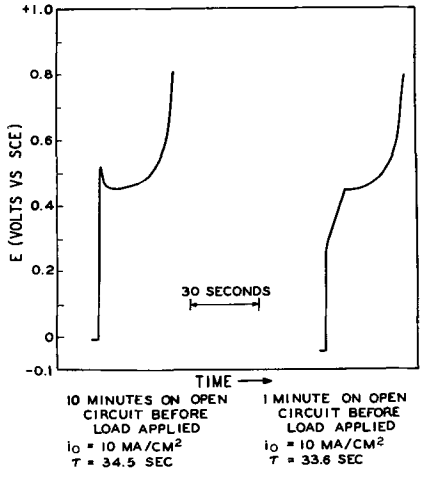

Fig. 11. Potential-time curves for the electrochemical oxidation of 0.1M formic acid in 2.5M H_2SO_4.

Formic acid.—Chronopotentiograms of 0.1M HCOOH in 2.5M H_2SO_4 have complicated shapes shown in Fig. 11. If the electrode remains in contact with the electrolyte for some time before current is drawn, the potential passes through a maximum after the load is applied. If the electrode is in contact with the solution for only a short time, this maximum is replaced by a shoulder. Transition times are not significantly different in the two cases.

Potential Oscillations

Oscillations during constant current anodic processes in acid solutions have been reported previously (3, 21-28). In the cases of methanol and formaldehyde, Pavela (3) believes that potential oscillations result from gas (CO_2) evolution at the electrode. Explanations invoking an alternation of processes, such as (i) the direct oxidation at the most negative potentials and (ii) oxidation via reaction with platinum oxide at the positive potential side of the oscillation, are difficult to defend. Whether or not the chemical reaction of the fuel with platinum oxide is slower than diffusion, the processes ought to seek a steady state at an intermediate potential.

A recent study by Sawyer and Seo (28) of the anodic oxidation of dissolved hydrogen suggests that potential oscillations arise from diffusion of absorbed hydrogen out to the electrode-solution interface from interior positions. Reduction of platinum oxides formed during the positive potential sweep brings the potential back to the negative extreme of the oscillation. In the meantime, the concentration of oxidizable material in solution at the interface has been replenished. This interpretation explains the sensitivity of the oscillations to time of exposure of the electrode to the solution before applying load.

Evidence for Surface Adsorption

All of our present evidence for a surface adsorption step in the mechanism for the oxidation of methanol and formaldehyde in base is indirect. It has been shown by Schlatter (10) that alcohols without an available hydrogen on the carbon containing the hydroxy group are not oxidizable on platinum anodes, *e.g.*, tertiary butanol is not oxidizable in aqueous base at room temperature. The only metals on which room temperature oxidations proceed are those commonly known as hydrogenation or dehydrogenation catalysts. The magnitude of the current peak heights for methanol may be smaller than those for formaldehyde because of a slow preelectrochemical adsorption step, and further, a slowing of the adsorption rate with current drain due to removal of methanol at the electrode surface may account, in part, for the small methanol peak currents. The presence of shoulders on the negative potential side of an oxidation current peak is analogous to the well-known adsorption prewaves in polarography.

These factors, plus the difficulty in reproducing voltammetric data depending on the time between the addition of the sample and the start of the potential sweep, suggest that adsorption plays a role in the mechanism. However, it is not clear that the adsorption rate is the slowest step or that it becomes entirely limiting during a potential sweep. Chronopotentiometric studies for the testing of adsorption rate limitation along lines suggested by Reinmuth (29) may elucidate the role played by adsorption.

Mechanisms and Conclusions

Our postulated mechanism for the oxidation of methanol, formaldehyde, and formate in base depends on extensive voltammetric studies and their analyses. No mechanism is proposed for the oxidation in neutral or acidic solutions. However, the over-all course of the reaction is clear in acidic media through the extensive product analyses of Schlatter (10). The suggestion that methylate, methylene glycolate, and formate anions are the electroactive species has already been suggested by Müller (1). Our mechanism is similar to one proposed by Pavela (3). The principal differences between his mechanism and ours are: (i) we consider that hydroxyl ion participates in a preelectrochemical step and not in the slow electron-transfer step, and (ii) we favor a dissociative chemisorption step which is of slower speed than the preelectrochemical reaction involving hydroxyl ion. Rate constants reported above are not corrected for fractional surface coverage by adsorbed species.

The mechanism for methanol oxidation in base appears to include

$$CH_3OH + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} CH_3O^- + H_2O \qquad (A)$$

$$CH_3O^- \xrightarrow[\text{slow}]{\text{Pt}} CH_2O^-(\text{ad}) + H(\text{ad}) \qquad (B)$$

$$H(\text{ad}) + OH^- \xrightarrow{\text{fast}} H_2O + e^- \qquad (C)$$

$$CH_2O^-(\text{ad}) \xrightarrow[k_{s,h}]{\text{slow}} CH_2O + e^- \qquad (D)$$

$$CH_2O + H_2O \xrightarrow{\text{fast}} CH_2(OH)_2 \qquad (E)$$

$$CH_2(OH)_2 + 3\,OH^- \xrightarrow{\text{fast}} HCOO^- + 3H_2O + 2e^- \qquad (F)$$

$$HCOO^- + 3\,OH^- \xrightarrow{\text{slow}} CO_3^= + 2H_2O + 2e^- \qquad (G)$$

Details of the process represented by (*F*) are the same as those occurring when formaldehyde is the fuel

$$CH_2(OH)_2 + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} CH_2(OH)O^- + H_2O \qquad (H)$$

$$CH_2(OH)O^- \xrightarrow[\text{moderate}]{\text{Pt}} CH(OH)O^-(\text{ad}) + H(\text{ad}) \qquad (I)$$

$$H(\text{ad}) + OH^- \xrightarrow{\text{fast}} H_2O + e^- \qquad (J)$$

$$CH(OH)O^-(\text{ad}) + OH^- \xrightarrow[k_{s,h}]{\text{slow}} HCOO^- + H_2O + e^- \qquad (K)$$

Process (*G*), the anodic oxidation of formate, may proceed by a mechanism analogous to those postulated above; however, we cannot rule out the possibility of a direct reaction of the formate without an adsorbed intermediate state. Also, we do not have evidence to exclude simultaneous direct reaction of methylate or methylene glycolate without an adsorbed intermediate state.

Acknowledgment

The authors gratefully acknowledge the support of the Army Ordnance Corps, Diamond Ordnance Fuze Laboratories, Washington. They wish to thank Drs. G. H. Denison, D. A. Hickson, D. R. Rhodes, M. J. Schlatter, and R. T. Macdonald for helpful discussions of this work and Mr. W. J. Doppe for assistance in data collection.

Manuscript received Dec. 15, 1961; revised manuscript received Aug. 1, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Effect of Acetylenic Molecules on Cathodic Overvoltage on Steel in Acid Solutions

E. J. Duwell

Minnesota Mining and Manufacturing Company, St. Paul, Minnesota

ABSTRACT

An apparatus was constructed for measuring changes in electrode potential at constant current density. Large increases in hydrogen overvoltage were noted when acetylenic molecules were adsorbed on a steel cathode, and cathodic reduction of dissolved oxygen was apparently inhibited. The effect on the anodic oxidation of steel was small. Thus, it can be concluded that these molecules slow down the oxidation of steel in acid solutions by inhibiting the cathodic reactions. The most effective adsorbates are characterized by steric availability of the acetylenic bond, non-ionic character, and large molecular size.

The adsorption of molecules from solution on a metal surface to prevent corrosion is a well-known process. Several techniques such as tagging the adsorbate with radioactive tracers, measurement of contact angles and surface potentials, and straightforward analysis of solution concentration before and after adsorption have been used to follow the adsorption process. The measurement of the change in potential of one electrode process as adsorption proceeds has been used to a much lesser extent to determine adsorption even though this technique has been used successfully by several investigators (1-3).

For an electrode process which is proceeding at a finite rate, the potential E is given by

$$E = E_R + \eta$$

where E_R is the reversible potential and η is the overvoltage. The overvoltage is related to current density i, by the well-known Tafel equation

$$\eta = a - b \log i$$

where a and b are constants. If the current is held constant, and the change in overvoltage is caused by adsorption, it may be assumed that

$$\Delta\eta = \eta' - \eta = b \log i/i'$$

where

$$i' = (1 - \theta)\, i$$

θ is the apparent fraction of the area covered by the absorbate. It then follows that

$$\theta = 1 - e^{-\Delta\theta/b}$$

The values of θ obtained by this method have been shown to be in reasonable agreement with values of θ obtained by double layer capacitance measurements for the adsorption of octanoic acid on silver

(3). It is assumed that the adsorbed layer is an inert blanket and does not change the reactions occurring at the electrode, and hence does not change the value of the constant b. This may not be entirely correct for the systems to be described in this paper, although some of the results support this assumption.

If η in the base solution is known, only a measurement of $\Delta\eta$ is needed for a comparison of adsorbates introduced to that solution. Since the purpose of this investigation was to compare the effect of various acetylenic chemicals on the electrode reactions which occur when steel is oxidized by acids, an apparatus was designed which gave a measurement of $\Delta\eta$.

It has been known for some time that some acetylenic chemicals will inhibit the oxidation of steel (4, 5). Our data support an earlier report that it is the cathodic process which is slowed down (5).

Apparatus

The essential features of the bridge circuit and cell are given in Fig. 1. The potential source consisted of two 6v lead storage cells in series. The loops in the left arms contain 1.5v batteries for a bias voltage, variable 300 ohm and 15 ohm resistors, and Texas Instrument 2N250 transistors. The current in the cell and reference arms were made equal by adjustment of resistors in the transistor circuit. These circuits then served to maintain a constant current even if the resistance of the cell changed. A Varian G-11A potentiometric recorder with variable ranges from 0-10 to 0-1000 mv was used to record the voltage difference between the cell and reference arms of the bridge. The reference "cell" consisted of a decade box which was adjusted to give a zero reading on the recorder. Thus, if the current in the cell is equal to that in the decade box, the resistance of the cell equals the resistance of the decade box when the experiment is begun. If an absorbate is now added to an electrode chamber and increases the overvoltage, the change, as a function of time, is noted on the potentiometric recorder.

The cell consisted of 500 ml cathode and anode chambers separated from a cylindrical center section by fritted glass disks. The fritted disks served as membranes to reduce the diffusion of molecules from the anode to the cathode chambers. The center section was also used to determine if a particular adsorbate changed the resistance of the solution by contributing to the ionic strength, or by changing the mobility of the ions in the base solution. Because the distance between the fritted glass disks was much larger than the distance from the electrodes to the disks, this type of change was magnified in comparison to what would be obtained in the anode or cathode chamber. Calibration could be accomplished by use of solutions of known resistance and measurement of the distances between the electrodes and the fritted glass disks. A buffered cell solution of 1M acetic acid-1M sodium acetate was used in all experiments reported in this paper.

The steel (S.A.E. 1010) cathode consisted of a flat plate with an exposed area of 8.25 cm^2. The back of the plate and the stem leading up out of the solution were coated with a high melting wax. Thus the entire exposed surface was at the same potential relative to the anode, and changes in the level of the liquid did not affect the size of the exposed area. Oxygen was evolved in the anode chamber on a rough platinum wire.

The cathode potential was measured relative to a saturated calomel half cell. The potentiometric circuit contained a Type 7552 L&N potentiometer and a Rubican multireflection galvanometer. A Luggin tubulus was used for electrical contact between the calomel cell and steel electrode. This technique for measuring electrode potentials in cells in which an appreciable current is flowing has been described in the literature (6).

Reagents

Butynediol was crystallized from 30% solutions obtained from General Aniline Company, and the crystals were washed with ethyl alcohol. Propargyl

alcohol and phenylacetylene were reagent grade from the Matheson Company. Reagents 6, 9, 13, 14, 15, 16, 17, and 19 (Table I) were commercial samples obtained from Air Reduction Company. The remaining reagents listed in Table I were reagent grade samples prepared by Farchan Research Laboratories.

Results

A determination was made of cathodic potential as a function of current density in the acetic acid-sodium acetate buffered solution (Fig. 2). Addition of propargyl alcohol or 1-hexyne-3-ol increased the voltage but did not appreciably change the shape of the curves within the limits of experimental error. This was found to be true in general for the acetylenic compounds which were investigated. With the exception of reagents 32 and 33 (Table I), none of the molecules investigated gave a change in cell potential when added to the center chamber.

Both the rate and total change in cathodic overvoltage depended on the concentration of the acetylenic compound. The maximum change, however, seemed to be reached at concentrations of about 0.01M for 2-butyne-1,4-diol, or 1-hexyne-3-ol (Fig. 3). The rate of change of overvoltage also depended on how vigorously the solution was stirred until some degree of agitation was reached, beyond which no increase in rate was obtained. The anode and cathode chambers were both rapidly stirred, so that neither an increase in agitation nor small decreases changed the rate at which the overvoltage increased.

0.0116 Moles of a number of acetylenic chemicals were added to the cathode chamber. If the compounds were soluble, this would result in 0.0232M solutions. Some of the molecules listed were not soluble to that extent, and the resulting solutions were therefore saturated. The solubilities are not in general known for the various compounds investigated.

Because the solutions were rapidly stirred and not protected from the atmosphere, it can be assumed that some oxygen was available for reduction at the cathode. Although a current of only 30 ma was used in all the experiments, the evolution of hydrogen gas was readily visible on the steel cathode surface. If no oxygen reduction had oc-

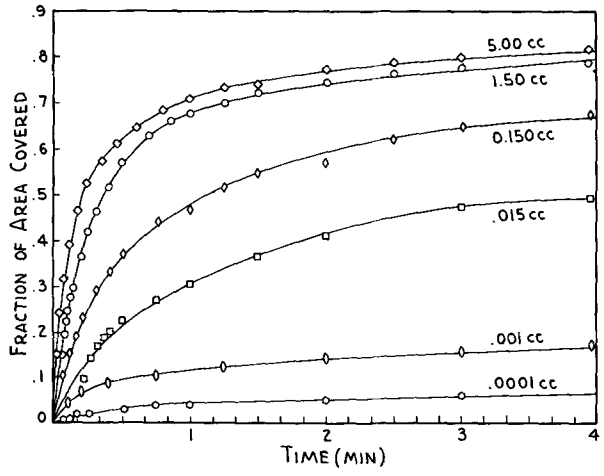

Fig. 3. Fraction of area covered on mild steel cathode as a function of time for additions of 1-hexyne-3-ol to 500 ml to 1M acetic acid-1M sodium acetate.

curred, the theoretical hydrogen production would have been 0.42 cc/min.

The bubbling of either hydrogen or nitrogen gas through the solution to remove oxygen resulted in a slow increase in cathode potential. If an acetylene compound such as 1-hexyne-3-ol was then added to the cathode chamber, the change in the cathode potential was decreased as compared to the changes noted in aerated acetic acid-sodium acetate buffer solutions (Fig. 4). The total increase in cathodic overvoltage resulting from oxygen removal and addition of 1-hexyne-3-ol to the deoxygenated solution was approximately equal to that obtained by addition of the 1-hexyne-3-ol to an aerated solution. Conversely, when oxygen was bubbled through a deaerated solution containing the acetylenic compound, there was a slow decrease in cathode potential. The magnitude of the decrease was less when the acetylenic compound was present.

The acetylenic compounds also increased the electrode potential for the anodic decomposition of iron.

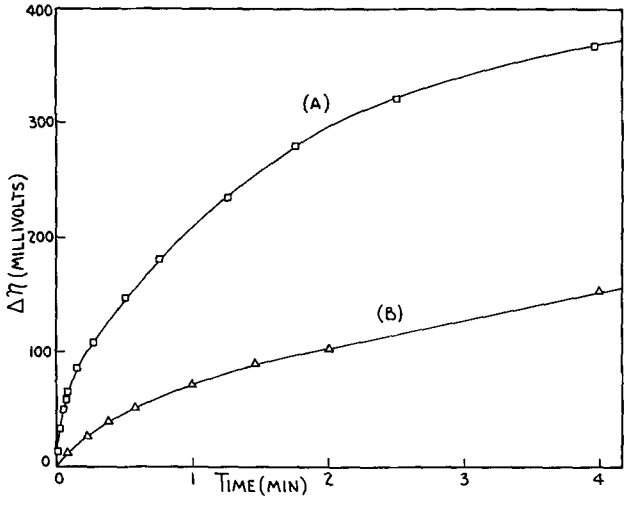

Fig. 4. Overvoltage as a function of time for the addition of 1-hexyne-3-ol (0.0116M) to an aerated 1M acetic acid-1M sodium acetate solution (A), and to the same solution except constantly deaerated with a hydrogen bubbler (B). The final change in $\Delta\eta$ was 530 mv for the aerated solution and about 200 mv less for the deaerated solution.

To measure this effect, the polarity of the cell was reversed. A slow but steady increase of the cell resistance was noted. Addition of one of the acetylenic compounds to the chamber containing the steel electrode gave an increase in electrode potential that was very small compared with the increase noted when the steel electrode was the cathode. 1-Hexynol, for example, gave an increase of 30 mv.

Discussion

Since there was no change in cell resistance when any of the acetylenic compounds were added to the center chamber, it can be concluded that the observed effects are due to changes on the electrode surface, and not to changes in the resistance of the solution. Therefore, the acetylenic molecules must in some way become adsorbed on the electrode surface.

The most apparent effect of the acetylenic chemicals is to raise the potential level of the Tafel plots (Fig. 2) rather than change their shape. The Tafel slopes as drawn have a value of about 250 mv, which is much higher than usually noted. However, a curved line of approximately the same slope would fit the experimental points better in each case (broken line). The slope of these curves at the higher current densities would be about 120 mv, which agrees more closely with the values usually reported. If the slope of the Tafel line is dependent on the reaction mechanism as has often been suggested, the data indicate that the reaction mechanism may change with current density. For this reason all of the acetylenic chemicals were compared at the same current density. The assumption that the addition of acetylenic chemicals does not change the reaction mechanism is of course very tentative in the absence of more complete analytical data.

The chemicals in Table I are listed approximately in order of increasing molecular size. It is apparent, all other things being equal, that there is an increase in overvoltage with increasing molecular size. Propargyl alcohol (reagent 1) is a notable exception. It gave a larger increase in overvoltage than some successively larger α-substituted acetylenic alcohols (reagents 2, 6, 7, and 9). The generalization is valid for all other α-hydroxy acetylene compounds listed. There are, however, other factors that greatly affect the change in overvoltage and lead to a partial understanding of how the acetylenic molecules become attached to the surface.

The position of the acetylenic bond in the carbon chain is the most important structural feature affecting cathodic overvoltage. If the acetylenic bond is not a terminal group, the effect on cathodic overvoltage is decreased or disappears as the size of the group on either end of the acetylenic bond is increased (reagents 4, 5, 14, 17, 19, 23, 24, and 28).

The acetylenic hydrocarbons are generally more effective than the acetylenic alcohols for increasing overvoltage. For example, 1-pentyne and 1-hexyne gave larger increases in overvoltage than any of the acetylenic alcohols with the same chain length. The hydrocarbons are much less soluble than the alcohols. Assuming that both the alcohols and hy-

drocarbons are held to the metal surface through the acetylene group, the alcohols would tend to be more easily solvated and desorbed as a result of hydrogen bonding of the alcohol group with water. The hydrocarbons are less rapidly adsorbed than the alcohols. This also is probably a result of their limited solubility.

The adsorbed layer of acetylenic molecules apparently behaves primarily as a barrier to diffusion, since both cathodic reduction of oxygen and reduction of hydronium ions are apparently inhibited. This would be effected by increasing the work necessary to bring oxygen and hydronium ions to the electrode surface. The larger the hydrocarbon tail on the molecule, the greater is the barrier to diffusion. The adsorbed layer appears to be loosely bound to the surface, however, since oxidation of the steel surface is not inhibited under ordinary atmospheric conditions. Also, the electrodes have a hydrophobic surface when withdrawn from the solution containing the acetylenic compound as evidenced by the high contact angle of water droplets on the surface. This hydrophobic surface is easily removed by rinsing in a stream of distilled water. Thus it appears that the acetylenic molecules are easily desorbed by either evaporation or dissolution.

Since the acetylenic molecules can be effective for increasing overvoltage even when the acetylenic group does not terminate the molecule, bonding to the surface probably occurs through the electron rich acetylenic group, rather than by displacement of the acetylenic hydrogen. The formation of acetylenic metal complexes of this type have been reported (7, 8, 9) and probably involve the filling of d band vacancies in the metal by π electrons of the acetylenic group. Though bonding both by this mechanism and by hydrogen displacement might occur, the former appears more likely since iron compounds formed by hydrogen displacement have been reported to be very unstable (9).

If the hydroxyl group is α to the acetylenic group, the increase in cathodic overvoltage is about twice that obtained for an isomer in which the hydroxyl group is β to the acetylenic group (reagents 2-3, 7-8). Since the hydroxyl group withdraws electrons from the acetylenic bond and makes the acetylenic hydrogen more acid, this observation does not appear to support the bonding hypothesis forwarded, but actually lends weight to the hypothesis that bonding may occur by displacement of the acetylenic hydrogen. However, since the acetylenic hydrocarbons give larger increases in overvoltage than the α-substituted alcohols, it is probable that there are other effects which may contribute or detract from a compound's ability to increase cathodic overvoltage.

Another factor which may contribute to increasing cathodic overvoltage is the insulating properties of the adsorbed layer. An adsorbed layer which is essentially a hydrocarbon can be expected to be a poor ionic conductor. Proprolic acid and acetylene dicarboxylic acid (reagents 32 and 33), which gave small decreases in cathodic overvoltage, may become adsorbed but serve as good conductors of hydronium ions to the surface because of their strongly acidic nature. These molecules gave decreases of only several millivolts in cell potential when added to the center chamber. Therefore, the change of over 30 mv resulting from their addition to the cathode chamber cannot be attributed to an increase in ionic strength.

Finally, the possibility that the acetylenic bond becomes hydrogenated must not be overlooked. Although such a reaction may change cathode potential and may occur to some extent, it is probably not a major factor contributing to the effect of the acetylenic chemicals on cathodic overvoltage. Qualitative observations support this conclusion. The evolution of hydrogen gas is readily visible and does not visibly diminish when the acetylenic chemical is added to the cathode chamber. Also, the increase in overvoltage continues far beyond the time at which the acetylenic additive would be consumed by hydrogenation. Finally, the effect of an olefin such as allyl alcohol on cathodic overvoltage is small (10 mv) compared to the effect of the acetylenic analog propargyl alcohol (370 mv).

Further work is in progress to elucidate the nature of the interaction of acetylenic molecules with metal surfaces. Initial efforts are being directed toward adsorption measurements.

The Effect of Gaseous Impurities on the High-Temperature Oxidation of Magnesium

J. E. Castle,[1] S. J. Gregg, and W. B. Jepson[2]

Department of Chemistry, University of Exeter, England

ABSTRACT

The kinetics of the oxidation of magnesium in oxygen at temperatures between 475° and 570°C have been investigated. It is found that the course of the oxidation is grossly different according to whether the oxidation is carried out on a vacuum microbalance in static oxygen at 10 cm pressure or on a thermal balance in flowing oxygen at 76 cm pressure. This discrepancy cannot be attributed to different surface pretreatments. It is shown that the ready film breakdown (and subsequent nonprotective oxidation) in flowing oxygen is brought about by the reaction of the impurities in the oxygen with the magnesium. If these impurities are removed from the oxygen by gettering, either with magnesium itself or with a mixture of copper and iron oxides, before the magnesium is oxidized on the microbalance, then the amount of oxidation is very small, *e.g.*, at 525°C only 3 $\mu g/cm^2$ after 50 hr. The impurities are thought to be hydrocarbons which are catalytically cracked on the oxide surface to deposit carbon which becomes incorporated in the growing oxide layer. The rate of film thickening is dependent on the partial pressure of impurities in the oxygen, and as a consequence the rate of oxidation shows an apparent dependence on the pressure of oxygen.

The oxidation of magnesium has been the subject of a number of investigations (1-3); it is generally recognized that if magnesium is heated in flowing oxygen on a thermal balance at a temperature such as 550°C, "breakaway" occurs after several hours; as the white oxide scale extends over the sample surface so the rate of oxidation continuously increases with time until the whole of the specimen surface is covered (3). The metal then oxidizes at a constant or linear rate (*e.g.*, 0.18 $mg/cm^2/hr$ at 550°C). If the oxidation is continued for a sufficiently long time, the rate may increase to a second constant value, some tenfold greater than the first and "second breakaway" is said to have occurred; the oxide formed over this second linear branch is buff in color and different in texture from the white oxide scale.

During the course of an investigation (4, 5) of the oxidation of a number of magnesium alloys in oxygen with a vacuum microbalance, it became necessary to obtain reference data for magnesium itself. Rather surprisingly it was found that when a magnesium sample was oxidized at 550°C in the same batch of oxygen as that used on the thermal balance, but under static conditions and at a reduced pressure (100 mm), the inception of breakaway was delayed for several hundred hours.

This discrepancy has led to a reinvestigation of the oxidation of magnesium in oxygen which has established that traces of organic impurity (probably hydrocarbon in nature) play a fundamental role in promoting breakaway. If the impurity is removed from the oxygen, either by gettering or by catalytic oxidation, the weight gained by the magnesium is extremely small, *e.g.*, 3 $\mu g/cm^2$ after 50 hr at 525°C.

Experimental

The magnesium, supplied by Magnesium Elektron Ltd. (England), was in the form of 1.6 mm thick sheet and was of the same stock (batch 2) as that used in previous work (3); the impurities amounted to 500 ppm (Table I). The major portion of the work was carried out with samples whose surfaces had been abraded to 4/0 emery and then electropolished according to the method of Jacquet (6) in a bath of phosphoric acid and ethyl alcohol.

Several grades of oxygen, all from B.O.C. Ltd. (England) were used; *viz.*, batch A, medical grade; batch B, spectroscopically standardized; and batch C, spectroscopically standardized which unlike batch B had been prepared in a single run and contained smaller amounts of impurity. Analyses are given in Table II.

The oxidation of magnesium was followed on a vacuum microbalance (7, 8) sensitive to 2.5 μg (*i.e.*,

0.2 $\mu g/cm^2$ of the sample used). The normal practice with experiments in the microbalance is to outgas the sample before the start of the run at the proposed reaction temperature; with magnesium, such a procedure was not desirable however because evaporation of the metal readily occurred [saturation vapor pressure of magnesium (9) at 525°C is 0.15 mm], and the following method was therefore adopted. At the start of an experiment, the sample was first outgassed at room temperature, then a furnace, preset to 450°C, was raised around the balance limb, and outgassing was continued for a further hour. Under these conditions, no evaporation of the metal could be detected. Next the furnace was replaced by a second furnace preset to the desired run temperature, and oxygen was admitted to a pressure of 100 mm; the zero of time was taken as the instant when oxygen was admitted, and the first reading was taken after about 3 min, subsequent readings being taken at suitable intervals.

The normal practice of obtaining the "balance correction"[3] by evacuating the balance case at the end of the run led to evaporation of magnesium and a consequent weight loss; a standard correction was therefore applied to data obtained in each run and was determined in several preliminary runs using an aluminum sample of the same dimensions as the magnesium samples. A useful check of the balance correction was provided by the fact that little oxidation occurred over the first few minutes of each run so that the first reading of the balance after admission of oxygen corresponded essentially to zero weight gain.

Results

Runs were carried out at 500°, 525°, and 550°C in oxygen of batch A. As is seen from Fig. 1, the rate of oxidation at 550°C at first decreases with time (OA) to become almost constant along AB until at C breakaway occurs and the rate increases along CD: by visual examination the breakaway was found to be associated with the formation of small mounds of buff-colored oxide, particularly along the edges of the sample (Fig. 2). At 500° and 525°C, breakaway was absent within the period of the experiments, and the weight gains after a given time were smaller than at 550°C. Comparison with a run on a thermal balance in flowing oxygen of commercial quality and at atmospheric pressure showed the weight gains to be lower by several orders of magnitude in the microbalance experiments, *e.g.*, 50 $\mu g/cm^2$ compared with 10 mg/cm^2 at 550°C on the thermal balance, after 30 hr. Furthermore, after breakaway, the oxide was white in the thermal balance runs and buff-colored in the microbalance experiments.

Possible reasons for the differences are: (*a*) in the runs on the microbalance the magnesium underwent a vacuum anneal at 450°C for 1 hr before oxygen was admitted, whereas in those on the thermal balance the furnace, already at temperature, was raised into position around the reaction chamber through which oxygen was already flowing; (*b*) the pressure of oxygen was 100 mm in the microbalance experiments compared with 1 atm in the thermal balance runs; and (*c*) oxidation may be promoted by some impurity in the oxygen which in the thermal balance runs would be both continuously supplied and present at a larger partial pressure than in the microbalance experiments.

To test possibility (*a*), the normal procedure of starting a run on the vacuum microbalance was carried through up to the point at which oxygen would have been admitted; the furnace was then removed, and after the sample had cooled to room temperature, it was transferred to the thermal balance and heated at 550°C in flowing oxygen. The oxidation followed the same course as that of a freshly abraded sample so that the vacuum anneal has negligible influence in retarding breakaway.

A further set of experiments gave results which, although not eliminating (*b*), favored the third possibility (c), *viz.*, that an impurity in the oxygen is responsible for the higher rate of oxidation in the thermal balance experiments; three runs were carried out on the microbalance at 525°C but at the different pressures of 1 mm, 10 mm, and 100 mm, respectively. As is seen from Fig. 3, the curves are all similar in shape, but the weight gain at a common ordinate along the branch AB is some threefold greater at 100 mm than at 1 mm. Since it was considered unlikely that the pressure of oxygen *per se* would account for these large differences it was inferred that the increase in weight gain with increasing pressure of oxygen is in fact caused by a corre-

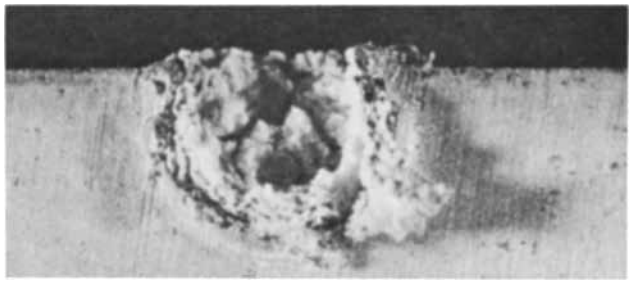

Fig. 2. Characteristic pit on the edge of a magnesium specimen which had undergone breakaway during oxidation at 550°C in static oxygen (batch A) at 100 mm pressure. Magnification approximately 32X.

[3] The balance correction is the change in deflection of the beam when the pressure of gas within the balance case is raised from 10^{-6} mm to 100 mm, the mass of the sample remaining constant. The magnitude of the balance correction is a function of pressure and is mainly due to the thermomolecular flow of gas molecules along the suspension wire (8).

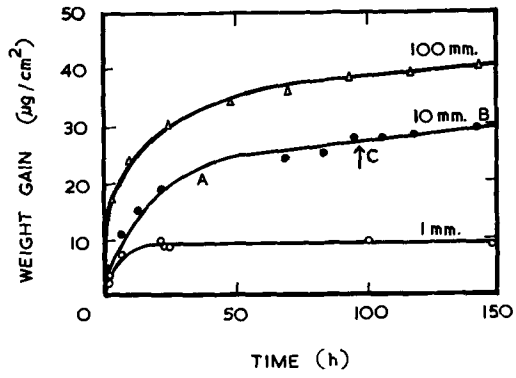

Fig. 3. Oxidation of magnesium at 525°C in static oxygen (batch B) at pressures of 1 mm, 10 mm, and 100 mm, respectively. The magnesium had been electropolished.

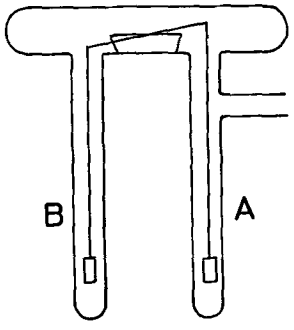

Fig. 4. Microbalance case in its modified form with the limb B extended to accommodate the second magnesium sample which was used to getter the oxygen.

sponding increase in the quantity of impurity, which being proportional to the pressure of oxygen would in the experiment at 100 mm be present in an amount one-hundredfold greater than in the experiment at 1 mm.

This conclusion was confirmed by experiments in which the suspected impurity was removed from the oxygen by "gettering" it with a sample of magnesium suspended in limb B of the microbalance case (Fig. 4) which was lengthened for the purpose. The sample under test was suspended in limb A in the usual way, and both samples were outgassed for 1 hr at 450°C in the standard manner, when the sample in limb A was allowed to cool to room temperature. Oxygen of batch B was then admitted to a pressure of 100 mm, and the temperature of the furnace around limb B was raised to 575°C and held there for 70 hr, in the expectation that the magnesium in the course of its oxidation would getter the impurity. After limb B had cooled to room temperature, a furnace preset to 525°C was raised into position around limb A, and the second magnesium sample oxidized. The resultant weight gain was very small (Fig. 5, curve 1) being only 3 $\mu g/cm^2$ after 50 hr; this strongly suggests that some impurity which can be gettered by magnesium is able to promote oxidation.

It now remained to attempt the identification of the impurity. Nitrogen and water vapor were obvious possibilities, but were eliminated from consideration by the following experiments. A number of runs were carried out at 525°C with oxygen of batch C containing a partial pressure of 0.05 mm (500 ppm) of nitrogen as an addendum, but the curves of weight

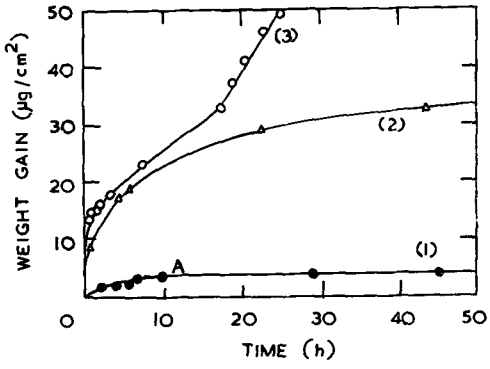

Fig. 5. Oxidation of magnesium at 525°C in static oxygen (batch C) at 100 mm pressure. Curve 1, gettered oxygen; curve 2, ungettered oxygen; curve 3, oxygen + 500 ppm of *n*-nonane. The magnesium had been electropolished.

gain against time did not differ appreciably from those obtained with batch C oxygen itself. In some further experiments, the oxygen (batch C) was thoroughly dried by leaving it in contact with a surface immersed in liquid oxygen for 24 hr, before starting the oxidation run at 525°C. Again the curves of weight gain against time did not differ appreciably from those obtained with batch C oxygen itself.

For various reasons it was suspected that the impurity might be organic in nature. A run was accordingly carried out in which an oxidizing catalyst, commercially available, consisting of a mixture of iron and copper oxides supported on kaolin, replaced the magnesium getter in limb B (Fig. 4). The catalyst was outgassed *in situ* at 620°C (the highest temperature it could withstand) until the vacuum was 10^{-6} mm, and the magnesium in limb A then outgassed at 450°C. The furnace was then removed from A and the sample allowed to cool to room temperature, oxygen of batch C was admitted to a pressure of 100 mm, and was left for 20 hr with the catalyst still at 620°C so as to allow ample time for oxidation of the impurity; a furnace preset to 525°C was then raised into position around the limb A. The resultant curve of weight gain against time (for the sample in A) closely resembled that obtained with magnesium as getter (curve 1, Fig. 5), strongly indicating that the relevant impurity is organic.

On general grounds it seemed that the impurity might be hydrocarbon in nature and was perhaps introduced during manufacture of the oxygen by leakage of lubricating oil from the compressors. In a further experiment therefore 500 ppm of a hydrocarbon, nonane ($n\text{-}C_9H_{20}$), was deliberately introduced into the oxygen (batch C). A run at 525°C (Fig. 5, curve 3) gave a curve which lies above that for oxygen of batch C containing no added hydrocarbon (curve 2); moreover signs of breakaway are present, the curve becomes convex to the time axis, and some white oxide scale was formed along the edges of the sample in a manner characteristic of oxidation in flowing oxygen.

The partial pressure and not merely the absolute amount of the impurity is important. This is evident from a comparison of two parallel experiments carried out with flowing oxygen of batch A, one on the microbalance at 100 mm pressure and the other

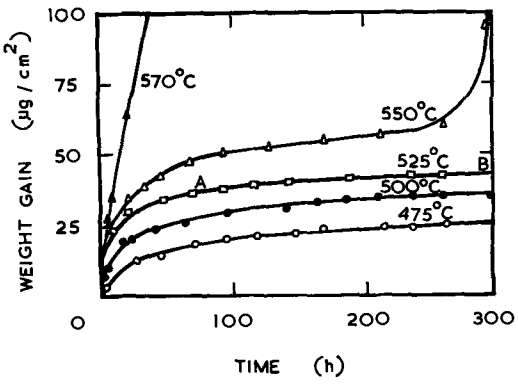

Fig. 6. Oxidation of magnesium at 475°, 500°, 550°, and 570°C in static oxygen (batch C) at 100 mm pressure. The magnesium had been electropolished.

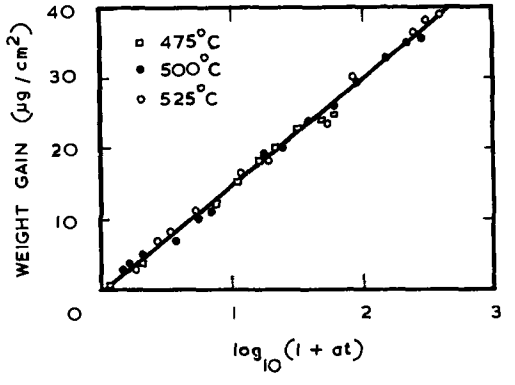

Fig. 7. Oxidation of magnesium at 475°, 500°, and 525°C in static oxygen (batch C) at 100 mm pressure. Data are tested for conformity to the logarithmic rate law by plotting w against log $(1 + at)$. Values of a were 0.22 hr^{-1}, 0.9 hr^{-1}, and 3.8 hr^{-1} at 475°, 500°, and 525°C, respectively.

on the thermal balance at atmospheric pressure, the mass of oxygen passed (equivalent to 6.6 liters at NTP/hr) and therefore the total quantity of impurity being the same in each case. In the run at atmospheric pressure breakaway commenced after only 10 min and was accompanied by the formation of the usual white oxide scale, whereas in the run at 100 mm the inception of breakaway was delayed for 11 hr and the oxide was buff in color.

Once a film has been formed in a closed system, *i.e.*, in the presence of a small and fixed amount of impurity, it confers protection on the metal when this is subsequently exposed to flowing oxygen with its more plentiful supply of impurity. This was demonstrated by oxidizing a sample of magnesium on the microbalance for 30 min at 550°C in oxygen of batch C at 100 mm pressure, then transferring it to the thermal balance and continuing the run there at the same temperature. Breakaway was now delayed for 19 hr as compared with the 10 min of a normal run on the thermal balance at this temperature.

It was thought desirable to study systematically the detailed kinetics of oxidation; untreated oxygen of batch C was used at a pressure of 100 mm. Three runs were carried out at each of the temperatures 500°, 525°, and 550°C; of these, two runs were continued for at least 25 hr and the third for at least 250 hr, the reproducibility as judged by the weight gain at 25 hr being ±7%, ±3%, and ±2% at 500°, 525°, and 550°C, respectively. Single runs were also carried out at 475° (250 hr) and at 570°C (23 hr).

The curves obtained (Fig. 6) fall into a regular sequence. At 475°, 500°, and 525°C the rate of oxidation continually decreased with time, whereas at 550°C in two out of the three runs the rate of oxidation increased after the initial protective stage, indicating breakaway, and at 570°C, breakaway occurred only after 15 hr. Visual examination of the oxidized samples showed that breakaway was associated with film breakdown at isolated points on the metal surface followed by the formation of buff-colored oxide. Samples which had been oxidized at 525°C and below showed a slight loss of luster, but no interference colors were discernible. At the three lower temperatures (although not at 550° and 570°C) the data conformed fairly well (Fig. 7), over the first 150 hr at least, to the logarithmic law

$$w = k \log (1 + at) \qquad [1]$$

where w is the weight gain at time t. The value of k was the same at all three temperatures, *viz.*, 15 $\mu g/cm^2$, but a varied with temperature from 0.22 hr^{-1} at 475°C to 0.90 hr^{-1} at 500°C and 3.8 hr^{-1} at 525°C.

At the longer times (branch AB, 525°C curve, Fig. 6) the rate, which was very small (*e.g.*, 0.02 $\mu g/cm^2$/hr at 525°C), was almost independent of temperature. This is a necessary consequence of the fact that the parameter k is independent of temperature, for from Eq. [1] we have

$$\frac{dw}{dt} = \frac{ak}{1 + at} \qquad [2]$$

which for values of t such that $at >> 1$ becomes

$$\frac{dw}{dt} = \frac{k}{t} \qquad [3]$$

and this for a given value of t is the same at all three temperatures.

Finally, information was sought as to the texture of the oxide film; the surface area of a sample of magnesium, oxidized for 268 hr at 525°C on the microbalance to a weight gain of 42 $\mu g/cm^2$ was measured by krypton sorption (10, 11). A value of 111 cm^2 was obtained, as compared with 68 cm^2 for a freshly polished sample. Both values contain a not negligible contribution for adsorption on the glass walls of the container, but the difference of 43 cm^2 should not be very different from the area of the oxide; it is equivalent to 3 cm^2 per cm^2 of geometrical area of the sample and suggests a degree of roughness which is inconsistent with the model of a uniformly thick oxide layer. Electron microscopic examination of a few representative samples by the replica technique unfortunately gave no clear evidence as to the texture of the oxide film.

Discussion

The present results strongly suggest that the well-known breakaway and subsequent nonprotective oxidation of magnesium, which occur at temperatures of 475°C and above in flowing oxygen, are promoted by an organic impurity, probably hydrocarbon in nature, present in the oxygen. When mag-

nesium is heated in oxygen the impurity must either be oxidized or consumed in some way, as evidenced by the successful use of magnesium at 570°C as a getter. Nevertheless the pronounced diminution in rate which occurs after a period of time (as at A on the 10 mm curve in Fig. 3) is not a simple consequence of the complete removal of the impurity; for when a further charge of oxygen, and with it more impurity, was admitted at B (Fig. 3) to increase the pressure to 100 mm there was no detectable change in the rate of oxidation. Thus while the rate of thickening of the oxide layer up to the 'knee' at A is dependent on the partial pressure p of impurity, the rate of oxidation beyond the knee is insensitive to p. These conclusions are supported by the experiment at 550°C in which it was shown that an oxide layer preformed in static oxygen is able to retard breakaway on subsequent oxidation in flowing oxygen.

If, as seems likely, the impurity is present as a complex mixture of hydrocarbons, the fates of the separate constituents could only be fully elucidated by a series of detailed studies. There is some evidence for decomposition resulting in carbon deposition on the oxide surface; a specimen of magnesium was oxidized at 525°C in gettered oxygen at 100 mm pressure containing C^{14}-labelled decane ($C^{14}H_3$ $(C_2H)_8$ CH_3) at a partial pressure of 0.035 mm. A "count" (12) of the surface of the specimen after 40-hr oxidation indicated the presence of 0.15 μg of carbon per cm^2, a value far in excess of that which could be attributed to chemisorbed carbon dioxide (from oxidation of the hydrocarbon).

Turning now to the kinetics of the oxidation, these can be regarded as proceeding in two stages: (*a*) the growth of a continuous oxide film which under certain conditions is followed by (*b*), the actual breakdown of this film (breakaway) and subsequent nonprotective oxidation.

The preceding discussion leads to the tentative conclusion that the enhanced rate of growth of the protective film, stage (*a*), in oxygen containing the hydrocarbon impurity is brought about by deposition of carbon on the oxide surface and its incorporation in the oxide. As to the mechanism by which this carbon promotes the outward diffusion of Mg^{++} ions and their electrons [it is generally agreed (3) that magnesium oxidizes by cationic diffusion] one can at present only speculate: possible factors are an increase in the electrical conductivity of the oxide film [experiments at 1000°-1500°C show (13) that magnesium oxide is a mixed ionic and electronic conductor], and the production of mechanical defects in the film. Regarding the kinetics of stage (*a*), it needs to be emphasized that the extant theories of oxidation refer by implication to systems free of impurity, and only the curve obtained with gettered oxygen (curve 1 of Fig. 5) fulfills this condition sufficiently well. Unfortunately the weight gains in this experiment were too small for detailed discussion, but it is obvious from casual inspection that the curve cannot be represented by a parabolic or cubic equation (the rate falls off too sharply in the region of A); it appears to be logarithmic in form, but unfortunately, even if conformity to a logarithmic law could be confirmed, this would be of little help in elucidating the mechanism of oxidation, since at least six derivations of this type of law have appeared in the literature (14).

When present in sufficient amounts, the hydrocarbon impurity is also able to promote breakaway and subsequent nonprotective oxidation with the production of a white, brittle oxide scale. If however the conditions are such that the supply of impurity is limited (as in the microbalance experiments with batch C oxygen at 100 mm), breakaway does not occur within 300 hr at 525°C. Breakaway was in fact only observed at 550°C and above and was associated with the formation of the powdery, buff-colored oxide in isolated regions on the specimen surface (Fig. 2); what probably occurs is that magnesium vapor erupts through mechanically weak areas in the oxide film (the saturated vapor pressure of magnesium (9) at 550°C is 0.29 mm) and reacts with oxygen in the vapor phase. The buff color is probably due to traces of metallic magnesium in the oxide, and if the latter is exposed to the laboratory atmosphere for several months, it becomes white (3).

The type of breakaway associated with lateral growth of the familiar white oxide thus seems to be attributable to the presence of hydrocarbon impurity in the oxygen; oxidation in "pure" oxygen, free of the impurity, is characterized by localized breakaway which results in buff-colored oxide.

Conclusions

The oxidation of magnesium in flowing oxygen at temperatures of 500°C and above is promoted by traces of an impurity, probably a mixture of hydrocarbons, but under "static" conditions and at 100 mm pressure of oxygen, *i.e.*, in a strictly limited supply of the impurity, the oxidation remains protective for at least 300 hr at 525°C. In oxygen from which the impurity has been removed, either by gettering or by catalytic oxidation, the oxidation is still protective and is very slight, a mere 3 μg/cm^2, or so, after 50 hr at 525°C.

The Oxidation of an Iron-5 Per Cent Chromium Alloy in the Temperature Range 600°-850°C

J. M. Perrow[1] and W. W. Smeltzer

Department of Metallurgy and Metallurgical Engineering, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

An investigation is reported on the oxidation of an iron-5% chromium alloy over the temperature range 600°-850°C. The film on abraded specimens underwent transformation by nodular-type growths to produce a scale containing iron chromite and ferric-chromic oxide. The alloy underlying iron chromite was susceptible to internal oxidation. These phenomena combined with mechanical breakdown of oxides gave rise to nonreproducible oxidation rate curves.

Despite the considerable number of investigations, an understanding has not been obtained of the complex oxidation behavior of iron-chromium steels at high temperatures. Scales may contain one or both of the rhombohedral sesquioxide, $Fe_2O_3 \cdot XCr_2O_3$ or of the spinel, $FeO \cdot XCr_2O_3$ depending on the exposure conditions. Yearian, Randell, and Longo (1) have characterized a single phase type, which consists of chromium oxide with some dissolved hematite, to be found at low oxidation rates, at low temperatures and/or high chromium content alloys, and a duplex type, which consists of an outer layer of hematite with a small amount of dissolved chromium oxide and an inner layer of iron chromite, to be found at high rates of attack. At long exposure times, both scales undergo breakdown by cracking.

Utilizing electron microscopic observations, Yearian, Derbyshire, and Radavich (2) have demonstrated that the transformation of a ferric-chromic oxide film to one containing iron chromite proceeds in localized oxide growths at randomly distributed positions on the surface. This behavior is typical of both abraded and electropolished specimens. Since the kinetics for formation of films undergoing this transformation have not been demonstrated, this study was designed to investigate the oxidation kinetics of an Fe-5% Cr alloy over the temperature range 600°-850°C. Such an investigation should lead to a further insight into the underlying causes of the poor reproducibility in the kinetic data found for these alloys (3-5).

Experimental

A vacuum microbalance assembly similar to that described by Gulbransen (6) was employed for the kinetic measurements. The sensitivity of quartz microbalance was 1 division (0.001 cm) of the microscopic micrometer per 11 μg for a sample of 0.6900g. The system, capable of maintaining a vacuum of 10^{-6} mm Hg, consisted of a mechanical pump, a three-stage oil diffusion pump, oxygen storage flasks, and a number of traps to protect the metal specimens and oxygen from moisture, oil, and mercury vapors. Temperatures were controlled to ±2°C.

All specimens were subjected to a standard annealing exposure before oxidation. Once a specimen was placed on the microbalance, the system was evacuated to 10^{-6} mm Hg. The temperature was brought to 800°C over a period of 1½ hr and the specimen was annealed for 2 hr at this temperature. Upon adjustment of the furnace to the desired temperature, oxidation was carried out in an oxygen atmosphere at 200 mm Hg pressure. After an oxidation test, the system was evacuated to allow the specimen to cool in vacuum. Oxidized specimens were vacuum mounted in a cold-setting polyester resin for metallographic examinations. The alloy grain structure could be determined after etching specimens for 40 sec in a 5% Nital solution.

The alloy contained 5.0% chromium with impurity contents of 0.01, 0.004, 0.04, 0.04% sulfur, phosphor, silicon, and manganese, respectively. Specimens with surface areas of approximately 2.0 cm^2 were cut from the as-received 0.035 in. thick sheet. A 1/64 in. suspension hole was drilled near one end of a specimen which was then abraded to 4/0 grade silicon carbide paper, degreased in acetone, and suspended in the reaction tube from the microbalance.

Results

Results are presented for the kinetic tests over the temperature range 600°-850°C in conjunction with metallographic examinations of the oxide scales. Since the transformation temperature of the alloy from the alpha to gamma structure is 855°C

[1] Present address: Metallurgy Division, Atomic Energy of Canada Ltd., Chalk River, Ontario, Canada.

(7), the oxidation phenomena are characteristic of a ferritic alloy.

Of the five initial tests for exposures of 3 hr at 800°C, Fig. 1, two rate curves (1 and 2) were similar, whereas the others were different in form and magnitude. The oxide topographies revealed features associated with these phenomena. Small nodular oxide growths were distributed over the surface of the specimen exhibiting the least oxidation, test 5, while the specimens which had undergone larger degrees of oxidation displayed larger nodules. To illustrate these localized growths, a photomicrograph of the nodules on specimen of test 1 is shown in Fig. 2. A series of oxidation tests was carried out at 700° and 850°C to determine the influence of temperature on these phenomena. As illustrated by the curves in Fig. 1, these kinetics were also nonreproducible. As before, oxidation proceeded via nodular growths. On the heavily oxidized specimens at 700°C, these growths had coalesced to a less protective scale. It was apparent from a correlation of the results from the kinetic tests with microscopic observations that the extent of nodular growths at a specific temperature was more important in determining the degree of oxidation than the absolute magnitude of temperature.

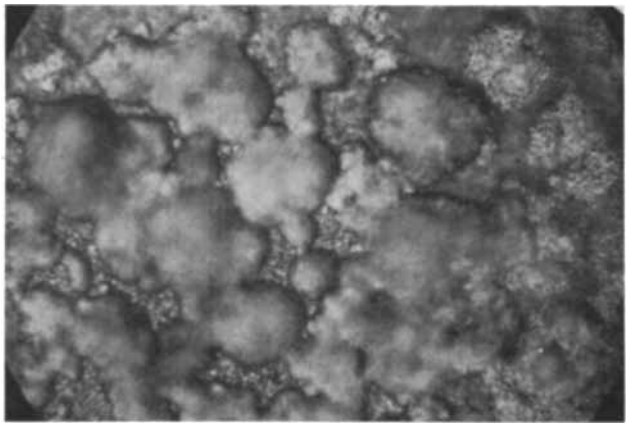

Fig. 2. Surface topography of specimen oxidized for 3 hr at 800°C (test 1, Fig. 1). Magnification approximately 250X.

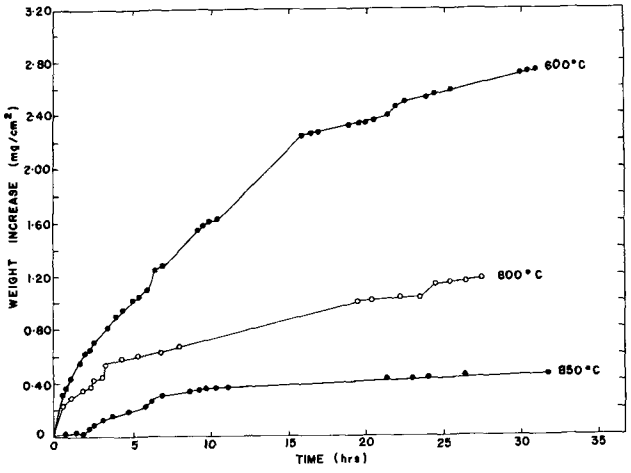

Fig. 3. Oxidation rate curves over the temperature range 600°-850°C.

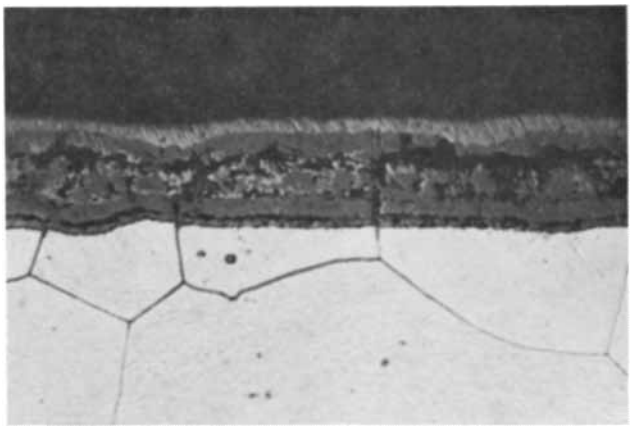

Fig. 4. Cross-section of specimen oxidized at 600°C for 31 hr, etched in 5% Nital. Magnification approximately 575X.

In order to examine the effect of exposure time at several temperatures on oxidation behavior, tests were carried out for exposures to 30 hr at 600°, 800°, and 850°C. These results are illustrated in Fig. 3. The curves were irregular; the specimen exhibiting the lowest initial oxidation rate at 850°C maintained this characteristic even though this temperature was of highest value.

Examination of scale cross sections illustrated features associated with this behavior. Photomicrographs are presented in Fig. 4-6 of the scales on the specimens of the three above tests. Iron chromite is distinguishable from ferric-chromic oxide by its darker color. At the lowest temperature of 600°C, the scale, which consisted predominately of iron chromite, was severely cracked. Voids in this oxide layer were encased by ferric-chromic oxide. On the other hand, the scale consisted predominately of this latter oxide at 800° and 850°C with large amounts of iron chromite occurring only in the nodular growths. Detailed examination of cross sections demonstrated that specimens whose scales contained the smaller amounts of iron chromite exhibited the less rapid oxidation rates in the temperature range 600°-850°C.

Internal oxidation of the alloy proceeded predominantly intergranularly at temperatures below 700°C

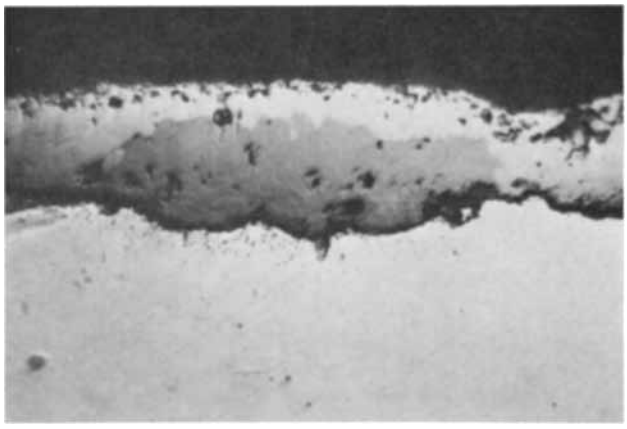

Fig. 5. Cross section of specimen oxidized for 51 hr at 800°C. Magnification approximately 575X.

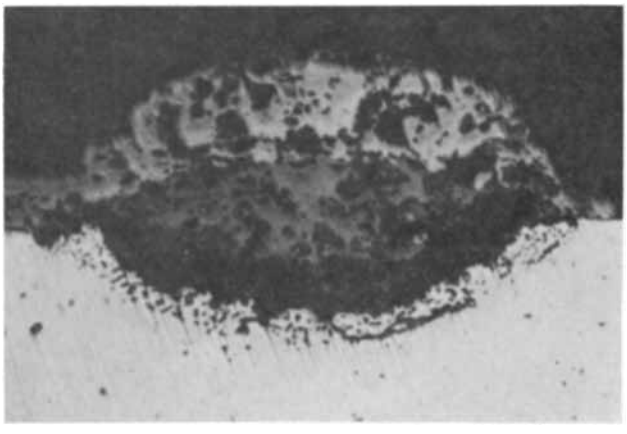

Fig. 6. Cross section of a localized oxide growth on specimen after 43 hr oxidation at 850°C. Magnification approximately 250X.

and predominantly intragranularly at temperatures above 800°C. These phenomena are illustrated in the photomicrographs of Fig. 4-6. Moreover, highly localized external and internal oxidation in the temperature range 800°-850°C gave rise to the unusual growths depicted in Fig. 6. These growths, which exhibited porosity, contained large amounts of both iron chromite and ferric-chromic oxide. It was possible to show by etching experiments that alloy grains had been completely converted to oxide by these growths.

Discussion

In this section, the salient oxidation characteristics are correlated insofar as possible with the mobilities of the reactants in the alloy and oxide phases and the Fe-Cr-O phase diagram.

The correlation of the results from the kinetic experiments with metallographic examinations has demonstrated that the degree of oxidation at constant temperature was dependent on the extent of nodular oxide growths from the metastable film on the abraded specimens. These findings substantiate the electron microscopic observations of Yearian, Derbyshire, and Radavich (2). They also demonstrate that a ferric-chromic oxide film on an Fe-5% Cr steel was stable for exposures to at least 30 min at 625°C. For the experimental conditions of this investigation, this oxide was extremely protective in the temperature range 800°-850°C and only transformed to localized growths containing large

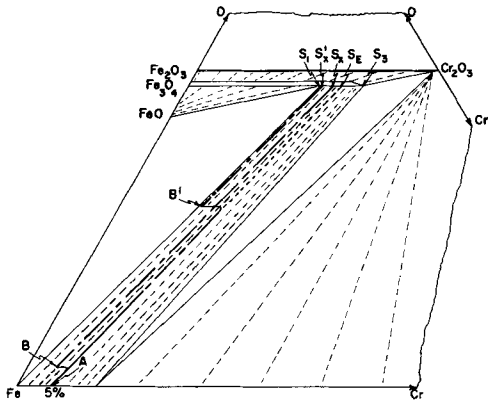

Fig. 7. Qualitative ternary phase diagram for the ferritic iron-chromium solid solution and oxides at temperatures higher than 600°C. ABS_x, hypothetical path for small degree of internal oxidation in 5% Cr alloy underlying iron chromite at 800°C. $AB'S'_x$, hypothetical path for large degree of internal oxidation in 5% Cr alloy underlying localized oxide growths at 850°C.

amounts of iron chromite for exposures in the order of 30 hr.

This transformation of ferric-chromic oxide to iron chromite is brought about by a simple chemical displacement reaction. As illustrated by the tentative Fe-Cr-O phase diagram for temperatures greater than 600°C in Fig. 7 (8), ferric-chromic oxide may exist only in stable equilibrium with alloys containing greater than 12% chromium. When this oxide exists in contact with a 5% Cr alloy, iron and oxygen react to transform this initial metastable film to one containing spinel and a rhombohedral oxide richer in iron

$$2O_2 + 3Fe + xFe_2O_3 \cdot 2Cr_2O_3 \rightarrow FeCr_2O_4 + (1 + x)\, Fe_2O_3 \cdot Cr_2O_3$$

For heavily oxidized specimens, this reaction leads progressively to formation of a scale containing distinct layers of the two oxides (Fig. 4).

The alloy beneath the localized oxide growths containing iron chromite was subjected to severe internal oxidation. Chromium was sufficiently depleted for oxide precipitation because the diffusion constant of metal in the spinel oxide is of the relatively large magnitude (9) (10^{-11} cm²/sec at 800°C). On the other hand, chromium was not depleted from the alloy beneath rhombohedral oxide because the diffusion constant for this oxide is relatively small (9) (10^{-16} cm²/sec at 800°C). The composition paths in the internally oxidized regions of the alloy at 800° and 850°C are qualitatively represented in the phase diagram of Fig. 7. Iron chromite which would exist in equilibrium with a 5% chromium alloy is designated S_E. Its composition lies within the range S_1-S_3 ($Fe_{1.5}Cr_{1.5}O_4$ to $FeCr_2O_4$). Since chromium may be depleted from 5% to as little as 2% by oxidation at 800°C (4), the oxide of the scale S_x, lies on the iron rich side of S_E. Consequently, a composition path ABS_x in the two phase field represents the depletion of chromium in the internally oxidized regions of the alloy. The position of B on the tie-line between the 2% alloy and spinel S_x is determined by the degree of internal oxidation (Fig. 5). This degree of oxidation was much larger beneath the

localized oxide growths at 850°C, where the pronounced depletion of chromium lead to complete conversion of alloy grains to oxide. Consequently, the composition of the spinel oxide would approximate closely to the composition S_1 for the spinel of smallest chromium concentration. The composition in the internally oxidized region may then be presented by the path $AB^1S_x^1$ where the position of B^1 represents the large degree of oxide precipitation (Fig. 6).

The irregular, nonreproducible oxidation rate curves are similar to those from previous investigations. Because the initial rates were not representative of uniform oxide growth, a distinction could not be made between the acting chemical and physical processes. We could only conclude that oxidation proceeded in the early exposure stages by localized external and internal oxidation. The large variations of such oxidation over the alloy surface at a specific temperature were more important than the absolute value of temperature in determining the magnitudes of oxidation in the range 600°-850°C. Since oxygen could also penetrate inwards through cracks in the localized oxide growths, spinel oxide growth and its cracking to more pervious oxide played effective roles in the occurrence of irregular transitions to more rapid rates in the oxidation curves. These results emphasize that reproducible curves for a ferritic alloy of low chromium composition will be obtained only under conditions where the initial metastable film is uniformly converted to the stable duplex film of iron chromite and ferric-chromic oxide prior to oxidation.

The Anodic Dissolution of Binary Alloys

R. F. Steigerwald[1] and N. D. Greene

Corrosion Research Laboratory, Interdisciplinary Materials Research Center, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

A method for calculating the anodic polarization curves of binary alloys from those of their components is presented. Heterogeneous alloys can be treated as simple galvanic couples, but homogeneous alloys are subject to a modification of Tammann's concept of surface enrichment. Potentiostatic anodic polarization curves are used to compare the calculated and experimental curves. Data are presented for the tin-zinc, cadmium-zinc, iron-chromium, titanium-chromium, and iron-titanium systems.

The practical and commercial importance of alloys has made their corrosion and dissolution the subject of numerous experimental investigations (1-7); however, no general, quantitative theory has been presented for the dissolution of alloys.

The recent application of potentiostatic polarization techniques to metallographic etching (8, 9) has shown that the phases of a heterogeneous alloy probably dissolve independently of one another, but only limited experimental evidence has been presented (10). The theory for homogeneous alloys has been largely an extension of Tammann's (11) explanation of parting limits in gold alloys.

[1] Present address: Research Division, Electrochemicals Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Theory

General.—The homogeneous or mixed potential theory of electrode kinetics was stated by Wagner and Traud (12) and extensively applied to corroding systems by Stern and Geary (13, 14). The basic assumptions are that electrochemical reactions may be treated as sums of partial reactions (usually considered as independent of one another) and that no net current flows at an electrode which is in equilibrium or at steady state. Thus the net rate of oxidation equals the net rate of reduction at steady

state; any polarizing current will be the difference between the oxidation and reduction rates at the polarized potential.

$$\vec{i}\ \text{applied} = \vec{i} - \overleftarrow{i} \qquad [1]$$

where $\vec{i}$ is the oxidation current and $\overleftarrow{i}$ the reduction current.

For the present discussion, consider an electrode corroding under activation control (13)

$$\epsilon = \vec{\beta} \log \vec{i}/i_{cor} = -\overleftarrow{\beta} \log \overleftarrow{i}/i_{corr} \qquad [2]$$

where ϵ equals $E - E_{cor}$ and $\vec{\beta}$, $\overleftarrow{\beta}$ are Tafel slopes, constants of the system.

Combining Eq. [1] and [2]

$$\vec{i}_{applied} = i_{corr}(10^{\epsilon/\beta} - 10^{-\epsilon/\beta}) \qquad [3]$$

Taking $\vec{\beta} = \overleftarrow{\beta}$ 0.10 volt/decade (typical for a corroding electrode), $\vec{i}/\overleftarrow{i} = 10$ at $\epsilon = 0.05$v. Thus at 50 mv noble to the corrosion potential, the applied current is approximately equal to the dissolution current. It is this fact that makes the polarization curve such a useful tool for studying the dissolution of metals.

For completeness, note that dissolution current, like any other rate process, can be expressed by a typical exponential equation

$$\vec{i} = A \exp\left(-\frac{\Delta G^*}{RT}\right)\exp\left(\frac{\alpha Z\mathbf{F}}{RT}\right)\epsilon \qquad [4]$$

where A is a constant, ΔG^* the free energy of activation, α the distribution coefficient, Z the oxidation number, and **F** equals 1 Faraday. Detailed discussions of electrochemical currents as rate processes can be found elsewhere (15, 16).

Dissolution of heterogeneous alloys.—Stern (17) studied the cathodic polarization of galvanic couples and found both theoretically and experimentally that at any potential E

$$i_T = i_A f_A + i_B f_B \qquad [5]$$

where the subscript T stands for total, A, B for the couple components, and f_A, f_B are area fractions of the components.

A heterogeneous alloy can be regarded as a galvanic couple in which electrical connection is made by direct contact. If the polarization curve for each phase is known, the polarization curve of the alloy can be calculated from Eq. [5]. The area fractions needed in Eq. [5] can be calculated from the composition of the alloy since a section through an alloy (in this case the exposed surface) has an area composition equal to the volume composition of the alloy. The volume composition is easily calculated from the weight composition and the specific gravity of the components.

Although Eq. [5] is generally applicable to dissolution of multiphase alloys, some exceptions must occur. Applicability of Eq. [5] depends on the fact that area fractions of each phase can be calculated from the alloy composition. Under some conditions, the surface composition of the alloy may not equal its volume composition. Consider a heterogeneous alloy containing an active phase dispersed as small isolated colonies in a relatively inert matrix. Under these conditions, the area fraction of the matrix would be greater than the one calculated from the composition since the rapid dissolution of the second phase exposes the matrix, not more of itself. However if the colonies are large or the active phase continuous, the surface composition would not be affected by the disparity of dissolution rates, and the area fractions could be calculated accurately. The occurrence of surface enrichment in heterogeneous alloys is determined by the relative and absolute dissolution rates and the dispersion of the phases. A large difference in rates, of course, is necessary for surface enrichment, and unless the dissolution rate of the active phase is relatively high deviations from Eq. [5] would not be observed in finite times. Because of the dispersion effects noted above, surface enrichment should be expected only in relatively dilute heterogeneous alloys; however, as the dispersion of the phases becomes finer, the possibility of surface enrichment extends to less dilute alloys.

This application of the mixed potential theory to a heterogeneous alloy surface extends it beyond Wagner and Traud's (12) original assumption that anodic and cathodic reactions occur randomly on the electrode surface. Equation [5] implies that the cathodic reaction may occur almost entirely on one phase and the anodic on the other. This localization of the partial reactions is the principle underlying the addition of noble metals to Ti and Cr (18-20). The high exchange current density for hydrogen ion reduction on the platinum rich areas of the surface leads to the passivation of the base metal.

The mixed potential theory is based on the conservation of charge and the existence of partial processes. Neither of these principles is concerned with the distribution of reaction sites, and therefore the character of the electrode surface is not basic to the theory.

Dissolution of Homogeneous alloys.—Equation [5] is applicable to the dissolution of any alloy; the problem is determining the proper area fractions and component current densities at any point in the dissolution process. In the previous section, the values of these parameters were set by assuming that each phase dissolved independently of the others. However, as the dispersion of the phases in the alloy becomes finer and finer, the possibility of surface enrichment, discussed above, becomes proportionately greater. Finally when the dispersion reaches atomic dimensions, a solid solution, surface enrichment controls the dissolution rate of the alloy. By considering surface enrichment as the rate-determining factor, Mueller (21) has derived an expression for the steady-state dissolution rate of a homogeneous alloy. A slight modification of this derivation follows:

If all possible solid-state interactions and interfacial energies are neglected, the current density for each component of a homogeneous alloy at any potential E would be that of the component as a

pure metal. Furthermore, if the dissolution is uniform (as opposed to dezincification where one component is removed selectively), the ratio of A to B is the same in the solution as the alloy. Hence it follows that surface enrichment of the more noble component occurs. This may be expressed

$$\frac{N_A}{N_B} = \frac{Z_B i_A f_A}{Z_A i_B f_B} \quad [6]$$

where N_A, N_B are the mole fractions in the alloy, Z_A, Z_B are the oxidation numbers of the ions, i_A, i_B are dissolution current densities of the components A and B at a given potential, and f_A, f_B are the area fractions of A and B.

By definition

$$f_A + f_B = 1 \quad [7]$$

Combining Eq. [6] and [7]

$$f_A = \frac{Z_A N_A i_B}{Z_A N_A i_B + Z_B N_B i_A}, f_B = \frac{Z_B N_B i_A}{Z_A N_A i_B + Z_B N_B i_A} \quad [8]$$

Substituting Eq. [8] into Eq. [5]

$$i_T = \frac{i_A i_B (Z_A N_A + Z_B N_B)}{Z_A N_A i_B + Z_B N_B i_A} \quad [9]$$

i_T is now the alloy dissolution current density. Equation [9] is Mueller's final expression for dissolution rate written in terms of current density.

When Eq. [9] was applied to experimental data measured in this study, it was found that even in systems in which there were negligible free energy changes on alloying the calculated and experimental steady-state dissolution rates were in agreement only when corrosion potentials of the pure components were nearly the same.

Equation [9] was derived on the basis that the components are independent on each other, that the atoms of the alloy are joined as minute galvanic couples. Even in an ideal solid solution this is not true; an A atom cannot dissolve without affecting both A and B neighbors. It is obvious that the effect of solid-state interactions on dissolution, a kinetic process, cannot be adequately evaluated on the basis of equilibrium thermodynamic data. It is, however, difficult to assess the magnitude of these kinetic interactions theoretically.

If the surface of a corroding alloy is enriched in the noble component, the polarization behavior of the alloy should be controlled by the polarization behavior of this component. Although Eq. [9] describes this kind of control, it does not take into account possible interactions between the components.

If dissolution is considered as an activated process (Eq. [2] and [4]), the rate is determined not by the potential E but by the overvoltage ϵ. Therefore, one correction that could be applied to Eq. [9] is to take currents at constant overvoltage rather than constant potential. This condition of constant overvoltage is most easily met by shifting the polarization curves of the components along the potential axis until their corrosion potentials coincide with that of the alloy and then calculating the curve for the alloy from Eq. [9].

Just as Eq. [5] is expected to fail in describing the behavior of heterogeneous alloys under certain conditions, Eq. [9] will fail for certain homogeneous alloys. Mueller (21) has pointed out that deviations are more likely when an alloy contains an excess of the active component. The principle underlying Eq. [9] is the surface enrichment of the more noble component. If the active component is in the majority, surface enrichment can occur only by the removal of a large number of atom layers from the surface of the electrode (*e.g.*, nine atom layers have to be removed from the alloy where the mole fraction of the noble component is 0.1). If the difference in the dissolution rates is large ($i_A/i_B > 10^3$), surface enrichment is probably hindered by the removal of loosely bound noble atoms by the rapidly dissolving active atoms of succeeding monolayers. In the extreme case, the dissolution current of the alloy would be given by Eq. [5]. It is worth noting that the limiting case for the dissolution of a homogeneous alloy is the normal case for a heterogeneous one and *vice versa*. The two alloy types are thus not as different as they seem.

Ideally, this discussion might include the calculation of the corrosion potentials of solid solutions. This very complex problem has been treated in detail by Akimov (22) and will not be considered here. Two points should be made about the corrosion potential, however: (i) considering the above discussions, the corrosion potential does not affect the shape of the calculated polarization curve, only its position on the potential axis. It should be noted that surface enrichment precludes any simple treatment of the corrosion potential; (ii) in many actual cases, the corrosion potential of a single phase varies almost linearly with composition (23-25). Therefore, when experimental values are not available, a straight line relationship can be used as an approximation.

Dissolution of intermetallic compounds and other intermediate phases.—Intermetallic compounds and intermediate phases are homogeneous alloys, but differ from the ordinary (terminal) solid solutions discussed above since they may have different crystal structures, ordered structures, and/or stronger solid-state binding. Since they are homogeneous, the general features of their dissolution behavior should be same as solid solutions; the principle of surface enrichment should apply, but the solid-state differences between the intermediate phase and its components may cause displacement of the calculated polarization curve along either the current or potential axis. Since the type and magnitude of these interactions differ greatly in the various alloy systems, and since little is known about the interfacial effects of different crystal structures, it is difficult to make predictions about the kinds and magnitudes of displacements which would occur. If the dissolution rate is controlled by surface enrichment, however, the shapes of calculated and experimental curves will be similar.

To summarize, the rules for calculating anodic polarization curves of alloys are:

1. Polarization curves of heterogeneous alloys can be calculated by Eq. [5]. The area fractions used are equal to the volume fractions calculated from the composition of the alloy. Care must be used in applying this method when the rapidly dissolving phase is present in very small amounts.

2. The polarization curves for homogeneous alloys can be calculated from Eq. [9] after the polarization curves of the components have been shifted along the potential axis until their corrosion potentials are at the corrosion potential of the alloy. If the corrosion potential of the alloy is not known, as a first approximation it can be assumed to vary linearly between those of the two components. Some caution should be used in applying these calculations to alloys in which the noble component is present in small amounts.

3. Intermetallic compounds and intermediate phases are treated in the same manner as other homogeneous alloys, but the stronger interactions in these materials may lead to displacements of their polarization curves along either axis.

Procedure

The experimental part of this investigation involved measuring the anodic polarization of a number of alloy systems. The systems chosen all exhibited active-passive transitions (26-28). Although the polarization curves of active-passive metals are much harder to reproduce than those of normal metals, their characteristic shapes provide points at which unambiguous comparisons can be made between theory and experiment. Simple dissolution curves have no such singularities.

Materials.—The difficulty in reproducing anodic polarization curves reported in the literature is probably the result of trace impurities in the metals under study (29). To minimize this difficulty, the alloys used in this study were prepared from very high-purity metals, and all alloys of a given series were prepared under identical conditions. Table I lists the component metals and their purity, Table II the alloys studied.

In general, buttons of the high melting alloys were prepared by arc melting in an argon atmosphere and machined into specimen electrodes. Low melting alloys were melted in Pyrex tubes under argon. The alloys were used in the as-cast condition unless heat treatment was needed to insure a particular structure (Table II).

All solutions were prepared from reagent grade chemicals and triply distilled water.

Experimental.—The dissolution studies employed conventional potentiostatic anodic polarization techniques. The greater part of the measurements were made with a classical potentiostat as described by Greene (28); in the later stages of the work, a transistorized electronic potentiostat[2] was used. Control in both cases was within 1 mv, and potentials were measured relative to a saturated calomel electrode using a Luggin probe and high impedance circuitry.

The polarization cell was similar to those described by Stern and Greene (28, 30). Two platinized platinum electrodes on opposite sides of the cell were used as cathodes. Electrodes of alloys that could be machined were cylinders of approximately 1 cm² surface area mounted on the electrode holder described by Stern and Makrides (31). The hardness and brittleness of the intermetallic compounds studied made it necessary to mount them in Bakelite or epoxy resin in order to make connections to them. Unwanted area and exposed portions of the connectors were masked with glytal paint. Control experiments showed that the presence of these materials did not affect the dissolution curves.

Polarization curves were measured in either normal sulfuric acid or normal sodium hydroxide depending on the alloy system. All solutions were hydrogen-saturated to simplify the reduction kinetics. Prior to polarization the specimens were exposed to the test solution for several hours to insure that a stable corrosion potential was attained.

At most potentials, the current reached steady-state values in a short time (less than 5 min), and these steady-state values are reported. In the passive region, however, current is time dependent (29, 32-34). Experiments showed that even after three or four days the passive current was still decreasing on some metals. Therefore, it is a practical impossibility to wait for steady state at each point on the polarization curve. As partial solution to this problem, it was decided to report the currents at these time-dependent points, usually 10 min. It must be emphasized that in the alloys studied only the passive current had this pronounced time-dependence. All other currents reported are steady-state values; the onset of passivity and the shapes of the polarization curves are not affected by this method of waiting stated intervals in the passive region.

All polarization measurements were made at room temperature which was 25° ± 2°C.

Results

Similar to all rate processes, dissolution is a logarithmic function of its driving force (cf. Eq. [4]). Current is expected to vary exponentially with overvoltage, and for this reason electrode po-

tential is plotted as a function of the logarithm of the applied current in this presentation, and agreement between calculated and experimental results is discussed in terms of these curves. In addition to the logarithmic nature of the processes involved, one other point should be made in favor of semi-log plotting of these data. The difference between the active and passive currents is usually from two to five orders of magnitude. Simple linear plotting could not reveal all the pertinent features of curves which contain such large changes in one of the variables.

Dissolution of heterogeneous alloys.—The tin-zinc system is a simple eutectic with no solid solubility in either component at room temperature (35). Alloys of this system are therefore simple mixtures, and their dissolution behavior should conform to Eq. [5].

Figure 1 shows the anodic polarization curves of tin and zinc in normal sodium hydroxide. Figures 2 through 5 compare the measured and calculated curves for several of their alloys. The curves for tin and the alloys were quite reproducible, but that of zinc varied by as much as a factor of three. The dashed lines indicate loss of potentiostatic control.

The agreement between the calculated and experimental curves is generally quite good. Although current values sometimes differ by as much as a factor of ten, the curves generally coincide, and their shapes are always the same. Note particularly the agreement between potentials for the calculated and experimental current maxima or "noses."

The calculations show that the polarization curves for each of the alloys should have two noses, one for tin, the other for zinc. Only in the absence of the more active nose in the 10.5 w/o Zn alloy (Fig. 2) is there serious disagreement between the calculated and experimental curves. This disagreement occurs under the circumstances which were discussed above, that is when the active component is present in small amounts. If this hypothesis is correct, refining the dispersion of the phases should extend this surface enrichment to alloys with higher zinc contents. To test the idea, the dispersion of a sample of the 15.7 w/o Zn alloy shown in Fig. 3 was refined by cold work and heat treatment and its anodic polarization curve was measured. As predicted, the curve shown in Fig. 6 was unchanged except that the more active nose was replaced by cathodic current.

Alloys of the cadmium-zinc system are also simple eutectic mixtures (36), and their polarization behavior can be described by Eq. [5]. Table III records the important parameters for the anodic polarization

of some Cd-Zn alloys. The critical current *Ic* is the current maximum; and the primary passive potential *Epp* is the potential corresponding to this maximum. *Ip* is the passive current measured at −0.2v *vs.* S. C. E. As noted above, there is some scatter in the polarization data of zinc; Table III shows this scatter. The agreement between the calculated and experimental values is generally within the limits of experimental reproducibility.

Dissolution of solid solutions.—The iron-chromium system is essentially a continuous solid solution (interrupted only by the sigma phase near 50% Cr); this solid solution approaches ideality (37), and it is of considerable practical interest. These factors make it a logical choice as the principle subject for an investigation of the dissolution of solid solution alloys. Although the polarization behavior of this system has been studied previously (38, 39), none of the data were complete enough to allow their analysis in terms of the present discussion.

Figure 7 shows the anodic polarization of iron and chromium[3] in normal sulfuric acid. Figures 8 through 11 compare experimental and calculated polarization curves for some Fe-Cr alloys. The curves were calculated according to the procedure outlined above:[4] the polarization curves of the pure components were shifted so that their corrosion potentials were at the corrosion potential of the alloy, and Eq. [9] was used to calculate the polarization curve of the alloy. It must be remembered that Eq. [9] can be applied only after the polarization curves of the components have been shifted.

The experimental results are consistent with the general rules described above. In the case of the dilute 5.48 w/o Cr alloy (Fig. 8), that portion of the curve where the rates differ widely, *e.g.*, at $E = -0.4$v $i_{Fe}/i_{Cr} = 3.3 \times 10^6$, follows Eq. [5] more closely than Eq. [9]. This is consistent with earlier discus-

[3] The negative loop (40), the region where the reduction current exceeds the passive current, was not shown for chromium or the 25 w/o Cr alloy.

[4] Z_{Cr}/Z_{Fe} was taken as 3/2.

sions of the behavior of dilute alloys. In the 10.5 w/o Cr alloy, only the relatively wide current maximum remains as evidence of the effect of greatly different dissolution rates on the polarization curves of relatively dilute alloys. Except for the magnitude of the passive currents, the experimental and calculated curves for the 20.6 and 25 w/o alloys agree quite well.

In Table IV, calculated and experimental values of the parameters for the anodic dissolution of some metastable solid solutions of titanium and chromium are listed. Again, calculated and experimental results compare favorably.

In both of the alloy systems discussed above, there is a noticeable difference between calculated and observed passive currents.[5] It should be noted that due to the large change in current during the transition from the active to the passive state, the differences observed in the passive currents are not significant in relation to the over-all polarization behavior of these alloys. Furthermore, these differences are no greater than would be expected in the values of passive currents reported by independent investigations on the same metal.

Dissolution of intermetallic compounds.—It was postulated above that the dissolution of intermetallic compounds should be controlled by the enrichment of the noble component on the surface, but it was also noted that the strong interactions that are characteristic of these alloys might lead to displacement of the polarization curve along either the current or potential axis. Figures 12 and 13 show the calculated and experimental polarization curves for $TiCr_2$ and TiFe. The experimental and calculated curves have the same shapes but are displaced from one another along the current axis. In general

$$i_{exp} = C i_{calc}$$

[5] Work in this laboratory has shown that the time-dependence of the passive current is different for different elements. Although discussion of this phenomenon is beyond the scope of this paper, it is natural that the behavior of alloys would be intermediate to that of their components. Such behavior could lead to the differences observed.
Mueller (21) has suggested that the formation of mixed oxides or spinels may lead to passive films on alloys which are less soluble than those of either component. Such reactions also could explain the observed differences.

Table IV. Anodic polarization of Ti-Cr alloys in NH_2SO_4

Ti-10 w/o Cr	26	33	−0.520	−0.520	1.4	2.0
Ti-20.4 w/o Cr	42	35	−0.520	−0.540	1.2	1.8
Cr	3,700	—	−0.560	—	1.25	—

Table V. Correction factors for the dissolution of some intermetallic compounds

Compound	C
$TiCr_2$	50
TiFe	2
$TiFe_2$	15

where C is an experimentally determined constant. Values from 2 to 50 have been found for C (Table V), but there is no method of predicting the constant for a particular compound.

The experimental results show that the polarization of these complex alloys is apparently determined by that of their most noble component, but the position of the curve is influenced to varying degrees by the fact that these compounds have characteristics which are usually quite different from their pure components.

Discussion

For the most part, the experimental results have been discussed in relation to the theory in the previous section; however, some general points merit further discussion.

The results of metallographic etching (8, 9) and the quantitative agreement between theory and experiment in this study make physical interpretation of the dissolution of heterogeneous alloys relatively sure. The dissolution behavior of the phases of a heterogeneous alloy are unaffected by the fact that they are in an alloy. Electrochemically, such an alloy is a galvanic couple in which the necessary electrical connections are made by physical contact between phases. It was noted above that this fact extends the mixed potential theory beyond its original assumption and requirement of randomly distributed anodic and cathodic sites.

Considerable care must be taken in attaching physical significance to the fact that the dissolution of homogeneous alloys can be treated by assuming that the noble component enriches on the surface of the alloy. The polarization curves of alloys are apparently controlled by surface enrichment or at least some surface enrichment-like effect, but there is no evidence that this enrichment is a gross effect like the dezincification of brass. On the contrary, the behavior of intermetallic compounds and the necessity of the potential shift in applying Eq. [9] make enrichment at only the active dissolution sites a much more likely explanation. If the noble component covered the entire electrode surface to any thickness, the behavior of the electrode would be independent of solid-state interactions in the alloy, yet allowance for these interactions had to be made in this study. Although the present theory is undoubtedly only an approximation of a very complex process, the quantitative agreement between it and experiment show that the approximation is generally valid.

Summary

1. A general quantitative theory has been presented for the anodic dissolution of binary alloys.

2. Experimental verification of the theory has been presented.

3. The rules for calculating the polarization curves of alloys can be summarized:

(*A*) Heterogeneous alloys behave as simple galvanic couples. If the polarization curve for each phase in the alloy is known

$$i = i_A f_A + i_B f_B \qquad [5]$$

The area fractions f_A, f_B can be calculated from the composition of the alloy. i is the total alloy current density at a potential E; i_A, i_B are the current densities of the components at this potential.

(*B*) Homogeneous alloys must be treated by extending Tammann's concept of surface enrichment. To compensate for interactions in the alloy, the polarization curves of the components are shifted along the potential axis until their corrosion potentials are at the corrosion potential of the alloy. The current at any potential can then be calculated

$$i = \frac{i_A i_B (Z_A N_A + Z_B N_B)}{Z_A i_B N_A + Z_B i_A N_B} \qquad [9]$$

N_A, N_B are the mole fractions of the components in the alloy; Z_A, Z_B are the oxidation numbers of the ions. The other symbols are as in (*A*).

(*C*) Intermetallic compounds and intermediate phases behave in general like other homogeneous alloys, but stronger solid-state interactions may shift their polarization curves along the current axis.

Acknowledgment

This work was partially supported by research grants from the Monsanto Chemical Company and the National Science Foundation. One of the authors (R. F. Steigerwald) wishes to thank the Union Carbide Metals Company for financial support under a Union Carbide Metals Company Fellowship.

The pure metals listed in Table I were gifts of the suppliers.

The authors wish to thank Messrs. H. L. Andrews, A. P. Lee, and J. C. Uy for their help in preparing the experimental alloys.

Manuscript received May 2, 1962. This paper was prepared for delivery at the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Darkening Speed Tests with Reversible Electroplating Shutters

S. Zaromb[1] and J. Y. Chang[2]

Philco Scientific Laboratory, Blue Bell, Pennsylvania

ABSTRACT

The design and construction of experimental reversible electroplating light shutters are described, and their preliminary evaluation by means of resistance measurements is outlined. Oscilloscope traces of simultaneous light transmission changes and plating pulses are presented and interpreted. An observed better-than-expected darkening efficiency may be attributed either to an anomalously high absorption coefficient of the very thin Ag films deposited by an unusually fast plating procedure or to increased turbidity and/or increased multiple light reflections. The maximum achieved plating speeds corresponded to average current densities of up to 80 amp/cm^2 for 250 to 400 μsec over an area of up to 16 cm^2. No damage in the tin oxide coating was observed after more than 13 such pulses with a plating solution of 3M AgI plus 8M NaI at a neutral *p*H. The maximum plating speeds expected from first order estimates of diffusion rate limitations were approached in five tests.

Preliminary experiments (1) with a Reversible Electroplating Light Modulator (RELM) of small area (0.2 cm^2) showed excellent resistance of transparent tin oxide-coated glass electrodes in alkaline AgI-NaI solutions to numerous plating-deplating cycles and fair general agreement with theory (2). The present work was aimed at demonstrating the feasibility of a RELM of increased area and plating speed. Furthermore, the experimental conditions used were much more drastic, the cells being subjected to high voltage and current pulses ($\simeq$200v and $\simeq$1000 amp), and the electrolyte being not strongly alkaline but rather acidic or neutral, and, therefore, more likely to damage the conductive tin oxide coating via formation of nascent hydrogen.

Shutter Design, Construction, and Evaluation

The shutter design was based on arrangement 6 of Fig. 2 of ref. (2) consisting of parallel (nonalternating) electrical connections between line-symmetric subelements of width *b* ($\simeq$0.3 cm). The contacts to each subelement were made by sawing parallel, narrow grooves (approximately 0.03 cm wide and 0.15 cm deep) in flat lime-glass plates, with a distance 2*b* between adjacent grooves, applying a conductive tin oxide coating over the entire grooved surface, and introducing Ag paint and Cu leads into the grooves so as to form good electrical contacts between the leads and the conductive coating within the grooves, as shown in Fig. 1. A protective insulating layer of Kimble CV 137 solder glass was formed in the upper half of the grooves by repeated filling with the solder glass frit, heating to 425°C at a rate of 10°C/min, sintering for 1 hr at 425°C, and cooling at a rate of 5°C/min. In order to allow for differ-

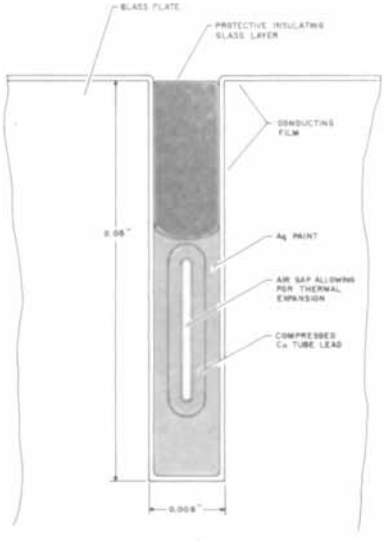

Fig. 1. Schematic cross-sectional drawing of groove, contacting lead, and protective layer.

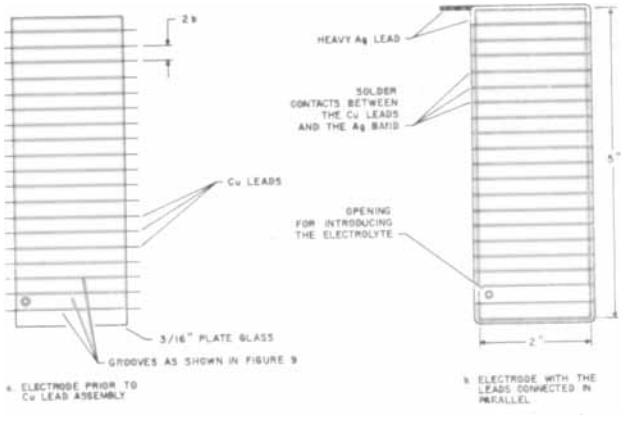

Fig. 2. Construction of the transparent electrodes

ential thermal expansion during the sintering process, the Cu leads were made of Cu tubing, 0.04 cm OD and 0.005 cm wall thickness, compressed into ribbons 0.012 cm thick and 0.05 cm wide so as to leave the narrow air hole shown in Fig. 1. The parallel connection of the Cu leads to a heavy Ag

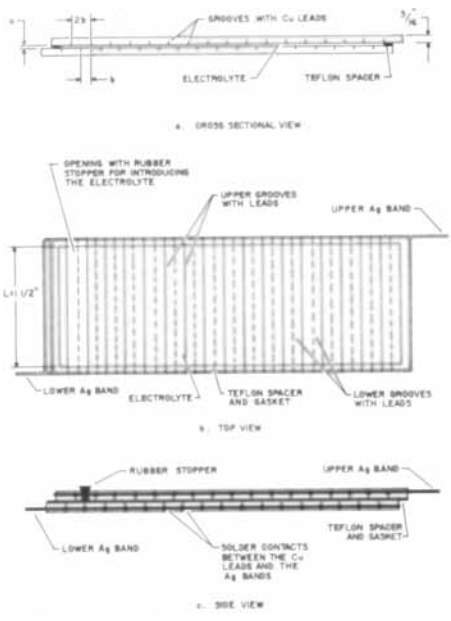

Fig. 3. Assembled reversible electroplating light shutter

band surrounding each plate is shown in Fig. 2. The dimensions of Fig. 2 correspond to those of the original plating cell design of Fig. 3. However, most of the actual plating cells used in the present experiments had a smaller shutter area, as listed in Tables I and II.

For maximum plating speeds, a low cell resistance was desired. Hence, special efforts were made during the tin oxide coating step to render the glass surface as highly conducting as possible. The grooved glass plates were cleaned with laboratory detergent (Alconox or Calgonite), rinsed with alcohol, air dried, etched for at least 1 min in a solution of 1.5:3:0.9 volume ratio of concentrated HF, H_2SO_4, and H_2O, rinsed with distilled water, placed on graphite holders, and preheated in a muffle furnace to 650°C. Holders and plates were then placed in front of several hot propane burners within a firebrick enclosure arranged so as to yield fairly uniform and intense heating of the entire glass plate and

holder. Dull-red heat, corresponding to the softening temperature of the glass, was reached within 10 to 20 min, at which time a fine spray of $SnCl_4$ solution was immediately directed at the grooved glass surface.

The spraying solution was made up by slowly adding anhydrous $SnCl_4$ to a solution of 100g $SnCl_4 \cdot 5H_2O$ in 50g distilled water plus 10g concentrated HCl and 1.0 or 1.5g $SbCl_3$ until a slight supersaturation was observed, and then adding a tenth part of the same solution to render the solution slightly undersaturated. The spray gun was constructed entirely of Pyrex glass. The spray was triggered by the passage of compressed O_2 through a gas inlet tube. The spray nozzle was held at a distance of 10 cm from the glass plate and the spray applied for 10- to 15-sec periods with a continuous horizontal and/or vertical motion of the nozzle aimed at obtaining a uniformly conductive coating. After allowing a few minutes for the glass to regain its softening temperature, the spraying was resumed; this was repeated 4-10 times depending on the desired conductivity and light transmission. The plates were then placed in an annealing furnace and allowed to cool slowly (in >2 hr) to room temperature.

Although the resistivity of the glass on the flat plate surface could readily be brought down to 5 ohms/sq by the above procedure, the resistivity inside the grooves usually tended to be much higher, especially when the groove widths were less than 0.025 cm. With grooves 0.03 cm wide, a satisfactory groove surface resistivity of approximately 20 ohms/sq was obtained in the best plates.

The average resistivity in the grooves was estimated in the following way: Let r be the ratio of the surface resistivities ρ_G and ρ_g of the conductive film inside and outside the grooves, respectively,

$$r = \rho_G/\rho_g \quad [1]$$

n_g the number of grooves or conductive strips between grooves, w_g and w_G the respective perimeters of a strip and groove cross section, and l_g the length of each groove or strip. Then the resistances R_{gl} and R_{Gl} between the long edges of each strip and groove, respectively, are

$$R_{gl} = \rho_g w_g/l_g \quad [2]$$

and

$$R_{Gl} = \rho_G w_G/l_g \quad [3]$$

whereas the respective resistances R_{gs} and R_{Gs} between the shorter edges are

$$R_{gs} = \rho_g l_g/w_g \quad [4]$$

and

$$R_{Gs} = \rho_G l_g/w_G \quad [5]$$

The total series resistance R_l between n_g alternating resistors $(R_{gl} + R_{Gl})$ is

$$R_l = n_g (R_{gl} + R_{Gl}) = (\rho_g w_g + \rho_G w_G)\, n_g/l_g \quad [6]$$

whereas the total conductance $(1/R_s)$ of n_g conductors $(1/R_{gs} + 1/R_{Gs})$ connected in parallel is

$$1/R_s = (n_g/R_{gs}) + (n_g/R_{Gs}) = \frac{n_g}{l_g}\left(\frac{w_g}{\rho_g} + \frac{w_G}{\rho_G}\right) \quad [7]$$

The ratio

$$\frac{R_l}{R_s} = \frac{n_g^2}{l_g^2}\,\frac{(\rho_g w_g + \rho_G w_G)(\rho_G w_g + \rho_g w_G)}{\rho_g \rho_G} \quad [8]$$

was measured readily by clamping two parallel soft-copper contacting strips first along the shorter and then along the longer edges of each conductive plate. Setting $w_G \simeq 2 \times 0.15$ cm $= 0.3$ cm and $w_g = 2b = 0.6$ cm one obtains

$$R_l/R_s \simeq n_g^2 w_g^2 (1 + 0.5r)(r + 0.5)/r l_g^2$$
$$\simeq w^2(1 + 0.5r)(r + 0.5)/l_g^2 r \quad \text{for } b \simeq 0.3 \text{ cm} \quad [9]$$

where

$$w \cong n_g w_g \quad [10]$$

is the total length (or width of the plate along the direction perpendicular to the grooves. The values of R_l/R_s corresponding to various resistivity ratios r were tabulated for $w^2/l_g^2 = 1$ (square plates). Multiplication of the actually measured ratios R_l/R_s by the dimensional correction factor l_g^2/w^2 and comparison with the tabulated values gave a direct estimate of r. Furthermore, since usually $w_g/\rho_g >> w_G/\rho_G$, the value of R_s gave an approximate estimate of ρ_g

$$\rho_g \simeq l_g R_s/w \quad [7']$$

As seen from Fig. 1, the contact resistance r_c between a Cu lead and the conductive film layer near the top of the groove may be written as

$$r_c = r_{Ag} + r_{tg} \quad [11]$$

where r_{Ag} is the resistance of the Ag paint layer and r_{tg} is that of the conductive film in the upper half

of the groove. If ρ_G is the surface resistivity of the latter film, then

$$r_{tg} \simeq \rho_G \times (0.05 \text{ cm}/5 \text{ cm}) \simeq 0.01\, \rho_G \quad [12]$$

where the factor 0.05 cm/5 cm corresponds to the approximate width and length of the top half groove wall. Considering that the resistance of each subelement must be at least

$$\rho_g b/2L \simeq 0.04\, \rho_g \quad [13]$$

where L ($\simeq$4 cm) is the length of each subelement (cf. Eq. [13'] of ref. (2)), and that there are two contacts per subelement [cf. Fig. 3], then the total resistance due to the r_{tg} component would be less than ½ of the theoretical cell resistance given by Eq. [24'] of ref. (2), if ρ_G were not larger than ρ_g. On the other hand, the r_{Ag} component should be negligible if no serious cracks, air gaps, or other sources of spurious resistance are present between the Cu lead, the Ag paint, and the conductive film at the lower half of the groove surface. Furthermore, the resistance of a Cu lead 2 cm long and 500 x 10^{-6} cm^2 in cross section is less than 0.01 ohm which is negligible, *i.e.*, less than 10% of $\rho_g\, b/2L$. Hence, according to the design of Fig. 1, the total resistance due to contacts would be nearly half the minimum theoretical cell resistance.

With the Cu leads and Ag paint imbedded in the lower part of the groove, the resistance R_{Cu} between two neighboring Cu leads was

$$\begin{aligned} R_{Cu} &= 2r_c + R_{gl} \\ &\simeq 2r_{tg} + \rho_g w_g/l_g \\ &\simeq 0.02\, \rho_G + 0.12\, \rho_g \text{ for } b \simeq 0.3 \text{ cm} \end{aligned} \quad [14]$$

Thus, for $b \simeq 0.3$ cm, $\rho_g \simeq 5$ ohms/sq, and $\rho_G = 20$ ohms/sq, one obtains $R_{Cu} \simeq 1.0$ ohm. The actual values of R_{Cu} measured in most of the plates subsequently found to be unsatisfactory were usually higher than 1.0 ohm. On the other hand, those plates which yielded the best experimental cells actually showed R_{Cu} values of 0.4-0.9 ohm suggesting higher conductivities or values of ρ_G even lower than 20 ohms/sq in the upper parts of the grooves.

The cells were assembled as shown in Fig. 3 and filled with an aqueous solution of 3M AgI plus 8M NaI and pH values ranging from 3 to 9 (usually approximately 8), in accordance with the recommendations of ref. (2).

These cells could be partly evaluated even without actual plating experiments by simply comparing their resistances with the theoretical values predicted by Eq. [24'] of ref. (2)

$$R_p \simeq (a\rho_e + 0.5\, \rho_g b^2)/A \quad [15]$$

Setting $\rho_e \simeq 10$ ohm-cm, $a \simeq 0.05$ cm (a rather high value usually necessitated by the warping of the plates), $\rho_g \simeq 6$ ohms/sq, $b \simeq 0.3$ cm, and $A \simeq 16$ cm^2, one would expect $R_p \simeq 0.05$ ohm.

The cell resistances were measured by the Cahan-Rüetschi square wave pulse method (3). The 100-kc square wave calibrator output V_s (50 or 100v) of a Tektronix 535 oscilloscope was connected to a series circuit comprising a 10 μfd condenser, a large current determining resistance $R_{c.d.}$ (10,000 ohms or 100,000 ohms), and the plating cell. The amplitude i_s of the square wave current pulse through the plating cell was then approximately

$$i_s \simeq V_s/R_{c.d.} \quad [16]$$

i.e., 1-10 ma, and the plating cell resistance R_p was given by the instantaneous voltage changes ΔV_p across the cell at the beginning or end of each pulse

$$R_p \simeq \Delta V_p/i_s \simeq R_{c.d.}\, \Delta V_p/V_s \quad [17]$$

The cells listed in Tables I and II actually had areas A of 3-16 cm^2 and resistances of only 0.14-0.4 ohm, in tolerable agreement with the minimum theoretical values of approximately 0.05-0.25 ohm (cf. Eq. [15]). These cells also yielded the best results (highest measured plating speeds as given in Table I).

Measurement of Plating Current and Optical Density Changes

Several 525 μfd-450v electrolytic capacitors connected in parallel were charged to the desired voltage and then discharged rapidly through the plating cell and a 0.1-ohm precision series resistor upon closing of an EM-1 Hg plunger-type relay (manufactured by Ebert Electronics Corp., Queens Village, New York). The voltage across the 0.1-ohm resistor connected to one trace input of a Tektronix 502 oscilloscope gave the instantaneous current through the plating cell (cf. Fig. 4). The second trace of the same oscilloscope showed the output of a photomultiplier tube circuit measuring the light transmitted through the shutter. Both simultaneous traces were photographed with a Polaroid camera. The data for the best experimental cells are listed and interpreted in Table I and typical oscilloscope traces are shown in Fig. 5 under the same test numbers (in Roman numerals). In each graph, the time coordinate is horizontal, starting at the second line from the right and increasing from right to left, whereas the vertical coordinate refers either to the current or voltage, increasing upward, in those traces which show an initial maximum followed by a typical downward capacitor discharge curve (V-trace) or to the light transmission, decreasing upward, in curves showing a steady upward climb towards an asymptotic value on the left-hand side. In test V, the (upper) light transmission curve shows an initial maximum followed by a slow decrease due either to partial spontaneous clearing of the shutter

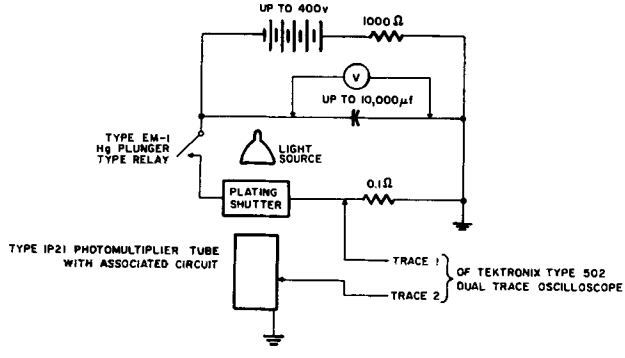

Fig. 4. Experimental arrangement for simultaneous measurements of plating current and optical density.

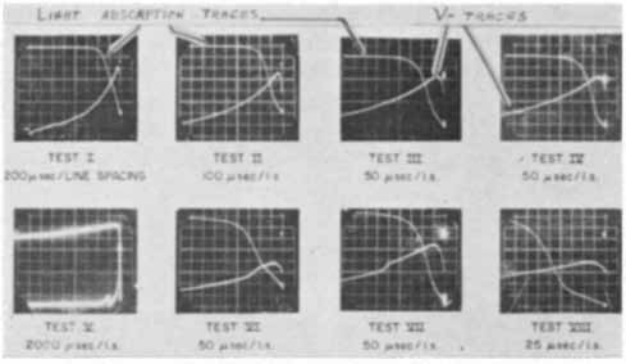

Fig. 5. Applied current pulses and light absorption changes in typical shutter closing experiments of less than 1000 μsec duration.

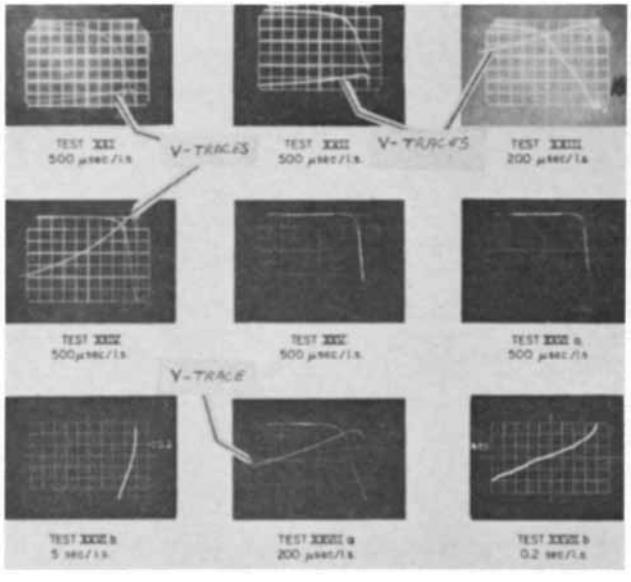

Fig. 6. Light absorption measurements of improved accuracy and, where indicated, current pulse shapes in shutter closing experiments of up to 10 μsec duration.

similar to that observed in tests XXVIb and XXVIIb of Fig. 6, or to a partial recovery of the photomultiplier circuit output from an initial "overshoot." The upper bright spots (near the second vertical line from the right and between the second and fourth lines from the top) mark the steady state output of the photomultiplier circuit when the light source was turned off. Hence, the asymptotes of the light transmission curves should all be located below the level of these upper bright spots. The actual upward displacement of the asymptotes was attributed at first to absorption of stray light upon closing the shutter, but was finally traced to an actual transient overshooting by the photomultiplier circuit. Because of this defect and partly also because of the inaccuracy of the ordinate scale, light absorption values of more than 90% (or optical densities exceeding 1.0) are unfortunately uncertain in the tests of Table I and Fig. 5. However, the times τ_1 corresponding to an optical density change δ of at least 1.0 could still be estimated from these curves and are listed in the tenth column of Table I. Comparison of the time values in columns 8, 9, and 10 shows a close parallelism and near equality of τ_1 and the time constant of the capacitor discharge circuit. The higher values of column 8 are probably due to nonlinear resistances in the circuit arising from a breakdown of spurious resistances under a high voltage. Because of the spurious and nonlinear circuit resistances, the current and voltage traces are also subject to uncertainties. Hence, the actual charge Q_1 passed through the cell up to the time τ_1 was estimated by means of the relation

$$Q_1/Q = 1 - e^{-\tau_1/\tau_c} \qquad [18]$$

where Q is the total capacitor charge (column 11) deduced from the product CV of columns 6 and 7, and τ_c is the time constant of column 9. Division of Q by the area A of column 3 yielded the total charge density q_d of column 12, and multiplication of q_d by the Q_1/Q ratio (column 14) yielded the charge density q_{d1} passed up to the time τ_1.

According to Fig. 1 of ref. (2), the actual optical density change δ_1 corresponding to a charge density q_{d1} should be

$$\delta_1 = 38q_{d1} \qquad [19]$$

and similarly, for δ corresponding to 100% capacitor discharge

$$\delta \simeq 38q_d \qquad [19']$$

The calculated values of δ_1 (column 16) are usually less than the estimated actual value of at least 1.0. This may be due either to a higher actual absorption coefficient of the very thin films produced by the rapid plating process, or to marked local refractive index changes giving rise to increased reflections and increased turbidity.

The last column $(\tau_1)_{min}$ gives the minimum values of τ_1 allowed according to Eq. [33] of ref. (2)

$$(\tau_1)_{min} \simeq 5 \times 10^{-6} q_d^2/c_p^2 \simeq 0.5 q_{d1}^2 \qquad [20]$$

the concentration c_p of platable ions being 0.003 mole/cc. Comparison of columns 10 and 17 shows that $(\tau_1)_{min}$ was barely approached only in tests V, VII,VIII, XII, and XIII, and was exceeded by a factor of 2-10 in all the other tests. Since the actual speed limitations in all these tests were due to circuit RC time constants rather than to electrochemical limiting factors, the results of Table I do not give any indication of the actual applicability of Eq. [33] of ref. (2), but they do at least suggest the absence of any more severe intrinsic speed limitation.

To check the accuracy of the τ_1 and q_{d1} values of Table I, measurements were made with a corrected photomultiplier tube circuit and more sensitive scales obtained with a Tektronix 535 oscilloscope and a type Z differential pre-amplifier. The data and interpretation are given in Table II and typical traces shown in Fig. 6. In tests XVIII, XIX, XXV, XXVI, XXVIII, and XXIX, the V-trace (current or voltage-time curve) was not recorded. Tests XXVIb and XXVIIb in Fig. 6 are simultaneous recordings of the same photomultiplier outputs as in the respective tests XXVIa and XXVIIa, but on more compressed time scales and a more sensitive (expanded) vertical (light transmission) scale. The downward slope in test XXVIb and XXVIIb shows the slow partial clearing in the absence of a continuous plating current following the initial charge pulse.

The time constants and τ_1 values in Table II are usually much longer than those in Table I due to

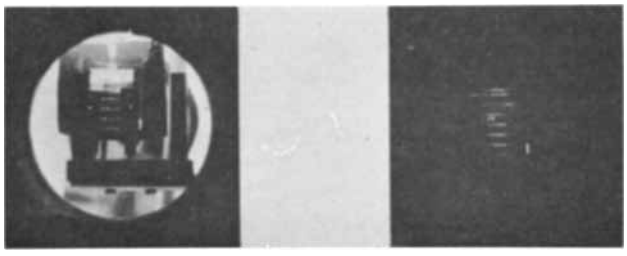

Fig. 7. Photographs of irregular incandescent lines resulting from a nonuniform distribution of high current pulses through an unsatisfactory plating cell.

breakage of the best experimental cells by the time the photomultiplier circuit was improved. However, the q_{d1} and $(\delta_1)_{calc.}$ values of Table II (columns 15 and 16) are usually comparable with, and thereby indirectly confirming, those of Table I. The unusually high value of $(\delta_1)_{calc.}$ in test XX is probably due to a nonuniformity of plating in the area directly in front of the photomultiplier tube.

As mentioned above, the cells used in tests XVIII through XXIX were generally poorer and less uniform than the earlier cells. Attempts to increase their plating speed by reducing the number of capacitors and charging to higher voltages invariably resulted in an incandescence of the grooves (cf. Fig. 7) probably due to an excessive value of ρ_G and associated I^2R power dissipation in the conductive film in the groove walls. Furthermore, a nonuniform current distribution could result in permanently damaged spots in the conductive film adjacent to the electrolyte in areas where the current densities were at a maximum. Since any such damage would tend to enhance subsequent plating nonuniformities, a single passage of an excessive current pulse would usually be followed by incandescence and further deterioration even with lower (previously acceptable) current pulses. These effects were especially serious in the larger area cells ($A \simeq 40$ cm^2) not listed in Table I and II.

In view of the extreme sensitivity of parallel circuits to imbalance under very high loads, it is almost surprising that the relatively high plating speeds of Table I could have been obtained. The average currents and current densities in tests VII, VIII, XII, and XIII correspond to between 1000 and 1300 amp and 70-80 amp/cm^2 for 250 to 400 μsec over a relatively large area of 15-16 cm^2. It should be noted that tests II through XIV were all performed with the same pair of matched plates, and that no damage due to the high current pulses was observed in these plates.

However, even these best plates had the serious shortcomings of (*a*) relatively poor light transmissivity (40-60%), resulting in an over-all light transmission of only 20% for the assembled cell; and (*b*) excessive warping, necessitating cell spacings of 0.04-0.09 cm, *i.e.*, 4-9 times the original design value of 0.01 cm.

Rate of Unplating

The time required for clearing of the light shutter was highly irreproducible and could vary from less than 10 sec to more than 5 min depending on cell structure. Since the gap widths a in most of the cells studied were 4-10 times larger than the design value

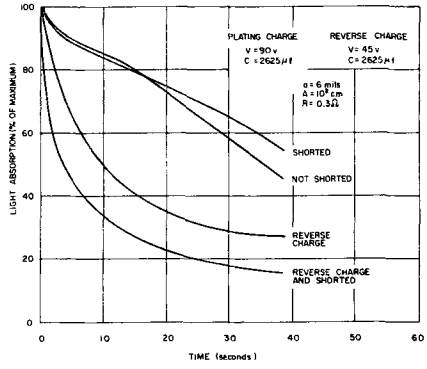

Fig. 8. Effect of a reverse charge pulse and/or shorting the cell terminals on the rate of clearing of a 6-mil gap width light shutter.

of 0.01 cm (required to revert to 78% of the original transmission in 1 sec or 90% in 3 sec), and since the clearing time is proportional to a^2, one would indeed expect the observed "clearing times" to range from 16 to 300 sec in cases where the proper reverse charge has been applied, and about fourfold longer "clearing times" without the reverse charge, in agreement with the actual observations. However, in addition to the effect of the spacing a, the following factors may further reduce the clearing rate: (*A*) Any loss of the oxidizing component (I_3^- or IO_3^-) via a reaction with the insulating material or with the metal leads would result in incomplete clearing. Hence, faulty insulation may be partly responsible for some observed irreproducibilities. (*B*) In cases where reversed charge pulses were applied, current density nonuniformities different in two pulse directions may produce an excess of Ag in some areas and of I_2 in others. Since the motion of I_3^- ions in directions parallel to the electrodes is extremely slow (considering the low a/L and a/w ratios), such areas of excess Ag and excess I_2 may remain dark for a very long time.

These last two factors may explain the type of discrepancy shown in Fig. 8. The nominal gap width a being only 0.015 cm, one would expect a return to 78% of the original transmission in 2 sec rather than the 20 sec shown by the lowest curve. However, the actual gap width in the cell must have fluctuated by at least ±50%, each of the two plates having a surface uneveness of about 0.01 cm. Hence, a reverse charge pulse was likely to result in separate areas of excess Ag and excess I_2. Shorting the cell terminals following the reverse charge pulse would then be expected to accelerate the rate of clearing of the Ag and I_2 spots via a type of battery discharge mechanism, as shown by the lower two curves of Fig. 8, whereas no marked effect resulted from shorting when a reverse charge had not been applied, as shown by the upper two curves.

Summarizing, then, the observed rate of deplating usually agreed in first order of magnitude with theoretical expectations. Occasional cases of irreproducibility or of marked discrepancy appear attributable to faulty cell structures.

Conclusions

The experimental results are usually in fair agreement with theory. Discrepancies in rate of unplating are obviously related to the following main devia-

tions from the design prescriptions of ref. (2): (*a*) uneven spacing between the electrodes; and (*b*) nonuniform electrode surface resistivities and the presence of spurious resistances in the contacts to the individual subelements.

These deviations were also responsible for: (*a*) the nonuniformities in plating density observed with unsatisfactory cells; (*b*) circuit imbalances associated with these nonuniformities, resulting in overloading of some of the parallel subelements; and (c) irreparable damage of the overloaded subelements or of the contacts due to excessive local I^2R heat generation on passage of excessive current pulses.

With satisfactory cells having negligible spurious contact resistances, the tin oxide coating was able to withstand average current densities as high as 80 amp/cm^2 for 250 to 400 μsec over an area of up to 16 cm^2 in solutions of neutral pH. No damage in the coating was observed even after more than 13 such high current pulses. The maximum plating speed expected on the basis of a first order estimate of diffusion rate limitations (Eq. [33] of ref. (2)) were approached but not exceeded in five of the tests listed in Table I. Since the plating speed in all these tests was limited by the RC time constant of the circuit used, no conclusion can be drawn as to the actual importance of diffusion limited mechanisms.

Optical density changes of 1.0 or higher were obtained with an average charge density q_{av} of 0.016 coul/cm^2 (in tests of both Tables I and II), *i.e.*, 60-70% of the charge density calculated on the basis of the absorption constant of thick Ag layers. This better-than-expected darkening efficiency may be due either to variation of absorption constant with film thickness and method of formation (possibly related to defect and impurity concentration in the film), or to increased turbidity and/or multiple light reflections. A more thorough investigation of these results should have an important bearing both on the optimization of the performance of the light shutter and on the understanding of the effect of growth parameters on the properties of very thin films.

Magnetic Electrodeposits of Cobalt-Phosphorus

J. S. Sallo and J. M. Carr

Research Center, Minneapolis-Honeywell Regulator Company, Hopkins, Minnesota

ABSTRACT

Means of preparing Co-P electrodeposits having a wide range of magnetic properties are discussed. X-ray diffraction data, electron micrographs, and Bitter patterns are presented. An explanation of the origin of the high coercivity is presented. Low flux density of the material is described, and a possible explanation is presented.

For many years there has been interest in magnetic electrodeposits having high coercivity for use in serial storage devices. Most of the electrodeposits used for this purpose have been Co-Ni alloys. These materials usually have coercivities of 200-300 oe, although recently a Co-Ni alloy having a coercive force of 500 oe has been reported (1). A coercive force of 810 oe has been previously reported from a Co-Ni-P system (2). This system has been shown to consist of clusters of small single domain platelets, thus explaining the high coercive force (3).

The Co-Ni-P material is prepared from a system containing hypophosphite ion. Since the total products of the electrolysis exceed a 100% cathode efficiency, the original workers (2) concluded that the material is formed through a combination of chemical (electroless) deposition and electrodeposition. Since the system operates at a pH of about 4, and since chemical deposition of cobalt does not take place from acid systems, it can be concluded that the nickel is essential for the occurrence of chemical deposition and that removal of the nickel ion from the system will eliminate the phosphorus from the deposit. Despite these conclusions, Co-P deposits are formed from such a system, and modifications of this system lead to a series of deposits having a wide range of magnetic properties. Figure 1 shows the effect of removing the nickel from the Co-Ni-P system. The mechanism by which these deposits are formed is not fully understood.

Experimental

The electrodeposition was done on flat 0.003 in. Be-Cu or phosphor bronze foil. Temperature control was provided by a "Glascol" heating mantle surrounding a 1-l beaker which served as a plating chamber. A d-c power supply was used as a current source. The standard system was a 1-l bath containing 100 g/l

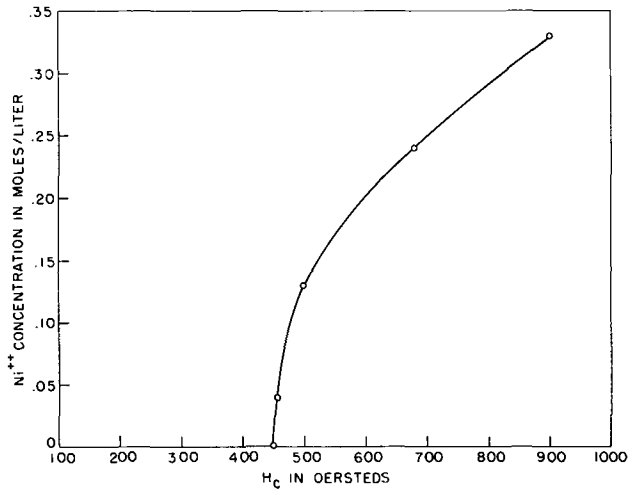

Fig. 1. Nickel ion concentrations vs. Hc of deposit in oersteds

$CoCl_2 \cdot 6H_2O$, 100 g/l NH_4Cl, and 15 g/l $NaH_2PO_2 \cdot H_2O$ at 50°C and operated at 60 amp/ft². This system produces a deposit having a coercive force of about 400 oe. Other coercivities are obtained by varying the concentration of bath constituents and the plating parameters of the system such as current density, temperature, and pH.

The phosphorous analysis was done with a "Spectronic 20" Colorimeter by the molybdovanadophosphoric acid method. The ethylenediamine tetraacetic acid (EDTA) titration method was used to determine cobalt with dithizone as indicator.

Magnetic measurements were obtained with a conventional 60-cycle hysteresis loop tester (4). Direct current measurements were obtained by the "moving coil method" by use of a ballistic galvanometer and a 6 in. Varian Magnet capable of producing fields of 10,000 gauss.

Electron microscopy was performed using an RCA model EMU3 by conventional collodian replication techniques using carbon shadowing and by the Craik technique (5) with an extension of this technique (3).

X-ray diffraction studies were performed using a North American Philips Norelco with a wide angle automatic Diffractometer.

All chemicals were reagent grade and were used without further purification. All solutions were prepared using distilled water.

Results

Under suitable conditions the coercive force of these deposits can be varied from 50 oe to 1300 oe. Under certain conditions a stepped hysteresis loop can be obtained.

The 400-oe material obtained from this system has shown good capabilities as a high density storage media. Results obtained from a conventional fixed head drum system show the deposit to have a packing density capability of about twice that of conventional magnetic oxide. Recording data will be published at a later date.

The coercive force of these materials is dependent on the crystal orientation of the deposit which, in turn, is dependent on the plating parameters of the system. The 50-oe coercivity material exhibits an uncertain crystal orientation and some samples appear to be amorphous. The 400-oe material has the 110 plane parallel to the substrate. The 1300-oe material has the 002 plane strongly orientated in the plane of the deposit. The nature of the latter material is described elsewhere (6).

The 60-cycle hysteresis loop of the deposit at all coercivities within the test range (50-2000 oe) shows a squareness (Br/Bm) of about 0.5. Remanence values are about 5500 gauss for a 400-oe deposit; however, full saturation may not have been attained. The properties are independent of the thickness of the deposit over the range studied (1-30μ).

The magnetic properties of the deposit are not dependent on an epitaxial growth from the substrate. Although most test samples were prepared on 0.003 in. Be-Cu and phosphor bronze foils, any substrate may be used which is used in normal electrodeposition techniques. The deposit may be plated on aluminum through use of the zincate method or by using electroless nickel-clad aluminum. Plastics can also be used as the substrate after being made conductive by one of the conventional techniques. In either of these cases, the magnetic properties are equivalent to those obtained on a copper based substrate.

The most significant factor influencing the coercive force of the deposited material is the pH of the system. A pH of 2 or less yields a deposit having a coercive force of about 50 oe. At pH of 3-4.5 a deposit having a coercivity of 400 oe is obtained. Increasing the pH to the precipitation point of the system, about 4.7, produces a deposit whose coercive force is 800 oe or higher. In all cases studied, the phosphorous content of the deposit remained in the range of 2-3%.

The concentrations of the bath constituents also have an effect on the coercive force of the deposit. Figure 2 shows the effect of varying the $CoCl_2$, NH_4Cl, and NaH_2PO_2 concentrations. Excluding the hypophosphite from the system produces an unsound deposit having a coercive force of about 100 oe. Replacing the ammonium ion with sodium ion also produces an unsound deposit. Small amounts of common impurities with the exception of iron have

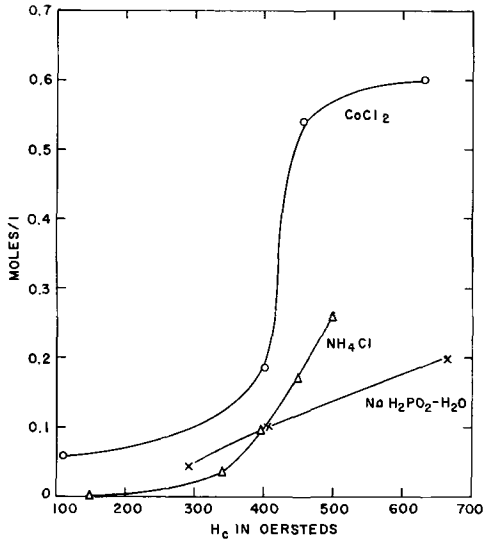

Fig. 2. Concentrations of Co^{++}, NH_4^+, $H_2PO_2^-$, vs Hc of deposit in oersteds.

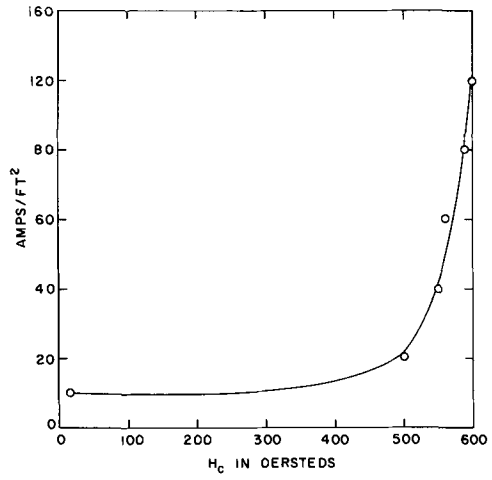

Fig. 3. Current density vs. Hc of deposit in oersteds

little or no effect on the deposit. Relatively large quantities of phosphite do not alter the properties of the deposit. Figure 3 shows the effect of varying the current density. The maximum coercivity obtainable by increasing the current is about 600 oe. In a still system current densities above 120 amp/ft^2 give an unsound deposit. As the temperature of the system is increased, the coercive force of the deposit increases. The highest coercive force deposit is obtained at 65°C. Further increases in temperature result in a decrease in the coercive force of the deposit until the deposit becomes unsound at a temperature of about 95°C.

When an inert anode is used, a rapid decrease in *p*H occurs. This leads to a change in the magnetic properties of the deposit as discussed previously. Replacement of the inert anode with a soluble cobalt anode minimizes the decrease in *p*H and results in a very stable system. By using the soluble cobalt anode and making periodic additions of hypophosphite, plating of a particular coercive force deposit can be continued almost indefinitely without an appreciable change in the *p*H of the system or the magnetic properties of the deposit.

Discusssion

The coercivity of these Co-P deposits is high enough to suggest single domain particle behavior. A very similar situation has been studied previously for Co-Ni-P electrodeposits (3). Figure 4a is an electron micrograph showing the platelet like structure of the Co-P deposit which is similar to the Co-Ni-P electrodeposit. These platelets differ from the Co-Ni-P platelets. They appear to be larger in the smallest dimension. The larger size of the platelet may explain the lower coercive force observed in the Co-P system. Figure 4b is an electron micrograph of the Co-P platelets in the demagnetized state with the use of the modified Craik techniques. The collection of magnetite shows flux leaving the plane of the film at cluster boundaries. The same technique applied to a magnetized sample shows no magnetite pattern.

These results can best be explained by use of Fig. 5. Each set of vectors represents a cluster of single domain platelets with the boundary between them

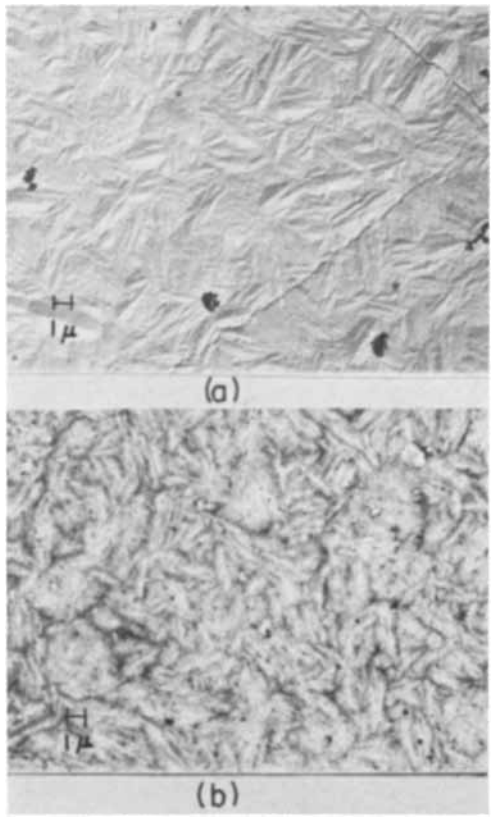

Fig. 4a. Electron micrograph of surface of Co-P deposit; magnification 3000X. Fig. 4b. Bitter pattern of demagnetized surface of Co-P deposit (Craik technique); magnification 3000X.

considered a cluster boundary. In the demagnetized state (a) each platelet has its magnetic vector at 180° to the platelet adjacent to it. Since all of these vectors are in the plane of the deposit (the uniaxial easy direction) there are no fields out of the plane of the film and no magnetite is collected within the

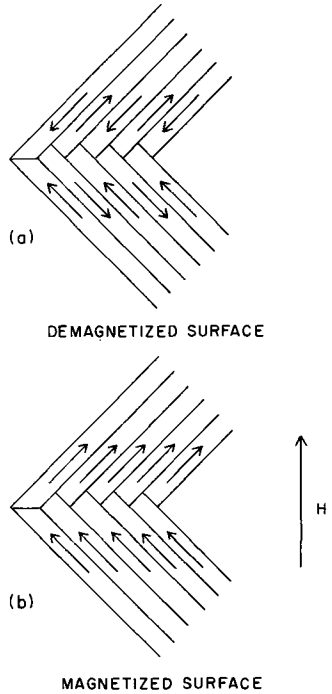

Fig. 5. Representation of flux state in (a) demagnetized state and (b) magnetized state.

clusters. At cluster boundaries each platelet may attempt to obtain closure with itself, with an adjacent platelet, or with a similarly oriented platelet in a neighboring cluster. Closure cannot be entirely between adjacent platelets as mismatching of the magnetic polarity of the platelets must occur to some extent. Self closure or closure between adjacent platelets will lead to some flux leaving the plane of the film at cluster boundaries particularly since the neighboring cluster may be attempting closure in the same area. This closure flux explains the magnetite pattern shown in Fig. 4b.

In the case of a magnetized sample, as shown in Fig. 5b, the platelets within the cluster have parallel magnetic vectors. In the remanent state of the material, all magnetic vectors will return to the easy direction of magnetization. Even so, each cluster has a component of magnetization in the direction of the previously applied field. Closure at cluster boundaries can take place between neighboring clusters and in the plane of the film, since mismatching of the magnetic polarities of the platelets cannot occur.

Smaller flux outputs were obtained from both the Co-Ni-P and Co-P deposits than would be expected from the chemical composition. A possible explanation for this is that the metal in the deposit is in the form of the phosphide. A lower saturation magnetization value is obtained for the Co-P deposit than for the Co-Ni-P. This is contrary to the expected value as cobalt has a much higher saturation magnetization value than nickel. This may be explained by assuming Ni to be in the form of the phosphide in the Co-Ni-P deposit and cobalt in the form of the phosphide in the Co-P deposit. Further studies of the saturation magnetization may reveal the nature of the phosphides in this type of deposit.

Conclusions

The magnetic properties of cobalt phosphorous electrodeposits have been determined. An extremely wide range of magnetic properties are available in this system. Studies of the crystalline structure of the deposit are presented along with an interpretation of the origin of the coercivity. Possible applications exist for this material in the field of hard magnetic materials. High density magnetic storage capabilities seem to exist.

Electroluminescent Lines in ZnS Powder Particles

I. Embedding Media and Basic Observations

Albrecht G. Fischer

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Several new embedding media of the same refractive index as ZnS are described which make possible the microscopic examination of the interior of electroluminescent particles taken from efficient industrial lots. Light is emitted in form of lines or striations extending through most of the diameter of the particles. The brightness of single lines has been measured in dependence of applied voltage, frequency, phase, and position along the line. Evidence is presented that the EL lines are associated with invisible copper-sulfide-decorated, conducting imperfection lines of submicroscopic diameter, and that coarse, visible imperfections are not the cause of EL.

Most studies of the electroluminescence (EL) of ZnS-type powders have been carried out on macroscopic cells containing a great number of particles. The study of the individual light-emitting elements in single particles, which alone can give reliable clues as for the acting mechanism, is difficult, and hence little has been done. There are several reports (1-3) that light emission takes place at the surfaces or tips of the particles or at contacts between grains. Due to the high refractive index of the irregularly shaped ZnS particles such observations are quite unreliable because of possible deceptions by multiply-reflected light.

To evade these difficulties, several authors have studied the EL of single crystals grown by sublimation. Light emission exclusively in front of the cathode (4, 5), or light emission in the bulk in the form of striations or dotted lines parallel to the field

(3, 6, 7) has been reported. Recently, and when the present work was already concluded (25), Gillson and Darnell (8) published results very similar to those to be reported here. They found light emission in the form of striations in insulatingly-embedded, small single crystals grown by sublimation from EL powder, similar to the method used by Zalm (3). Their crystals were embedded in a dark resin and had a ground and polished flat surface through which viewing of the interior without disturbance by scattered light was possible. In view of the importance of these findings for the theoretical interpretation of EL in ZnS powder, which may lead to improvements of brightness and efficiency, and since several different forms of EL are possible in ZnS so that conclusions by analogy may lead to errors, it is justified to confirm these results on particles taken from efficient industrial powders,[1] and to measure the properties of these striations.

Matched Embedding Media for EL Particles

If ZnS particles ($n = 2.37$) are immersed in the conventional immersion liquid with the highest refractive index, methylene iodide ($n = 1.75$), the Becke fringes (9) are so thick that microscopic observation reveals no details of the bulk. A mixture of sulfur, white phosphorus, and methylene iodide (10) of index 2.08, which was used for the same task by Lehmann (11), gives better but still unsatisfactory results and is unpleasant to handle. In a search for matched embedding media for ZnS, several new materials were found to be described in the following.

Sulfur-Selenium Glass and Cell Preparation Technique

A red-orange mixture of sulfur [26 w/o (weight per cent)] and selenium (74 w/o), which can be easily prepared by fusing the elements together in a test tube, matches the index of ZnS. Samples for optical observation can be prepared by melting a small piece of the S-Se glass on a microscope slide on a hot plate (180°C). The EL powder is mixed into the viscous liquid and squeezed as flat as possible under a cover slide. The cell is cooled to room temperature slowly to prevent peeling.

For the observations, a Leitz Panphot microscope with oil immersion objective was used, giving a total magnification of 1200.

The exact matching of refractive indices can be accomplished by using the method of disappearing Becke fringes, or the method of oblique illumination (9). Small amounts of S or Se have to be added to the main charge, melted, and mixed, and new test cells have to be prepared and checked under the microscope until the surfaces of the particles disappear completely. The crystallites can then be discerned only by the difference in color, provided the embedding layer is not much thicker than the particle diameter. It is advantageous to have a slight remaining mismatch so that the fringe of the largest diameter of the particle appears as a faint dark line. Any larger mismatch can lead to misinterpretations due to multiple scattering.

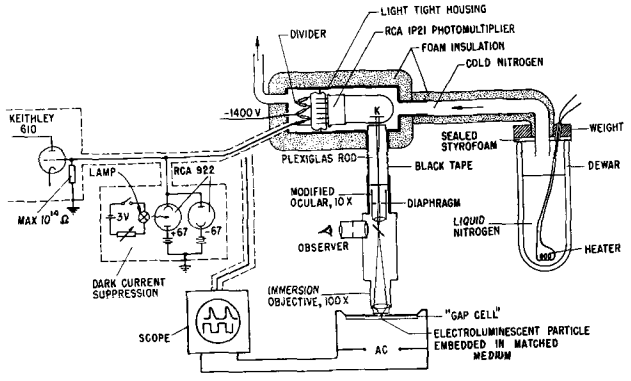

Fig. 1. Apparatus used to observe and measure EL lines. For most of the measurements, cooling of the photomultiplier is unnecessary. Vertical sensitivity of dual-sweep oscilloscope 50 mv/cm. Leitz Panphot microscope with immersion objective. Upper lens of ocular removed and replaced by adjustable diaphragm. Audiofrequency generator and amplifier not shown.

It is unfortunate that the findings of visual microscopic observations are difficult to document by photographs. Due to the shallow focal depth it is necessary to move the focus up and down through the volume of the particles to see all the details.

For the observation of EL emission, a "gap cell" has to be prepared, which consists of a microscope slide with an evaporated aluminum film. A gap of 1 mil width is produced by the shadow of a 1 mil wire strung across the slide under spring tension prior to evaporation. EL powder is mixed into the molten embedding medium, spread across the gap, squeezed as thin as possible with a cover slide, and cooled. In the center of the gap, the alternating electrical field is perpendicular to the optical axis. It is supplied by a generator giving up to 1000 v, 25 kc of a sinusoidal voltage. The experimental setup is indicated in Fig. 1.

The specific electrical resistance of this S-Se glass is in the order of 10^{14} ohm-cm. The optical absorption edge is at 6100Å. Observation of EL emission is only possible for orange-emitting phosphors like ZnS-Cu, Mn. Other ZnS-phosphors can be examined for imperfections with external illumination.

Thallium Bromide-Thallium Chloride Mixtures

For the examination of green and blue emitting phosphors, and in order to see inclusions which have a body color which is only slightly off white, an embedding medium with a wider transmission range is desirable.

It was found that a mixture of about 70/30 w/o TlBr-TlCl has the refractive index of ZnS. TlCl alone has an index of $n = 2.2$; TlBr has an index of $n = 2.4$. Both materials are white, of cubic crystal structure, and completely miscible as liquids and solids. In pure state their melts solidify without air inclusions, completely transparent in areas large enough for microscopical examination. The melting point of the mixture is about 450°C. At that temperature, chemical reactions between the EL powder and the TlBr-TlCl take place, resulting in a slight

[1] Gillson and Darnell (8) state that they were able to find powder particles with flat surfaces into which viewing was possible, and that they found the same results as in larger crystals. The author was unable to find such flat powder particles. In the work presented here, a more convenient method is described, as well as physical measurements on EL lines. An interpretation of the mechanism is presented which, though containing elements of former models, is different from previous theories.

discoloration. Nevertheless, the EL properties of the powder are preserved; only the photoluminescent response is quenched due to absorption of the exciting light.

Since the molten mixture etches away the evaporated metal film, it is difficult to prepare gap cells with this mixture. Iridium or platinum films have to be used. Conductive, transparent tin oxide coatings on glass also withstand the corrosive effect so that plate capacitor cells consisting of two conductive cover slides, with the electric field parallel to the optical axis, can be made.

Arsenic-Chalcogen-Halogen Glasses

It is known that molten arsenic sulfides solidify as yellow glasses of high refractive index. It was found that a mixture having a refractive index of 2.4 has a very high viscosity even at temperatures beyond 400°C. This glass is not very suitable.

In the older literature on highly refractive immersion media for mineralogical purposes (12) it is reported that arsenic tribromide (mp 28°C) can dissolve large amounts of arsenic sulfide. It was found that with increasing sulfide content the solutions become more viscous and finally solid at room temperature. Due to impurities in the chemicals, these glasses were dark brown, so that synthesis from spectroscopically pure elements had to be used. This can be accomplished by first melting arsenic and sulfur together in a test tube, and then adding small increments of liquid bromine until the desired refractive index has been reached. The synthesis is very simple and can be carried out in a chemical hood without difficulty. The mixture which matches ZnS has a composition of 33/30/37 w/o As, S, and Br, as determined by chemical analysis. The thermal expansion coefficient of this glass is similar to that of aluminum. The softening point is at 140°C; at 180°C the glass is liquid enough for cell preparation. The resistivity is 10^{13} ohm-cm, the dielectric constant is 7.5. The optical absorption edge is situated at 5000Å, and the glass is transparent in the infrared up to 13μ. The glass has excellent stability and imperviousness against moisture. This glass is the most suitable and convenient embedding medium for ZnS and was used in most of this work (13).

The existence of an extended range of arsenic-sulfur-iodine glasses has been recently reported; however no data on refractive indices and optical transmission were given (14). It was found that these glasses have a pink body color, with absorption edges around 5500Å. They can be made with indices higher than 2.4 which makes them suitable for red-emitting ZnS-CdS, ZnS-ZnSe-ZnTe, and GaP phosphors. The melting points of some of the mixtures are below 100°C. The resistance to moisture is poor.

Other glasses in this system, with absorption edges in the red and infrared and still higher refractive indices, are As-Se-Br and As-Se-I glasses. Glasses containing tellurium are p-type semiconductors (15). Glasses of this group are also of interest as optical cements to reduce reflection losses in combinations of EL and photoconducting crystals.

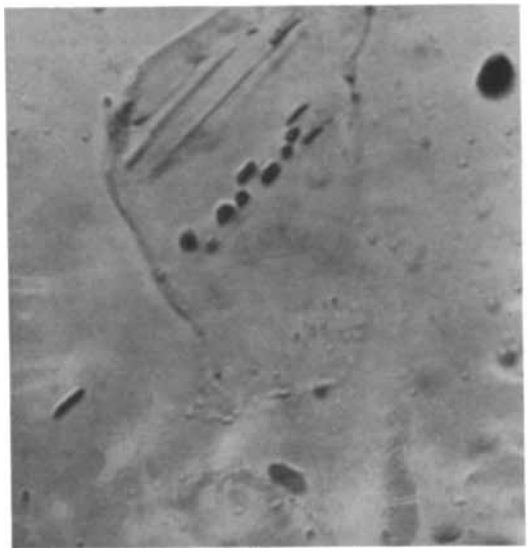

Fig. 2. Cavities in EL particles. The particle (about 15μ diameter) is embedded in matched As-Br-S glass. Illumination from below. The striations in the upper part are probably decorated imperfection lines.

It was ascertained that the inorganic polymers described above do not appreciably impair the EL properties of the powder. This was assured by dissolving the glass with methylene iodide or alkaline solution and comparing the recovered powder with fresh powder in castor oil cells.

Due to trapping of light in matched layers in the absence of scattering, the apparent brightness of ideally matched cells is only about 1/22 of that of unmatched cells.

Visual Microscopic Observations

In most of this work, green-emitting ZnS-Cu,Al phosphors of various United States manufacturers were used. It was ascertained, however, that halogen-coactivated and manganese-containing materials show the same features.

With external illumination the finding of Lehmann (11) was confirmed that EL particles contain numerous round spots (Fig. 2). It could be established that these "inclusions" are not filled with copper sulfide, as Lehmann assumed, but are voids which look black only because of their strong Becke fringes. The same spots, often in clusters of up to 10, occur in powders which were prepared like EL powders but without copper doping. Most probably these cavities are caused by rapid, disorderly growth in the presence of volatile flux. The presence of these coarse imperfections, which makes it likely that submicroscopic imperfections are also present in large numbers, seems to be a necessary (but not sufficient) condition for efficient EL, since all EL particles, active and inert ones from the same preparation, contain them, whereas particles of comparable size taken from commercial photoluminescent and cathodoluminescent powders show fewer voids.

It is most likely that the walls of these voids are coated with copper sulfide layers which are thin enough to be transparent. As is well known, EL phosphors have to be prepared with an excess of copper which precipitates at the surfaces during cooling. The following cyanide washing process re-

moves the precipitated excess copper sulfide from external surfaces, but does not reach the internal surfaces. Only if the EL powder is reheated in halogen-containing atmosphere (16) or in molten KCN (17) can the internally precipitated copper sulfide be removed, but then the EL properties are destroyed. The photo-and cathodoluminescence, which are due to dissolved copper, remain and change only their color due to secondary effects.

That such thin, conducting, and transparent copper sulfide layers can indeed exist was established by washing a large, polished wafer of melt-grown ZnS (18) in copper nitrate solution. After careful rinsing and drying, this crystal, which now looked yellowish, had a conducting surface layer with a square resistance of 500 ohms, which gave a p-type signal with thermoelectric probes. It could be easily removed with cyanide solution. The same treatment of the crystal with silver or gold solutions gave layers whose resistance was higher by at least three orders of magnitude. The high conductivity of the copper precipitates may serve as an explanation why only copper doping produces efficient EL in ZnS.

The voids are never associated with EL emission. In some cases, especially in inefficient phosphors with higher than optimum copper doping levels, the black spots are associated in lines or strings (Fig. 3a). Parallel to these dotted lines one finds, by observation with polarized light, birefringent striations (Fig. 3b). When the field is applied, electroluminescent striations can be found along these birefringent striations (Fig. 3c). This indicates that the occurrence of EL is closely connected with crystal imperfections (imperfection lines), a finding that has been expressed in the literature repeatedly (8, 19-24).

In efficient EL particles, however, observation with crossed nicols shows that the particles are isotropic and that the sites of EL lines are indistinguishable from the bulk. Some hexagonal particles are present, but these are usually inert. With intense x-ray excitation, the particles luminesce uniformly throughout the volume. It must be concluded that in efficient EL particles the imperfection lines have submicroscopic diameters.

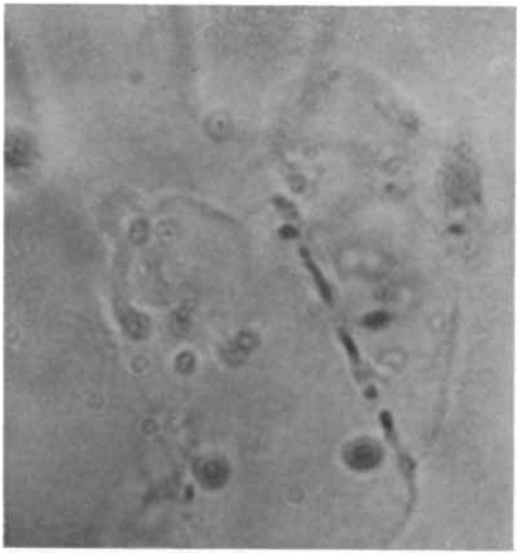

Fig. 3a. External illumination: Long hollow channel (cavity) in EL particle. Fig. 3a-c show the same particle.

Fig. 3b. External illumination, crossed nicols. Birefringent lines extending parallel to long cavity. Bright areas: Strained glass.

Fig. 3c. A-C field applied. Electroluminescent double-line at site of birefringent striation.

With a-c excitation, light is emitted in long lines along those orientations fixed within the crystals which form an acute angle (usually less than 45°) to the field. If, in a specially constructed cell, the direction of the field was rotated, the EL lines faded away as they became more perpendicular to the field, whereas new ones lighted up and became brighter as they became more parallel to the field.

The lines start with a bright, thick "head" near one surface and extend far into the bulk, forming a thinner and dimmer tail. In many cases, in straight continuation of the tail of one line, the tail of a new line starts which has its head at the opposite end of the particle (Fig. 4 and 5). It is therefore a natural conclusion, which was also independently drawn by Gillson and Darnell, that the two lines which have the form of two comets fleeing each other, are actually one unit. The dark interspace in the center shortens with increasing voltage.

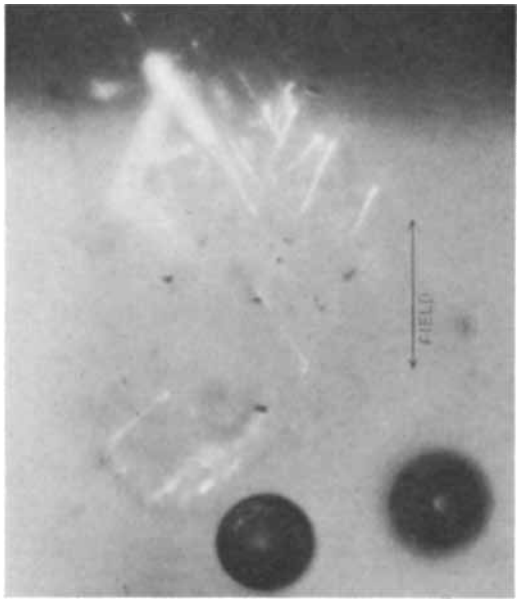

Fig. 4. EL lines in single particle. Due to the shallow focal depth of the microscope at high magnification (up to 2000X) most of the lines are slightly out of focus. With visual observation and continuous accommodation, the lines appear much sharper.

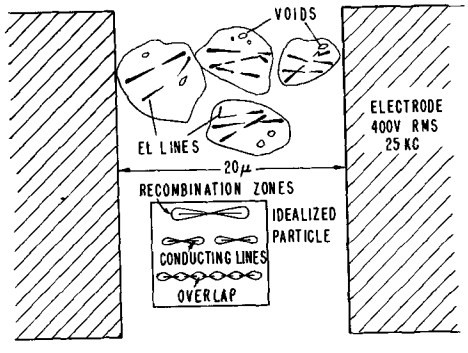

Fig. 5. EL lines drawn from visual observation. Some rather round, non-EL cavities are also shown. In the "idealized particle" below, several possible interactions of EL lines are indicated. The upper case is the most frequent one.

In well-crystallized, efficient powders, the EL lines are coherent; they do not consist of series of fine dots. (The resolution of the microscope is about 0.1μ.) The slow, time-dependent movements of EL lines which Lehmann reports (11) could not be observed.

Thus, our observations on powder particles are in complete accord with the findings of Gillson and Darnell on larger crystallites.

Brightness Measurements

Waymouth and Bitter (1) and Gillson and Darnell (8) state that the time-integrated light output of single particles or lines has a threshold and then rises linearly, whereas Zalm, Diemer, and Klasens (2) and Lehmann (26) report that it follows about the same exponential relation as holds for the light output of a complete cell. This situation requires clarification.

The various brightness measurements to be described here were carried out with the setup shown in Fig. 1. Since most particles have many (up to 30) EL lines so that it is difficult to measure the

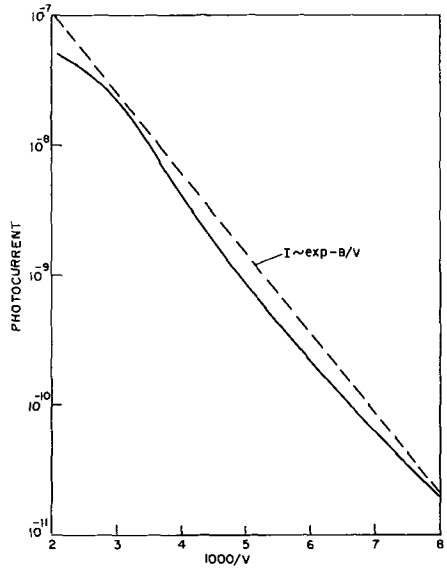

Fig. 6. Log brightness vs. (voltage)$^{-1}$ for a single line. Very long, bright lines show deviations towards linear dependence near breakdown. There is no threshold voltage. The fit to the equation $I \sim \exp - C/V$ is not too good.

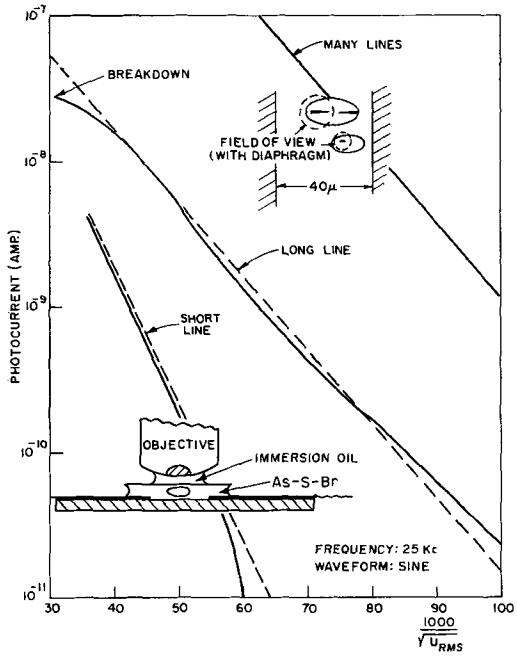

Fig. 7. Log brightness vs (voltage)$^{-1/2}$ for single lines. Short, dim lines rise faster than long, bright lines and have no linear range. The fit to the equation $I \sim \exp - C/V^{1/2}$ is good only for measurements which integrate over many lines.

light from one line without interference from other lines, it was necessary to inspect a great number of particles to find some with isolated, single lines of typical shape. To eliminate light from neighboring lines, a diaphragm with a fine slot was inserted into the ocular of the microscope.

The measurements of brightness *vs.* voltage indicate (Fig. 6-8) that there is no apparent voltage threshold, but that the light emission of a single line rises exponentially. The points do not yield a good straight line either for a plot of log I *vs.* $1/V$ (I = brightness, V = voltage) or for the plot of log I *vs.* $V^{-1/2}$. This could have been caused by the nonhomo-

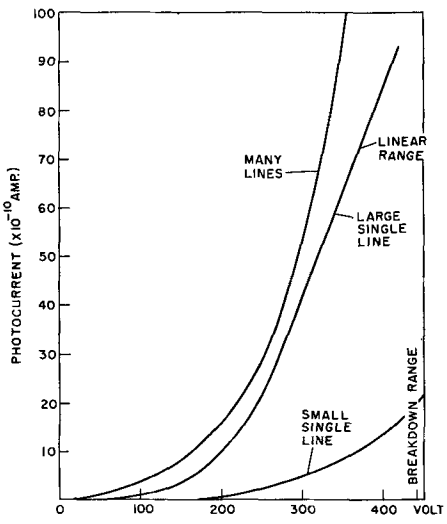

Fig. 8. Brightness *vs.* voltage. Some very bright, long lines show a linear range.

geneous field in the gap cell; however, a measurement integrating over about 100 single lines yields an excellent straight line on the plot log I *vs.* $V^{-1/2}$. The slope of short, dim lines, which require higher voltages to reach the same brightness as long lines, is steeper than that of long lines. Some very bright, long lines were found which showed a linear increase of brightness with voltage in the last half decade of brightness before electric breakdown. This linear range at high voltage is of significance for the theoretical interpretation.

By moving the EL line under the microscope with the microscope stage, the brightness of a line *vs.* its length could be measured. For this purpose, the slotted diaphragm was arranged with the slot perpendicularly to the EL line. The brightness increases from "tail" to "head" in a strongly superlinear fashion.

By displaying the signal of the photomultiplier, which was focused on one or the other half of a double-comet line, on a dual-trace oscilloscope together with the a-c voltage which excited the gap cell, the phase relation of the light bursts or "brightness waves" of a single line could be obtained. (Fig. 9). At 100 cps the light waves extend only over a fraction of the cycle, whereas at higher frequencies the decay time becomes longer than the cycle so that a background develops. For all phosphors examined, the phase relation of light emission is such that light is emitted at that half of a line which points to the electrode which is becoming less negative or more positive. Both halves of a line go on and off alternatingly with a phase shift of 180° (6). The primary and secondary peaks observed in the emission of complete cells exist also at the elementary level in green-emitting particles (not in manganese-containing ones). With sine-wave excitation, the peaks of the brightness waves of Mn-doped phosphors coincide exactly with the voltage peaks. In contrast, the brightness waves of phosphors not doped with Mn lead the voltage slightly. The study of these elementary brightness waves may yield better insight into the mechanism than the study of integrated light waves.

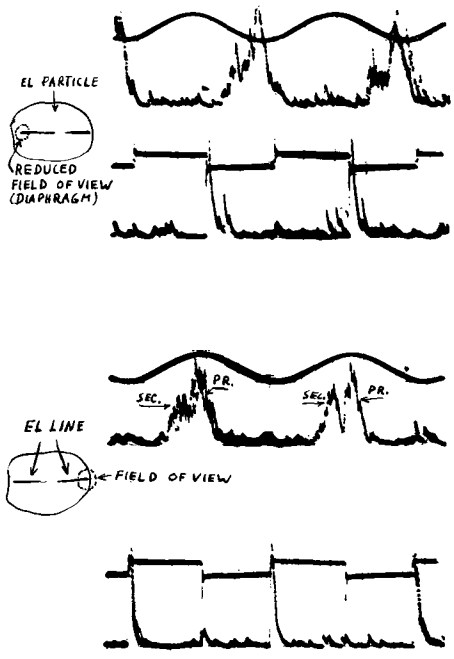

Fig. 9. Brightness waves of single lines, ZnS-Cu,Al particle. Above: photomultiplier focused on left half of "double-comet" line, sine and square-wave excitation, 100 cps. Below: Photomultiplier focused on right half. With sine excitation, the "primary" and "secondary" peaks are recognizable. In all phosphors light is emitted at that half which points to the electrode which is turning positive.

By counting the number of perceptible lines in a given field of observation, which exceed the threshold of visibility, *vs.* the applied voltage, the plot of Fig. 10 was obtained, which differs from the linear increase reported by Zalm (3).

The approximate brightness of single lines at 10 kc near breakdown voltage was measured by raising the external illumination of the microscope (green light) to such a level that the EL line just disappeared against the bright background. The

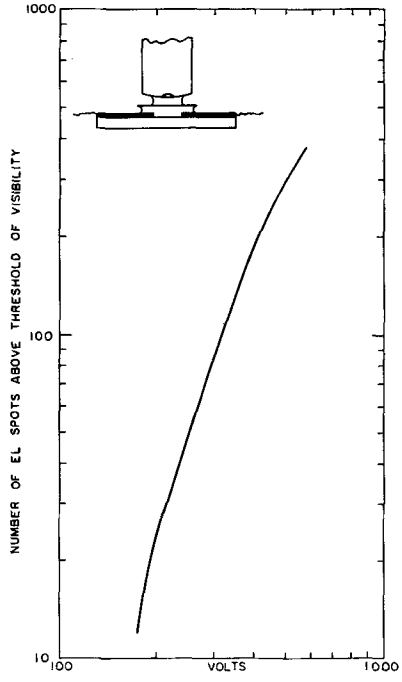

Fig. 10. Number of spots above threshold of perceptibility of dark-adapted eye in a constant viewing area, *vs.* voltage (7 kc).

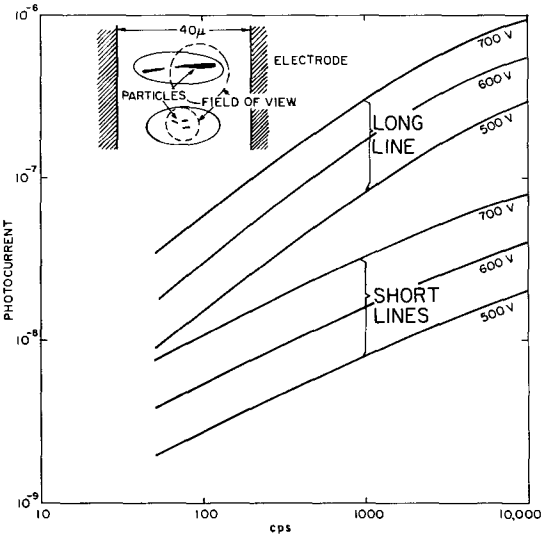

Fig. 11. Log brightness vs. log frequency at constant voltage for short and long lines.

brightness of the background was then measured with a brightness meter. A value of about 5.10^3 ft-L was obtained.

The brightness of single lines *vs.* frequency of the applied voltage, which is kept constant, is plotted in Fig. 11. Whereas the brightness of complete cells increases with a power only slightly less than one at low frequencies (3), the brightness of short lines increases with a power of about 0.6. Long bright lines show a steeper rise.

Conclusion

Microscopic observation of the interior of EL particles which are embedded in the matched-refractive-index-media described, is a new, convenient tool for studying the active elements of the EL process, which heretofore have been almost inaccessible. Electroluminescence is by no means a surface process, as previously believed, but is associated with crystal imperfections in the bulk. Previous theories do not describe the real situation.

In a separate article, a new model (25) will be treated in which it is assumed that insulating luminescent ZnS particles contain conductive, copper-sulfide-decorated imperfection lines, which, by means of geometrical field intensification at their ends, are capable of field-emitting both holes and electrons from opposite ends into the crystal. The injected holes become trapped in luminescent centers and recombine radiatively with field-injected electrons and electrons returning through the bulk at field-reversal.

Acknowledgment

The author received invaluable help by Allen S. Mason during several phases of this work, especially in the preparation of the As-S-Br glass. Gratitude is expressed to Dr. R. E. Shrader for valuable discussions and criticism and suggestion of the dark-current bucking circuit. Dr. S. M. Thomsen supplied several samples and stimulating discussions. Special thanks are due to Dr. S. Larach for his continuing interest in this work.

Luminescence in the System Al_2O_3-AlN

I. Adams,[1] T. R. AuCoin, and G. A. Wolff[2]

U.S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

ABSTRACT

Aluminum nitride and aluminum oxide are mutually soluble at high temperatures. A number of solid solutions and reaction products of various compositions in the system AlN-Al_2O_3 have been prepared at about 2000°C, which can be described by one general formula

$$Al_{(2+x/3)}O_{(3-x)}N_x$$

where x represents the number of nitrogen atoms.

Five phases were observed: (i) Al_2O_3 of corundum structure with negligible solubility of AlN; (ii) a phase similar to δ-alumina, found when the AlN content was about 5.5 mole %; (iii) a spinel phase with an AlN content up to 50 mole %; (iv) a phase obtained when the AlN content was between 50 and 67 mole % (this phase always occurred mixed with phase iii); (v) AlN of wurtzite structure with up to about 17 mole % Al_2O_3.

Phases (ii) to (v) show no observable fluorescence, but broad band phosphorescence in the blue when excited with 2537Å radiation. Manganese activation produces a green or a red luminescence which is attributed to transitions of Mn^{2+} and Mn^{4+} at different lattice sites. Electroluminescence in the visible is observed in all phases when suitably activated.

The similarity of the crystal structures of α-Fe_2O_3 and α-Al_2O_3 (1) has long led to conjecture concerning the formation of an aluminum spinel similar to Fe_3O_4. The metastable γ-form of Al_2O_3 has a spinel-like structure with a deficiency of metal ions with respect to the hypothetical spinel Al_3O_4. In 1957 Filonenko *et al.* (2) reported an aluminum spinel to which they assigned the formula $AlO \cdot Al_2O_3$. This product was formed by the reduction of Al_2O_3 with carbon according to the formula

$$3Al_2O_3 + C \rightarrow 2Al_3O_4 + CO$$

In the same year, Vert *et al.* (3) reported the formation of an aluminum spinel by firing a mixture of Al_2O_3 and carbon at 1500°-1900°C. Long and Foster (4) reported formation of a δ-Al_2O_3 and a phase similar to the spinel-type lithium-ξ-alumina when AlN and Al_2O_3 mixtures were fused in an argon atmosphere, but did not explain the mechanism of the phase transformations involved. The formation of a spinel phase was found (5) during the preparation of AlN in an Al_2O_3 crucible. This phase was described as a solid solution of AlN in Al_2O_3 with a maximum AlN:Al_2O_3 ratio of 1:1 corresponding to the formula Al_3O_3N. Recently Yamaguchi and Yanagida (6) revised their previous Al_3O_4 formulation for the spinel phase to the formula $AlN \cdot Al_2O_3$.

Electroluminescence has been reported for AlN (7, 8). As early as 1934, Guntherschulze and Gerlach (9) reported a faint red emission when a thin film of pulverized ruby was subjected to an alternating field in a high vacuum. A bright emission has recently been observed in specially treated Al_2O_3 excited by an electric field (10, 11).

[1] Present address: Airtron, Division of Litton Industries, Morris Plains, New Jersey.

[2] Present address: Solid State Research Laboratory, The Harshaw Chemical Company, Cleveland, Ohio.

In the present study, the reaction products of various compositions, heated to 2000°C, are identified, and a comparison of their luminescent properties is presented. An Al_2O_3-AlN phase, not previously reported in the literature, was detected.

Experimental Procedure

The AlN used for this study was prepared in an autoclave, similar to that shown schematically in Fig. 1, by reacting high-purity aluminum powder with nitrogen at 1000°C and 1000 psi in AlN or Al_2O_3 crucibles. Solid solutions containing more than 50 mole % AlN were also prepared in the autoclave by mixing aluminum powder with Al_2O_3 powder (ALCOA A-14) and firing in nitrogen at 1000°C and 1000 psi. The reaction of nitrogen with aluminum is exothermic and served to increase the temperature to about 2000°C as indicated by the beginning of melting of the container when an Al_2O_3 (melting point 2050°C) crucible was used. Samples

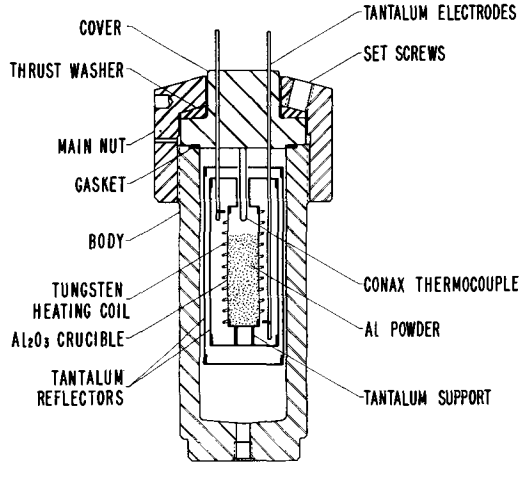

Fig. 1. Autoclave pressure reactor

containing less than 50 mole % AlN could not be prepared in the autoclave, since the heat generated by the reaction of small amounts of aluminum with nitrogen was insufficient to increase the temperature to the required 2000°C; therefore these samples were prepared by fusing mixtures of Al_2O_3 and AlN in an arc image furnace at 2000°C or above for 5 min, the raw mix serving as its own container. An argon atmosphere of 5 psi was admitted into a previously evacuated reaction flask, and the temperature was measured pyrometrically.

Unreacted aluminum was removed by treating the fused material with a hot dilute solution of sodium hydroxide. Nitrogen was then determined by a modified Kjeldahl procedure (12) in which 1-5 mg samples in 10 cm^3 of 50% NaOH were heated to 200°C. This served to decompose aluminum nitride quantitatively. The reaction was carried out in a specially designed apparatus made of quartz which contained a nickel reaction tube. The ammonia was entrained in a stream of wet nitrogen and determined by acidimetric procedures.

Doping was achieved by two methods. One method consisted of mixing the dopant (as a salt or oxide in amounts of fractions of a per cent to several per cent) with the compound to be activated and placing the mixture in an alumina boat. A large number of different dopants were used, but only a few will be discussed here. The boat was then fired in a quartz tube at 600°-1000°C in nitrogen for ½ hr followed by a similar treatment in chlorine which removed unreacted aluminum (and, incidentally, was responsible for producing the electroluminescent response property). Generally, it also removed most of the added activators such that only a small fraction of the amount added was retained in the finished phosphor.

The second method, used to produce red luminescent Mn-doped AlN, consisted of firing a mixture of the dopant (salt or metal) powder and aluminum powder in the autoclave at 2000° under nitrogen pressure. The sample was then reacted as described before.

For luminescence studies, the samples were excited using two mercury lamps, one rich in 2537Å and one rich in 3650Å. Electroluminescence was excited by applying a d-c potential of 500v across the powdered sample, about ½ mm thick, between a metal base plate and a conducting glass plate. Spectra were measured as described in ref. (7) and (13).

A square wave generator was built to study the effect of square voltage pulses on light output. It consisted of a motor-driven commutator to control the frequency, a high voltage thyratron circuit for switching, and a rotating brush assembly for selecting pulse width. The unit was designed to produce the very low frequency range of 0.2-2000 cycles/min, an output pulse width of between 1.0 and 99.0% of the period, and output pulse amplitudes of ± 1000v. The operation was such that, after a part of each cycle, the applied voltage was reversed in sign for the rest of the cycle.

Results

Four crystalline phases were identified in the products obtained in the reaction between Al_2O_3 and AlN at 2000°C. A tetragonal phase similar to δ-alumina (14) was found when mixtures consisting of 40 to 1 and 18 to 1 molar ratio of Al_2O_3 and AlN were fused. As the concentration of AlN was increased beyond $18Al_2O_3$ to 1AlN a spinel phase appeared. When the molar amount of AlN exceeded that of Al_2O_3 a new phase was observed. This new phase was the only one which could not be obtained as a single phase. It was always found mixed with the spinel and could not be separated from it. For a molar ratio of Al_2O_3:AlN of less than 1 to 6, only a wurtzite-like phase was detected. The nitrogen content of some of the phases is shown in Table I. X-ray powder diffraction patterns of the dominant phases are shown in Fig. 2.

A comparison of the fluorescence, phosphorescence, and electroluminescence of these phases doped with Mn, Cr, and Eu is presented in Table II. The observed intensity of the electroluminescence varied from 1 to 10 ft-L. About 10 ft-L were observed for Mn-doped AlN of green electroluminescence, and about 5 ft-L for Mn-doped AlN of red electroluminescence. The intensity of the electroluminescence of the various undoped materials was below 1 ft-L. The strongest phosphorescence intensity of about ½ ft-L was found on the Mn-doped red emitting AlN when it was irradiated with filtered u.v. from a Hanovia lamp at a distance of about 5 cm. Electroluminescence in these materials is observed only after the addition of an activator as

a chloride and subsequent heat treatment, or after heat treatment with chlorine gas. The chlorine treatment was not necessary, however, to obtain fluorescence and phosphorescence. The materials that were treated with chlorine, but prepared without an activator, emitted only the N_2 band systems during d-c excitation as reported previously (7, 8). In suitably activated materials, an emission characteristic of the activator was observed in addition to the N_2 bands.

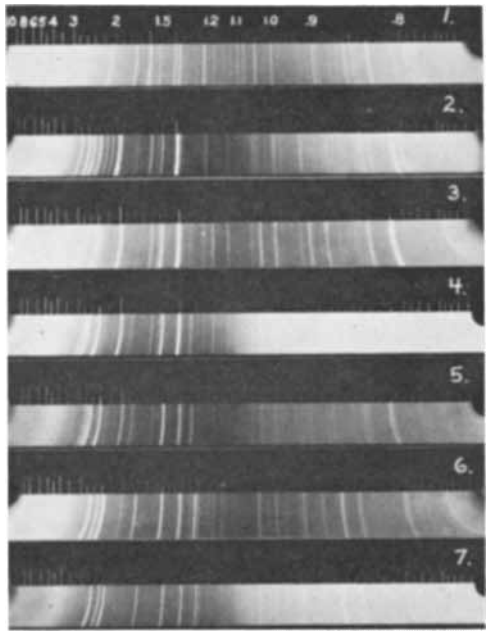

Fig. 2. X-ray powder diffraction patterns (Cu K_α) of the dominant phases in the Al_2O_3-AlN system. 1, α-Al_2O_3; 2, 18 Al_2O_3-AlN; 3, $2Al_2O_3 \cdot AlN$; 4, $Al_2O_3 \cdot AlN$; 5, $2AlN \cdot Al_2O_3$; 6, $6AlN \cdot Al_2O_3$; 7, AlN.

During electroluminescence excitation, chlorine-treated samples exhibited increased conductivity over the untreated material as measured by a microammeter, and the current was proportional to the light intensity. Figure 3 shows characteristic light wave forms from an AlN sample using square wave voltage excitation. Similar behavior is exhibited by the other phases 1 to 4 as defined above. The voltage was varied from positive (with respect to the metal electrode) to negative with a frequency of 60 cycles/min. When the pulse was positive less than 60% per cycle, no light was emitted from the powder. For positive pulse durations greater than 60% of the cycle (Fig. 3a), a slow increase in light was seen. This light intensity increase on the oscilloscope was followed by a fast decrease to zero and a very intense and short burst of light at the moment of polarity reversal. When the pulse width was 75% (Fig. 3b) the intensity was much greater and the light reached its maximum much more rapidly. On field reversal the decay no longer reached zero. The subsequent increase was still rapid, but the decay extended over the full period of field reversal. At 78% positive pulse, (Fig. 3c) the decay of the light burst is seen to be slower still and falls to zero only on field reversal. Using a.c., light output was obtained for frequencies as high as 25 kc; the light intensity increased with decreasing frequency down to 20 cps, which was the low-frequency limit of our a-c amplifier.

Discussion

An oxide spinel with only one cation species is formulated as R_3O_4. The defect spinel γ-Al_2O_3, which can also be written as $Al_{8/3}O_4$, has one-ninth of the

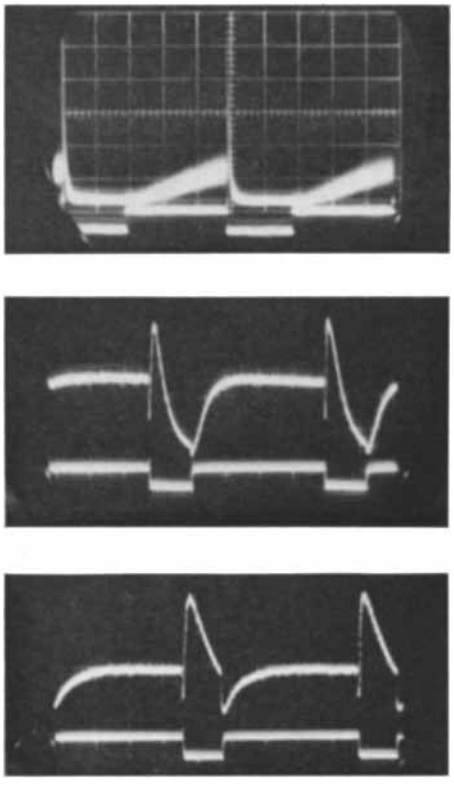

Fig. 3. Light wave forms emitted from AlN when applying square waves at 60 cycles/min: (a) (top) 62% pulse width; (b) (center) 75% pulse width; (c) (bottom) 78% pulse width.

total number of spinel cation sites vacant. This can be represented as

$$Al_{8/3}\boxed{S}_{1/3}O_4 \qquad [1]$$

where $\boxed{S}$ represents spinel cation vacancies. For every aluminum atom added to fill a vacancy $\boxed{S}$ in formula [1], charge compensation can be achieved by three nitrogen atoms replacing three oxygen atoms. Thus the spinel Al_3O_3N is obtained by adding one third of an aluminum to formula [1] and compensating with the substitution of one nitrogen for one oxygen. Consider the formula

$$Al_{\left(2+\frac{x}{3}\right)}\boxed{S}_{\left(\frac{3-4x}{12}\right)}O_{(3-x)}N_x \qquad [2]$$

where x represents the number of nitrogen atoms. Setting $x = 0$ and multiplying through by 4/3, formula [2] reverts to $Al_{8/3}\boxed{S}_{1/3}O_4$. When $x = 3/4$, implying that all spinel sites are occupied, formula [2] becomes

$$Al_{9/4}O_{9/4}N_{3/4}\ (\text{or } Al_3O_3N) \qquad [3]$$

This corresponds to one mole of AlN for one mole of Al_2O_3. Thus formula [2] is an empirical formula describing the solid solution series Al_2O_3-$Al_2O_3 \cdot AlN$ with $O \leq x \leq 3/4$.

From stability considerations it appears plausible that very small values of x will yield a γ-type spinel which, like γ-Al_2O_3, is probably unstable at high temperatures, changing into a structure which resembles δ-alumina. For larger values of x, enough additional aluminum and nitrogen atoms have entered the structure to stabilize it as a spinel at high temperatures. The spinel vacancy sites are then filled, and further addition of AlN yields a wurtzite-type phase with substantial oxygen impurity and cation wurtzite vacancies.

A wurtzite-type phase requires a 1:1 ratio of anion to cation, *e.g.*, AlN. Formula [3] formulated from the point of view of a wurtzite structure, appears as

$$Al_{9/4}\boxed{W}_{3/4}O_{9/4}N_{3/4} \qquad [4]$$

where $\boxed{W}$ represents wurtzite cation vacancies. Again, the introduction of one aluminum atom in a vacancy can be compensated by substituting three nitrogens for three oxygens. Thus AlN of wurtzite structure is obtained by adding three-fourths of an aluminum to formula [4] and compensating by substituting nine-fourths oxygen. Consider the formula

$$Al_{\left(2+\frac{x}{3}\right)}\boxed{W}_{\left(\frac{3-x}{3}\right)}O_{(3-x)}N_x \qquad [5]$$

When $x = 3$, the wurtzite structure is filled, oxygen disappears, and we have Al_3N_3 (or AlN). Formula [5], with $3/4 \leq x \leq 3$, is thus an empirical formula for describing the solid solution series $Al_2O_3 \cdot AlN$-AlN.

Disregarding cation vacancies in considering the series $Al_2O_3 \rightarrow Al_3O_3N \rightarrow AlN$, it follows that all the phases in this series can be described by the general formula

$$Al_{\left(2+\frac{x}{3}\right)}O_{(3-x)}N_x \qquad [6]$$

with $O \leq x \leq 3$.

In α-Al_2O_3 it is apparently possible to replace aluminum atoms with other cations, but not to introduce additional cations toward R_3O_4, although one third of the octahedral sites and all the tetrahedral sites are unfilled. To accommodate more Al atoms when nitrogen is introduced, the spinel phase appears which accommodates three cations for every four anions present. When still more cations are added, the wurtzite-type phase appears which can accommodate one cation for every anion present. If aluminum could exist in a divalent as well as a trivalent state, as does iron, then increasing aluminum concentration would form α-$Al_2O_3 \rightarrow \gamma$-$Al_2O_3 \rightarrow Al_3O_4 \rightarrow AlO$. Since this sequence would entail a valence change of aluminum, it cannot occur in a solid. The following sequence is observed, however; α-$Al_2O_3 \rightarrow \gamma$-$Al_2O_3 \rightarrow Al_3O_3N \rightarrow AlN$. In the process the anion close packing changes from hexagonal to cubic and back to hexagonal.

The action of Cl_2 gas on these materials is complex. The effects are possibly (*a*) incorporation of Cl into the lattice causing an apparent increase in the electrical conductivity, and (*b*) increase in the diffusion velocity of impurities into these materials. For instance, doping of Al_2O_3 with Cr^{3+} occurs at substantially lower temperatures than is possible in the absence of Cl.

Since Cr^{3+} shows a strong octahedral site preference, it therefore readily replaces Al atoms in corundum and in the spinel Al_3O_3N, where two-thirds of the Al occupy octahedral sites. In AlN where only

tetrahedral sites are occupied, no substitutional Cr doping is possible. Manganese, on the other hand, produces a characteristic green electroluminescent emission in AlN and Al_3O_3N which is attributed to Mn^{2+}. No green emission was observed in α-Al_2O_3. Red emission has been reported in Al_2O_3 doped with Mn (15, 16), but we were unable to duplicate these findings. Red emission was observed only in AlN when the latter was fired in the autoclave, not by simple doping followed by the Cl treatment. However, some spinel may have been present in this material causing the red emission. In fact, with Mn activation the spinel and the new phase did produce a red luminescence as well as a green one. Kröger (16) reported green emission from Al compounds of structures other than α-Al_2O_3. This is most likely only when Al (or some other cation) is displaced from tetrahedral sites. It would appear then that green emission is observed in these materials only when Mn^{2+} replaces Al^{3+} in tetrahedral sites (AlN, Al_2O_3-AlN spinel), and red emission only when Mn^{4+} replaces Al^{3+} in octahedral sites (α-Al_2O_3, Al_2O_3-AlN spinel). More extensive investigation of Mn substitution in these structures must be undertaken to substantiate the valence states and activator coordination in crystals which give rise to the emission observed and the position of Mn in the structures. The results of a chemical analysis cannot be considered as conclusive proof of the valence state of Mn; disproportionation, decoration of dislocations and segregation of small undetectable amounts of a Mn-containing second phase could interfere with its proper identification. A physical determination, *e.g.*, ESR, must therefore supplement the chemical analysis. In particular, a rigorous proof is required before one can say with certainty that the red emission is due to Mn^{4+}, *i.e.*, until the absence of oxide in solid solution or as a second phase in AlN is ascertained. A red luminescence can be produced in AlN by Mn-doping, yet no octahedral sites are available in AlN except interstitial sites. It is also not quite understood why a red Mn-luminescence is difficult to obtain in α-Al_2O_3, since an octahedral Mn^{4+} site is available by Al^{3+} substitution.

The luminescence and electroluminescence observed in the system Al_2O_3-AlN are radiations characteristic of the activators. Both emissions, the activator and the nitrogen band system emission, are observed in all Al_2O_3-AlN samples after chlorine heat treatment. The N_2 band emission might be explained by electron emission and/or by the energy transfer of the electron-hole recombination at the surface to adsorbed or impinging N_2 molecules. The latter process would be the reverse of the excitation of luminescence in solids by impinging excited gases as investigated by Sancier, Fredericks, and Wise (17). Ultraviolet light is available from the emission of the N_2 systems and could secondarily excite fluorescence in the phosphors. Further work on the effects of nonsinusoidal voltage pulses on the light wave forms and measurements of the electrical conductivity under these conditions is needed to obtain a clear picture of the exact mechanism involved in the electroluminescence observed.

Impurity Distribution in Epitaxial Silicon Films

C. O. Thomas, D. Kahng, and R. C. Manz

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A differential capacitance-voltage method for determining doping profiles in depth in epitaxial semiconductor films is described. Experimental profiles, in which the doping level generally is not flat but decreases with film thickness, are shown for several film growth conditions. A possible explanation for the observed distribution is discussed.

The measurement, understanding, and control of doping distribution in depth is necessary for proper utilization of epitaxial semiconductor films in device fabrication, especially for very thin films, for structures in which the substrate-film interface is a functional part of a device, or for structures in which the profile must be tailored (as with grown junctions).

The impurity distribution in epitaxial semiconductor films is determined by two factors: (i) that related to the growth method *per se*, and (ii) that related to diffusion, especially from the substrate into the film. The first of these is dealt with in this paper. The diffusion effects are considered in a separate paper (1).

Experimental Methods

The epitaxial films were grown by means of the hydrogen reduction of silicon tetrachloride. The method is standard at this point and has been reported in detail by a number of investigators (2-5). For these experiments, the substrate slice in every case was subjected to a 30-min preheat treatment (cleaning) at 1240°-1250°C in flowing dry hydrogen immediately before film growth. The film growth temperatures were selected in the range 1060°-1220°C. All temperatures have been corrected for emissivity and for wall transmission losses and are measured by means of an optical pyrometer viewing the upper surface of the slice.

The silicon tetrachloride saturator temperature was stabilized at -40°C (±0.2°C) which gives a calculated mole fraction of 0.01 in the vapor. The hydrogen flow rate was 2.5 liters min^{-1} through a 1¼-in. ID chamber. The apparatus was a single slice, vertical, RF heated system with a silicon pedestal. The pedestals were preheated with projection lamps to facilitate RF coupling and did not contain doped inserts. Both purified and doped silicon tetrachloride, as well as lightly and heavily doped pedestals, were used in these experiments.

Unless specifically stated otherwise, all of the substrate slices were from the same, arsenic-doped, pulled ingot, 0.004-0.006 ohm-cm and about ⅝-in. diameter. The slices were cut to a (111) orientation and electrochemically polished (6). Each slice was cleaned immediately prior to use by means of a 1-min room temperature etch in 250 cc HNO_3, 50 cc HF, and 220 cc (I_2 saturated) HAc followed by a deionized water rinse in a counter-current flow system. The samples were dried in a continuously purged nitrogen atmosphere oven and immediately placed in the deposition chamber.

Diodes were fabricated by a ¼μ boron diffusion through a photoresist oxide mask.[1] A 10 by 10 array of 18 mil diameter dots was prepared on each slice. Six to eight diodes were measured on each slice. Comparable results have been found using aluminum alloy diodes. However, the percentage yield of good diodes was better with the shallow boron diffusion, and consequently it was used for the major portion of this investigation.

Growth temperatures of 1200°C or higher have been widely reported in the past as necessary for the preparation of good electrical quality films. Figure 1 shows the forward and reverse characteristics of a typical diode (¼μ boron diffused, 18 mil diameter) in one of the low-temperature films of about 7μ thickness. The current just before breakdown is about 10^{-7} amp. Diode characteristics as shown in Fig. 1 are quite adequate for the electrical measurements described below. The essential point for preparation of good device material at this temperature appears to be scrupulous attention to the substrate and system cleanness.

The measurement method is based on the fact that for a junction between a heavily doped and a

[1] Oxidation at 1100°C for 30 min, diffusion at 900°C for 70 min.

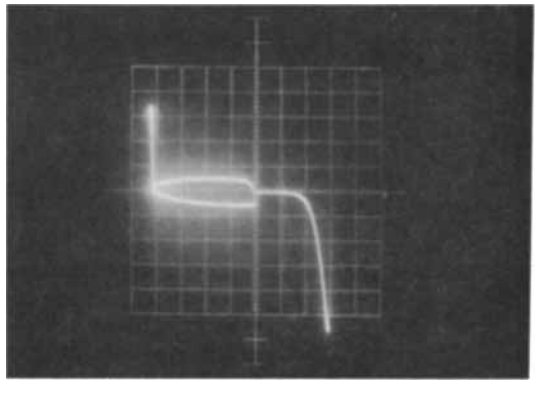

Fig. 1. Diode characteristics for film grown at 1060°C. Boron diffused 18 mil diameter dots, ¼μ depth; measured current just before breakdown about 10^{-7} amp.

← Reverse — Forward →

10 v/cm H, 10 μa/cm V — 0.2 v/cm H, 10 μa/cm V

more lightly doped semiconductor, the slope of $1/C^2$ *vs.* the applied reverse voltage (V) is a simple function of the doping concentration at the edge of the space-charge, (N_s) (7). The basic equations are as follows

$$d\,(1/C^2)/dV = 2/\epsilon q N_s \qquad [1]$$

$$C = dQ/dV = \epsilon/s \qquad [2]$$

$$d(1/C^2)/dV = -2C^{-3}(dC/dV) \qquad [3]$$

A nomograph based on these equations is shown in Fig. 2.[2] The measurement method is as follows. Capacitance is measured at a given voltage. Then the capacitance bridge dial setting is changed by a small increment, roughly 1%. The applied reverse voltage is changed to rebalance the capacitance bridge. This gives $\Delta C/\Delta V$ ($\sim dC/dV$) at the given values of C and V. After suitable correction for diode area, the doping concentration, the depth at which the measurement is made, and the resistivity in ohm-cm (for n-type silicon) may be determined directly from the nomograph. Thus, a doping profile in depth may be determined by multipoint measurements on each diode.

Experimental Results

Figure 3 shows the point-to-point measurements in depth for six diodes on a typical epitaxial silicon film grown at 1220°C. A 70-90 ohm-cm arsenic-doped pedestal was used. The saturator contained purified silicon tetrachloride (8) at -40°C. The film thickness is measured from the junction. Angle-lap and staining indicate that the interface is approximately 6.85μ below the junction.

The main body of the curve approximates a straight line which may be extrapolated to give an "effective" initial doping concentration at the apparent interface, which is labeled as N^*_o. Near the interface, there is also a diffusion tail. In some instances, it has been possible near the junction to see the compensation effect of the boron diffusion.

[2] This specific measurement method was first suggested by M. M. Atalla and D. Kahng who constructed the nomograph.

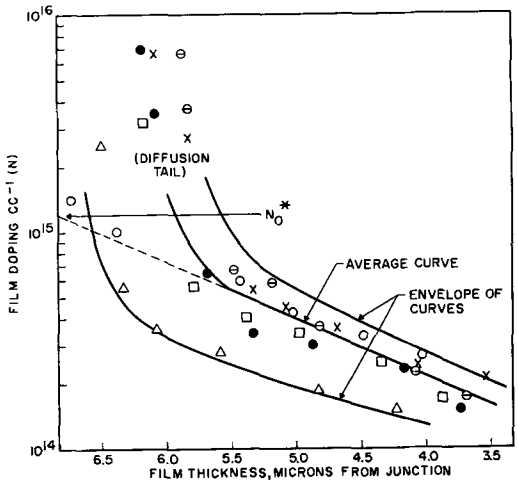

Fig. 3. Diode data for an epitaxial silicon doping profile. Substrate (As-doped) 0.004 ohm-cm; $SiCl_4$ (purified) saturator at —40°C; pedestal (As-doped) 70-90 ohm-cm silicon; growth temperature 1220°C; growth rate 2.5μ min^{-1}; interface estimated at 6.85μ below junction.

Since the doping is not uniform with depth, some of the spread between the diodes may be caused by film thickness variations across the sample. Figure 4 shows the effect of making a lateral adjustment in the points from Fig. 3 to bring the diffusion tails to a common level. The maximum adjustment required is about 0.5μ which is within the range of normally observed thickness variations. The result is to significantly reduce the data spread without changing the slope or the intercept by any appreciable amount. However, the adjustment introduces a degree of approximation in the film thickness coordinate. In like manner, some of the vertical data spread probably is related to variations in diode area. Average curves shown throughout this paper are based on the unadjusted data as shown in Fig. 3. Figure 5 shows a composite profile for three films of different thicknesses grown with a doped saturator under otherwise identical conditions. The points are mean values, and the vertical lines indicate the maximum spread in the measurements. Five to six

diodes selected at random were measured on each sample. The three films were grown at 1180°C using a doped saturator. Figure 6 shows the detailed diode data for sample 1 and clearly illustrates the compensation effect near the junction. Figure 7 shows the usual capacitance vs. reverse voltage plot for the boron diodes on sample 2. This is the same raw data as above, but is merely plotted differently. Figure 8 shows capacitance vs. reverse voltage data for aluminum alloy diodes (15 mil diameter dots) prepared on a portion of sample 2. Four diodes selected at random were measured. There is a reasonable resistivity check between the four plots in Fig. 5, 6, 7, and 8.[8] However, the advantage of the differential method for determining the detailed profile shape is clearly shown. On sample-2 the differential method indicates a profile shape that cannot readily be determined from the capacitance *vs.* reverse voltage plots.

[8] Obtained by treating the data of Fig. 7 and 8 as if the slopes were −0.5.

Figure 9 shows the variation in the slope of the straight line portion of the profiles as a function of the temperature at which the film is grown (using purified $SiCl_4$). There will, of course, be a diffusion tail (not shown here) near the interface for each of the profiles. The profiles extrapolated to the apparent interface give an "effective" interface concentration labelled as N^*_0. The profile at each growth temperature is a composite for three to eight slices.

There are several important points in Fig. 9: (i) the semilog plots are straight over a rather wide thickness range; (ii) flat profiles are approached only at the lower growth temperature; and (iii) there appears to be a common intercept or pivotal point somewhere near the interface. These points will be considered in more detail in the Discussion section. The temperature dependence of the profile slopes, ϕ, is shown in Fig. 10.

Figure 11 shows the shift in N^*_0 produced by a shift in substrate resistivity. However, the ratio of N^*_0 to substrate resistivity is not constant. This point

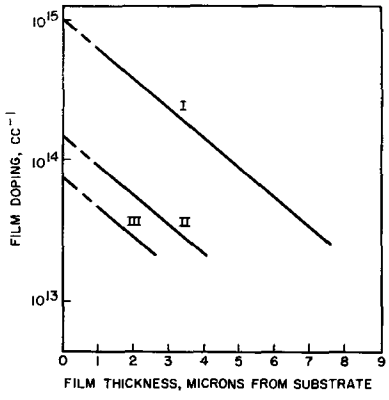

Fig. 11. Effect of substrate resistivity on profiles. I, Substrate 0.004 ohm-cm ($2x10^{19}$); II, substrate 1 ohm-cm ($5.5x10^{15}$); III, substrate 15 ohm-cm ($3x10^{14}$); All substrates As-doped; growth temperature 1180°C with purified $SiCl_4$.

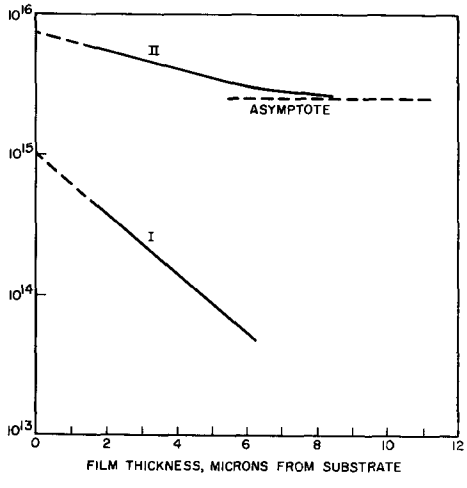

Fig. 12. Effect of gas-phase doping on profiles. I, Purified $SiCl_4$, 70-90 ohm-cm pedestal; II, doped $SiCl_4$, 2000-3000 ohm-cm pedestal. Substrates 0.004 ohm-cm; growth temperature 1150°C.

will be considered further in the Discussion section. The slopes remain identical within the sensitivity limits of the measurement method.

Figure 12 shows the effect of heavy gas phase doping. In thick films (10-14μ) grown with this doped saturator, there is an asymptote of about 2.5×10^{15} which is approached at a distance of 10-11μ from the substrate.

Model

It has been shown above that the experimentally measured doping level in a given epitaxial silicon film (grown by the hydrogen reduction of silicon tetrachloride in a flow system) generally decreases as a function of distance into the film from the substrate. This distribution is distinct from and in addition to diffusion from the substrate into the film. In addition, the doping level in the film is affected both by the ambient gas-phase doping level and by the substrate doping level.

At present, there is insufficient data for an analysis of the kinetics of the system. However, there is considerable evidence that dopant is transferred from the silicon pedestal and from the backside of the substrate slice to the growing film through the gas phase (2). We propose here that a similar transfer from the upper surface of the substrate (or the film after it has begun to grow) into the working gas phase is a major factor in determining the shape of the doping profile in the film. Since the mechanism is not understood, we merely write

$$(\text{silicon, dopant})_{gas} \rightleftarrows (\text{silicon, dopant})_{solid}$$

Distribution expressions which appear to agree in form with the measured profiles (n-type) have been derived by treating the film growth as a discontinuous process in which the sequential steps are:

1. Silicon and dopant are removed from the solid in the ratio in which they are found at the solid surface, *i.e.*, the step involves an "etch" phenomenon with no preferential leaching of either silicon or dopant.
2. The working gas-phase composition is modified by mixing with the incoming gas ambient which contains $SiCl_4$ and may or may not contain dopant.
3. Silicon and dopant are deposited in the ratio in which they are now present in the modified working gas phase. These steps constitute a complete cycle in which there is a net increase in film thickness. Thus, some dopant from the substrate (as well as that supplied by the incoming gas ambient) is available for redistribution in the film.

The discontinuous model is used here on the grounds of mathematical convenience, reasonable agreement with the measured profiles, and the absence of adequate kinetic data at present. It is not intended to imply that the actual process is discontinuous.

In developing the model, we ignore diffusion from the substrate into the film or diffusion within the body of the film. These effects are considered in a separate paper (1).

In the first step, material is removed from the solid phase in the dopant-to-silicon ratio.

$$(\text{dopant/silicon})_s = (N/N^\circ) \qquad [4]$$

This material mixes with the incoming gas phase to give a working gas concentration near the surface

$$(\text{dopant/silicon})_g = (N + bn)/(N^\circ + bn^\circ) \qquad [5][4]$$

On the deposition half of the cycle, the dopant and silicon deposit in the ratio shown in [5] with a net increase in film thickness

$$y = ax = 1, 2, 3, \ldots . \qquad [6]$$

The value of x for $y = ax = 1$ is analogous to the HETP (height equivalent to a theoretical plate) in distillation and extraction theory and defines the incremental thickness in microns equivalent to one theoretical cycle. From the above considerations it follows that

$$(N_1/N^\circ) = (N_o + bn)/(N^\circ + bn^\circ) \qquad [7]$$

$$N_1 = N^\circ(N_o + bn)/(N^\circ + bn^\circ) = \alpha(N_o + bn) \qquad [8]$$

where

$$\alpha = N^\circ/(N^\circ + bn^\circ)$$

[4] The dimensions of N and N° are atoms-cc^{-1}(s), and of n and n° are atoms-cc^{-1}(g). Therefore the exact form of [5] is

$$(\text{dopant/silicon})_g = (wN + Bn)/(wN^\circ + Bn^\circ)$$

where

$$w = d_g/d_s \text{ and } b = B/w$$

$$N_2 = \alpha^2 N_o + \alpha^2 bn + \alpha bn \quad [9]$$

$$N_y = N_o\alpha^y + \alpha bn(1 + \alpha) + \ldots + \alpha^{y-1} \quad [10]$$

Rewriting the geometrical progression in exact terms gives

$$N_y = N_o\alpha^y + \alpha bn(1-\alpha^y)/(1-\alpha) \quad [11]$$

or

$$N_x + N^*_o\alpha^{ax} + \alpha bn(1-\alpha^{ax})/(1-\alpha) \quad [12]$$

where N^*_o is the effective N_o at the interface between the film and the substrate.

Equation [12] is the generalized expression for the case where dopant is present both in the substrate and in the gas phase. The ambient gas-phase doping may originate with the silicon tetrachloride, the system contamination, the pedestal, or even from the backside of the substrate by a transfer mechanism discussed elsewhere (2).

For a pure gas phase, $n = 0$ and [12] reduces to

$$N_x = N^*_o\alpha^{ax} = N^*_o e^{-\phi x} \quad [13]$$

since by definition, $0 < \alpha < 1$. Also for an intrinsic substrate and doped gas, the expression reduces to

$$N_x = \alpha bn(1-\alpha^{ax})/(1-\alpha) = [\alpha bn/(1-\alpha)](1-e^{-\phi x}) \quad [14]$$

For larger values of x, (*i.e.*, thick layers)

$$N_{x\to\infty} = \alpha bn/(1-\alpha) = A, \text{ (an asymptote)} \quad [15]$$

The various derived equations are summarized in Table I. The physical significance of these expressions is shown in Fig. 13 where log N_x is plotted against x. The several curves are discussed below.

Curve I.—This is the asymptotic limit for a system in which gas doping occurs, *i.e.*

$$N_x = Kn = n(N^\circ/n^\circ) = A \quad [16]$$

This is obvious from the fact that the exponential term $N^*_o e^{-\phi x}$ becomes vanishingly small for large x-values, while the summation term approaches a constant value. The absolute position of the asymptote will depend on the gas-doping concentration, n, as shown in Table I.

Curve II.—This is the exponential profile for a doped substrate with an intrinsic gas phase. The diffusion tail is not shown. The slope of this curve is given by ϕ and will be discussed later.

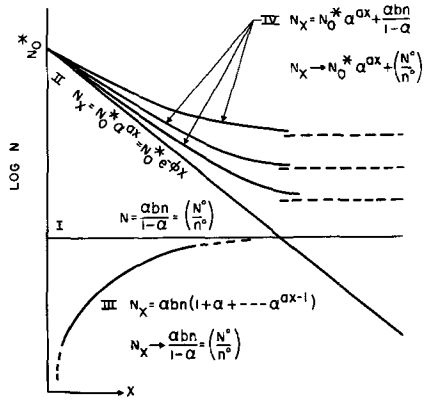

Fig. 13. Theoretical doping profiles derived from model discussed in text; diffusion effects not shown. I. Hypothetical profile for process with no etch-back; also determines the asymptote at a given doping level in the gas phase; II, profile for doped substrate and pure gas; III, profile for pure substrate and doped gas; IV, profiles for doped substrate and doped gas showing the approach to an asymptote.

Curve III.—This is the profile for a gas-doped system with an intrinsic substrate. N_x theoretically approaches zero at the interface. This profile will approach the asymptotic limit defined earlier for thick films.

Curve IV.—This is the generalized profile for the case where both the substrate and the gas phase are doped. As the gas doping contribution increases, the asymptote moves up. It is apparent that the gas-phase doping contribution will alter the slope of the curve and also affect its straightness on the semilog plots.

There are only two constants involved in these expressions. They are b, the gas-phase mixing constant, and a, the constant involved in the HETP. If the gas-phase concentration is known accurately, then b may be determined by an analysis of the curves, and α may then be calculated. Unfortunately, the gas-phase concentrations generally are not known with sufficient accuracy and, in fact, are usually adjusted by trial-and-error to give a specified film resistivity. Also, there is the added difficulty that the desired gas-phase concentration is that of the working gas near the surface rather than the ambient supplied by the saturator. The working gas may contain miscellaneous contributions

Table I. Doping profile equations for hypothetical epitaxial growth process

Case	For any x-value	For large x-values
Substrate and gas doping (general)	$N_x = N^*_o\alpha^{ax} + \alpha bn\left(\frac{1-\alpha^{ax}}{1-\alpha}\right)$	$N_x = N^*_o\alpha^{ax} + \alpha bn\left(\frac{1}{1-\alpha}\right) = N^*_o\alpha^{ax} + \left(\frac{N^\circ}{n^\circ}\right)n$
Substrate doping only	$N_x = N^*_o\alpha^{ax} = N^*_o e^{-\phi x}$	$N_x = N^*_o\alpha^{ax} = N^*_o e^{-\phi x}$
Gas doping only	$N_x = \alpha bn(1-\alpha^{ax})/(1-\alpha) = [\alpha bn/(1-\alpha)](1-e^{-\phi x})$	$N_x = \alpha bn\left(\frac{1}{1-\alpha}\right) = \left(\frac{N^\circ}{n^\circ}\right)n$

from the system, the pedestal, and the slice backside (2).

Discussion

Experimentally it is found that substrate dominated (*i.e.*, purified gas phase) profiles appear to decrease exponentially with distance from the substrate. Also, it is found that, with sufficiently thick films, the profiles approach an asymptotic limit defined by the gas-phase doping level. For purified silicon tetrachloride, the asymptote is below about $5 \times 10^{13} cc^{-1}$. As the gas-phase doping level is increased, the asymptote moves up, and the shape and slope of the profile are modified accordingly. These observations are consistent in form with predictions which derive from the counter-current model.

The model suggests that the profile slopes should be temperature dependent. However, neither the quantitative dependence of the slopes nor the location of the interfacial intercepts may be predicted from the model. Experimentally it is found that the slopes decrease with temperature and that the exponential portion of the profile pivots about a point in the vicinity of the interface. A practical consequence is that flattening the profile by decreasing the growth temperature also produces a lower film resistivity at a given thickness level. This effect is opposite to that which would be produced by a diffusion phenomenon. This problem may be offset somewhat by increasing the substrate resistivity and thus shifting the location of N^*_o. The ultimate limitation will be that of device specifications on substrate resistivity since a very large shift in substrate resistivity is necessary to produce a factor-of-ten shift in N^*_o.

We have found that for given experimental conditions the mean film resistivity generally increases with film thickness. This observation also is consistent with the preceding points.

The position of the gas-phase mixing constant b in the profile expressions indicates that a higher dilution factor in the working gas volume should produce a more rapid approach to the asymptote and, consequently, a more nearly flat profile. If the working gas volume extends sufficiently far into the gas phase, this might be accomplished by higher gas velocity, etc.

For the counter-current model, as stated, the amount of substrate dopant involved in the initial etch-back step is the total amount available for redistribution throughout the film. Table II shows the integration of the profiles in Fig. 9 from N^*_o to 10^{13}. For the lower growth temperatures this, of course, requires a considerable extrapolation of the profiles. The dimension of the third column is atoms-cc^{-1}-micron. If we assume etch back into a substrate with a uniform doping level at 2×10^{19} then the required etch-back distance is about 1-6Å. The calculations in Table II are based on experimental data from runs with purified $SiCl_4$, where the ambient gas-phase contribution to the integrated value is negligible. The etch-back concept has been discussed elsewhere (9, 10).

Table II. Computed etch back distance based on a substrate surface concentration of 2×10^{19}

Temp, °C	x at 10^{13}, μ	$\frac{N^*_o}{\phi}(1 - e^{-\phi x})$	Etch back distance, Å
1060	66.5	1.16×10^{16}	5.77
1105	20.7	2.48×10^{15}	1.74
1150	10.1	2.11×10^{15}	1.05
1180	9.5	2.08×10^{15}	1.04
1220	7.9	2.01×10^{15}	1.01

A second point not explained by the model is the fact that N^*_o is about $N_{sub} \times 10^{-4}$ for heavily doped substrates and about $N_{sub} \times 10^{-1}$ for lightly doped substrates. These two points indicate that the nature of the process at the boundary layer is not clearly understood and that the counter-current model should not be interpreted in a literal mechanistic sense. Infrared and electron microscope studies of surfaces of n-type silicon (doped in the range of 2×10^{19}) show considerable changes in the surface properties of the starting substrate material as a function of the heat treatment given the substrate prior to film deposition (11). Furthermore, the numerical value of N^*_o has been found to be sensitive to the heat treatment conducted prior to film deposition.

Equation [5] indicates the nature of the dopant/silicon ratio in the working gas phase. It was assumed that, on the deposition half of a cycle, the deposit occurs in this ratio. If this is not true, then the effect will be to modify the value of the term α (and consequently ϕ) without changing the form of the equation. Earlier work by Theuerer (3) indicates that the assumption is reasonable for n-type doping (phosphorus), but that for p-type doping (boron) α should be reduced by a factor of about 10.

Summary

An experimental method for determining doping distribution along the thickness coordinate in epitaxial semiconductor films has been described. The doping concentration generally is found to decrease with distance from the substrate. A model has been described which leads to a distribution expression which is in reasonable agreement with the experimental data. The model has obvious pragmatic value. However, additional information will be necessary before the kinetics and mechanism of the film growth process are clearly understood.

Acknowledgments

The authors are indebted to M. M. Atalla for valuable discussions related to the measurement method, to C. E. Shoemaker for providing the purified silicon tetrachloride, and to A. Loya for assistance with the electrical measurements.

Preparation of Epitaxial GaAs and GaP Films by Vapor Phase Reaction

R. R. Moest and B. R. Shupp

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Single crystal films of GaAs and GaP have been grown from the vapor phase on several substrates in a closed system containing source material and hydrogen chloride. The GaAs and GaP source material reacts with HCl to form gallium chlorides and elemental arsenic or phosphorus. These are transported along a temperature gradient in the ampoule and deposited at the cooler end as GaAs or GaP, several hundred degrees below their melting points. Epitaxial GaAs films have been grown on monocrystalline Ge and GaAs substrates of various crystallographic orientations and GaP epitaxial films on GaAs and GaP. The conductivity type of the films was controlled by appropriate doping of the source material. The growth rates were determined as a function of temperature and intial HCl pressure.

The successful growth of Si and Ge epitaxial films has stimulated considerable interest in methods for growing epitaxial films of III-V compound semiconductors from the vapor phase, in particular of GaAs and GaP. An inherent problem to the growth of compound semiconductors is the stoichiometry of the material. Experiments to grow some III-V compound films by simultaneous evaporation of the constituents from separate containers have been reported (1, 2). This technique, however, is for all practical purposes limited to constituents with a relatively high vapor pressure at moderate temperatures and cannot be readily applied to the controlled growth of substantial GaAs and GaP films. A more promising method appears to be the vapor growth of these compounds by a chemical reaction. Deposition from the vapor phase by a chemical reaction was first reported by Antell and Effer (3). They reacted iodides and chlorides of gallium and indium with arsenic or phosphorus in a sealed tube at elevated temperatures and grew small crystals of GaAs, GaP, InAs, and InP in the cooler end of the ampoules. The chemical methods for the preparation of III-V compounds were further investigated by Effer and Antell (4). Lyons and Silvestri (5) and Hagenlocher (6) described the growth of GaAs films in a sealed tube using iodine as transfer agent. Holonyak (7) disclosed methods for the growth of III-V compound films with halogen or metal halides as transfer agents, also in a closed system. Another approach to the growth of III-V compounds from the vapor phase is the open flow method in which a steady flow of a suitable carrier gas with a reacting agent, mostly hydrogen halides, reacts with some source material at higher temperature and redeposits the compound at a cooler region of the reaction tube. Reactions of this type have been reported by Effer and Antell (4), Williams and Ruehrwein (8), and Newman and Goldsmith (9). Frosch (10) reported the evaporation of GaAs and GaP at elevated temperatures in a flow of hydrogen gas and the subsequent redeposition of the compound in a cooler zone of the system.

This communication describes the epitaxial growth of GaAs or GaP on an appropriate substrate from the vapor phase in a sealed tube initially containing HCl. These compounds were transferred from GaAs or GaP sources and deposited on a substrate at a somewhat lower temperature. Gallium arsenide or germanium substrates were used for

GaAs growth and GaP or GaAs substrates for GaP growth. The effects of growth rate on source and substrate temperatures and initial HCl pressure were determined.

Experimental

Epitaxial GaAs or GaP films were grown in sealed quartz ampoules with an ID of 9 mm and 10 to 15 cm long. One end of the ampoule was flattened so that its cross section was semicircular. After adding the source and substrate the ampoule was evacuated to 10^{-4} torr, outgassed by heating with a torch, cooled, backfilled with HCl, and sealed off. The ampoule containing the substrate at the flattened end of the tube and the source at the opposite end was heated in a furnace shown schematically in Fig. 1. Growth was restricted to the substrate by introducing a local cold spot on the ampoule directly beneath the substrate. Either a metal wire or strip extending from the substrate to outside the furnace is a satisfactory heat sink. A silver wire 1 mm in diameter with a flat button at one end was generally used. Thermocouples located beneath the source and substrate were used to measure their temperatures. The quartz tube shown on the left side of Fig. 1 supported the substrate thermocouple and cold sink. The furnace was either a 12-in. cylindrical microcombustion type or a 10-in. hinged microcombustion type. The latter proved to be very convenient with respect to ease of loading in addition to its short heat-up time. Typical temperature profiles are indicated in Fig. 1. The dotted curves show schematically the temperature profile along the bottom of the ampoule beneath the substrate. Failure to make this region the minimum temperature of the ampoule results in spurious growth (generally whiskers) on the wall.

After growth for a desired time the ampoule was cooled locally with wet asbestos and then quenched in water. Monocrystallinity and epitaxy of the deposited films were demonstrated by Laue back reflection and electron diffraction analyses.

Growth of GaAs *Films*

Epitaxial GaAs films 1μ to 2 mm thick have been grown on GaAs substrates. These films were

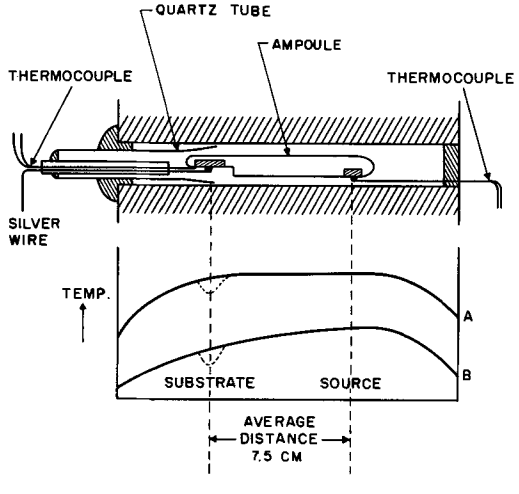

Fig. 1. Furnace arrangement for epitaxial growth and typical temperature profiles.

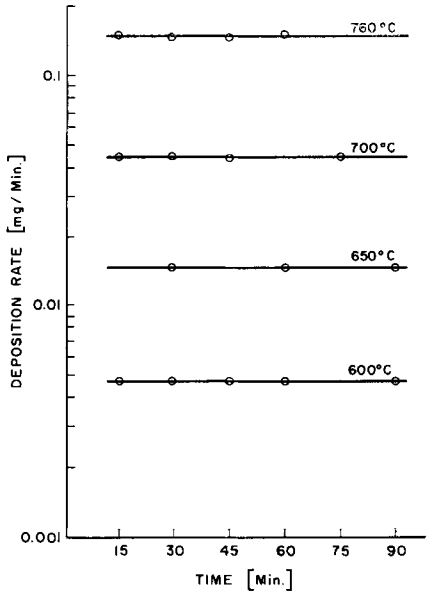

Fig. 2. Deposition rates of GaAs at various time intervals and source temperatures. Initial HCl pressure, 240 torr.

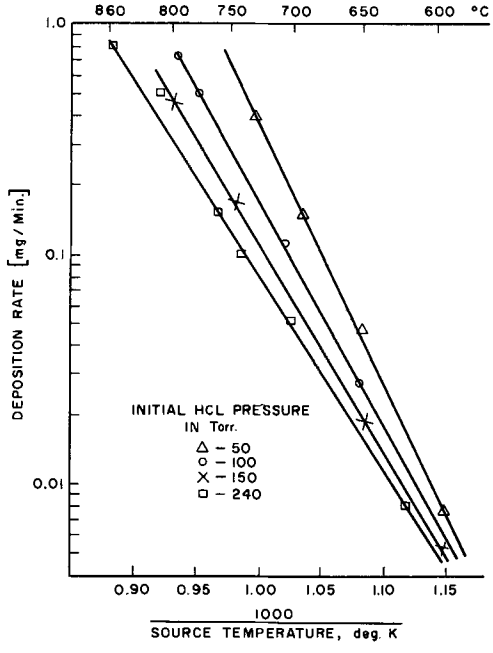

Fig. 3. Deposition rates of GaAs as a function of source temperature and HCl pressure.

either n- or p-type, depending on the conductivity type of the source. They were grown over the temperature range 550°-750°C. Source temperatures varied from 600° to 850°C. Films were grown at temperatures 20°-150°C below the source temperature. The initial HCl pressure varied from 50 to 240 torr. Within the above limits, the growth rates of the films depended only on the source temperature and the initial HCl pressure. As mentioned earlier, growth was restricted to the substrate so that the growth and transfer rates are identical. Independence of the rate on the substrate temperature is illustrated by the data in Table I. It remained constant well within experimental error when the substrate was 67°-125°C below the source temperature, 700°-707°C, and was independent of the substrate size.

Table I. Growth rate for GaAs films on GaAs substrates at various substrate temperatures. Initial HCl pressure in ampoules, 240 torr

Exp. No.	Temperatures in °C Source	Substrate	Δ Temp, °C	Growth rate, mg/min
1	707	640	67	0.054
2	700	623	77	0.045
3	700	610	90	0.049
4	700	600	100	0.048
5	700	595	105	0.049
6	700	584	116	0.048
7	703	578	125	0.049

Substrate wafers of different crystallographic orientations were used to determine possible effects on the growth rate. No variation was found for deposition on {100}, {110}, {111}, or $\{\overline{111}\}$ planes. Spherical or polycrystalline substrates may show preferential deposition on one plane. However, the over-all transfer rate is independent of orientation within the experimental conditions described above.

The growth rate is independent of time for a given source temperature and HCl pressure except for an initial starting period of less than 15 min required to establish steady-state conditions. These observations are summarized in Fig. 2.

Four different initial HCl pressures were used. The effects on growth rate are shown in Fig. 3, where the log of the growth rate is plotted *vs.* the reciprocal of the source temperature for the different initial HCl pressures. The growth rate increases with increasing source temperature and decreasing HCl pressures. Since the growth rates were found to be independent of substrate temperature, the slopes of the curves in Fig. 3 may be related to average activation energies for reactions at the source. These are 85 and 39 kcal for initial HCl pressures of 50 and 240 torr, respectively. These relatively high values indicate that the process is not diffusion limited. A strong dependence of the activation energy on the initial HCl pressure justifies an assumption that competing reactions take place at the source. Upon cooling the ampoules condensation of arsenic and gallium trichloride could be observed. Melting point determinations (77°-79°C) and chemical analyses indicated that the condensed chloride was essentially gallium trichloride. Within the analytical limits of accuracy, approximately 10%, there was no evidence of unreacted HCl.

Smooth uniform films were obtained with thickness variations of less than 10% over 60-80% of the total substrate area. Figure 4 shows interferometric microphotographs of a polished GaAs substrate and of a uniform epitaxial film approximately 2μ thick. Over the viewing field of the surface, diameter 2.1 mm, the average thickness variation was less than 0.27μ, the wavelength of the thallium light used with the interferometer. The substrate slices were generally flatlapped with Carborundum 1800 and chemically polished on a rotating Teflon plastic block in a solution of 70% sulfuric acid, 15% hydrogen peroxide, and 15% water to a mirrorlike finish (11). It was observed that the smoothness and film uniformity depended mainly on the preparation and cleanliness of the original substrate surface, and not on the crystallographic substrate orientation. Microphotographs of typical films grown by this method are shown in Fig. 5. The film surfaces are essentially free of growth patterns.

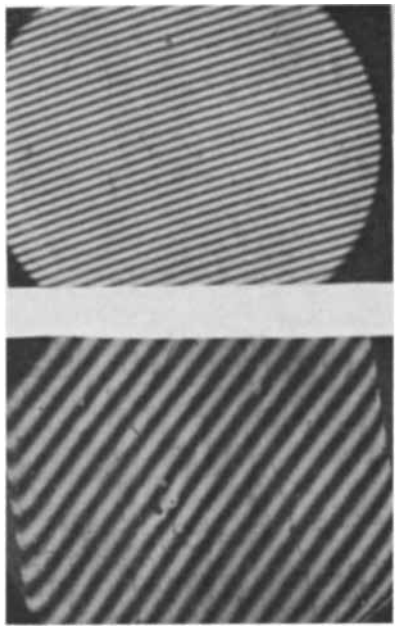

Fig. 4. Interferometric microphotographs of GaAs substrate (top) and film surface (bottom). Explanation in text. Magnification 34X.

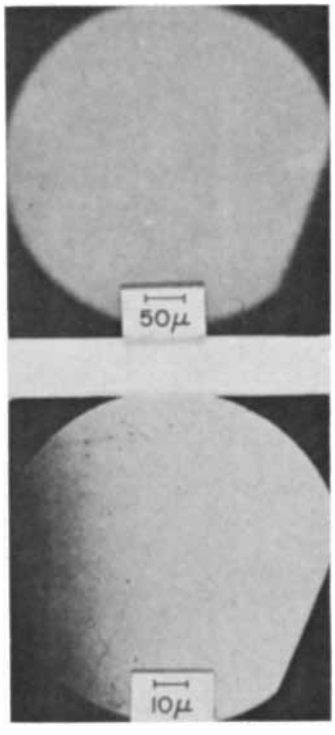

Fig. 5. Microphotographs of typical surfaces of epitaxial GaAs films. Magnification 100X.

As mentioned earlier, the conductivity type and resistivity of the films were determined primarily by the conductivity type and resistivity of the source material. Epitaxial p-n junctions have been grown with this method. Figure 6 shows a section of a typical p-n junction after angle lapping and staining. The sharpness of the junction is noteworthy. Since the sample was beveled in a 10° angle, the scale of

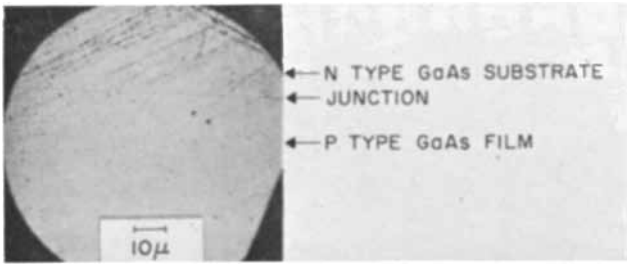

Fig. 6. Microphotograph of GaAs p-n junction. Magnification 100X

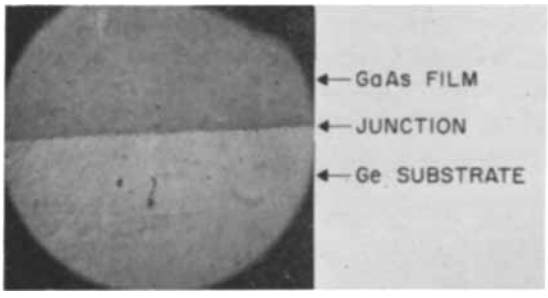

Fig. 7. Microphotograph of GaAs-Ge junction. Magnification 100X

1 cm on the photomicrograph plane perpendicular to the junction corresponds to a thickness difference of 1.7μ of substrate or film. Thus the apparent width of the junction is less than 0.1μ.

Epitaxial films of GaAs have also been grown on germanium substrate wafers. The temperature of the GaAs source material was between 680° and 780°C whereas the Ge substrate temperature was between 550°-600°C. Figure 7 shows part of an angle lapped heterojunction of a GaAs film grown epitaxially on a Ge substrate.

Growth of GaP Films

Epitaxial GaP films with thicknesses from 1μ to 100μ have been grown on GaAs substrate wafers. The temperatures in these experiments varied from 750° to 900°C for the GaP source material. The GaAs substrate wafers were generally 100°-200°C below the source temperature. Within these limits the deposition rate was independent of the substrate temperature.

Growth rates of GaP were measured as a function of source temperature at an initial HCl pressure of 240 torr. The dependence on source temperature is shown in Fig. 8. From the slope of the curve we estimate the average activation energy of the source reaction(s) to be 45 kcal. This compares with 39 kcal found for GaAs under similar conditions.

Film smoothness and uniformity were again found to depend mainly on the initial surface preparation and cleanliness of the substrate wafer. A section of a heterojunction with a GaP film on a GaAs substrate after 10° angle lapping and staining is shown in Fig. 9.

Summary

A method is described for the growth from the vapor phase of epitaxial films of GaAs and GaP on several substrates. The reaction products of either GaAs or GaP source material and HCl constitute the vapor phase. Gallium arsenide substrates were used for both GaAs and GaP film growth; Ge substrates

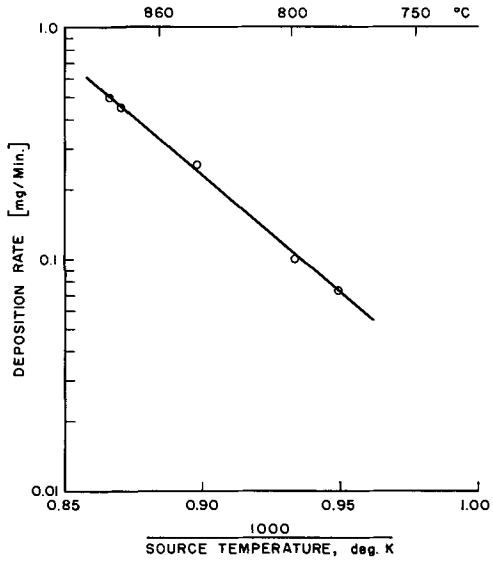

Fig. 8. Deposition rate of GaP as function of source temperature at constant HCl pressure.

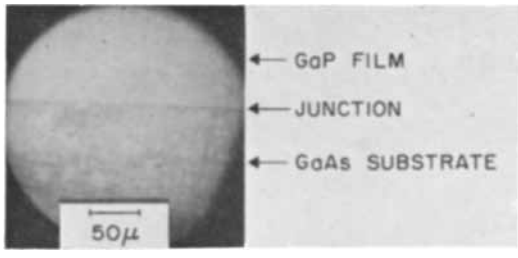

Fig. 9. Microphotograph of GaAs-Ge junction

were also used for GaAs growth. Deposition from the vapor phases was in all cases restricted to the substrate located at a cold spot in the system.

The growth rate of GaAs was dependent on source temperature and initial HCl pressure and independent of the substrate temperature or orientation. Source and substrate temperatures were in the ranges 600°-850°C and 550°-750°C, respectively. Initial HCl pressures varied from 50 to 240 torr. The growth rates were proportional to exp $(-\Delta H/RT)$ where T °K is the source temperature, R the gas constant, and ΔH is interpreted to be the average activation energy for reactions at the source. The value of ΔH was 39 and 85 kcal for initial HCl pressures of 240 and 50 torr, respectively. The strong dependence of ΔH on pressure is taken as evidence for competing source reactions. Growth rates for GaP exhibited the same general dependences as for GaAs.

The physical qualities, smoothness, and uniformity of epitaxial GaAs and GaP films were independent of substrate orientation, but dependent on the substrate surface preparation prior to deposition.

The Diffusivity of Arsenic in Silicon

W. J. Armstrong

Components Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

The diffusion coefficient of arsenic in silicon has been investigated over the temperature range of 1100°-1350°C using the formation of p-n junctions to determine diffusion depths and concentrations. Diffusion coefficients are in good agreement with previously published data, but the diffusion equation

$$D = 68.6 \exp\left(\frac{-97{,}600}{RT}\right)$$

has a higher D_o and activation energy. Surface concentrations of arsenic were in the 10^{17} to 10^{19} range.

The use of arsenic as an impurity for making diffused silicon devices has received little attention compared to boron and phosphorus. Only two references to this diffusant are known: the work of Frosch and Derrick (1), and that of Fuller and Ditzenberger (2). The former paper reports a scattering of open tube experiments with no attempt to calculate a diffusion constant. The latter paper gives data obtained from experiments carried out in sealed capsules. The present work is concerned with diffusion of arsenic from the vapor phase over the temperature range of 1100°-1350°C in an open tube system. The experimental results are consistent with a diffusion model exhibiting a complimentary error function distribution of diffusant in the bulk material.

Experimental Procedure

Three-quarter inch diameter slices were cut parallel to the (111) crystallographic direction from approximately 0.35 ohm-cm boron doped silicon. The slices were lapped with 12μ alumina, then with 5μ alumina, cleaned ultrasonically in distilled water, and polished to a mirror finish on one side with 0.3μ alumina powder on Pellon Pan-W cloth. Final sample thickness was approximately 7-9 mils. After degreasing, cleaning, and etching in HF acid the resistivity of each slice was measured on the lapped side using a four-point probe.

The arsenic diffusion was carried out in a 1¾ in. ID Zirco tube which was fitted with ground Pyrex taper joints cemented to each end. The As_2O_3 source material was placed in a Pyrex tube which was immersed in a constant temperature bath and connected to the Zirco tube via the ground joint. The Pyrex tube joining the source with the Zirco tube was maintained at a rising temperature gradient from source to silicon through the use of a glass-covered resistance-heated wire. Automatic controllers and Pt-Pt 10% Rd thermocouples maintained the SiC heated sample furnace at ±3°C while the constant temperature bath held the As_2O_3 at ±1°C. A carrier gas of 99.4% nitrogen-0.6% oxygen was dried to less than 1.5 ppm H_2O, mixed by volume, and passed into the diffusion tube at 1.5 l/m. Water vapor content was continuously scanned on a CEC Model 26-301 Moisture Monitor.

Due to the slow sublimation rate of As_2O_3 it was necessary to replenish the source supply only once in this entire group of experiments. A constant source area of about 1140 mm² was maintained, and reagent special grade As_2O_3 was used as source material. The silicon slices were diffused two or three at a time on a flat quartz slab which was removed from the furnace only long enough (5-10 sec) to place the slices.

After removing the As_2O_3 glassy layer in concentrated HF acid, the diffused slices were measured with a four-point probe to determine sheet resistivity. The samples were then beveled on a 1° block, stained with a HF, H_2O_2, H_2O etch, and photographed. Interference fringes produced with sodium light were used to determine the junction depth on the samples. Surface concentrations were calculated using curves of Irvin (6).

Results and Discussion

Junction depth as a function of time.—To determine if the surface concentration was constant as a function of time, diffusion runs were made at 1100°, 1150°, 1200°, 1225°, 1240°, 1300°, and 1350°C for

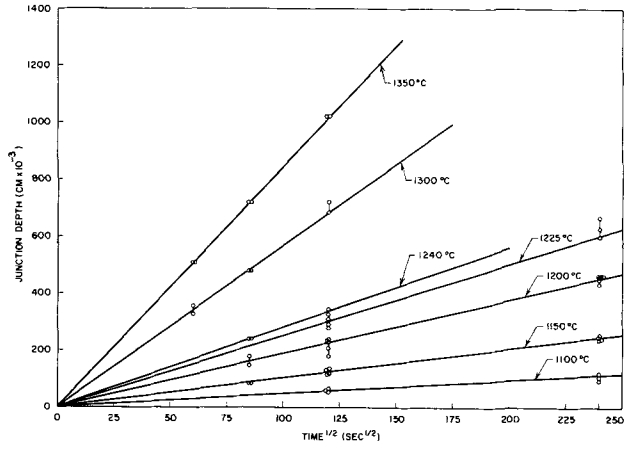

Fig. 1. Junction depth as a function of the square root of time

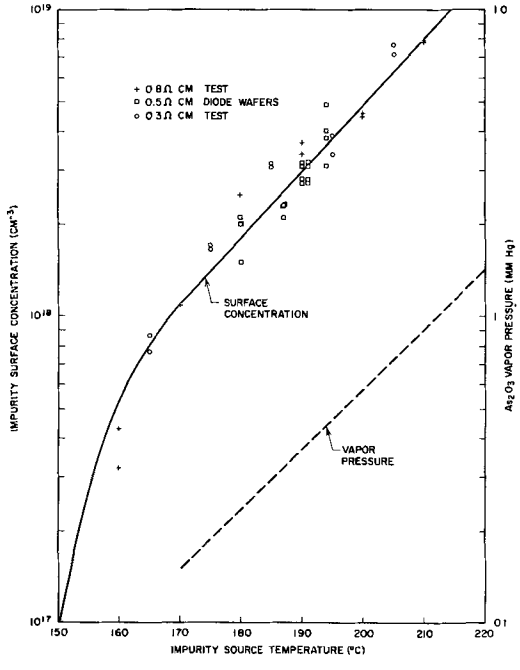

Fig. 2. Surface configuration and vapor pressure as functions of arsenic trioxide source temperature.

times ranging from 1 to 16 hr. A source temperature of 180° was used for all experiments. Results are presented graphically in Fig. 1. The junction depth is proportional to the square root of time indicating that the surface concentration is constant for the duration of the experiments.

Surface concentration as a function of source temperature.—Solution of the differential diffusion equation for these boundary conditions of constant diffusant surface concentration and a semi-infinite solid give a complementary error function distribution of diffusant. Under these conditions the measurement of junction depth, sheet resistivity, and bulk doping level permits calculation of surface concentrations from the previously mentioned curves. The results of the experiments to determine the effect of source temperature on arsenic surface concentration are shown in Fig. 2. All experiments were done at a silicon temperature of 1300°C, and carrier gas conditions were as described earlier. As expected, differences in silicon resistivity of 0.3-

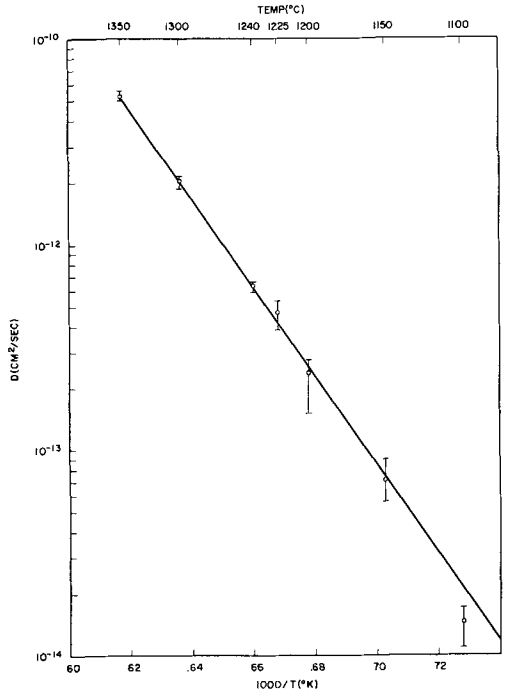

Fig. 3. Diffusion constant as a function of reciprocal absolute temperature.

0.8 ohm-cm did not appear to affect the surface concentration results.

For arsenic surface concentrations greater than 10^{18}, the natural logarithm of the impurity surface concentration is linear with the source temperature and has a slope of 0.050. A curve for the natural logarithm of As_2O_3 vapor pressure as a function of temperature is shown in the same figure. This curve is based on data from several authors given in the "Handbook of Physics and Chemistry" and extrapolated below 212°C. This curve, which also approximates a straight line in the region of interest, has a slope of 0.049. Thus, the two curves are in excellent agreement over the 170°-200°C range, demonstrating the direct relationship between impurity surface concentration and vapor pressure.

Determination of diffusion constant.—The diffusion equation solution for these boundary conditions may be written

$$C_x = C_o \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right)$$

where C_o is the surface concentration, C_x the concentration at a distance x from the surface, erfc the error function complement, t the time of diffusion, and D the diffusion constant. For each diffusion, C_x, C_o, x and t are known and D may be calculated. A plot of ln D *vs.* the reciprocal of absolute temperature is shown in Fig. 3. The slope of this curve is the activation energy for arsenic diffusion in silicon and has been determined to be 97,600 cal/mole. D_o has been calculated as 68.6 cm²/sec; the diffusion equation for arsenic in silicon is then

$$D = 68.6 \exp\left(\frac{-97{,}600}{RT}\right)$$

The paper of Fuller and Ditzenberger gives a value of:

$$D = 0.32 \exp\left(\frac{-82{,}000}{RT}\right)$$

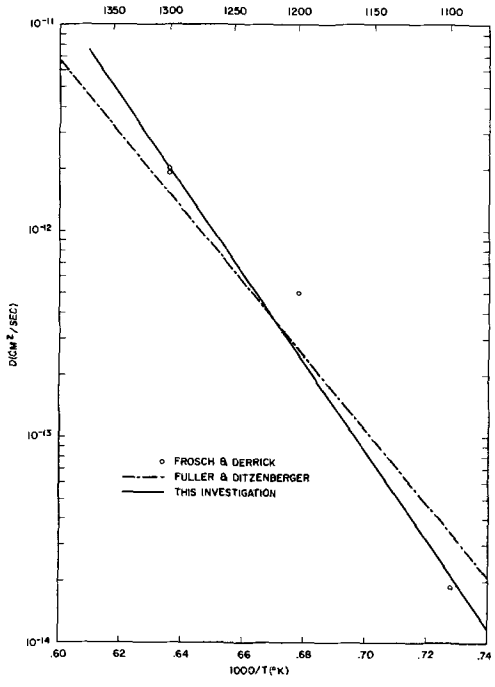

Fig. 4. A comparison of diffusion curves from this investigation with other published data.

for diffusion in sealed capsules. Not enough data are given in the paper of Frosch and Derrick to permit calculation of the activation energy; however, the diffusivity data agree much better with this investigation than with the work of Fuller as can be seen from Fig. 4.

The reason for the discrepancy in the values of ΔH and D_o between this investigation and that of Fuller is not readily apparent. It is evident from their data, however, that some irregularity with regard to arsenic diffusion is present. Fuller and Ditzenberger's classic investigation covers the elements boron, phosphorus, aluminum, gallium, indium, tellurium, antimony, and bismuth as well as arsenic. All diffusions were done in sealed capsules where the source material is maintained at the same temperature as the silicon. Thus, one would expect the surface concentration in each case to be near the solid solubility of the impurity in silicon at the temperature of diffusion. Table I gives a comparison of the surface concentrations obtained by Fuller and the solid solubilities as given by Trumbore (3).

Of the seven elements for which data are available, there is gross discrepancy for two, aluminum and arsenic. Results from the investigation described herein have shown that higher arsenic surface concentrations are obtainable than those reported by Fuller. These facts could indicate some anomaly which would effect the value of D as reported in the earlier investigation.

Table I. Comparison of surface concentration and solid solubility data for various elements in silicon

Element	Temperature	Solid solubility (Trumbore) cm^{-3}	C_o (Fuller *et al.*) cm^{-3}
Al	1300	1.7×10^{19}	5×10^{16}
	1085	2×10^{19}	3×10^{16}
Ga	1320	3.5×10^{19}	6.7×10^{19}
	1105	3.5×10^{19}	5.8×10^{19}
As	1380	10^{20}	4.5×10^{18}
	1200	1.5×10^{21}	5.8×10^{17}
Sb	1200	3×10^{19}	5.7×10^{19}
	1095	5×10^{19}	1.4×10^{18}
Bi	1305	8×10^{17}	5.4×10^{17}
	1220	5×10^{17}	1.0×10^{17}
B	1275	5.5×10^{20}	1.0×10^{21}
	1122	4.5×10^{20}	1.0×10^{22}
P	1235	1.4×10^{21}	6.0×10^{20}
	1030	1.2×10^{21}	3.0×10^{21}

A good estimate of the activation energy for arsenic diffusion can be obtained through a method suggested by Nowick (4). This estimate utilizes the value of D_o for self-diffusion which can be estimated from entropy data (5). An estimate of this type has been made for silicon by Fuller who reports a value of 0.8 cm^2/sec. It should be borne in mind that this is probably a minimum D_o and the introduction of foreign atoms will result in a change in its value. Using 0.8 cm^2/sec for D_o and the experimental value of D at the highest temperature of diffusion to minimize effects of internal surfaces, ΔH can be calculated from

$$D = D_o \exp\left(\frac{-\Delta H}{RT}\right)$$

giving a result of $\Delta H = 85$ kcal. Since this should be a minimum value, the agreement with this investigation is good.

Acknowledgments

It is a pleasure to acknowledge the contribution of T. Nagasaki who carried out many of the experiments from which data for this paper were gathered.

Growth of Silicon Bicrystals by the Dash Pedestal-Method

R. Gereth

Shockley Transistor, Unit of Clevite Transistor, Palo Alto, California

ABSTRACT

Silicon bicrystals are grown in an inert atmosphere avoiding quartz crucibles. The oxygen content of the bicrystals is below the limit of detection with the 9μ absorption line. The Dash pedestal method is modified, and the bicrystals are pulled from the melt by means of a "bi-seed" which contains a small angle grain boundary. A float zone scanner is converted into a crystal grower. A "drill press"-etching apparatus facilitates the etching of the seed crystals to a needle-like shape with the grain boundary in the center of the 0.1 mm diameter of the tip.

Small angle grain boundaries consist of a regular array of edge dislocations (1-3). Bicrystals with such boundaries are an excellent tool to investigate dislocations. From the result of grain boundary experiments one can draw conclusions about the behavior of isolated dislocations.

Silicon bicrystals have been studied in the past (4-8). Enhanced diffusion along small angle grain boundaries in silicon has been found in this laboratory (5). Phonon drag measurements in silicon grain boundary specimens have been carried out by Hubner and Shockley (6), and light emission at high voltage from a grain boundary junction has been observed by Goetzberger and Stephens (7). All these experiments were made with oxygen-rich bicrystals grown from a quartz crucible by the Czrochralski method (9). It is, however, not well known what role oxygen plays in the behavior of silicon crystals together with dislocations. Hooper and Queisser (8) recently found a strong influence of heat treatment on the photoresponse of Si bicrystals. They assumed that oxygen particularly accounts for these effects. For further studies it is, therefore, desirable to have both oxygen-rich and oxygen-free silicon grain boundary crystals available. All bicrystals obtained by the standard crucible procedure are contaminated with oxygen. This paper describes a method and an apparatus for growing oxygen-free silicon bicrystals.

Method of Growing Dash Bicrystals

Dash (10-12) describes a method of growing silicon monocrystals free of dislocations and oxygen. This procedure does not employ the quartz (SiO_2) crucible necessary with the well-known Czochralski method (9). The use of quartz crucibles gives rise to high oxygen content in the pulled crystals. With the Dash method, the crystal is pulled from the molten top of a silicon rod, commonly called the "pedestal." A seed consisting of material of low dislocation density is used. It is tapered at the tip to a diameter of approximately 0.1 mm. The crystal is pulled in an inert argon atmosphere to avoid contamination and oxidation.

For these experiments, a Dash crystal-growing apparatus was constructed. After many perfect silicon monocrystals had been grown, the equipment was used to grow grain boundary crystals with low oxygen content. Silicon material containing grain boundaries was chosen for the seeds, instead of the dislocation-free bars employed in the conventional Dash method.

Crystal grower.—A Lindberg float zone scanner (Model LA-VSE-24 ZR) was converted into a crystal grower. The basic arrangement is shown in Fig. 1.

The quartz tube, L, contains the main components of the crystal grower. The tube (35 mm OD) is

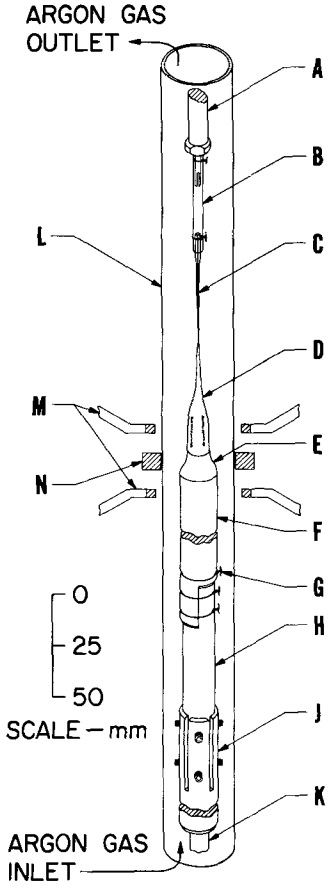

Fig. 1. Schematic drawing of the Dash crystal grower

aligned inside the heating coil, N, and shading coils, M, of the Lindberg RF generator (Model LI-10-C-1, 4MC, 10 KW). During growth, argon gas containing less than 0.1 ppm of oxygen flows through the quartz tube.

The pedestal, F, is connected to the quartz chuck, H, (15 mm diameter, 100 mm length). A slotted steel tube, J, with centering screws supports the quartz rod. The top of the rod is cut to a step shape to fit a corresponding step on the pedestal material. The parts are connected by tantalum wires. One of these wires, G, establishes the coupling of the RF field before the silicon pedestal is heated. The quartz chuck, H, insulates the hot parts of the grower. It also helps to reduce contamination of the pedestal, and improves the ease of aligning the whole assembly. The supporting shaft, K, is mechanically connected to a motor unit. Thus the operator is able to rotate and move all parts, F-K, according to any desired program.

A small quartz tube, B, is used as a "seed holder." It is connected to the elevator shaft A. The crystal, D, is pulled from the melt, E, by moving the seed, C, upward. At the same time it rotates with a constant speed of 6 rpm. The solid liquid interface is kept at a constant level by feeding the pedestal upward to compensate for the removed material.

Preparation of silicon starting material.—Czochralski-grown crystals (25-500 ohm-cm, n-type and 7-15 ohm-cm, p-type) with a diameter of about 18 mm were used as pedestal materials. The top portions of all these rods were tapered to a cone with a SiC-abrasive, while the lower parts were cut to fit the quartz chuck. Subsequently, the pedestal was etched in a solution consisting of 1 part HF (49%) and 3 parts of HNO_3 (70%).

The seed was prepared in the following way: A bicrystal containing a 10.5° grain boundary was grown by the Czochralski method using two seeds disoriented with respect to each other [as described by Mataré and Wegener (13)]. From this crystal a rectangular piece, containing the grain boundary (14) was cut (2 x 2 x 60 mm). It was lapped by hand

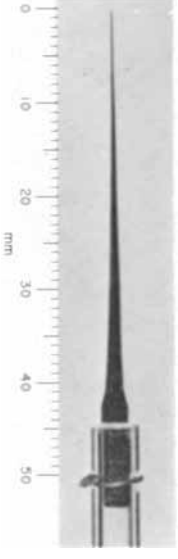

Fig. 2. Etched bi-seed containing a 10.5° grain boundary (diameter of the tip is about 0.1 mm).

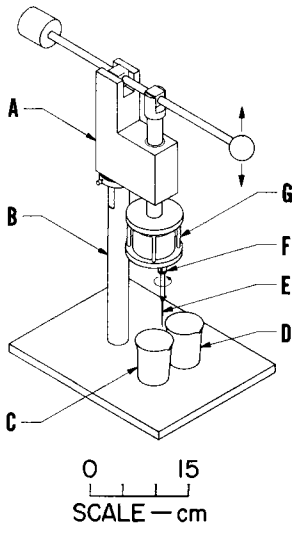

Fig. 3. Etching apparatus

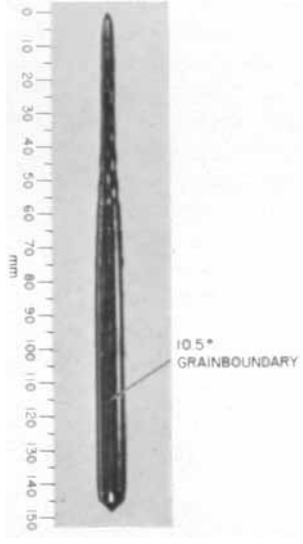

Fig. 4. Oxygen free, 10.5° grain boundary crystal with [100] pull axis.

until the grain boundary was equidistant from both sides parallel to the grain boundary plane. This "bi-seed" was etched to a needlelike shape (see Fig. 2) with the grain boundary still remaining in the center of the tip. The bi-seed must have a small diameter (approximately 0.1 mm) at the tip in order to avoid freezing of the molten silicon on top of the pedestal when the seed is lowered into the melt.

An apparatus for facilitating the etching of the seed crystals was constructed (see Fig. 3). The etching apparatus moves the seed vertically, while simultaneously rotating it at 10 rpm. This way, seed crystals can be etched very accurately to the desired concentric geometry. The etching apparatus is similar to a drill press. The supporting block, A, can be turned about the column, B, so that the seed, E, may be alternatively dipped into the etching solution, C, [1 part HF (49%), 3 parts HNO_3 (70%)] or cooling water, D. The seed is connected to the synchronous motor G, by means of the Teflon chuck, F.

Experimental Results

Figure 4 is a photograph of a Dash grain boundary crystal. The 10.5° grain boundary is seen on the

crystal surface as a fine, sharp line which is not completely parallel to the growth lines. This is caused by inaccurate orientation of the grain boundary with respect to the bi-seed. The crystal is 147 mm long and has a nearly constant diameter of 9 mm over a length of approximately 80 mm. It was grown with a starting pull rate of 4 mm/min and a final pull rate of 1.4 mm/min. The output energy of the RF generator was manually controlled to achieve optimum growing conditions, and the temperature of the molten Si was determined using an optical pyrometer.

Earlier infrared transmission measurements had indicated that Dash crystals grown from unrefined normal Czochralski crystals or from float zone refined silicon bars showed the same absorption peak height at 9μ. The absorption coefficient of all these slices was calculated to be in the order of 0.8 cm^{-1}. This value is known to be the background absorption of silicon itself (15). All measurements were carried out with a Beckman spectrophotometer (Model IR4). Since this instrument has a double-beam arrangement, the test slices cut from crystals grown by the Dash-method could be directly compared with equivalent float zone material placed in the reference path. A slice taken from the bicrystal shown in Fig. 4 was checked in this manner. No oxygen content could be detected by the 9μ absorption line.

Acknowledgments

The author wishes to express his thanks to Dr. W. Shockley and Dr. H. J. Queisser for valuable advice and stimulating discussions. He also is very obliged to K. E. Alvin who assisted in the experimental work. The help of the Stanford Research Institute in making the infrared measurements possible is gratefully acknowledged.

The Effect of Hydrogen Reduction on the Morphology of Copper Oxide Whiskers

William R. Lasko and Warren K. Tice

Research Laboratories, United Aircraft Corporation, East Hartford, Connecticut

ABSTRACT

A series of closely controlled experiments was conducted to determine the effect of hydrogen reduction on the morphology of oxide whiskers formed on unannealed and preannealed copper. Initial reduction occurred along random sites at the whisker surface. No preferential reduction at the whisker tip was observed. During the reduction cycle, the whiskers collapsed to form small irregularly shaped high-opacity nodes. Some differences were observed in the rate and manner in which the whiskers reduced on the unannealed and preannealed samples which were attributed to initial variations in size and shape of the whiskers. Selected area diffraction analyses of the reduced products revealed that the whiskers changed from CuO to Cu_2O and then to Cu. Cu_2O appeared to form adjacent to the metal surface.

Replica examinations of the oxidized-reduced surfaces when compared with replicas of the original surface revealed considerable surface rearrangement with the formation of subgrain-type structure. The size of the subgrains formed on the preannealed sample appeared to be smaller than that obtained on the unannealed sample. In most cases, the reduced oxide whisker growth products appeared to emanate from subgrain boundary intersections rather than from subboundary interiors.

Unusual growth products resembling needles, blades, serrated blades, etc., have been observed by many workers in the oxidation of metals (1-3). In most cases the growths have been identified by x-ray and electron diffraction techniques to be oxides of the base metal. The whisker shape, in some instances, has been related to the pretreatment given the metal (4) and the environment (5). The exact mechanism

by which this growth occurs is still quite obscure. Some investigators have postulated growth from the base (6) while others have indicated that growth occurs from the tip (7). To date, not too much work has been done on the effect of a reducing atmosphere on whisker morphology, particularly to determine how and where the reduction process is initiated on the whisker surface. A common assumption, although infrequently supported by experimental evidence, is that reaction occurs at dislocation sites. Unquestionably, whiskers grow by many different mechanisms and may even grow at both ends at once.

Since copper oxide is readily reduced by hydrogen at relatively low temperatures, a systematic series of experiments was conducted to determine the effect of hydrogen on the morphology of the oxide growth products. Particular emphasis in this study was directed toward determining the site or sites of initial reduction. In addition, an attempt was made to detect differences in reactivity between the whiskers formed on the cold-rolled and preannealed samples, since previous studies (8) have indicated that whiskers formed on cold-rolled copper are somewhat different in size and shape from whiskers grown on preannealed copper. Electron transmission replication and diffraction techniques were employed to evaluate the various reaction products critically.

Experimental Procedure

The copper oxide whiskers used in the reduction experiments were grown by a technique previously described (4). Briefly, high-purity (99.999%) cold-rolled and preannealed slotted copper disks (0.3 cm diameter) were oxidized in air. The disks were held in porcelain boats at a temperature of 400°C for 1 hr and whiskers were formed in the area of the slot. The annealed specimens were prepared by heat treating the cleaned, slotted disks at 450°C for 4 hr. In order to insure that the copper disks were not oxidized during the annealing step, standard precautions such as flowing argon gas over the disks prior to reaching the annealing temperature and maintaining the gas flow while the specimens were being cooled to room temperature were exercised.

Chemical reduction of the oxide growths was conducted in a specially designed tubular furnace. The whisker-coated disks were held in porcelain boats and reduced by flowing dry high-purity (99.995%) hydrogen over the boats at a rate of ~0.98 l/min. The hydrogen was dried by flowing the gas through a drying column containing indicating-type Drierite. The reaction time was varied from 1 min to 2 hr while the reaction temperature was maintained at 200° ± 2°C. Examinations were made of various specimens at various phases of reduction, but only micrographs necessary for clarity are illustrated in this paper.

Electron optical studies were performed to detect the reaction products in the area of the slot as well as the top surface of the disk as shown in Fig. 1 for both the unannealed and preannealed samples. Transmission techniques were employed primarily to detect the effect of hydrogen reduction on whisker morphology during reduction and, in particular, to determine the site or sites of initial reaction. Negatives were taken at electronic magnifications of 3000X. Prints were made by optical enlargement to 5000X and 25,000X.

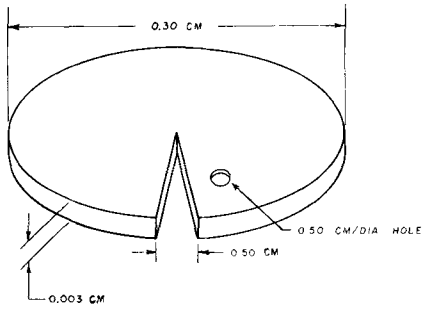

Fig. 1. V-slot copper specimen. (Not to scale)

Replicas were made of the unannealed and preannealed disk surfaces prior to oxidation and after reduction of the oxidized surface using the direct carbon-chromium, post-shadowed, and preshadowed replica techniques. High-purity, reagent-grade nitric acid was employed as the solvent for copper. Both negative and positive replicas of the oxidized-reduced surfaces were prepared. All replica micrographs were processed to the negative print stage in an attempt to simplify the interpretation of the various surface features.

Selected area diffraction analyses were conducted at various stages of the reduction cycle to ascertain the structure of the reduction products. In order to improve the accuracy of determining the lattice constants of the reduced products utilizing the selected area diffraction attachment, a method was devised for incorporating an internal standard. A small hole was punched in the area of the slot as shown in Fig. 1. After the disks were oxidized and reduced, Mg ribbon was ignited and the MgO smoke was collected along the sides of the holes. An appropriate mask was employed to restrict the deposition of the smoke to the region of the hole only. Selected area diffraction patterns were taken of the reduced products formed in the area of the slot. Without changing any of the instrumental dial settings (intermediate current, high voltage, objective current, etc.), the specimen stage was moved into the MgO-coated area and the diffraction pattern was photographed in an identical manner. The lattice constants of the oxidized-reduced products were then determined in terms of the instrumental correction factor established from the MgO standard as was previously described in ref (9).

Results and Discussion

Three methods (transmission, replication, and selected area diffraction) were used to evaluate the effect of hydrogen on the morphology of the oxide whiskers formed on unannealed and preannealed copper. Particularly, it was of interest to determine by high magnification microscopy the site or sites of initial reduction on the oxide whiskers. In addition, an attempt was made through the application of replication techniques to determine the whisker growth site as well as to determine differences in surface rearrangement produced by the oxidation-reduction

treatment on copper samples which were unannealed and preannealed.

Transmission.—Typical whisker growths induced on unannealed and preannealed copper after exposure to dry air for 1½ hr at 400°C are shown in Fig. 2a and 2b. The oxide whiskers formed at this temperature on the unannealed sample are normally thicker than the whiskers obtained on the preannealed samples as indicated in the electron micrographs. After exposure to dry hydrogen for 1 min at 200°C (Fig. 3a and 3b), the oxide whiskers show

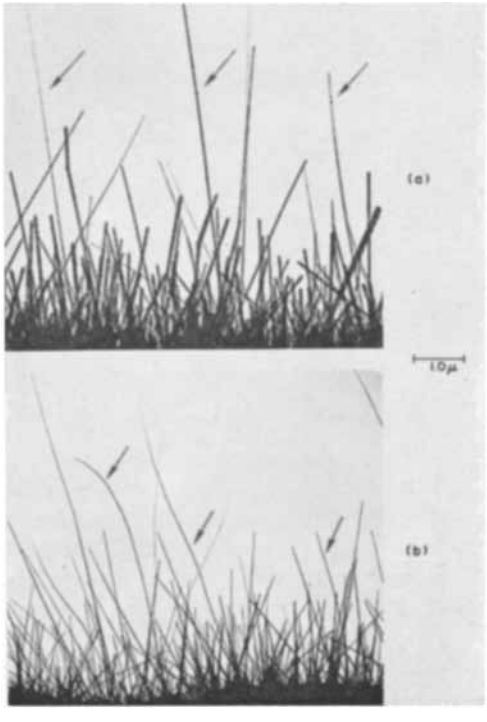

Fig. 3. Copper oxide whiskers reduced in hydrogen for 1 min at 200°C: (a) unannealed; (b) preannealed. Magnification 5000X.

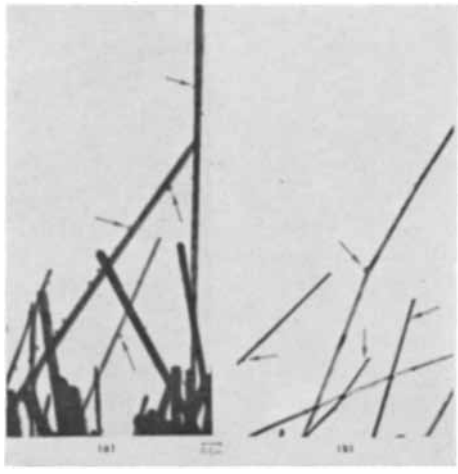

Fig. 4. Copper oxide whiskers reduced in hydrogen for 1 min at 200°C: (a) unannealed; (b) preannealed. Magnification 25,000X.

some evidence of attack at the whisker sides (revealed by untailed arrows). The attack apparently occurs more or less randomly along the whisker sides, and no preferential attack at the tip was indicated. Further examination (Fig. 4a and 4b) of some specimens at higher magnifications (25,000X) revealed that the attack proceeds with the formation of small high-capacity nodules (shown by untailed arrows) of varying size and shape along the whisker sides. No difference could be detected between the unannealed and preannealed samples, particularly in the degree of surface attack.

The micrographs in Fig. 5 illustrate the change in whisker morphology after exposure in hydrogen from 16 min to 2 hr. The amount of whisker collapse is shown to increase with time of exposure to hydrogen for both the whiskers formed on the unannealed and preannealed samples. However, the oxide whiskers grown on the preannealed sample appeared to collapse faster than the whiskers formed on the unannealed specimens. This observation is to be expected since the whiskers grown on the former are

normally thinner and longer than those grown on the latter. Further evidence of some difference in reactivity between the unannealed and preannealed samples is shown in Fig. 5c and 5f where the reduction time was increased to 2 hr. The unannealed sample still reveals small, irregular, high-opacity nodules projecting out from the surface while the preannealed sample reveals only minor variations in surface roughness.

Selected area diffraction.—Tables I and II contain lattice spacing data obtained by application of the selected area diffraction technique to the various oxidized-reduced products at different stages of the reduction cycle. The tables also list the literature *d* spacings for CuO, Cu_2O, and Cu obtained from the ASTM card file. To simplify the interpretation of the data, all high intensity lines are designated by the letter "S". In all the diffraction analyses, the selected area diffraction leaves were kept relatively close together to insure that the resulting pattern was restricted to the whisker reaction products rather than to the base oxide. In the sample that was reduced for

2 hr (Fig. 5c and 5f), the reduced products were quite small; consequently, some of the base surface was also included in the field made available by the diffraction leaves.

Prior to reduction, the whiskers show primarily the CuO structure. After reduction for 1 min, trace amounts of Cu_2O were observed, while after 16 min the intensity of the Cu_2O lines became more pronounced. However, no strict comparison between the observed and literature intensities can be made since anomalous intensities are encountered in electron diffraction. Further reduction for 32 min resulted in a mixture of CuO, Cu_2O, and Cu, with Cu_2O being the predominant oxide. Final reduction for 2 hr showed copper as the major constituent with only trace amounts of Cu_2O. No differences in structure could be detected in the reduced products formed on either the unannealed or preannealed samples.

From these diffraction results, it would appear that the oxide whisker growths initially reduce from CuO to form Cu_2O and then ultimately from Cu_2O to Cu. It is suspected that the small spherical opaque-shaped droplets (shown by untailed arrows in Fig. 5b and 5e) are Cu, with the remaining portion of the collapsed whisker (shown by tailed arrows) being a mixture of Cu_2O and CuO. Since trace amounts of Cu_2O were present even after 2 hr of reduction, it would appear that in the reduction process of the mixed oxides (CuO and Cu_2O), Cu_2O is the final oxide to be reduced to Cu. CuO is the principal oxide component in the whiskers.

Replication.—In electron transmission studies of specimens of the type shown in Fig. 1, particularly in the area of the slot which exhibits considerable depth to the electron beam, it is possible to obtain a false impression of the over-all product distribution. This is attributed to the large depth of field in the electron microscope where the maximum thickness permissible for specimens in electron microscopy is normally less than the depth of field. As a result, relatively sharp images of the reduced-oxide products will be obtained regardless as to where the products are situated in relation to the object plane of the specimen. In order to offset this problem, particularly in determining the manner in which the oxidized-reduced products are distributed, a direct carbon replica technique was utilized. Typical electron micrographs of the unannealed and preannealed surfaces prior to the oxidation-reduction treatment prepared by the positive replica technique are shown in Fig. 6. The unannealed sample (Fig. 6a) reveals considerable surface roughness such as striations and pitting possibly instituted by the cold-rolling process. On the other hand, the preannealed surface (Fig. 6b) is relatively free of pits, but numerous surface striations are still evident. The formation of what appear to be subgrains (shown by untailed arrows) is also revealed.

After subsequent oxidation at 400°C in air for 1½ hr and reduction in hydrogen for 2 hr at 200°C, considerable alteration of the surface topography had occurred for both the unannealed and preannealed samples, Fig. 7. The hydrogen-reduced topography of the unannealed sample shown in Fig. 7a no longer resembles the surface prior to oxidation (Fig. 6a). Large grain boundaries as well as surface striations are no longer evident. Instead "patch-like" areas which may be subgrains ranging in size from ~0.1 to 1.0μ are readily visible. Metal-coated carbon shells (light areas on the micrograph) of the reduced oxide whisker growth products are distributed randomly over the surface. From the size of the shells it would appear these represent clusters of reduced-oxide whisker growths (Fig. 5c) rather than individual whiskers. In some instances the shells cast shadows (illustrated by an untailed arrow) indicating these regions are elevations. In other areas the shadows are on opposite sides of the shells indicating that some of the shells may represent depressions. It is more probable that these shells are located in the valleys between two subgrains and consequently receive no metal during shadow casting. Similar type structures can be observed in the reduced oxidized surface of the preannealed sample (Fig. 7b). However, the size of the subgrains on the preannealed sample appears somewhat smaller. Close inspection of the micrograph also reveals that the shells appear to emanate from subgrain boundary intersections. Fur-

ther examination of the micrographs particularly at the shell-subgrain interfaces reveals that the subgrains appear to form around the reduced whisker growth products and definite interface boundaries are formed. It is not conclusively known whether the whiskers and the base oxide reduce in a similar manner. However, it is suspected that the physical processes (liberation of copper from the lattice of the oxide and subsequent condensation of the copper atoms to produce the rearrangement of the surface) occurring in the reduction rearrangement of the whiskers are somewhat different from those occurring in the base oxide. Otherwise, if the physical processes of reduction were similar for both the whiskers and base oxide, it would be reasonable to expect that there would be no resolvable differences in topography between the reduced-oxide whisker sites and the base oxide subgrain boundaries.

High magnification examinations (Fig. 8) (13,300X) of the same surfaces further reveal the extent of the surface rearrangement resulting from the reduction treatment. At this magnification the characteristic subgrain structure with the carbon shells of the reduced whisker products is clearly revealed. Projections (shown by tailed arrows) are easily distinguished from the depressions (shown by untailed arrows). Some subboundary migration is also indicated (open untailed arrows). Close examination of the shell-type structures also reveals that the carbon layer around the depressions and elevations has partially collapsed accounting to some extent for the unusual shapes. The lack of shadows behind some of the shells (shown by untailed arrows) is believed to be caused by the variation in topography of the subgrains. The reduced oxide whisker products in this case are emanating from a valley between a cluster of subgrains whose faces are relatively normal to the electron beam. As a result, during the preshadowing step employed in the preparation of the direct positive carbon replica, these areas would receive no metal and appear as depressions.

To substantiate these observations, negative replicas were prepared of the same specimens. In this technique, since it represents a reverse of the true surface, the low regions between subgrains should cast shadows while the narrow valleys would appear as wavy white lines. From the micrographs shown in Fig. 9, it would appear that these observations have been substantiated. The white outlines surrounding the reduced-oxide whisker products represents a long dimension of carbon or carbon and metal to the electron beam. At these regions on the replica, increased inelastic scattering occurs accounting for the abrupt change in photographic density observed on the micrographs. In addition, when comparing the distribution of reduced-oxide products (Fig. 5c and 5f with Fig. 7a and 7b), it would appear that product distribution shown by the shadow images in Fig. 5c and 5f are somewhat exaggerated.

Conclusions

From these studies it has been demonstrated that both transmission and replication electron microscopy are required to define completely the manner in which the oxide growth products reduced on copper. The studies have shown that the oxide whiskers reduce more or less randomly at the sides with no indication of preferential reduction at the tip. On this basis, one could perhaps conclude, if the assumption is made that the reaction occurs more readily at a dislocation site, that the mechanism of growth in this case was basal growth rather than growth from the tip. This assumption is based on the proposition that a growth step exists at the whisker tip. In order for the tip growth mechanism to be operable, it is required that the whisker tip be a much better heat sink for the oxidation products than the whisker sides or the base oxide layer. However, this is purely a qualitative assumption which is difficult to prove experimentally. There is also some probability that the oxidation growth and reduction processes are not morphologically equivalent. On this basis the transport mechanisms for the oxidation and reduction processes would be dissimilar, and no quantitative conclusions for the failure to observe reduction at the tip can be made.

The observation that reduction occurred along the whisker sides may indicate the formation of defects, such as growth steps, whereby reduction occurs preferentially. However, transmission and replication examinations of individual whiskers revealed rela-

tively smooth surfaces. It is interesting to note in the replica examinations of the oxidized-reduced surfaces that the reduced products appeared to emanate from subgrain boundary intersections rather than from the interior. This is understandable since a greater concentration of dislocations is expected at the boundaries than at the interior of the grains. It is hoped through the controlled oxidation and reduction of thin metallic foils, planned for the future, that the role of specific dislocations in the whisker growth process and the nature of the growth site will be more clearly defined.

High-Temperature Electrical Conduction in the System UO_2-ZrO_2

H. A. Johansen and J. G. Cleary

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A method for determining the a-c electrical conductivity of ceramic oxides to 2000°C in neutral atmosphere is described. The electrical conduction of the system UO_2-ZrO_2 is investigated. All compositions of $(UO_2)_x$ $(ZrO_2)_{1-x}$, where $0.1 \leq x \leq 0.9$, show two modes of conduction: a low-temperature region below about 1100°C with an activation energy of 0.26 ev, and a high-temperature region with an activation energy of about 1.59 ev.

The property of electrical conduction in refractory ceramic oxides has been a relatively neglected study until recent years. High-temperature measurements, in particular, have been scanty and the results frequently conflicting.

It was the purpose of the present investigation to develop a technique for measuring electrical conductivity to 2000°C and to use this technique to examine the electrical behavior of a ceramic oxide system which combined both wholly ionic and wholly electronic type conduction. The system UO_2-ZrO_2 was chosen because no previous high-temperature conductivity data were available for this system, and recent published work on UO_2 and on CaO stabilized ZrO_2 afforded a convenient starting point.

The high-temperature electrical conductivity of $(CaO)_{0.15}(ZrO_2)_{0.85}$ has been measured by Kingery, Pappis, Doty, and Hill (1), and their results indicated that over the range 700°-1725°C the conductivity, σ, could be represented by the relation

$$\sigma = 1.50 \times 10^8 \exp\left(\frac{-1.26}{kT}\right) \qquad [1]$$

where k is the Boltzmann constant and T the absolute temperature. Measurements of the conductivity under varying partial pressures of oxygen indicated no dependence on oxygen pressure; hence conduction in $(CaO)_{0.15}(ZrO_2)_{0.85}$ was judged to be due to the presence of oxygen ion vacancies, the number of which is fixed by the composition.

The case for the conductivity of UO_2 is less clear. Willardson, Moody, and Goering (2) have summarized the more recent data on the electrical conductivity of UO_2. The electrical properties of nonstoichiometric UO_2 have been studied in a recent paper by Aronson, Rulli, and Schaner (3). The material behaves as an amphoteric semiconductor; that is, the sign of the current carrier may be plus or minus depending on the composition. Nonstoichiometric UO_2 is therefore an electronic conductor. The sensitivity of the electrical conductivity to a variety of factors is attested to by the wide variations in conductivity values reported in the literature.

Experimental

Material.—Materials used were a commercial grade ZrO_2 with an analysis of 99.8% $ZrO_2 + HfO_2$ with Cu, Ti, and Fe as principal impurities. Hafnium was determined to be about 1%. The UO_2 was prepared from U_3O_8 by hydrogen reduction. Analysis showed UO_2 to be 99.9% with Si as chief impurity. No special attempt was made to avoid the slight oxidation of UO_2 attending the mixing and briquetting operations prior to the firing of the UO_2-ZrO_2 specimens in argon. However, there is no question that some slight oxidation occurred so that the initial firing composition of urania should properly be referred to as UO_{2+x}. X-ray diffraction patterns for the UO_2 showed only the cubic phase and an $a_o = 5.466$Å.

Preparation of specimens.—The mixed powders were pressed in carbide dies at approximately 50,000

psi with no binder, and the briquets were fired in argon in a split graphite resistor furnace to 1900°C for approximately 15 min. The fired briquet was then ground, re-pressed, and refired as before. This procedure produced a well-sintered cylinder 1 x 2 cm with densities between 65% and 70% of theoretical.

The sintered briquets were then coated on the ends to obtain a low ohmic contact. This was done in two ways, either of which appeared to be satisfactory: a coating of $TaSi_2$ was applied by means of an argon plasma jet, or a coating of platinum could be obtained by painting on platinum paste.

X-ray diffraction.—X-ray powder diffraction patterns were obtained for all compositions of $(UO_2)_x(ZrO_2)_{1-x}$ prepared. The pattern for $x = 0.1$ showed what appeared to be a cubic phase plus traces of monoclinic ZrO_2. At $x = 0.15$ only the cubic phase was obtained. However, published phase diagrams indicate that the first phase formed is actually a face-centered tetragonal phase with c/a ratio nearly equal to one. At $x = 0.2$ a second phase was detected by the presence of a slight splitting of the lines. This indicated the phase boundary between the face-centered tetragonal and the face-centered cubic plus face-centered tetragonal region. The two phase region then continued to about 70 mole % UO_2. From $x = 0.7$ to 1 the patterns showed the face-centered cubic structure of UO_2.

Electrical conductivity measurements.—Measurements were carried out from room temperature to 2000°C. The range from room temperature to 1000°C was obtained using a conventional split tube furnace and argon atmosphere. The range from 800° to 2000°C was obtained by use of a split graphite resistor furnace with argon atmosphere. Temperature in the lower range was measured by thermocouple and in the higher range by optical pyrometer.

Alternating current conductivity measurements were made using a General Radio Impedance Bridge, Type 1650-A. This instrument gave satisfactory readings on the oxides down to approximately 0.2 ohm-cm.

In order to establish the reliability of the measuring apparatus, the conductivity of $(CaO)_{0.15}(ZrO_2)_{0.85}$ was determined to 2000°C. The plot of the logarithm of the electrical conductivity *vs.* the reciprocal temperature gave a straight line which was represented by the relation

$$\sigma = 1.27 \times 10^3 \exp \frac{-1.26}{kT} \qquad [2]$$

Our value for the activation energy, 1.26 ev, agrees directly with the value of Kingery, Pappis, Doty, and Hill (1) as shown in Eq. [1]. Our somewhat lower pre-exponential term probably reflects the lower density of the specimens. Since quite similar results were obtained using different methods of preparation, the apparatus and techniques were considered provisionally satisfactory.

Results and Discussion

Figure 1 shows the plot of the logarithm of the conductivity *vs.* the reciprocal temperature for the composition $(UO_2)_{0.1}(ZrO_2)_{0.9}$, and for comparison, the composition $(CaO)_{0.15}(ZrO_2)_{0.85}$. The curve for

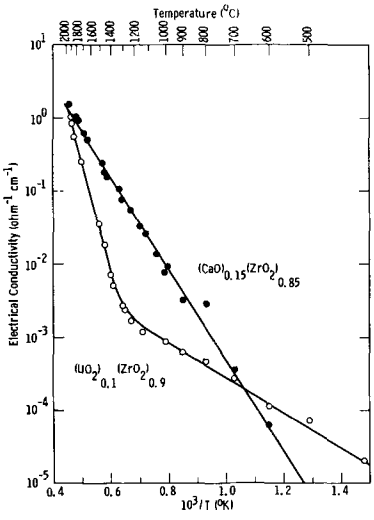

Fig. 1. Electrical conductivity for $(UO_2)_{0.1}(ZrO_2)_{0.9}$ and $(CaO)_{0.15}(ZrO_2)_{0.85}$.

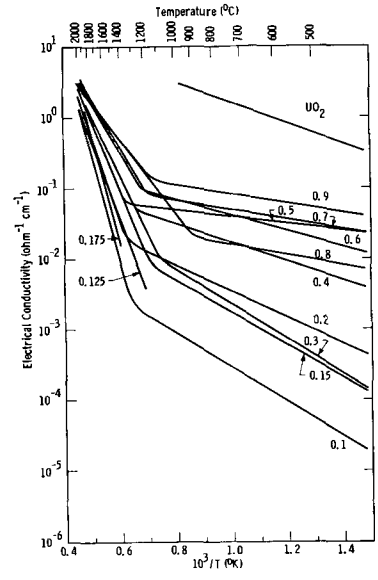

Fig. 2. Electrical conductivity for $(UO_2)_x(ZrO_2)_{1-x}$

$(UO_2)_{0.1}(ZrO_2)_{0.9}$ is seen to consist of two straight line portions which intersect near 1200°C. This behavior is typical for all compositions $(UO_2)_x(ZrO_2)_{1-x}$ where $0.1 \leq x \leq 0.9$.

Figure 2 shows the straight lines from the plot of the log conductivity *vs.* reciprocal temperature for the curves for $(UO_2)_x(ZrO_2)_{1-x}$ for x values of 0.1 to 1. While the progression is not perfect, it can be seen that the conductivity in the lower temperature region ranges steadily upward with increasing x. Conduction in the high-temperature region is also higher with increasing x. The variations from a direct progression in both high- and low-temperature regions may possibly be ascribed to variations in oxygen stoichiometry in UO_2, which are reported (2, 3) to influence profoundly the electrical properties.

From the slopes of the straight line portions of the data plotted in Fig. 2, the activation energy for each composition was calculated and the results are shown in Fig. 3 where the activation energy and logarithm of the conductivity at two temperatures are plotted *vs.* the composition. With increasing UO_2 content the

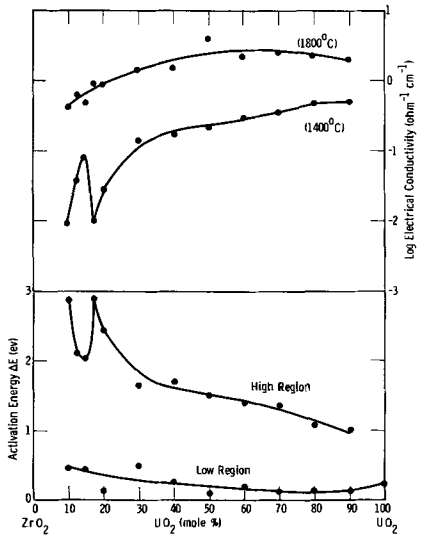

Fig. 3. Results of calculation of activation energy for each composition, from data plotted in Fig. 2.

activation energy in the high region falls sharply from 2.9 ev to a minimum of about 2 ev at 15 mole % UO_2, rises sharply again to another maximum 2.9 ev at 17.5 mole %, then falls steadily to a value of 1 ev at 90 mole % UO_2. In the low region the activation energy falls off gradually from about 0.5 ev at 10 mole % UO_2 to 0.26 ev for pure UO_2. This value for the activation energy of UO_2, 0.26 ev, agrees reasonably well with the 0.30 ev activation energy in the single phase UO_{2+x} region found by Aronson, Rulli, and Schaner (3).

The plot of the logarithm of the conductivity at 1400°C *vs.* composition in Fig. 3 shows corresponding changes with the changes in the activation energy, *i.e.*, the conductivity rises to a maximum simultaneous with the fall to a minimum in the activation energy at 15 mole % UO_2, then falls to a minimum, again corresponding to the maximum in the activation energy at 17.5 mole % UO_2. The conductivity then steadily rises to its highest value at 90 mole % UO_2. At 1800°C, the conductivity curve is much smoother, rising to an apparent maximum at about 50 mole % of UO_2, and without the pronounced maximum-minimum in the 15 mole % UO_2 region at 1400°C.

The problem of the abrupt change in slope often observed in plots of log conductivity *vs.* reciprocal absolute temperature has been examined in detail by Mitoff (4) for the case of the electronic conductor NiO. It is possible that the argument for the abruptly changing slope in NiO applied as well to the UO_2-ZrO_2 system. Our results for UO_2 (in argon), however, do not show an abrupt change in slope up to 1400°C, nor is a change in slope observed in the system CeO_2-ZrO_2 up to 1200°C as reported by Pal'guev and Volchenkova (5). However, time-temperature dependent effects in the UO_2-ZrO_2 system may be a factor and should be considered.

Considering the data as presented in Fig. 2, the tendency is very strong to believe the conduction mode in the high-temperature region, with its high activation energy, to be principally ionic. However, if the mode of conduction in the high-temperature region is ionic and proceeds by oxygen vacancy, then some other mechanism of producing oxygen vacancies in the ZrO_2 fluorite lattice must be found than the mechanism proposed for $(CaO)_{0.15}(ZrO_2)_{0.85}$: that is, oxygen vacancy production by substitution of divalent Ca ions in the zirconium lattice, thus upsetting the charge balance. In the case of UO_2, the substitution of tetravalent U in the zirconium lattice would produce no charge imbalance.

However, we may consider that the total conductivity, σ, in $(UO_2)_x(ZrO_2)_{1-x}$, $(0.1 \leq x \leq 0.9)$ is composed of the low-temperature conductivity, σ_L, where

$$\sigma_L = A_L \exp -\frac{\Delta E_L}{kT} \qquad [3]$$

and the high-temperature conductivity σ_H, where

$$\sigma_H = A_H \exp -\frac{\Delta E_H}{kT} \qquad [4]$$

In these equations A_L, A_H, ΔE_L, and ΔE_H are constants, k is the Boltzmann constant, and T is the absolute temperature. For Eq. [3] the average value for ΔE_L is found to be 0.26 ev, which is also the identical value found for UO_2. This also corresponds to the activation energy for electronic conduction in UO_{2+x} (3), but there is no indication as to the possible contribution from the ionic mode. The pre-exponential term A_L is found to be between 1 and 10^{-1}, in fair agreement with values determined from ref. (2).

For Eq. [4] an average value for ΔE_H is found to be 1.59 ev. While this corresponds to the activation energy for ionic conduction in calcia stabilized ZrO_2, again we have no indication as to the possible contribution from the electronic mode. The pre-exponential term A_H is found to show a wide scatter with values between 10^3 and 10^6, and thus is higher than the value of about 10^3 found for $(CaO)_{0.15}(ZrO_2)_{0.85}$.

The peculiar behavior of the conductivity at 1400°C in the 15 mole % UO_2 region as shown in Fig. 3 cannot as yet be explained. Repeated measurements in this region indicate, however, that the pronounced maximum-minimum at 15 and 17.5 mole % UO_2, respectively, are real. It may be possible that the variations at 1400°C are associated with phase changes, or ordering. Such a maximum-minimum in the conductivity is also shown in the systems CaO-ZrO_2 and La_2O_3-ZrO_2 as reported by Trombe and Foex (6, 7) and at the same 15 mole %. However, it cannot yet be decided whether the maximum at 15 mole % UO_2 at 1400°C in the UO_2-ZrO_2 system is associated with the stabilization of the tetragonal phase, or with the appearance of the two phase region at $x = 0.2$, or with an ordering phenomenon. The same fluctuations do not appear at 1800°C, and this may indicate that the upper consolute phase boundary suggested by Wolten (8) has been exceeded.

In summary, a method has been described for obtaining the a-c electrical conductivity to 2000°C in inert atmosphere for various ceramic oxides. The method gave good agreement with values obtained by other investigators for CaO stabilized ZrO_2.

The system $(UO_2)_x(ZrO_2)_{1-x}$ ($0.1 \leq x \leq 0.9$) has been found to exhibit two modes of electrical conduction: a low-temperature region (below about 1200°C) which obeys approximately the relation

$$\sigma_L = 5 \times 10^{-1} \exp - \frac{0.26}{kT}$$

and a high-temperature region (1200°-2000°C) which obeys approximately the relation

$$\sigma_H = (10^3 \text{ to } 10^6) \exp - \frac{1.59}{kT}.$$

The Existence and Formation of the Solid B_6O

H. F. Rizzo, W. C. Simmons, and H. O. Bielstein

Aeronautical Research Laboratories, Office of Aerospace Research, United States Air Force, Wright-Patterson Air Force Base, Ohio

ABSTRACT

The suboxide of boron, B_6O, has been prepared as a pure crystalline powder and in dense solid masses. The existence of B_6O was substantiated from crystallographic, chemical, and density data. Information on x-ray diffraction, chemical formation, oxidation resistance, and stability is also described. B_6O was found to have a greater diamond pyramid hardness than boron carbide.

Studies in this Laboratory on the oxidation of boron and the reactions in the Si-B-O system have revealed the existence of a crystalline suboxide of boron which has been identified as B_6O.

A number of investigations on the B-O system have been on the detection and identification of vapor species. Inghram, Chupka, and Porter (1) reported that between 1300° and 1500°K the major gaseous species above $B_2O_3 + B$ was $B_2O_{2(g)}$. Another gaseous species recently reported on by Kaskan, Mackenzie, and Millikan (2) is $BO_{2(g)}$. Although the condensed suboxides of boron, B_7O, B_6O, B_5O, B_3O, and BO, have been mentioned briefly in the literature only the existence of BO has been established. Wartik and Apple (3) prepared $BO_{(s)}$ by dehydration of $B_2(OH)_4$ *in vacuo*, and Kanda *et al.* (4) prepared it by reacting $B_2O_3 + B$ at 1050°C *in vacuo*. This solid amorphous suboxide was reported to decompose at 450°C. The other suboxide of boron mentioned frequently in the literature is B_7O which was reported some fifty years ago by Weintraub (5). He prepared the suboxide by the reduction of B_2O_3 with Mg. This suboxide was frequently referred to as "Moissan's boron" since Moissan prepared his boron by the Mg reduction of B_2O_3. Kahlenberg (6) produced evidence that the B_7O was a mixture of B_3O and B. Chemical analysis of a similar material by Pasternak (7) had a composition $B_{6.6}O$ which he concluded to be the compound B_7O. Pasternak also determined the structure of B_7O to be orthorhombic with $a = 8.21$, $b = 5.35$, $c = 5.13$Å, and a density of 2.64 g/cm³. One of the difficulties in establishing the correct composition for this oxide is that only boron was determined with the difference assumed to be oxygen. Thus no consideration was given to the possible solution of Mg in the suboxide or the presence of small amounts of MgB_6 or MgB_{12}. In a study of the Si-B-O system (8) it was found very difficult to prepare B_6O free from SiB_6 unless the composition, temperature, and particle size of the reactants were all controlled. A series of papers by Mikheeva and co-workers (9) elaborate on the problem of producing boron by the reduction of boron oxide and show the effect of various methods of preparation on the amount of bound boron (in suboxides or boride).

Formation

We have observed the presence of B_6O after the oxidation of boron in air and O_2 above 1100°C (10), as a reaction product between B and B_2O_3, and as a reaction product between Si and B_2O_3. It was determined, by reacting mixtures of B_2O_3 and boron in oxidizing and inert atmospheres, that the major reaction was the reduction of liquid B_2O_3 by B. The formation of B_6O from $B_2O_3 + B$ questions the validity of the thermodynamic data on B_2O_2 of Inghram *et al.* (1). However, the free energy of formation of $B_2O_{2(g)}$ from $B_2O_3 + C$ by White *et al.* (11) and the reduction of MgO by B, by Searcy and Meyers (12) were in moderately good agreement with Inghram's

data indicating that B_6O was not a major reaction product under their experimental conditions.

In studying the possible effects of $B_2O_{2(g)}$ and other gaseous oxides of boron on the kinetics of the formation of B_6O the following reactions may be considered:

$$5B_{(s)} + B_2O_{3(l)} \rightarrow B_6O + BO_{2(g)} \quad [1]$$

$$6B_{(s)} + B_2O_{3(l)} \rightarrow B_6O + B_2O_{2(g)} \quad [2]$$

$$6B_{(s)} + B_2O_{3(l)} \rightarrow B_6O + 2BO_{(g)} \quad [3]$$

$$2B_{(s)} + 2B_2O_{3(l)} \rightarrow B_6O + 3O_{2(g)} \quad [4]$$

$$5\text{-}1/3B_{(s)} + 1/3B_2O_{3(l)} \rightarrow B_6O_{(s)} \quad [5]$$

Although no thermodynamic data exist for B_6O, it is possible by considering the effect of the gaseous products to select the reactions which would be more likely to occur. Thermodynamically $BO_{(g)}$, $BO_{2(g)}$, and $O_{2(g)}$ would be most difficult to form so that the most favorable reactions are [2] and [5]. From existing thermodynamic data the calculated pressure of $B_2O_{2(g)}$ at 1500°K in an inert atmosphere is 2×10^{-5} atm; however, in air at 1 atm the partial pressure is 10^{-16} atm. The indication is, then, that at 1500°K a much smaller amount of $B_2O_{2(g)}$ would be formed in air than in an inert atmosphere. Correspondingly, there would be a greater yield of B_6O in He than in air. This was found not to be the case. Reactions between B_2O_3 + B in flowing atmospheres of air and helium produced comparable amounts of B_6O, thus ruling out reaction [2]. Reaction [5] was further substantiated when a molecular mixture of B_2O_3 and B corresponding to B_6O was heated at 1500°C for 1 hr in 2 atm of He. The reacted material contained B_6O and a small amount of unreacted B. The small weight loss (9%) coupled with the high concentration of B_6O clearly points out that reaction [5] is the controlling and major reaction for the formation of B_6O.

Discussion

The establishment of the composition of the suboxide has been difficult due to analytical problems and the lack of pure material. These problems would be further compounded if the suboxide was found to be merely a solution of oxygen in boron. With the method of producing pure B_6O by the B reduction of B_2O_3, the effects of the formation temperature of the suboxide on the chemical composition and lattice parameters were studied. The lattice constants of the suboxide, B_6O, prepared at 1200°, 1300°, 1400°, 1500° and partially decomposed at 1850°C were initially determined, based on Pasternak's (7) assignment of an orthorhombic cell. The data indicated a rather poor fit and a greater degree of inaccuracy than would be expected. This has recently been clarified by La Placa and Post (13) who have found that the powder pattern data of Pasternak could be indexed more satisfactorily on the basis of a rhombohedral cell with hexagonal cell constants $a = 5.37$ and $c = 12.31$Å. They also applied the formula $B_{12}O_2$ to the suboxide which would require a calculated density of 2.80 compared to Pasternak's observed value of 2.64 g/cm³ (7). La Placa and Post indicated that the discrepancy in these densities could be explained on the basis that a small amount of B_2O_3 was present. However, the presence of B_2O_3 would indicate that Pasternak's composition of $B_{6.6}O$ determined by chemical analysis would be low and thus favor a composition B_7O.

Table I. Chemical analyses of B_6O compositions

Source of B_6O*	B, w/o	O, w/o	Si, w/o	Total
B_2O_3 + 15 w/o B, 1300°C, 72 hr, air	79.50	21.2		100.7
B_2O_3 + 15 w/o B, 1400°C, 24 hr, argon	80.10	20.5		100.6
B_2O_3 + 15 w/o B, 1400°C, 24 hr, argon	80.30	20.6		100.7
	(0.017%H, 0.018% N, <0.001% Si)			
Hot-pressed B_6O (HP-21)**	79.43	20.0		99.4
Hot-pressed B_6O (HP-22)**	80.06	19.5		99.6
Hot-pressed B_6O (HP-23)**	79.85	19.9		99.8
Hot-pressed B_6O + 5 w/o Si**			2.32	
B_2O_3 + Si, 1315°C, 75 hr, air	79.1		5.28	
B_2O_3 + Si, 1370°C, 4 hr, air	77.12		5.30	

Chemical analyses reported by Paul Close, Owens-Illinois Glass Co., Air Force Contract No. AF 33(616)-7431.
* The crucible materials for B_2O_3 melts were BN for inert atmospheres and Si-B-O refractory material (8, 16) for reactions carried out in inert and oxidizing atmospheres.
** Solid samples, others are fine powders.

In the present investigation density measurements on the powdered suboxide never exceeded 2.62, and the highest density of hot pressed B_6O was 2.588 g/cc. This hot pressed sample contained less than 3% free boron. Thus it is highly unlikely that the true density is 2.80 as calculated by La Placa and Post. Assuming two molecules per unit cell and a composition $B_{12}O_2$ with the hexagonal cell constants determined for this hot pressed B_6O sample of $a = 5.395$ and $c = 12.342$Å, the calculated density was 2.59. The possibility of $B_{12}O_2$ structure with unoccupied B sites in the lattice appears unlikely in that no density above 2.64 g/cm³ was ever observed and no significant changes in lattice parameters and chemical analyses were observed in this study. From the chemical analyses shown in Table I, it can be seen that the first three entries, which are high-purity powders, fall very close to the theoretical boron content for B_6O of 80.23 w/o. It can also be seen that the boron and oxygen content totals 100.7% which indicates good accuracy and the absence of substantial impurities. The boron analysis was accomplished by conventional methods following the fusion with sodium potassium carbonate-sodium nitrate mixture as described by Close (14) and Bielstein (15). The accuracy is considered to be ± 0.15%. Boron values from three different laboratories for sample three of Table I were 80.30, 80.30, and 80.33, respectively. Oxygen content was found by the fluorination method (14) and is considered to be accurate within ±0.5%. It appears that nitrogen, if present, is carried along and reported as oxygen. However, sample three of Table I was found to contain only 0.018% nitrogen, and of course a higher nitrogen concentration would be expected on the surfaces of the hot-pressed samples. No free boron was observed in the first three samples reported in Table I, either by x-ray diffraction or microscopic examination of the powders. The presence of free crystalline boron as low as 3 w/o could be detected in samples of B_6O by x-ray diffraction techniques. For example, hot-pressed samples HP-21 and HP-22 contained

in the order of 3 w/o free boron while no boron could be detected in HP-23. These observations were confirmed by metallographic examination of these samples. In the hot pressed samples containing 3% free boron, one would expect the total boron content to increase from 80.23 w/o to 80.8 w/o. From Table I it is seen that the boron content is somewhat low, as is the oxygen content and, consequently, the total analyzed content. This indicates that approximately 1% impurity, other than boron and oxygen, has been introduced possibly during hot pressing, *i.e.*, nitrogen from BN die, or during crushing for chemical analysis, *i.e.*, iron from steel mortar. Therefore, the composition B_6O is the most reasonable one to assume.

The interplanar spacings and relative diffraction intensities were determined on powder samples using a spectrogoniometer and are presented in Table II. Lattice parameter data on B_6O prepared at 1200°, 1300°, 1400°, 1500°C and hot pressed B_6O (small amount of free boron present) indicated only slight changes such that the volume of the unit cell remained practically constant. In addition, chemical analyses of B_6O prepared at various temperatures and presented in Table I indicate no significant changes in composition. Thus the solubility of oxygen and boron in this compound must be small. Evidence of oxygen deficiency was noted when the reddish-brown B_6O powder turned black upon heating in a vacuum in a tungsten crucible or hot pressing in BN dies to temperatures between 1850° and 1950°C. The hot-pressing cycle usually included heating to temperature within 15 min with 1-5 min soak time at maximum temperature. Chemical analysis of B_6O prepared by reacting Si + B_2O_3 mixtures (Table I) indicated a solubility of Si or the presence of SiB_6 (which could not be removed by chemical treatment). Since B_6O prepared in this manner did not conform to equilibrium conditions it would be expected that SiB_6 would be present. The possibility of Si solubility in B_6O was tested by hot pressing a mixture of 5 w/o Si and B_6O. The resulting sample was a single phase by x-ray analysis, and chemical analysis indicated 2.32 w/o Si. The extent of Si solubility and its effect on the structure and properties of B_6O are currently being investigated.

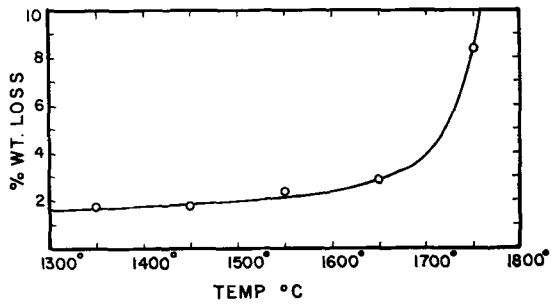

Fig. 1. Decomposition of B_6O in helium atmosphere after 1 hr

Properties

The chemical and physical properties of B_6O have not been completely established. The compound decomposes above 1760°C into crystalline boron and presumably oxygen. Figure 1 presents the weight loss, presumably oxygen, at temperatures up to 1750°C in helium. Decomposition temperature was determined by heating pressed pellets of B_6O powder in an inert atmosphere for 1-hr periods until free boron was detected. The compound is not attacked by HF, HCl, or dilute nitric acid. It can be oxidized by concentrated nitric acid if heated vigorously, and its oxidation resistance is slightly better than boron. However, it suffers from the same problems as boron in that the oxidation product B_2O_3 is a glass whose viscosity and vapor pressure at high temperatures result in a nonprotective coating. The oxidation rates of rectangular slabs (approximately 0.5 x 1.5 x 0.2 cm) of dense boron and hot pressed B_6O were comparable at 700°, 800°, 900°C. The per cent boron of the samples oxidized was, in both cases, determined to be 2.2, 4.0, and 7.4%, respectively, on weight gain and the weight loss of B_2O_3 from the oxidized sample when treated with a HF solution. The only physical property that has been explored is its hardness which was found to be greater than all commercially available materials except diamond and Borazon. The average Vickers hardness (100-g load) of B_6O was 3820 kg/mm^2 as compared to 3450 for B_4C and 3100 for TiB_2 which were also tested.

Ionic Movement during the Growth of Anodic Oxide Films on Aluminum

W. J. Bernard

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Anodic oxide films formed on aluminum in aqueous phosphate solutions resist hydration, whereas those formed in conventional borate solutions react readily with water. This property has been used to determine the mode of ion movement during the growth of duplex films. The results show that both cations and anions move through the films, but that the metal ion motion predominates.

During the growth of anodic films on aluminum, tantalum, zirconium, and similar metals the current, exclusive of electronic current, must be transported by metal ions, by oxide ions (or other anions in the film), or by a combination of both. Although it has not yet been definitely established which of the three possibilities is the correct one, the bulk of the work to date has favored the idea that growth is due almost entirely to cationic motion. Vermilyea's work with tantalum (1) presents a strong argument for the belief that the metal ion is the mobile species in the formation of films on that metal. In his experiments, anodic films were formed successively on the same specimen in two electrolytes which were known to give films of different chemical characteristics. The spatial relationship between the films, which were assumed to remain discrete, was then deduced by their known difference in solubility in HF solution. An objection which may be raised to this procedure is that small differences in rates of solubility of a pure film and one present in the composite film may go unobserved. Young (2) has arrived at the same conclusion as Vermilyea by establishing the relationship between the anodic film on tantalum and the residual layer on the metal (an extremely thin film of what is presumed to be an oxyfluoride of tantalum) created during the chemical polishing of the metal prior to electrochemical oxidation. However, as was recognized, the oxyfluoride layer is not a barrier layer (in the sense of the anodic oxide film) and although it may not impede the passage of tantalum ions to the electrolyte-oxyfluoride interface, there is no evidence that establishes the subsequent motion of ions once the oxyfluoride layer has been traversed. The work of Bernard and Randall (3) on aluminum is subject to somewhat the same criticism, even though in that case the existing film before anodization consisted of an air-formed oxide having barrier properties. The experiments showed only that the pre-existing oxide was covered by an anodic film, not that the original layer retained its identity throughout the course of oxidation. In other work with aluminum, Lewis and Plumb (4) used a multiple layer method in which one of the layers was tagged with sulfur-35 and its position identified by the rate of loss of radioactivity during a chemical stripping process. The results were interpreted to favor the theory of metal ion mobility, but these results are obscured to some extent because of the formation of one of the films in an electrolyte (dilute sulfuric acid) which normally gives rise to a porous film on aluminum.

On the other hand, the observations of Flint and Varley (5, 6) on the thermal and anodic oxidation of zirconium indicate that, depending on the surface condition of the metal and applied field strength, both cations and anions can demonstrate mobility during film growth. Haas and Bradford (7) have also

shown that in the formation of multiple layers of Al_2O_3 and TiO_2 oxygen must be the mobile species at least during some part of the anodic process.

The work reported here supports the idea that cationic motion is the major contributor to the growth of barrier oxides, but also indicates that there is a nonnegligible contribution from anion movement.

Experimental

Films of different compositions may be laid down on aluminum by anodic oxidation in suitable electrolytes. Plumb (8) has shown that appreciable deviation from stoichiometric aluminum oxide is obtained in films formed in aqueous solutions of potassium phosphate. The work of Hunter *et al.* (9) with sodium phosphate solutions has been interpreted in the same way. Plumb has found that films formed in a neutral solution of dilute potassium phosphate contained phosphorous equivalent to about 8% $AlPO_4$ distributed uniformly throughout the film; we have since made measurements which are in essential agreement with this. On the other hand, nearly stoichiometric Al_2O_3 may be formed in solutions of ammonium pentaborate in ethylene glycol (10). These two types of films have somewhat different chemical characteristics, among them being their relative resistance to hydration. The stoichiometric oxide becomes hydrated readily in boiling water (9, 11), whereas the phosphate-containing oxide resists attack. Hydration, if it occurs at all, does so at a very slow rate (9). This property was utilized to observe the manner of growth of the anodic films, since the degree to which a barrier oxide film has been attacked by water may be determined by the change in the capacity of the film after reaction. The procedure for this has been described in an earlier paper (11). Thus, by successively forming films of different composition on the same specimen of aluminum and comparing the rate of hydration of such composite films with the known reactions of the individual films, the position of the two oxide layers with respect to each other and to the underlying metal may be deduced, assuming that discrete layers persist under these conditions. If the individual layers lose their identity, then this also should be recognized through the hydration data.

Films were prepared in two different sequences: one set was formed in 0.1M NaH_2PO_4 solution, followed by formation in a 30% solution of ammonium pentaborate in ethylene glycol, and a second set was formed by reversing the order of electrolytes. Anodic oxidation was carried out at 25°C at an initial current density of 1.0 ma/cm² and a final current density of 0.1 ma/cm². Specimens were scrupulously washed with distilled water between formations in order to remove adsorbed electrolyte as much as possible. Electropolished aluminum of 99.986% purity was used for all experiments. After treatment with boiling water, capacitance of the specimens was measured at 25°C. The values of reciprocal capacitance are then used as a measure of the thickness of the unhydrated oxide. The data may also be expressed in terms of the equivalent barrier voltage of the films. Pertinent experimental details have been described earlier (11).

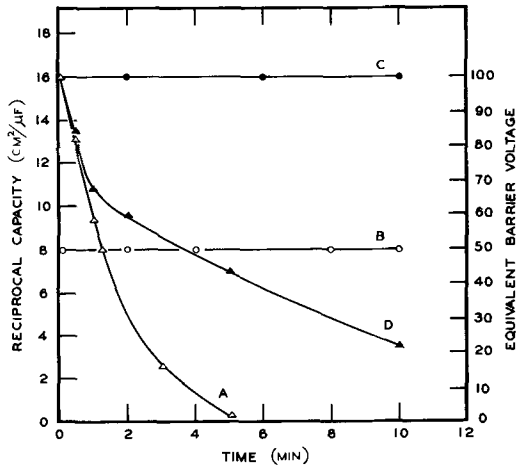

Fig. 1. Reciprocal capacitance and barrier voltage vs. hydration time at 100° for anodic oxide films: A, 100v in borate electrolyte; B, 50v in phosphate electrolyte; C, 50v in borate electrolyte and then to 100v in phosphate electrolyte; D, 50v in phosphate electrolyte and then to 100v in borate electrolyte.

Results and Discussion

In Fig. 1, curves A and B show the hydration rate at 100° of films formed to 100v in ammonium pentaborate solution and to 50v in NaH_2PO_4 solution, respectively. Over the range of reaction time considered here, the phosphate-containing film is completely unaffected by water whereas the comparatively pure oxide film is converted entirely to a nonbarrier hydrated oxide. The behavior of a film formed first in the borate solution to 50v and then in the phosphate solution to a final value of 100v is shown in curve C. It is quite clear from this plot that the outermost portion of the film must contain phosphate; this would suggest cation movement during film growth since the film has grown at the oxide-electrolyte interface. However, curve D shows that film growth cannot be attributed only to the mobility of cations. In this case the film was first formed in the phosphate solution and then in the borate solution. The rate of hydration of this duplex film at first closely follows that of the stoichiometric oxide, but begins to show an appreciable deviation from that rate at a remaining barrier voltage of about 70v. This reduction in rate can only be explained by the presence of phosphate ion in the outermost oxide layer. Furthermore, the originally formed layer is shown to be depleted of phosphate by the fact that hydration of this portion of the film can now proceed at a measurable rate. If the two layers had remained completely discrete, hydration would have ceased entirely at a remaining barrier voltage of 50v. However, it should be noted that hydration of the original phosphate-formed layer occurs at a far slower rate than with normal oxide layers, indicating that the amount of phosphate lost from this layer to the subsequently formed film probably is not very great.

The relative thickness of the two films has no effect on the results. For comparison, the curves in Fig. 2 show the behavior of films in which the nor-

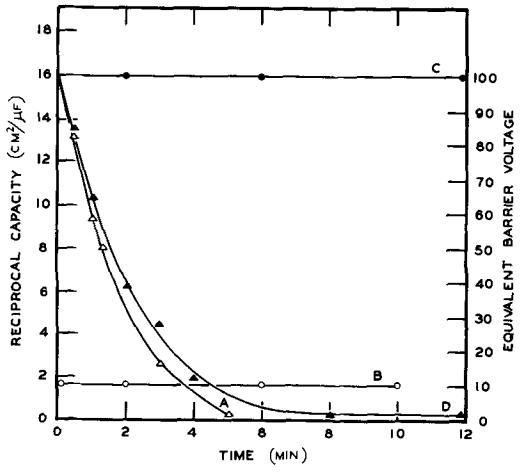

Fig. 2. Reciprocal capacitance and barrier voltage vs. hydration time at 100° for anodic oxide films: A, 100v in borate electrolyte; B, 10v in phosphate electrolyte; C, 90v in borate electrolyte and then to 100v in phosphate electrolyte; D, 10v in phosphate electrolyte and then to 100v in borate electrolyte.

mal oxide was nine times as thick as the phosphate-formed layer. In this case, in curve D, the composition of the outermost portion of the film is even more clearly shown to be that of a phosphate-free oxide. An appreciable fraction of the film must be penetrated before the mixed nature of the underlying oxide, and thus the movement of anions, is manifested.

Although these experiments show that both ions move during formation, the relative mobilities under these conditions cannot be determined. However, it is reasonable to believe that metal ion motion predominates. The work of Lewis and Plumb (4) to some extent substantiates this view since an examination of their data shows that it can be used to demonstrate a partial contribution of anion movement to film growth.

Manuscript received Jan. 31, 1962; revised manuscript received May 31, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Electrochemical Measurements at High Pressures

A. Distèche

Laboratory of General Biology, University of Liège, Liège, Belgium

ABSTRACT

*p*H measurements with a glass electrode at 1000 kg cm^{-2} give direct evidence of the pressure induced ionization constant shift and permit calculation of the corresponding volume change for the reaction $HA \rightarrow A^- + H^+$. Extrapolation at zero ionic strength and zero acid concentration is used to determine log K_{1000}/K_1 for formic acid, phosphoric acid, and phosphate buffer (step 1). Data concerning phosphate buffer (step 2), acetic acid, acetate buffer, carbonic acid, bicarbonate buffer, sodium bicarbonate, sodium acetate, and ammonia are given together with the results of direct *p*H measurements at great ocean depth (2350m). Work done in the same field but based on conductivity determinations is briefly reviewed.

The field of application of electrochemical technique in high-pressure chemistry is almost completely restricted to electrolytic conductance and galvanic cell emf measurements, the former receiving much more attention.

Conductance Measurements

New cell design [Teflon-Pt (1)] has made it possible to obtain more accurate results over a wide pressure range (1-12,000 atm) in the last 10 years. The subject has been fully reviewed by Hamann (2) and co-workers (3, 4), Ellis (5), Clark and Ellis (6), and is briefly dealt with here.

The results show that the limiting conductance of strongly dissociated salts first increases slightly up to 1000-2000 atm, but decreases at higher pressures. The effect is related to viscosity and dielectric constant changes in the solvent. HCl and KOH behave differently, their conductance being reduced much less by high pressures.

In contrast, the molal conductance of weak acids and bases increases steadily with pressure. This is due to enhanced ionization and is best demonstrated by the shift of the ionization constants (K) computed from conductivity measurements. Formic acid, acetic acid, propionic acid, carbonic acid, benzoic

acid, o-, m-, p-nitrobenzoic, salicylic, and 3-5 dimethyl-4-nitrobenzoic acid, ammonia, mono-, di, trimethyl amine (2-7) in water have been thoroughly studied, and some results are reported in nonaqueous solvents (2, 6).

Log K_p/K_1 varies almost linearly with pressure between 0 and 3000 atm. In this range, at 25°C, log K_{1000}/K_1 lies between 0.1 and 0.25 for organic acids, is equal to 0.4 for carbonic acid, and amounts to ~ 0.45 for ammonia and amines.

The basic ionization constant of ammonia at 45°C is increased from 1.9 10^{-5} mole kg^{-1} at 1 atm to 1010 x 10^{-5} mole kg^{-1} at 12,000 atm (7). David and Hamann (3, 4) have measured the conductivity of water and several liquids at shock pressures between 33,000 and 127,000 atm. The ionic product of water increases by a factor as great as 10^{12} at 127,000 atm. In these spectacular experiments, the pressures are produced by Schall's method (8) of using an explosion to drive an intense shock wave into the water. The cell is made from polyethylene and has platinum electrodes.

Some polarographic measurements at high pressure have been made by Ewald and Lim (9) and by Hayashi and Kono (10); the results are consistent with the fact that pressure shifts chemical equilibria in the direction of the more ionic species.

Galvanic Cell emf Measurements

The effect of pressure (p) on the emf (E) of a galvanic cell can be predicted from the classical relations

$$\left(\frac{\partial \Delta G}{\partial p}\right)_{m,T} = \Delta V \qquad [1]$$

$$\left(\frac{\partial E}{\partial p}\right)_{m,T} = \frac{-\Delta V}{n\mathbf{F}} \qquad [2]$$

where ΔG represents the free energy, ΔV the volume change when n Faraday ($\mathbf{F}$) are passed through the cell at constant molal concentration (m) and temperature (T).

$$\text{If } \Delta V = 1 \text{ cm}^3,\ n = 1,\ \left(\frac{\Delta E}{\Delta p}\right)_{m,T} = \frac{1 \text{ x } 0.10133}{96.500}$$

= 1.05 10^{-6} volt/atm or 1.016 10^{-6} volt/kg cm^{-2}; 0.10133 is the factor which converts cubic centimeter-atmospheres into joules.

Cohen and Piepenbroek (12) showed that ΔV can be considered independent of pressure for the cell Tl-amalgam-TlCNS, KCNS | KCl, TlCl-Tl-amalgam. Hainsworth, Rowley, and MacInnes (13) have given an integrated form of Eq. [2] for the cell Pt-H_2 | HCl 0.1N | HgCl-Hg up to 1000 atm. pH values for some standard buffers are given by Le Peintre (15) at 150 atm between 20° and 250°C, using a symmetrical Pt-H_2 cell with liquid junction (quartz cell).

In a paper published in 1959, Distèche (14) showed that the symmetrical glass electrode cell: Ag-AgCl | HCl 0.1N | glass | X, KCl 0.1M | AgCl-Ag, where X stands for various electrolytes, can be used for precise pH measurements up to 1500 atm. A similar cell has been tested for industrial use in the 0-150 atm range by Le Peintre (15). The cell assembly (whole glass) is reported to have been patented in 1957, and a few preliminary results up to 150°C are given (Pb-amalgam is used for the inner electrode), but glass corrosion very much reduces the reliability of the electrode at high temperature. Marburger, Anderson, and Wigle (16) described a glass cell capable of withstanding pressure, where one of the junction electrodes is made of lead, apparently directly deposited on the active glass (U tube).

A conventional glass electrode easily can be made to withstand 1500 kg cm^{-2} simply by applying the pressure to a layer of silicone oil, which acts as a liquid piston on the inner and outer solutions of the electrode (Fig. 1).

Figure 2 represents a cross section through part of a cell designed for laboratory work, which has some advantages compared with the apparatus described in 1959 (14). The use of araldite (potting resin) for making highly insulated pressure resisting seals around the electrical connections has been avoided. Crevices appear in this type of seal after prolonged use. The electrical connections shown in Fig 2. is a variant of that described by Poulter (17). Low-pressure leakage is avoided by the use of "O"

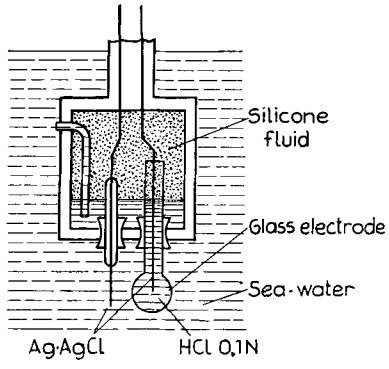

Fig. 1. Schematic drawing showing how a glass electrode can be made to withstand high pressure. From Distèche (14).

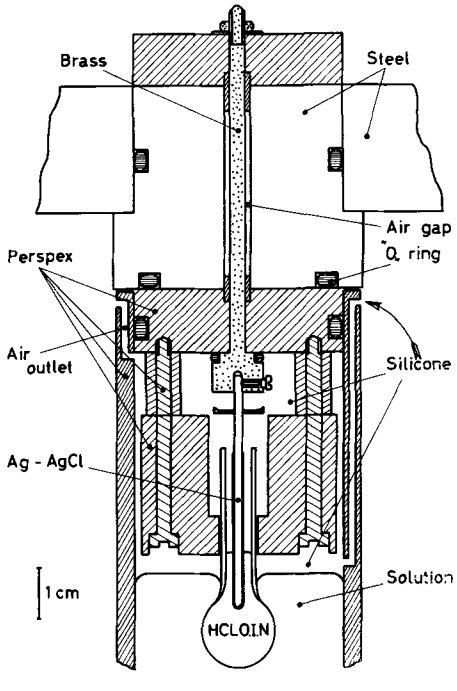

Fig. 2. Cross section through part of the glass electrode assembly

rings. The connector, which can be taken to pieces in a few minutes, is easy to build, and the insulating resistance is extremely high (>10^4 meg).

The glass electrode is blown from a Corning 015 glass tube and fits into a Perspex mounting block which occupies a volume as large as possible compared to the volume filled with silicone oil. This is to minimize heat transfer between the silicone and the solution.

The Ag-AgCl electrodes are made from pure silver wire, and the surface separating the two liquid phases falls on the AgCl coating. Silvered Pt wire, first sealed at the extremity of a glass tube, is to be avoided. The glass seal seldom stands repeated pressure application and short circuits appear at the junction between the AgCl coating and the glass stem. In fact, the greatest difficulty in these experiments lies in the Ag-AgCl electrodes. The slightest scratch or irregularity in the coating makes the electrodes behave erratically, and the defect is greatly emphasized at high pressure. Care also should be taken to eliminate dust deposits which generally gather at the liquid interface. Carefully made electrodes generally stand a week or more of intensive experimental work before showing some sign of aging. An emf hysteresis loop is observed when pressure is applied and suppressed. The Ag-AgCl electrodes then have to be replaced which means that the whole cell must be designed to be taken to pieces quickly and easily. Glass electrodes last indefinitely and, when carefuly washed and wiped, never show any defects.

The silicone oil has a viscosity of 1 cS at 25°C. The use of a liquid of low viscosity makes filling easier and air bubbles escape quickly. One disadvantage is the rather high compressibility, which means that positive or negative heat is generated in the silicone layer. It can be shown that, with a pressure step of 1000 kg cm^{-2} applied in 40 sec, the rise of temperature is 3°C in the silicone fluid, and never exceeds 1°C in the solution.

With 250 kg cm^{-2} increments applied every 5 or 10 min, it is estimated that the total temperature rise is less than 0.25°C when the final pressure is reached. The effect can be minimized further by the use of a water-jacket at constant temperature around the pressure bomb.

The results obtained with pressure resisting glass electrodes show that the hydrogen electrode constant (2.303 $RT/\mathbf{F}$) of the glass electrode is not affected by pressure. The asymmetry potential measured with 0.1M HCl or any buffer solution on both sides of the membrane varies slightly, but linearly with pressure in the investigated range (0-1000 kg cm^{-2}). The variation generally does not exceed 1 mv and is carefully determined to correct the pH measurements.

Weak Acids and Buffers

The effect of pressure on the dissociation constant (K) of a weak acid and on the activity coefficient (γ_i) of an ion species i is given by

$$\left(\frac{\partial \ln K}{\partial p}\right)_{m,T} = \frac{-\Delta V^\circ}{RT} \text{ and } \left(\frac{\partial \ln \gamma_i}{\partial p}\right)_{m,T} = \frac{V_i - V^\circ_i}{RT} \quad [3]$$

where ΔV° is the algebraic difference between the partial molal volumes of the products and the reactants of the chemical equilibrium in their standard states and V_i the partial molal volume of the ion species i.

For acetic acid, acetate buffer, phosphate buffer (step 2), carbonic acid, and bicarbonate buffer, at concentrations where H^+ is negligible compared with the stoichiometric acid or salt concentrations, it is easy to show that log K_p/K_1 can be calculated from Eq. [4] and [5], valid respectively for acids and buffers at 22°C

$$E_1 - E_p = 0.0293 \log K_p/K_1 + 0.0293 \log \frac{\gamma_{A^-1}\,\gamma_{H^+P}}{\gamma_{A^-P}\,\gamma_{H^+1}} \quad [4]$$

$$E_1 - E_p = 0.0585 \log K_p/K_1 + 0.0585 \log \frac{\gamma_{A^-1}}{\gamma_{A^-P}} \quad [5]$$

where A^- = acid anion, E_1 and E_p the emf of the glass electrode assembly at pressure 1 and P.

Figure 3 (14) shows a plot of $E_1 - E_p$ against pressure from which ΔV_1 corresponding to the reaction $HA \rightarrow H^+ + A^-$ at 1 atm in 0.1M KCl (reference electrode HCl 0.1M) can be estimated. The values are given in Table I (column 1) together with ΔV°_1 (columns 3 and 4) obtained from density and conductivity determinations ($E_1 - E_{1000\text{ kg cm}^{-2}} = 1$ mv, corresponds almost exactly to $\Delta V_{1\text{ atm}} = 1$ cm^3 (see page 1085); $E_{1000\text{ kg cm}^{-2}}$ is obtained from the slope of $E_1 - E_p = f(P)$ at 1 atm and generally coincides with the reading at 1000 kg cm^{-2}).

Except for carbonic acid ΔV_1 is always lower than ΔV°_1. Part of the difference lies in the contribution of the activity coefficient term in Eq. [4] and [5] ($\gamma_p > \gamma_1$). The data necessary to calculate log γ_1/γ_p generally are not available, but the effect of this

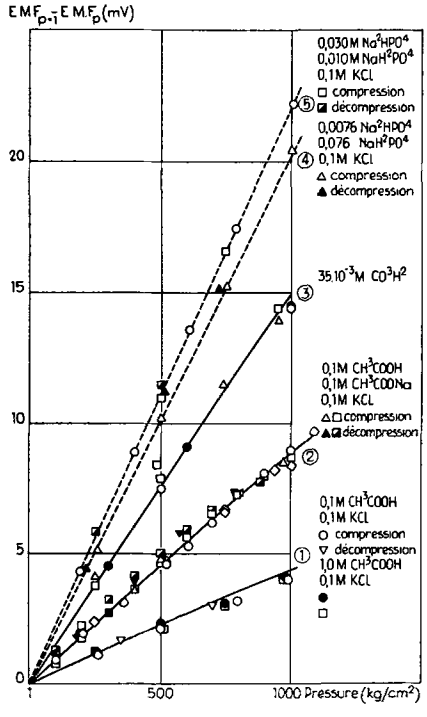

Fig. 3. Variation of the glass electrode potential with pressure for various acid and buffer solutions in 0.1M KCl (reference half-cell: 0.1M HCl). Solid lines are calculated from the data of Owen and Brinkley (11). From Distèche (14).

* The lower values are read from the curves of Fig. 3 and similar ones at 1000 kg cm⁻²; the higher values are obtained from the slope of the curves at 1 atm.

** $\Delta V^1 = -24.1$ cm³ is reported from dilatometric experiments by Linderstrom-Lang and Jacobsen (22).

factor is expected to be small (18). It also should be noticed that we have assumed so far that the pH of the reference half-cell (0.1M HCl) is not affected by pressure and that the effects of pressure on the specific electrode reactions cancel out. ΔV_1 corresponds in fact to the total volume change in the observed cell at 1000 kg cm^{-2}.

We will now describe how the $\Delta V°_1$ values listed in column 2 of Table I have been obtained.

When $[H^+]$ is no longer negligible compared to the stoichiometric concentrations, K_p and K_1 must be calculated using the classical methods to determine dissociation constants from electromotive force data.

For acids (formic acid, phosphoric acid (step 1), $E_1 - E_p$ is then given by

$$E_1 - E_p = 0.0293 \log \frac{K_p}{K_1} + 0.0293 \log \frac{(m_{HA} - m_{H^+})_p}{(m_{HA} - m_{H^+})_1} + f(\sqrt{\mu}) \quad [6]$$

where $f(\sqrt{\mu})$ stands for the activity coefficient term and m for the stoichiometric acid and H^+ concentrations on the molal scale [$m_1 = m_p = (M_1/\rho_1)_1 = (M_1/\rho_1)_p$ in diluted solutions; M_1 is the corresponding concentration on the molar scale, ρ_1 the density of water at 1 atm; the approximation $m_1 = m_p \simeq M_1$ has been used throughout this paper].

Figure 4 shows how $E_1 - E_p$ varies with the concentration M_1 of formic acid in 0.1M, 0.01M, and 0.001M KCl, the corresponding reference half-cells containing 0.1M, 0.01M, and 0.001M HCl.

Figure 4 also gives $\Delta pK' = -\log k'_1 + \sqrt{\mu_1} + \log k'_p - \sqrt{\mu_p}$ where $k' = m'^2_{H^+}/(m_{HA} - m'_{H^+})$ and $\sqrt{\mu}$ is the usual estimate for the activity coefficient term. The primes indicate the uncertainty introduced by the values of γ_{H^+} used to calculate m'_{H^+}. They correspond to the mean activity coefficient for HCl in KCl solutions, used by Harned and Owen (20) in their determinations of the dissociation constant of formic acid. As a first approximation it has been assumed that the activity coefficients do not change with pressure.

Values for $\Delta pK'$ in 0.001M KCl agree fairly well with the expected one which lies between 0.137 [$\Delta V°_1 = -8.0$ cm³ (2, 7)] and 0.150 [$\Delta V°_1 = -8.8$ cm³ (7)].

In 0.1M KCl, $\Delta pK'$ drops unexpectedly at low acid concentrations, with 0.1M HCl as reference. It is easy to show that the anomaly disappears when a small constant is added to the observed emf shifts, and there exists experimental evidence to give a meaning

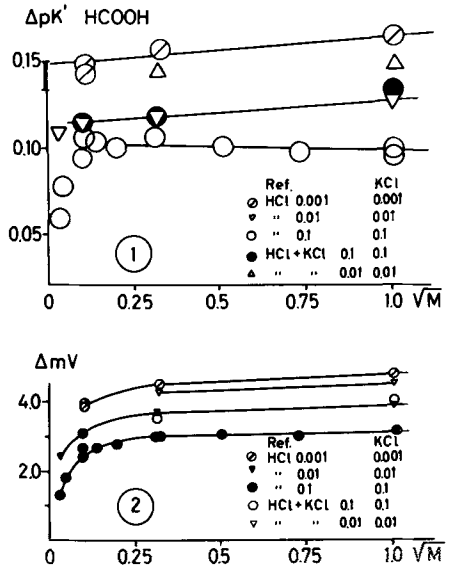

Fig. 4. Formic acid in KCl solutions. Top: $\Delta pK' = -\log k'_1 + \sqrt{\mu_1} + \log k'_p - \sqrt{\mu_p}$ (p = 1000 kg cm^{-2}) as a function of the acid concentration. Bottom: observed emf shifts (Δmv). (HCl + KCl 0.1 and 0.001 is simplified for HCl 0.01M + KCl 0.09M and HCl 0.001M + KCl 0.009M).

to this constant increment. If 0.01*M* KCl + 0.09*M* KCl is used as reference, the observed Δ mv values for formic acid in 0.1*M* KCl are about 0.8-0.9 mv greater than with 0.1*M* HCl. Similarly a 0.6 mv shift is obtained when 0.001*M* HCl + 0.009*M* KCl is used instead of 0.01*M* HCl. A further tenfold dilution of the reference solution indicates that the differences with 0.001*M* HCl are within the experimental errors (±0.1 mv), but the emf of the reference electrode shows then a slow linear drift which makes the determination of the absolute *pK* values impossible, although pressure induced emf changes are still measurable.

It is to be expected that with HCl + KCl as reference solution, the effect of pressure on the activity coefficient γ_{H^+} almost or completely cancels on both sides of the glass membrane. This might not be the case with HCl alone, except at high dilutions, but there remains the difficulty that the activity coefficient in pure HCl solutions than appears to be more affected by pressure then when KCl is present. The pH of 0.1*M* HCl would have to decrease from 1.09 to 1.075 to explain the observed shift, if γ_{H^+} in presence of KCl is supposed to remain constant. Such a large change is rather unexpected (18). Another explanation is that the asymmetry potential of the glass electrode changes with pressure when KCl is absent in one of the half-cells which might imply that the glass membrane under pressure would become slightly sensitive to K ions also. The phenomenon might also take place at the Ag-AgCl electrodes or more likely, represent the net effect of pressure on the protode reaction ($H_3O^+ \rightarrow H_2O + p$) on both sides of the glass membrane. A complete analysis of this problem needs more experiments and is beyond the scope of this paper.

Figure 5 is a plot of $-\log k'$ as a function of $\sqrt{\mu}$ to attempt to extrapolate the results both at $\mu = 0$ and zero acid concentration. The general aspect of this diagram is in reasonable agreement with the results of Harned and Owen (20) regarding the ionic strength and medium (undissociated acid) effects.

Great accuracy is not claimed for the absolute value of the dissociation constant ($pK_1 = 3.71$ instead of 3.75); it can be seen that a better value (3.74) is obtained when the results in 0.1*M* KCl

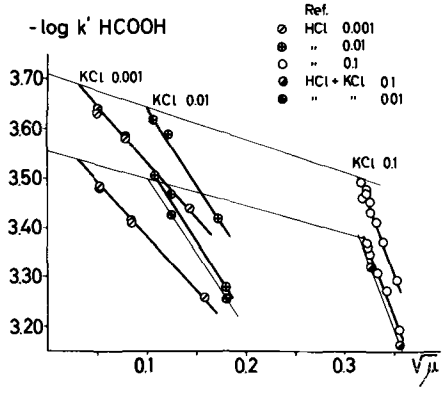

Fig. 5. Formic acid in KCl solutions. Extrapolation of $-\log k'_1$ and $-\log k'_p$ at $\mu = 0$ and zero acid concentration (HCl + KCl 0.1 and 0.01 is simplified for HCl 0.01M + KCl 0.09M and HCl 0.001M + KCl 0.009M; $-\log k'_1 > -\log k'_p$).

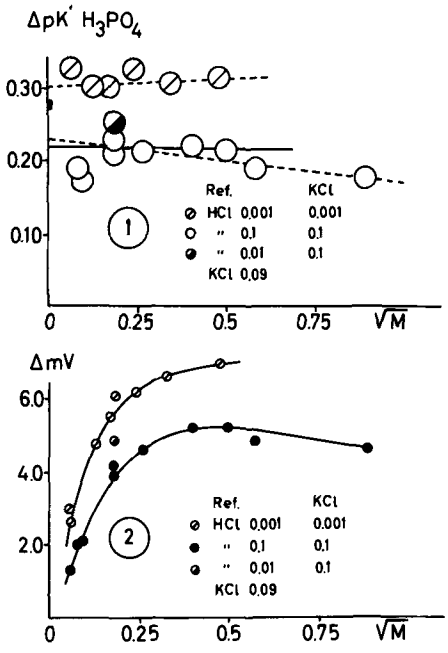

Fig. 6. Phosphoric acid (step 1) in KCl solutions. Top: $\Delta pK' = -\log k'_1 + \sqrt{\mu_1} + \log k'_p - \sqrt{\mu_p}$ (p = 1000 kg cm^{-2}) as a function of the acid concentration ($\sqrt{M}$). Bottom: observed emf shifts (Δ mv).

and 0.01*M* KCl alone are considered. More data are needed in 0.01*M* and 0.001*M* KCl, but those available are sufficient to determine ΔpK with some accuracy. The linear extrapolation of $-\log k'_p$ from $\mu = 0.1$ to $\mu = 0.001$ through $-\log k'_p$ at $\mu = 0.01$ is seen to be possible only when HCl + KCl is used in the reference half-cell instead of 0.1 and 0.01*M* HCl. The diagram shows that the activity coefficient term ($\sqrt{\mu}$) used to calculate $\Delta pK'$ in Fig. 4 is an overestimate. The corrected values are: $-0.66\sqrt{\mu_1}$ and $-0.52\sqrt{\mu_p}$ at $\mu = 0.1$, in agreement with the value at 1 atm given by Harned and Owen (20) and derived from the equation

$$-\sqrt{\mu_1}/(1 + 1.175\sqrt{\mu_1}) + 0.19\mu_1 = \log \gamma_{H^+}\gamma_{A^-}/\gamma_{HA}$$

Pressure mainly affects the coefficient of the term in μ_1.

The most probable value for ΔV°_1, 8.8-9.1 cm^3, corresponding to $\Delta pK = 0.150 - 0.155$ is in good agreement with the density and conductivity data (2, 7). The contribution of the activity coefficient change is about 1.5 cm^3 at $\mu = 0.1$.

The effect of pressure on the ionization constant of phosphoric acid (step 1) has also been studied.

Figure 6 shows $E_1 - E_p$ as a function of $\sqrt{M_1}$ in 0.1*M* and 0.001*M* KCl, using 0.1*M* and 0.001*M* HCl as reference. As for formic acid, a shift of about 0.9 mv is observed when 0.01*M* HCl + 0.09*M* KCl is used. The corresponding $\Delta pK'$ values calculated in the same way as for formic acid are shown in the upper part of Fig. 6. Again $\Delta pK'$ drops too much at high dilution in 0.1*M* KCl and the same explanation holds.

The contribution of the second term on the right side of Eq. [6] is very important in the case of H_3PO_4 and makes the $\Delta pK'$ values much more sensitive to experimental errors. $\Delta pK'$ extrapolates around 0.300 ($\Delta V^\circ_1 = -17.5$ cm^3) in 0.001*M* KCl, which is rather

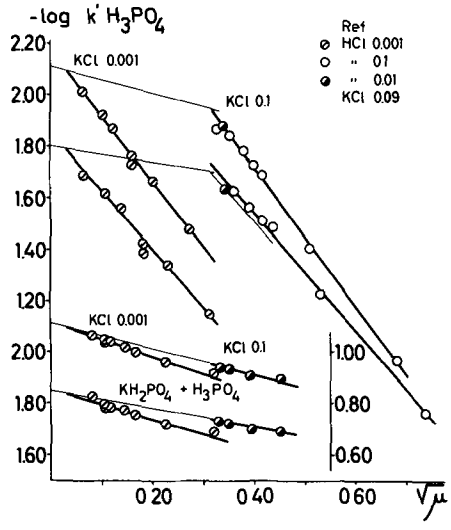

Fig. 7. Phosphoric acid (step 1) and phosphate buffer (buffer ratio $[A^-]/[HA] \simeq 10/1$) in KCl solutions. Extrapolation of $-\log k'_1$ and $-\log k'_p$ at $\mu = 0$ and zero acid and buffer concentration ($-\log k'_1 > -\log k'_p$; the upper left hand scale is continued on the right below).

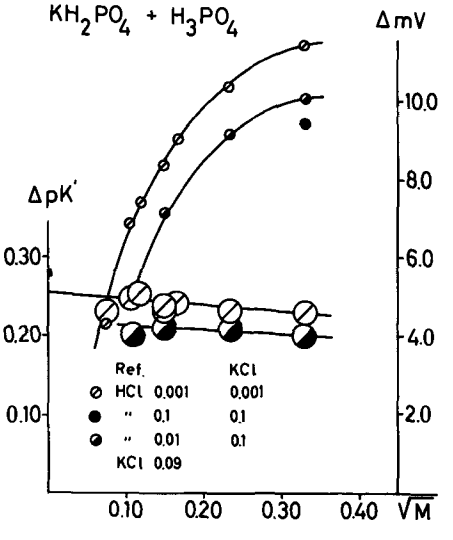

Fig. 8. Phosphate buffer (step 1) in KCl solutions. $\Delta pK' = -\log k'_1 + \sqrt{\mu_1} + \log k'_p - \sqrt{\mu_p}$ (p = 1000 kg cm^{-2}) and Δ mv observed (emf shifts) as a function of the buffer concentration ($[HA] + [A^-] = M$).

too high compared to the −16.2 cm³ obtained by Smith (21) from density measurements.

Figure 7 gives $-\log k'_1$ and $-\log k'_p = f(\sqrt{\mu})$ and may be extrapolated to $\mu = 0$ and zero acid concentration. The absolute value of pK_1 (2, 11) is in agreement with the value 2.13 given by Bates (23); the most probable value for ΔpK is again 0.300, and the contribution of the activity term at $\mu = 0.1$ is equal to 1.03 cm³ which is somewhat less than for formic acid.

The results gathered for phosphate buffer (step 1) are given in Fig. 7, 8, and 9. The stock buffer solutions contained 0.1M KH_2PO_4, 0.011M H_3PO_4, and KCl, and were diluted with corresponding KCl solutions. This buffer ratio explains why the medium effect of undissociated H_3PO_4 is very much reduced, compared with pure H_3PO_4 solutions. The extrapolated value of ΔpK lies around 0.260 ($\Delta V°_1 = -15.2$

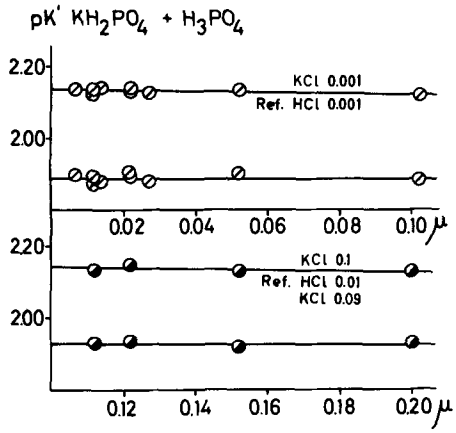

Fig. 9. Phosphate buffer (step 1) in KCl solutions. Extrapolation of $pK' = pk' + \sqrt{\mu}/(1 + 1.96\sqrt{\mu})$ at 1 and 1000 kg cm^{-2} on the μ scale ($pK'_1 > pK'_p$).

cm³) on both Fig. 7 and 8. The contribution of the activity coefficient term is $\simeq 0.7$ cm³ at $\mu = 0.1$. Figure 9 indicates that the results are better represented on the μ scale. $pK' = pk' + \dfrac{\sqrt{\mu}}{1 + 1.96\sqrt{\mu}}$ is then used to extrapolate at $\mu = 0$ (23), again assuming that pressure has no effect on the activity coefficients. ΔpK seems now to be closer to 0.250 ($\Delta V°_1 = -14.6$ cm³), whereas the absolute value of pK_1 is in excellent agreement with the data of Bates.

We have so far no explanation for the fact that $\Delta V°_1$ for phosphate buffer is about 2 or 3 cm³ smaller than $\Delta V°_1$ for H_3PO_4 alone. It should be noticed however that extrapolation at nearly equal buffer ratios on the $\sqrt{\mu}$ scale (Fig. 8) yields values for ΔpK between 0.280 and 0.270 (−16.4 and −15.8 cm³) in much better agreement with the density data of Smith (21).

Preliminary results for acetic acid in 0.001 KCl lead to $\Delta pK = 0.180$ ($\Delta V°_1 = -10.8$ cm³); for acetate buffer, $\Delta pK = 0.175$ ($\Delta V°_1 = -10.3$ cm³). Some uncertainty arises from the slight curvature of $E_1 - E_p = f(P)$ which is generally absent in the other investigated media. The emf values at 500 kg cm^{-2} give for $\Delta V°_1$ −11.5 and −10.8 cm³ for the acid and the buffer, respectively. The agreement with the results obtained from conductivity and density measurements is satisfactory (see Table I).

The effect of the ionic strength on ΔpK in phosphate buffer (step 2) seems to be quite small. The importance of the buffer ratio will have to be investigated carefully, but the observed shifts in 0.001M KCl point toward $\Delta pK = 0.390$ or $\Delta V°_1 = -23.0$ cm³, a value which is still about 5 cm³ too small compared to the one obtained from density measurements (21).

We have not reinvestigated (14) the effect of pressure on H_2CO_3 and bicarbonate buffer in dilute KCl solutions. Taking into account the apparent reference cell shift (0.8–0.9 mv) for 0.1M HCl and a reasonable estimate of 0.5 mv for the activity coefficient contribution, would lead to $\Delta V°_1$ values for bicarbonate buffer between −22.0 and −24.0 cm³, not too far from the value (−24.9 cm³) proposed

recently by Ellis (5) from conductivity measurements. These ΔV°_1 values are however much lower than the figure given by Owen and Brinkley (11) (29.0 cm³) and are in disagreement with the pH shift observed in H_2CO_3 solutions, which lies between 14.5 and 15.0 mv in 0.1*M* KCl (reference 0.1*M* HCl) ($\Delta V_1 = -30.6$ and -31.8 cm³, after correction for the reference shift).

The increase of the second dissociation constant of carbonic acid is not measurable with a glass electrode without careful investigation of the effect of pressure on the alkaline error at pH > 9. The shift can be computed however from the emf change observed in $NaHCO_3$ solutions, the pH of which is known to be given by

$$pH = \tfrac{1}{2}\, pK_1 + \tfrac{1}{2}\, pK_2$$

The observed value, with 0.1*M* HCl as reference, is 22.6 mv at 1000 kg cm^{-2} for a 0.1*M* solution in 0.1*M* KCl. It is close to the 22.7 mv change obtained for bicarbonate buffer. This gives, after correction for the reference half-cell shift, a corresponding value of ΔV_1 equal to -23.6 cm³. The expected ΔV°_1 is -27.8 cm³ (11).

It appears from Table I, which summarizes our findings, that the observed pH shifts induced by pressure in acetic acid, formic acid, phosphoric acid (step 1), and perhaps carbonic acid are in reasonable agreement with the *pK* decrease or ΔV°_1 values calculated from density and conductivity data. However, the recorded emf changes in buffer solutions appear to be systematically too small and the difference is too great to be accounted for in terms of activity coefficient contributions or reference cell shifts. On the other hand, the experiments described in the next section tend to show that the behavior of the glass electrode under pressure is normal in the alkaline region, so that the cause of the observed discrepancy will have to be sought elsewhere (ionic association, hydration, incompletely dissociated salts, etc.).

Sodium Acetate, Ammonia (Ionic Product of Water)

The ionic product of water K_w increases by a factor of 2.36 at 1000 atm according to the calculation of Owen and Brinkley (11). Several experiments can be carried out with a glass electrode to obtain experimental data about this shift. The pH of a sodium acetate solution is known to be given by

$$pH = \tfrac{1}{2}\, pK_w + \tfrac{1}{2}\, pK_{HA} + \tfrac{1}{2} \log M$$

The *pK* decrease observed from pH measurements for acetic acid lies between 0.180 and 0.195 at 1000 atm, the pK_w shift is expected to be 0.373. The observed pH change for Na-acetate should thus be equal to 0.277-0.284 pH, or 16.2-16.6 mv at 21°C. The experimental values in four successive experiments with 0.1*M* HCl as reference are: 16.0, 16.5, 16.7, 17.2 mv. The mean value corrected for the reference shift is 17.4 mv. The agreement is acceptable despite the fact that the pH of Na-acetate solutions is somewhat unstable. The solution should be prepared from acetic acid and CO_2-free NaOH, and very carefully adjusted at the neutralization point (pH = 8.4). At lower pH values, the observed shifts fall between that for acetate buffer and Na-acetate.

The pH of ammonia solutions is given by

$$pH = pK_w - \tfrac{1}{2}\, pK_{NH_4OH} + \tfrac{1}{2} \log M$$

The expected pH shift estimated from the data of Hamann and co-workers (24, 7) ($\log Kp/K_1 = 0.465$) can be shown to be 0.140 pH or 8.2 mv. The observed values for a $10^{-4}M$ solution in 0.1*M* KCl, with 0.1*M* HCl as reference, are 9.2 and 8.4 mv at pH 9.64. However, the glass electrode is known to present an alkaline error above pH 9, and the effect of pressure in this region has not been investigated. Further, Ag-AgI electrodes should be substituted to the Ag-AgCl electrodes, AgCl being soluble in NH_4OH. The agreement is thus to be accepted with caution, although no change in the asymmetry potential shift could be detected before and after 20-min treatment in $10^{-4}M$ NH_4OH.

Sea Water

The effect of pressure on the pH of sea water reveals a linear pH decrease which amounts to 0.3 pH at 1000 kg cm^{-2} (14).

The pressure resisting glass electrode has been adapted for deep sea investigations, and Distèche and Dubuisson (25) have been able to record the pH of the water of the Mediterranean Sea from the French Bathyscaphe to 2.350m depth.

The electrode cell is shown on Fig. 10 which is self-explanatory. The cell assembly is attached to

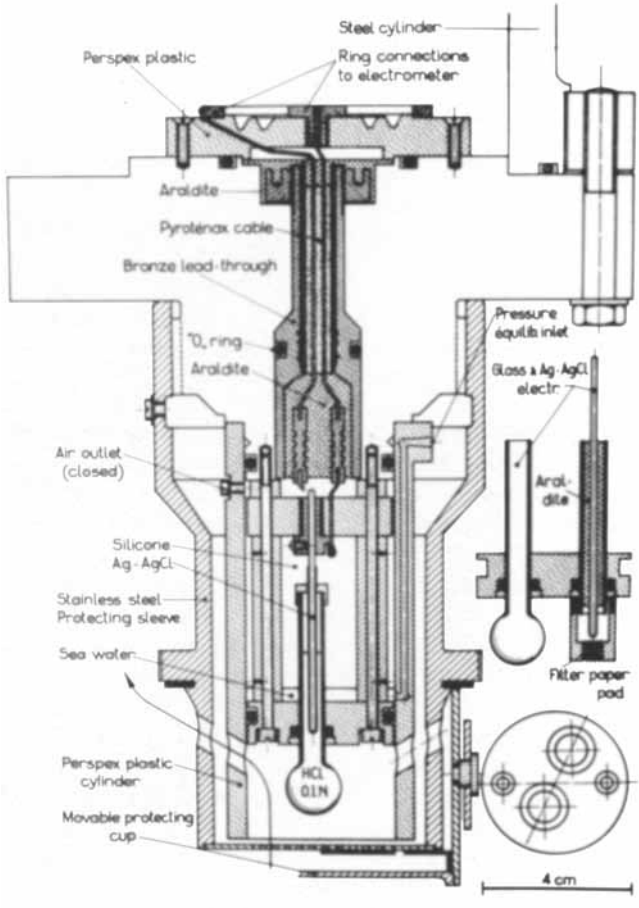

Fig. 10. Glass electrode assembly for deep sea investigations. From Distèche and Dubuisson (25).

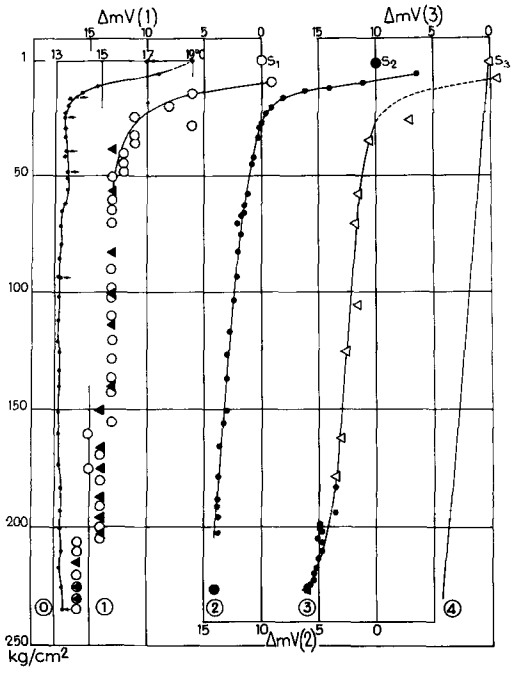

Fig. 11. pH changes recorded from the Bathyscaphe FNRS III between 0 and 2350m in the Mediterranean Sea. Curves 1, 2, 3 give $E_1 - E_p = f(P)$, E_1 corresponding to the pH values at the surface (S_1, S_2, S_3). Curve 4 gives $E_1 - E_p = f(P)$ for sea water of constant composition. Curve 0 represents the simultaneous temperature record. From Distèche and Dubuisson (25).

the lower end of a pressure resisting steel cylinder containing a d-c amplifier with cathode follower output, driving a pen recorder, on which the pH shifts are observed as the distance between two traces, one of which represents the zero drift of the apparatus. The error on ΔpH is certainly less than 0.01 pH unit and very close to 0.005 pH unit.

The curves on Fig. 11 were obtained during two dives. They represent direct manual measurements (large dots) with a precision potentiometer circuit and the data taken from the recorded curves (small dots). After a small increase near the surface, the pH is seen to decrease exponentially (~0.15 pH unit) from 0 to 400m. From 400m to 2350m, the bicarbonate/CO_2 ratio remains constant since the observed pH change corresponds to the effect of pressure on water of constant composition. A slight acid gradient is found near the bottom. The results obtained from the surface to the sea bottom agree with those recorded during the return to the surface, and there is a distinct correlation between the temperature curve and the pH curve.

Conclusion

The author is fully aware that his investigations on the behavior of a glass electrode at high pressure in various electrolytes cover only an extremely small portion of a very wide field. The important fact is that the reproducibility and the precision of the pH measurements with a glass electrode are affected by pressure but little or not at all. This statement is not a proof that the electrode gives, under all circumstances, the value of the hydrogen ion activity, but considering as a whole the results which have been obtained so far, makes one feel confident, since many results agree well with what is known from conductance and density data.

Further instrumental development is possible. A bright gold electrode can be added to the glass electrode cell for rH measurements[1] and it is planned to try glass electrodes sensitive to Na^+ and K^+ (26, 27).

The use of multielectrode cells, including a conductivity cell, would certainly broaden the field of electrochemical investigation at high pressures (properties of electrolytes, protein chemistry, kinetics, oceanography, and industrial technology).

Acknowledgment

The author wishes to express his gratitude to Professor B. B. Owen, Yale University, U.S.A., Dr. R. Bates and Dr. W. Hamer, National Bureau of Standards, U.S.A., for very helpful discussions and suggestions. Part of this work was supported by the "Centre Belge d'Océanographie."

The Performance of Hydrocarbons in Ion Exchange Membrane Fuel Cells

L. W. Niedrach

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Exploratory work has been performed on the behavior of hydrocarbons and carbon monoxide in acidic ion-exchange membrane fuel cells having platinum and palladium black electrodes. Electrical output was obtained from such cells when propane, propylene, ethylene, methane, and carbon monoxide were used as fuels. In all cases qualitative tests indicated at least partial oxidation to CO_2. All of the gases performed better on platinum than palladium. In all cases the performance improved with increasing temperature in the range 27°-85°C. None of the fuels tested performed as well as pure hydrogen in the same cells.

In the development of the ion-exchange membrane fuel cell, the greatest emphasis to date has been placed on its utilization as a hydrogen-oxygen cell. Detailed accounts of the construction, operation, and performance of such cells operating on hydrogen have been given elsewhere (1-3). Some exploratory work on the performance of hydrocarbons has now been done using the platinum and palladium black electrodes that have been regularly employed in the studies with hydrogen. Only cells with acidic electrolytes were used. While it was recognized that such catalysts had little chance of proving optimum for the desired oxidations, it seemed likely that their performance would be illustrative of some of the general effects which will be encountered during the electrolytic oxidation of hydrocarbons. This paper presents the results of the experimental work.

Experimental

A diagram showing the cell construction appears in Fig. 1. The heart of the unit is the membrane-electrode structure. A reinforced sulfonated phenol formaldehyde casting resin in its acidic form was used for the electrolyte. Thin layers of the electrode materials (platinum or palladium black) were bonded on the surfaces of the membrane electrolyte. These layers had a thickness of about a mil and a circular area of 11.4 cm^2. The thickness of the electrolyte was approximately 0.06 cm. Since the catalyst layers are relatively poor electronic conductors, platinum gauzes (80 mesh) were buried in the electrolyte surfaces to serve as current collectors. Tabs on the gauzes served as terminals for the cells.

The membrane-electrode structure was mounted in a Lucite housing having a diameter of 3 in. Neoprene rubber gaskets (1/64 in. thick) were used for all seals. Stainless steel backing plates were used to prevent warping of the Lucite during operation at elevated temperatures.

Experiments at room temperature were performed with the cells mounted in air. For operation at temperatures above room ambient, they were mounted in a water bath containing distilled water. The gases that were fed to the cells were then preheated and saturated with water by passing them through coils of copper tubing followed by glass saturators that were also immersed in the bath. A schematic diagram of the arrangement is shown in Fig. 2.

To facilitate handling, individual cell assemblies were prepared as modules which could be inserted

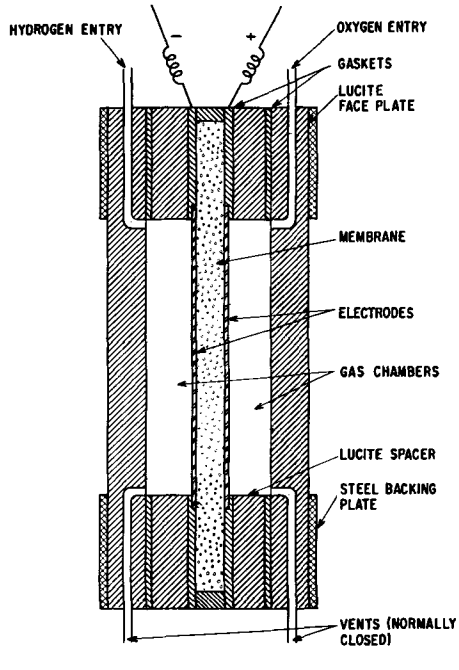

Fig. 1. Cell structure

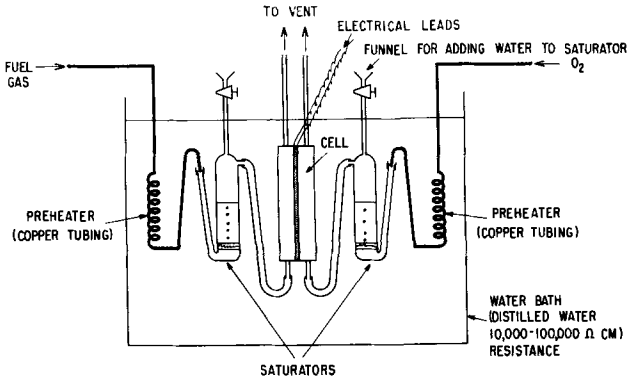

Fig. 2. Diagram showing arrangement for experiments at elevated temperatures.

through openings in the lid used on the water bath. In preparing the modules a cell housing was fastened to a rod extending down from a Bakelite cover which fitted a hole in the lid of the water bath. Leads from a terminal jack on the cover were connected to the cell terminals. The vent lines from the cell were led through holes in the cover.

By using distilled water in the thermostat bath the leakage path across the cell terminals could be maintained at reasonable values even at 85°C. Actual leakage resistances measured with the aid of a dummy cell housing were 15,000 ohms at 55°C and 6000 ohms at 85°C. Under these conditions the effect of the leakage current was negligible when the cell was operating under load. Leakage through the bath, however, prevented the measurement of true "open-circuit" potentials.

Performance measurements were made at three temperatures: 27°, 55°, and 85°C. At each temperature a reference polarization curve was first obtained with the cell operating on hydrogen and oxygen in order to insure that the units were functioning properly. Then successive runs at a given temperature were made with the various test gases. Immediately after changing the fuel gas the cells were placed on 1-ohm loads and permitted to operate with a gas flow of a few milliliters per minute until a steady state was established. In some cases this took as long as 1 hr. This procedure was employed in order to remove remaining traces of the previous fuel from the catalyst surface as well as from the feed lines and saturators. During operation a continuous slow flow of gas was used. The exhaust gases were bubbled through $Ba(OH)_2$ to test for CO_2.

Electrolytic oxygen was used as the oxidant in all cases. Electrolytic hydrogen was also used. With the exception of the natural gas, which was obtained from the house line, all of the remaining gases were Matheson C.P. grade. While all are reported to be low in hydrogen, the tank gases were checked mass spectrographically with the results shown in Table I.

Table I. Amount of hydrogen in test gases

Gas	Vol. % H_2
Propylene	<0.00010
Propane	<0.00002
Ethylene	0.033
CO	<0.015

While the gases were not analyzed quantitatively for carbon dioxide, qualitative tests were performed by bubbling through $Ba(OH)_2$ solutions under conditions simulating those later used during cell operation. No precipitates developed from the tank gases during periods exceeding those used in testing the operating cells. All gases were used without further purification.

Polarization curves were obtained by measuring the current with a Sensitive Research Instrument Company milliammeter and the cell potential with a Rubicon potentiometer. To aid in following slow changes in the voltage with time, a Varian recorder was connected across the cells during measurements. The time required to establish a steady state varied from a few seconds to over an hour.

Normally potentials were followed for a minimum of 10-15 min before final measurements were taken; however, in extreme cases over an hour was required to reach a steady state. Recordings showing time effects in such extreme cases appear in Fig. 6 and are discussed later. In no case were voltage oscillations observed.

The reproducibility of the data varied considerably among the fuels and was somewhat dependent on the temperature and current density. With the more reactive fuels, potentials could generally be reproduced to within 15-20 mv in the current density region under 2 ma/cm^2. As current densities increased, larger uncertainties were incurred so that above 5 ma/cm^2 they were of the order of 100 mv. In the case of propane two regions of operation were found with the transition between them being temperature dependent. At low current densities (no greater than 1 ma/cm^2) potentials could be reproduced to within 15-20 mv; however, conditions became very unstable at higher current densities as discussed below.

Results and Discussion

Figure 3 shows the performance of a number of fuels at room temperature in a cell having platinum electrodes. The curve for the hydrogen fuel serves as a reference. It is to be noted that the per-

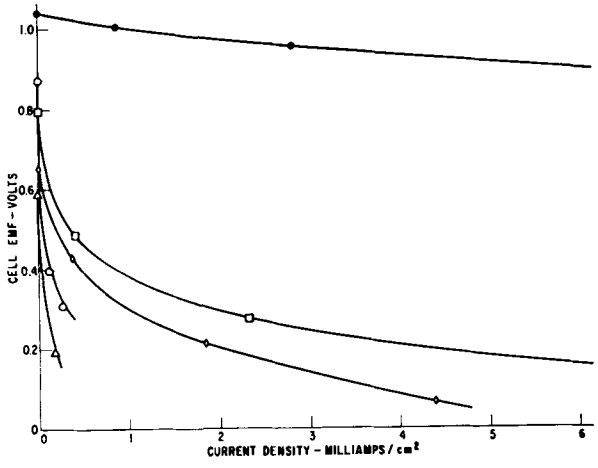

Fig. 3. Performance of several fuels in a membrane cell with platinum electrodes, sulfonated phenol formaldehyde resin; 0.018 g/cm^2 Pt/electrode; room temperature; • H_2; □ CO; ◇ C_2H_4; ○ C_3H_8; △ natural gas.

formance of the natural gas, which was 95% methane, was the poorest among the hydrocarbons, as is to be expected.

In this case it is possible that small traces of sulfur-containing impurities had some influence on its performance. Subsequent tests with hydrogen and the pure hydrocarbons, however, indicated that if such were the case the effect was not a permanent poisoning of the catalyst.

When a cell was run on a gas that contained a carbon compound, a continuous flow was employed, and the effluent fuel gas was bubbled through a $Ba(OH)_2$ solution. In all cases white precipitates of $BaCO_3$ indicated that at least partial oxidation to CO_2 occurred. No attempts were made to identify other products of the oxidations.

A cell operating on ethylene, one of the more reactive hydrocarbons, was used to obtain more quantitative information about the extent of oxidation at room temperature. For this purpose the fuel cell chamber was connected to a small gas buret, and the cell was operated on the fuel within the system. The net rate of change in volume of the gas phase was then followed at several current densities. The data, both volumetric and analytical, indicated that a minimum of 50% of the ethylene was oxidized completely to CO_2.

Performance data for the hydrocarbons in a cell having palladium electrodes are shown in Fig. 4. In general, the performance paralleled, but was inferior to, that of the cell having platinum electrodes. In part, at least, the poorer performance may have resulted from a somewhat lower surface area (12 m^2/g *vs.* 36 m^2/g for Pt as determined by krypton adsorption).

Data were also obtained for a number of gases at elevated temperatures, 55° and 85°C. For illustration the data obtained with cells having platinum electrodes are shown in Fig. 5 (for propane), Fig. 7 (for propylene), and Fig. 8 (for CO). Just as at room temperature, the corresponding data (not shown) for cells with palladium electrodes paralleled, but were inferior to, those for the cells having platinum electrodes.

The data in Fig. 5 for the cell operating on propane show the typical improvement in performance with temperature associated with an activated process. On each curve the points are numbered to indicate the order in which they were taken. From the clustering of points 3, 5, and 7 at 55° and 85°C it is seen that reasonable reproducibility is obtained independent of whether a point is approached from a previous operating point on a higher or lower load.

Up to currents of the order of 1 ma/cm^2 the curves are concave upward as is normal for activated electrode processes. At currents greater than 1 ma/cm^2 the polarization curves become concave downward, and indications of an approach to a limiting current are evident. This type of behavior is indicative of concentration polarization and could be associated with diffusion control. It could also be associated with slow adsorption or desorption kinetics, if, as is likely, adsorption of the hydrocarbon on the electrode is a prerequisite to reaction. Because the effect occurs at relatively low current densities, it appears more likely to be associated with slow sorption kinetics.

Eventually still another effect becomes apparent when on higher loads both the current and potential fall. This is most clearly shown by point 11 at 85°C. When a steady state is attained the current and

voltage relationship shows a marked transition in the performance. The changes in potential with time as the cell approached a steady state on point 11 are shown by the potential-time plot in Fig. 6.

From previous experience with the ion-exchange membrane fuel cell it is known that the observed behavior is not associated with the oxygen electrode. This means, then, that the potential of the fuel electrode finally reaches a value approximating that of the oxygen electrode so that the net voltage across the cell is close to zero. It is therefore felt that the break in the current-time curve of Fig. 6 is associated with the formation of an adsorbed oxygen (oxide) layer on the platinum electrode and that the gradual change in performance on point 11 represents a shift in the kinetics from those on a clean metal electrode to those on an oxide film electrode. It is likely that this transition would have been observed on points prior to 11 had sufficient time been allowed. However, it is also clear that, below some critical load, operation is stable under conditions that result in moderate cell potentials, cf. points 3, 5, 7 in Fig. 5 and curve b in Fig. 6 which shows the change in potential with time when the cell was shifted from a 10-ohm load to 100 ohms. In this case the prolonged pause in the potential corresponds to the destruction of the oxide film on the electrode.

This behavior is by no means unique and has been observed in the electrolysis of such substances as formic acid (4), methyl alcohol (5, 6) and formaldehyde (7). In all these cases the potentials at which the change in performance has occurred has also been consistent with the formation of an oxide film on the metal surface and has resulted in this explanation having been invoked in the past.

As already noted, it seems likely that adsorption of propane on the electrode surface is a prerequisite for reaction. It is also probable that this adsorption step results in the dehydrogenation of the propane to propylene or beyond as a preliminary step in the reaction chain. For this reason it was felt of interest to test the behavior of propylene in the cell. Performance data are shown in Fig. 7.

It is to be noted that at current densities less than 1 ma/cm² the cells operating on propane seem to be slightly better than those operating on propylene. While the data are not adequate to assure that this is a real difference, it is quite possible that the hydrogen that would be split from the propane could account for this effect.

The absence of the limiting current from the polarization curves for propylene is of interest. An implication is that the sorption kinetics are more favorable in the case of the unsaturated molecule. Preliminary adsorption measurements with ethane and ethylene using related cell structures tend to confirm that it is actually the rate of adsorption of a saturated hydrocarbon that is limiting. It was found that the unsaturated molecule adsorbed at a much greater rate on clean electrode surfaces than the corresponding saturated species (8).

Another point of interest in connection with the propylene is the absence of the transition in performance to that on an oxide surface during operation on high loads. While probably relating to a higher rate of adsorption, it also appears to be related directly to the rate of reduction of oxide films on platinum by the various materials. In separate tests it was found that propane reacts with such a film extremely slowly and, when an oxidized electrode is exposed to propane, the time required for the potential to reach that of a fuel electrode is of the order of an hour. In addition a prolonged break is observed in the transition curve at a potential of about 0.1v *vs.* the oxygen electrode. The same reduction with propylene is rapid (a few minutes) and, for comparison, the reaction with hydrogen occurs in seconds. With the propylene, therefore, the direct reduction of the oxide film by the fuel gas is sufficiently rapid that the film is not encountered under the usual operating conditions.

The behavior of carbon monoxide at two temperatures is shown in Fig. 8. Its performance is analogous to that of propylene. Again no indication of a limiting current is evident. In this case, of course, the number of products is much more limited than in the case of the higher molecular weight hydrocarbons and the product, CO_2, is not tightly adsorbed. Furthermore CO, like propylene, reacts rapidly with surface oxides on the platinum electrode.

Summary and Conclusions

The ion-exchange membrane fuel cell employing platinum and palladium black electrodes has been shown to be operable on hydrocarbons and carbon

monoxide. Performance of the cells with these fuels is inferior to that obtained with hydrogen as the fuel. The performance of the cells with the present electrode materials is probably illustrative of the general type of effects which will be encountered during the electrolytic oxidation of hydrocarbons.

Electrical Double Layer Capacities of Iron During Forced Cathodic Decay of Passivity

G. M. Schmid and Norman Hackerman

Department of Chemistry, The University of Texas, Austin, Texas

ABSTRACT

A study of the behavior of the differential capacity of the electrical double layer of high-purity, zone-refined iron in 0.1N Na_2SO_4, pH 2.3-6.5 has been made during forced cathodic decay of passivity using a fast single pulse technique. The capacity-time curve shows a maximum >22 $\mu f/cm^2$ (but <35 $\mu f/cm^2$) at the end of the Flade plateau. This is explained on the basis of a desorption step of an as yet undefined charged particle. The capacity at O_2 evolution potentials is 6-8 $\mu f/cm^2$, compatible with an oxide film; at H_2 evolution potentials it is 19 $\mu f/cm^2$, independent of pH in both cases. The charge involved in the Flade plateau is 550-850 $\mu coul/cm^2$ with an average 680 $\mu coul/cm^2$.

The exact causes for the electrochemical passivity of metals, and especially that of iron, are still largely in dispute. One school of thought suggests that the responsible agent is a stoichiometric, three-dimensional oxide film (1), or a sandwich type film consisting of different oxides (2). Oxide films with a defect structure, n-type at the metal-film and p-type at the film-electrolyte junction, have also been proposed (3). A second school assumes the sorption of oxygen or some oxygen-containing species as the reason for passivity (4). Ample experimental evidence for both points of view can be found. A postulate reconciling both standpoints has been proposed by one of us (5). It suggests that the immediate cause of passivity is the rapid sorption of a monolayer of some oxygen-containing species. In time this monolayer grows into a three-dimensional oxide film, self-limiting in thickness and responsible for "longlived" passivity. The sorbed monolayer accounts for the rapid potential changes associated with passivity.

The usefulness of measurements of the differential capacity of the electrical double layer (edl) in the study of adsorption on metal-solution interfaces has been demonstrated (6). On solid electrodes in the region of their nearly ideal polarizability empirical calibration of edl capacity *vs.* amount adsorbed seems to be possible in some cases (7). The potential region in which the adsorption, or desorption, occurs is characterized by a maximum in the capacity-potential curve. For nonideally polarizable electrodes the difficulties in obtaining "true" edl capacities free of the influence of faradaic processes have been solved recently with the aid of high-frequency bridge techniques (8) and short risetime single pulses (9). These techniques have made possible a study of the behavior of the edl of iron during forced cathodic decay of passivity, especially during the course of the Flade plateau.

Experimental

The electrodes consisted of zone-refined, high-purity iron containing $<$ 10 ppm C, 28 ppm O_2, 2 ppm N_2 (10). This was kindly provided by Battelle Memorial Institute as a billet. The electrodes were cut into cylinders topped by a hemisphere, approximately 0.3 cm^2 in projected area, thoroughly electropolished and base mounted on Pyrex glass using Teflon washers. Pretreatment consisted of polishing with No. 4/0 emery paper, etching with concentrated HCl, and degreasing with acetone. It was estimated that the roughness factor was about two. The electrolytes were made up with thrice recrystallized Na_2SO_4 and conductivity water obtained from a Barnstead conductivity still ($\sim 2 \times 10^{-7}$ ohm^{-1} cm^{-1}), to 0.1*N*. The pH was adjusted with

H_2SO_4 to values between 2.3 and 6.5. The electrolytes were pre-electrolyzed for 48 hr at 80 ma between Pt electrodes. The conventional type all-Pyrex cell had a water jacket and was thermostated at 5°C. Grade A helium was bubbled through the electrolyte at all times. Immediately after immersion the electrodes were either cathodically protected with 5 ma/cm² or were made passive.

Differential capacities were measured with a single pulse method described in detail elsewhere (9). The method consists of calculating the capacity from the initial slope of the potential-time curve produced by the pulse under the assumption that the slope of the potential-time function just before onset of the pulse is zero. This is not true here. The slope before onset of the pulse (< 0.01 v/sec) can however be neglected as compared to the slope produced by the pulse (> 5 v/sec), with the exception of the steep transition from O_2 evolution potentials to the Flade plateau and from the Flade plateau to H_2 evolution potentials, of about 1 sec duration each. The electrical circuit used in the experiments is shown in Fig. 1. The test electrode was passivated from a negative potential corresponding to a polarizing current of 5 ma/cm² cathodic with a strong (~ 200 ma/cm²) anodic pulse from an auxiliary battery. The electrode was then kept passive with a constant anodic current of 80-160 μa/cm² drawn from the pulse generator (9) through a large area platinized Pt wire gauze. The potential of the test electrode was measured with respect to a saturated calomel electrode (SCE) through a Haber Luggin capillary by feeding the output of this cell through a type-L preamplifier into the lower beam of a Tektronix type 555 oscilloscope used on single sweep push button triggered operation.

In addition to the steady anodic current the pulse generator delivered cathodic pulses at the regular rate of 1 pulse every 3.5 sec. Pulse risetime was 0.1 μsec, duration 100 μsec, height 0.211 ma. The potential changes of the test electrode caused by these pulses were displayed using a type-D preamplifier and the upper beam of the oscilloscope, triggered by the pulse itself. The gate output of the lower beam was also fed into test electrode and polarizing electrode. The scope delivers + 30v to the gate as long as the beam is in motion. This results in a cathodic current at the test electrode which is superimposed on the anodic steady-state current delivered by the pulse generator and with a suitable series resistor gives an over-all cathodic decay current of 30-100 μa/cm². With this circuit, manually starting the lower beam simultaneously initiates cathodic decay of passivity. A limited number of pulses displayed by the upper beam, and occurring during this decay, could be identified by changing the vertical and horizontal control settings between pulses. Figure 2 shows a schematic of the type of photographs obtained with a Dumont Polaroid Oscilloscope camera. These allowed calculation of capacity-time curves, which should not be confused with the more familiar capacity-potential curves. The accuracy of the capacity measurement was limited by the nonlinearity of the oscilloscope amplifiers to 3%.

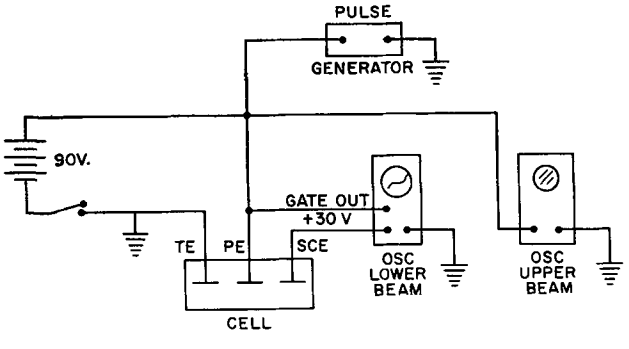

Fig. 1. Experimental arrangement, circuit diagram: TE, test electrode; PE polarizing electrode; SCE saturated calomel electrode.

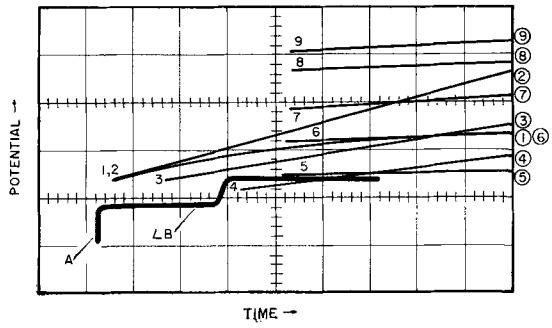

Fig. 2. Oscilloscope tracing: LB, lower beam displaying cell potential, 1 v/cm, 5 sec/cm, 55 μa/cm² cathodic; 1-9, upper beam displaying variations in cell potential due to the pulse, 2 mv/cm, 10 μsec/cm, 0.211 ma pulse current. Traces are numbered in their sequence and correspond to points on the lower beam 3.5 sec apart starting at A.

Results

The first capacity value on the capacity-time curves (Fig. 3) represents the capacity of the passive electrode. This value is established shortly after the electrode is passivated and is independent of the time during which the electrode is kept passive up to 24 hr. It is also independent of the applied anodic current density (80-160 μa/cm²), the *p*H between 2.3 and 6.5, and the potential between + 0.9 and + 1.1v *vs.* SCE. It is reasonably reproducible, varying between 6.0 and 8.0 μf/cm².

After the initial low value, the capacity rises to a maximum during the course of the Flade plateau,

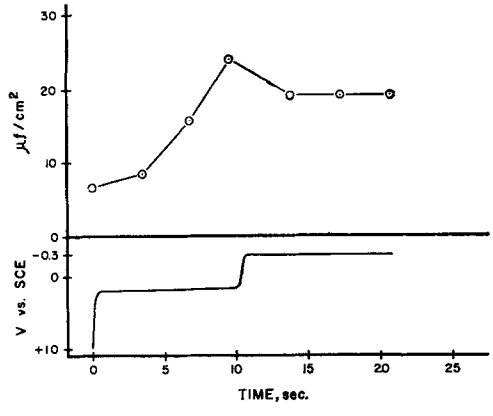

Fig. 3. Capacity-time (upper) and potential-time (lower) curves; 65 μa/cm² cathodic, pH = 4.5. The time-potential plateau at about +0.3v vs. SCE is the Flade plateau; the other plateau at —0.3v is hydrogen evolution.

culminating right at the breakdown of passivity within the limit of timing error of ± 1 sec. With the method used in this investigation, the values of the maximum could not be determined precisely. The value is > 22 μf/cm^2 in all cases, sometimes as high as 35 μf/cm^2.

After the passivity has broken down and H_2 evolution potentials have been reached, the capacity rapidly assumes a constant value of 19 μf/cm^2. This is independent of *p*H in the investigated region of the cathodic current (30-100 μa/cm^2) and of the potential between —0.3 and —0.5v *vs.* SCE, within the limit of experimental error.

The amount of charge involved in the Flade plateau varied from 550 to 850 μcoul/cm^2 with an average value of 680 μcoul/cm^2. Within these limits no influence could be detected of the time during which the electrode was kept passive prior to decay (up to 24 hr), of the magnitude of the cathodic decay current, or of the *p*H between 2.3 and 6.5.

Discussion

Various attempts have been made to measure the steady-state differential capacity of the edl on iron. Alternating current methods with frequencies up to 10 kcps were used by Engell and Ilschner (11) and by Prazak and co-workers (12); low-frequency measurements were reported by Franke, Knorr, and Breiter (13). It has already been pointed out (9, 14) that the use of these methods entails the danger of measuring some part of the faradaic capacity together with the "true" edl capacity. Correspondingly, the reported values are rather high and show frequency dependence, as would be expected if faradaic phenomena are involved. The dynamic method used by Sukhotin and Kartashova (15) and the square wave method as used by Popat and Hackerman (16) seem to suffer from the same faults. The "steady-state" values reported here, 6-8 μf/cm^2 for O_2 evolution potentials and 19 μf/cm^2 for H_2 evolution potentials, agree well with data obtained in this laboratory with a potentiostatic technique using a square wave signal and a method of calculation similar to the one used in this paper (17).

Low capacity values, especially on the oxygen evolution side, have frequently been associated with the presence of oxide films (18). This interpretation is certainly correct in some cases. However, one should allow from the definition of the differential capacity,

$$C = \delta q/\delta E$$

that small capacity values indicate primarily that the surface in question is in a quiescent state, that is, in a state and a potential region where little variation of charge with potential occurs, a region where adsorption and desorption processes are absent. Correspondingly, high-capacity values indicate an "active" surface, one which is in a potential region where adsorption processes do take place.

In these experiments the capacity shows a rapid rise immediately after the cathodic decay current is switched on. Whereas the presence of well-defined three-dimensional oxide films at actual oxygen evolution potentials cannot be ruled out, the behavior of the capacity-time curve does not support the presence of an oxide film at the Flade plateau, but rather the occurrence of a desorption (or adsorption) process. As would be expected, the iron surface is most "active" at the point where the passivity breakdown actually occurs.

As can be seen from Fig. 3, it is not possible in this case to relate capacity values directly with the amount of coverage on the electrode as was done on Pt (7). The constant cathodic current should lead to a linear decrease of coverage with time. Moreover there is a possibility of chemical dissolution of the film, as is suggested by the poor reproducibility of the amount of charge associated with this coverage. Evidence to the same effect was also obtained by Bonhoeffer (19).

Both neutral and charged particles are expected to exhibit a maximum in the capacity-potential curve when the capacity is measured by a low or intermediate frequency a-c technique. In the case of adsorption of neutral molecules one measures an adsorption capacity in the sense of Bockris (20), the magnitude of which is caused by the accompanying charge transfer into the adsorbed layer. High-frequency measurements show that the peaks caused by neutral substances disappear with increasing frequency (8). What remains is a step in the capacity function which can be explained by the difference in the geometrical and dielectric properties of the edl before and after the adsorption step. No sudden changes in the charge of the metal with potential occur. High-frequency data on the adsorption of charged particles are not available at present (21). It would be expected that the peaks do not disappear in this case since the charge of the adsorption layer causes an increase in charge on the metal side and with it an increase in capacity in the potential region of adsorption.

The single pulse technique as used in this paper is equivalent to a-c measurements at high frequencies (> 500 kcps). This leads to the conclusion that the high-capacity region the electrode exhibits when going through the Flade plateau is caused by the desorption of charged particles. Obviously capacity data alone do not allow firm conclusions as to the nature of these particles. We may be dealing with OH^- or HO_2^- ions, created by the reductive action of the cathodic current.

The nondependence of the capacity values on the *p*H is not surprising if it is kept in mind that the data reported here are "dynamic" rather than steady-state values and should be influenced primarily by the structure of the surface and not by the properties of the electrolyte.

Summary

The differential capacity of high-purity, zone-refined iron has been measured during cathodic decay of passivity with a single pulse technique in 0.1*N* Na_2SO_4 solutions of *p*H 2.3-6.5 (with H_2SO_4).

The capacity-time function during this decay exhibits a maximum at the end of the Flade plateau. It is shown that high-capacity values when meas-

ured with a fast single pulse method coincide with the surface being in an "active" state and that adsorption and desorption phenomena of charged rather than neutral particles are involved. It is concluded that the desorption of an undefined charged particle is part of the reaction sequence occurring during the regime of the Flade plateau.

The capacity during O_2 evolution (80-160 $\mu a/cm^2$) was found to be 6-8 $\mu f/cm^2$, during H_2 evolution (30-100 $\mu a/cm^2$) 19 $\mu f/cm^2$. No dependence on pH in the investigated region could be detected. The charge involved in the Flade plateau was calculated to be 550-850 $\mu coul/cm^2$ with an average value of 680 $\mu coul/cm^2$.

Acknowledgment

The authors take this opportunity to express their sincere appreciation for support of this research by a grant from the Robert A. Welch Foundation of Houston, Texas, and by Contract Nonr 375(15) with the Office of Naval Research. They also are pleased to acknowledge their appreciation for the sample of zone-refined iron provided by the Battelle Memorial Institute.

Manuscript received April 26, 1962; revised manuscript received July 3, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Anodic Oxidation of Methanol on Platinum

II. Interpretation of Potentiostatic Current-Potential Curves in Acidic Solution

S. Gilman and M. W. Breiter

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The shape of periodic potentiostatic current-potential curves at low sweep rate in 1*N* $HClO_4$ at different methanol concentrations is discussed on the basis of the methanol and oxygen coverage of the surface. At the foot of the first oxidation wave the current is due solely to the oxidation of adsorbed methanol molecules for $0.3 \leq \theta_M < 0.9$. Adsorption and the subsequent discharge step are rate-determining. For $\theta_M < 0.3$ methanol oxidation occurs at a larger rate. Two possible interpretations are suggested. The decrease of the current after the first peak is attributed to the blocking action of adsorbed oxygen atoms. The shape of anodic current-potential curves which were taken with single sweeps of different sweep rate in 1*N* $HClO_4$ + 1M CH_3OH is interpreted on the basis of a concept of two partial currents of methanol oxidation.

The characteristic shape of current-potential curves and the results of the analysis of reaction products have been widely reported as evidence for theories of the oxidation mechanism of fuels such as CH_2O, CHOOH, CH_3OH, etc., in alkaline and acidic solutions (1-13). Potentiostatic current-potential curves show current peaks which divide the whole oxidation range into two or more parts. The occurrence and the potential of the peaks depend on many parameters (nature and concentration of the fuel and of the electrolyte, pretreatment of the electrode, temperature, electrode material).

As the knowledge of the adsorption of fuel and oxygen in the potential range of fuel oxidation has been inadequate, the interpretation of the shapes of the current-potential curves and, even to a greater extent, the theories of the oxidation mechanism have remained of a more or less speculative nature. Results on the adsorption of methanol and oxygen under the conditions of quasistationary

potentiostatic current-potential curves were reported in the first paper of this series (14). An interpretation of the current-potential curve of methanol oxidation at low sweep rate which is based on the results of the first paper and additional investigations is attempted in this paper. The shape of potentiostatic current-potential curves which were obtained with single potential sweeps of different sweep rate is discussed. The approach is suggestive for further studies which could lead to the complete elucidation of the reaction mechanism.

Experimental

All measurements were made at 30°C using the equipment and chemicals previously described (14). All recorded potentials are referred to a hydrogen electrode in the same solution as the test electrode. The technique by Will and Knorr (15) was used for the measurement of the *I-U* curves.

Periodic potentiostatic I-U curves at low speed in unstirred solutions.—The anodic and the cathodic part of a potentiostatic *I-U* curve on smooth platinum in 1*N* $HClO_4$ + 1M CH_3OH at 30°C are shown in Fig. 1a and 1b. The sweep rate was 30 mv/sec. The *I-U* curve is fairly reproducible in unstirred solutions which are saturated with argon. It was obtained after a few cycles had been performed in the quiet solution. The coverage (14) with methanol (θ_M) and oxygen (θ_O) is plotted as a function of potential below the *I-U* curve. An oxygen monolayer was attributed (16) to $Q_O = 2_sQ_H$ where $_sQ_H$ is the number of coulombs per square centimeter for the formation of a monolayer of hydrogen atoms on the same electrode in 1*N* $HClO_4$ at 30°C.

The *I-U* curve during the anodic and cathodic cycle has the characteristic form described in earlier work (1-13). High resolution at small sweep rates shows the existence of a prewave at the foot of the first wave. The peak of the first wave appears at +0.9v in 1*N* $HClO_4$ + 1M CH_3OH at 30°C. The peak is shifted toward less positive potentials with decreasing methanol concentration. The first wave is narrow in 1*N* $HClO_4$ + 1M CH_3OH. The current decreases rapidly with increasing potential on the right side of the peak. The first wave becomes broader with decreasing methanol concentration. A current minimum is reached practically independent of the methanol concentration at about +1.1v. Then a second, relatively broad wave with a peak current at about 1.4v is observed. The location of the second peak is less defined than that of the first one. The current decreases only slightly with potential after the peak at +1.4v because O_2 evolution and methanol oxidation on top of the oxygen layer (7) increase rapidly with potential above +1.5v. During the cathodic sweep the current is small between +1.4 and +0.9v in 1*N* $HClO_4$ + 1M CH_3OH. Oxygen evolution and methanol oxidation on the surface covered with an oxygen monolayer do not occur at a significant rate in this potential range. If the methanol bulk concentration $_oC_M$ is smaller than 0.01M, a small cathodic wave appears between +0.9 and +0.8v. The cathodic wave is due to the reduction of the oxygen coverage. It is too small to be recognizable at larger methanol concentrations

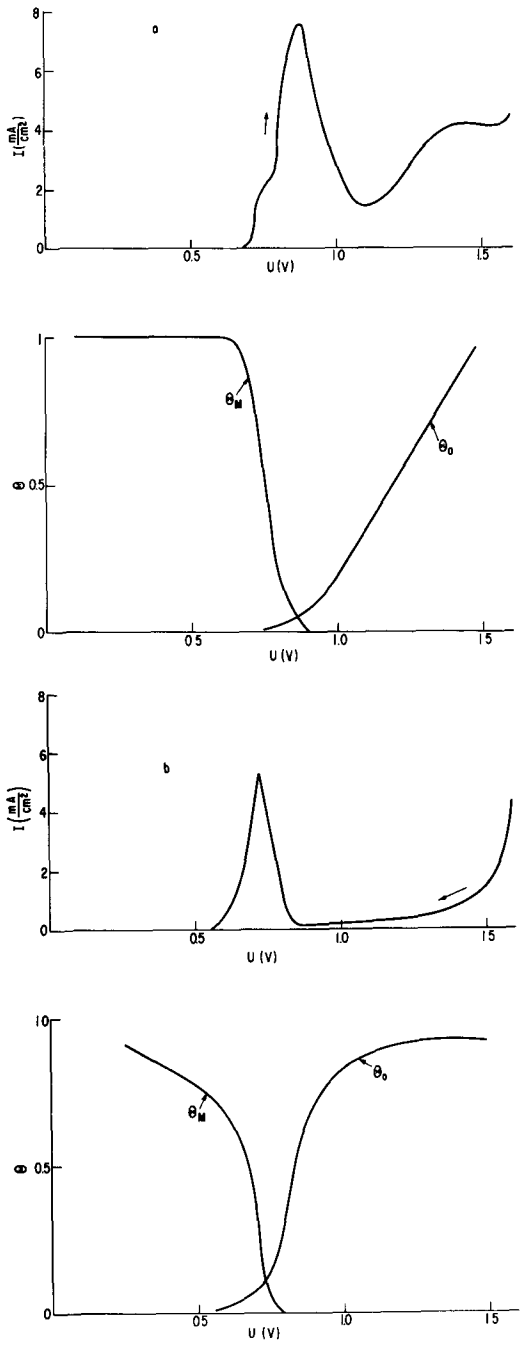

Fig. 1. Anodic (a) and cathodic (b) part of an *I-U* curve in unstirred 1*N* $HClO_4$ + 1M CH_3OH at 30°C. The methanol coverage (θ_M) and the oxygen coverage (θ_O) are plotted as functions of potential below the *I-U* curves.

(see Fig. 1b). The current becomes anodic again after the cathodic wave, reaches a peak, and finally decreases with decreasing potential to a very small value.

The comparison of the *I-U* curve with the θ_M-*U* curve in Fig. 1a shows that part of the methanol oxidation in 1*N* $HClO_4$ + 1M CH_3OH below +0.9v and practically all oxidation between +0.9 and +1.3v takes place on a surface whose coverage with adsorbed methanol or adsorbed intermediates is very small. The coverage is too small ($\theta < 0.1$) to be detected with certainty by the techniques used here. A similar statement holds for the concentration range 0.001M $\leq {}_oC_M \leq$ 1M. It is assumed that the decrease of methanol coverage with poten-

tial is not due to a replacement of adsorbed methanol molecules by water molecules. Such a displacement is formulated in the theories of the electrocapillary curve on mercury (17, 18). The assumption is confirmed by the result of the previous paper (14) that θ_M is independent of potential during the anodic sweep between +0.1 and +0.6 at bulk concentrations $0.001M \leq {}_0C_M \leq 1M$. If a desorption due to an electrostatic effect would occur, θ_M could not be potential-independent in such a broad potential range at moderate and small coverage. Therefore it is concluded that the depletion of the methanol coverage during the anodic sweep is solely caused by the oxidation process.

The current decrease after the peak at +0.9v may result from the blocking action of adsorbed oxygen or intermediates. Initially it can only be a blocking of active centers because the oxygen coverage and the coverage with intermediates are small in the immediate vicinity of the peak. Figure 1a shows that the current decreases while the oxygen coverage increases steadily in the same potential range. Therefore the current decrease after the first peak is attributed to oxygen blocking. This conclusion is confirmed by the shape of *I-U* curves of formaldehyde and formic acid oxidation (1, 3, 5, 8, 11, 12). A current decrease is always observed in a potential range where the formation of the oxygen layer starts in the absence of fuel (19). Müller and co-workers (1-5) have already concluded that the current decrease after the first peak is caused by the surface oxidation of platinum. The fact that these investigators did not observe a sharp drop-off in current and a second maximum above 0.9v (as recorded in Fig. 1a) may be simply explained on the basis of the large internal resistance of their slide-wire device to apply a potential potentiostatically. Recently Giner (20) and Lingane (21) studied similar passivity phenomena during the oxidation of oxalic acid on platinum. Blocking mechanisms of small amounts of adsorbed oxygen were discussed in detail by Ershler (22) in a paper on the passivity of platinum.

It follows from Fig. 1b that methanol oxidation and oxygen evolution are strongly hindered during the cathodic sweep between +1.3 and +0.9v where the surface is covered with practically a monolayer of oxygen atoms. The anodic current of methanol oxidation in 1*N* $HClO_4$ + 1M CH_3OH rises with decreasing potential between +0.9 and +0.75v where most of the oxygen layer is reduced cathodically. Methanol is oxidized at a higher rate between +0.75 and +0.6v during the cathodic sweep than during the anodic sweep. The methanol coverage is larger and the oxygen coverage is smaller at the same potential between +0.6 and +0.9v during the anodic than during the cathodic sweep. A similar statement holds for $0.001M \leq {}_0C_M \leq 1M$. This suggests that methanol is oxidized on the free surface at a larger rate. Another interpretation (11) attributes the current peak to a large oxidation rate on a fresh surface activated by the preceding covering with oxygen. An activation of this type is likely to occur. However, this interpretation

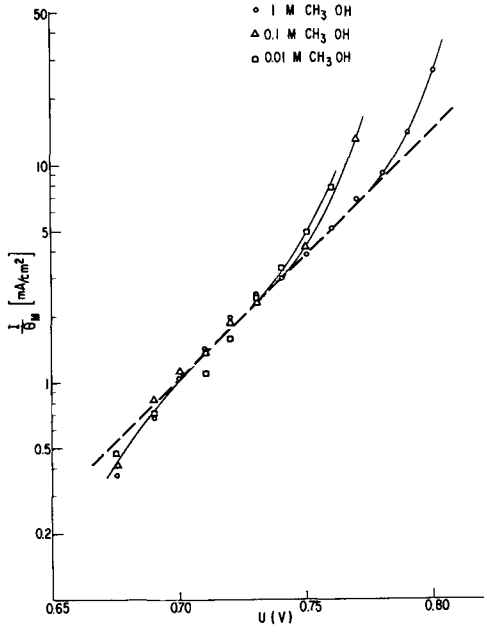

Fig. 2. Semilogarithmic plot of I/θ_M vs. U in the region of the prewave of *I-U* curves at different methanol concentrations in 1*N* $HClO_4$ at 30°C.

cannot explain the higher oxidation rate of formic acid (23) during the cathodic sweep when the potential is reversed at a value between +0.7 and +0.8v where the oxygen coverage is very small.

It was thought that the prewave during the anodic sweep could be due to the oxidation of adsorbed methanol molecules alone. This assumption was tested for three bulk concentrations (see Fig. 2) in the following way. If the rate-determining step after the adsorption is a discharge reaction which involves the adsorbed molecules only, then

$$I \approx I_1 = k_1\theta_M \exp\left(\frac{\alpha nFU}{RT}\right) \qquad [1]$$

Here, I designates the net current density; I_1 is the current density due to the oxidation of adsorbed molecules; k_1 is the rate constant of the discharge step; n is the number of electrons involved in the discharge step; and α is the transfer coefficient. In Fig. 2 I/θ_M is plotted on a logarithmic scale *vs.* U for 0.01M CH_3OH, 0.1M CH_3OH, and 1M CH_3OH. The respective θ_M-values were reported in the previous paper (14). Equation [1] is applicable for $0.3 \leq \theta_M < 0.9$ at ${}_0C_M = 1M$. For $\theta_M < 0.3$ the current rises more rapidly with potential than follows from Eq. [1]. For $\theta_M \geq 0.9$ deviations in the opposite direction are observed. A similar statement holds for ${}_0C_M = 0.1M$. The points of the measurements at ${}_0C_M = 0.01M$ deviate slightly at small current. Equation [1] is in fair agreement with the experiments for $0.3 \leq \theta_M \leq 0.9$. The agreement can be called "fair" if it is considered that the same term "fair" applies to the reproducibility of the *I-U* curves.

The validity of Eq. [1] in the said θ_M-range has another implication. During the sweep

$$F\Gamma \frac{d\theta_M}{dt} = I_a - I_1 \qquad [2]$$

Here $F\Gamma \approx 0.3 \frac{\text{m coulomb}}{\text{cm}^2}$ and I_a is the rate of adsorption. I_a depends on ${}_0C_M$, θ_M and U. Equation [1] can only be fulfilled if

$$F\Gamma \left| \frac{d\theta_M}{dt} \right| << I_1 \approx I \qquad [3]$$

It was found that $F\Gamma \left| \frac{d\theta_M}{dt} \right| < \frac{I}{10}$ holds at $\nu = 30$ mv/sec in the θ_M-range where Eq. [1] is applicable. The coverage θ_M is determined by the difference between I_a and I_1. The decrease of θ_M with increasing potential implies that I_1 is slightly larger than I_a at low speed. Adsorption and a subsequent discharge step are both rate determining in the region of the prewave.

The deviation from Eq. [1] below $\theta_M = 0.3$ can be interpreted in two different ways which do not differ much formally. Below $\theta_M = 0.3$ methanol molecules may be oxidized without previous adsorption with the rate, I_2. The net current, I, is equal to $I_1 + I_2$, and $I_1 >> I_2$ for $\theta_M > 0.3$. This statement holds for the vicinity of the first wave where the partial currents due to the oxygen layer formation, and to methanol oxidation and oxygen evolution on the oxygen covered surface are negligible. It is assumed with the second interpretation that the rate constant k_1 and the rate of adsorption increase with decreasing θ_M for $\theta_M < 0.3$. Methanol adsorption and oxidation occur on the very active sites of the heterogeneous platinum surface. Then I_2 designates the partial current of methanol oxidation on these sites. The active sites are made available by oxidizing off the molecules which are adsorbed in the hydrogen region during the cathodic and subsequent anodic sweep.

The rate constant, k_1, referred to the hydrogen electrode as reference electrode, and the αn-value were determined from Fig. 2. It was found

$$\log k_1 = -8.1, \quad \alpha n = 0.67$$

Here the rate constant is given in the units ma/cm^2. The experimental αn-value suggests a one-electron transfer ($n = 1$). The discharge step is a first order reaction with respect to the adsorbed methanol molecules. This implies that the first discharge step in the over-all reaction is the slowest discharge step. If it were a subsequent discharge step and if the equilibrium of one or more of the subsequent discharge steps were established, αn should be greater than 1. Another possible interpretation is that all the discharge steps are hindered to nearly the same extent. However, this interpretation is discarded because of the low probability of the assumption on the same hindrance of all the discharge steps. It should be noted that rate constants and transfer coefficients calculated without consideration of the change of θ_M at the foot of the first wave are incorrect.

Thus far, the shapes of the first wave during the anodic sweep and of the wave during the cathodic sweep of low-speed periodic I-U-curves have been discussed in detail. A similar discussion would be

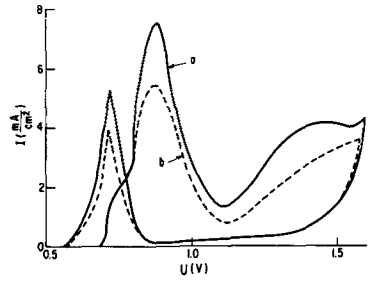

Fig. 3. I-U curve in unstirred (curve a) and stirred (curve b) 1N $HClO_4$ + 1M CH_3OH at 30°C.

desirable for the second wave. However, the analysis of the experimental results did not lead to a conclusion which differs essentially from that of Müller and co-workers (1-5) on the origin of the second wave. Müller and co-workers suggested that another mechanism becomes increasingly effective at higher potentials. It cannot yet be decided if the difference in the two mechanisms is of the specific type postulated by Müller and co-workers. More work is required.

Periodic potentiostatic I-U-curves at low speed with argon-stirring.—Curve b in Fig. 3 represents an I-U-curve with $\nu = 30$ mv/sec in 1N $HClO_4$ + 1M CH_3OH at 30°C when the solution was stirred intensively with argon. Curve a is the I-U-curve in the unstirred solution which had been saturated with argon before. It takes about five cycles before curve a is obtained after interruption of the stirring. The reproducibility of curve b is not good, as the shape of curve b changes slightly with time.

Stirring reduces the current at the same potential U above the region of the anodic prewave during the anodic sweep and in the region of the oxidation wave during the cathodic sweep. The following interpretation is suggested for the stirring effect. Stable intermediates (CH_2O, CHOOH) of methanol oxidation do not exist in a high concentration on the surface between +0.9 and +1.5v during the anodic sweep. After they have been formed, they can either be oxidized or diffuse into the bulk of the electrolyte. A high stirring rate favors diffusion while a low stirring rate is favorable for oxidation. This interpretation has to be considered a tentative one. The relative decrease of the current with stirring at $U > +1.0$v appears rather large and cannot be explained on the basis of the preceding interpretation alone. It indicates the presence of a second hindering effect. It appeared conceivable that the second hindering effect might be caused by a difference in the θ_0-U-curves for the stirred and unstirred solution. However, no difference could be detected in the experimental θ_0-U-curves under the two conditions.

Single I-U curves at different sweep rates in stirred solutions.—The anodic parts of potentiostatic I-U curves at variable voltage speed are shown in Fig. 4 for 1N $HClO_4$ (dotted curves) and 1N $HClO_4$ + 1M CH_3OH (solid curves) at 30°C. The I-U curves were measured by applying a single triangular voltage sweep. The pretreatment consisted of a single triangular sweep extending from 0.4 to 2.0v and returning to 0.4v. This served to

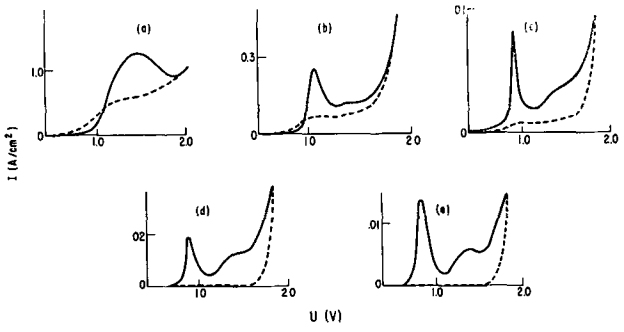

Fig. 4. Anodic parts of *I-U* curves, measured with a single sweep of different sweep rate which started from the open circuit potential: curve a, v = 800 v/sec; curve b, v = 70 v/sec; curve c, v = 7 v/sec; curve d, v = 0.7 v/sec; curve e, v = 0.07 v/sec.

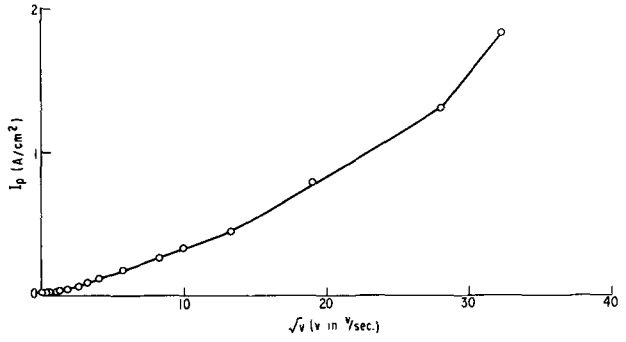

Fig. 5. Peak current density, I_p, of the first anodic wave as a function of the square root of the sweep rate of the single sweep.

clean the electrode surface of adsorbed materials. After 10 msec at 0.4v, the electrode was open-circuited and methanol allowed to adsorb for 1 min with argon flowing. A triangular sweep was then applied and the *I-U* curve recorded. These conditions approximate those used in determining the methanol adsorption isotherm (14).

The *I-U* curves in Fig. 4 can be understood on the basis of the concept developed in the preceding sections. The current density I_M of methanol oxidation is

$$I_M = I_1 + I_2 = I_a - F\Gamma \frac{d\theta_M}{dt} + I_2 \qquad [4]$$

The curves d and e at low speed have the characteristic shape discussed in the preceding sections. They coincide with the *I-U* curves in 1*N* $HClO_4$ at a potential $U < +2.0$v in the region of O_2 evolution. The scale is such that the anodic current due to the formation of the oxygen coverage in 1*N* $HClO_4$ between +0.8 and +1.5v is rarely recognizable. The heights of the first and second peaks increase with the voltage speed (curves e, d, c). The first peak appears at more positive potentials with increasing voltage speed, while the second peak remains at nearly the same potential. Curves d, e, and c show a narrowing of the potential range of the first wave. Above $v = 7$ v/sec the first wave begins to broaden until only one peak is observed at 800 v/sec (curve a). These observations can be interpreted as follows. Methanol molecules which diffuse to the surface and are oxidized there on the free surface with the rate I_2 represent the main contribution to the first peak current in the curves e, d, and c. The term

$F\Gamma_m \frac{d\theta_M}{dt}$ in Eq. [4] begins to contribute more and more with increasing voltage speed above $v = 7$ v/sec (curves a and b). Finally the current I_M results mainly from the oxidation of the initially adsorbed molecules (14). The potential of reversal has to be made more positive with increasing voltage speed so that the *I-U* curves in the electrolyte with and without methanol coincide. The current which is due to the formation of the oxygen layer becomes larger with increasing voltage speed and contributes considerably to the net current (curves a, b, and c).

The above results make the form of the $I_p - \sqrt{v}$ curve in Fig. 5 understandable. There I_p designates the current density at the first peak of the *I-U* curves. Kinetic data are often deducted from $I_p - \sqrt{v}$ curves. Figure 5 shows a nonlinear dependence between I_p and $\sqrt{v}$ which appears linear between 1 v/sec and 100 v/sec. In general a linear dependence is characteristic for a reversible (24) or irreversible (25) electrode process with diffusion control. However, this interpretation does not apply here as the following consideration shows. I_p is smaller for an irreversible process with diffusion control than for a reversible one (25). It is for an irreversible process (25)

$$I_p = 3.01\ 10^5\, n\, (\alpha n_a)^{1/2}\, D^{1/2}\, {}_0c\, v^{1/2} \qquad [5]$$

Here, n designates the number of electrons involved in the net process; α is the transfer coefficient of the discharge step; n_a is the number of electrons involved in the discharge step; D is the diffusion coefficient; ${}_0c$ is the bulk concentration of the reacting species; and v is the sweep rate. By taking $\alpha n_a = 0.5$ (close to the experimental αn-value of Eq. [1]), $D = 10^{-6}$ cm²/sec and $n = 2$ (assuming that the methanol oxidation only goes to the first stable intermediate CH_2O) the I_p-values in Table I are obtained from Eq. [5] as the lowest estimate for I_p at ${}_0c_M = 1$ M. The computed I_p-values in Table I are considerably larger than the observed ones.

It is concluded that the first current peak is caused at $v < 10$ v/sec by a blocking action of adsorbed oxygen on the oxidation mechanism with the partial current density I_2. The partial current due to the surface oxidation and that due to the oxidation of adsorbed methanol contribute considerably to I_p above $v = 10$ v/sec. At $v > 200$ v/sec I is practically equal to $-F\Gamma \frac{d\theta_M}{dt} + F\Gamma \frac{d\theta_0}{dt}$ with $F\Gamma_0 = 0.65$ mcoulomb/cm². The oxidation of the adsorbed molecules occurs at such positive potentials that I_2 is not observed any longer, owing to the considerable oxygen coverage in the respective

Table I. I_p-values from Eq. [5] and from Fig. 4

v	v/sec	0.07	0.70	7	70	800
$I_{p,\,comp}$	A/cm²	0.116	0.35	1.16	3.5	11.8
$I_{p,\,exp}$	A/cm²	0.014	0.019	0.08	0.18	1.27

Table II. Comparison of measured and computed I_p-values

$_oc_M$	M	1	0.1	0.01	0.001
$I_{p,\,comp}$	ma/cm²	76	7.6	0.76	0.076
$I_{p,\,exp}$	ma/cm²	8.3	2.7	0.75	0.20

potential range (compare curves a and c in Fig. 4).

The same conclusions hold for unstirred solutions. The peak current was determined as a function of the concentration at a sweep rate of 0.03 v/sec in 1*N* $HClO_4$ (see Table II). Table II shows clearly that the required linear dependence between $I_{p,\,exp}$ and $_oc_M$ (see Eq. [5]) is not observed. I_p decreases with $_oc_M$ in a way which is indicative for the presence of the postulated adsorption step. The shifting of the peak potential to less positive values at lower methanol concentration is correlated to the depletion of the adsorbed methanol at less positive potentials during the anodic sweep at the smaller bulk concentrations of methanol [see Fig. 6 of the preceding paper (14)].

Technical Notes

Sodium Borohydride, An Interesting Anodic Fuel (1)

Maurice E. Indig and Richard N. Snyder

Delco-Remy Division, General Motors Corporation, Anderson, Indiana

Sodium borohydride has long been considered as a potential source of limited amounts of hydrogen, based on the work of Schlesinger (2) and co-workers. In an aqueous solution sodium borohydride is a powerful reducing agent. Reactions with metal ions can result in precipitation of a metal (3), precipitation of a metal boride (4), formation of a volatile metal hydride (5), or reduction of the oxidation state of a metal ion (4).

The standard electrode potential of the reaction $BH_4^- + 8\ OH^- \rightarrow BO_2^- + 6\ H_2O + 8e$ has been calculated as 1.23v by Pecsok (6) and 1.24v by Stockmayer (7) and co-workers. Pecsok also indicated that the oxidation of sodium borohydride was highly irreversible.

The possibility of using sodium borohydride as an anodic fuel appeared attractive due to its extremely low equivalent weight of 4.73g, the fact that concentrated solutions of $NaBH_4$ in a highly basic medium can be quite stable, and the favorable electrochemical potential of the oxidation of the borohydride ion.

Experimental Procedure

A series of laboratory experiments were conducted to characterize the properties of the sodium borohydride electrode. Weighed amounts of $NaBH_4$ were dissolved in 30% KOH solutions. Four milliliter aliquots containing 0.12g of $NaBH_4$ were introduced into Lucite cell containers. The cells consisted of a sintered nickel anode of 80% porosity, an auxiliary cathode of silver sheet, and a mercury-mercuric oxide reference electrode located adjacent to the anode. The concentration of potassium and, later, sodium hydroxide were the same in ref-

erence electrodes as in the bulk solution. The reference electrodes were drawn down, and an asbestos wick was sealed into the fine tip. The apparent areas of anode and cathode were 6.45 cm². Current was supplied to the cell by an external d-c power supply. Potential measurements were obtained between the nickel anode and reference electrode with the aid of a potentiometer. Coulombic efficiencies were obtained in the constant current discharge by comparison of the total coulombs passed and the theoretical capacity of the $NaBH_4$, based on the theoretical eight electron oxidation.

In later experiments a commercial 12% solution of $NaBH_4$ in 40% sodium hydroxide was used as the source of borohydride ion. At 21°C these solutions had a decomposition rate of 0.000005% per day (8). In these experiments a 60-cycle interrupter (9) was used in order to determine polarization values without residual IR losses. It should be mentioned that any activation polarization that had a decay time faster than 1/120 of a second would not be measured with the interrupter. A schematic of the cell and discharge circuit are shown in Fig. 1.

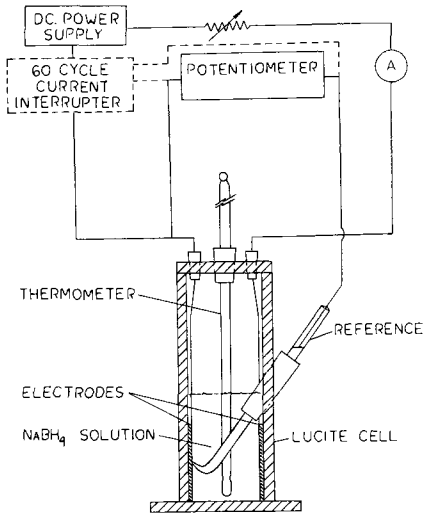

Fig. 1. Schematic of cell and discharge circuit

Results and Discussion

The results of the polarization studies of the sodium borohydride electrodes at three different temperatures are shown in Fig. 2. The curves represent data obtained in the constant direct current discharges and data obtained with the current interrupter technique.

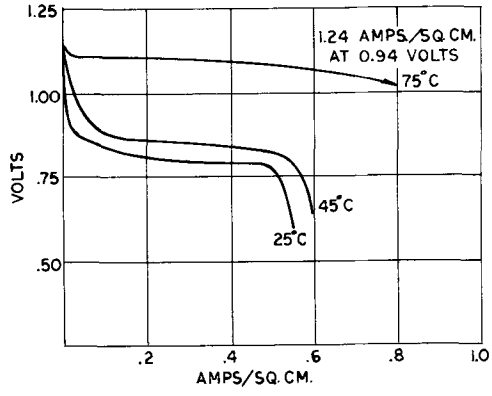

Fig. 2. Polarization of $Ni/NaBH_4$ electrode vs. Hg/HgO reference as a function of current density at three temperatures for electrolyte composition of 20% NaOH, 6% $NaBH_4$.

One of the major problems encountered in the discharges was the formation of large amounts of hydrogen gas. Although the sodium borohydride solutions were quite stable on storage, in contact with the porous nickel electrodes, the solutions gassed slowly. The gassing rate increased with the electrochemical oxidation, and at a rate of 775 ma/cm² much hydrogen was evolved. This indicated that hydrogen was formed as a product of the electrochemical oxidation. This was further substantiated by the coulombic efficiency studies. The coulombic efficiencies in separate discharges varied between 43 and 49% of a possible eight-electron change. At low current densities, 100 ma/cm² and below, the latter figure was approached and the efficiencies dropped as the current density increased. Thus, apparently a four-electron oxidation could be approached. The decomposition of $NaBH_4$ under open-circuit condition was due to a simple hydrolysis reaction, $BH_4^- + 2H_2O \rightarrow BO_2^- + 4H_2$. This reaction is accelerated by sintered nickel and other types of low overvoltage metals (2).

The average measured open-circuit potential of the borohydride electrode was 1.15v *vs.* the mercury-mercuric oxide reference electrode. It was possible to raise the open-circuit and operating potential by 0.075v with the use of platinum metal catalysts, but this caused severe gassing.

Although the observed potential of the nickel-borohydride electrode was almost 0.2v below the calculated reversible borohydride oxidation potential, it certainly could not be mistaken for the lower hydrogen potential in a basic medium, which is 0.926v *vs.* the mercury-mercuric oxide reference electrode. Further evidence of the fact that hydrogen was not contributing to the electrochemical performance was noted in a blank run. A sintered nickel electrode, with hydrogen as a fuel, gave an open-circuit potential of 0.63v *vs.* a mercuric oxide reference electrode. On application of a small load the electrode rapidly polarized to the oxygen evolution potential, thus indicating that the electrode had no activity for hydrogen.

The possibility of achieving a reversible sodium borohydride electrode with an eight-electron oxidation appeared unlikely. One might have to settle for a reaction involving a four-electron change and a lower potential. This reaction may be given as

$$BH_4^- + 4\,OH^- \rightarrow BO_2^- + 2H_2 + 2H_2O + 4e.$$

Anomalous Impurity Diffusion in Epitaxial Silicon near the Substrate

D. Kahng, C. O. Thomas, and R. C. Manz

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Ingham and McDade (1) have reported in epitaxial germanium grown by the closed tube method (2) an interfacial region (up to 100μ thick) which contained a relatively large concentration of imperfections. Figure 1 is a composite photograph which illustrates a similar, but thinner, interfacial region in epitaxial silicon grown on a heavily doped substrate by the hydrogen reduction of silicon tetrachloride in an open tube flow system (3) at 1105°C. The interface was located by beveling and staining. After this the bevel was polished again and etched with a silver etch (4) which revealed the "gross imperfections" at the interfacial region. It was found that such gross imperfections were not revealed when a CP etch was used. When an epitaxial film was grown on a lightly doped (10-20 ohm-cm) substrate neither the silver etch nor the CP etch revealed gross imperfections at the interfacial region. We have found that in the interfacial region immediately above a heavily doped substrate, where the region of gross imperfections is located, the impurity diffusion rate also is anomalously high, while in the remainder of the film the normal diffusion rate found in bulk silicon obtains.

Figure 2 shows impurity concentration profiles as measured by a differential voltage-capacitance method in an epitaxial silicon film grown at 1060°C on an arsenic doped substrate. The measurement method is described elsewhere (5). Note that the abscissa is the distance from the substrate rather than from the surface. Curve 1 is for a film which has been subjected to the normal film growth cycle (3) followed by a diode fabrication step consisting of an oxidation at 1100°C for 30 min, in order to provide an oxide diffusion mask, and a boron diffusion at 900°C for 70 min. One-half of the sample slice was used for curve 1. The other half slice was heat treated at 1200°C in air for 45 min after film growth but before diode fabrication. Curve 2 is the profile measured on the second half slice after the heat treatment at 1200°C and the diode fabrication.

For the film grown at 1060°C, the incremental arsenic diffusion distance (Δ) of about 2μ (at the 10^{15} level) is attributed to the heat treatment at 1200°C, since all the other heat treatments were the same for the two half slices. For films grown at 1105°C the incremental arsenic diffusion distance

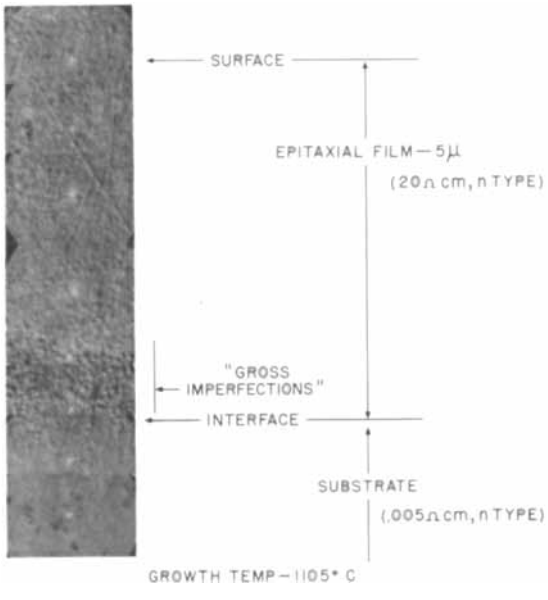

Fig. 1. Cross section of epitaxial silicon film on heavily doped (As) substrate. Interface located by staining. Gross imperfections developed by silver etch. This is a composite photograph.

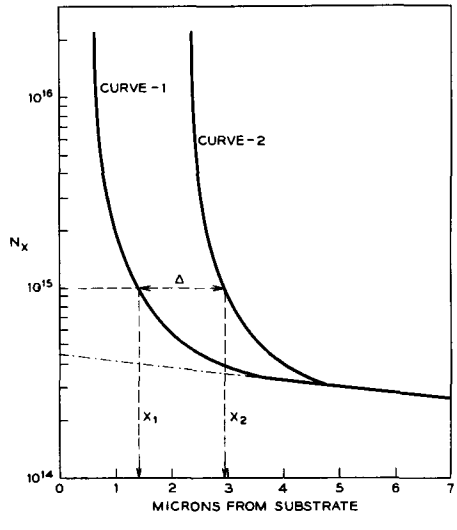

Fig. 2. Impurity profiles for n-type epitaxial silicon film grown on 0.005 ohm-cm (As doped) silicon substrate. Saturator contained purified silicon tetrachloride at —40°C. Film grown at 1060°C for 4 min. Δ = incremental diffusion distance produced by 1200°C heat treatment for 45 min after film growth.

was found to be about 1μ at the 10^{15} level using the same post-growth heat treatment as above.

An effective diffusion rate at the heat treatment temperature, in this case 1200°C, was estimated as follows. Since the diode fabrication involves much more heat treatment than does the film growth one may assume that the impurity distribution near the interface after the diode fabrication has the form

$$N'_x = \frac{N_o}{2} \operatorname{Erfc} \frac{x}{2\sqrt{K}} \qquad [1]$$

where N'_x is the impurity concentration at a distance x from the interface, N_o is the substrate doping level, and K is a constant. Equation [1] is a straightforward consequence of Fick's law where a concentration and position insensitive diffusion constant is assumed. As for curve 2, the distribution can be written as

$$N_x = \frac{N_o}{2} \operatorname{Erfc} \frac{x}{2\sqrt{K + Dt}} \qquad [2]$$

where D is the diffusion constant at the major heat treatment temperature, *i.e.*, 1200°C, and t is the duration of the major heat treatment. It is seen that the initial condition prior to this major heat treatment is simply N'_x given in Eq. [1]. In actuality, the major heat treatment was performed prior to the diode fabrication part which both halves underwent. The order of heat treatments should be interchangeable since simple superposition is expected so far as the final impurity distribution is concerned, aside from possible annealing effects which we ignore for simplicity.

We can now compute the effective diffusion constant as follows. Let x_1 and x_2 denote for the first and for the second half-slice, respectively, the distances from the stained interface at which the impurity concentration is a given value. Then

$$\frac{x_2}{x_1} = \sqrt{1 + \frac{Dt}{K}} \qquad [3]$$

Since N_o is known and x_1 is measurable from curve 1, K can be calculated. Use of this K and x_2 from curve 2 enables one to calculate the effective diffusion constant D from Eq. [3].

When the data in Fig. 2 were analyzed as outlined above, the effective diffusion constant was found to be larger by a factor of five than the published bulk diffusion constant (6). Since x_1 and x_2 are measured from the stained interface, the actual interface where the concentration is $N_o/2$ may not be coincident with the stain. When an allowance of $\pm 0.5\mu$ was made for this ambiguity, the calculation still yielded a value of 3-8 for the ratio of the effective diffusion constant to the published bulk value.

The effective diffusion constant estimated in the manner described above showed a dependence on the film growth temperatures. Higher film growth temperatures in general produced films whose interfacial effective diffusion rate is in better agreement with the bulk value. As the film growth temperature is lowered, the agreement becomes worse and the ratio of the effective diffusion constant to the bulk value reaches a value as high as nine. This suggests that the film structure near the interface has a direct bearing on the diffusion rate. If concentration dependent diffusion rates are responsible for the observed anomaly, the film growth temperatures should have no significant influence on the measured effective diffusion constant.

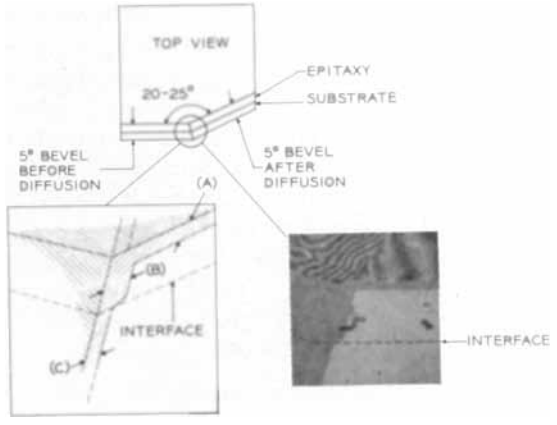

Fig. 3. Relative diffusion depths of boron (15 min at 1200°C) in epitaxial silicon and in substrates. Film resistivity ~ 2 ohm-cm (n-type). Substrate resistivity 0.005 ohm-cm (n-type). Film thickness 25μ. A = 3.25μ, B = 3.25μ, C = 2.5μ.

As illustrated in Fig. 1, the epitaxial film away from the interface shows no gross imperfections. Therefore, a normal diffusion of impurity into this region is expected. The diffusion of boron into the main body of the film and into the substrate has been studied by means of a double bevel technique as illustrated in Fig. 3. An n-type film was grown at 1060°C on an n^+-type substrate. After the film was grown the slice was beveled and polished along one edge at a 5° angle to the surface. It was then given a shallow boron diffusion (1200°C for 15 min) and beveled and polished at 5° again as shown. The intersection of the two bevels was stained and photographed. The junction depths in the film from its upper surface (A) and from the first bevel surface (B) are both 3.25μ as determined by interferometry. The apparent visual difference is an artifact of both the photographic and lapping angles. The junction depth in the substrate (C), also measured by interferometry, is 2.5μ. These junction depths are consistent with the diffusion constant for boron in normal bulk silicon when allowance is made for the background donor concentration in the film and in the substrate.

One might expect an excursion in junction depth to occur near the substrate film interface. However the thickness of the region in which the larger diffusion rate exists is of the same order of the magnitude as the diffusion depth in the sample of Fig. 3. In addition, out-diffusion of the background dopant from the substrate tends to minimize such an excursion. In a similar experiment in which the diffusion depth was smaller than the interfacial region thickness (~2μ), the surface irregularities (strain, lapping damage, etc.) resulted in an irregular junction front obscuring the expected excursion near the interface.

Summary

The interfacial region for epitaxial silicon films grown on heavily doped substrates appears to have unusual and undesirable characteristics as exhibited by characteristic etch patterns and anomalously high diffusion rates. For very thin films this interfacial region may occupy the major portion of the total film thickness and so cause serious problems in device fabrication in such very thin films on highly doped substrates. The diffusion rate of impurities in the main body of the film, however, is consistent with the rate in normal bulk material.

Acknowledgments

The authors are indebted to T. B. Light for assistance with the imperfection studies and to A. Loya for assistance with the electrical measurements.

Manuscript received June 19, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

X-Ray Studies of Twinned GaAs Blades Grown from the Vapor Phase

Roch R. Monchamp, William J. McAleer, and Peter I. Pollak

Electronic Chemicals Research Department, Merck Sharp & Dohme Research Laboratories, Division of Merck & Company, Inc., Rahway, New Jersey

In a recent paper (1) McAleer *et al.* reported on the preparation of GaAs bladelike crystals from the vapor phase. This paper reports on the x-ray studies of these crystals. Using the rotating crystal technique, the major growth axis was determined to be $[\bar{2}11]$ and the major faces were shown to be (111) and $(\bar{1}\bar{1}\bar{1})$ by microscopic examination of etched surfaces and x-ray reflection studies. The same general crystallographic characteristics have been observed in silicon ribbons grown from the vapor (2) and are also found in Ge and Si dendrites grown from supercooled melts (3). The similarities of the GaAs blades to the Si and Ge dendrites, which have been demonstrated to grow via a twin mechanism, suggest that blades may also contain a coherent twin plane. In both the Ge and Si dendrites {111} twin planes were observed by fracture and etch techniques (3). Although twin planes were indicated also in the GaAs blades by these techniques, more positive evidence for the existence of such structures was sought from x-ray examination.

For a twinned crystal belonging to the diamond class geometric considerations require that the crystallographic axes of one section of the twin, when continued across the twin plane, are transformed into a new set of axes having rational indices (4).

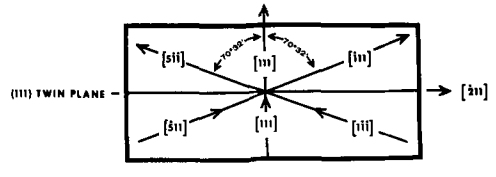

Fig. 1. Transformation of crystallographic directions across a single twin plane.

For twinning in the (111) plane, the $[\bar{1}11]$ direction is transformed into a $[\bar{5}11]$ direction after passing through the twin plane, the [011] is transformed into the $[\bar{4}\bar{1}\bar{1}]$ and the [100] into the $[1\bar{2}\bar{2}]$. Figure 1 illustrates the relationship for a single twin plane and the $[\bar{1}11]$ and $[\bar{5}11]$ case.

When a twinned crystal of the type depicted in Fig. 1 is rotated about the $[\bar{1}11]$ axis or the $[5\bar{1}\bar{1}]$ axis, layer lines characteristic of both $[\bar{1}11]$ and $[5\bar{1}\bar{1}]$ are observed in a rotation photograph and identical patterns are produced (see Fig. 2c). On the other hand, when an untwinned crystal is rotated about the $[\bar{1}11]$ and the $[5\bar{1}\bar{1}]$ axes, clearly distinguishable layer line patterns are obtained (Fig. 2a and 2b). Comparing only the layer lines produced on rotating a single crystal about its $[5\bar{1}\bar{1}]$ axis (Fig. 2b) and those produced by twinned crystals when rotated about $[5\bar{1}\bar{1}]$ and $[\bar{1}11]$ axes, one finds that the layer line structures are indistinguishable. This results from the fact that the $[5\bar{1}\bar{1}]$ rotation yields many more layer lines than the $[\bar{1}11]$ rotation and the 3rd, 6th, and 9th lines produced by [511] rotation are coincident with the $[\bar{1}11]$ layer lines. Thus, on the basis of layer line structure, rotation about the $[5\bar{1}\bar{1}]$ axis does not distinguish between twinned and untwinned crystals.

If it were possible to mount the crystal to clearly rotate about the $[\bar{1}11]$ axis, a single rotation photograph would distinguish between a single crystal and a twinned one. If the crystal is untwinned, it will produce the pattern shown in Fig. 2a, if twinned, a pattern as in Fig. 2c.

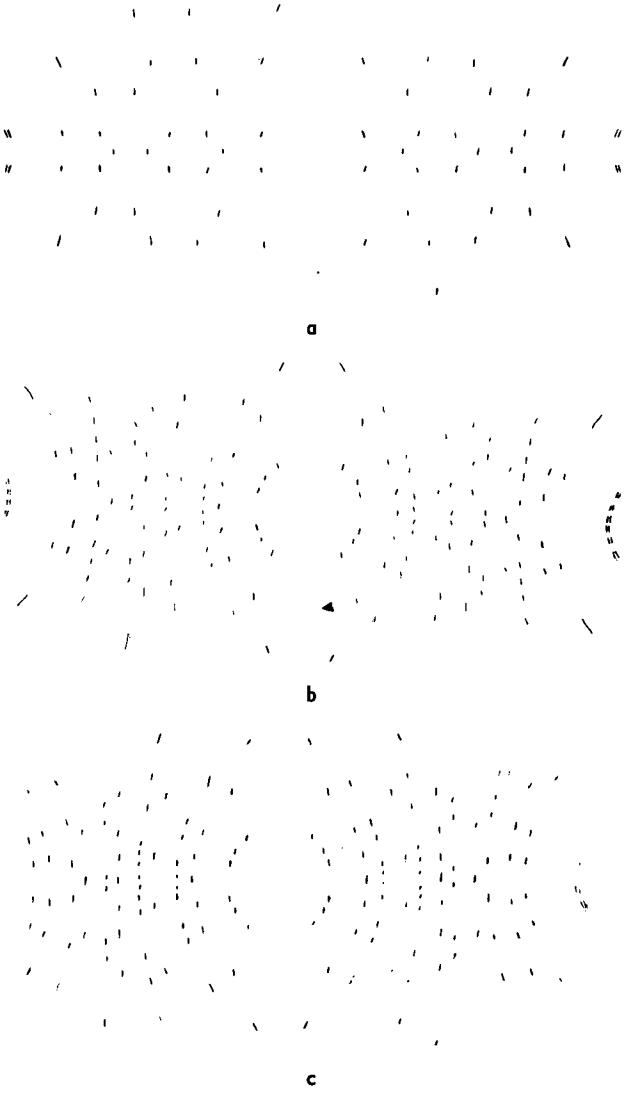

Fig. 2. Reproduction of x-ray film showing layer line structures for (a) (top) [$\bar{1}11$] rotation of a single crystal; (b) (center) [$5\bar{1}\bar{1}$] rotation of a single crystal; and (c) (bottom) [$5\bar{1}\bar{1}$] and [$\bar{1}11$] rotation of a (111) twinned crystal.

The specific selection of the [$\bar{1}11$] axis is possible if the precise orientation of the crystal is established. This step can be avoided, however, by taking two photographs rotating about opposed axis (see Fig. 2a) both 70° 32″ from the [111] axis, thus insuring that the [$\bar{1}11$] axis has been examined. When this was done with the GaAs blades, both photographs were identical, showing that the blade is twinned.

An alternate approach in distinguishing between twinned and untwinned crystals rotated about [$5\bar{1}\bar{1}$] axis resides in the indexing of the individual spots of the photographs (5). For instance a single crystal rotated about the [$5\bar{1}\bar{1}$] would not show any reflection on the zero layer line due to a {422}, whereas

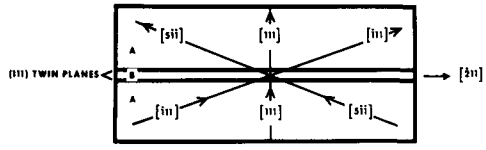

Fig. 3. Transformation of crystallographic directions across two twin planes.

a twinned crystal has this reflection due to the presence of the [$\bar{1}11$] axis.

The same x-ray technique was also applied to silicon and germanium dendrites grown from the melt. For germanium dendrites identical x-ray photographs were obtained when the crystal was rotated about both the [$\bar{1}11$] and the [$5\bar{1}\bar{1}$], which, in accordance with the geometric requirements given above, demonstrated the existence of a twin plane. In the case of a silicon dendrite, rotations about [$\bar{1}11$] and [$5\bar{1}\bar{1}$] produced layer line photographs corresponding to the rotation axis, *e.g.*, Fig. 2a and 2b. Since the presence of twins in this crystal has been demonstrated by other means, it must be concluded that this x-ray method can fail under two conditions: (*a*) if a very narrow B section is present, as in Fig. 3, reflections from this region would not be detected (a limiting value of ~5% of the crystal would be expected), or (*b*) the overlying section is of such a thickness as to prevent penetration of the x-ray beam to the twins.

Considering the limitation cited above for the case of the silicon dendrite, it is clear that all available techniques must be employed in examining a crystal for the presence of twin structures. The ancillary problem of determining the number of twins in these crystals is not amenable to solution by this technique. This aspect of the work may best be handled by fracture and etch techniques described by Faust *et al.* (3).

The Preparation of Single Crystals of Some Rare Earth Tellurides

P. Bro

Research and Advanced Development Division, Avco Corporation, Wilmington, Massachusetts

We report the first preparation of single crystals of some rare earth tellurides which were made by the vapor transport method described by Schäfer and his co-workers (1). Data have been reported (2, 3) on the properties of several rare earth tellurides in polycrystalline form; however, polycrystalline materials are unsatisfactory for the proper electrical and structural characterization of these semiconductors.

The reactions between the rare earth metals and tellurium gave rise to MTe, M_3Te_4, M_2Te_3, MTe_2, and MTe_3 of which the La, Ce, Pr, and Nd compounds have been studied in our laboratories so far. This note is concerned with the growth of single crystals of the sesqui- and di-tellurides. M_2Te_3 was synthesized from the elements in degassed, evacuated quartz tubes at 800°C. The crude product contained a tellurium rich phase near the surface and a metal rich phase in the interior, and it was not suitable for the preparation of single crystals without further treatment. Satisfactory results were obtained with sesquitellurides which had been melted in graphite crucibles at temperatures up to 1800°C in evacuated quartz tubes by means of induction heating. The single crystals were prepared in a bithermal furnace in an evacuated quartz tube containing iodine and sesquitelluride in weight ratios between 0.09 and 0.37. The MTe_2 crystals appeared within 1-2 days in the middle of the tube at temperatures between 700° and 830°C, and the M_2Te_3 crystals formed near the M_2Te_3 source at approximately 900°C. The cooler end of the tube was maintained at approximately 650°C, and a deposit which formed at that end was probably the metal iodide. The MTe_2 crystals grew to various sizes up to 4 x 2 x 1 mm and were suitable for electrical measurements, whereas the M_2Te_3 crystals were too small for any measurements other than x-ray diffraction. Transfer periods of two weeks were required for the growth of large, regular, single crystals.

The crystals were stable in air, except for the formation of a barely noticeable tarnish in a few weeks. The tarnish could be removed by a chemical polishing solution consisting of bromine, acetic acid, and ethanol. The M_2Te_3 compounds possessed a body-centered cubic structure, and the MTe_2 compounds were tetragonal. Some of the compounds in the MTe_2 series exhibited two reversals in their Hall effect and a strongly anisotropic thermoelectric effect.

The Rapid Determination of the Conductivity Type of Materials at 4°K

R. C. Bourke[1]

Battelle Memorial Institute, Columbus, Ohio

In a specimen of a semiconductor there may be a "crossover" in conductivity type at some temperature depending on the material parameters and on the acceptor and donor concentrations. Hence, the true extrinsic conductivity type, *i.e.*, the predominance of donors or acceptors, may not be determinable by thermoelectric probing or other means at ordinary temperatures, but may require investigation at liquid-helium temperature, especially in the case of low-band-gap materials. Conventional methods for making quantitative cryogenic measurements of the Seebeck and Hall coefficients are complex and time consuming. Therefore, a simple probing method has been devised for the rapid determination of the sign of the Seebeck coefficient at liquid-helium temperature. Very small specimens of arbitrary geometry may be used, and soldering or welding of leads to the specimen is not necessary.

Several modifications of the system have been devised; Figure 1 shows the one that has been found the most useful. The sample is held in the bottom of an open-ended 8-mm Pyrex guide tube by a slight constriction in the end of the tube. A small-diameter copper wire is wrapped around the bottom end of the specimen and a large-diameter copper wire is placed in contact with the upper end. When the sample is cooled by immersion of the end of the tube in liquid helium, the large-diameter wire becomes a "hot"

[1] Present address: Allison Division, General Motors Corporation, Indianapolis, Indiana.

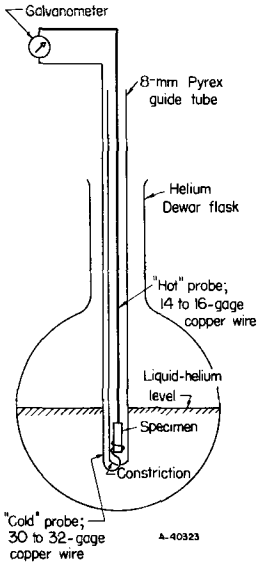

Fig. 1. Details of liquid-helium hot-probe technique

probe because of its greater heat capacity and higher rate of heat conduction from the atmosphere above. As the tube is immersed, the small-wire probe and the sample attain the temperature of liquid helium in a short time, whereas the large probe remains at a higher temperature for a relatively long period of time. Thus, a changeover in conductivity type, indicated by a reversal in the direction of the galvanometer deflection, can easily be detected before the temperature difference between the two probes approaches zero. The determination can be repeated by raising the large-diameter wire above the surface of the liquid helium and allowing it to warm slightly. The probe is then lowered quickly until contact is made with the specimen which is still immersed in the helium. Ice or frozen air on the surface of the specimen can prevent good contact between the hot probe and the sample and, thus, cause erratic galvanometer deflections. Therefore, the tube must be thoroughly flushed with helium prior to immersion This is conveniently done by forcing most of the escaping helium to flow up through the guide tube by the insertion of packing material between the neck of the Dewar flask and the outside of the guide tube.

The method indicates only the sign of the Seebeck coefficient of a specimen and is not quantitative. However, it is quite useful when, for example, a series of doping experiments are being made in an attempt to change the conductivity type of the material being studied. When it has been found that the desired change has been produced, more detailed measurements can be made. The technique has been used successfully on certain specimens of Ag_2Se and Ag_2Te which undergo conductivity-type changes at low temperatures.

Impurity Incorporation into CdSe and Equilibria in the System CdSe-$CdCl_2$

A. Reisman and M. Berkenblit

Thomas J. Watson Research Center, International Business Machines, Yorktown Heights, New York

Because of its high melting point, 1239° (1), and high dissociation pressure, approximately 100 mm Hg at 1000° (2), and because of restriction of container and substrate materials to silica or Al_2O_3, CdSe is most conveniently sintered into polycrystalline layers or grown as single crystals from fluxes such as $CdCl_2$. Since the selenide has always been observed to exhibit n-type conductivity, undoubtedly contributed to by a high excess selenium vacancy count (1), one normally compensates the material by addition of acceptors, such as Cu, to the flux. The effectiveness of such doping will be a function of the degree of selenide solution attained at a given temperature and flux concentration, as well as the distribution of the impurity between the flux and semiconductor. The present report describes equilibria in the system CdSe-$CdCl_2$ and discusses the gross manner in which Cu and Ag, another common activator, are incorporated into the lattice using the chlorides of each as dopant sources.

The DTA technique has been described elsewhere as have the x-ray techniques used for phase identification (3, 4).

Results and Discussion

Equilibria in the system CdSe-$CdCl_2$.— Studies were conducted in both closed and open sample holders since each type of arrangement has certain practical advantages. Thus, sintered layer preparation is most easily accomplished in open systems while single crystal growth may be conducted in either type of arrangement. Above 500° however, the vapor pressures of CdSe and $CdCl_2$, the latter particularly, become appreciable, and consequently an open system cannot be considered to conform to the reduced phase rule since composition changes would be occurring in the condensed phases as a function of time. To prevent oxidation of CdSe in the open system, experiments were conducted in an N_2 atmosphere.

Table I presents the results of thermal studies for the closed system experiments, and Fig. 1 depicts the proposed equilibrium diagram in unbroken lines. The results of open system experiments are also presented in Fig. 1 by the dashed lines. In the low-temperature regions, the results of both investigations are essentially the same, the eutectic composi-

tion being detected at about 77.5 mole % $CdCl_2$ in both studies. As higher temperatures become necessary, the open system curve, as expected, becomes displaced to the CdSe-rich side of the system. Thus, the 70 mole % of $CdCl_2$ starting sample in the closed system exhibited a liquidus at 612° while the open system value was 644°. At 40 mole % $CdCl_2$, the respective values were 928 and 963°. While it is evident that the open system value will depend on the sample surface area, the data obtained in closed system experiments should not, within the limits of error involved in measuring liquidus temperatures, 2-3°, since liquidus values will be a function of the sample container volume only. The latter, with respect to vapor-available space, was kept small, about equal to the volume of the condensed phase, so that

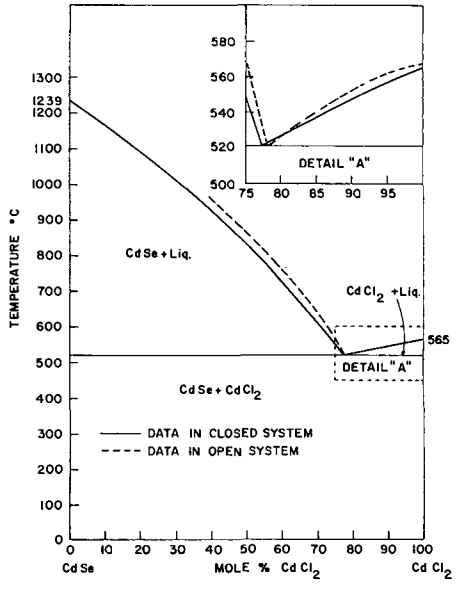

Fig. 1. Phase diagram for the system CdSe-$CdCl_2$ in open and closed systems.

composition variation due to the presence of vapor might be ignored. It is evident that Fig. 1 represents a projection on the T-X plane rather than a constant pressure plane in a T-P-X set of coordinates. Since the pressures developed in the sealed systems are not very great, however, Fig. 1 is probably equivalent within experimental limits to T-P-X representations at 1 atm. Additional experiments were performed to establish an upper limit on the solubility of $CdCl_2$ in CdSe. Quantities of $CdCl_2$ to give 0.5-2.5 mole % of this material were fired in 0.5 mole % steps with CdSe and examined with x-rays. The $CdCl_2$ pattern was detected in the 0.5 mole % sample placing the solubility limit below this value.

Reactions of CdSe *with* $CuCl_2$ *and* AgCl.—Anhydrous $CuCl_2$, 0.1, 1.0, 5.0, and 20 mole %, was mixed with CdSe, and the samples were treated at 550° and 900° in evacuated quartz containers for varying lengths of time. The samples were then either quenched or cooled slowly. In all cases, except one, identical results were obtained. The samples containing 0.1 mole % $CuCl_2$ yielded only the CdSe diffraction pattern while all the others exhibited the pattern of CdSe, CuSe, and $CdCl_2$. Samples were then prepared containing $CuCl_2$, CdSe, and $CdCl_2$ in which the compositions were $CdCl_2$ relative to CdSe, 20 mole %, $CuCl_2$ relative to CdSe 1 and 5 mole %. These were heat treated in open containers under an atmosphere of N_2 at 600° and 700° for 30 min and quenched. X-ray examination again indicated the presence of CuSe in addition to CdSe and $CdCl_2$.

The above data indicate that, rather than incorporation of copper via the mechanism

$$2CuCl_2 \rightleftarrows 2CuCl + Cl_2(v) \qquad [1a]$$

$$(1-x)\ CuCl + x\ CdSe \rightarrow Cd_xCu_{1-x}Se_xCl_{1-x} \qquad [1b]$$

the reaction proceeds via

$$CuCl_2 + CdSe \rightarrow CdCl_2 + CuSe \qquad [2]$$

followed by a partial solution of CuSe in CdSe. The extent of solution is presumably less than 1 mole % on the basis of the x-ray data, and the reaction appears to go to completion.

While the failure to detect Cu_2Se or CuCl, irrespective of firing temperature or cooling cycle, is not proof that copper is initially incorporated in the lattice as a bivalent ion, it is an indication that such is the case. One would, of course, expect that within the lattice an equilibrium between Cu^+ and Cu^{++} would obtain.

Experiments similar to those employed in studying the reactions of $CuCl_2$ with CdSe were conducted with AgCl and CdSe. As with $CuCl_2$, a reaction rather than a simple solution occurred, and Ag_2Se and $CdCl_2$ were products of the reaction according to

$$2AgCl + CdSe \rightarrow Ag_2Se + CdCl_2 \qquad [3]$$

The silver selenide is then incorporated into the selenide lattice with the formation of one selenium vacancy for each two added silver atoms. It appears therefore that when the molar quantity of AgCl is less than that of CdSe, the system AgCl-CdSe is not an equilibrium one under normal ambient or vacuum conditions, being more properly designated by the ternary representation Ag_2Se-CdSe-$CdCl_2$. When

the molar quantity of AgCl exceeds that of CdSe, a binary representation is again invalid, a proper designation being Ag_2Se-AgCl-$CdCl_2$. Similarly, the system $CuCl_2$-CdSe is more properly designated by either CuSe-CdSe-$CdCl_2$ or CuSe-$CuCl_2$-$CdCl_2$.

Reactions of CdSe *with silica, silica-based materials and* Al_2O_3.—In attempts at growing single crystals of CdSe at its melting point in silica containers evacuated with a mechanical pump, the interior of the containers had severely corroded during the experiments, in some instances sufficiently to cause fragmentation of the containers. When the initial pressure was reduced to the 10^{-4} mm region, the container corrosion was greatly reduced. This was evidenced primarily by decreased wetting of the silica surface in contact with the melt. In the 10^{-5}-10^{-6} mm range wetting effects disappeared, the selenide separating cleanly from the silica when the containers were broken open after cooling. These experiments indicated that the apparent reactivity of CdSe with silica is not due to the compound itself but rather to the presence of CdO. To resolve this question, distilled Cd, Se, CdSe, and CdO were each heated in silica. Only the latter gave visual evidence of reaction, so much so that in each attempt fragmentation of the containers resulted.

The product of the reaction of the CdO with SiO_2 gives a very distinct powder pattern which, however, is not listed in the A.S.T.M. card index. In all probability, the pattern is representative of a mixture of two compounds having compositions nominally represented by $xCdO \cdot ySiO_2$ in the system CdO-SiO_2. These results are of some practical concern since, in addition to indicating cautions to be observed in high-temperature handling of CdSe, they indicate a means of obtaining sintered layer adhesion to smooth silica and silica-based substrates. In the preparation of photoconductive polycrystalline sintered layers on such substrates, two processes must be considered. (i) interparticle adhesion and (ii) sintered layer-substrate adhesion. Since cadmium oxide-silica based glues would be expected to exhibit high melting points, they should, on forming, tend to solidify immediately because of the high SiO_2 concentration and not contaminate the sintered layer to any degree. CdSe sintered layers using $CdCl_2$ fluxes were prepared on soft glass substrates in the absence of O_2 and these failed to adhere although sintering of the selenide itself did occur. When prepared in a 1% O_2 atmosphere just above the eutectic temperature in the system CdSe-$CdCl_2$, 522°, the layers did adhere. By treating in higher concentrations of O_2, a quantity of the interlayer between the substrates and sintered layers was formed sufficient to allow x-ray and spectroscopic analysis. These x-ray patterns were distinct, but could not be identified. Spectroscopic analyses showed the normal constituents of the glass employed plus Cd.

Neither CdO nor CdSe was found to exhibit any detectable attack on recrystallized Al_2O_3 even in the presence of $CdCl_2$ flux. Sintered layer adhesion to the latter when serving as a substrate is therefore mechanical. In fact, if the particle size of a sintering CdSe layer is permitted to became too large, the layer flakes off the substrate.

Brief Communication

A Dislocation Etch for Lead Selenide Crystals

Marriner K. Norr

United States Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland

The etch recently published for PbSe by Coates *et al.* (1) can be modified to give sharp, square, pyramidal dislocation etch pits at room temperature. This modified etch was found to be an improvement over the one published by Brebrick and Scanlon (2), because their etch required a temperature of 60°C and its pitting action was quite slow.

The modified etch was prepared by dissolving 10g of KOH in 10 ml of distilled water and then adding 1.0 ml of glycerol. After the solution had cooled to room temperature, 0.5 ml of 30% H_2O_2 was added. Reagent grade chemicals were used throughout. Fresh cleavage-surfaces of PbSe were etched in the solution for 2 min at 25°, after which they were rinsed with water and carefully dried on lens paper. It is recommended that the surfaces to be etched should be freshly cleaved because they are very susceptible to mechanical damage and chemical contamination.

The etch produces results (see Fig. 1) qualitatively very similar to those obtained by Gilman and Johnston (3) (using their "A" etch) on LiF and by

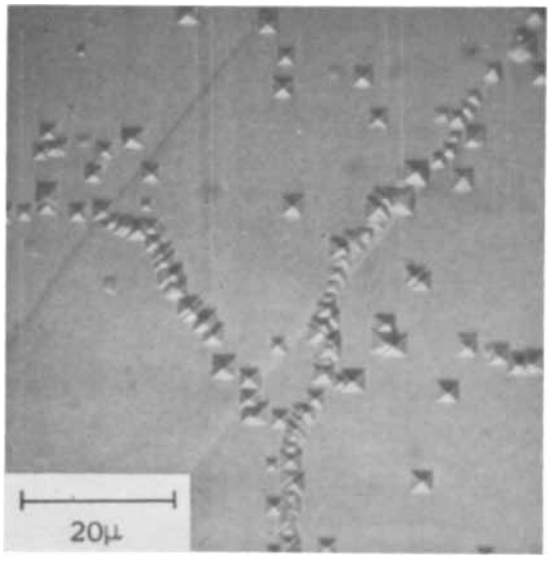

Fig. 1. Dislocation etch pits on a PbSe cleavage surface

Houston and Norr (4) on PbTe. Sharp, square, pyramidal pits were formed on both n- and p-type material. The pits were 2-6μ across, and their edges were parallel to the <100> directions of the crystal. They were obtained along small-angle grain boundaries, along the traces of active slip planes, and at points distributed randomly over the surface. The edges of cleavage steps were attacked. When previously etched material was lightly deformed and etched again, new pits were produced which appeared to be due to dislocations introduced by the deformation. When the two surfaces formed by the cleavage of a crystal were etched, their pit patterns were approximate mirror images of each other, except in areas which showed traces of active slip planes.

The PbSe crystals used above were grown by the Bridgman-Stockbarger technique in silica crucibles. The best material had pit densities (excluding pits along subgrain boundaries) of 1 x $10^6/cm^2$. The angle of tilt between adjoining subgrains, as estimated from the number of pits per unit length along the boundary, was of the order of 1-5 minutes of arc. The subgrains averaged about 0.1 mm across.

Chemical and Electrical Characteristics of the Alkali Carbonate High-Temperature Fuel Cell

Y. L. Sandler

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

When hydrogen is used as a fuel in an alkali carbonate-type fuel cell operating at about 580°C, carbon monoxide and methane are being evolved by formed by secondary reactions with the products H_2O and CO_2, the latter from decomposition of $CO_3^=$. The reactions and resulting emf's under conditions of equilibrium are discussed. With natural gas, the reforming reaction with water was carried out in a separate reactor in contact with the cell. At the temperatures used, the conversion to hydrogen on a nickel-alumina reforming catalyst can be brought to near completion before the gas mixture enters the cell. The experimental cell, a modified version of the cell of Broers and Ketelaar, is leak-proof and gives higher outputs than heretofore obtained (up to 230 ma/cm² at 0.6v with hydrogen at 20% reaction).

This paper deals with a high-temperature fuel cell that employs a fused mixture of alkali carbonates as electrolyte and is operated near 600°C. The reactions taking place at the fuel electrode of the cell, and the effect of these reactions on the electrical characteristics, are discussed. Some performance data are also given.

Experimental

The experimental cell is shown in Fig. 1. It resembles the cell used by Broers (1, 2) in his earlier work. It was, however, developed to be practically leak-proof and to give substantially higher outputs than heretofore obtained. The electrolyte consists of a melt of alkali carbonates contained in a porous magnesia disk. The fuel electrode is a nickel mesh filled with nickel particles, and a silver mesh filled with silver particles serves as the oxygen electrode. The perforated plates in the gas inlet caps serve to admit the gases to the electrodes and to press the electrodes firmly against the electrolyte disk. A strong closing pressure was used to leakproof the cells and to minimize the electrode-electrolyte resistance. An electrode area of 11 cm² was used in all experiments presented in this paper.

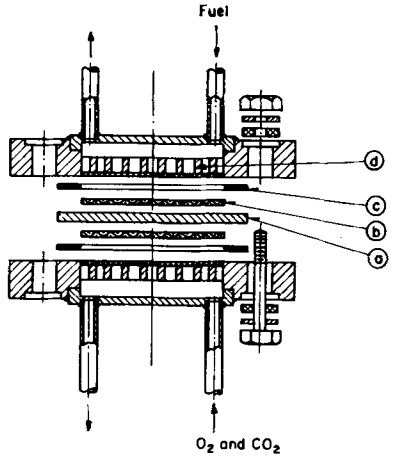

Fig. 1. Blown-up view of the cell. (a) electrolyte disk, (b) electrode, (c) gasket, (d) perforated plate.

The reactions were monitored by mass-spectrometric analysis. They were investigated under realistic flow conditions; this is essential because, at the high flow rates that must be employed in leaking cells, the secondary reactions discussed in this paper may not take place to any appreciable extent. A relatively low temperature of about 580°C was chosen because the life and output of the carbonate type of fuel cell are limited by rate processes such as the evaporation of electrolyte, corrosion reactions, and grain growth of the electrode particles. It will be seen that, despite the low temperature, substantial outputs can be obtained.

When hydrocarbons are used, the electrode has a twofold task: the first is a catalytic one, *via.*, to produce the electrochemically reactive species. In the chosen temperature range, this is essentially hydrogen. The second task is the electrochemical oxidation of the hydrogen. In the following paragraphs, the operation of the cell with hydrogen will first be discussed in greater detail. When hydrocarbons are used, the electrochemical cell functions in essentially the same manner.

Electrode Reactions with Hydrogen as Fuel

Primary reactions.—The primary reactions taking place at the electrodes of a carbonate cell are

$$\text{Anode: } H_2 + CO_3^= = H_2O + CO_2 + 2e \qquad [1]$$

CO_2 is thus liberated at the anode; it must be replaced by adding CO_2 to the oxygen at the cathode.

$$\text{Cathode: } \tfrac{1}{2}O_2 + CO_2 + 2e = CO_3^= \qquad [2]$$

The emf of a pure hydrogen-oxygen cell, as, for example, realized when a solid oxygen ion conductor (3) is used, is given by the Nernst relation

$$E = E^\circ - (RT/2\mathbf{F}) \ln (p_{H_2O} p_{H_2}^{-1} p_{O_2}^{-1/2}) \qquad [3]$$

It is assumed that all concentrations are uniform throughout the gas phase. When st: rting with pure

hydrogen, the degree of electrochemical oxidation of the fuel is: $x = p_{H_2O}/(p_{H_2O} + p_{H_2})$. Then, with $p_{O_2} = 1$ atm, Eq. [3] becomes

$$E = E^\circ - (RT/2\mathbf{F}) \ln [x/(1-x)] \quad [4]$$

In the carbonate cell, CO_2 is in electrochemical equilibrium at both anode and cathode (1, 4). We assume for the present that the primary reaction [1] is the only reaction taking place at the fuel electrode. Then

$$E = E^\circ - (RT/2\mathbf{F}) \ln [(p_{H_2O} p_{H_2}^{-1} p_{CO_2})_{anode} (p_{O_2}^{-1/2} p_{CO_2}^{-1})_{cathode}] \quad [5]$$

A corresponding expression for the emf as a function of the fraction x of hydrogen consumed in the cell is easily derived from [5] and the following three conditions at the anode

(a) $p_{H_2O} = p_{CO_2}$ (one mole of CO_2 is formed from the electrolyte with each mole of H_2 reacted)

(b) $x = p_{H_2O}/(p_{H_2} + p_{H_2O})$

(c) $p_{H_2} + p_{H_2O} + p_{CO_2} = 1$ atm

This leads to

$$E = E^\circ - (RT/2\mathbf{F}) \ln (C x^2/(1-x^2)),$$

$$\text{with } C = (p_{O_2}^{-1/2} p_{CO_2}^{-1})_{cathode} \quad [6]$$

Usually the cells were run with a ratio O_2:CO_2 at the cathode of 1:2 and at 1 atm total pressure. This gives a value of $C = 2.6$.

Secondary reactions.—Actually, when an active electrode is used, the situation is complicated by secondary reactions taking place at the fuel electrode between hydrogen and the reaction products, water and carbon dioxide (the latter being formed by decomposition of the carbonate ion). Carbon monoxide and methane are formed. This appears to have remained unnoticed until now.

The following typical analysis was obtained with a cell run with dry hydrogen at 580°C. The flow rate was 25 cc (STP)/min and a current of 700 ma was drawn. Assuming a current efficiency of 100%, about 20% of the hydrogen must have been electrochemically oxidized. The analysis given in Table I shows that both CO and CH_4 are formed at 580°C.

The chemical reactions to be considered are

$$H_2 + CO_2 = CO + H_2O \quad [7a]$$

(the reverse water-gas shift reaction)

$$4H_2 + CO_2 = CH_4 + 2H_2O \quad [7b]$$

(the reverse methane reforming reaction)

The equations do not necessarily represent the actual course of the reactions; in principle, two more reactions of this type can be written which, however, are not independent. Only two of these four equations together with three mass balance equations for the number of oxygen, hydrogen, and carbon atoms before and after the reaction, determine the equilibrium amounts of the gases H_2, H_2O, CO_2, CO, and CH_4.

Table I. Composition of gases emerging from hydrogen cell

CO_2	CO	H_2O*	H_2	CH_4
18.8%	4.8%	(7.2%)	66.8%	2.4%

* Gas compositions were determined by mass spectrometer. Later tests showed that the H_2O values thus obtained were consistently too low. This explains that the analyses gave somewhat inaccurate material balances. Lack of equilibrium with the electrolyte and carbonyl formation (by reaction of CO with the stainless steel gas exit tube) may also have contributed to this. The present data must be considered preliminary, and discussion of the analytical results is therefore given in a qualitative fashion.

No carbon was found in the cells after cooling the cells to room temperature in an inert gas. After removal of the carbonates, the electrodes were reacted with oxygen. No CO or CO_2 was found in excess of the amount present in the starting material.

It can also be shown from thermodynamic data that no carbon can be formed under equilibrium conditions. At low electrochemical fuel conversion the hydrogen prevents carbon formation; instead, CH_4 is formed. At higher conversions the water formed prevents carbon deposition.

At high electrochemical conversions at 580°C, the concentrations of CH_4 are very small; this is best seen by considering the mass action law for Eq. [7b]. When the concentration of H_2O is large and at the same time the concentration of H_2 is small, then the concentration of CH_4 must be very small. Also, on raising the temperature, the methane rapidly vanishes from the products; reaction [7b] is highly exothermal and, therefore, the equilibrium constant must rapidly decrease with temperature. On the other hand, on lowering the temperature, the methane concentration rapidly increases and this actually may set the lower temperature limit at which the cell can be run effectively.

The formation of CO (reaction [7a]) is endothermal; the amount of CO is thus smaller at lower temperatures.

Figure 2 shows the calculated emf as a function of the degree of fuel conversion in the cell at 580°C for the three different cases: curve 1, the pure hydrogen cell, in accordance with Eq. [3] or [4]; curve 2, for the carbonate cell in absence of secondary reactions, in accordance with Eq. [5] or [6]; and curve 3, for the same cell when a complete chemical equilibrium is established at the fuel electrode. This curve is shown only at higher conversions where

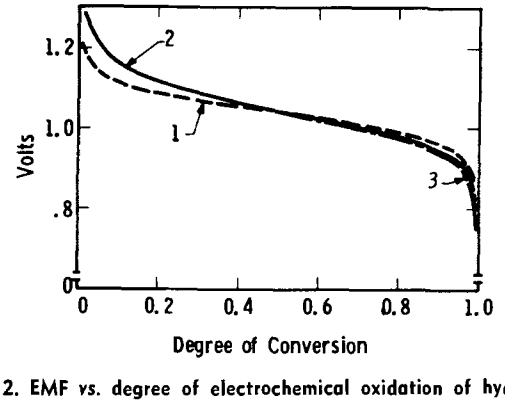

Fig. 2. EMF vs. degree of electrochemical oxidation of hydrogen for: 1, solid oxide cell; 2, carbonate cell, in absence of secondary reactions; 3, carbonate cell, equilibrium established.

only the water-gas shift reaction has to be taken into account.

The equilibrium curve 3 was calculated from the same Eq. [5] which was used for the nonequilibrium curve 2, but using calculated equilibrium values for the partial pressures of H_2, H_2O, and CO_2 at the anode.[1] The difference in emf between curves 2 and 3 is seen to be small.

Results with Hydrocarbon Fuels

When a hydrocarbon like propane is used, the gas undergoes cracking reactions. The hydrogen formed reacts electrochemically; the water thus formed again reacts with the fuel and intermediates to give more hydrogen. Essentially, the function of the hydrocarbon fuel in the present cell is to provide hydrogen to the electrochemical system.

In order to increase the rate of catalytic reactions a separate catalyst can be used. This was found to be of particular advantage when a relatively unreactive fuel like natural gas was used. Outputs with this important fuel as published have thus far been rather low, and higher temperatures (~700°C) have generally been employed (2, 4, 5).

In the case of natural gas, the reforming reaction with water was carried out upstream from the cell. An efficient catalyst made it possible to run the reaction at a temperature low enough to obtain a fairly complete conversion into hydrogen before the gas came in contact with the electrochemical system.

One may distinguish between two different reforming reactions with water

$$CH_4 + 1H_2O = CO + 3H_2 \qquad [8a]$$

and

$$CH_4 + 2H_2O = CO_2 + 4H_2 \qquad [8b]$$

Around 700°C or above, Eq. [8a] is the main equation to be considered. However, at the low temperatures used in the present work (~580°C), Eq. [8b] is the main reaction. This has the advantage that more hydrogen is produced. If an even lower temperature is chosen, the equilibrium will shift to the left and the reaction will be incomplete. The degree of completion of the reaction also depends on the excess of water used in the entering gas mixture. In Table II, analytical results are given of gases emerging from the catalytic reactor containing a nickel-alumina catalyst. Different concentrations of steam were used in the CH_4-steam mixture entering the reactor. The water concentration is again uncertain (cf. footnote to Table I), but the expected trend is clearly visible: the higher the water concentration, the lower is the CH_4 concentration; at high water concentrations practically no methane and little CO are found.

The standard emf's for the direct oxidation of methane and for the oxidation of hydrogen happen to be the same at the chosen temperature, *viz.*, 1.04v. Then even under reversible conditions (strictly, only when all gases are at one atmosphere partial pressure), no additional heat supply is required for the reforming reaction: the heat required is just equal to the heat supplied by the electrochemical oxidation of the hydrogen, as a consequence of the theoretical inefficiency (1) of the latter reaction ($T\Delta S = 11$ kcal/mole of H_2).[2]

Table II. Composition of gas mixtures emerging from reforming reactor at 580°C

CO_2	CO	Mole % H_2O	H_2	CH_4
14.32	4.90	(0.43)	77.81	2.54
13.98	4.91	(0.54)	78.61	1.95
13.82	3.54	(1.20)	80.73	0.70
15.79	2.44	(6.25)	75.34	0.19
8.73	1.21	(50.19)	39.86	0.02

Since methane is the most stable hydrocarbon, the low-temperature reforming method can obviously also be applied to other hydrocarbons. The same equilibria will occur and the same products will be formed, *viz.*, only H_2, H_2O, CO_2, CH_4, and CO. Since the reforming reaction involves a larger free energy change for the higher hydrocarbons, the reaction is practically complete. The natural gas used in the experiments contained 6% higher hydrocarbons and these completely disappeared while passing through the reforming reactor, before entering the cell. Thus, in all the reactions discussed, including the reaction of pure hydrogen in the carbonate cell, the same five species are formed. Only the ratios of C:H:O are different and consequently the relative concentrations will be different.

Cell Performance

In Fig. 3, terminal voltage-current characteristics are shown for reformed natural gas at two different flow rates, and, for comparison, a curve taken with undiluted hydrogen. The percentage conversion is indicated for the end points. The upper natural gas

[2] It can be shown that this is a consequence of the given conditions and the fact that the oxidation of methane involves no entropy change.

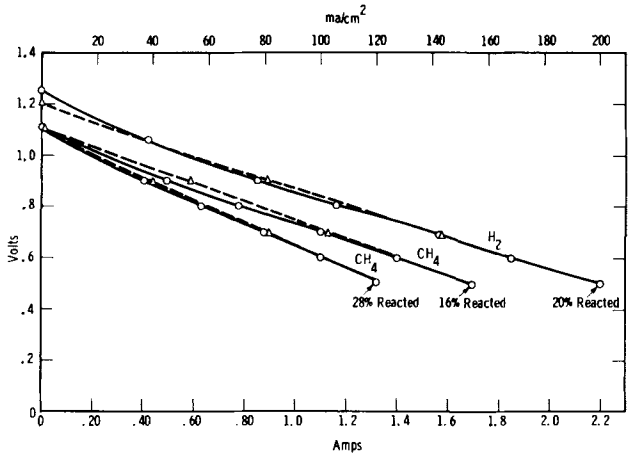

Fig. 3. Terminal voltage vs. current with hydrogen, and with reformed natural gas at two different flow rates. ○, increasing currents, △, decreasing currents; 1½ in. effective ϕ; hydrogen and natural gas (CH_4).

[1] If x is the degree of electrochemical oxidation and y the degree of chemical reaction in accordance with the equation $H_2 + CO_2 = H_2O + CO$, the partial pressures are $(1-x-y)/(1+x)$; $(x-y)/(1+x)$; $(x+y)/(1+x)$; $y/(1+x)$. (Total pressure = 1 atm.)

Then $K = \dfrac{(x+y)\,y}{(1-x-y)\,(x-y)} = 0.35$ at 580°C. This gives y and the partial pressures for any x.

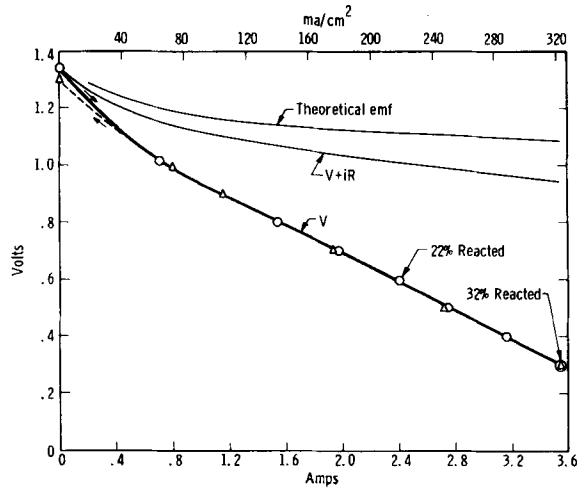

Fig. 4. Terminal voltage V, voltage + iR drop and theoretical emf as a function of current with hydrogen as fuel. ○, Increasing current; △, decreasing current; fuel, H_2; 580°C.

curve gives a current density of 130 ma/cm² at 0.6v. The points were taken at 2-min intervals for increasing and decreasing current. The CH_4 curves lie below the H_2-curve because the hydrogen obtained by reforming is diluted. Similarly, the CH_4-curve obtained at the lower flow rate gives the stronger decline of voltage with current because of the larger change of fuel composition with current. It is seen that, despite the relatively low temperature chosen and the low reactivity of the fuel, a considerable output can be obtained by use of the low temperature reforming reaction.

Cell life was limited to about one week. This is probably a consequence of poor retention of the carbonate melt by the relatively coarse MgO disk. Use of such disks was necessary because of the high clamping pressure employed to leakproof the cells. Characteristically, the voltage declined 5-10% per day during the first days when run at 25 ma/cm². Similar outputs have been obtained with many cells. The ohmic cell resistance, measured at 1000 cps, accounted for 80% of the voltage drop if allowance was made for the change in the theoretical emf with increasing degree of fuel conversion.

Even higher outputs were obtained with one cell. To improve the electrode-electrolyte contact, the MgO disk in this case was machined flat after soaking it with the melt in vacuo. The voltage-current curve for this cell, operated with hydrogen, is shown in Fig. 4, curve V. A current density of 230 ma/cm² was obtained at 0.6v at a gas flow rate giving a 20% reacted mixture at this point. The a-c cell resistance, R, again accounted for 80% of the voltage drop as shown in the same figure. (The theoretical emf curve was calculated from Eq. [6], neglecting the minor decreases in emf caused by secondary reactions.)

The output obtained is close to the maximum achievable with this type of cell for the chosen geometry: the resistivity of the melt by itself, consisting of 30 wt% Li_2CO_3, 30% K_2CO_3, and 40% Na_2CO_3, was 1.1 ohm cm (±20%) at 580°C. Assuming that there was no contact resistance, the resistance of the electrolyte disk of 0.41 cm thickness, 11 cm² electrode area and 45% porosity would be expected to be 1.1 (0.41/11) (1/0.45) q, where q is the "tortuosity factor" (6) of the disk. Comparing this with the measured a-c resistance of the cell of 0.18 ohm, one finds $q = 2.0$ (±20%). This factor accounts for blind alleys in the sintered MgO disk as well as for the tortuosity of the conduction path and is close to the attainable minimum value (6). The electrode-electrolyte contact resistance, usually assumed to limit the performance of this type of cell (1), must have been quite small.

The Silver-Silver Oxide Electrode

II. Anodization at 0° and 25°C in Alkaline Solutions

Charles P. Wales

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

Silver electrodes were studied in 20% KOH at 25°C and in 35% or 50% KOH at 0°C. The capacity decreased when an electrode was cycled in 20% KOH at 25° mainly due to loss of active material during current flow. In 35% KOH at 0° the electrode capacity was close to that at 25°, the capacity decreased with increasing charge current similar to results at 25° although polarization had increased, and the charge-discharge efficiency was 100% at low currents but less when using high currents. In 50% KOH at 0° the capacity was much less than at 25°, the charge acceptance was relatively poor, under certain conditions a silver peroxy compound may form, and the electrode discharged even less readily than it charged.

Although silver-zinc storage batteries can discharge readily at high currents, experience has shown that recharging the Ag electrode is more difficult. A 12 to 24 hr rate of charge is usually recommended by the manufacturers of commercial Ag-Zn batteries, but a more rapid charge is highly desirable and in some cases essential from the user's point of view.

The anodic oxidation of Ag electrodes is being examined to find a method of improving their charge characteristics. Results have been reported using 35% and 50% KOH at 25°C (1). The work was extended to 20% KOH and to 0°C as a part of the study of the chargeability of the Ag electrode under various charge currents, electrolyte concentrations, and temperatures.

Experimental Procedure

The Ag electrodes were made by cutting Ag plates taken from an unused commercial Ag-Zn storage battery. The test electrodes were slightly larger than those used previously (1). They averaged 30.5 x 63.5 x 0.8 mm and weighed 8.3-8.4g including the grid. The grid weight was relatively minor, about 0.6g. The capacity theoretically possible was about 3.9 amp-hr if all of the Ag could be fully utilized, but the average actually measured was 2.8 amp-hr in the period of peak capacity. The experimental setup was similar to that previously reported, using the same cell assembly and control equipment (1). Ag electrodes served as both positive and negative electrodes. In order to slow the transfer of active material from an electrode to the bulk of the solution, the electrodes were wrapped with several layers of separator material of a type normally used in commercial Ag-Zn batteries. Potentials were measured with a Ag, Ag_2O/OH^- reference electrode.

Results

The Ag electrodes were cycled in 35% KOH for the first 8 to 16 cycles to ensure electrodes of normal, reproducible capacity. The capacity increased during the initial cycles. The KOH concentration was then changed for the electrodes that were studied in 20% or 50% KOH.

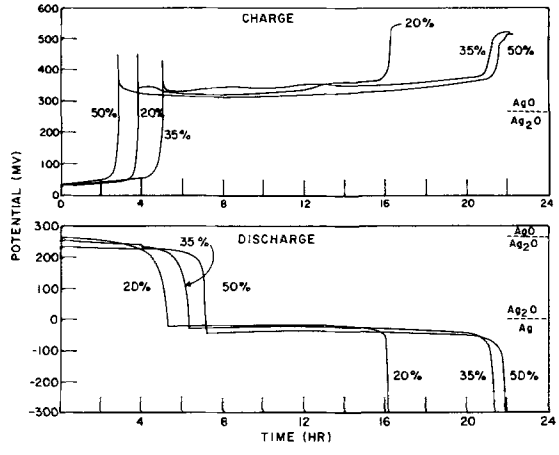

Fig. 1. Typical 100-ma constant current charges and discharges of silver electrodes in 20%, 35% and 50% KOH at 25°C. Potentials are given with respect to a Ag/Ag_2O reference electrode.

20% KOH at 25°C.—The capacity of electrodes cycling in 20% KOH decreased rapidly, a fifth being lost in the first 5-10 cycles. Typical results after the electrodes had been cycled 5-20 times are shown in Fig. 1. Charge and discharge potentials usually were closer to the equilibrium values in 20% KOH than they were in 35% or 50% KOH when using a charge or discharge lasting the same length of time. After 50 cycles the capacity in 20% KOH had dropped to near 60% of its original value. Attempts were then made to improve capacity. An electrode was charged 12.5 hr at 100 ma ending at the gassing potential. After a stand of 5 hr the electrode accepted a further 2.5 hr of charging before the potential made the sharp rise to gassing. Then stands of 15 and 5 hr allowed a total of 0.2 hr of additional charging below gassing potentials. This improved the capacity of the next discharge to 75% of the original value although there was little permanent improvement from this treatment. The decline in capacity when

using 20% KOH contrasted with the results reported earlier using more concentrated KOH at 25°C. The capacity of Ag electrodes had increased gradually with cycling in 35% KOH and although there was a decrease in 50% it was gradual (1).

One Ag electrode lost 0.6 amp-hr after 58 cycles in 20% KOH. Its weight loss was 1.00g which is equivalent to 0.50 amp-hr. Another electrode lost 0.3 amp-hr after 30 cycles in 20% KOH and had a weight loss of 0.65g which is equivalent to 0.32 amp-hr. The rate of loss was reproducible for both electrodes and was on the order of ½% of the original capacity per cycle. This active material loss accounted for most if not all of the capacity decrease. The capacity loss of a Ag electrode cycling in 20% KOH is included in Fig. 2. The slight rise in capacity after cycle 60 was the result of charges followed by stands and additional charges. The capacity was quite low compared to the original capacity in 35% KOH. For clarity Fig. 2 shows only one electrode in the early cycles, but all electrodes were similar during the initial cycling. Although the capacity varied from cycle to cycle the average capacity of each electrode was within 5% of 2.1 amp-hr in the early cycles using 35% KOH at 25°C.

The charge efficiency of the Ag electrodes was below 100% in 20% KOH, in contrast to the results reported for 35% and 50% KOH at 25° (1). There were 34 cycles at 100 ma in 20% KOH in which the charge was stopped before gas evolution (Fig. 3). The straight line fitted to these points in Fig. 3 by the method of least squares shows the tendency for the loss to increase with longer charges in 20% KOH. The scatter of these points can be attributed in part to variation in the length of time between one discharge and the following charge.

35% KOH at 0°C.—The Ag electrode gave good results at 0°C in 35% KOH. Initially the capacity averaged about 10% greater than it had been at 25°C. The capacity increased for over 100 cycles (Fig. 2). This was similar to the results reported at 25°C (1). At cycle 168, after the electrode had cycled

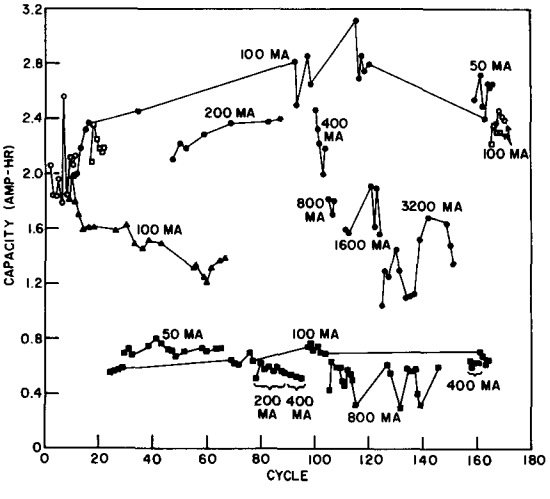

Fig. 2. Changes in electrode capacity with cycling under various conditions. All discharges were at 100 ma to —300 mv. Only discharges that followed a charge to gas evolution are shown. △, 25°, 20% KOH; •, 0°, 35% KOH; ○, 25°, 35% KOH; ■, 0°, 50% KOH; □, 25°, 50% KOH.

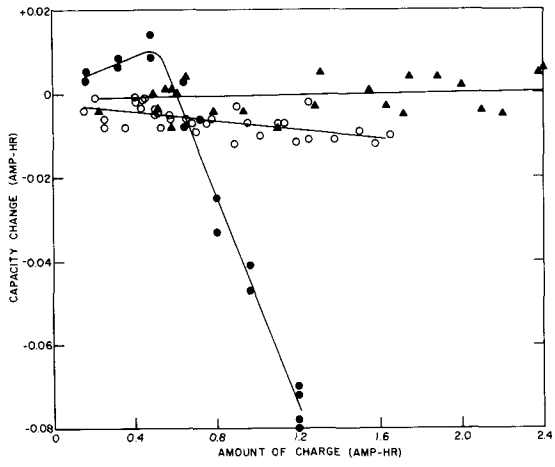

Fig. 3. Loss or gain of capacity for cycles that did not reach gassing. All discharges were at 100 ma. ○, 100 ma, 20% KOH, 25°C; ▲, 100 ma, 35% KOH, 0°C; •, 3200 ma, 35% KOH, 0°C.

156 times at 0°, it was cycled at 25° again. Capacity was then slightly higher than it had been in the early cycles at 25° (Fig. 2). The electrode weight loss at cycle 170 equaled 0.30 amp-hr.

The charge efficiency was 100% at low currents using 35% KOH at 0°C. Efficiency decreased as the electrode became more completely charged using a high current, with very short charges apparently giving over 100% efficiency (Fig. 3).

The electrode was charged at currents from 50 ma to 3200 ma (56 hr to ⅝ hr rates) at 0°C (Fig. 4). The arrows on the charge curves, denoting the capacity of the following 100-ma discharge, indicate that once gassing began there was little additional charge acceptance at the lower currents. At 3200 ma, much of the active material not having been oxidized before gassing began, there was up to 50% charge acceptance after gas evolution had commenced. The capacity using a 3200 ma charge could be increased to 1.9 or 2.0 amp-hr by halting the charge for ¼ to 1 hr after gas evolution had commenced and then charging to gas again. The potential peak between the first and second charge plateaus disappeared as the current was increased to the 2 or 1 hr rate. There

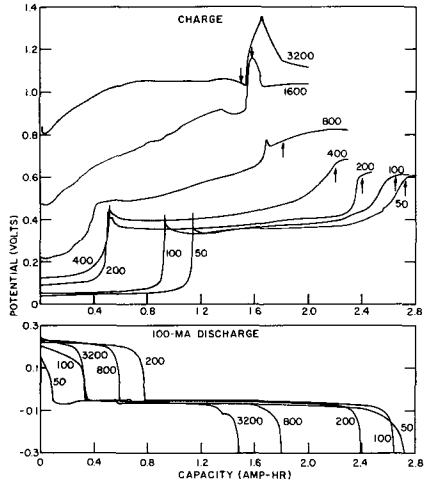

Fig. 4. Results of typical constant-current charges in 35% KOH at 0°C. Arrows on the charge curves indicate the length of the following 100-ma discharge. Numbers indicate the charge rate. Potentials are given with respect to a Ag/Ag_2O electrode.

Table I. Effect of charge current on the upper potential plateau of 100 ma discharges in 35% KOH at 0°C

Charge current, ma	Number of measurements	Ratio of upper discharge plateau length to total discharge length: Mean	Ratio of upper discharge plateau length to total discharge length: Standard deviation of mean
50	3	0.050	0.006
100	14	0.118	0.004
200	7	0.325	0.005
400	5	0.339	0.013
800	3	0.335	0.005
1600	7	0.278	0.007
3200	14	0.203	0.007

was a different peak near the end of the charge at the higher rates.

Discharges following low-rate charges had relatively short plateaus at the AgO/Ag_2O potential. The longest plateau was obtained using 200 ma (the 12-hr charge rate). For clarity Fig. 4 does not include discharges for every charge rate. Table I gives the change in length of the upper discharge potential when varying charge current and indicates the high reproducibility of the measurements under the given experimental conditions. All charges were to gas evolution. For these measurements the end of the upper plateau was taken to be at the end of the sharp drop in potential, which was at about —50 mv.

The decrease in discharge capacity when using higher charge currents was similar to the logarithmic relationship previously reported (1). Figure 5 includes the results at 25° corrected for the small differences in electrode capacity.

50% KOH at 0°C.—The electrolyte is referred to in this paper as being 50% KOH, but after the temperature was lowered to 0°C some crystals precipitated and the actual concentration did not exceed 49.2% at equilibrium (2). The results at 0° were quite different from those obtained at 25°C in 50% KOH. The low temperature gave only a quarter of the normal capacity with 100 ma charge current. High charge currents did not reduce the capacity sharply (Fig. 2) and the rate of decrease was less at 0° than at 25°C (Fig. 5). A comparison of the potentials at 25° and 0° reveals the increased polarization at the lower temperature (Fig. 6).

The lower potential plateau was unusually short during discharges at 0° in 50% KOH. The open-circuit potential rose to above 0 mv after the discharge, indicating that the electrode had not discharged fully. The electrode gave a second discharge of appreciable length after standing on open circuit (Fig. 7). Note in panel VII of Fig. 7 that the electrode sustained a discharge even after three previous discharges and a relatively short stand, and in panel VIII the stand potential still rose. Longer stands gave longer discharges. The relationship was approximately linear for up to one day of stand. One set of these discharges followed a nearly complete charge that went an estimated 95% of the way to gas evolution. The capacity of the discharge shown in panel I of Fig. 7 was 92% of this so-called 95% charge, and the total discharge by panel V was 120%. After the Ag electrode was given a series of discharges and stands the length of the following charge was much longer than the normal 0° charge (after one continuous discharge to —300 mv) although still much shorter than the usual 25° charge.

Charge efficiency varied with the amount of charge at 0° in 50% KOH, with results resembling the curve for 3200 ma shown in Fig. 3 although the points were scattered more widely. The efficiency was above 100% for short charges since the active material not reduced in the previous cycle could be utilized. The excess of discharge capacity over charge capacity gradually decreased to zero during a series of consecutive cycles in which gassing was not reached.

The effect of increasing charge current at 0° in 50% KOH is shown in Fig. 8. The Ag electrode was discharged twice before these charges, with a stand period of 6-20 hr between discharges, to ensure that the electrode was mostly discharged. A borderline

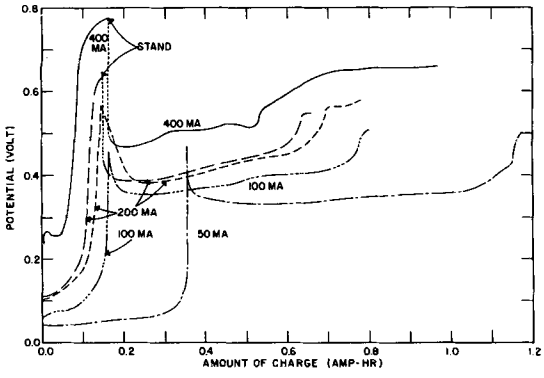

Fig. 8. Constant current charges in 50% KOH at 0°C. Potentials are given with respect to a Ag/Ag_2O electrode.

condition was reached at 200 ma, and occasionally the electrode charged at both plateaus, but at other times the potential rose to a high gassing potential instead of the electrode charging at the second plateau of charge. At 400 ma the potential usually rose to gassing. An open-circuit period at this point changed conditions so that charging could proceed. Charges following these stands are shown for 200 and 400 ma (Fig. 8). When there was no stand the charging potential remained high (although gradually declining) and the following discharge capacity was well below the normal for a given rate unless there had been a long overcharge.

The open-circuit potentials for these stands showed several plateaus (Fig. 9). The potential reported for Ag_2O_3 is shown despite its questionable value. There were three open-circuit plateaus, the first at 0.41-0.42v, the second at 0.26-0.27v, and finally the potentials approached zero. The length of the first plateau depended on the final charge potential (Fig. 10). When the electrode was discharged without a stand period the electrode sustained a few minutes of discharge at this highest plateau. These measurements were made in the first 96 cycles (6 months of cell life). The cell was put into use again after it was one year old (cycle 97, Fig. 2). Capacity had not changed, but the potential seldom rose to gassing at the beginning of the second plateau. After rewrapping the electrode with a new separator, charges at 400 ma rose to gassing at the second plateau more often. Cycles 165 to 168 at 25° indicated a

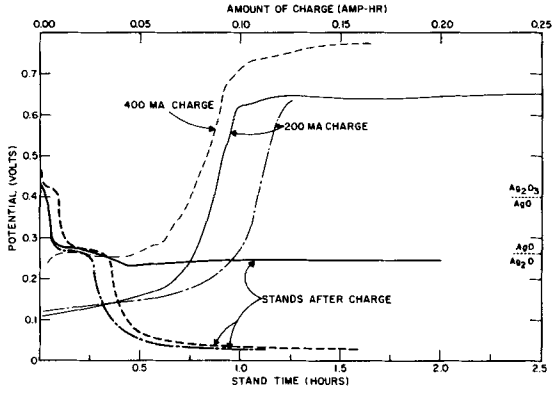

Fig. 9. Constant current charges in 50% KOH at 0°C and the subsequent open-circuit potentials.

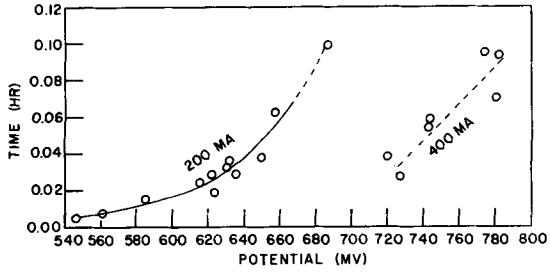

Fig. 10. Relationship between the final charge potential and the length of time the subsequent open-circuit potential takes to reach 390 mv in 50% KOH at 0°C. Potentials are given with respect to a Ag/Ag_2O electrode.

slight gain in capacity compared to cycles 17 to 22 (Fig. 2). The loss in weight of this electrode was equal to 0.31 amp-hr after cycle 168.

Ag electrodes were put in a U-tube containing 50% KOH at 0°. When an electrode was at the high gassing potential attempts were made to detect O_3 in the evolved gas. Filter paper test strips wet with $MnSO_4$ or TlOH solutions were exposed to the gas but did not indicate O_3. Since the fine gas bubbles rise very slowly it seemed possible that any O_3 present may have decomposed before reaching the surface. Another Ag electrode in 50% KOH at 0° was arranged so that air swept through the electrolyte and carried the evolved gas into a buffered 5% KI solution. It is claimed in atmospheric pollution work that 0.06 ppm O_3 can be detected with this indicator, but none was detected in the anodic gas.

Discussion

The slightly decreased polarization that resulted from using 20% KOH was desirable, but this was more than offset by the decrease in capacity with cycling. Capacity was improved by permitting the charged Ag electrode to stand on open circuit for several hours and then recharging. AgO had time to react with remaining metallic Ag during this open-circuit period. Therefore the plate charged more deeply after a stand. The additional capacity was removed readily in the following discharge, indicating that the difficulty was in the oxidation portion of the cycle and not in the reduction. The charging potential during the first hour was lower after a stand than it was during the second plateau before the stand. This raises the question of why the potential of the upper charge plateau is normally so high above the equilibrium potential. The answer is probably connected with the mechanism of the charge reaction at this plateau. It is hoped that work now being carried out at this Laboratory will shed light on this problem.

It was somewhat surprising that the loss in weight correlated so closely with the loss in capacity in 20% KOH since only a little over half of the theoretical capacity was obtained when the electrode was first put into 20% KOH, and the loss of the original surface material should expose more usable material. If the electrode still oxidized to the same depth the surface area must have decreased as the active material left the electrode. From Fig. 3 the loss was 0.008(0) amp-hr for the average charge of 10.9

amp-hr. (This average included 23 charges that reached gassing.) If this rate of loss remained constant, in 58 cycles the total loss would be 0.46 amp-hr. This was close to the value 0.50 amp-hr calculated from the weight loss. Thus the inefficiency was due to loss of oxidized silver from the electrode, and not due to gassing. It was concluded that most or all of the loss of silver occurred during cycling, most likely during the charge, with little or no loss during open-circuit periods. The difference between these results and those in 35% and 50% KOH at 25°C may be an effect of the separator becoming more porous and allowing active material to diffuse away from the electrode. As indicated by figures given earlier, the weight loss per cycle was 5-6 times as great in 20% KOH as in 35% or 50% KOH. The capacity increase when cycling in 35% or 50% KOH (presumably due to forming the plates more deeply) more than made up for the active material loss equivalent to only 0.3 amp-hr.

The inefficiency in 35% KOH at 0° was attributed to slow gas evolution during high rate charges (Fig. 3) although no attempts were made to measure gas. About an eighth of the charging current was lost after the potential reached 1.03v at 3200 ma (Fig. 3 and 4). Efficiency was 100% at low currents. An additional 0.005-0.010 amp-hr was obtained when a discharged electrode was discharged a second time after standing for one day. This residual capacity was probably the cause of the apparent efficiency being slightly over 100% for very short charges at 3200 ma.

The short discharge plateaus at the upper potential which were observed following low-rate charges at 0°, *i.e.*, at the 26 and 54 hr rates in Fig. 4, can be attributed to the reaction of Ag with AgO to form Ag_2O. This reaction is known to decrease the upper discharge plateau when charged Ag electrodes are allowed to stand on open circuit. Although the time required for the charge was long, time alone was insufficient to account for all of the large decrease in length of the upper discharge plateau. Even if the electrode had been converted completely into Ag_2O the maximum discharge at the lower plateau would only have been one half of the theoretical capacity or 1.95 amp-hr. After a 50 ma charge 71% of the theoretical capacity was obtained (Fig. 4). Therefore a minimum of 21% of the theoretical capacity must have been obtained from silver oxidized higher than Ag_2O. Assuming that this oxide was AgO, a minimum of 42% of the electrode must have been oxidized to AgO using 50 ma although less than 3% of the theoretically possible AgO capacity was obtained. Due to the reaction of Ag with AgO the electrode surface probably was not covered completely with AgO to a very great depth when the electrode was charged at a low current at 0°. Ag_2O covered the surface after a relatively short discharge and then the potential reached the lower plateau, although there was considerable AgO remaining in the electrode.

There was a potential peak near the end of the high rate charges at 0°C using 35% KOH (Fig. 4). AgO had been forming, and by the time this late peak was reached its formation was hindered greatly. There was a lack of one or more reactants due to the slow diffusion at this temperature and the need for rapid diffusion at the high current density, therefore passivation increased and the potential rose. A possible explanation of the drop in potential at the end of the charge is that given by Cahan *et al.* (3) for the decrease in resistance measured just as gassing began. They believed this was not rupture of a film, but proposed that further incorporation of oxygen in the AgO film had taken place, producing an unstable film of an oxide higher than AgO having a lower resistance.

There may be a connection between this peak and the potentials that were recorded in 50% KOH at 0°C (Fig. 8). The lower two open-circuit plateaus corresponded to the well-known oxides of silver (Fig. 9). It is possible that the upper plateau corresponded to a higher oxide of Ag, but the existence of trivalent Ag_2O_3 or other higher oxides of Ag has not been proven (4-6). Many of the claims for it could be explained by the presence of a peroxy linkage. Note that the Ag_2O_3/AgO potential measurements cited in the literature use the values of Luther and Pokorny (7) which were obtained with silver peroxysulfate and silver peroxynitrate and not actually with Ag_2O_3.

The open-circuit plateau at the AgO/Ag_2O potential lasted longer after a long charge at 200 ma than after a short charge, although the upper plateau length was the same (Fig. 9). This first plateau could be shortened by interrupting the charge while the potential was still rising. The length of the first plateau did not depend on the amount of charge given the electrode at a high potential, *i.e.*, over 600 mv at 200 ma, but it varied instead with the final charge potential (Fig. 10). The points at 400 ma were too few and scattered to determine whether a curved line should be drawn through them although they gave the same trend as that shown for 200 ma (Fig. 10). It was not surprising that the potentials were higher at 400 ma since the IR drop was higher.

It was mentioned earlier that the electrodes charged poorly after the potential rose to the high values. Conditions changed during a short stand so that the electrode accepted a charge again. Very short stands in which the potential did not fall below about 0.35v did not aid further charging, nor did long stands in which the potential fell to well below the AgO/Ag_2O value. The charge potential usually rose again to high values in these cases. The only beneficial stands were those ending near the AgO/Ag_2O potential.

The presence of a certain amount of AgO was necessary for good charge acceptance above the Ag/Ag_2O potential plateau. This was indicated by the differing results when the stand ended above or below the AgO/Ag_2O plateau. Either AgO was rendered inactive at the beginning of these stands or the necessary AgO was not present until some other compound decomposed. At room temperature the potential peak was reached when the electrode surface was covered with Ag_2O and ohmic resistance

then reached its maximum (3). By using high currents at a low temperature the gradients in the concentrated electrolyte were greater than when using lower charge currents at room temperature. The combination of these factors resulted in an unusually high electrode potential and may have allowed some intermediate material having the peroxy linkage such as O_2^- or HO_2^- to form in larger than normal amounts, in addition to O_2 the final product. The failure to detect any O_3 in the evolved gas does not prove that O_3 was never present since it would be in contact with Ag_2O and Ag_2O catalytically decomposes O_3. Any O_3 remaining could decompose while passing through the alkaline electrolyte, since aqueous alkali decomposes O_3. The potentials measured, however, were low for the formation of O_3.

There is evidence that O_2 forms through a peroxide mechanism in alkaline solution instead of directly according to $4\ OH^- = O_2 + 2H_2O + 4e^-$. Oxygen was reported to establish a reversible equilibrium with HO_2^- ion in alkali (8). It is likely that OH^- goes first to O_2^- and this to HO_2^-, although possibly OH^- goes directly to HO_2^- at high current densities. The low temperature used would tend to stabilize for a longer time any O_2^- or HO_2^- that formed, and these may react with the Ag_2O instead of producing O_2.

Jirsa and Jelinek (9) reported that Ag or Ag_2O oxidized with a mixture of $O_3 + O_2$ gave a compound that in KOH showed the potential reported for Ag_2O_3 (really the potential of silver peroxy compounds) before this compound decomposed into AgO. AgO did not react with O_3, casting some doubt on their report that O_3 was producing trivalent Ag. Schwab and Hartmann (10) reported that Ag with a mixture of $O_3 + O_2$ formed two compounds: AgO and a compound that gave a typical silver peroxy x-ray diffraction pattern. It is postulated that this type of reaction with a substance having the peroxy linkage formed a silver peroxy compound when the high charging potentials were observed to 0° in 50% KOH, and that the silver peroxy compound gave the initial high open-circuit potential plateau (Fig. 9). The reaction may be analogous to the formation of silver peroxysulfate when Ag is anodized in H_2SO_4 (5, 11). The decomposition of the silver peroxy compound produced AgO during the initial part of the open-circuit period. With a longer open-circuit period this AgO reacted with Ag to give highly resistive Ag_2O, and again charging difficulty could occur.

The final potentials at the end of the high-rate charges following the beneficial stands were lower than those reached before the stands (Fig. 8) since the final resistance was less due to the AgO present. An open circuit at this point gave only a very brief period of high potential before the potential dropped to the AgO/Ag_2O plateau.

High potentials at the beginning of the second plateau occurred less often late in the life of the cell before the electrode was rewrapped. By this time the separator was not as effective and diffusion through it was easier. After rewrapping with a new separator high potentials occurred more frequently. Then the cell was cycled without any separator and the high potentials occurred less often. This indicated that the presence of the separator was not essential although it was a factor in the high potentials.

The discharges in 50% KOH at 0°C were unusual in that the Ag_2O/Ag plateau was about the same length as the upper plateau instead of being two or three times as long (Fig. 6). This was not an effect of temperature alone since it was not noted in 35% KOH. The high open-circuit potentials after a discharge indicated that all of the AgO had not been reduced (Fig. 7). Another indication of this was obtained by interrupting a discharge after it was 90% complete. The potential then rose to the AgO/Ag_2O plateau after 1½ days of stand. This indicated that a sizeable quantity of AgO must have remained, since the AgO decreased during a stand as it reacted with Ag. The results suggest that the reaction rate was affected by the concentration of the electrolyte and by temperature. The O^{--} diffused from within the electrode to its surface where it combined with H_2O to give OH^- Increasing the KOH concentration decreased H_2O and increased OH^-, both changes making the reaction with O^{--} more difficult. The low temperature slowed the reaction and the flow of ions, the complete formation of Ag on the electrode surface was inhibited as the O^{--} concentration built up, and the electrode potential fell before the discharge was complete. After a high rate charge at 0°C in 50% KOH a second discharge of appreciable length could be obtained following a shorter stand than after a low rate charge, since the electrode had not formed as deeply. The electrode charged more readily than it discharged under these conditions since there was no shortage of OH^- ions to supply the needed oxygen during the charge.

Many problems were pointed out in the work described above. A further study with experiments designed to clarify these problems is necessary for a full and definite explanation.

Manuscript received May 16, 1962; revised manuscript received July 20, 1962. This paper was prepared for delivery before the Boston Meeting, Sept. 16-20, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Use and Behavior of Aluminum Anodes in Alkaline Primary Batteries

Solomon Zaromb[1]

Scientific Laboratory, Philco Corporation, Blue Bell, Pennsylvania

ABSTRACT

The two- to threefold reduction in over-all theoretical reactant weight (and usually also volume) which results from replacing Zn by Al in alkaline primary batteries could best be preserved in practice with a 3M KOH "self-regenerating" electrolyte in large (>1 kw) Al-air (or $-O_2$) power sources, whereas small Al-air (or $-O_2$ or $-AgO$) reserve cells should function best with a consumable 10M KOH solution. Special attention is given to the use of Al in Al-air cells with porous C or, preferably, porous Ni air cathodes. Anode polarization and current efficiency data are presented for both the self-regenerating and the consumable electrolytes with and without several effective corrosion inhibitors consisting of alkyldimethylbenzylammonium salts and/or Hg with or without ZnO. It is concluded that optimum battery performance would result from the use of some of these inhibitors, as well as from elimination of sulfides and other corrosion accelerators, use of highly pure Al or specially resistant Al-Mg, Al-Zn, or Al-Hg alloys, effective heat removal, operation at high current densities (preferably $\geq$10 ma/cm^2), and anode-electrolyte separation during periods of inaction.

In spite of the highly attractive anode characteristics of Al, all previous attempts (1-8) to utilize it in practical batteries failed (9-11) either because of the formation of passivating, resistive oxide layers in those electrolytes in which Al oxides are not readily soluble (1-6, 12) or because of high rates of corrosion in those electrolytes in which the oxide layers are dissolved, *e.g.*, in concentrated alkali solutions (7, 8). Nevertheless, the author was interested in the possibility of using Al anodes under conditions wherein the corrosive alkaline electrolyte would be in contact with the metal during current drain only.

Thanks to encouraging initial experimental results suggesting the possibility of achieving outputs of 1.0-1.5v at current densities of up to 50 ma/cm^2 (cf. Fig. 3 and the relevant text) and current efficiencies of 60-100% at current densities of 3.5-140 ma/cm^2, a systematic study was initiated toward incorporating Al anodes in practical alkaline primary batteries.

In order to survey and define the most promising applications of Al anodes, a comparison was made of the theoretical reactant requirements in three types of alkaline primary batteries. Table I shows that, in all three types, a reduction by a factor of 2-3 in the minimum reactant weight (and usually also volume) is theoretically achievable by substituting Al for Zn. With an actual output voltage of 1.3v, battery type 1 can thus yield 4 kw-hr/kg Al. Since the O_2 is obtainable from air and H_2O is usually plentiful, the over-all cost of portable electricity would amount to \$0.15-0.20/kw-hr for a battery operating at an optimum achievable current efficiency of 80-100%. This might conceivably be

6	$1/2\ Zn + 1/2\ AgO + OH^- \rightarrow 1/2\ ZnO_2^= + 1/2\ Ag + 1/2\ H_2O$	32.7g Zn + 61.9g AgO + 100 cc 10M KOH	234.6	112.8				

reduced further by recovering the $Al(OH)_3$ product, worth about half the cost of the Al. Partly in view of this promising price estimate, and in view of the high theoretical energy to weight and volume ratios, battery types 1 and 2 were selected specifically for the present studies.

The Aluminum-Oxygen Or-Air Cell

Basic Components and Reactions

The following battery reactions are to be considered

Anode: $(Al + 4OH^- \rightarrow Al(OH)_4^- + 3e^-) \times 4$ $E^\circ = -2.35v$ [1][2]

Cathode: $(O_2 + 2H_2O + 4e^- \rightarrow 4OH^-) \times 3$ $E^\circ = -0.40v$ [2][2]

Over-all: $4Al + 3O_2 + 4OH^- + H_2O \rightarrow 4Al(OH)_4^-$ $E^\circ = -2.75v$ [3][2]

Electrolyte regeneration: $(Al(OH)_4^- \rightarrow Al(OH)_3 + OH^-) \times 4$ [4]

Net over-all reaction [3] + [4]: $4Al + 3O_2 + 6H_2O \rightarrow 4Al(OH)_3$ [5]

The corrosion process can be considered as the sum of reaction [1] and

$$2H_2O + 2e^- \rightarrow 2OH^- + H_2 \quad E^\circ = 0.83v \qquad [6][2]$$

both occurring at the Al electrode, yielding the over-all corrosion reaction

$$2Al + 6H_2O + 2OH^- \rightarrow 2Al(OH)_4^- + 3H_2 \quad E^\circ = -1.5v \qquad [7][2]$$

Thus, the performance of Al-air cells is contingent on: (*a*) a suitable means of supplying the reactants and removing the product of reaction [5] or [3]; (*b*) the occurrence of reactions [1] and [2] and possibly also [4] at sufficiently high rates; and (c) the inhibition of reaction [7].

Although the present paper is concerned mainly with the chemical aspects (*b*) and (c), especially with the study of electrolyte and anode behavior, a brief preliminary discussion of the cathode and over-all battery design features is presented first.

Air Electrodes

At the time of writing, the best commercially available carbon-air cathodes (Eveready type CG-500, manufactured by the National Carbon Company) could deliver current densities of up to 15 ma/cm^2 with reasonably low polarization, but they would be too bulky for practical Al-air cells. However, the author obtained air cathodes by impregnating 0.06 cm thick 60-80% porous sintered Ni sheets first with C and Ag and finally with a Teflon emulsion. With a proper impregnation and heat treatment procedure, the Teflon prevents leakage of the electrolyte through the pores, while allowing atmospheric O_2 to diffuse readily from the ambient atmosphere toward the cathode-electrolyte interface. These porous Ni cathodes have current density-polarization characteristics comparable to those of the above-mentioned Eveready type CG-500 carbon-air electrode (cf. Fig. 1), but with the advantage of a tremendous reduction in thickness and weight. The maximum Ni-air electrode sizes that could be conveniently made with the initially available laboratory facilities were 5 cm x 5 cm. Hence, for most experiments it was found expedient to use the type CG-500 carbon cathodes, sometimes in modified form (as in Fig. 8).

[2] The listed E° values correspond to maximum theoretical energy conversion, and not to actually observed open-circuit voltages.

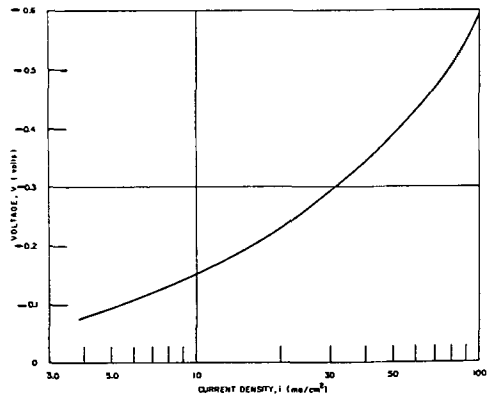

Fig. 1. Polarization curve for a typical 0.06 cm thick sintered Ni air-cathode prepared in January-February 1961. The ordinate V is given relative to the Hg-HgO half-cell.

It is worth noting that the electrode sheets serve also as container walls, as shown in Fig. 8. This arrangement may be adapted to a collapsible accordion-like cell design, which could eliminate the air gaps during periods of inaction and thereby (i) reduce the inactive, portable volume of Al-air (and possibly also Zn-air) batteries to a minimum and (ii) prevent corrosion of Al and slow deterioration of electrolyte by evaporation and CO_2 pick-up on shelf.

Optimum Electrolyte Concentrations for Minimum Volume and Weight Requirements

Self-regenerating electrolyte (type 1 of Table I).—For a battery to maintain its characteristics over prolonged periods of operation and/or storage, the electrolyte composition must remain constant or at least confined within satisfactory concentration ranges. Electrolyte composition may be affected by the following factors: (*a*) absorption of atmospheric carbon dioxide; hence direct contact between the electrolyte and atmospheric air should be prevented by using a properly sealed system; (*b*) loss of water by evaporation, corrosion reaction, and over-all battery reaction [5]; this loss must be compensated for by replenishing the water at various intervals; (c) comparative rates of reactions [3] and [4]. Under conditions of prolonged heavy current drain, marked changes would occur in the concentration of hydroxide ions if the rate of the regeneration reaction [4] were slower than that of the battery reaction [3]. However, the experiments reported in a concurrent paper (13) show that, with 2-3M KOH concentrations, reaction [4] occurs soon and fast enough to permit a continuous heavy current drain far in excess of the maximum charge theoretically achievable without electrolyte regeneration.

The optimum alkali concentrations for the occurrence of reaction [4] are $\leq$3M [cf. ref. (13) and references quoted therein], whereas those yielding high anode current densities are $\geq$3M [cf. Fig. (2)].

Hence, the most suitable alkali concentration for type 1 batteries should be approximately 3M.

Electrolyte in reserve cells (type 2 of Table I).— According to the best available phase equilibrium data (14) the maximum obtainable solubilities of $Al(OH)_3$ in alkali solutions are ≧7.5M in 12.9M NaOH and ≧5M in 10.5M KOH. However, the polarization data of Fig. 2-4 suggest that the 10.5M KOH solution is preferable, yielding satisfactory current densities and voltage outputs for up to 7 moles $Al(OH)_3$ per liter of 10.5M KOH (cf. Table II). This corresponds to a minimum actual reactant requirement of only 3.5 g/w-hr or 2.2 cc/w-hr.

Corrosion Inhibiting Additives

The control of Al corrosion in caustic solutions is discussed extensively in a concurrent paper (15) which lists a number of corrosion inhibitors. Of the most effective ones, those showing no excessive anode polarization in preliminary tests were used for further studies. These include approximately 0.5M ZnO with surface-amalgamated Al anodes and/or "Hyamine" (alkyldimethylbenzyl ammonium salt) surfactants (supplied by the Rohm and Haas Company, Philadelphia).

Anode Polarization and Current Efficiencies

Dilute alkali solutions (type 1).—All anode polarization measurements were performed with small Al strips placed between two large-area air cathodes. Figure 2 shows the current-voltage characteristics of smooth amalgamated Al anodes in solutions saturated with ZnO and containing in addition 0.5M $Al(OH)_3$ and 3 to 5M KOH or NaOH. The current efficiency as function of current density is shown in Fig. 1 of ref. (15).

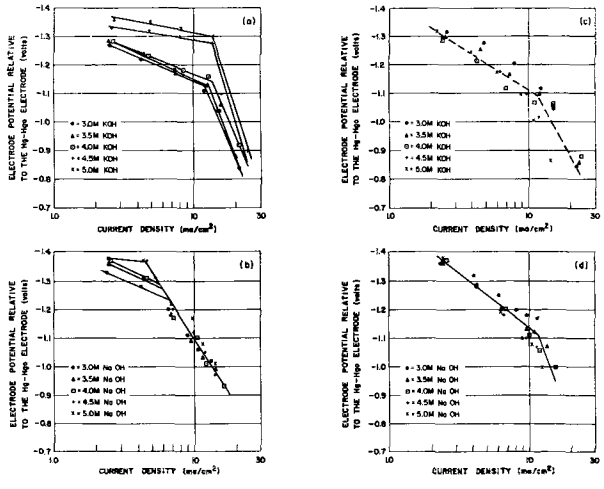

Fig. 2. Room temperature current-voltage characteristics of smooth amalgamated Al anodes in 3.0-5.0M alkali solutions saturated with ZnO and containing 0.5M $Al(OH)_3$. The anodes, with dimensions of 2.9 x 1.7 x 0.01 cm, were contained in a Patterson L-1400 parchment paper bag, dipping in Hg contacts along the shortest (bottom) edge, and suspended between two large area carbon-air cathodes (Eveready type CG-500, manufactured by The National Carbon Co.). (a) Al grade 1145, 3.0-5.0M KOH; (b) Al grade 1145, 3.0-5.0M NaOH; (c) Al grade 2S, 3.0-5.0M KOH; (d) Al grade 2S, 3.0-5.0M NaOH.

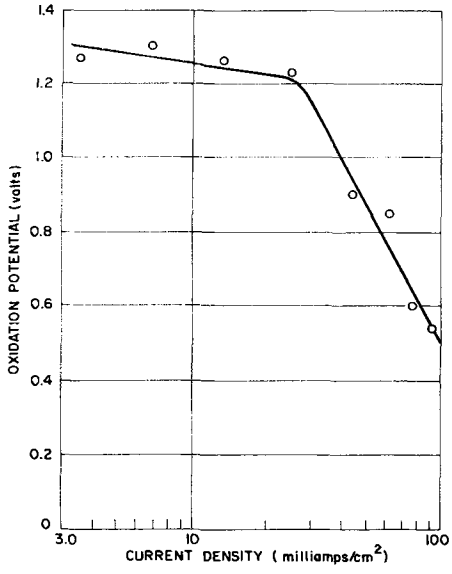

Fig. 3. Room temperature oxidation potential of surface-amalgamated Al anodes relative to the Hg-HgO reference electrode as a function of anode current density. Electrolyte composition: 10M KOH saturated with ZnO.

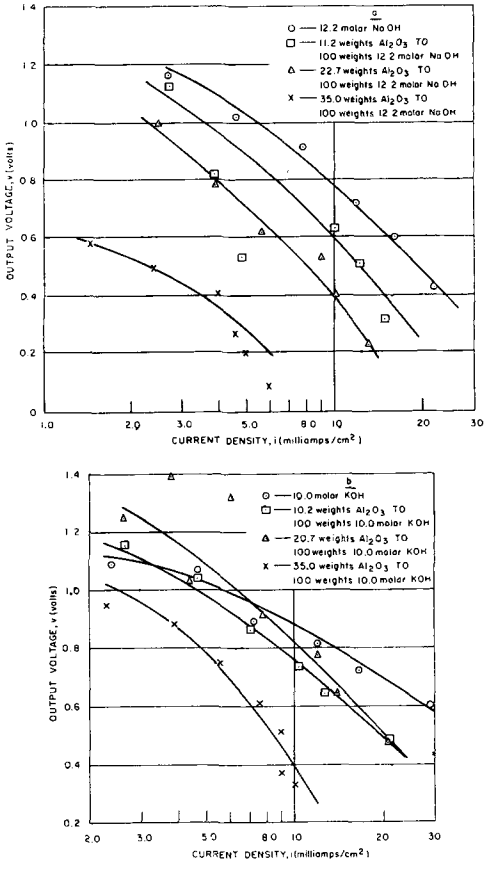

Fig. 4. Room temperature polarization curves for surface-amalgamated Al grade 2S (≧ 99.0% Al) anodes in concentrated alkali solutions containing dissolved Al_2O_3 (the ordinates V are anode oxidation potentials relative to an Hg-HgO reference electrode).

In Fig. 2 (b), (c), and (d) there is no appreciable decrease in allowable current density as the OH^- concentration is reduced from 5M to 3M, and even in Fig. 2 (a), where such a decrease occurs, current densities of 15 ma/cm² produced additional polarization of not more than 0.3v for the lowest OH^- ion concentration. The observed differences between NaOH and KOH solutions and between the two

different grades of Al [grade 1145 containing ≥99.45% Al, ≤0.55% (Si + Fe), ≤0.20% Mn and ≤0.09% other impurities, and grade 2S containing ≥99.0% Al, ≤1.0% (Si + Fe), ≤0.20% Cu, ≤0.05% Mn, ≤0.1% Zn, and ≤0.15% (Be + other impurities)] are interesting and deserve further study.

It is also worth noting that no appreciable increase in the polarization of the unamalgamated high-purity (≥99.99%) Al anodes occurred on supersaturation of the 3M KOH solution with $Al(OH)_3$ in the electrolyte regeneration experiments described in ref. (13).

Concentrated alkali solutions (type 2).—The polarization curve of surface-amalgamated Al grade 1145 anodes in ZnO-saturated 10M KOH solution is shown in Fig. 3. Similar curves were obtained with 10M solutions of both technical and chemically pure KOH grades containing an excess of ZnO or of Zn0.3CaO, and also with 10M NaOH solutions with or without the same additives. All such curves overlapped within a band of ±0.1v. On the other hand, integration of the complete discharge curves of the weighed, surface-amalgamated Al grade 1145 or 2S anodes showed average current efficiencies ≥60% for the following current density ranges in the indicated electrolytes: 10M or saturated NaOH solutions, 30-65 ma/cm²; solutions saturated with both ZnO and NaOH, 5-30 ma/cm²; 10M solutions of NaOH or KOH (chemically pure or technical grades) saturated with ZnO or Zn 0.3CaO, 3.5-140 ma/cm². Thus addition of ZnO definitely helps inhibit the corrosion of surface-amalgamated Al over a very wide current density range without significantly affecting polarization.

Without the ZnO additive, the current density-voltage characteristics of Al anodes in concentrated NaOH and KOH solutions containing various concentrations of dissolved $Al(OH)_3$ (prepared by utilizing the corrosion reaction [7]) are shown in Fig. 4 to 6. The data in Fig. 4 are for surface-amalgamated Al (grade 2S), while those in Fig. 5 and 6 are for high-purity Al (grade 1199 containing at least 99.99% Al) not exposed to Hg. The purer, unamalgamated Al anodes obviously have the better polarization characteristics. The KOH electrolyte is definitely more satisfactory than the NaOH, in spite of the higher solubility of $Al(OH)_3$ in concentrated NaOH solution. The scatter of experimental points in Fig. 5 and 6 appears mainly due to accidental impurities. From the upper curves in Fig. 6 (a) through (d) one obtains Table II in which is shown the variation in output voltage on continued dissolution of $Al(OH)_3$ at a constant current density of 10 ma/cm².

Effect of "Hyamine" inhibitors.—Upon addition of 0.1M "Hyamine 3500" the corrosion rate of surface-amalgamated Al was reduced sufficiently to yield an almost satisfactory cell performance at temperatures of 50° and 70°C [Fig. 7(a)]. However, anode polarization was barely acceptable at these temperatures [Fig. 7(b)] and, at room temperature, proved too high to yield useful current densities even with the KOH concentration increased to 10M.

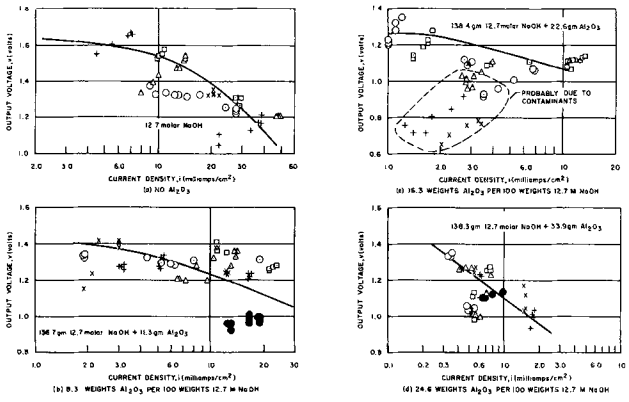

Fig. 5. Room temperature polarization curves for high purity (≥ 99.99%) Al anodes in 12.7M NaOH solutions with various amounts of dissolved Al_2O_3. The anode strips were clamped with rubber gaskets between two large-area Ni-air cathodes.

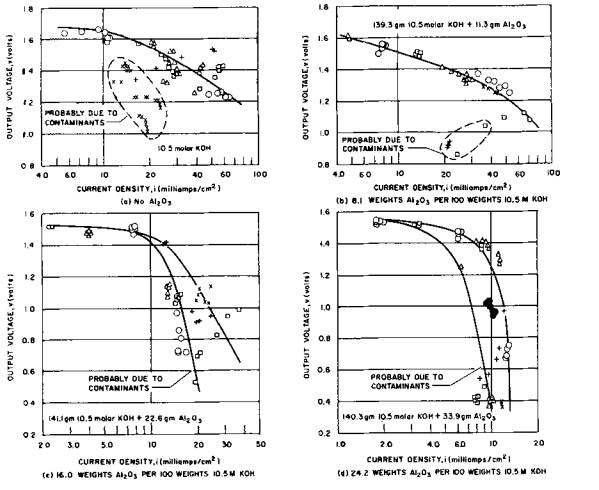

Fig. 6. Room temperature polarization curves for high purity (≥ 99.99%) Al anodes in 10.5M KOH solutions with various amounts of dissolved Al_2O_3.

Table II. Variation in output voltage at a current density of 10 ma/cm² on continued dissolution of aluminum hydroxide

Moles of $Al(OH)_3$ per liter of 10.5M KOH	Anode oxidation potential (volts) relative to the Hg-HgO half-cell
0	1.66
2.3	1.51
4.5	1.45
6.7	1.26

Similar results were obtained with the other Hyamine inhibitors listed in ref. (15).

In experimental cells with unamalgamated high-purity (>99.99%) Al anodes in 10M KOH (Fig. 8), addition of about 0.1M "Hyamine 3500" or "Hyamine 10-X" reduced the maximum rate of H_2 evolution by a factor of 3 at a current density of 4 to 5 ma/cm² (Fig. 9). The corrosion current in the presence of the inhibitors reached maximum steady values of 7-12 ma/cm² after 30-50 min (corresponding to a steady temperature of 40°-50°C) at current densities of both 4-5 ma/cm² and 18-19 ma/cm², with the effect of the additives being most pronounced at the lower current density. On the other hand, the Hyamines showed no adverse effect on the polarization of the unamalgamated anodes, the outputs being

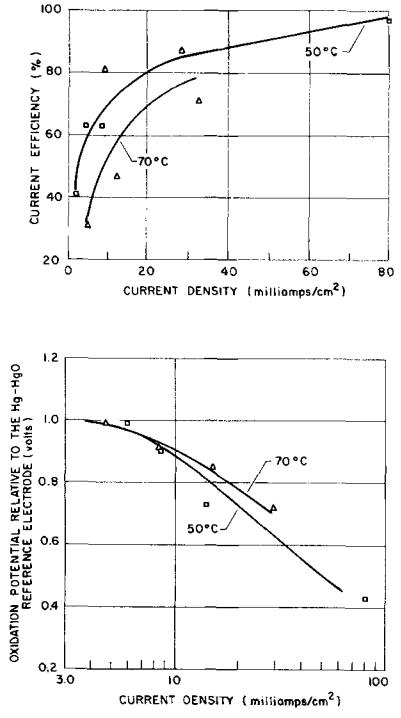

Fig. 7. Current efficiency and oxidation potential (relative to the Hg-HgO reference electrode) as a function of anode current density for surface-amalgamated Al grade 1145 anodes in a ZnO-saturated solution of 2.7M KOH plus 0.5M $Al(OH)_3$ plus 0.15M Hyamine 3500 inhibitor at 50° and 70°C. The experimental procedure was similar to that used for Fig. 2. (a) Current efficiency; (b) oxidation potential.

1.5v for the lower and 1.1v for the higher current densities in all three cases.

Conclusions

Both the current-voltage characteristics and the rate of corrosion of the Al anodes vary with temperature, anode composition, and electrolyte composition. Furthermore, the corrosion rate in alkaline solutions decreases with increasing current density. For a constant anode potential, parallel decreases in current densities and corrosion rates have usually been observed with decreasing temperature, decreasing concentration of hydroxide ions (or other corrosion accelerators), and increasing effectiveness of corrosion inhibitors. Only a few inhibitors such as Hg plus ZnO but no Hyamines or a Hyamine but no Hg would reduce corrosion without seriously decreasing the current density or increasing the anode polarization. With amalgamated Al anodes it may prove possible to develop relatively long-lasting batteries with medium or even low and intermittent current drain by taking proper precautions to eliminate harmful corrosion accelerators.[3] At the present time, however, alkaline Al batteries appear most promising for applications requiring a high energy capacity per unit weight and/or volume and a medium or high power density. For such applications corrosion may be kept under adequate control by: (a) a Hyamine inhibitor; (b) precautions to avoid obvious corrosion accelerators such as sulfides; (c) use of highly pure (>99.99%) Al or a specially resistant Al-Hg, Al-Zn or Al-Mg alloy; (d) an arrangement for effective heat removal by air convection (exposure of the back side of the anode to air) and/or electrolyte circulation; and (e) preferably operation at high current densities and an arrangement for not exposing or for separating the anode(s) from the electrolyte during appreciable periods of inaction.

[3] Such amalgamated anodes will, of course, require precautions to prevent direct contact with air, such as permanent immersion in the electrolyte (or in oil during inactive periods) or use of an air-tight enclosure.

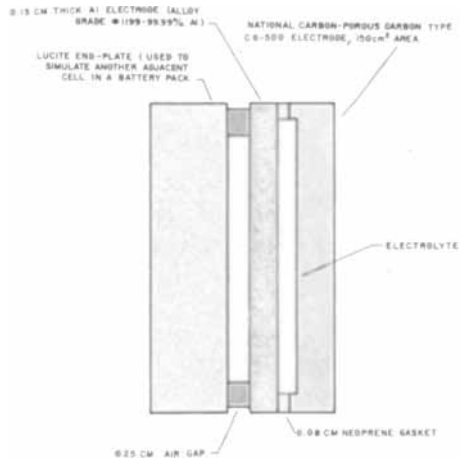

Fig. 8. Experimental Al-air test cell (schematic drawing). Electrolyte volume: 34-38 ml; electrolyte thickness: 0.3 cm.

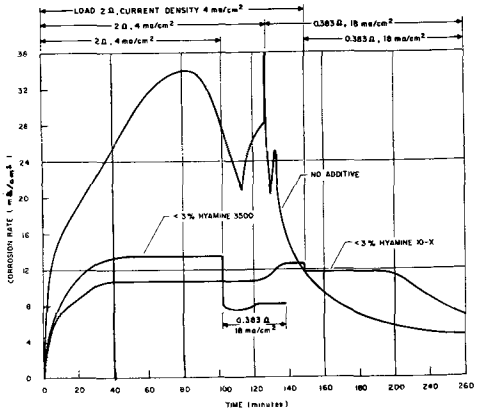

Fig. 9. Effect of Hyamine additives on the anode corrosion rate in the cell of Fig. 8.

For small batteries, a 10.5M KOH solution (with or without 0.1M Hyamine inhibitor) appears most suitable, with the electrolyte being replaced after Al dissolution to a concentration of 6-7 g-moles $Al(OH)_3$ per liter of 10.5M KOH. On the other hand, for larger power supplies (of >1 kw) a 3M KOH solution with auxiliary circulating and $Al(OH)_3$ removing equipment should offer the highest energy to weight and to volume ratios.

Dissolution of Brass in Sulfuric Acid Solutions

I. 85/15 Brass

J. Bumbulis[1] and W. F. Graydon

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario

ABSTRACT

The dissolution of 85/15 brass from rotating cylindrical samples by aerated dilute sulfuric acid solutions was investigated over the range of 15°-35°C. The reaction was found to proceed in three successive steps, dezincification of the brass surface, dissolution of redeposited copper and etching of the brass surface, and dissolution of the etched, dezincified surface. The dissolution rates of the last two steps were determined by the rate of dissolution of copper, zinc being dissolved as fast as it was uncovered by the dissolved copper.

The mechanism of dissolution of copper from 85/15 brass was found to be similar to that of pure copper, controlled by the rate of oxidation of cuprous ions to cupric. Rate equations are given for the apparent dissolution rate of copper at each stage. Hydrogen peroxide was a reaction product.

Corrosion of metals and alloys is of great importance to industry, and a large amount of work has been devoted to this subject. The main effort has been devoted to the comparison of the resistance of various materials to corroding agents. There are relatively few studies of the kinetics and mechanism of dissolution of pure metals, and even fewer of the effect of alloying on dissolution rate.

The study of the kinetics and mechanism of the dissolution of copper in sulfuric acid (1) prompted a similar study using α-brass, to evaluate the effect of zinc on the dissolution of the base metal. An alloy of 85% copper and 15% zinc was selected, to provide an appreciable amount of zinc, while still maintaining a single metal phase.

Experimental

The apparatus and experimental procedure used were the same as for the study of dissolution of copper reported earlier. A cylindrical brass specimen three quarters of an inch in length and diameter was mounted on a vertical shaft and rotated in aerated dilute sulfuric acid solutions.

The brass samples were cut from bar stock supplied by Anaconda American Brass Limited. Two samples were cut from each of three different bars. The analyses of the bars are shown in Table I. Duplicate experiments with samples from each bar did not show a significant difference in the reaction rates. Therefore, no distinction was made between samples from different bars.

Table I. Analysis of 85/15 brass

Bar No.	1	2	3
Cu, wt %	85.36	84.55	85.26
Pb, wt %	0.005	0.005	<0.005
Sn, wt %	0.04	0.00	0.01
Fe, wt %	0.01	0.02	0.02
Zn, wt %*	14.58	15.42	14.72

* By difference.

All reagents used were of "AnalaR" grade. Water was redistilled in an all glass apparatus. Air was taken from a compressed air line, filtered, dried, and saturated with water at the operating temperature.

The reaction was followed by measuring polarographically the concentrations of copper and zinc at regular intervals. A manual polarograph was used, with a dropping mercury electrode and a saturated calomel half-cell. The copper concentration was measured at −0.5v and zinc at −1.3v against the calomel electrode. Hydrogen peroxide, present in the solution, complicated the zinc measurement, since its half-wave potential is very close to that of zinc. To measure the quantities of zinc and hydrogen peroxides, duplicate samples of the solution were taken. One of these was evaporated to dryness and redissolved in water. The diffusion current at −1.3v for the evaporated sample gave the zinc concentration, while the difference in the diffusion current at −1.3v between the two samples gave the hydrogen peroxide concentration. Duplicate meas-

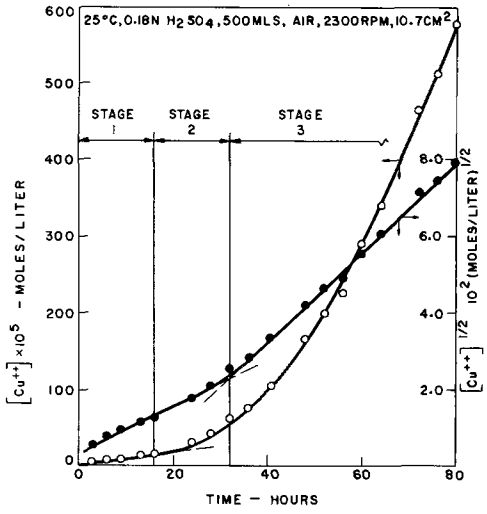

Fig. 1. Typical experimental results. The numbers at the top of the figure refer to temperature, acid strength and volume, composition of gas phase, sample rotational speed and surface area.

urements of the copper concentration on each sample were obtained.

A constant liquid volume was maintained during the experiment by replacing the samples taken with an equivalent volume of the starting solution. The measured concentrations were corrected for this dilution, which usually was very small. At the end of the run the brass sample was dried and weighed. The weight loss was in good agreement with the amount of metal in solution.

Results

The results are presented mainly in terms of dissolution of copper. The zinc data are less accurate due to the low concentration of zinc in the metal.

Reaction Rate Order

The dissolution of 85/15 brass in sulfuric acid proceeded in three distinct, successive stages. For the dissolution of copper, these stages can be best represented by a zero-order reaction, followed by two half-order reactions with respect to cupric ion concentration in solution. Figure 1 shows the three stages for a typical run. The reaction rates for these stages can be represented by the following equations:

$$\text{Stage 1:} \quad \frac{d\,[Cu^{++}]}{dt}\,1 = k_1 \qquad [1]$$

$$\text{Stage 2:} \quad \frac{d\,[Cu^{++}]}{dt}\,2 = k_2\,[Cu^{++}]^{1/2} \qquad [2]$$

$$\text{Stage 3:} \quad \frac{d\,[Cu^{++}]}{dt}\,3 = k_3\,[Cu^{++}]^{1/2} \qquad [3]$$

where $k_2 < k_3$.

The order of the reaction rate with respect to copper ions could not be confirmed by extending the time of reaction because of the several successive stages. Therefore, it was checked by the addition of various concentrations of cupric and/or zinc ions to the starting solution. The results should give a set of parallel straight lines, when plotting the copper ion concentration against time for a zero order reaction, or on a plot of the square root of the copper ion concentration against time for a half-order reaction. A typical set of results, for stage 2 at 25°C is shown in Fig. 2, and results are summarized in Fig. 3.

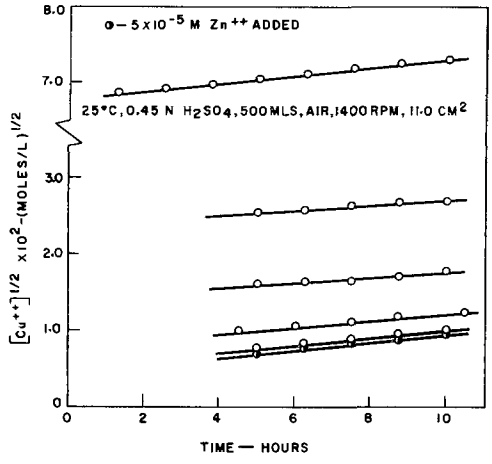

Fig. 2. Addition of copper ions, stage 2

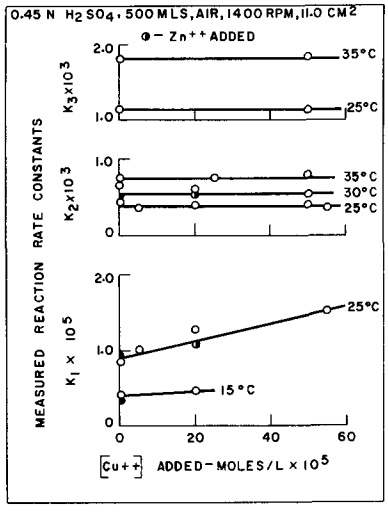

Fig. 3. Effect of copper and zinc ions

The data in Fig. 1 could be interpreted as showing only two half-order reaction rates, because the change in cupric ion concentration during stage 1 gave a straight line both for a zero-order and a half-order reaction. However, addition of cupric ions to the starting solution gave straight lines on a zero-order plot, curves for half-order, indicating a zero-order reaction.

There was no sharp transition from one stage to the next, and the duration of stage 1 and 2 varied with the experimental conditions. The transition from one stage to another could be correlated with the amount of copper dissolved from the brass and appeared to be associated with changes in the brass surface. The change from stage 1 to stage 2 occurred when approximately 0.25 mg/cm^2 of copper had been dissolved, and stage 3 set in after dissolution of approximately 1.07 mg/cm^2 of copper. A brown coating was formed on the surface during stage 1. The brown layer dissolved in stage 2, leaving a greenish, crystalline surface in stage 3.

It was found that the addition of zinc ions had no effect on the rate of dissolution of copper for

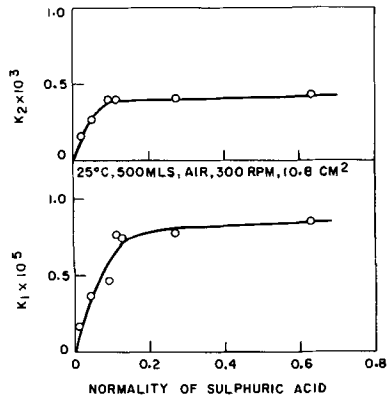

Fig. 4. Effect of acid strength

all stages. The addition of copper ions showed stages 2 and 3 to be of the half-order in copper ion concentration. While stage 1 was best represented by a zero-order reaction at all copper concentrations added, the rate constant increased with increasing copper ion concentration, indicating that at least two different reactions were occurring during stage 1.

Effect of Experimental Variables

Changes of the speed of rotation in the range 300-3500 rpm had no noticeable effect on the rate of reaction of any stage. Therefore diffusion of reagents or products did not control the reaction under the conditions investigated.

The sulfuric acid concentration had no effect on the reaction rates as long as it was above 0.1*N*. The reaction rate decreased at lower acid concentrations (Fig. 4). The acid concentration was maintained above 0.1*N* for all experiments.

The amount of copper dissolved in a given time should be directly proportional to the surface area of the metal sample. Also, when the rate of dissolution is expressed in terms of the metal ion concentration in solution, rather than the amount of metal dissolved, it should be inversely proportional to the volume of the solution, as shown by the relation:

$$\frac{dc}{dt} = \frac{1}{v}\frac{dn}{dt} \qquad [4]$$

where n is moles of metal dissolved. Combining these two effects, the measured reaction rate should be proportioned to A/V. It was found that with changes in the metal surface area from 3.8 to 14.8 cm², and in solution volume from 250 to 750 ml the reaction rates of stages 1 and 2 were directly proportional to A/V up to 25 cm²/l, but there was some deviation at higher values (small solution volumes).

The reaction rates of all three stages were proportioned to the square root of the oxygen partial pressure.

Plots of log k against the inverse of the absolute temperature (Arrhenius' plots) gave an activation energy of approximately 11,000 cal/mole for stages 1 and 2. Limited data for stage 3 indicated an activation energy of 7000-8000 cal/mole. The relatively high values obtained support the conclusion that diffusion effects do not influence the reaction rate.

The presence of hydrogen peroxide as one of the reaction products was detected polarographically, and confirmed by the phenolphthalein method of Schales (2). Addition of hydrogen peroxide to the starting solution indicated that the reaction rate of stage 1 was directly proportional to the hydrogen peroxide concentration. Little change was observed in the rate of stage 3. The addition of hydrogen peroxide shortened stage 2 so that the concentration data indicated a direct transition from stage 1 to stage 3; however, visual observation of the sample showed stage 2 to be present briefly. The concentration of hydrogen peroxide in the solution appeared to have a limiting value of approximately 150-200 $\times$ 10^{-5} moles/l. Higher hydrogen peroxide concentrations decomposed to this limiting value. The existence of a limiting concentration would explain the lack of effect of hydrogen peroxide on stage 3, since essentially constant concentration is reached by the onset of stage 3 regardless of the initial concentration.

The transition between stages appeared to be related to the amount of metal dissolved, accompanied by noticeable changes in the appearance of the metal surface. It was postulated that the transition from stage 1 to stage 2 was caused by changes in the composition of the metal surface, because there was a change in the order of reaction. Stages 2 and 3 had the same order of reaction, but different values of the rate constant. This change could be due to an increase in the surface area. Since dissolution was not diffusion controlled the measured reaction rate should be proportional to the true surface area, and changes in the surface roughness would give a different value of the measured rate constant. To test the latter assumption, samples that had reached stage 3 were washed carefully, to remove all traces of the corroding solution, and placed in fresh solution. In every case, a stage 3 reaction rate was obtained from the start. As a check, freshly polished samples were etched for 15 and 30 min in an acid solution containing 0.035M H_2O_2, when visual appearance of the sample resembled stage 3. The same reaction rate was obtained by both treatments, indicating that the nature of the surface, and not the history of the sample, determine the onset of stage 3. The increase in the surface area must have been the same, regardless of the treatment.

Correlating Equations

The results of these experiments can be summarized by the following general equations

Stage 1:

$$\frac{d[Cu^{++}]}{dt} = 1.93 \times 10^2 \, e^{-\frac{11400}{RT}} \, [P_{O_2}]^{1/2} \, \frac{A}{V} \qquad [5]$$

Stage 2:

$$\frac{d[Cu^{++}]}{dt} = 5.94 \times 10^3 \, e^{-\frac{10700}{RT}} \, [Cu^{++}]^{1/2} \, [P_{O_2}]^{1/2} \, \frac{A}{V} \qquad [6]$$

The limits investigated were:

	Stage 1	Stage 2
Temperature, °C	15-30	25-35
Oxygen partial pressure, atm	0.21-1.00	0.21-1.00
Sample surface area, cm^2	3.8-14.8	10.7-14.8
Solution volume, liters	0.25-0.75	0.50-0.75
Acid concentration	0.2-0.6*N*	0.2-0.6*N*

The standard deviation of the constant in Eq. [5] was 0.19×10^2 (9.8%), calculated from data of 26 individual experiments, and for Eq. [6] 0.28×10^3 (4.7%), determined from 21 experiments. These equations do not include the effect of H_2O_2. Equation [5] is valid until approximately 0.25 mg/cm^2 of copper is dissolved, while Eq. [6] applies for the range of 0.25-1.07 mg/cm^2 of copper dissolution. An equation similar to Eq. [6] should represent stage 3, but enough data were not obtained, to permit an accurate evaluation of the constant term.

A comparison of the relative amounts of copper and zinc in solution, shown in Fig. 5, revealed that at the start of the experiment there was dezincification. The ratio of total zinc to total copper in solution approached that in the metal as the reaction progressed. Therefore, as far as the bulk of the metal is concerned, there was little dezincification.

Discussion

Dissolution of 85/15 brass in sulfuric acid is very similar to the dissolution of pure copper reported by Lu and Graydon (1). The main difference is the existence of an initial stage of relatively slow copper dissolution for brass, caused by the dezincification of the brass surface, which can not exist for pure copper. Both copper and 85/15 brass show an increase in the reaction rate, caused by changes in the surface roughness or surface area (transition from stage 2 to stage 3), without an apparent change in the reaction mechanism.

There is disagreement in the literature on the production of hydrogen peroxide. Traube (3) and Bengough (4) reported the presence of hydrogen peroxide and proposed reaction mechanisms to include its production. There is evidence that hydrogen peroxide is decomposed by the presence of metal ions, particularly copper, in solution (5-8). This would explain why some investigators could not find hydrogen peroxide in measurable quantities. A fairly rapid hydrogen peroxide decomposition is indicated by the present study. The hydrogen peroxide concentration in solution has not exceeded a value of 0.002M. Solutions to which larger concentrations were added showed a loss of hydrogen peroxide.

The standard electrode potential for the reaction $Cu \rightarrow Cu^{++} + 2e^-$ is +0.34v relative to the reaction $H \rightarrow H^+ + e^-$, and copper should not dissolve in air-free acid solutions. In the presence of air copper can dissolve according to the following mechanism:

$Cu \rightarrow Cu^{++} + 2e^-$	anode
$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2$	cathode
$Cu + O_2 + 2H^+ \rightarrow Cu^{++} + H_2O_2$	over-all

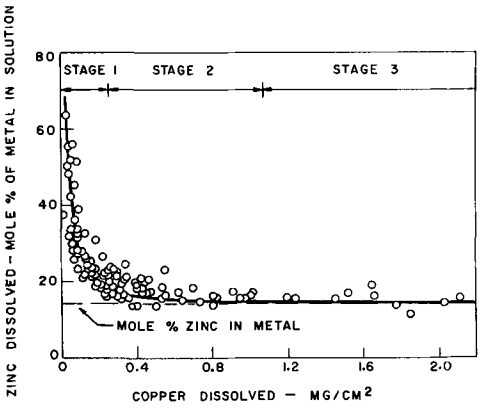

Fig. 5. Zinc content of dissolved brass

The cathode reaction is the same as proposed by Churchill (9), and accounts for the formation of hydrogen peroxide as well as depolarization by oxygen.

Lu and Graydon (1) proposed a mechanism for the dissolution of copper, which accounted for the half-order rate by the following assumptions:

1. The cupric ion concentration in the bulk of the solution is essentially the same as at the copper-solution interface.
2. The cuprous ion, cupric ion equilibrium $Cu + Cu^{++} \rightleftharpoons 2\ Cu^+$ is established at the interface.
3. The rate of dissolution of copper is assumed to be controlled by the removal of cuprous ions from the interface by a reaction which is first order with respect to cuprous ion.

Using the same assumptions the following set of equations represent a possible mechanism for the dissolution of copper from brass:

$O_2(gas) \rightleftharpoons O_2(solution) \rightleftharpoons O_2 i$	equilibrium
$Cu + Cu^{++} \rightleftharpoons 2\ Cu^+$	equilibrium
$2\ Cu^+ + O_2 i + 2H^+ i \rightarrow 2\ Cu^{++} + H_2O_2$	slow
$Cu + O_2 i + 2H^+ i \rightarrow Cu^{++} + H_2O_2$	over-all

The subscript i refers to concentrations at the metal-solution interface. The slow step accounts for the dependence of the dissolution rate on the square root of the oxygen partial pressure, on the hydrogen ion concentration at low acid strength, and, together with the assumed cupric-cuprous ion equilibrium, it also accounts for the dependence on the square root of the cupric ion concentration.

The addition of copper ions to the starting solution showed that the reaction rate order of stage 1 was somewhat higher than zero order, although the latter was the best representation. Since the next stage is of the half-order in copper ion concentrations, it was thought that the measured reaction rate might be the sum of a zero-order reaction for stage 1, and the half-order reaction of stage 2, an attempt was made to relate the experimental data from stage 1 by the equation

$$\frac{d[Cu^{++}]}{dt} 1 = k' + k'' [Cu^{++}]^{1/2} \qquad [7]$$

It was found that the experimental data could be represented reasonably well by the above expression. However, the values of k'' required to produce this agreement were considerably smaller than the rate constants of stage 2 for the same experimental conditions.

Another reaction affecting the concentration of copper ions should also be considered. Studies by Centnerszwer (10, 11) and King (12) indicate that solution of zinc in copper sulfate-sulfuric acid solutions is of the first order in copper ion concentration. The reaction has been shown to proceed by the displacement of copper ions from solution (13). Thus, Eq. [7] should be modified to include the decrease in cupric ion concentration due to displacement by zinc

$$\frac{d[Cu^{++}]}{dt} 1 = k' + k'' [Cu^{++}]^{1/2} - \frac{d[Zn^{++}]}{dt} \text{ displ.} \quad [8]$$

The experimental data do not permit an evaluation of the order of the displacement reaction with respect to cupric ion concentration. If a cupric ion concentration gradient exists at the brass surface, it would be first-order in cupric ion concentration. The existence of a displacement reaction is supported by the formation of a brown surface layer during stage 1.

Little can be said about the mechanism of dissolution of zinc. Comparison of the quantities of copper and zinc in solution (Fig. 5) indicated dezincification of the brass surface during the initial stage. As the reaction progressed, the ratio of zinc to copper in solution approached that in the bulk metal, indicating dissolution of a copper surface followed by dissolution of brass as a unit.

The zinc data from stage 1 showed considerable scatter, and did not permit an evaluation of the dissolution mechanism. In stage 3, where more reliable zinc data were available, the changes in zinc concentration could be predicted from changes in the copper concentration. This agrees with the assumption that in stage 3 the brass dissolves as a unit, controlled by the rate of dissolution of copper.

Addition of zinc ions to the starting solution showed no effect on the rate of copper dissolution in all stages.

Summary

The dissolution of 85/15 brass in sulfuric acid proceeds through three successive stages. There is an initial period of surface dezincification accompanied by some copper redeposition. This is followed by the dissolution of copper by a mechanism similar to that of pure copper. During the later stages, zinc is dissolved from the brass surface as fast as it is uncovered by the dissolution of copper. The copper dissolution proceeds in two stages, depending on the area of surface exposed to solution. The rate controlling step is believed to be the oxidation of cuprous ions to cupric ions at the metal surface. Hydrogen peroxide is found in the corroding solution.

Dissolution of Oxygen Layers on Platinum in Chloride Solutions

M. W. Breiter and J. L. Weininger

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Oxygen layers on platinum are dissolved at open circuit in electrolytes containing chloride ions. The dissolution of layers formed at 1.4 and 1.6v in 1*N* H_2SO_4 was investigated in two solutions with different concentrations of chloride ions at 25° and 85°C, and it is shown that the dissolution occurs by the following mechanism. The electrode is the seat of simultaneous cathodic and anodic reactions, in which the sum of the partial currents of anodic platinum dissolution on the free surface is equal to the cathodic partial current of the oxygen reduction.

The role of oxygen on anodized platinum has received much attention in the past. Oxygen at platinum electrodes was alternately believed to be an oxide film (1-7), or an adsorbed film of oxygen (8-17). The oxide-film hypothesis has gained greater credence even for oxygen layers formed at potentials below oxygen evolution in recent years. We are re-opening this question, however, because the present potentiostatic and potentiometric measurements on the dissolution of oxygen layers from platinum in chloride solutions, as well as the earlier experiments of Anson and Lingane (5), are satisfactorily explained by a mechanism that may involve adsorption of oxygen alone. It is postulated that at the platinum electrode, after anodization, simultaneous reduction and oxidation processes occur.

Generally, the anodic formation of oxygen layers on platinum is retarded in electrolytes containing chloride ions (9, 12, 18). Obrucheva (12) observed that the oxygen branch of cathodic charging curves on smooth platinum was larger after the same anodic polarization in sulfuric acid than in a mixture of H_2SO_4 and HCl. Anson and Lingane (5) studied the dissolution of oxygen layers on smooth platinum at open circuit in a gently boiling solution of 0.2*N* HCl + 0.1M NaCl by determining photometrically the concentration of the ions $PtCl_4^=$ and $PtCl_6^=$ after the oxygen layer had been formed either anodically in 1*N* H_2SO_4 or by chemical oxidation. They found that the chemical analyses of the dissolved platinum corresponded quantitatively with the electrometrically measured charges for the cathodic removal of the oxygen layer from the platinum. From this quantitative agreement it was concluded that the oxygen layer consists of PtO and PtO_2. But the dissolution of the oxygen layer may occur according to the following mechanism

$$Pt - O + 2H^+ + 2e^- \xrightarrow{I_1} Pt + H_2O \qquad [1]$$

$$Pt + 4Cl^- \xrightarrow{I_2} PtCl_4^= + 2e^- \qquad [2]$$

$$Pt + 6Cl^- \xrightarrow{I_3} PtCl_6^= + 4e^- \qquad [3]$$

with the condition that $|I_1| = |I_2 + I_3|$. The oxygen layer is formally denoted by Pt — O above. Reactions [1] to [3] are themselves net reaction. The cathodic reaction [1] takes place on the oxygen layer, the anodic reactions [2] and [3] on the free platinum surface. If the mechanism is correct, then the formation of $PtCl_4^=$ and $PtCl_6^=$ during dissolution is not evidence for the presence of PtO and PtO_2. This would follow only for a purely chemical process without charge transfer across the platinum-solution interface.

The described mechanism can be verified by observing the dissolution of the oxygen layer in a stripping solution at open circuit under the experimental conditions of Anson and Lingane (5) and by taking cathodic charging curves to determine the amount of oxygen in coulombs per square centimeter on the surface after different times of dissolution. This technique was used by one of us (M.W.B.) in a similar problem concerning the reduction of the oxygen layer on platinum by molecular hydrogen (19). Dissolution should only take place in the potential range of the cathodic reaction [1] in the case of the suggested mechanism. The surface area free of oxygen will have another effect on the dissolution rate in case of the above mechanism as in a chemical dissolution process. Processes of the type described by Eq. [1] to [3] are of importance in a recent general theory of passivity advanced by Schwabe (20).

Experimental

The following technique, used to study the dissolution process with time, involves the anodic formation of an oxygen layer on platinum in 1*N* H_2SO_4 in one cell, washing the electrode in double-distilled water, and transferring it to another cell with an electrolyte containing Cl^- ions (5). The stripping solution was the same as that of Anson and Lingane. A periodic voltage of triangular shape was potentiostatically applied to the platinum electrode in 1*N* H_2SO_4 at 25° with helium-stirring in a vessel of conventional design. The electrode potential was changed at 30 mv/sec between 0.05v and 1.62v, the potential U being referred to a hydrogen electrode in the same solution. When the potential reached a suitable value in the oxygen region (+1.4v and 1.6v, respectively), the circuit was interrupted manually. The electrode, now covered with an oxygen layer (4, 16), was taken out of the vessel, washed in double-distilled water, and transferred within a few seconds to a second vessel containing the stripping

solution which was stirred with purified argon to remove molecular oxygen. Little oxygen is gained or lost in this transfer. It is not lost because the rate of self-decomposition of the oxygen layer on platinum is very small in sulfuric acid or other solutions (8, 15). Nor is oxygen gained because the adsorption of molecular oxygen does not even occur at a measurable rate on a free platinum surface immersed in an aqueous solution at open circuit and room temperature (8, 15). Since the method involves the study of the following cathodic charging curves a small change in the concentration of oxygen would not interfere with the subsequent conclusions. On immersion the electrode was quickly connected to the circuit of the second cells and the potential decay was measured with an electrometer (Keithley 610A-input resistance $> 10^{14}$ ohms). When the potential had reached a given value during the open-circuit decay a cathodic charging curve was taken by switching on a current of 10 ma/cm^2 with a mercury relay (Western Electric 275C) and registering the potential-time curves oscillographically (Tektronix 502). The method of connecting the oscilloscope with the electrode by means of the relay was used to avoid current being drawn by the input resistance of 10^6 ohms of the oscilloscope. In the second cell the potential was measured against a calomel electrode in the stripping solution, but all potentials are reported below against a reference hydrogen electrode at 25° and 85°C, respectively, in the stripping solution. The voltage between the calomel and hydrogen electrode was measured at 25° and 85°C, respectively. After the charging curve was obtained, the electrode was washed thoroughly and transferred to the 1N H_2SO_4 solution. In the cell with 1N H_2SO_4 at least one potentiostatic cycle was passed before repeating the above procedure. At the end of a series of charging curves at least three of the initial curves were checked for reproducibility, which was found to be within 10% of the amount of oxygen Q_o in mcoul/cm^2.

Results

The dissolution of oxygen layers formed at 1.4 and 1.6v in 1N H_2SO_4 at 25° was studied under conditions comparable to those of Anson and Lingane (5) at 25° and 85° in 0.2N HCl + 0.1M NaCl (denoted below as the "dilute" chloride solution). To investigate the influence of the chloride ion concentration the same experiments were carried out in 0.2N HCl + 2.8 NaCl ("concentrated" chloride solution).

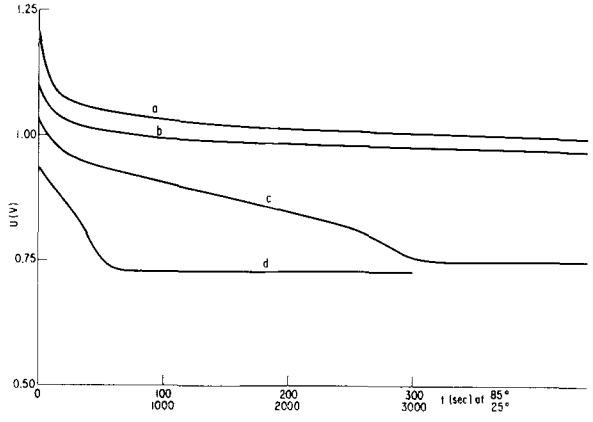

Fig. 1. Potential decay at open circuit in 0.2N HCl + 0.1M NaCl during the dissolution of oxygen layers on smooth platinum. Curve a, layer formed at +1.6v, dissolved at +25°C; curve b, layer formed at +1.4v, dissolved at +25°C; curve c, layer formed at +1.6v, dissolved at +85°C; curve d, layer formed at +1.4v, dissolved at +85°C.

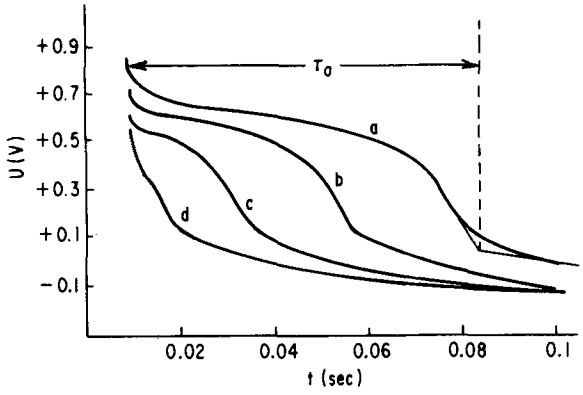

Fig. 2. Cathodic charging curves taken after different times of dissolution of an oxygen layer, formed at +1.6v, in 0.2N HCl + 0.1M NaCl at 85°C. Curve a, taken after 3.8 sec; curve b, taken after 52 sec; curve c, taken after 106 sec; curve d, taken after 195 sec.

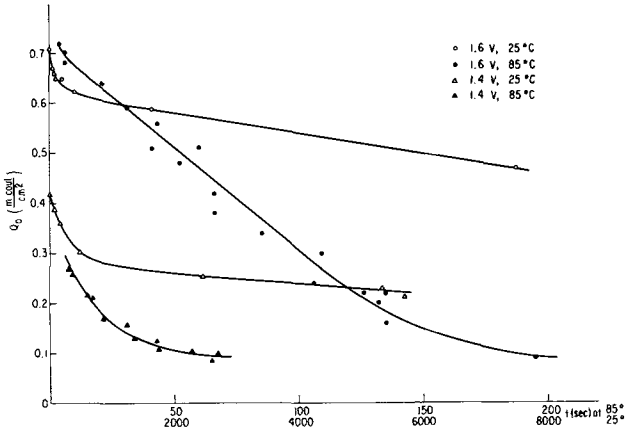

Fig. 3. Amount of oxygen on the surface as a function of time during dissolution in 0.2N HCl + 0.1M NaCl under different conditions.

For convenience the experimental results are arranged graphically in Fig. 1 to 5, which with their legends, and with reference to the above discussion of experimental procedure, are largely self-explanatory. Figure 1 illustrates the potential decay of platinum electrodes, covered with oxygen, at open circuit in the dilute chloride solution. Figure 2 shows cathodic charging curves for one of the platinum electrodes of Fig. 1. Figures 3 and 4 give the amount of oxygen on the surface after different times of dissolution at 25° and 85°, in the dilute and concentrated chloride solutions, for layers formed at 1.4 and 1.6v, respectively. Finally, the potentiostatic current-voltage curves of Fig. 5 show some of the individual electrochemical steps occurring in the dissolution process.

Potential decay of platinum electrodes covered with oxygen.—The potential decay is very slow at room temperature. After 6.5 hr the potential reached a value of 0.95v in the case of curve a of Fig. 1. Ob-

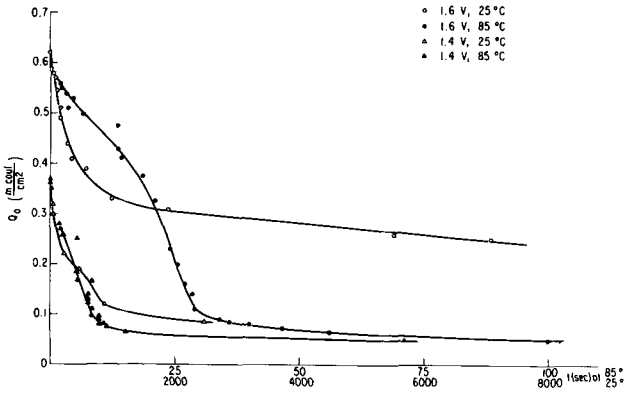

Fig. 4. Amount of oxygen on the surface as a function of time during dissolution in 0.2*N* HCl + 2.8M NaCl under different conditions.

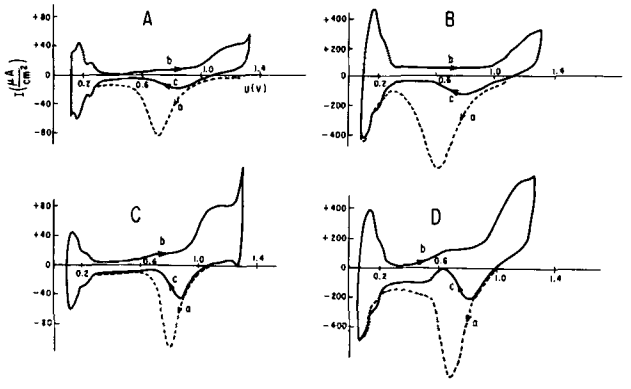

Fig. 5. Potentiostatic current potential curves in 0.2*N* HCl + 0.1M NaCl. Initial oxygen layer formed at +1.6v for 2 min in 1*N* H_2SO_4. Curve A, 0.03v/sec, 25°C; curve B, 0.30 v/sec, 25°C; curve C, 0.03 v/sec, 85°C; curve D, 0.30 v/sec, 85°C. Sweep a, initial reduction; sweep b, anodic wave; sweep c, second reduction wave.

viously the dissolution of the oxygen layer is slow. At 85° the potential decays more rapidly and tends towards a time-independent value at about 0.75v. As may be expected, the final value of the potential is reached more quickly for the oxygen layers formed at 1.4v. Also the initial potential decay is larger at 25° than at 85°.

Cathodic charging curves.—Figure 2 shows four charging curves which were started at different potentials of curve c of Fig. 1. The approximate determination of the transition time τ_o for a cathodic reduction of the oxygen layer is demonstrated for curve a. A correction of the value of τ_o for the charging of the double layer was not applied since this error is smaller than 10%. With increasing time of dissolution τ_o becomes smaller, and the curves are shifted to less positive potentials. Some of the oxygen, having a higher heat of adsorption (17) than that originally being dissolved, requires a higher overvoltage. It was found, similarly to Anson and Lingane, that about 10-15% of the oxygen layer did not dissolve within a reasonable experimental time (cf. Fig. 1). Generally, the dissolution times were shorter under equivalent conditions than those observed by Anson and Lingane. This difference may be attributed to the use of wire electrodes of relatively small apparent surface area (0.5 cm²), which are known to be more active than larger foil electrodes. Figure 2 refers to measurements at 85°. Similar curves are obtained at 25°, but the decrease of τ_o with dissolution time is considerably smaller as expected on the basis of the results of Fig. 1.

Dissolution of oxygen layer.—The dissolution of oxygen layers in the dilute and concentrated chloride solutions is shown respectively in Fig. 3 and 4. The oxygen layer which still exists after the dissolution time t is represented by Q_o, the number of millicoulombs per square centimeter required for its cathodic reduction. At 85° the dissolution proceeds at a reasonable rate until the last part is reached when the slower dissolving oxygen comes off. This occurs about three times faster in the concentrated than in the dilute chloride solution.

Current-voltage curves.—The example of potentiostatic measurements chosen for Fig. 5 is a platinum electrode with an oxygen layer formed at 1.6v in 1*N* H_2SO_4. After the transfer the cathodic sweep a was applied first, followed by an anodic sweep b, and finally another cathodic sweep c. The four curves were taken at two different voltage rates (0.3 and 0.03 v/cm) at the two different temperatures. During sweep a the originally present oxygen layer is reduced (dotted lines). At low speed this reduction takes place between 1.1 and 0.6v. In the hydrogen region, between 0 and +0.3v, the I-U-curves of sweeps a and c coincide. During the anodic sweep b a small wave is observed between 0.6 and 0.9v. This is probably due to reactions [2] and [3], which occur on an electrode not yet completely passivated (18, 21). During sweep b evolution of chlorine (18, 22) takes place for U > 1.4v, as well as reactions [2] and [3], which become increasingly inhibited by the growing oxygen layer (21). Finally sweep c shows the reduction of the oxygen layer formed during sweep b. The potential range for this reduction is between 1.1 and 0.6v, narrower at 85° than at 25°. At 85° the current has a tendency to become anodic between 0.6 and 0.8v during the cathodic sweep c as a result of anodic reactions [2] and [3] setting in when the oxygen layer has been partly removed.

Discussion

The above experiments were performed to see whether one can characterize the oxygen layers formed on platinum electrodes. A mechanism is given to show the "electrochemical" nature of the dissolution process. This is supported by two principal observations. First, dissolution takes place between 1.0 and 0.7v, and second, the rate of dissolution does not have an order to be expected from a purely chemical reaction without charge transfer at the electrode interface. The present mechanism should apply to the dissolution of oxygen layers formed by moderate oxidation processes at platinum, either anodically with voltages at or below 1.6v, or in oxidative solutions. These were also the conditions used by Anson and Lingane; hence their observations are consonant with the present mechanism.

The experiments on the dissolution of the oxygen layer in the dilute chloride solution at 85° (Fig. 1 and 3) show clearly that the process takes place between 1.0 and 0.7v. This is the potential range in

which the oxygen layer formed in 1*N* H_2SO_4 is reduced during the cathodic sweep at low voltage speeds (Fig. 5, branches a and c). At room temperature the same conclusion holds for that part of the oxygen layer which is dissolved within the studied time interval.

The present experiments show that the order of the dissolution reaction cannot be one or higher as would be expected for a chemical reaction. Comparing two platinum electrodes covered by oxygen to a different extent, it can be seen from Fig. 3 that about 0.6 mcoul/cm^2 are removed at 85° within the studied time for the oxygen layer formed at 1.6v and about 0.2 mcoul/cm^2 for that formed at 1.4v. The first half of 0.6 mcoul/cm^2 is dissolved in about 80 sec, half of 0.2 mcoul/cm^2 in about 17 sec. The fact that dissolution is more rapid if Q_o-values are smaller can be understood on the basis of the suggested mechanism. A larger part of the surface is free of oxygen and is available for reactions [2] and [3] in the case of small Q_o-values, when as in the present case, the Q_o-value of the oxygen layer formed at 1.6v corresponds to no more than a monolayer (13). The same conclusion follows from Fig. 4.

Regarding the influence of temperature and the concentration of chloride ions it is difficult to give a quantitative interpretation of the dissolution rates because reactions [2] and [3] are inhibited by the oxygen layer (18, 21). But qualitatively the increase in dissolution rates can be observed by a comparison of Fig. 3 and 4.

In conclusion, the present measurements substantiate a dissolution mechanism of oxygen layers in which the cathodic reduction of oxygen and anodic dissolution of platinum occur simultaneously at the same electrode. The experimental results and the proposed mechanism are consonant with a concept of adsorbed oxygen on the Pt surface, but do not exclude the possibility of oxide formation. Conversely, if such a mechanism is valid, chemical evidence of reaction products is not sufficient proof that an oxide film exists. Oxide films and adsorbed oxygen layers on other metals than platinum should also be approached with the same caution and should be examined for the possibility of complying with a similar mechanism.

The Structure of Oxide Films Formed on Aluminum After Exposure to High-Temperature Pure Water

J. H. Greenblatt

Department of National Defence, Defence Research Board, Naval Research Establishment, Dartmouth, Nova Scotia, Canada

ABSTRACT

The structure of the oxide films formed an aluminum after exposure to high-temperature pure water over the temperature range 150-350°C has been examined after periods of exposure varying from 1 min to 7 hr. The technique used to prepare samples for examination shows up the different structural zones in the oxide by intensifying the contrast in refractive index between them. It was observed that the number of distinguishable zones increased as exposure conditions became more extreme and that the time for appearance of more than two zones was minimum with the least corrosion resistant material and maximum with the most corrosion resistant material. Columnar structures joining the outer crystalline layer to the metal surface at the site of second phase particles protruding through the metal interface were also observed. These columns also appeared to be connected to the third layer when such a layer was present.

The structure of oxide films formed on aluminum after exposure to high-temperature water has been investigated by a number of previous workers (1-7). This previous work consisted of electron microscopic examination of the topology of the inner metal-oxide interface and the outer oxide-water interface of the film, as well as examination, in silhouette, of crystals protruding from the surface. In addition considerable work was also done on the optical microscopy of cross sectioned specimens bearing oxide films. As a result of this past work it has been established that: (i) the oxide film is multilayered with two and possibly more zones of differing structure in the film; (ii) that the outer zone is crystalline with the crystalline material being generally Boehmite but under certain conditions may also include diaspore needles; (iii) that the inner surface (oxide-metal interface) is amorphous.

No detailed study on the development of structure in the oxide film with time at various temperature has been published although Biefer (2) and Hart and Ruther (3) have given some values on the variation of the thickness of the outer crystalline layer and remainder of the oxide with time. The work reported here was therefore undertaken to provide more detailed information on how the various zones and structures develop in the oxide film formed on aluminum exposed to high-temperature water. Commercial 2S Aluminum and two special alloys containing iron and nickel were used in the work described, and specimens were exposed for eight different times at five different temperatures.

Experimental

Cylindrical samples of aluminum 3/8 in. in diameter and 5/16 in. long were machined from extruded 1/2 in. diameter rod and then one end was polished down to 0.25μ diamond. Polishing was done in a special jig holding 14 samples. Following this preparation the specimens were degreased in refluxed trichloroethylene for 2 hr and then annealed in argon in the test autoclaves for 2 hr at 340°C. The specimens were then brought to test temperature in argon, and water at the test temperature was added to the system. The apparatus and procedure have been described more fully in an earlier paper (8). The nominal composition of the alloys is given in Table I.

After exposure the samples were coated with a thin film of vacuum-evaporated aluminum to demarcate the boundary between oxide and mounting medium. They were then mounted in diallyl phthalate plastic and cross sectioned by grinding on a polishing wheel. The cross sections were then polished down to 0.25μ diamond with kerosene as a lubricant followed by polishing down to 0.1μ using "Gamal" and water. This phase of specimen preparation was reported in detail earlier (9, 10). The specimens prepared this way showed no detail of oxide structure, but did show excellent detail at the oxide metal interface and the information obtained has also been reported (9).

A further stage of sample preparation revealed detail in the oxide itself, and the results of this further examination of the oxide films form the subject of the present paper. The polished samples prepared as above were then mounted in batches of six

Table I. Composition of the alloys

Alloy	% Ni	% Fe	% Si

in a special jig in a bell jar so that all samples had the same vertical incidence to the source, and a thin film of aluminum was evaporated over the polished face of the cross section. The thickness of this film was of the order of 400Å, and it showed about 50% transmission. This thin film increases the contrast between zones in the oxide film that have different indices of refraction when viewed by reflected light in the microscope. The first film of aluminum deposited on the specimen before mounting acts as sharp demarcation of the boundary between oxide and mounting plastic. The specimens coated in this way were examined at 1000X.

Results

Examination of cross sections showed that on all alloys the number of discernible zones in the oxide film increases with time. For 10155 at the most extreme exposure condition, 350°C and 7 hr of exposure, four distinct zones could be distinguished below the demarcating aluminum boundary: the outer crystalline layer, a second layer next to this one, a third layer following the second, and a thin band next to the metal surface. These can be seen in Fig. 1. The bright metallic flecks seen protruding into the oxide are unattacked second phase particles. After 2 hr of exposure at 350°C only two zones are definitely present, and the third layer is seen only as a thin discontinuous line, while at shorter times the number of layers decreases to two. After 7 hr and with decreasing temperature a similar trend is observed, and the number of layers observed decreases. Thus at 300°C after 7 hr of exposure the third layer is very thin, and no fourth layer is observed.

With 10157 no more than two distinct zones were distinguishable after the exposure times studied,

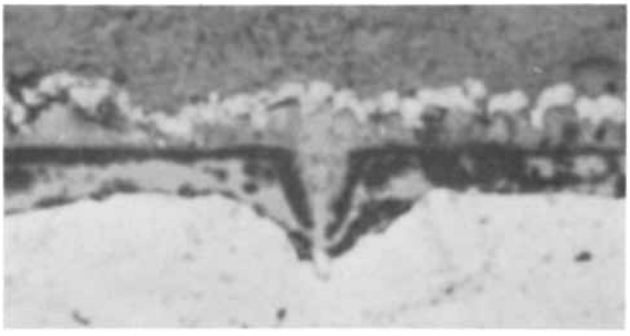

Fig. 2. 2S aluminum after 7 hr exposure at 300°C. Three layers can be seen distinctly and a very thin discontinuous fourth layer. A columnar structure joining the third layer to the outer layer can also be seen. Magnification 4000X.

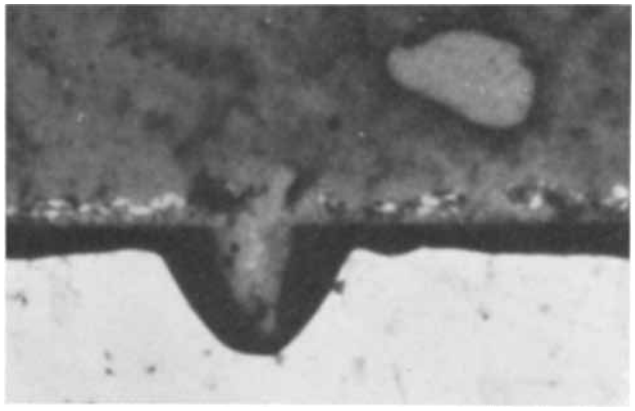

Fig. 3. 2S aluminum after 7 hr of exposure at 250°C. Magnification 4000X.

while with 2S four layers were observed at more extreme conditions. Figures 2 and 3 are photographs showing the layers observable in 2S. The number of layers discernible in the oxide films of the alloys studied is tabulated in Table II. It must be emphasized that the numbers in the table should be accepted as indicating general trends and should not be taken as completely unequivocal. This is due to the fact that the appearance of the film is conditioned to a degree by the thickness of the aluminum layer deposited over the specimens, and contrast may not be great enough in some cases to indicate an additional layer when it is very thin.

Certain structural features were also observed in the oxide cross sections. These were columnar structures between the outer layer and the metal surface. The "columns" appeared to be connected to the third layer when one could be distinguished. They appeared to occur at places where second phase particles were protruding through the metal oxide interface either at the regular metal surface or in pits. Examples of these columns are shown in Fig. 2, 3, 4, and 5. It cannot be stated unequivocally whether

these columns grow up from the metal or down from the crystalline layer. The general configuration of the columns, thick on top, thin on the bottom, their presence even in very thin films, their lack of penetration beyond the third layer at times, indicates they grow down from the crystalline layer. Their appearance at the site of second phase particles at the surface or in pits could indicate evidence either of downward or upward growth. In Fig. 2 and 3 the columns certainly would seem to be the result of downward growth, but Fig. 4 shows several types of such columns including some very small thread-like ones connecting second phase particles at the metal interface with the crystalline layer that could have grown from the bottom up.

The percentage of total film thickness of the crystalline zone and other zones was also determined by measuring projected images of the photographed cross sections. Over the range of times and temperatures covered in our work the crystalline layer on 10157 constituted 48% of the total film thickness with the smallest value measured being 37% and the largest 61%. For 10155 the average was 48% with the smallest value measured 32% and the largest 66%. For 2S the average was 44% with the minimum being 22% and the maximum 62%. The low minimum for 2S occurred at 350°C. At this temperature the film on 2S appeared to be different than that on the other alloys. The low values measured when determining the average showed no definite pattern of either increasing or decreasing thickness of the crystalline layer with time. With 10155 and 10157 more of the larger values occurred at shorter exposure times than longer ones, but with 2S the reverse was true and more of the lower values occurred at earlier times.

The second layer constituted 41% of the total thickness of the oxide film on 10155 when three zones were visible and 35% when four were. The third layer increased from 8% of total film thickness when only three layers could be detected to 20% when four were detected.

With 2S the second layer averaged 36% of the total with a low of 16% and a high of 61%. The third layer made up 22% on the average with a low of 8% and a high of 35%.

Discussion of Results

The examination of the structural zones in oxide films formed on aluminum exposed to high-temperature water shows that the corrosion film on the alloys examined differs. With 10157 only two distinct zones could be discerned at the most extreme conditions of exposure time and temperature used. With 10155 as many as four zones were observed at the most extreme condition, while with 2S the maximum number of zones observed was four, and three zones were observed after as short an exposure time of 1 min at 350°C compared with 2 hr at 300°C. Since other work has shown that 10157 has better corrosion resistance than the other materials tested, the results indicate that the delay in formation of such structural zones may be tied up with the protective properties of the oxide film. Further evidence for this is the fact that the worst material, 2S, shows the third zone after extremely short exposures at 350°C.

All the films examined showed columnar structures between the crystalline outer layer and the metal surface or a visible third layer. The columns tended to occur at the protruding second phase particles when these were in pits or at the more regular metal-oxide interface. The evidence indicates, although not unequivocally, that they grow down from the crystalline layer. Because the visible third layer appears to spread laterally from such columns, Fig. 2, and appears to be separate and distinct from the metal surface, Fig 1 and 2, this layer could also be a crystalline layer nucleating from the column parallel and close to the metal surface.

Values of percentage of crystalline oxide to total film thickness agree with previously reported ones. Biefer's (2) data show a levelling off in the rate of increase of thickness of the crystalline layer with time after about one week's exposure with 10157 and two week's exposure with 10155. At the bend in Biefer's curves of layer thickness against time the values are 40% for both 10155 and 10157. Over the period three weeks to 30 weeks (1, 2) the values given for both alloys decreased gradually to about 25%. Hart and Ruther's (3) values averaged 33% over the period 24 hr to 32 days where general attack occurred and 50% when local attack occurred. These values all indicate that with times of exposures larger than ours, the outer crystalline layer forms a smaller proportion of total film thickness.

Measurements of Biefer's (1) cross sections after 62 days exposure at 350°C show that the third layer on 10155 constituted 17% of total film thickness while that on 10157 constituted 13%. Although the difference is just significant it adds further support to our finding of the absence of any distinct third zone on 10157 during the exposure times investigated by us as it indicates the slower growth of such a layer on 10157.

Conclusions

The examination of cross-sectioned aluminum oxide corrosion film shows that the number of structural zones observed in the oxide is least for the most resistant material, and that in the least resistant material a third layer appears after very short exposure times at 350°C. The linking of the third zone to the crystalline outer layer by columnar structures through the oxide suggests that this layer may also be crystalline. If this is the case, it could explain spalling and cracking that occurs after longer exposure times.

The Mechanism of the Niobium Reaction with Water Vapor and with Oxygen

P. E. Blackburn[1]

Chemistry Department, Research Laboratory, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The low-temperature oxidation of niobium in water vapor and in oxygen occurs by diffusion of oxygen into the metal and formation of NbO and NbO_2 on the surface. NbO_2 forms a porous scale on NbO, growing linearly from the oxide-oxide interface. Solution of oxygen in the metal and the growth of NbO on niobium are believed to be diffusion controlled. The so-called breakaway oxidation occurring between 400° and 500°C in oxygen and between 750° and 950°C in water vapor is shown to be caused by nucleation and growth of Nb_2O_5 on NbO_2.

The oxidation of niobium has been the subject of a considerable amount of research over the last 20 years. Niobium is a relatively abundant refractory, and in addition to its high melting point and low vapor pressure, it has good ductility and a low neutron cross section. A major deterrent to its use at high temperatures, however, is its low oxidation resistance above 400°C. The poor oxidation resistance manifests itself between 400° and 500°C where the initially protective film is supplanted by a scale which offers no barrier to rapid oxidation (1). The transition from a protective film to the nonprotective scale is rather abrupt, resulting in a prompt increase in the oxidation rate at an oxygen pickup of around 50-80 $\mu g/cm^2$. This change has been termed breakaway oxidation. Several investigators have proposed a mechanism for the change.

[1] Present address: Arthur D. Little, Inc., Acorn Park, Cambridge, Massachusetts.

Cathcart, Campbell, and Smith (2) on the basis of a microtopographic study, propose that the transition to a high linear rate is due to mechanical stress in the film. These stresses lead to occurrence of cracks and blisters in the film and subsequent breakdown of protection. These authors suggest that the linear oxidation results from continual healing and cracking of the film.

A report published by the author (3) in March 1959 on the reaction between water vapor and niobium proposed a new mechanism for the so-called breakaway oxidation. It was suggested that this phenomenon could be related to the nucleation and growth of Nb_2O_5 on NbO_2. Hurlen, Kjøllesdal, Markali, and Norman (4) in their study of the reaction of oxygen with niobium independently proposed nucleation and growth of Nb_2O_5 as the cause of breakaway oxidation.

There is some disagreement over the oxidation mechanism occurring before the transition to a high linear rate. Gulbransen and Andrew (1), Inoye (5), Cathcart *et al.* (2), and Bridges and Fassell (6) all found protective oxidation (*i.e.*, parabolic rates), while Klopp, Simms, and Jaffee (7) found the low-temperature oxidation to be linear. Klopp *et al.* make no mention of the transition.

An excellent review of the niobium oxidation research through 1958 is contained in the Hurlen *et al.* report (4). It is interesting to note that only Phelps, Gulbransen, and Hickman (8) were able definitely to identify NbO as one of the low-temperature products of oxidation. This compound was found on a specimen oxidized at 400°C for 5 min in 0.1 atm O_2. These conditions are such that the measurement was made well before the transition to the high linear rate. The stripped film showed Nb_2O_5 electron diffraction lines, but Hurlen *et al.* (4) state that the stripping process could have produced the pentoxide.

In all of the studies reviewed by Hurlen, with the above exception and one study at 300°C by Brauer and Müller (9), the oxide scale formed below the transition point was not successfully identified.

Klopp *et al.* (7) found some evidence for NbO above 500°C.

In the Hurlen *et al.* (4) studies which covered the temperature range of 100°-1000°C and 10^{-2} to 760 mm of oxygen, neither NbO, NbO_2, nor Nb_2O_5 were found below the transition point, although in some cases two oxides, designated NbO_x and NbO_y, were detected. Hurlen suggests that the initial reaction is entirely due to solution of oxygen in the metal. At pressures of 1 mm or less, there were some instances where NbO and NbO_2 were found in addition to Nb_2O_5.

The phase designated NbO_x was found earlier by Brauer and Müller (9) on niobium powders oxidized in air at 330°C. These authors suggested the formula Nb_2O for this phase. NbO_y was not identified by Hurlen except to indicate that there were two strong spectral lines which could not be identified as belonging to previously reported phases.

Hurlen *et al.* have shown that the nucleation and growth of Nb_2O_5 can be related to the transition to "breakaway" oxidation. Since there was no x-ray evidence for NbO and NbO_2 before the transition they speculated that the nuclei were formed in NbO_x or in the oxygen saturated metal.

A report by Kofstad, Kjøllesdal, Markali, and Norman (10) covers the oxidation between 500° and 1200°C and at oxygen pressures from 10^{-1} to 760 mm. Their work concerns oxidation above the transition point.

Brewer's survey of thermodynamics of oxides (11) indicates that the stable oxides of niobium are NbO, NbO_2, and Nb_2O_5. In terms of crystal structure, NbO possesses a defective NaCl-type lattice (12), NbO_2 has a rutile structure (13, 14), and Nb_2O_5 occurs in three forms. Brauer (13) reports that the pentoxide exists between 500° and 900°C as an pseudohexagonal phase, γ, between 1000° and 1100°C as an unknown phase, β, and above 1100°C as a monoclinic phase, α. Recently Holtzberg, Reisman, Berry, and Berkenblit (15) investigated the polymorphism of high-purity Nb_2O_5. They found three forms: (i) amorphous to 435°, (ii) γ to 830°, and (iii) α above 830°C. The γ phase, a two-dimensional array, is Brauer's γ and β phases which Holtzberg *et al.* show to be a single phase. They found the α phase to be monoclinic. Brewer (11) also reports that Nb_2O_5 has an oxygen solubility range of $NbO_{2.4-2.5}$. Seybolt's data (16) indicate an oxygen solubility from 5.5 atom per cent (a/o) in niobium at 1100°C to 1.4 a/o at 775°C.

There have not been any studies involving the oxidation of niobium in pure water vapor. However, Inoye (5) found that water vapor mixed with air appeared to accelerate the rate of reaction at temperatures below 400°C.

The purpose of this study is to determine the stability of Nb_2O_5, the rate of reaction of niobium with water vapor, and the mechanism of reaction of niobium with oxygen and with water vapor.

Experimental Procedure

Apparatus.—The apparatus for the thermodynamic and kinetic experiments consists of an all quartz microbalance sealed into a Pyrex glass system. Using this balance, weight changes could be read to ± 2.2 x 10^{-7}g. Alpert (17) valves and all-metal diaphragm valves were used to permit the system to be baked out at 300°C. Pressures were measured with a mercury manometer isolated from the system by a null manometer (18), while vacuums were measured with a Bayard-Alpert (19) gauge. At room temperature, vacuums of about 1 x 10^{-9} mm were obtained, but at high temperatures vacuums were on the order of 1 x 10^{-5} mm.

Thermodynamic equilibrium method.—The CO/CO_2 equilibrium over the Nb_2O_5-NbO_2 two-phase region was measured by suspending a platinum crucible containing niobium oxide with a composition of $Nb_2O_{4.59}$ from one arm of the microbalance into a mullite furnace tube. The system was evacuated. The temperature of the furnace was regulated at a constant value. A measured pressure of spectroscopically analyzed CO containing 0.25% CO_2 was then admitted to the furnace section, the volume of which had been established previously. The weight of oxygen lost from the niobium oxide as a result of reduction by CO gas was measured with the microbalance. The experiment was continued until there was no further change in weight (about 24 hr). The amount of CO_2 formed was calculated from the oxygen weight loss of the niobium oxide.

Kinetic method.—The rate of reaction of niobium with water vapor was measured by suspending a specimen from one arm of the microbalance into the evacuated furnace tube. The temperature of the furnace tube was raised and held constant to ± 0.5°C while the rest of the system was heated to prevent condensation of water vapor. Water vapor was generated into a storage bulb from a container of distilled water which had been thoroughly degassed. These two components were joined to each other and to the rest of the system with metal

valves and Kovar-to-glass seals. Water vapor was admitted to the furnace section and weight change as a function of time was observed.

X-ray diffraction method.—Monochromatic filtered nickel radiation from a fine focus x-ray tube was used with a Guinier camera. Diffraction patterns of powder scraped from oxidized niobium specimens by sapphire and carbide tools were made at room temperature.

Samples.—The Nb_2O_5 was prepared by oxidizing 2 mil sheet manufactured from powder melted by electron bombardment. Oxidation was carried out at 1200°C until there was no further weight gain. The composition of the fully oxidized sample was assumed to be stoichiometric Nb_2O_5. Its resistivity was found to be about 3×10^8 ohm-cm at room temperature.

The above oxide was reduced with hydrogen and from the weight change a composition of $Nb_2O_{4.69}$ was calculated. This material, assumed to be in the two-phase region $Nb_2O_{4.8}$-NbO_2, was used in the CO/CO_2 equilibrium study.

Niobium monoxide and dioxide were prepared by mixing the metal and Nb_2O_5 in the correct ratios and arc melting them in an atmosphere of pure argon. The monoxide was silver and metallic in appearance. This material had a diamond pyramid hardness of 830. Its electrical conductivity was very high, with a room temperature resistance of 5×10^{-4} ohm-cm. Chemical analysis indicated a composition of $NbO_{1.005}$. The dioxide was a black polycrystalline sintered porous solid whose resistivity was about 4000 ohm-cm. The composition of several samples varied from $NbO_{2.01}$ to $NbO_{2.04}$.

Two different types of niobium sheet were used for the kinetic study. The first, employed in the 200° and 225°C measurements, was the electron bombarded metal mentioned above. It had the following impurities as determined by spectroscopic analysis: Al, 0.04; Fe, 0.015; Si, 0.01; Ta, 0.1-0.2; V, 0.05; Na, 0.01; and K, 0.01. The second specimen, used for the remaining studies, was prepared from Fansteel high-purity vacuum sintered Nb sheet which contained the following impurities: C, 0.016; Ta, 0.14; Fe, 0.008; Zr, 0.65; Ti, 0.013; N, 0.028; and O, 0.11. Two types of surface preparation were used: (i) abrading with polishing paper under kerosene, (ii) abrading with a blast of Al_2O_3 powder forced through a nozzle under pressure.

Results

Thermodynamic equilibrium.—Three experiments, performed at 927°, 977°, and 1027°C, were carried out with one CO charge admitted at room temperature before the sample was heated. This method required a correction for the altered balance reading caused by temperature induced variations in convection currents. The convection coefficient was equivalent to 1.1×10^{-7} g/C° at a pressure of 5.9 mm.

In two experiments made at 1077° and 1227°C, the CO charge was added after the sample was at temperature. Here the effect of convection currents on the readings was eliminated by extrapolating the weight *vs.* time curve to zero time.

Factors limiting accuracy of the experiments were thermal diffusion of the lower molecular weight gas to the furnace tube and reaction of CO with the mullite furnace tube. The former effect was believed to be small. The latter circumstance occurred only during the 1227° measurement, when the weight change of the sample with time reached zero and then reversed. The reversal may have occurred in the following manner: (i) the sample loses weight by reaction with CO, *i.e.*,

$$Nb_2O_{4.8} + 4/5CO = 2NbO_2 + 4/5CO_2 \qquad [1]$$

(ii) A second reaction is assumed to occur simultaneously with the first

$$CO + SiO_2(s) \text{ (in mullite)} = CO_2 + SiO(g) \qquad [2]$$

The excess CO_2 produced then reacts with NbO_2 reversing Eq. [1]. Although the calculated pressure of SiO(g) is very low ($10^{-7.1}$ atm at 1227°C), SiO may condense in cooler parts of the apparatus allowing more CO_2 to be produced. Thus the total amount of CO_2 formed may not be entirely accounted for by reaction [2]. This effect could also be caused by diffusion of oxygen through the mullite tube. It is estimated from the weight gain after equilibrium was reached, that 15% of the total CO_2 produced at 1227°C was due to one of these effects. This is equivalent to 0.36 kcal of the free energy change. The 1227° measurement was corrected for this effect.

Table I summarizes the data and gives the calculated free energy of formation of $Nb_2O_{4.8}$ from NbO_2. The composition of the former is the lower limit of the oxygen solubility in the Nb_2O_{5-x} phase.

A least squares fit to the free energies of formation in Table I gives for

$$2NbO_2 + 2/5O_2 = Nb_2O_{4.8} \qquad [3]$$

$\Delta H_{1350} = -56.6$ kcal/mole of the oxide and $\Delta S_{1350} = -13.8$ e.u./mole of the oxide. Brewer (11) calculated the heat of solution of oxygen in $Nb_2O_{4.8}$ for the reaction

$$Nb_2O_{4.8} + 1/10O_2 = Nb_2O_5 \qquad [4]$$

to be $\Delta H_{298} = -15.3$ kcal/mole of oxide. The latter value may be combined with the heat of reaction [3] to give the heat of formation of Nb_2O_5 from NbO_2, $\Delta H_{1350} = -71.9$ kcal/mole of oxide. In the absence of entropy data for the solid solution region, the entropy for reaction [3] is multiplied by 5/4 to give the entropy of formation of Nb_2O_5. from

[a] ΔF_1: $2NbO_2 + 4/5CO_2 = Nb_2O_{4.8} + 4/5CO$.
[b] ΔF_2: $4/5CO + 2/5O_2 = 4/5CO_2$ from Coughlin (20).
[c] ΔF_3: $2NbO_2 + 2/5O_2 = Nb_2O_{4.8}$.

Table II. Thermodynamic values for formation of Nb_2O_5 from NbO_2 at 1300°K

	This research	Coughlin's tables (20)
$-\Delta H$ kcal/mole of oxide	71.9	71.9
$-\Delta S$ e.u./mole of oxide	17.2	17.2
$-\Delta F_{1300}$ kcal/mole of oxide	49.5	49.5

NbO_2, $\Delta S = -17.2$ e.u./mole of Nb_2O_5. Table II compares the author's thermodynamic values for formation of Nb_2O_5 from NbO_2 at 1300°K with those from Coughlin's tables (20). The agreement is excellent.

From Coughlin's tables the hydrogen-water vapor ratio may be calculated for the reaction

$$2NbO_2 + H_2O\ (g) = Nb_2O_5 + H_2 \qquad [5]$$

At 225° and 1125°C this ratio is $10^{5.2}$ and $10^{1.1}$, respectively. As long as less than 90% of the water is consumed in these reactions, thermodynamically there is no reason why Nb_2O_5 would not be a stable product of the reaction of water and niobium at temperatures up to 1125°C.

Kinetics of Niobium-Water Vapor Reaction

There are three rate equations which appear to be followed in this study

$$W = k_1 t \qquad [6]$$

$$W^2 = k_2 t \qquad [7]$$

$$W^3 = k_3 t \qquad [8]$$

where W is the weight gained by the sample in time, t, and k_1, k_2, and k_3 are, respectively, the linear, parabolic, and cubic rate constants. To find which equation applies, the logarithm of the weight gain may be plotted against the logarithm of the time.

The linear rate is obeyed by reactions which are controlled by processes occurring at one of the interfaces. Parabolic reactions have been shown by Wagner (21) to apply to an oxidation mechanism governed by the rate of diffusion of either or both the oxygen anion or the metal cation through the oxide film. It is conceivable that a process controlled by gaseous effusion of the reacting gas through a growing porous oxide layer could also result in parabolic oxidation, assuming that the pore diameters remained relatively constant and only their length increased with time. A decrease in the area of the interface at which the reaction takes place would also yield a curve of decreasing slope. Hence a curve of this type alone is not incontrovertible evidence for a diffusion controlled reaction.

The cubic rate has been observed empirically, but except for the case of thin films, has not been explained theoretically. Hurlen (22) suggests that it may be a transition region between inverse logarithmic and parabolic oxidation.

Figures 1, 2, and 3 show the weight gain *vs.* time for the reaction of niobium in 5 cm of water vapor. Figure 4 gives the logarithm of the weight gain *vs.*

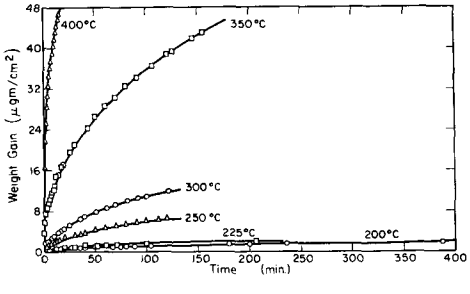

Fig. 1. Niobium oxidized in 5 cm H_2O vapor, weight gain *vs.* time.

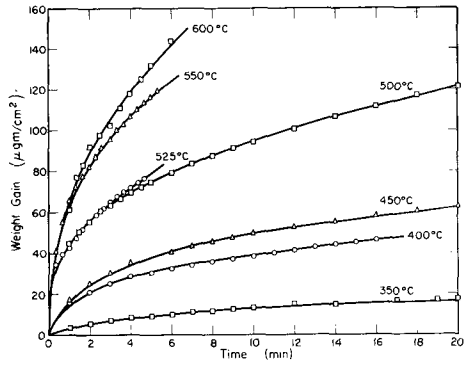

Fig. 2. Niobium oxidized in 5 cm H_2O vapor, weight gain *vs.* time.

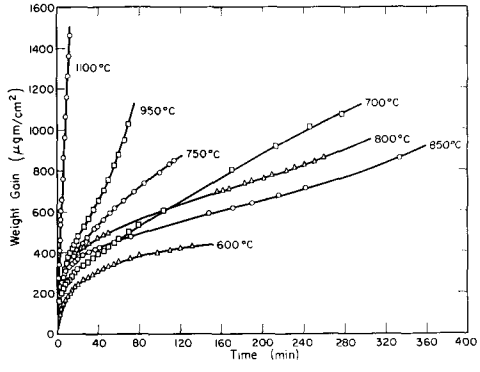

Fig. 3. Niobium oxidized in 5 cm H_2O vapor, weight gain *vs.* time.

time for the reaction of niobium in 5 cm of water vapor. Figure 4 gives the logarithm of the weight gain *vs.*

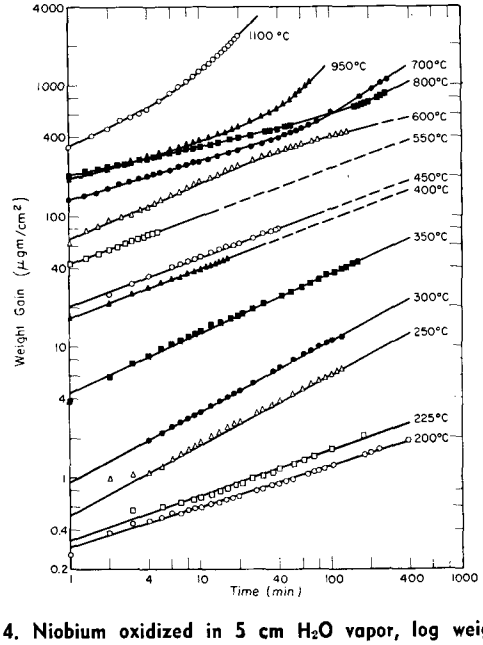

Fig. 4. Niobium oxidized in 5 cm H_2O vapor, log weight gain *vs.* log time.

the logarithm of the time for all the runs from 200° to 1100°C (the 750° and 850° curves are not included for the sake of clarity). The slopes of the curves obtained between 250°-350°C are close to 0.5, while the measurements between 200°-225° and 400°-750°C have slopes of about 0.33. Above 750°C the log-log curves do not fit either category.

Niobium samples for 250°-500°C runs were prepared by abrasion with a blast of Al_2O_3 powder. The remaining experiments were made on samples prepared by polishing specimen through 4/0 emery paper under kerosene.

The effect of surface treatment on reaction rate is clearly demonstrated in Fig. 5, which compares two samples with different surface preparations, each reacted at 200°C. The manually polished metal reacts cubically over the full test time, whereas the blast cleaned sample failed to oxidize for the first 40 min of the run. This behavior was upheld by a second blast-abraded specimen, also measured at 200°C.

When the measurements are plotted by surface treatment of the sample, curves indicating two kinetic rates emerge. The slope for the polished samples is 0.33 for the temperature range 200°-700°C. For the abraded metal a slope of 0.5 was found up to 350°C, but from this temperature to 750°C the samples followed cubic curves.

The upper limit for application of the cubic rate occurs at an approximate weight gain of 400 $\mu g/cm^2$ in 5 cm of water vapor as shown in Fig. 6. This weight gain is from 6 to 8 times as much as that observed for the protective phase of oxygen reacting with niobium. In some of the measurements shown in Fig. 3 an acceleration in the reaction rate may be observed after an oxygen weight gain between 500 and 800 $\mu g/cm^2$. This is believed to correspond to the so-called breakaway oxidation of niobium found between 400° and 500°C. However, in the water vapor experiments, the temperature range for accelerated activity is between 750° and 950°C. The rate of reaction of niobium with 5 cm of water vapor is within a factor of two of the oxidation rate in 0.1 atm oxygen up to 400°C (*i.e.*, the protective oxide scale range) (1).

The specimens varied in color after oxidation from dull gray to dark blue or black. The intensity of the color increased with oxygen pickup.

There was no evidence in these studies for spalling of the oxide film, a factor which has been observed in

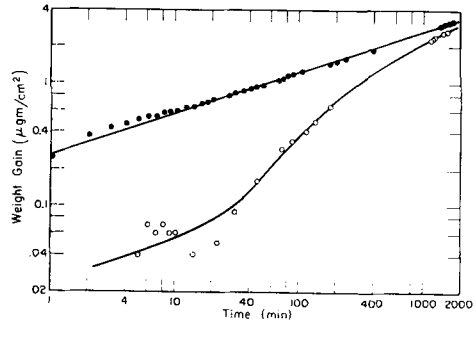

Fig. 5. Effect of surface treatment; niobium oxidized at 200°C in 5 cm H_2O vapor, log weight gain *vs.* log time. •, abraded through 4/0 polishing paper, annealed at 300°C; ○, abraded with Al_2O_3 blast, no anneal.

other studies (1, 4, 7) of the niobium-oxygen reactions.

An Arrhenius plot of the cubic rate constant (Eq. [8], *i.e.*, for the reaction occurring before the transition to breakaway oxidation, *vs.* the reciprocal of the temperature is presented in Fig. 7. It is evident that a change in the reaction mechanism occurs above 750°C, where a decrease in the rate constant manifests itself.

Since the pretransition weight gain curves represent the sum of at least three simultaneous processes, *i.e.*, oxygen solution in the metal and formation of NbO and NbO_2, no heat of activation can be assigned to the oxidation of niobium.

In addition to studies on the rate of oxidation of the metal in water vapor, kinetic measurements were made of the reaction of water vapor with two of the niobium oxides. Both samples were heated in a small platinum crucible in 5 cm of water vapor. The NbO

was oxidized at 500°C for 2 days. Oxidation for the first 3 hr was linear, with a rate of 4.2 x 10^{-9} $g/cm^2/sec$. The rate slowly decreased with time to 1.3 x 10^{-9} $g/cm^2/sec$ after 50 hr.

The porous NbO_2 sample was heated for 18 hr at 500°C in 5 cm of water vapor with no apparent change in weight. The temperature was then raised to 900°C, where the sample readily oxidized. During the 40-min measurement the reaction rate was amplified by a factor of 4. Since the sample was exposed to water vapor while being heated from 500° to 900°C, the increase in rate with time was measured after some reaction had already taken place. This oxidation behavior appears to be a nucleation and growth process in the formation of the pentoxide from the dioxide. By comparing the 900° curve with measurements of NbO_2 in air (see below), an induction period of about 100 min could be estimated. This may be compared to 25 min at 950° and 200 min at 850°C for the onset of the high linear rate in the oxidation of the metal. This rate appears to be caused by the nucleation and growth of Nb_2O_5 on NbO_2 in water vapor.

The amount of hydrogen produced in the water vapor-niobium reactions was never greater than 1.4% of the total pressure well below the thermodynamic limit for reduction of Nb_2O_5 to NbO_2 at 1100°C. The pressure of hydrogen produced in all cases was so small compared to the equilibrium pressure over a saturated solution of hydrogen in niobium that the niobium should have dissolved less than 1.6 a/o of hydrogen (220 ppm) during the water vapor reaction. The maximum capacity for hydrogen occurred in the 200°C measurements. The solubility of hydrogen as a function of hydrogen pressure was calculated from Katz and Gulbransen's data (23). Katz's data were extrapolated below the minimum concentration of 3 a/o. It is possible that solution of hydrogen in the metal may have been much less than that calculated, since hydrogen may not be able to diffuse through an oxide layer. The presence of hydrogen gas is not believed to have any effect on the oxidation mechanism. The amount of hydrogen gas present was far too small to prevent the formation of Nb_2O_5 under any of the conditions presented in this study.

X-Ray Diffraction Spectra of Oxides Formed on Niobium

Some of the samples were scraped with carbide and sapphire tools to remove the oxide film. The extreme hardness of NbO (830 DPH) requires diamentine tools to assure its removal. Other samples were completely ground for use as x-ray samples. There was not enough oxide to make an x-ray measurement on specimens oxidized below 450°C. These samples reacted with less than a total of 400 μg of oxygen.

Table III gives the results of the x-ray measurements. Except for the 450° measurement, where only dioxide was observed, both monoxide and dioxide were found on samples up to 950°C. Since no lines were found for niobium in the 1100° sample the absence of the two lower oxides may have been caused by failure to remove the oxide layer to a sufficient depth. The lack of NbO lines at 450° may be due to either small crystal size or low concentration. The lack of pentoxide spectra at 850° and 950°C may perhaps be due to inadequate x-ray exposure time or sample size.

The lattice parameters given here are compared to literature values in Table IV.

Seybolt's data (16) for oxygen dissolved in niobium gives a room temperature niobium lattice parameter of 3.3125Å for niobium saturated with 4.6 a/o oxygen at 1000°C. The room temperature parameters measured here indicate that the saturated metal may expand at least to as much at 3.320Å after oxidizing between 500° and 700°C. This value may be compared to that of Hurlen who found a maximum value of 3.342Å for a sample oxidized at 350°C. It appears that niobium can take up more than 4.6 a/o oxygen at lower temperatures.

With the exception of Hurlen's (4) low oxygen pressure results, the x-ray data for the samples differ from earlier work on the oxygen-niobium reactions in that all three oxide phases were found at higher temperatures. Most of the published results have indicated only Nb_2O_5 as the product of oxidation. It would be very desirable to know what phases are present on the samples oxidized below 450°C.

Contact Resistance of Oxides and Oxidized Niobium

Hurlen (4) has suggested that neither of the two oxides, NbO and NbO_2, forms before the pentoxide

[a] Two surfaces, each 1 cm².
[b] Sample oxidized in 0.1 atm O_2, all others in 5 cm H_2O.
[c] 1 cm thick, total resistance.

in oxygen pressures greater than 0.1 mm and that oxygen dissolves in the metal initially without forming an oxide film.

In order to test this hypothesis, the contact resistance of the three oxides and the oxidized samples was measured. These data are given in Table V. The values are for two contacts of 1 cm² each. Indium foil was used to improve the electrical contact.

The contact resistance in all cases is at least 10 times greater than that for either the metal or NbO. This is evidence that even the samples oxidized at 200°C have some oxide present, either NbO_2 or Nb_2O_5. The dark gray to black color of the oxide films support this finding, indicating that the oxide is probably NbO_2 or nonstoichiometric Nb_2O_5.

Oxidation of NbO *and* NbO_2 *in Air*

In order to prove the assumed analogy between the oxidation of niobium in water vapor and in oxygen, the kinetics of NbO and NbO_2 oxidation in air were studied. The results of the NbO_2 oxidation between 400° and 500° are shown in Fig. 8 where the oxygen-niobium ratio is plotted against the logarithm of the time. The surface area of the sample was not known, prohibiting the calculation of a quantitative rate of reaction. These curves do demonstrate that NbO_2 oxidizes in a manner which is characteristic of a nucleation and growth controlled reaction. The induction periods agree favorably with the time elapsed before the onset of the high linear oxidation of niobium (breakaway oxidation) observed by other authors.

Figure 9 shows the oxidation of NbO in air between 350° and 450°C. These curves show that NbO oxidizes linearly and that NbO_2 is present before the pentoxide is formed.

Discussion

The thermodynamic study on the NbO_2-$Nb_2O_{4.8}$ phases indicate that the Nb_2O_5 is stable in water vapor, so that its failure to form in water vapor at low temperatures cannot be attributed to this factor. There is excellent agreement between the data obtained here and the tables calculated by Coughlin.

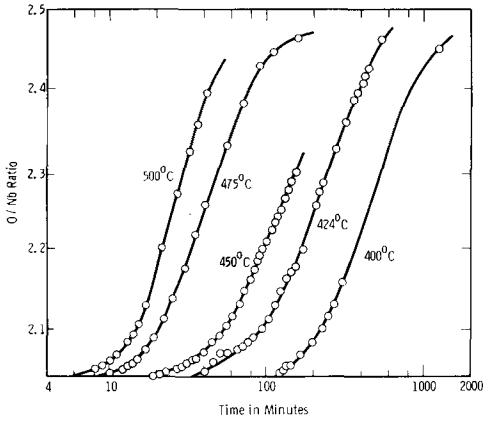

Fig. 8. Oxidation of $NbO_{2.04}$ in air

○, $NbO + O_2 \rightarrow Nb_2O_5 + NbO_2$; ●, $NbO + \frac{1}{2} O_2 \rightarrow NbO_2$.

The use of a vacuum balance for determining the CO/CO_2 ratio in a static system has the advantage that the equilibrium point may be precisely defined.

The suggestion by earlier authors that the breakdown of protective oxidation is due to a physical mechanism involving stresses and strains in what was assumed to be a protective film of Nb_2O_5 is incompatible with findings in this study. First, it has been shown that a protective oxide film can grow in water vapor to a thickness almost 10 times that of a film grown in oxygen. Thus failure cannot be related to a physical breakdown. Second, there is good evidence that Nb_2O_5 is not present before the breakdown occurs; rather, the breakdown can be directly correlated with the appearance of Nb_2O_5. It seems possible that the cracks and blisters observed by Cathcart *et al.* (2) are due to the formation of a nonprotective film of Nb_2O_5 growing into the underlying films of NbO and NbO_2.

The interference colors observed on pretransition samples oxidized in oxygen and in water vapor must be caused by NbO_2. Optical properties for NbO and NbO_2 have not been found in the literature. However, with regard to the former, it seems very likely that it will behave in a fashion similar to metals, since its electrical conductivity is within an order of magnitude of several metals. Because of their high conductivity, metals are known to be practically opaque (25).

It appears that interference colors observed on oxidized niobium must be due to NbO_2 or Nb_2O_5. Since it has been shown that Nb_2O_5 forms only after temperature dependent induction periods, the interference colors observed before the nucleation and growth of Nb_2O_5 must be due to NbO_2. Hurlen has attributed the interference colors on his samples to an oxide of unspecified composition, NbO_x. This

phase has a cubic lattice parameter slightly greater than niobium (NbO_x, $a_o = 3.384$; Nb, $a_o = 3.300$) and is referred to by Hurlen as a suboxide of niobium. It is presumably more metal rich than NbO. Its electrical conductivity and metallic character should therefore be even greater than NbO. Hence, it would appear to be less likely to cause interference colors than NbO, and there is good reason to doubt that NbO could form the transparent films necessary for the occurrence of interference colors.

Hurlen (4) has observed that niobium oxidizes initially at a linear rate, contrary to several other studies in which a parabolic rate has been reported. He believes that this linear rate corresponds to solution of oxygen in the metal without the formation of an oxide film. Both Gulbransen's work in oxygen and the present work in water vapor give initially higher rates than found by Hurlen. A possible explanation for the difference in the shape of the curves and rates may be found in the surface preparation of the various samples. In this study it was found that the initial low-temperature rate was either parabolic or cubic depending on whether the sample was abraded with a blast of Al_2O_3 or polished with emery paper. At 200°C a more profound effect was found: the blast abraded sample failed to oxidize for the first 40 min. Hurlen, on the other hand, did not observe any differences between samples polished with alumina and electropolished specimens.

The absence of diffraction spectra for NbO and NbO_2 at lower temperatures in Hurlen's study is not unambiguous evidence that these phases are not present. The amount of oxide which can be detected by x-ray diffraction depends on a number of factors, among which are (i) crystallinity and crystallite size, (ii) crystal structure, (iii) atomic number of elements present, and (iv) sensitivity of the measuring instrument. Under the most favorable conditions Cu_2O oxide films as thin as 100Å have been detected by x-ray diffractometer (26). Some studies by Blackburn, Weissbart, and Gulbransen (27) on the oxidation of UO_2 indicated that an oxide layer of cubic U_3O_7 less than 600°-800Å thick could not be detected in a powder camera using a fine focus x-ray beam. Taylor (28) has estimated that an oxide film as much as 10^5Å thick may be needed for effective detection with a diffractometer. Thus, the minimum level for detection cannot be stated categorically. It certainly is finite, and failure to detect x-ray spectra cannot be taken as evidence for complete absence of an oxide film.

The difference in the oxidation behavior of niobium in water vapor and oxygen is pertinent to this problem. It has been shown that the protective layer grown in water vapor is as much as 10 times thicker than that grown in oxygen. This of course gives both more oxide material to analyze and larger crystals. These factors may account for the detection of the lower oxides in this study where they were not found in most cases before. Even though the color and the resistivity of samples reacted with less than 80 μg of H_2O indicated the presence of an oxide film, the amount was inadequate for analysis in the present study.

Contrary to what might be expected, the pretransition rates (*i.e.*, before breakaway oxidation) are not a function of the partial oxygen pressure in equilibrium with water vapor and the hydrogen produced by the reaction. Instead, the water vapor rates at 5 cm pressure appear to be similar to oxidation rates of niobium in 5 cm of oxygen. For example, after 100 min at 350°C; Gulbransen's sample gained 45 $\mu g/cm^2$ in 7.6 cm of oxygen; Hurlen's sample gained 16 $\mu g/cm^2$ in 10 cm of oxygen; the sample in this study gained 35 $\mu g/cm^2$ in 5 cm of water vapor. Unfortunately, data were not obtained over a range of water vapor pressures, and it is therefore not possible to compare rates at other pressures.

The oxidation of NbO to NbO_2 may go at a somewhat faster rate in oxygen than in water vapor. In 1 atm of air or about 15 cm of oxygen the rate at 472°C was around 3×10^{-8} g/cm^2 compared to 4×10^{-9} g/cm^2 for 5 cm of water vapor at 500°C. On the other hand, there is a very significant difference between the nucleation and growth of Nb_2O_5 or NbO_2 in oxygen and water vapor. Whereas detection of this reaction begins at 400°C in 15 cm of oxygen, after 100 min a temperature of 900°C is required with 5 cm of water vapor for a similar induction period.

The data from this research indicate that the mechanism of the low-temperature oxidation of niobium is very similar in both oxygen and water vapor. Before the transition to a high linear rate or to breakaway oxidation, the reaction involves solution of oxygen in the metal and formation of NbO and NbO_2 on the surface. Since NbO_2 grows at a linear rate which is less than the total oxidation rate, it must grow at the NbO-NbO_2 interface offering no barrier to the penetration of gaseous oxygen or water to the NbO surface. If this were not the case, of course, the over-all rate would be controlled by the rate of formation of NbO_2. The cubic or parabolic rate which accounts for the bulk of the low-temperature oxidation involves solution of oxygen by diffusion in the metal and possibly diffusion controlled formation of NbO simultaneously. From the available data it is not possible to tell much about the mechanism for NbO formation since it cannot be separated from the solution of oxygen in the metal. One method which has not been tried to determine the method of NbO formation would be the use of oxygen-saturated niobium as kinetic specimens. If these are oxidized below the temperature at which the pentoxide forms, both NbO and NbO_2 would appear. Subtracting the rate of conversion of NbO to NbO_2 from the total curve would leave the curve for NbO formation.

The mechanism for the breakaway oxidation in both water vapor and oxygen is the nucleation and growth of Nb_2O_5 on NbO_2. By contact resistance measurements, by oxidation of NbO and NbO_2, and by x-ray data it has been shown that NbO_2 is present before the Nb_2O_5 phase appears. The oxidation of NbO_2 to Nb_2O_5 has been shown to occur by nucleation and growth where the induction period agrees favorably with the time elapsed before breakaway oxidation of the metal begins. The principal difference between the water vapor and oxygen reaction with niobium is the much slower nucleation and growth

rate of Nb_2O_5 in water vapor. The result is that protective oxidation proceeds for a longer time at higher temperatures in water vapor.

Conclusions

Niobium reacts in water vapor at low temperatures forming NbO and NbO_2 as well as dissolving oxygen in the metal. That NbO and NbO_2 form in oxygen before Nb_2O_5 may be inferred from (i) contact resistance measurements on an oxygen reacted sample, (ii) interference colors arising most likely from an NbO_2 film, (iii) pretransition films observed microscopically by Cathcart *et al* (2), (iv) induction periods for Nb_2O_5 formation on NbO_2 in good agreement with the time elapsed before breakaway oxidation of the metal, and (v) over-all kinetics quite similar in both oxygen and water vapor. The NbO_2 grows as a porous film on NbO. The solution of oxygen occurs by a diffusion process. The mechanism of NbO growth has not been established although it is suspected that it may also grow by diffusion.

At higher temperatures and after decreasing induction periods, breakaway oxidation occurs by the nucleation and growth of Nb_2O_5 on NbO_2. The over-all rate becomes linear after the pentoxide has grown part way through the protective NbO layer. The rate is controlled by conversion of NbO or NbO_2 to Nb_2O_5. Since the rate of growth for Nb_2O_5 is greater than that for NbO_2, the latter phase should eventually be completely consumed.

Acknowledgment

The author is very grateful to H. A. Johansen for preparing the NbO and NbO_2 samples.

Manuscript received Nov. 6, 1961. Much of the material discussed in this paper was presented before the American Chemical Society Meeting in Boston, April 1959. This study was supported in part by the United States Air Force through a contract with the Wright Air Development Center of the Air Research and Development Command.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Some Factors Controlling Gross Leakage Currents in Sputtered Tantalum-Film Capacitors

N. W. Silcox and L. I. Maissel

Components Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Methods for producing sputtered tantalum-film capacitors are described. The breakdown voltage of such capacitors is shown to depend on the type of metal used for the counterelectrode and on the counterelectrode area. This dependency is explained as being due to microfissures (in the oxide), which some metals are more likely to enter than others. Electron micrographs of these fissures are shown. The origin of the microfissures is thought to be lattice mismatch between oxide and metal in those regions where the original tantalum was not sufficiently smooth. It is suggested that anodizing these films in hot solutions will establish a thermal mismatch between metal and oxide, which will partly compensate for the lattice mismatch.

As is well-known in the industry, and as first shown by Berry and Sloan (1) in 1959, excellent capacitors can be made by the anodization of sputtered (or evaporated) tantalum films. These units, unlike capacitors made of sintered or bulk tantalum, exhibit breakdown characteristics that are largely independent of the sign of the applied voltage. The counterelectrodes are applied by vacuum evaporation, but very few metals have proved suitable in this connection. In fact, only gold has been regarded as really satisfactory, although good results have occasionally been reported with other metals, such as aluminum. It has also been widely observed that sputtered counterelectrodes generally yield lower performance than do evaporated counterelectrodes.

Experimental

The tantalum films used in these investigations were all deposited by cathodic sputtering. Films were deposited in an argon glow discharge (3000v at 1 ma/cm^2) at a pressure of 60μ onto microscope slides at the rate of about 10 Å/sec, generally for about 15 min, resulting in sheet resistivities of about 4 ohms/square.

Films were usually anodized to a formation voltage of 100v. A number of anodizing baths, all aqueous, were used in the early stages of the investigation, but no systematic differences were found among the resulting oxide films. For convenience, therefore, a standard bath consisting of a 1% Na_2SO_4 aqueous solution was later adopted. In general, anodization was carried out at room temperature, again for convenience. However, several anodizations in hot solution were also performed, primarily to see if the tantalum-oxide film would recrystallize. No such recrystallization was observed.

Nature of the counterelectrode.—As mentioned earlier, counterelectrodes of evaporated gold generally give better results than electrodes of other metals such as nickel, copper, chromium, etc., which would normally be preferred because of their better adhesion, both to the oxide itself and to the glass substrate. This investigation shows that this superiority of gold is due to the structure of gold films rather than to such things as metal-to-oxide work function, preferential alloying with impurities in the oxide, etc.

Langmuir (2) showed that atoms from a metal vapor condensing onto a substrate do not, in general, remain at the exact location at which they land; instead, they move over the surface with a finite mobility which is a function of, among other things, the substrate temperature. These mobile metal atoms have a limited lifetime on the substrate surface, after which they will return to the vapor phase. If, however, a metal atom meets up with another of its own species during its brief lifetime on the surface, the atom-pair that is formed has both a very much greater probability of remaining on the substrate and a much lower surface mobility. Thus, unless the deposition rate is very high and/or the substrate temperature very low, the film will not grow as a continuous sheet but as a series of discrete globules (nucleated by the original atom-pairs just mentioned) which eventually touch, after which the film grows "normally." Films of this sort, therefore, are in true contact with the surface in only a very limited number of places. On many substrates, gold films are known to be an extreme case of this.

This tendency toward the formation of an agglomerated film is usually determined by two factors, the free energy of formation of the metal oxide and the melting point of the metal. The larger the former and the higher the latter, the more continuous will be the film deposited under a given set of conditions.

If the anodic oxide film contains a number of relatively widely spaced cracks or microfissures, the probability of a gold film penetrating one or more of these fissures will be a great deal less than the probability of penetration by a high-melting-point metal having a large free energy of oxide formation, such as chromium or tantalum. This behavior, which is somewhat analogous to the phe-

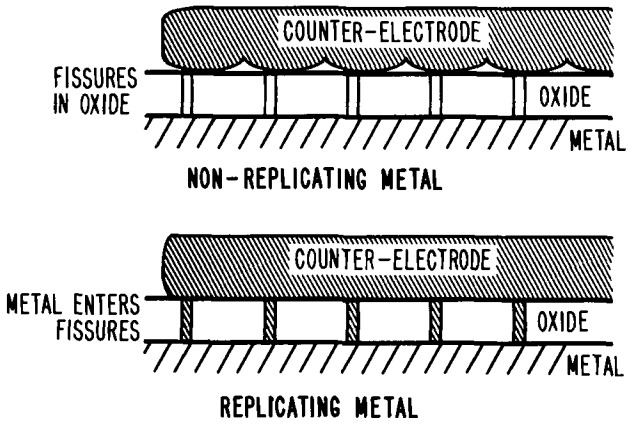

Fig. 1. Tendency for high-mobility (non replicating) metal to stay out of microfissures.

nomenon of liquids keeping out of the capillaries of a porous material that they do not wet, is illustrated diagramatically in Fig. 1.

If this notion is correct, we would expect to find that other metals that tend to agglomerate when deposited would also make good counterelectrodes. Note that this tendency to agglomerate also makes for poor adhesion, so that one would not normally have occasion to investigate these metals as possible counterelectrodes.

In addition, if (as postulated) occurrence of these cracks is relatively rare, the probability of any particular metal penetrating a crack should be a function of the counterelectrode area.

Results

Two criteria have been used for the evaluation of various metals as counterelectrodes. The first is the breakdown voltage, expressed as a percentage of the forming voltage and measured in the anodic direction (tantalum electrode positive). We define breakdown as occurring when the leakage current through the capacitor exceeds 1 ma/cm^2. The second criterion that we have used is the yield of capacitors. For this purpose, the leakage current is measured at 5% of the forming voltage, and units showing leakage currents in excess of 10 ma/cm^2 are defined as "shorts." In practice, leakage currents were found to be either very high or in the vicinity of 10^{-3} amp/cm^2.

Table I shows the range of breakdown voltages observed for a number of counterelectrode materials on tantalum oxide films formed to 100v. Occasional shorts occurred, and these have not been included. Results are given for large- and small-area electrodes. At least 100 capacitors were made of each metal.

The breakdown in the cathodic direction (tantalum electrode negative) was not systematically measured, but was periodically spot-checked. It was consistently found to be between 60 and 80% of the anodic breakdown voltage.

Several interesting facts may be seen in Table I. Perhaps the most noticeable are the much higher breakdown voltages measured for the small-area than for the large-area counterelectrodes in the case of low-mobility metals such as copper, chromium,

Table I. Breakdown voltages of anodized tantalum film capacitors for various counterelectrode materials

Metal	Per cent formation voltage Small electrodes, area, 1 × 10^{-3} cm^2	Large electrodes, area, 200 × 10^{-3} cm^2
Gold	95-98	80-90
Cadmium	95-98	60-65
Lead	80-95	45-55
Zinc	75-90	40-50
Tin	70-75	55-60

Nickel	70-85	<0.1
Copper	80-90	<0.1
Chromium	60-75	<0.1
Aluminum	50-70	<0.1
Tantalum, sputtered	0-15	<0.1
Gold, sputtered	70-80	<0.1

etc., contrasted with the more nearly equal voltages measured for each electrode area in the case of high-mobility metals such as gold, cadmium, tin, etc. Gold, in particular, has breakdown voltages that are practically independent of electrode area. Although not shown in the table, on one occasion a cadmium unit was observed to have a breakdown voltage of 102% of the forming voltage. This is possible as a consequence of our definition of breakdown; *viz.*, the voltage at which the leakage current is 10^{-3} amp/cm^2. At the termination of anodization, the residual current is in the vicinity of 2 to 3 x 10^{-6} amp/cm^2; hence subsequent application of higher current density at the same temperature results in a greater voltage drop across the dielectric.

The two sets of electrodes deposited by means of sputtering also have the poorest characteristics. Two factors are believed to be responsible for this. First, other things being equal, sputtered thin films are known to be considerably more continuous than evaporated ones. This was shown by Ditchburn (3) and is evidenced, for example, by the better adhesion to glass of sputtered, as opposed to evaporated, films of copper or gold. The other factor believed responsible for the low quality of sputtered counterelectrodes is the very rapid heating of the substrate that occurs during sputtering. As we shall see presently, this would tend to increase both the size and number of the microfissures.

Table II shows the evaluation of various metals as counterelectrodes using the criterion of percent-

age yield. An electrode area intermediate in size between the two extremes used in Table I was deliberately chosen.

It is apparent from the data given in Table II that electrodes of this size are still too small to discriminate effectively between most counterelectrode materials. However, in two cases, nickel and copper, a significantly low yield was obtained, indicating that these metals are particularly unsuitable for counterelectrodes.

Direct Evidence for the Microfissures

Assuming that at least the widest and deepest of the microfissures should be detectable by electron microscopy, we may estimate from the data in Table II that the largest microfissures, that is, those that represent a complete break in the oxide, are, on the average, 200-300 mils apart. The probability of finding one in a random examination of the oxide surface is therefore quite slight. However, by restricting the electron microscope search to a small region within which one or more fissures are definitely known to be present, this probability may be greatly increased. This was accomplished by examining the oxide underneath a small gold dot which electrical measurements had shown to be a complete short, itself a very rare event. A typical electron micrograph obtained in this manner is shown in Fig. 2.

Origin of the Microfissures

A mechanism for the formation of fissures, such as the one shown in Fig. 2, has been proposed by Young (4). It will be recalled that the ratio of the molar volumes of tantalum pentoxide to tantalum is 2.3. During normal growth of the oxide film on a plane surface, this "lattice mismatch" does not produce any strain since the film is not constrained during its growth; *i.e.*, the ratio of the total thickness of oxide to the depth of the oxide below the metal surface will automatically adjust itself to 2.3. If, however, the surface of the tantalum, prior to anodization, is not perfectly smooth, strain due to lattice mismatch will occur as the oxide forms at a surface irregularity (see Fig. 3). As the oxide grows in thickness, the higher fields at the irregularity cause the oxide to form more rapidly there so that a smooth oxide surface is eventually formed.

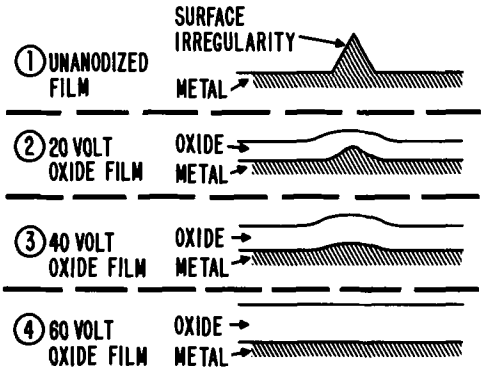

Fig. 3. Effect of anodizing irregular tantalum surface (voltages shown are only approximate).

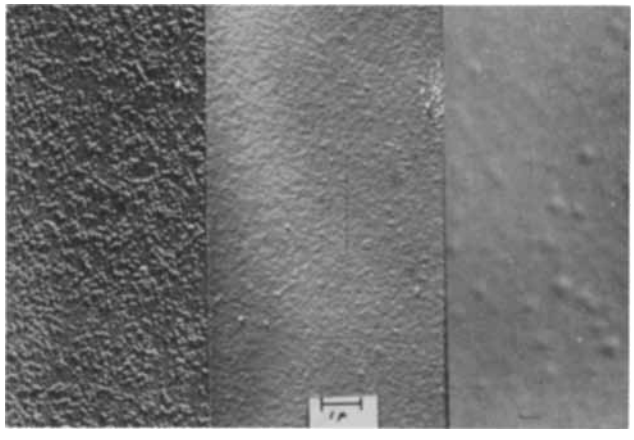

Fig. 4. Smoothing effect of anodization. Left to right, unanodized, as-sputtered film; oxide film formed to 30v; oxide film formed to 100v.

Thus, in the vicinity of the original irregularity, more material than was originally there will have been forced into a given volume, and the oxide in that vicinity will be under tensile stress. This stress can be relieved by cracking. This smoothing effect on an actual oxide surface is illustrated in Fig. 4. From left to right we see an unanodized tantalum-film surface, an oxide surface formed to 30v, and one formed to 100v.

One interesting consequence of this theory of fissure formation is that very thin oxide films should be free of cracks since sufficient strain will not have developed in the oxide to generate them. Experiments confirmed that this was indeed the case; the breakdown voltages of films formed (at room temperature) to 15v or less were no longer a function of the electrode area or of the tendency of the metal to agglomerate.

We believe that the roughness of the metal film cannot be completely eliminated simply by using a sufficiently smooth substrate. This is illustrated in Fig. 5, in which the surface of the tantalum film is compared with that of the clean substrate. Of course, if the substrate surface is itself rough to begin with, we would expect the number of microfissures subsequently occurring in the oxide film to be proportionately greater. The consequences of this, *viz.*, poor quality capacitors on rough substrates, are well-known.

In conclusion, we would like to indicate one method for reducing the incidence of the microfis-

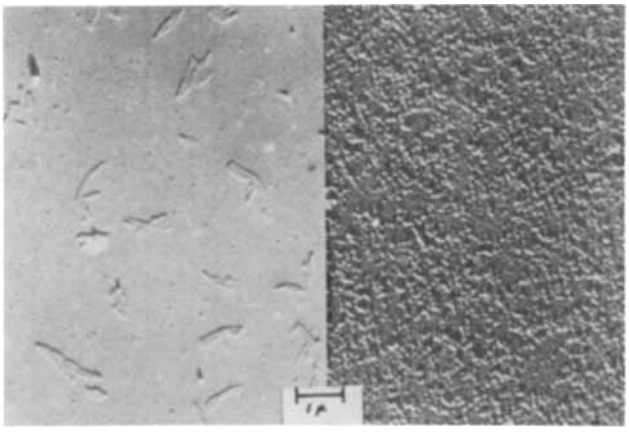

Fig. 5. Comparison of original substrate surface (left) and surface of tantalum film deposited on substrate (right).

sures. In the vicinity of room temperature, the linear coefficients of thermal expansion of tantalum and tantalum pentoxide are, respectively, 64.6 x 10^{-7}/°C and 5.5 x 10^{-7}/°C. If, therefore, the anodic oxide film is formed in a hot solution and then allowed to return to room temperature, it will be under compressive stress, thus relieving the tensile stress in the oxide. The use of solutions at 105°C, as described by Berry (1), is an example of this. Similarly, Ruscetta *et al.* (5) have shown that anodizing in hot solution often leads to superior oxide films. Even higher anodizing temperatures can be and have been achieved through use of pressure bombs. It should also be noted that films formed at room temperature will have their tensile stresses increased still further if subsequently heated. This has already been mentioned as one of the reasons why sputtered counterelectrodes are generally inferior to evaporated ones.

Summary

It has been shown that gross leakage currents in sputtered tantalum-film capacitors are due to the penetration of microfissures or cracks in the oxide film by the counterelectrode material. Some metals, such as gold, cadmium, etc., which do not follow the contours (on an atomic scale) of the surface on which they deposit, are much less likely to enter these microfissures and consequently make better counterelectrodes. The origin of the microfissures is believed to be the microroughness of the as-sputtered (unanodized) tantalum film; this leads to tensile stresses in and eventually cracking of the oxide film. By anodizing in hot solutions, it is possible to create compressive stresses which will partly compensate for this.

Acknowledgments

The authors wish to thank M. H. Whitehill for tantalum sputtering, K. L. Brown and E. E. Pacher for electrical measurements, and D. P. Cameron for the electron micrographs.

Optical Measurements on ZnS:Cu Produced by Neutron Irradiation of ZnS

R. M. Potter, M. Aven,[1] and J. Kastner[2]

Lighting Research and Development Operation, General Electric Company, Cleveland, Ohio

ABSTRACT

ZnS powder, irradiated in a high density thermal neutron flux, was partly converted to radioactive Zn-65, Zn-69, and S-35. These radioisotopes decay to Cu-65, Ga-69, and Cl-35, respectively. One week after removal from the nuclear reactor the sample was fired at 900°C to anneal out radiation damage occurring in the reactor. The brightness and spectral distribution under 3650Å excitation and the diffuse reflectance spectra of the annealed sample were monitored during a period of 600 days. The principal results are interpreted in terms of an increasing concentration of uncompensated copper centers produced by the decay of Zn-65.

The common method of preparing zinc sulfide phosphors is to mix zinc sulfide with the necessary amount of activators and coactivators and to fire the mixture at temperatures above approximately 800°C. When equimolar amounts of activators and coactivators are added one expects a fully compensated material, *i.e.*, one which contains no unpaired electrons. Bowers and Melamed (1) showed, however, that even when activators alone (Cu) or coactivators alone (Cl) are added to zinc sulfide, the material comes out of the firing fully compensated. Evidently it is energetically favorable at the firing temperature to produce physical "self-activator" or "self-coactivator" species in the form of vacancies

[2] Present address: Argonne National Laboratories, Lamont, Ill.

or interstitials which compensate the added chemical coactivators and activators. For this reason there exists very little information about the optical properties of uncompensated zinc sulfide.[3]

The objective of the present work was to prepare uncompensated copper-activated zinc sulfide by introducing the activator through the decay of a radioactive isotope of zinc, Zn*-65, which becomes Cu-65, and to study the optical properties of the material as a function of the concentration of the newly formed Cu-65. This method of introducing copper was also found useful in another connection. In a series of publications Prener and Williams (7-9) have advanced a theory which contends that a definite spacial relationship must exist between activators and coactivators in zinc sulfide phosphors in order for them to function as efficient recombination centers. According to this theory, only activator atoms with a coactivator atom at a second, third, etc., to approximately 10th or 15th nearest neighbor position are active in luminescence recombination. First nearest neighbors are excluded because too great an overlapping of wave functions causes the activator and coactivator levels to recede to within a few hundredths of an electron volt from the valence and conduction bands, respectively. Too distant neighbors are excluded because of insufficient overlap of wave functions which results in a low transition probability.

In phosphors prepared by conventional techniques, the distribution of distances between activators and coactivators is determined by the balance between their mutual coulombic attraction and the thermal randomizing effect. At a relatively high firing temperature, say 1200°C, the thermal agitation is probably strong enough to keep singly charged activators and coactivators randomly distributed. As the phosphor is cooled to room temperature the activators and coactivators start associating due to their mutual attraction. The degree of completion which this process will attain depends on how effectively the necessary diffusion processes can take place. As a result, the phosphor will contain activators and coactivators in a wide variety of associations. It is therefore difficult to verify the concepts of the ion association theory by working with conventional phosphors. The degree of association can be controlled to a certain extent by varying the concentration of activators and coactivators and by using thermal treatments like annealing and quenching. A more effective way to obtain at least one extreme type of association, namely a random distribution, is to introduce either the activator or the coactivator through the process of radioactive decay of one of the base lattice components.

Such a method was used for the first time by Prener and Williams (8). They irradiated a sample of zinc oxide with a flux of neutrons which produced about 50 ppm[4] of Zn*-65. They subsequently converted the zinc oxide to zinc sulfide by firing in hydrogen sulfide mixed with some hydrogen chloride. During the ensuing two years, as the Zn*-65 was decaying to Cu-65, they monitored the green-to-blue luminescence emission ratio of their sample and found that it stayed constant within approximately 10%. From this they concluded that the newly formed copper, appearing at random sites with respect to the chlorine coactivators, did not produce luminescence centers.

In the present work copper was introduced into zinc sulfide also through the radioactive decay of Zn*-65. The preparation of the sample and the optical measurements were, however, different from those carried out by Prener and Williams. It will be evident from the discussion below that this made it possible to obtain new information bearing on the problem of ion association and the position of the level introduced by substitutional copper into zinc sulfide.

Experimental

A 0.12g sample of luminescence grade zinc sulfide was fired at 900°C in purified hydrogen sulfide. It contained ~2 ppm copper, ~2 ppm combined iron, cobalt, and nickel, and a very small concentration of halogens. It showed practically no luminescence response under 3650Å excitation at room temperature. The sample was placed in a spectroscopically pure graphite crucible which was inserted into a quartz tube. Hydrogen sulfide was passed through the quartz tube for 1 hr at 1000°C, and the tube was sealed off while hot. The sealed sample was then irradiated for 15 days at the Idaho Falls Materials Testing Reactor. About four days after removal from the pile, the sample was refired for 3 hr at 900°C, removed from the graphite crucible, and placed in a brass sample container provided with a "nonbrowning"[5] quartz window. The sample container could be attached to a slide which fit into a track fastened to the spectrometer used for optical measurements. The sample was removed from the brass container 326 days after the firing and divided between two quartz capillaries. One was used for the annealing experiments to be described later, and the other was used for the continuation of the luminescence response versus time measurements.

Optical measurements were performed with a Perkin-Elmer Model 99 Spectrophotometer. As the experiment was originally conceived, it was desired to measure the ratio of the luminescence emission in the green to that in the blue band as a function of time. To obviate measuring the complete spectrum each time, most luminescence intensity measurements were made only at two energies: in the blue at 2.82 ev and in the green at 2.44 ev. The actual peak intensities of the resolved bands were calculated from these data by a formula derived from comparing complete resolved[6] emission spectra measured initially and at 235 days with simultaneously taken intensity measurements at 2.82 ev and 2.44 ev. Complete spectra were also obtained at 378, 413, and 604 days.

[3] Since this experiment was started a number of publications have appeared in literature describing optical properties of materials which probably contain uncoactivated copper (2-7).

[4] Throughout this paper ppm (parts per million) will signify atom fraction × 10^6.

[5] Supplied by W. A. Graff of Glass Technology Laboratory, General Electric Lamp Glass Department, Cleveland, Ohio, this quartz was designed to show minimal discoloration under high energy irradiation.

[6] See section: Fluorescence Spectra.

In order to assure approximately constant excitation intensity the ultraviolet source (an AH4 mercury lamp mounted in a microscope illuminator housing, with a 7-37 Corning filter) was calibrated before each run. This was accomplished by precisely reproducing the settings of the photomultiplier voltage, spectrometer slits and wavelength (3650Å), and amplifier gain. The intensity of the source was then adjusted so as always to obtain the same recorder deflection when the 3650Å was diffusely reflected from a placque of powdered magnesium carbonate mounted on the same slide as the radioactive sample. To afford a further check, the brightness of a standard green ZnS:Cu,Al phosphor held in a brass container identical with the one holding the radioactive sample was measured before each reading of the response of the radioactive sample. Due to these precautions it is believed that the green luminescence intensities obtained during the first 326 days are precise to ±1%. The reproduction of these conditions was considerably more difficult after the sample was transferred to the quartz capillary. Therefore the accuracy of the measurements at times longer than 326 days was approximately ±5%. The 3650Å excitation intensity during all luminescence measurements was of the order of 5×10^{13} photons/cm² sec.

Diffuse reflectance spectra were obtained by dividing the reflectance of the sample by the reflectance of the standard at each spectral energy. Magnesium oxide was used as standard in the visible and ZnS:Cu,Al phosphor in the infrared.

Nuclear Reactions

When a compound such as zinc sulfide is placed in a nuclear reactor and irradiated with slow and fast neutrons, gamma rays, etc., certain reactions take place, introducing several types of defects. As noted above, the sample of zinc sulfide powder was refired after neutron irradiation, for 3 hr at 900°C. As Smith and Turkevich (10) were able to repair neutron damage to zinc sulfide by heating for only a few minutes at 900°C, it can be safely assumed that all the annealable damage, *e.g.*, displaced atoms, existing in the present sample after irradiation, was repaired by this annealing. The only nuclear reactions to be considered therefore are those which occur or contribute to effects in the period since the firing.

Of the postfiring defects, those of major interest are impurity atoms and displaced atoms. The creation of impurity atoms as a result of radioactive decay of such nuclides as Zn*-65, S*-35, etc., is the basis of the whole experiment. Displaced atoms are produced when a nucleus ejects mass and/or electromagnetic radiation and the recoil energy is sufficient to cause permanent displacement. Thus a very pertinent question is whether, for example, the impurity daughter atom, Cu-65, ends up in an interstitial or in a substitutional position. This problem will be discussed later. The identities, the abundance, and the decay rates of the produced isotopes will be detailed below.

The zinc sulfide sample used in this study was irradiated for 15 days in a position where the thermal neutron flux was 1.3×10^{14} (±20%) neutrons per cm² sec associated with a fast neutron flux of about 1.5×10^{13} neutrons/cm² sec. After capturing a neutron the target nucleus forms a different atomic species which in turn transforms to new products by radioactive decay. The rates of formation of these new products and the resultant concentration of new elements can be calculated from the well-known laws of radioactive decay. This was done for the present sample of zinc sulfide which was composed of several isotopes of zinc and sulfur each with known relative abundances. Each of these isotopes can absorb neutrons to a certain degree, with resonance absorption occurring for neutrons of a particular energy. The most important nuclear reactions from the point of view of the described experiment are those involving the transmutations listed in Table I.

Table I. Neutron reactions with zinc sulfide

Target, % abundance	Product nuclide	Half-life	Daughter
Zn-64 (49%)	→ Zn*-65	245 days	Cu-65
	→ Cu*-64	12.8 hours	Ni-64
Zn-68 (19%)	→ Zn*-69	14 hours	Ga-69
S-32 (95%)	→ P*-32	14.3 days	S-32
S-33 (0.8%)	→ P*-33	24.4 days	S-33
S-34 (4.2%)	→ S*-35	87.1 days	Cl-35

Of the radioisotopes listed in Table I, Cu*-64, P*-32, and P*-33 are present in sufficiently low concentrations, ~0.6 ppm, ~1 ppm, and ~0.01 ppm, respectively, to be neglected. The fate of the remaining radioisotopes, Zn*-65, Zn*-69, and S*-35, is summarized in the chart in Fig. 1, which also illustrates the complete course of the experiment.

As shown, the irradiation produced approximately 49 ppm Zn*-65, 37 ppm Zn*-69, and 2 ppm S*-35. While in the reactor and on the way from the reactor to this laboratory all the 37 ppm of Zn*-69 had decayed to Ga-69, and 2 ppm of Zn*-65 had decayed to Cu-65. In the ensuing firing process the 2 ppm of Cu-65 presumably was coactivated by an equivalent amount of Ga-69 and formed 2 ppm of "ordinary" green copper centers. The remaining 35 ppm of Ga-69 formed self-activated blue centers ($V_{Zn}Ga^-$ . . Ga^+),[7] in a concentration corresponding to its (unknown) equilibrium solubility at or near the firing temperature, the excess diffusing out of the zinc sulfide lattice.

The last box in the chart shows the census after a 600-day decay period. Practically all S*-35 had then decayed to Cl-35, and 39 additional ppm of Zn*-65 had decayed to Cu-65. Since chlorine acts as a donor in zinc sulfide, and copper as an acceptor, 2 ppm of the copper formed in this period will accept electrons from the 2 ppm of newly formed chlorine, leaving 37 ppm of copper acceptor states empty. The effect of these transmutations on the optical properties of the sample will be described below.

Fluorescence Spectra

The room temperature emission spectra of the sample under 3650Å excitation shortly after the

[7] The self-activated blue center will be represented by the model proposed by Prener and Weil (11), *i.e.*, $(V_{Zn}Ga)^-$ . . Ga^+. This model indicates that the activator is a zinc vacancy in close association with a gallium, and the coactivator is another gallium two or more lattice distances apart.

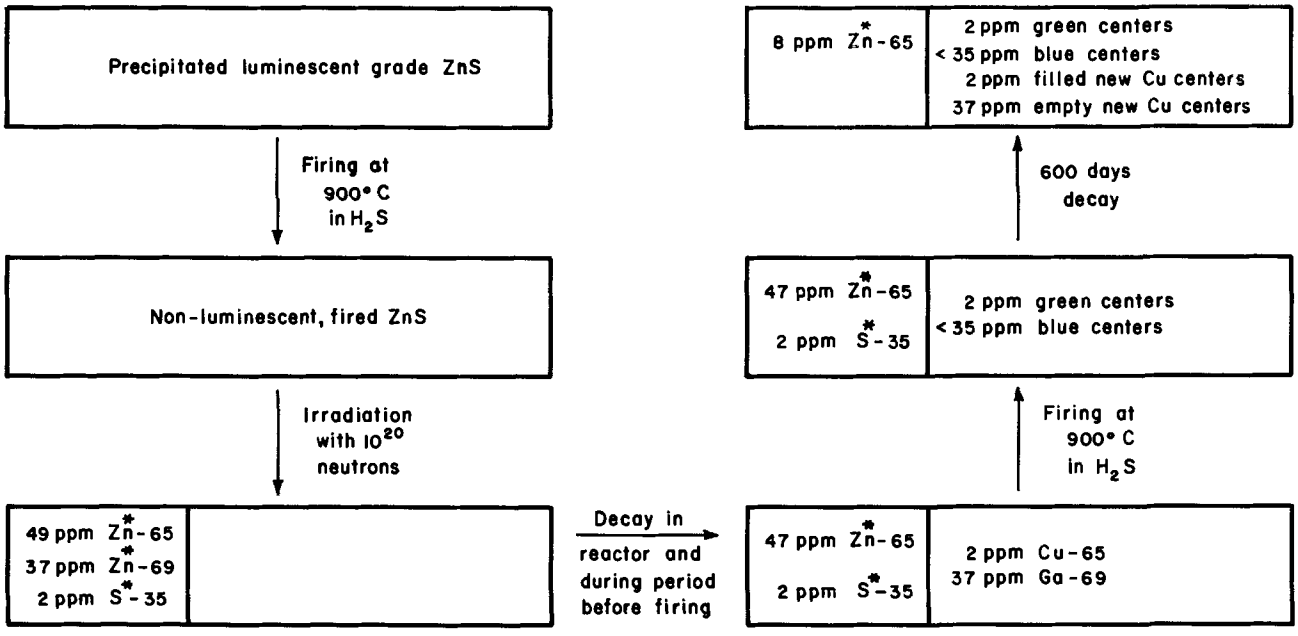

Fig. 1. Sequence of operations in preparing radioactivated zinc sulfide (the radioactive species appear in the left-hand side of the divided boxes).

900°C annealing and at 378 days are shown in Fig. 2 and 3, respectively. These spectra, plotted as energy emitted per unit photon energy interval, were resolved into three approximately Gaussian subbands peaking at 2.72 ev, 2.36 ev, and about 2.06 ev. The first two bands are identified as the "self-activated" blue band, due to zinc vacancies promoted by gallium, and the "copper green" band. The yellow band is probably identical with the one described by Apple and Williams (12) as due to copper-gallium associated pairs.

The green-to-blue ratio, expressed in terms of photons corresponding to the resolved green and blue bands, is plotted in Fig. 4. The ratio increased by a factor of two in the first 180 days and thereafter decreased asymptotically to about 60% of the initial value. The figure also shows the trend of behavior of the green-to-yellow and yellow-to-blue photon emission ratios. The dashed parts of the curves is an interpolation between the initial and the 235 day points.

The dependence of the ratio of emission in the green to that in the blue on intensity of 3650Å excitation was measured initially and at 182 days. The results are shown in Fig. 5. It can be seen that initially the green-to-blue ratio of the radioactive

sample showed a fairly strong dependence on the excitation intensity; at 182 days, however, the green-to-blue ratio was almost independent of the excitation intensity.

The green luminescence brightness of the sample increased slightly initially and thereafter decreased exponentially without limit. Figure 6 shows a semilog plot of the relative intensity at 2.44 ev as a function of time.

Diffuse Reflectance and Infrared Fluorescence

The diffuse reflectance spectrum of the sample was measured at 305 days. In Fig. 7 the spectrum of the sample is shown along with that of a control sample containing about the same concentration of impurities as the radioactive sample did initially. Two absorption bands are present, a broad one extending from about 1.2 ev to the zinc sulfide fundamental absorption edge and a narrow one peaking at 0.95 ev. Diffuse reflectance readings at 3.13 ev and 3.42 ev were taken at 16 days, and at 3.42 ev at 182 days. These readings in conjunction with the complete diffuse reflectance spectra of the control and of the radioactive sample at 305 days show that the strength of the absorption band extending from 1.2 ev to the fundamental absorption edge increased with increasing concentration of Cu-65.

It was possible to detect infrared fluorescence in the sample by exciting with visible or near infrared light. The fluorescence appeared to peak in the energy range found by Browne (2) in zinc sulfide which had been fired in sulfur vapor and which presumably contained uncoactivated copper, and by Halsted *et al.* (4) and Potter and Aven (5) for ZnS:Cu fired in sulfur vapor to promote incorporation of copper without coactivation.

Annealing Experiments

It was suspected that part of the Cu-65 produced by decay of Zn*-65 might be ejected into interstitial sites because of the 10-16 ev recoil energy of the nuclear reaction. Two experiments designed to give evidence of displaced copper were carried out. In the first experiment (performed at 326 days) part of the sample was placed in a quartz tube, and annealed at 200°C. The fluorescence in the blue and green (2.82 ev and 2.44 ev) was measured after each heating period. The intensity in both the blue and green bands increased with annealing, but the blue showed a greater increase, which led to a decrease in the green-to-blue ratio. A similar annealing experiment was done on the same sample at 413 days. Again both the green and the blue luminescence intensity increased after annealing and the green-to-blue ratio decreased. In a series of control experiments it was found that copper could diffuse into a ZnS:Ga powder phosphor (*i.e.*, one containing zinc vacancies) in 5 hr at 200°C, and change the luminescence response from blue to green. At this temperature, the copper probably diffuses by an interstitial mechanism. There was no change, however, in the luminescence response of a green-emitting ZnS:Cu,Ga phosphor (which presumably had all copper and gallium in substitutional sites) when it was annealed at 200°C for the same period of time.

In the second experiment, a sample of neutron-irradiated zinc sulfide was obtained from Dr. J. S. Prener which had decayed for about 4 years. The diffuse reflectance spectrum of this sample was measured before and after a 5-hr annealing at 200°C. The spectrum was qualitatively similar to that obtained on the present sample (see Fig. 1) and showed no significant change after annealing.

Discussion

The purpose of this work was (i) to prepare and measure certain optical properties of zinc sulfide containing "uncoactivated" substitutional copper;

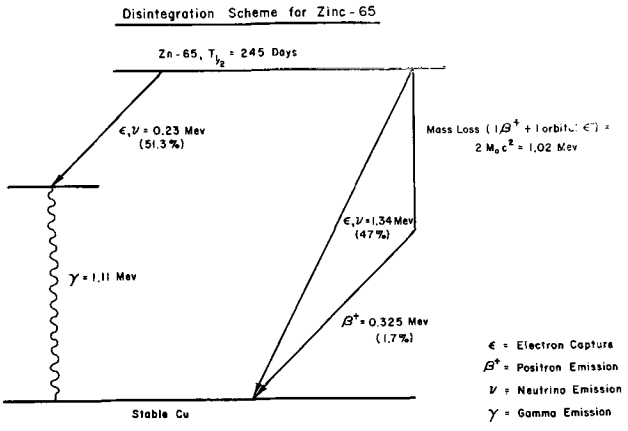

Fig. 8. Disintegration scheme of Zn-65

and (ii) to obtain evidence on the question of whether copper green centers must have coactivators associated with them in order to be luminescence-active. The first purpose was largely accomplished. The evidence obtained from the experiment, however, does not allow an unambiguous answer to the question in the second purpose.

For the first purpose, it was necessary to show that most of the Cu-65 produced by decay of Zn*-65 remained in substitutional sites and that the properties measured were due to this majority of the copper, and not to the minority which was ejected into metastable sites.

Zn*-65 has a rather complex decay scheme as shown in Fig. 8. Forty-seven per cent of the disintegrations occur by pure electron capture where the complete excess energy is removed by the ejection of a neutrino. The recoil energy may be computed to a good approximation by treating the neutrino as a photon (13). Thus the recoil energy is given by

$$E_r = E^2/2Mc^2 = 15 \text{ ev}$$

Similarly, for the 51.3% of the disintegrations giving rise to the 1.1 Mev gamma ray, the important recoil energy is approximately 10 ev.

To evaluate the recoil energy for the positron emission the relativistic relation should be used (14).

$$E_r = E(E + 2mc^2)/2Mc^2$$

For $E = 0.325$ Mev this yields only about 3.5 ev.

Whether any of these recoil energy values are sufficient to cause displacement will depend on the threshold energy for such a process, E_d. This parameter has been studied theoretically and experimentally for a number of materials (15). Unfortunately, there are few specific references to zinc sulfide, and so one can only make a reasonable estimate based on materials of similar structure. Seitz and Koehler (16) derived the value of $E_d = 25$ ev for tightly bound solids on theoretical grounds. This value is borne out in the case of germanium as most of the experiments yielded displacement energies of about 30 ev (17, 18) although special types of displacements requiring lower energies could be produced with a small probability (19, 20). Kohn (21) calculated a value for germanium of $E_d = 10$ ev, but suggests that the interstitials arising this way would be very unstable and would recombine spontaneously. This type of recombination probably accounts for the annealing which is stated to occur at room temperature (22).

It is admittedly difficult to extrapolate from germanium to zinc sulfide. There is a clue, fortunately, in a report by Czyzak *et al.* (23) on a radiation damage study of single crystals of zinc sulfide, cadmium sulfide, germanium, and silicon. They used a 2 Mev electron beam of about 1 μa and could observe no significant damage in either cadmium or zinc sulfide whereas the germanium and silicon crystals were badly damaged. The average energy transferred to a zinc or germanium atom struck by a 2 Mev electron is of the order of 100 ev, and thus one would expect that the germanium would be damaged. On the other hand, the implication from these data is that the threshold energy for displacement of zinc in zinc sulfide is greater than 100 ev, and therefore neither the emitted gamma-ray nor the neutrino should displace the nucleus by recoil. Experiments have been carried out in this laboratory in which zinc sulfide single crystals have been irradiated with beta-rays of a maximum energy of 2 Mev with no significant changes in the transmission spectrum.

There is one piece of information which seems to be in disagreement with these observations. The United States Radium Corporation reports (24), without amplification, that cadmium sulfide is damaged by electrons of energy greater than 0.23 Mev. As no details are available one must explain the discrepancy by assuming either that the U.S.R.C. method of observing radiation damage was much more sensitive or that the much greater specific ionization of 0.23 Mev electrons compared to the more penetrating 2 Mev electrons can account for the difference in results. The possibility of displacement by electronic excitation can be eliminated in the case of the emission of a gamma ray or a neutrino because the latter are not charged particles. The threshold energy in cadmium sulfide corresponding to 0.23 Mev electrons is about 19 ev. Thus if one assumes that sulfur displacement would show up as radiation damage and extrapolates to zinc sulfide (by considering E_d to be roughly proportional to the heat of formation) one arrives at a value for displacement of sulfur in zinc sulfide of about 27 ev. This is still greater than the maximum recoil energy for any disintegration of Zn*-65.

On the basis of the evidence available at present, therefore, it is likely that the majority of the copper atoms resulting from decay of Zn*-65 in ZnS will remain in substitutional positions.

A similar conclusion can be reached by analyzing the changes in optical properties of the present as well as the Prener-Williams sample during annealing. The change in the green-to-blue ratio of the radioactive sample during annealing at 200°C is definitely suggestive of rearrangements involving interstitial migration, as this temperature is too low for appreciable substitutional or vacancy diffusion. The conclusion is supported by the control experiments mentioned earlier. The 900°C firing after neu-

tron irradiation should have stabilized the phosphor structure with respect to imperfections then present, so that initially the sample should not have contained any metastable interstitials. Therefore, it follows that the interstitials must have been formed during the ensuing radioactive decay of Zn*-65. As this isotope is a part of the zinc sulfide base lattice, the Cu-65 formed from it must also be substitutional, unless it is ejected by recoil. Hence one is forced to conclude that at least a part of the Zn*-65 was ejected from its substitutional position while decaying to Cu-65. It is likely that the interstitial copper exists as Cu_i^+, the compensating negative charge residing on the lattice position from which it was ejected. Such Cu_i^+ would be coulombically attracted to any negative charges present in the crystal. Besides the lattice position from which the Cu_i^+ was ejected, such negative charges are located on initially present coactivated (substitutional) copper centers and on gallium-coactivated zinc vacancies (created during the firing). It is impossible to be certain to which of these sites the Cu_i^+ was migrating. Because of this uncertainty and because of the complicated nature of the equilibrium involved, the blue-to-green ratio changes cannot be used for a quantitative estimate of the fraction of ejected copper.

However, one can obtain a rough estimate of the maximum fraction of ejected Cu-65 from the annealing experiment performed on the Prener-Williams sample. It will be recalled that, within experimental error, no change in the strength of the absorption bands was detected. The probable error in this measurement was 0-3%. Using the approximate expression $n \propto (1-R)^2/R$ for the relation between the diffuse reflectance R and the number of absorbing centers n, gives 0 to 0.23 as the fraction of ejected Cu-65 which could go undetected due to experimental uncertainty. It should be noted that whatever the true value for the fraction of ejected copper, it is clear from the constancy of diffuse reflectance that the copper remaining in substitutional sites was responsible for the observed absorption.

Diffuse Reflectance Spectrum

The significant conclusion of the preceding section was that the appearance of uncoactivated substitutional copper at the Zn sites was accompanied by the appearance of absorption bands in the diffuse reflectance spectrum. The same absorption bands have also been found in conventionally prepared zinc and cadmium sulfide by many workers (25-29) as stimulation or quenching bands in measurements of fluorescence or photoconductivity. In these cases, simultaneous or previous excitation with light of energy near that necessary to excite across the band gap was necessary. These bands have also been found in ZnS:Cu relatively free of coactivator in infrared excitation (2) and in photoconduction (3) without simultaneous or previous excitation of higher energy. Some of these workers ascribed these bands to electron transitions to the conduction band (25, 29) and some to hole transitions to the valence band (2, 3, 26-28). In the present work, the latter explanation is strongly supported.

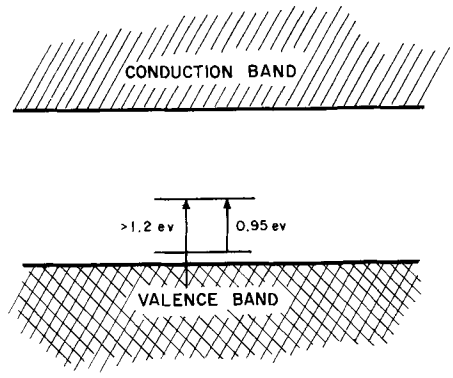

Fig. 9. Energy level diagram for copper in zinc sulfide

In the first place, because the same bands are found in conventionally prepared ZnS:Cu and in the radioactivated ZnS:Cu, it can be concluded that the copper is the same environment in both cases. Since in this work it has been shown that the copper responsible for the absorption bands in radioactivated ZnS:Cu is substitutional, copper must also be at substitutional sites in conventionally prepared ZnS:Cu.

The transitions responsible for the absorption bands are indicated in Fig. 9. According to this model, in the radioactivated sample, the absorption in the broad band corresponds to exciting an electron from the valence band into an empty level about 1.2 ev[8] above the valence band. The 0.95 ev band is ascribed to excitation of an electron from a state about 0.25 ev from the top of the valence band into the empty level. This assignment is based on the observation that infrared quenching or stimulation in fully coactivated phosphors takes place at room temperature by absorption of light in this band. At lower temperatures, where the hole ionization from the lower level into the valence band is negligible, only absorption in the broad band is effective (27).

In conventionally prepared, coactivated phosphors, four models are possible to account for the broad stimulation or quenching band: a discrete level about 1.2 ev above the valence band or 1.2 ev below the conduction band, with or without an electron in it. The models involving an empty level near the valence band or a filled level near the conduction band can be ruled out because, for these models, absorption would be observed in the broad band without simultaneous short wavelength excitation. The choice between the remaining two models is made on the following basis: If the model with a filled level near the valence band is correct for fully coactivated ZnS:Cu, then in radioactivated (uncoactivated) ZnS:Cu, with one less electron available for each copper, the level would be empty, and the observed absorption is readily understood. If the model with an empty level near the conduction band (for fully coactivated ZnS:Cu) is correct, it is difficult to understand how in the radioactivated ZnS:Cu, with one less electron for each copper, this level could have been filled by an electron. Thus the location of

[8] 1.2 ev is the approximate minimum energy for this transition at room temperature. This figure is used because the absorption band does not show a clear maximum. Quenching and stimulation spectra show a maximum at about 1.65 ev.

the level about 1.2 ev from the top of the valence band can be made without any other supporting evidence, such as electrical measurements demonstrating hole conduction (5, 30).

Kinetics of Luminescence

The second purpose of this work, to obtain evidence on the question of whether copper green centers must have associated coactivators in order to be luminescence-active, was not fulfilled unambiguously. The experimental results pertaining to this aspect are that: (i) the over-all brightness, after a brief rise, decayed exponentially without limit, (ii) the green-to-blue and probably green-to-yellow ratio went through a maximum and then tended asymptotically to a value below the initial values, and (iii) the green-to-blue ratio, initially sensitive to excitation intensity, became independent of it later.

The first result can be partially explained by (*a*) the increasing absorption of 3650Å exciting light and fluorescence emission in the broad absorption band due to uncompensated copper and (*b*) possible killer center formation associated with migration of ejected copper.

Result (iii) can be understood as a change from the kinetics of a compensated phosphor to a p-type phosphor. The initial dependence of green-to-blue ratio on excitation intensity is predicted by the Schön-Klasens (31, 32) model for compensated phosphors. As the concentration of uncompensated copper increases, the rate of thermal ionization of holes from copper centers increases and eventually exceeds the excitation intensity. The distribution of holes between green and blue centers (and therefore the green-to-blue ratio) is then determined by thermal equilibrium and is independent of excitation intensity.

It should be possible to explain result (ii) by setting up a number of models for the steady-state kinetics of luminescence. Unfortunately, any realistic model would have to be rather complicated because of the presence of three emitting states and probably a killer state. Also the 3650Å exciting light can be absorbed strongly at both filled and unfilled Cu centers.

An attempt was made to fit the observed data on blue-to-green ratio with two models which considered only blue and green emitting states and a single trapping level. In the first model, it was assumed that all substitutional Cu centers were active in luminescence recombination; in the second, that only Cu centers with coactivator centers within a certain distance were active. It turned out that neither model could be made to fit the data with reasonable assumptions for the kinetic constants, but the second model looked more promising than the first. It is felt that this slightly better agreement of the experimental data with the associated center model is not sufficiently clear-cut to be regarded as evidence in favor of one model or the other. In the opinion of the authors, further work on kinetic models is not justified by the present experimental data.

Comparison to the Prener-Williams Experiment

It was mentioned in the preceding text that Prener and Williams (8) had performed an experiment which also involved the decay of Zn^*-65 to Cu-65 in zinc sulfide. They employed a different preparative technique, and their results were different in some respects. The green-to-blue ratio *vs.* time relationship of their sample exhibited no initial strong increase and no subsequent drop. The fluorescent spectrum after approximately four years of decay was very nearly identical with the initial spectrum. The luminescence brightness-time relationship of the sample was not measured, which makes it impossible to compare this feature of the two experiments. However, diffuse reflectance measurements on the Prener-Williams sample (which they kindly made available to us) revealed the presence of the same absorption bands as found in our sample.

Visual inspection under ultraviolet light of the Prener-Williams sample showed bright green particles scattered throughout a nonluminous background (the sample was thoroughly mixed in the course of transfer from the original container to the quartz tube used for examination). A rough particle count under the microscope indicated that the green particles comprised about 2-3% of the total. On the basis of this observation it is suggested that the Prener-Williams sample was not homogeneous, but consisted of two different kinds of materials. The bulk, which after four years of decay became practically nonluminescent, corresponds closely to this laboratory's sample. The latter exhibited an approximately tenfold decrease in brightness in one year. Based on the logarithmic relationship between brightness and time, four years of decay should then have reduced the brightness of the Prener-Williams sample to approximately 10^{-4} of the initial, accounting for the experimentally observed practically nonluminescent appearance of the bulk of their sample. By the same reasoning, since the loss of brightness was interpreted at least partly on the basis of the appearance of empty copper levels near the valence band, this part of the sample ought to have exhibited more prominent infrared absorption bands than this laboratory's sample, as it in fact did. The smaller part of the Prener-Williams sample had different properties. Its brightness had not decayed, and its most recently measured spectral response corresponded to the initial spectral response of the whole sample.

This is not the place to speculate as to what the cause of the heterogeneity of the sample could be. The above arguments do, however, present one way to explain the different behavior of the Prener-Williams and this laboratory's sample. The small portion of the strongly luminescent green particles can account for the constancy of the green-to-blue ratio of the whole sample between, say, the end of the first year of decay (*i.e.*, when the brightness of the bulk was down by a factor of 10) and now. Not knowing the relative brightness of the two components of the sample, it is hard to say whether this also could account for the constancy of the green-to-blue ratio during the first year of decay. It is

conceivable that the presence of a small amount of a bright component, which stayed constant in its spectral distribution, would partly mask the changes occurring in a less bright but more abundant component. In fact, a closer look at Fig. 2 on page 343 of the quoted reference (8) will reveal that this curve may have a weak maximum somewhere between the 20th and 50th day of decay.

Manuscript received March 16, 1962; revised manuscript received July 17, 1962. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Red-Emitting (Zn,Cd)(S,Se) Electroluminescent Phosphors

F. C. Palilla and D. H. Baird

General Telephone & Electronics Laboratories, Inc., Bayside, New York

ABSTRACT

Red electroluminescence at 60 cps has been obtained with copper-activated, bromine co-activated, $Zn_{1-x}Cd_xS_{1-y}Se_y$ systems at field strengths as low as 50 v/mil. Emission color depends on the Cd and/or Se contents. Electroluminescence sensitivity depends on crystal structure. The ratio of host lattice components, together with the conditions of firing, etablishes the crystallographic nature of the matrix. The results suggest a similarity to the structural features associated with optimum electroluminescence in ZnS. Details of phosphor preparation and performance are discussed.

In recent years, considerable progress has been made in the preparation of phosphor systems suitable for use in electroluminescent lighting sources. Synthesis techniques are available for green-, blue-, and yellow-emitting electroluminescent phosphors of good quality, and appropriate mixtures of these phosphors yield white emission at practically useful levels. Comparable performance has not yet been achieved with red-emitting electroluminescent phosphor systems. The investigations described in this paper form part of an effort directed toward that end.

Investigations in the synthesis of electroluminescent phosphors have been most extensive and successful for materials based on zinc sulfide as the host and activated with copper. Experience in this laboratory and elsewhere (1-3) has indicated that optimum electroluminescence in ZnS is obtained when the crystallites exist as a complex structure consisting of faulted hexagonal and/or cubic modifications. It is probable that the peculiar excellence of ZnS as host in electroluminescent phosphors is due in part to its susceptibility to forming such complex structures. In seeking a host material for effective red-emitting electroluminescent phosphors, we therefore felt it desirable to select systems chemically and structurally related to ZnS, but with suitable lattice substitutions to shift the emission to longer wavelengths. Two binary systems are well known which produce this desired shift in emission: ZnS-CdS and ZnS-ZnSe. In neither case, however, is the desired degree of structural similarity to ZnS maintained in

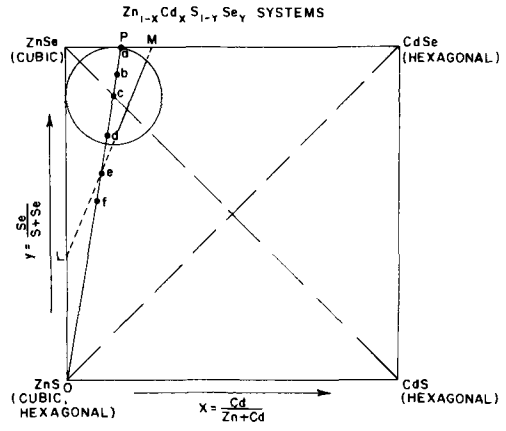

Fig. 1. Composition diagram for the $Zn_{1-x}Cd_xS_{1-y}Se_y$ system

the composition ranges which yield red emission. Substitution of cadmium for zinc in ZnS rapidly stabilizes the hexagonal modification and, at the same time, the electroluminescent sensitivity obtainable by synthesis methods employed to date diminishes (4). Thus, with sufficient Cd substitution to give red emission, little if any, electroluminescent sensitivity remains. Substitution of selenium for sulfur stabilizes the cubic modification (5). The electroluminescent sensitivity also falls, particularly at the low frequencies of excitation which are the most important for practical applications.

The structural characteristics of the binary systems described above suggest that, in the more general family of materials, (Zn,Cd) (S,Se), compositions exist that are characterized by the desired long-wavelength emission, and which are also close to a region of transition between stable hexagonal and stable cubic structures. Such materials might be expected to show some of the structural features characteristic of ZnS. The approach to the delineation of this compositional region and the investigation of the luminescent properties of materials within it is conveniently described in terms of the diagram of Fig. 1. Here composition is plotted as a function of x and y, where x represents the fraction of Cd substitution for Zn, and y the Se substitution for S. On this diagram, departures in any direction from ZnS ($x = y = 0$) may be expected to produce increases in the wavelength of emission. Compositions near the lower right corner may be expected to be hexagonal in structure, those near the upper left cubic. In order to define the region of structural transition and also to determine the dependence of emission color on composition in the central part of the diagram, preparations were made initially of compositions along the diagonals, *i.e.*, in the binary systems ZnS-CdSe and ZnSe-CdS. These served to focus attention on the circled region as being of primary interest in terms both of emission color and structural characteristics. Synthesis was then carried out of compositions along the line OP, a line possibly representing a division between cubic structures on the left and hexagonal materials on the right. These syntheses resulted in the best red-emitting electroluminescent phosphors obtained. It should be noted that Wachtel (6) has obtained red electroluminescence by a route essentially similar in principle, namely the incorporation of HgS in suitable (Zn, Cd)S compositions in order to bring the product from the range of hexagonal to that of cubic stability. In this case the high volatility of HgS necessitates special techniques of phosphor preparation. Lasof, Shrader, and Leverenz (7), as part of an investigation of the photo- and cathodoluminescence of (Zn,Cd) (S,Se) phosphors, also determined the structures of a number of compositions of this family, most of them predominantly comprising ZnS. Their preparations were carried out at temperatures below 900°C where the cubic phase of ZnS is stable, while ours were carried out at 1000°C and above where the hexagonal phase is stable so that the results are not directly comparable.

Experimental

Evaluation procedures.—A 1x1x0.006 in. demountable cell was used with one brass and one transparent conductive glass electrode. A phosphor volume fraction of 0.32 was used with castor oil as the dielectric medium.

The phosphor emittance was determined in terms of the surface brightness of the demountable cell measured with a 1P21 photomultiplier corrected to yield the eye response with a Wratten 106 filter and calibrated against a regulated brightness source.

It should be noted that because of problems inherent in the photometry in the red region of the spectrum (detector response and approximate correction to eye response with the Wratten 106 filter), the emittance values presented herein should be considered on a relative, rather than on an absolute, basis.

The spectral energy distribution was measured with a General Electric Automatic Recording Spectroradiometer, modified according to Hardy & Kirkpatrick, for increased sensitivity (8).

Phosphor preparation.—The synthesis of all phosphors described in the succeeding sections involves blending the mixture of host materials with 0.06-0.2% Cu as $CuSO_4$, and with 5-20% NH_4Br. Within these ranges no significant changes in emittance were observed. The luminescent grade ZnSe and CdSe used were obtained from Merck and the ZnS and CdS from Sylvania Electric Products, Inc. From 40 to 60g of the blend, contained in a quartz boat, is then fired in a lightly plugged quartz tube at 1000°-1200°C for a period of from 20 to 60 min. A self-generated atmosphere is thereby established. The tube is next removed from the furnace for cooling. After washing with hot solutions of 50% HAc, H_2O, 5% KCN and H_2O, the final product is dried at 160°C and sieved through a 400-mesh sieve.

Results

Binary system ZnS-CdSe.—In the case of the ZnS-CdSe system, increasing the amount of CdSe from 0 to 100% results in a progressive shift of the photoluminescence color under 3650Å excitation from blue-green to yellow to red and finally to no emission in the visible region. The electroluminescence color goes through a similar transition and the photoconductive sensitivity increases. In all cases, the host composition was fired with

Table I. Summary of results

Mole % CdSe	Body color	Photoluminescence under 3650A excitation	Electroluminescence, 60-6000 cps, 30-100 v/mil
0	White	Blue-green	Blue-green
25	Yellow	Yellow	Yellow
50	Red	Deep red	Red (weak)
75	Black	None	None
100	Black	None	None

0.1% Cu (as $CuSO_4$) and 10% NH_4Br at 1000°C for 40 min. The results are summarized in Table I. The crystal structure of these compositions is hexagonal in every case and the hexagonal lattice parameter a_o increases linearly with increase in CdSe content in accordance with Vegard's law.

Binary System ZnSe-CdS.—In the case of the ZnSe-CdS system, increasing the amount of CdS from 0 to 100% results in a transition of emitted color under 3650Å excitation from orange-red, to red, and finally to no emission in the visible region. Again the electroluminescence color goes through a similar transition and the photoconductive sensitivity increases. The preparative procedure here was the same as with the previous binary system. The results are summarized in Table II. These results indicate the compositional region of interest to be near 25 mole % CdS, both since it is the region of phase transition and since is corresponds to the desired red emission color. To define the compositional range of interest more closely, additional syntheses were made of phosphors of this binary system in the range of 0 to 25 mole % CdS. In these syntheses, the host composition was fired with 0.1% Cu as $CuSO_4$ and 10% NH_4Br at 1200°C for 20 min, conditions which earlier experience indicated gave the most satisfactory results with ZnSe itself. The results of these experiments are summarized in Table III.

It will be noted that the region of stability of the hexagonal structure appears to be larger at the higher firing temperature used in these experiments: the product with 25 mole % CdS contains only the hexagonal phase in this case, whereas the earlier product of this composition, fired at 1000°C, contains both cubic and hexagonal phases. In the 1200° preparations, the region of phase transition occurs at 15 mole % CdS. There is clearly indicated a maximum in electroluminescent brightness near this composition. Increasing the content of CdS shifts the peak of the spectral energy distribution

Table III. Summary of results

Mole % CdS	Structure	Electroluminescent brightness (ft-L), 400 cps, 600v	Peak of spectral energy distribution, Å
0	Cubic	0.03	6350
5	Cubic	0.07	6550
10	Cubic	0.07	6700
15	Hexagonal-cubic	0.12	6900
25	Hexagonal	0.01	7000

to progressively longer wavelengths, from 6350Å for 0 mole % CdS to more than 7000Å for 25 mole % CdS. Since luminosity decreases with wavelength in this range, it is clear that up to 15 mole % CdS, the emitted power is increasing with CdS content more rapidly than is the brightness. In the case of the product containing 25 mole % CdS, a substantial part of the emission, probably most of it, lies beyond 7000Å, the limit of detection of the spectroradiometer used. For this reason, no measurement is available of the power emitted by this phosphor and hence the question of whether there is a maximum in emitted power in the vicinity of the phase transition is not resolved. Thus the present results are in accord with the hypothesis concerning the desirability of mixed structures in that they show substantial increase in electroluminescent sensitivity as the composition of the host lattice is changed from the region of high stability of the cubic phase to the region of phase transition. However, they do not serve to show whether or not a corresponding decrease takes place as the composition is changed to a region of high stability of the hexagonal phase. From the point of view of obtaining improved red electroluminescent phosphors in the ZnSe-CdS system, they indicate that the region of the phase transition is most promising, although this may be coincidentally due to the fact that the emission of hexagonal materials in this system is primarily in the infrared.

Ternary system ZnSe-ZnS-CdSe.—From the results in terms of brightness, emission color, and structure obtained with the binary system ZnSe-CdS above, the composition range represented by the circled area of Fig. 1 was selected for further study in order to obtain further improvement. Syntheses were carried out of the compositions a through f along the line OP which was taken as a first approximation to the line separating the

Table II. Summary of results

Mole % CdS	Body color	Photo-luminescence under 3650A excitation	Electro-luminescence, 60-6000 cps, 30-100 v/mil	Structure
0	Yellow	Orange-red	Orange-red	Cubic

100	Brown	Deep red (faint)	None	Hexagonal

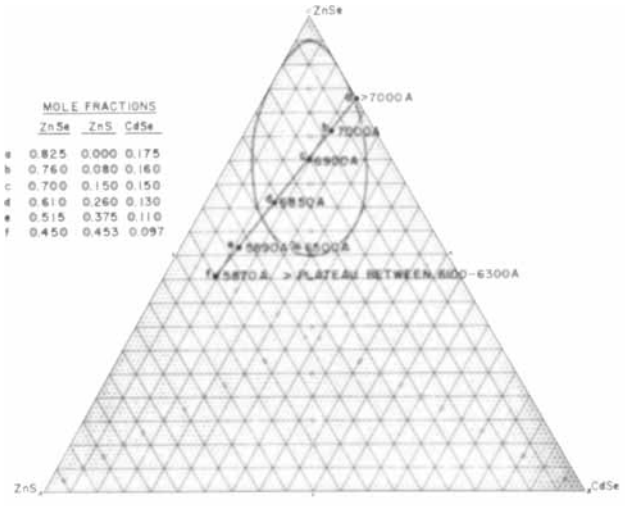

Fig. 2. Ternary composition diagram for ZnS, ZnSe, CdSe

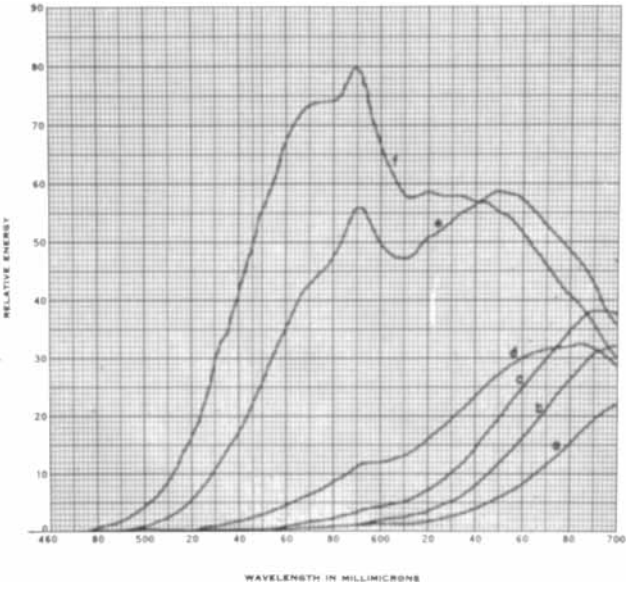

Fig. 3. Spectral energy distributions of phosphors in Fig. 1 and 2

regions of cubic and hexagonal stability. These compositions all fall in the ternary system ZnSe-ZnS-CdSe and are shown in Fig. 2 on the conventional triangular coordinate composition diagram of this system. Also listed are the wavelengths of peak emission of the phosphors which will be discussed further below. The enclosed area corresponds to the circle of Fig. 1. The samples were all prepared by firing at 1200°C for 20 min the appropriate blends of ZnSe, ZnS, and CdSe with 0.06% Cu as $CuSO_4$ and 10% NH_4Br.

The spectral energy distributions of these phosphors under 6000 cps electroluminescent excitation are shown in Fig. 3. The curves have not been normalized and therefore indicate the relative emitted energies of the phosphors. As we progress from sample f to a, there is a shift in peak emission of a red band from 6200 to above 7000Å with decreasing ZnS content. In the same sequence, there is the gradual disappearance of a yellow-orange band, which peaks at about 5770Å, but which does not shift its peak position appreciably with variation of composition. This is analogous to the shifts observed with increasing ZnSe in the Zn(S, Se) system where there is observed a decrease in intensity of a short wavelength band and a simultaneous shift in emission peak of a long wavelength band. In Table IV are listed the compositions and the structural characteristics of this series.

Table IV. Compositions and structural characteristics

Sample	ZnSe	ZnS	CdSe	Solid-solution structure	Lattice constant, A
a	0.825	0	0.175	Cubic	5.742 (Cubic)
b	0.760	0.080	0.160	Cubic	5.716 (Cubic)
c	0.700	0.150	0.150	Cubic	5.690 (Cubic)
d	0.610	0.260	0.130	Cubic with some hexagonal	5.658 (Cubic) 4.826 (Hex. a_o)
e	0.515	0.375	0.110	Hexagonal-cubic	5.611 (Cubic) 4.772 (Hex. a_o)
f	0.450	0.453	0.097	Hexagonal	4.656 (Hex. a_o)

There is observed a structural shift from the cubic modification in the low ZnS samples (a, b, and c) to the hexagonal modification in the highest ZnS sample (f) with concomitant decrease in lattice constants of both the cubic and hexagonal solid-solution structures. This implies that the line representing the transition between materials of cubic and hexagonal structures, under these conditions of preparation, passes through the lower portion of the circled area as possibly indicated by the line LM in Fig. 1. It is probable, however, that the entire series lies in a compositional region in which the energy difference between the two structures is relatively small. This factor is probably responsible for the relatively high level of brightness displayed by the phosphors of this series in that it is conducive to the formation of mixed and faulted structures in spite of the apparent existence of only single phases in some of these materials.

On the basis of emission colors of the phosphors of this series, composition d was selected for investigation of the effects on electroluminescent brightness of varying the temperature and time of firing. The results are given in Table V. These data are presented here for illustrative purposes only, without implication as to the optimized conditions for other compositions. It is probable that, with the complex mixtures involved in such a system, optimized thermal conditions may be different for different compositions.

In Fig. 4 and 5, the brightness-frequency and brightness-voltage characteristics of a phosphor of composition d, prepared by firing for 20 min at 1200°C, are compared with those of a ZnSe phos-

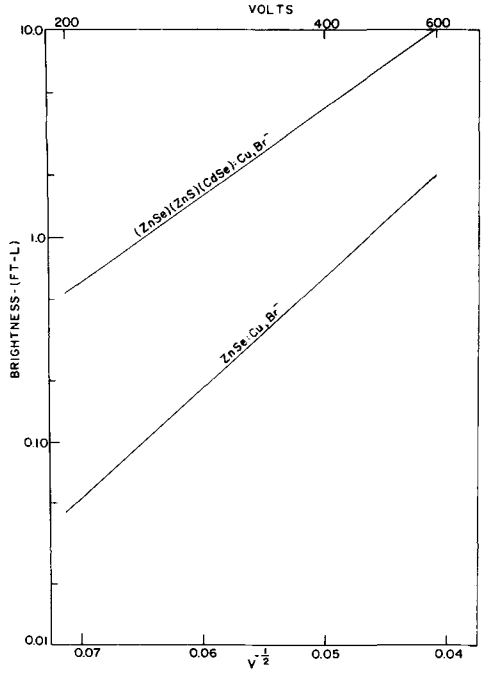

Fig. 5. Brightness vs. voltage for $ZnS_{(0.260)}ZnSe_{(0.610)}CdSe_{(0.130)}$: Cu,Br (composition d) and ZnSe:Cu,Br.

phor for which the preparative conditions were identical. Emission of the former peaks at 6850Å while that of the latter peaks at 6350Å. The most striking feature of these figures is the superiority they show in the brightness of the ternary phosphor over that of the selenide phosphor. Figure 4 shows this to be particularly the case at low frequencies. At 60 cps the brightness of the selenide phosphor is too low for measurement, but extrapolation from higher frequencies indicates the factor of superiority of the ternary phosphor to be at least two orders of magnitude. Figure 5 shows that both systems display the same brightness-voltage relationship commonly observed for electroluminescent phosphors.

Summary and Conclusions

In seeking improved red-emitting electroluminescent phosphors, investigation has been carried out of the system (Zn,Cd) (S,Se):Cu,Br. Increases in the content of either Cd or Se serve to shift the emission from the blue-green of ZnS to longer wavelengths. In addition, Cd serves to stabilize the hexagonal modification, Se the cubic. By suitably balancing these two substituents, it has been shown to be possible to produce a series of electroluminescent phosphors with emission peaks ranging from the yellow to near infrared, each close to a region of transition between the hexagonal and cubic modifications. These are thus to some extent the structural analogues of electroluminescent ZnS itself. Detailed evaluation of the brightness characteristics of a red-emitting member of this series shows it to represent a large improvement over those displayed by ZnSe:Cu,Br electroluminescent phosphors. This tends to confirm earlier speculation concerning the significance of mixed structures in achieving high-level electroluminescence in ZnS. It suggests that more detailed investigations of the present system of phosphors will lead to a better understanding of the role of such structures.

Acknowledgments

It is a pleasure to express thanks to Drs. P. Goldberg and A. K. Levine for many helpful discussions and for their encouragement. Grateful acknowledgment is made to J. Ragusin for his assistance in the preparation of the phosphors, and to C. Creter and P. Lublin for the x-ray analyses.

Manuscript received May 19, 1962; revised manuscript received Aug. 8, 1962. This paper was prepared for delivery before the Los Angeles Meeting, May 6-10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

Large-Area "Jet" Electrolytic Polishing of Ge and Si

G. R. Booker and R. Stickler

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Germanium and silicon specimens have been electrolytically polished by scanning the surface of the specimen in a systematic manner with a narrow diameter jet of electrolyte. A comprehensive examination showed that the surfaces of p-type Ge specimens polished in this manner are smooth, flat, and strain-free. Brief examinations indicated that the method is probably also satisfactory for polishing n-type Ge and p-type Si specimens.

Highly polished, flat, strain-free semiconductor surfaces, particularly Ge and Si, are frequently required for semiconductor device fabrication purposes. For example, such surfaces would be valuable for epitaxial layer and shallow diffused devices. However, such surfaces are difficult to prepare. A procedure frequently adopted is first to polish the specimen mechanically to obtain a highly polished, flat surface, and then to polish the specimen chemically to remove the strained surface layers formed during the mechanical polishing. However, the removal of the strained surface layers by chemical polishing usually causes a significant deterioration in the high polish and/or flatness of the surface (see later).

An alternative procedure is mechanical polishing followed by electrolytic polishing, the latter being performed by either a 'bath' method, the rotating disk method (1, 2), or a "jet" method (3-5). Bath methods are not entirely satisfactory and are not often used.

In the rotating disk method, recently introduced by Sullivan and his colleagues (1, 2), a flat disk is rotated close to the surface of the specimen to be polished, thereby intensively stirring an electrolyte introduced between the two surfaces. High points on the specimen surface are preferentially removed, and the resulting surface is highly polished and strain-free. The surface is slightly convex owing to different stirring rates at different distances from the center of rotation, the deviation from flatness over an area 25x25 mm being 2.5μ. The surface roughness is 25Å. The method loses some of its simplicity when applied to n-type specimens. This is because with such specimens it is necessary to produce holes at the surface being electropolished, and the standard procedure for doing this (to shine strong illumination directly onto the surface) is complicated by the closeness of the rotating disk. Sullivan *et al.* (1, 2) overcome the difficulty by shining light through the disk, various procedures being devised for making the disk both transparent and conducting. Polishing rates for p-type Ge specimens are 0.3 to 33μ/min, and for n-type Ge, p-type Si, and n-type Si specimens are of the order of 1.5μ/min.

In the jet method (3-5) a nozzle sprays a narrow circular jet of electrolyte onto the specimen, and polishing occurs over the area of impingement. Extremely fast polishing rates (100-500μ/min) can be obtained, and the resulting surfaces are highly polished and strain-free. However, the surfaces are not flat, a circular depression being formed on the surface opposite the jet.

The possibility of scanning a jet across the surface of a specimen so that the polished surface is also flat does not appear to have been investigated for semiconductor materials. The method is, however, used for metals. Thus, Farmer and Glaysher (6) used a scanning jet method to polish cylindrical iron tensile specimens in order to obtain smooth strain-free surfaces, while Nutting and Kelly (7) used a scanning jet method to thin metal specimens as a preliminary stage in the production of metal foils approximately 1000Å thick for transmission electron microscope studies. For both of these applications the complete surface of the specimen was scanned in a systematic manner by combining a rapid scan in one direction with a slow scan in a perpendicular direction.

The rate of removal of material (g/min) for a scanning jet is similar to the rate of removal of material (g/min) for a stationary jet. However, the average polishing rate (μ/min) for a scanning jet is very much less than the polishing rate (μ/min) for a stationary jet. This is because with a scanning jet the material is removed from a much larger area. If a jet with a cross-sectional area A_s and a stationary polishing rate (μ/min) R_s is scanned over an area A_m, then the average scanning polishing rate (μ/min) R_m is given approximately by $R_m = (A_s/A_m)\,R_s$. For a jet 2 mm in diameter and an area of scan 25x25mm the reduction factor A_m/A_s is approximately 200 times. This gives for semiconductor specimens polishing rates in the range 0.5-2.5 μ/min, *i.e.*, rates still adequate for most of the likely semiconductor applications. Moreover, the apparatus used for the electropolishing can be made fully automatic so that it can be run for several hours if necessary with little or no attention.

In order to investigate the possibility of applying the scanning jet method to semiconductor specimens we have used a scanning jet apparatus originally constructed for polishing metal specimens. The

present paper describes some results obtained for p-type Ge, n-type Ge, and p-type Si specimens.

Electropolishing Method

A slice approximately 25x25x1 mm thick was cut from the semiconductor material, and the two main faces were ground flat. One of the faces was then mechanically polished with progressively finer abrasives, the final abrasive being 0.25μ diamond. The resulting specimen was placed on a flat plastic plate with the mechanically polished side uppermost; lacquer was applied around the edges of the specimen and allowed to dry. In this manner the specimen was held in position and electrolyte was prevented from reaching the back surface. The specimen was mounted vertically opposite a plastic nozzle attached to a horizontal metal (platinum) tube (Fig. 1a). The nozzle contained a hole 2 mm in diameter, and the distance between the end of the nozzle and the specimen surface was 3 mm. The specimen was the anode, the metal tube was the cathode, and the anode to cathode distance was 15 mm. The electrical lead for the anode passed through a hole in the plastic plate and was soldered to the back surface of the specimen. This surface previously had been completely coated with solder so that during the subsequent electropolishing there would be no variation in the electrical polishing conditions from a point to point on the front surface of the specimen. However, other less permanent methods for making the electrical contact would also no doubt have been satisfactory.

The nozzle moved horizontally backwards and forwards at a uniform rate across the specimen, while the specimen had a similar but slower movement in the vertical direction (Fig. 1a and b). The scanning speeds were: horizontal, 25 mm/sec; vertical, 0.083 mm/sec. The jet thus scanned the specimen horizontally 300 times during the course of one vertical scan. The amplitudes of the scans were both 25 mm so that a specimen surface up to 25x25 mm could be polished. The scanning movements were obtained with the aid of two synchronous electric motors, gear-wheels, and two eccentric cams.

The electrolyte after impinging on the specimen was collected and pumped up to a reservoir, from whence it returned to the nozzle via a gravity feed. The pressure head was 60 cm and the jet had a flow rate of 0.4 liters/min and a flow speed of 200 cm/sec. The total amount of electrolyte circulated was 2 liters so that polishing could be continued for long periods without significant deterioration or heating of the electrolyte.

Mechanical and Chemical Polishing

Before describing the electropolishing results some observations on the mechanical polishing and subsequent chemical polishing of Ge and Si specimens are given. These observations enable the electropolishing results to be more clearly followed.

A single-crystal p-type Ge specimen was mechanically polished, the final abrasive being 0.25μ diamond, and examined at progressive stages with the optical and interference microscopes (Fig. 2). Details of the polishing procedure are given in Table I. As the polishing proceeded the abrasive

Table I. Mechanical polishing procedure

marks became less pronounced. After the 0.25μ diamond polish the specimen possessed a highly polished, very flat surface.

This mechanically polished specimen was then chemically polished with a modified CP4 solution[1] and similarly examined (Fig. 3). After a polishing time of 5 sec a dense array of sharply defined "scratch marks" was observed. After 15 sec the scratch marks were shallower, and after 30 sec still shallower. After 60 sec the trend continued, but a number of clear areas were now visible. After 90 sec all the fine scratch marks were eliminated, broad scratch marks only remaining. After 150 sec only a few broad scratch marks were still present. Moreover, during the chemical polishing the surface progressively lost its flatness and became wavy on a coarse scale. The waviness was slight after a polishing time of 5 sec, was pronounced after 30 sec, and very pronounced after 90 and 150 sec. The total thickness of the specimen removed during the chemical polishing was approximately 60μ, corresponding to an average chemical polishing rate of 24μ/min.

A single-crystal p-type Si specimen was then prepared and examined in the same manner. The chemical polishing proved to be similar to that of the p-type Ge specimen. In particular, scratch marks were rapidly revealed and then slowly removed, and the surface became progressively wavy. However, the scratch marks were much less pronounced on the Si specimen than on the Ge specimen.

[1] 200 ml HNO_3 : 120 ml HF : 120 ml CH_3COOH : 1.6g Ge : 1.2 ml liquid Br_2. The addition of Ge to CP4 introduces reaction products which improve the reliability of the etch by reducing the induction period to essentially zero (8). The action of CP4 on Si is reliable without the addition of Si (8).

These observations are interpreted (8) as follows. When Ge and Si specimens are mechanically polished in the manner described, a 'damaged layer' extending no more than a few microns below the surface is formed.[2] Chemical polishing with CP4 for approximately 5 sec removes this layer. The scratch marks then covering the surface result from nonuniform chemical polishing occurring while the damaged layer is being removed. This nonuniform polishing arises because of local differences in chemical polishing rates due to local differences in damage. After the damaged layer has been removed, further chemical polishing gradually smooths over the scratch marks but does not eliminate them until much later. During the chemical polishing the surface becomes progressively wavy on a coarse scale. This waviness is characteristic of the chemical polishing process and is not related to the damaged layer. The scratch marks are more pronounced on Ge than Si specimens because the damaged layer extends further below the surface of Ge than Si specimens.

Electropolishing

p-Type Ge.—Single-crystal p-type Ge specimens were electropolished using an electrolyte of composition 0.1*N* H_2SO_4 plus a few ml of HF (48%) per liter. The electrical polishing conditions were not critical, 150v and 200 ma[3] being typical. The electropolishing was similar to the chemical polishing in that scratch marks were revealed and later eliminated (Fig. 4). However, the electropolishing differed in that the initially flat condition of the surface was not significantly altered. The polishing times were longer than the corresponding times for the chemical polishing, the final electropolished surface being obtained after 120 min. The total thickness of the specimen removed was again approximately 60μ, corresponding to an average electropolishing rate of 0.5μ/min.

The final electropolished surface possessed a high-quality mirror-like finish. Optical micrographs at 1000X did not reveal any structure (Fig. 5a), while electron micrographs at 20,000X of shadow-cast replicas indicated only a slight granular structure (Fig 5b). The surface roughness was estimated from the electron micrographs to be approximately 25Å. Thtis value was subsequently confirmed by multiple-beam interference microscopy. The flatness of the final electropolished surface over an area 25x25 mm was in general equivalent to approximately 1 to 2 interference fringes, *i.e.*, approximately 0.5μ.

A p-type Ge specimen possessing numerous gross crystallographic imperfections, *e.g.*, twin planes and irregular boundaries, was electropolished as

[2] It is emphasized that the damage associated with the final mechanically polished specimens arose from the final 0.25μ diamond polishing treatment. No damage remained from the previous coarser abrasive treatments. This was established as follows. Similar specimens were cut, lapped, chemically polished to remove all the damage, and mechanically polished with 0.25μ diamond. When these specimens were chemically polished with the modified CP4 solution, the results obtained were precisely the same as those shown in Fig. 3.

[3] A current of 200 ma corresponds to a current density of approximately 6 amp/cm^2 when referred to the cross-sectional area of the 2 mm diameter jet used. The current density at the surface of the specimen is somewhat lower because of the spreading of the electrolyte on impingement.

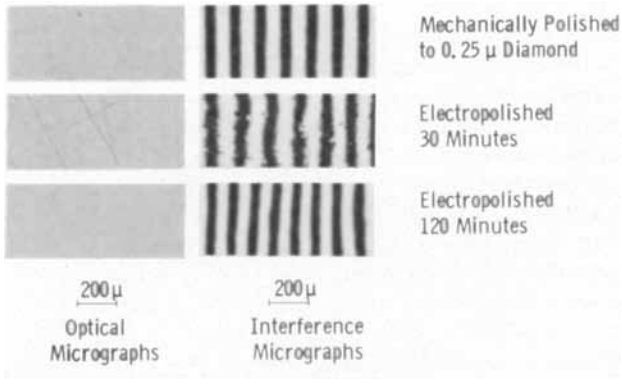

Fig. 4. Mechanically polished single-crystal Czochralski-grown p-type Ge at progressive stages during subsequent electrolytic polishing. Micrographs show typical random areas.

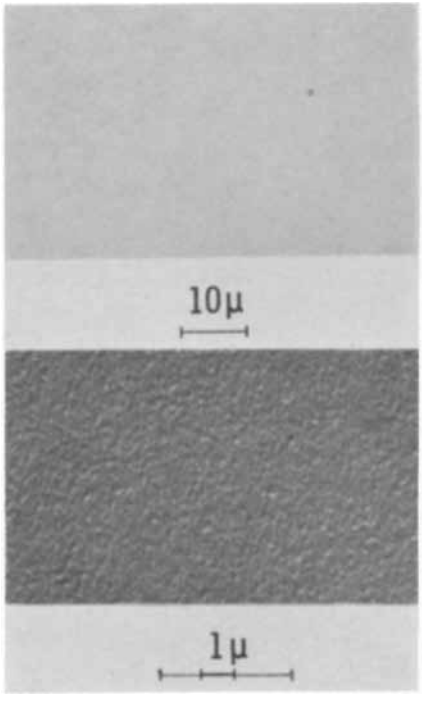

Fig. 5. Final electropolished surface of p-type Ge specimen of Fig. 4. a, (top) Optical micrograph; b, (bottom) electron micrograph of a shadow-cast replica. The shadow-casting angle was $\cot^{-1} 2$.

above. Examination of the final electropolished surface with the optical microscope showed that the imperfections were delineated in an extremely sharp manner (Fig. 6) (without etching the surface), while the remainder of the surface was structureless. The surface deviated slightly from flatness in the areas of the imperfections and was flat in the areas away from the imperfections.

n-Type Ge.—When single-crystal n-type Ge specimens were electropolished as above, the surface of the specimens became covered with a white film. However, if the electropolishing was performed while the surface was strongly illuminated, *e.g.*, by focusing the light beam from a high intensity lamp onto the surface, polishing occurred over the area illuminated. Moreover, if the small circular area of the jet only was illuminated then, owing to the vertical movement of the specimen, a narrow vertical strip was polished. The electrical polishing

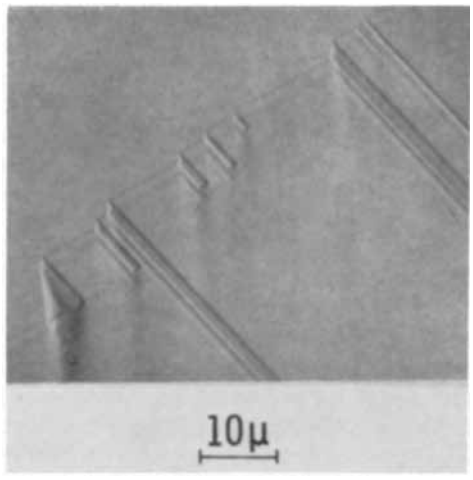

Fig. 6. Final electropolished surface of p-type Ge specimen similar to that of Fig. 4. but containing gross crystallographic imperfections.

conditions were somewhat critical, 90v and 100 ma being typical. Although polishing was effected in this manner, the polished surfaces were not always of the high quality of the p-type Ge specimens. However, highly polished surfaces could usually be obtained if, before electropolishing, the specimens were chemically polished for 5 sec with CP4.

p-Type Si.—Single-crystal p-type Si specimens were electropolished in a similar manner to the p-type Ge specimens but using an electrolyte of composition 0.2*N* HF. The electrical polishing conditions were not critical and highly polished surfaces were obtained.

Discussion

The large-area jet electropolishing method has been applied to p-type Ge, n-type Ge, and p-type Si specimens: all three types of specimen were satisfactorily polished. A comprehensive investigation of p-type Ge specimens showed that the method is capable of producing a final electropolished surface which possesses a surface roughness of approximately 25Å, is flat to approximately 0.5μ over an area 25x25 mm, and is strain-free.[4]

In order to obtain such high-quality electropolished surfaces, the specimens were initially mechanically polished, the final abrasive being 0.25μ diamond. This was necessary because the electropolishing method only slowly preferentially removes high points from irregular surfaces. Moreover, the electropolishing was continued appreciably beyond the stage at which the damaged layer arising from the mechanical polishing was removed, at least in the case of Ge.

For p-type Ge specimens 25x25 mm the electropolishing rate was 0.5μ/min and the electropolishing time was 120 min. Although the polishing time was relatively long, the apparatus required little or no attention during this period, except occasional observation of the specimen surface to see how the polishing was proceeding. Moreover, a reduction in the polishing time by a factor of 2 or 3 could prob-

[4] By "strain-free" is meant that no strains are present in the surface of the specimen due to the surface preparation method. Strains in the surface arising from strains previously present in the bulk material may, presumably, exist.

ably have been obtained by increasing the jet flow speed.

The method is directly applicable to n-type specimens because the surface of the specimen can readily be illuminated during electropolishing. For n-type Ge specimens electropolishing occurred as long as the light intensity exceeded a certain minimum value. However, a highly polished surface was often obtained only if, after mechanical polishing, the specimen was chemically polished for 5 sec with CP4 and then electropolished. The reason for this behavior is not definitely known. It is thought to be in some way associated with local variations in the lifetimes of the induced electron-hole pairs due to local variations of strain within the damaged layer. The difficulty might not have arisen if higher intensity illumination had been used during the electropolishing.

When the method is applied to n-type specimens, it would be advantageous if the jet remained stationary, and the two scanning movements were applied to the specimen. It is then only necessary to illuminate the area of the jet, *i.e.*, an area a few millimeters in diameter, in order to electropolish the complete area of the specimen, and several advantages result. First, by using a suitable optical system to focus the illumination, sufficient intensity can be obtained from a standard light source. Second, any nonuniformity in the intensity of the light over the area illuminated, a possible source of nonuniform polishing, is automatically compensated by the two scanning movements. Third, heating of the specimen, and hence the electrolyte, by the light beam is minimized. Consequently, any variations in the electrical polishing conditions resulting from an increase in the temperature of the electrolyte are also minimized. Fourth, by suitable modulation of the intensity of the light beam, selected areas of the specimen surface can be polished, *i.e.*, specific geometric areas can be isolated. However, the resolution which could be obtained in this way has not been ascertained. The same result could, of course, be obtained by placing the light on the same support as the jet. However, it is simpler practically to apply both scanning movements to the specimen.

Summary and Conclusions

A scanning jet electrolytic polishing method has been applied to Ge and Si specimens. A comprehensive examination showed that the surfaces of p-type Ge specimens polished in this manner were smooth, flat, and strain-free. Brief examinations indicated that the method is probably also satisfactory for polishing n-type Ge and p-type Si specimens.

Kinetics of Silicon Crystal Growth from $SiCl_4$ Decomposition

E. G. Bylander[1]

Texas Instruments, Inc., Dallas, Texas

ABSTRACT

The relationship of silicon epitaxial growth, following $SiCl_4$ decomposition in hydrogen, to classical heterogeneous reaction theory is discussed. The expected behavior of mass transfer control which shifts to a surface effect rate control is found to fit the observations. No conclusion is made whether the surface rate control is, say, due to reaction rate or adsorption rate, but the results appear to favor the adsorption rate of $SiCl_4$. Experimentally a competing etching reaction is found which appears to explain $SiHCl_3$ and $(SiCl_2)_n$ production. The diffusion of a reactant away from the surface appears to play the role of reducing the deposition reaction rate, and at high halide concentrations may be responsible for the etching reaction predominating. The variation of the surface morphology with substrate temperature appears to be explainable from the kinetics. The low temperature morphologies of etched and deposited slices were found to be similar.

Methods for epitaxial growth of silicon on silicon have been of recent interest (1-4). The purpose of this study was to explore the morphologies and growth rates of single crystal silicon films formed by $SiCl_4$ decomposition in hydrogen. A by-product of the investigation was the reaction kinetics data. Since the investigation was mainly ex-

[1] Present address: Melpar, Inc., Falls Church, Virginia.

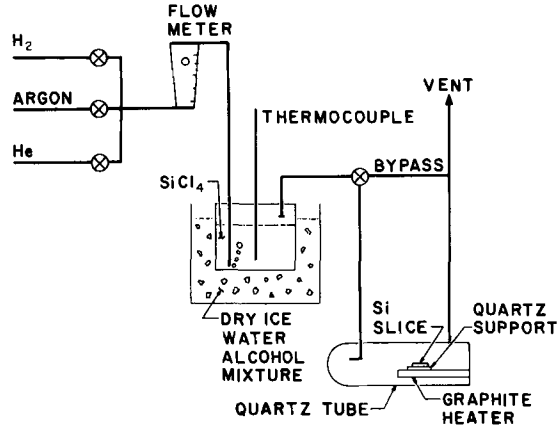

Fig. 1. Deposition apparatus

ploratory, no attempt was made to use a special kinetic reactor design. During the course of the work an etching reaction was found to be a part of the decomposition process, a fact which led to complications in the crystal growth study.

Experimental

The experimental arrangement was similar to that used earlier by Theuerer (3) and is shown in Fig. 1. Either hydrogen, helium, or argon was arranged to bubble through cooled $SiCl_4$ whose temperature was monitored directly with a thermocouple. Before a run was made, the bypass valve was opened until the $SiCl_4$ temperature reached steady state at the desired temperature with the gas flowing, and at which time the vapor was switched to blow over the slice.

Although the actual concentration will depart from that calculated using the vapor pressure because of the change in residence time of the gas with flow rate and possibly droplet entrainment, these factors are unimportant at the flow rates of interest and for concentrations up to at least 8%. This result was established from the close agreement which was obtained between growth rates using the bubbler and average rates using an evaporator in which the above items were not a factor. In the evaporator, halide was metered onto heated quartz chips and subsequently the vapor was picked up by the hydrogen. The bubbler was used in preference to the evaporator because of better reproducibility of results at low concentrations. The flow meter was calibrated for hydrogen flow rate. The slices were generally of (111) orientation and were placed in the center of a quartz carrier plate which in turn rested on a graphite heater. The slice temperature was measured pyrometrically, and an emissivity correction was applied. Deposit thicknesses were measured by measuring the slice thickness before and after deposition (5). Questionable results were checked by interferometry. The halide concentration was calculated from its vapor pressure. It is to be noted that the $SiCl_4$ concentration varied with position along the 4 in. hot zone and is some 40% less at the reactor exit than at the inlet for a 6% halide concentration at 1250°C and 10 liters/min. Also reaction product concentrations

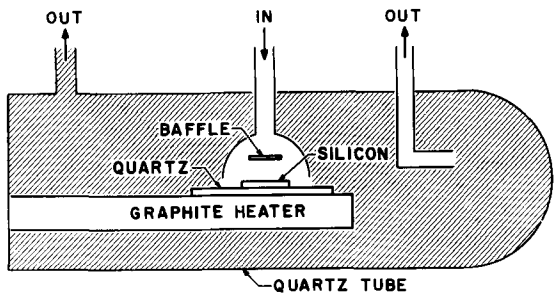

Fig. 2. Vertical reactor geometry

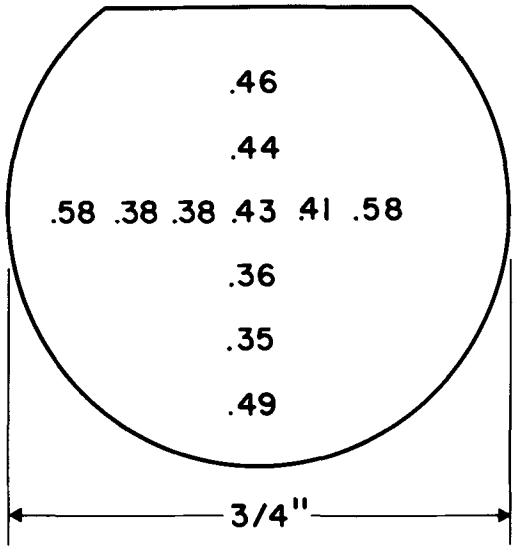

Fig. 3. Slice thickness variation for a slice deposited in the vertical reactor for a flow of 2 liters/min and halide concentration of 2%. Numbers are thickness in mils.

built up along the reaction zone as determined from quite rough gas chromatograph results. At high flow rates or low temperatures this perturbation should have little effect on the results, whereas under other conditions it may give rise to misleading results.

Two reactor arrangements were used. Either the gas was blown across the slice as in Fig. 1 (horizontal reactor) or it was blown down on the slice as in Fig. 2 (vertical reactor). The same 50 mm diameter quartz envelope was used in both cases. In the latter, a 4-cm diameter bell housing directed the gas down on the slice over a 1½ cm diameter baffle. The baffle was positioned for the best flow pattern by blowing smoke across it. Slice thickness variation for the horizontal reactor was only about 10% front to back at a 2% concentration and 10 liters/min flow, whereas under similar conditions it was much greater for the vertical reactor. A result from one vertical reactor run is shown in Fig. 3. The numbers on the slice are film thickness in mils. It is thought from this result that measurements made near the center would be meaningful within ± 20%, and the data seem to bear this out.

Flow patterns in the reactors were observed by blowing air through a lighted cigar in the feed line. Quite large convection currents were observed above the hot regions. In both cases a stagnant layer formed along the bottom of the tube and below the heater strip. Convection currents around the strip

were found not to affect the horizontal reactor results, since the slice was far enough away from the heater edge. It is thought that a similar situation held for the vertical reactor.

Results

The observed morphologies for (111) oriented slices are (i) whisker growth around 900°C; (ii) triangle growth 950°-1100°C; (iii) rippled growth 1150°C up. At $SiCl_4/H_2$ concentrations of $> 6\%$ and around 1250°C localized dimpling occurs.

Figures similar to etch figures were observed for the other orientations for step (ii). No systematic measurements of growth rate *vs.* orientation were made, but (110) oriented slices grew faster than (111) when the deposition conditions were such that there was an orientation dependence of growth.

During the course of the experiments the behavior of $SiCl_4$ in helium and argon was investigated. It was found in every case that material was removed, and there was no evidence of deposition (on the quartz support boat for example). In addition large amounts of the yellow, waxy polymer[2] were formed. Qualitatively more of it appeared to be formed during etching than was observed to be formed during similar deposition runs. The etching rates for helium flows of roughly 8 liters/min are also shown in Fig. 4, 5, and 8. The morphology of a slice etched at 1050°C is shown in Fig. 9. Figure 10 is a micrograph of a slice deposited under conditions similar to those for the slice of Fig. 9. As mentioned earlier, the concentrations in Fig. 5 and 8 above 8% are expected to be only relative because of departures from halide saturation of the gas.

Discussion

Although there is some controversy as to whether the $SiCl_4$ decomposes on the silicon surface or just near it,[3] it will be convenient to discuss the results in terms of heterogeneous reaction theory (8). A classical heterogeneous reaction is supposed to follow the steps:

1. Mass transfer of the reactant to the surface.
2. Adsorption onto the surface.
3. The reaction or series of reactions which take place on the surface.
4. Desorption of product molecules.
5. Mass transfer of the product molecules to the main gas stream, and for a growing crystal.
6. Addition of atoms to growth steps.[4]

If one of the above steps is much slower than the others, it will control the growth rate. In addition,

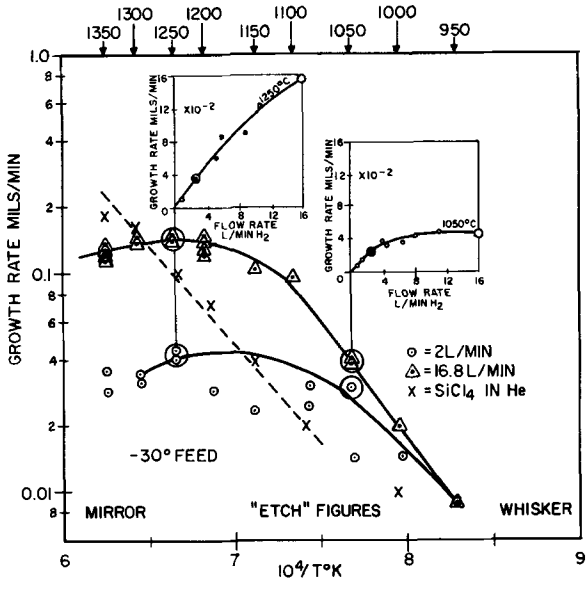

Fig. 4. Horizontal reactor: temperature and flow dependence of deposition and etch rates. The upper curves are the flow rate dependence of growth rate at 1250° and 1050°C. The large open circles are not data points but correspond to equivalent conditions. The lower curves are the temperature dependences of both the deposition and the etching rates.

the mass transfer step will be influenced by the gas flow rate yet be relatively temperature independent (10). The surface controlled steps 2, 3, 4, or 6, are expected to be quite temperature dependent and flow rate independent. The 950°-1100°C region (hereafter referred to as region I) of Fig. 4 is seen to be quite temperature dependent but relatively flow rate independent. The slope is about the same as reported by Theuerer for a different reactor (3). The surfaces observed for slices deposited in this region are quite rough and uneven; apparently this is due to surface rate control and the resulting independence of the various regions on the surface. That it is not due to mean free path effects of silicon may be seen by reference to Fig. 9 and 10. Since the morphology is the same in both cases, it must arise from localized etching.

The etching rate in helium, for a flow rate of about 8 liters/min,[5] is much slower, but it has the same slope. This result suggests that the etching rate is governed by the same mechanism as is the growth, either as a competing reaction or as that and a growth initiating reaction. These possibilities would rule out a hydrogen process as a limiting factor, but rather would suggest a $SiCl_4$ process. It is hypothesized that the etching reaction is

$$SiCl_4 + Si \rightarrow 2\,SiCl_2$$

based on the $(SiCl_2)_n$ polymer observed and on the $SiHCl_3$ which is observed to be formed in the growth plus etching reaction as follows

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \quad \text{(major growth reaction)}$$

$$SiCl_2 + HCl \rightarrow SiHCl_3$$

One would expect orientation independent growth in the mass transfer control region, but orientation

[2] Early wax samples taken from a similar process here were identified as the polymer $(SiCl_2)_n H_2$, $n \approx 10$, when formed under deposition conditions (6).

[3] Kurov (7) supposes from the morphology change with distance in a $GeCl_4$ reaction tube and arguments based on the heating times of H_2 that the germanium reacts in the gas and is carried as supercooled liquid droplets. Others (unpublished) have supposed that similar arguments apply to $SiCl_4$ decomposition. However, Kurov does not examine the effect of concentration changes with distance on the morphology, or the differences in the heating time of $SiCl_4$, with its different mass and viscosity, over that of H_2. In addition, he supposes the supersaturation of germanium is around 10^4. Similar "supersaturations" would obtain during $SiCl_4$ decomposition in the gas phase and one wonders how whiskers could grow under these circumstances.

[4] Some investigators have considered the possibility that for a similar reaction that the reaction and growth take place at the same site, i.e., steps 3 and 6 would be combined. See for example reference (9).

[5] Estimated from an indicated flow rate of 17 liters (H_2)/min. Note from Fig. 4 that this flow rate is still well into the surface reaction rate-controlled region, provided that $SiCl_4$ diffusion in helium is similar to that in hydrogen. Unpublished results of others for growth rates in $He-H_2$ and $A-H_2$ mixture indicate that it is.

dependence in region I. No systematic observations of this point have been made, but polycrystalline substrates which were inadvertently run in early tests were reinspected. Marked rate differences for slices deposited under region I conditions were found, but little if any difference was found for the regions of mass transfer control. The marked temperature and orientation dependence and the similarity of the etching and the growth rate activation energies make it not unreasonable to suggest that $SiCl_4$ adsorption is the rate-controlling step. These arguments would not, of course, rule out a step with similar features such as $SiCl_4$ bonding at a growth step.

At the higher temperature (region II), the rate is seen to be mass transfer controlled. The lower curve of Fig. 4, taken for flow rates of 2 liters/min, is seen to shift gradually from surface rate to mass transfer rate control. Note that if the two high temperature etching rate points of Fig. 4 are reliable (also see footnote 5) the growth is not $SiCl_4$ mass transfer rate limited but suggests that reaction product mass transfer limits the rate. Also the predominance of the etching curve leads to a greater than expected temperature dependence for the region II deposition rate. A mirror surface was obtained here and is apparently due to mass transfer control of the growth rate.

In Fig. 5 is shown the concentration dependence of the etching and growth rates. The growth curve has the same general shape as previously observed elsewhere (3). The etching curve appears to level out although the data is sketchy and suggests either an adsorption isotherm or a fractional order reaction. The etching behavior for low concentrations is not known in detail. It seems nearly certain that the etching is a competing reaction since localized dimpling of slices is observed at 1250°C and at concentrations greater than 6%. Also in another experiment, for a room temperature $SiCl_4$-H_2 source, etching and deposition on a thin, hot silicon film deposited on a quartz window were observed microscopically to occur adjacent to one another.

In Fig. 6 is shown the temperature dependence of growth rate for the vertical reactor and two concentrations. The growth rate is seen to have the

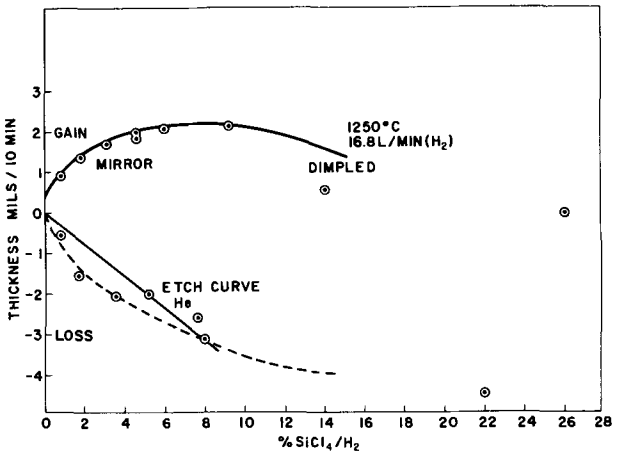

Fig. 5. Horizontal reactor: concentration dependence of silicon deposition rate and etch rate.

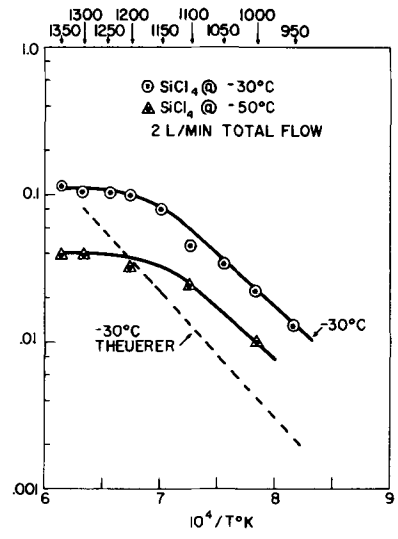

Fig. 6. Vertical reactor: temperature dependence of growth and etch rates.

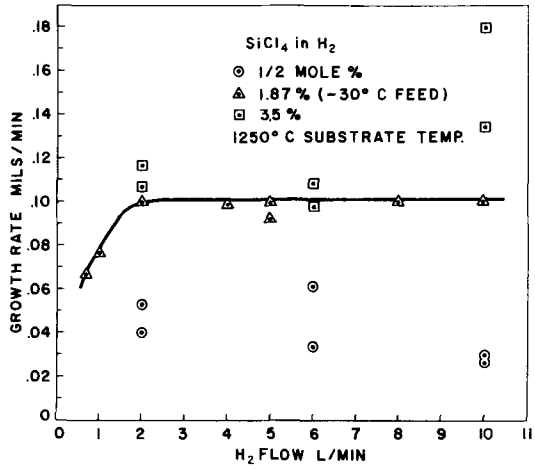

Fig. 7. Vertical reactor: flow rate dependence of the deposition rate for a 1250°C slice temperature. The data points shown for the highest and lowest halide concentrations were taken before the thermocouple was installed. The spread shows the importance of temperature control of the halide source.

same form at low temperatures as for the horizontal reactor. The higher rate than observed by Theuerer (3) is attributed to reactor geometry differences. The fact that a constancy of rate is observed for the higher temperatures here but not in ref. 3 is attributed to a high-temperature rate-limiting mechanism which was not reached for the lower rates. Interestingly enough the high temperature rate mechanism is flow rate independent (Fig. 7) and suggests that a low activation energy, surface rate controlling mechanism is operating.

The highest and lowest rates of Fig. 7 were run before a thermocouple was installed to aid temperature control of the source, and the variability seen emphasizes the importance of source temperature control. There is also an indication of a shift to mass transfer control at the higher concentration.

Figure 8 shows the concentration dependence of etching and growth rate for the vertical reactor and 1250°C slice temperature. The curve's behavior is similar to that of the horizontal reactor. Although

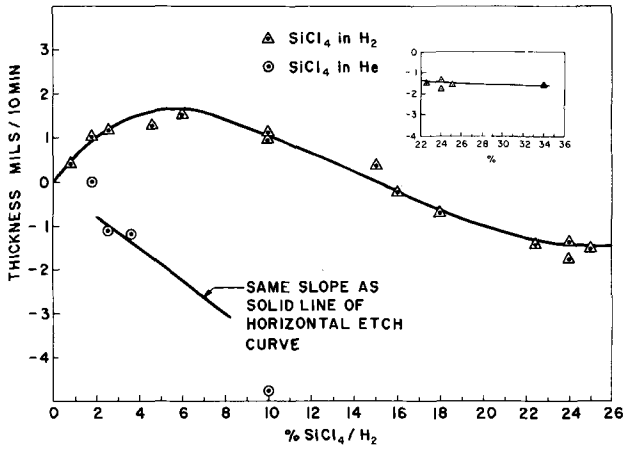

Fig. 8. Vertical reactor: concentration dependence of growth and etch rates.

the growth is constant above about 20% out to above 30% as pointed out earlier, there is some suspicion attached to the concentrations since they were measured indirectly. It would be preferable to repeat the experiment and measure them directly near the reaction point. Etching rates were not measured at high halide concentrations for the vertical reactor because about that time the work was shifted to a study of slice polishing by $SiCl_4$ etching. Polishing was found to be feasible. One is tempted to analyze the reaction by combining the growth plus etching and the etching rate curves to obtain a growth rate curve, but the data does not warrant it. Also it would be useful to fully identify the reactants and products in order to continue.

Figures 9 and 10 were taken for slices etched and deposited under similar conditions. Figure 9 is an etched slice. Figure 10 is of a deposited slice which, of course, was both deposited and etched during the course of the deposition. Although etching and growth are the same to the first order, the complication introduced by the etching reaction, which operates during growth, makes the interpretation of morphologies and growth rates difficult.

To summarize, $SiCl_4$ decomposition and etching have been observed in horizontal and vertical reactors. The reactions in both the horizontal and vertical reactors seem to be surface reaction rate controlled at low temperatures. Reasoning from high activation energy, orientation dependence, flattening of rates with concentration, and similarity of growth and etching rate slopes, it is suggested that $SiCl_4$ adsorption rate controls here. The horizontal growth rate was found to shift to mass transfer control at the higher temperatures while the etching rate did not. It is suggested that reaction product mass transfer governs the growth rate here. The vertical reactor behaved somewhat differently at these temperatures. An etching reaction of $SiCl_4$ on Si was observed which complicated the study. Where it was studied it appeared to always be surface reaction rate dependent and possibly involves the same rate limiting mechanism as low temperature growth, *i.e.*, $SiCl_4$ adsorption. The morphologies appear to be explainable from the kinetics. A suggested next step is to identify all of the reactants and products.

Aluminum Nitride Containers for the Synthesis of GaAs

G. Long and L. M. Foster

Alcoa Research Laboratories, Physical Chemistry Division,
Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

High-purity aluminum nitride refractory ware has been produced for use as containers in the synthesis of semiconductor gallium arsenide. Use of these containers essentially eliminates contamination of the GaAs with silicon, as is usually encountered when the synthesis is carried out in quartz. The principal problem encountered in the use of this material is wetting by the molten gallium and GaAs, which results in sticking of the solidified ingot. This problem is circumvented if synthesis is carried out in crucibles from which the charge is subsequently drawn by Czochralski techniques. Room temperature mobilities of 7000-8000 cm^2/volt-sec have been reported in GaAs synthesized in these crucibles.

Progress in gallium arsenide semiconductor technology has been disappointing in some areas, and a number of the desirable characteristics that were early predicted for this material have not been fully realized. In general, electron mobilities, although frequently obtainable at sufficiently high levels for some applications, could not be obtained consistently and correlated poorly with known impurity levels. Minority carrier lifetime has been several orders of magnitude below that determined by radiative recombination. Whereas this has had other tentative explanations, it has also been suspected of originating with unidentified impurities.

Gallium arsenide synthesis is generally carried out in quartz systems; certainly in quartz outer envelopes and, with few exceptions, in quartz boats or crucibles. Silicon almost invariably occurs in GaAs and, since it is absent in gallium and probably very low or absent in arsenic, its pickup from the synthesis system is assumed.

Cochran and Foster (1) described the nature of the attack of gallium and GaAs on quartz and demonstrated that silicon pickup is not only possible but unavoidable in the usual synthesis. That work could not treat the possible contamination by oxygen because of the absence of information on the solubility of the oxygen species, Ga_2O and SiO, in gallium and GaAs, but the possibility of oxygen pickup cannot be excluded.

Few alternative container materials can be considered. A refractory material consisting of elements from Groups III and V of the periodic table would, of course, be ideal for gallium arsenide synthesis. Boron nitride ware was an obvious early choice because of its commercial availability. However, it was found to suffer from problems attributable to the binder used in fabrication and to chalking and dusting of the surface when the binder was largely removed.

Aluminum nitride, AlN, also a III-V compound, emerges as a promising container material since it can be fabricated into refractory ware without objectionable binder material. Its suitability for this purpose was demonstrated by Blum, Weiser, and Ainslie, who reported obtaining room temperature electron mobilities from 7000 to 8000 cm^2/volt-sec consistently in GaAs synthesized in and drawn from AlN crucibles (2). The present report describes the properties of this new material, particularly as related to gallium arsenide synthesis.

Preparation of Ware

A method of preparation of AlN sintered bodies was described by Long and Foster (3). Modifications of that preparation to result in a more pure product were made. These modifications were in the nature of use of higher purity starting materials, better cleanliness throughout all operations, selection of grinding media to minimize contamination, use of diamond machining tools, etc., and will not be described in detail.

Both crucibles and boats have been evaluated in GaAs synthesis. The crucibles are 38 mm OD by 30 mm high and 33 mm OD by 26 mm high, with capacities of 25 and 16 ml, respectively. Both have 2 mm wall and bottom and a very slight taper on the side walls. The boat is 100 mm inside length by 25 mm inside width, hemicylindrical in shape, with 2 mm wall. The capacity of the boat is about 40 ml.

Articles with thinner walls could be produced, but the loss of pieces due to breakage during fabrication would be appreciable. Other shapes could be produced as long as suitable draft could be provided for removal from the mandrels on which the pieces are formed, and no re-entry surfaces are required.

Properties of AlN

Several properties determined in ref. (3) have implications in the synthesis of GaAs. Being electrically insulating, the material cannot be used as its own susceptor in heating by RF induction. Either a graphite susceptor must be employed or it is necessary to induce directly in the gallium or GaAs.

The coefficient of expansion of 5.7×10^{-6}/°C is identical to that reported by Welker and Weiss for GaAs (4). It is possible, therefore, to freeze GaAs in a crucible and remelt it without cracking the crucible, although, if coupling is directly to the

gallium arsenide, heating must be carried out with great care to avoid setting up steep temperature gradients.

The AlN ware that has been evaluated in GaAs synthesis is blue in color. Completely pure, single crystal AlN is water white. The blue color results from very carefully controlled addition of a trace of aluminum oxycarbide, Al_2OC, to the crystal. Al_2OC is also water white, but its solution in AlN is blue. The nature of the color is not known. It is obviously a color center situation since the color can be radiation bleached. The oxycarbide is isomorphous with AlN (5) and is in complete solid solution. This addition affects the nature of crystal growth during sintering, and a strong, impervious body results that cannot be obtained in pure AlN itself.[1]

It is interesting to speculate on the effect of contamination by Al_2OC on the GaAs crystal. Although an oversimplification, Al_2OC can be regarded as resulting from two nitrogen atoms in the AlN lattice being replaced by one oxygen (—2 charge) and one carbon (—4 charge). The average charge is thus —3. The average radius (carbon = 2.6Å and oxygen = 1.4Å) is just that of nitrogen (2.0Å) in AlN, and the substitution occurs with very little parameter shift. The oxygen and carbon thus are an internally compensated pair that should contribute neither carriers nor scattering centers to the crystal. This view is supported by the insensitivity of the electrical conductivity of AlN single crystals to their Al_2OC content.

Conceivably this favorable situation might exist as well in GaAs that picks up traces of oxygen and carbon in equal atomic amounts from the Al_2OC in the refractory.

Chemical Stability

Aluminum nitride is completely stable in contact with graphite to very high temperatures, and outer graphite susceptor crucibles have been employed. It is also stable in contact with tungsten and molybdenum up to about 1800°C, but the use of these materials in GaAs synthesis systems presents other problems.

Highly sintered AlN is very stable in almost all chemical environments at room temperature. It is insoluble in acids and bases and shows no evidence of hydrolysis in water over extended times. Nevertheless, since there is always some inherent porosity in a sintered body, cleaning in aqueous media should be strictly avoided if the article is intended for use in semiconductor synthesis.

Sintered aluminum nitride begins to react with chlorine at about 600°-700°C to form nitrogen and aluminum chloride. This treatment should not contaminate the AlN since aluminum chloride is volatile. A chalkiness develops on the surface during this treatment, however, that could interfere with crystal pulling, and in general, such cleaning treatments should be avoided.

It is possible to clean small amounts of GaAs from a crucible by first pumping off the arsenic at 1000°-1100°C, then removing the gallium as $GaCl_3$ in a stream of chlorine at about 300°C. Obviously this will be a laborious operation if considerable quantities of gallium arsenide must be removed.

[1] Patent applied for.

Thermal Stability

The usefulness of aluminum nitride ware in GaAs synthesis is contingent on a high stability at the synthesis temperature. Previous thermodynamic data for AlN have differed widely. For example, Neugebauer and Margrave (6), in a survey of the literature, found values for the heat of formation ranging from —55 to —80 kcal/mole. The uncertainty of this value reflected similar uncertainties in other thermodynamic data for AlN.

The heat of formation was redetermined recently by Neugebauer and Margrave (6), and by Mah *et al.* (7), using opposite approaches. The former used the nitridation of aluminum powder to obtain —76.47 ± 0.20 kcal/mole, and the latter used combustion calorimetry to obtain —75.6 ± 0.4 kcal/mole, using aluminum nitride supplied by the authors. Mah *et al.* also obtained heat content and entropy functions, using the same material.

The calculated equilibrium nitrogen partial pressures for the reaction

$$AlN_{(c)} \rightarrow Al_{(g)} + \tfrac{1}{2} N_{2(g)}$$

are shown in Table I for the temperature range 1000°-1600°K. These are equilibrium values which will not be achieved in practice because of kinetic effects. In particular, gas-producing reactions at a surface proceed slowly if there is no intermediate liquid phase because of the difficulty in transporting heat to or from the reaction site (8). Margrave (9) studied the decomposition in vacuum of massive, sintered AlN, supplied by the authors, in the temperature range 1450°-1870°K, and found the rates to be only 2.5×10^{-8} of the thermodynamically calculated values. Thus, at 1500°K, the observed nitrogen partial pressure would be about 2.5×10^{-7} mm instead of the equilibrium value of 1×10^{-4} mm. Moreover, vaporization should be even further suppressed in an atmosphere of arsenic.

Purity of Sintered AlN

Very pure single crystals of AlN have been produced, usually as accidental growths in high-temperature furnaces in which AlN was being employed. In high-pressure bomb reactions between aluminum and nitrogen gas, AlN can be prepared whose purity is presumably determined entirely by the purity of the reactants. Experience has shown, however, that the purity of the final sintered shape is determined more by procedures used in grinding, milling, shaping, and sintering than by the purity of the starting materials.

Table I. Calculated equilibrium nitrogen partial pressures from decomposition of AlN

$AlN_{(c)} \rightarrow Al_{(g)} + \tfrac{1}{2}N_{2(g)}$

T, °K	N_2 pressure, mm
1000	5×10^{-12}
1200	2×10^{-8}
1400	1×10^{-5}
1500	1×10^{-4}
1600	9×10^{-4}

Sintered ware that has been evaluated in GaAs synthesis shows the following "typical" spectrographic analysis

Si	0.005-0.03 %
Mg	0.001-0.005
Cu	0.001
Ti	0.001
Fe	0.001
Ga	0.001
All others	<0.01

Preparation of a sample for analysis is made difficult by the extremely hard, abrasive nature of the material, and absence of suitable standards in an AlN matrix limits the sensitivity of detection of many elements. Consequently, the analysis is only semiquantitative and serves principally to indicate the high purity of this product. The silicon figure is probably real as it is known that there is some silicon pickup during a grinding operation.

It is significant that because of the extremely high temperature employed for sintering (2200°C), many impurities will be volatilized, and the rest must certainly be in solid solution in the crystal. It is unlikely that they could be selectively extracted by the GaAs without a corresponding pickup of aluminum. Thus, for every ppm of aluminum pickup there should be no more than 0.0003 ppm of silicon, and substantially less of the other metallic impurities.

GaAs that has been drawn from AlN crucibles is reported to contain 10-20 ppm aluminum (2). Thus, about 0.005 ppm of silicon pickup is all that would be expected from the AlN container. Higher pickup must be attributed to remaining quartz components of the apparatus. There are several possible mechanisms for transporting silicon through the vapor phase. The most likely appears to be through the action of water vapor. Water vapor will react with gallium or gallium arsenide to produce hydrogen and Ga_2O. The reaction can reverse at the quartz surface to deposit gallium and regenerate the water. The gallium can subsequently reduce SiO_2 to volatile SiO, which can condense back into the ingot (1). Great care in baking out all of the quartz parts of a synthesis system is recommended, even when the synthesis itself is not carried out in quartz. Moreover, if a graphite susceptor is employed, and this rests on a quartz support, the reaction

$$SiO_2 + C \rightarrow SiO + CO$$

can occur to also generate SiO, which can dissolve in the ingot.

GaAs Synthesis in AlN Ware

The electrical properties of GaAs synthesized in and drawn from AlN crucibles have recently been described by Blum (2). Effort in the authors' laboratory has been directed toward the general aspects of the physical and chemical stability of AlN in the synthesis environment.

The AlN ware is not completely dense. How much of the porosity communicates with the surface is not known. It has been a practice to outgas the containers at 750°C overnight in a quartz vacuum system with oil diffusion pumping and a liquid nitrogen trap. A noticeable improvement in vacuum is observed over this pumping period, and 10^{-6} mm pressure is ultimately attained. The nature of the gases that are evolved during this period has not been established. If the crucibles are not to be used in synthesis immediately, vacuum is broken with helium and the articles are hermetically sealed in polyethylene containers. They are stored over a desiccant until required. It has been observed that only superficial outgassing of the crucible is subsequently required in the synthesis system.

The stability of AlN toward gallium and arsenic could have been predicted from thermodynamic considerations. Arsenic does not form a nitride, and GaN loses its stability at low temperatures (10).

In one experiment, ALCOA Ga-6 grade gallium (99.9999+%) was heated by induction in an AlN crucible for 1 hr at about 1200°C in a few centimeters of helium pressure to suppress volatilization of the gallium. The residual resistivity ratio of the gallium

$$\frac{\rho 4.2°K}{\rho 298°K}$$

between helium and room temperature was determined. The ratios were $2.6 \times 10^{-5} \pm 0.1 \times 10^{-5}$ before heating and $2.7 \times 10^{-5} \pm 0.1 \times 10^{-5}$ after heating. From previous calibration of the contribution to the resistance at 4.2°K of known amounts of impurities (11) it is estimated that less than 0.1 ppm total impurities was picked up by the gallium.

Most of the gallium was poured out of the crucible, and the remainder was volatilized as $GaCl_3$ in a stream of chlorine at 300°C. The crucible regained its original appearance and showed no weight change within the sensitivity of the analytical balance. AlN similarly shows no change in appearance or weight when heated in an atmosphere of arsenic vapor at 1250°C.

The principal problem that has been encountered in the synthesis of GaAs in AlN is partial or complete wetting of the container by the molten GaAs, and subsequent sticking of the ingot. For this reason evaluation of AlN as crucible material in Czochralski crystal pulling, rather than boat synthesis, has been encouraged. Here, sticking presents no problem other than possibly precluding the reuse of crucibles. Actually, a crucible can be reused if most of the previous charge is pulled out and care is exercised in remelting the remaining heel.

GaAs can be removed from AlN boats and, with somewhat greater difficulty from crucibles, by freezing it rapidly in 1 atm of arsenic. This is slightly in excess of the equilibrium arsenic pressure at the freezing point, and some of the excess dissolved arsenic comes out of solution as small bubbles at the interface between the charge and the container. These tend to release the GaAs from the wall so that it will fall out. It is not possible, of course, to obtain large crystal ingots in this way, but it does offer a possible procedure for preparing GaAs in a boat for subsequent crystal pulling, or for removing

the heel from a crucible so that the latter can be reused.

The manner in which GaAs adheres to AlN containers is not known. There is undoubtedly considerable mechanical keying in of the GaAs to the surface, which cannot be produced completely smooth. In addition, however, both gallium metal and molten GaAs appear to wet the AlN surface truly at the synthesis temperature. In the case of other III-V compounds it has been observed that there is a sharp maximum in viscosity at the stoichiometric composition just above the melting point (12). It would be expected that there would also be a maximum in the surface tension. Similar measurements have not been made on GaAs, but it is expected that it follows the same pattern. It would seem, therefore, that if stoichiometric gallium arsenide could be melted carefully in aluminum nitride, or if a molten stoichiometric charge could be poured into an AlN container, the wetting and sticking problem might be minimized.

This has been confirmed to a degree. Synthesis has been carried out in a double boat arrangement where one boat was inverted to serve as a cover for another similar boat. After outgassing of the boats, gallium was introduced into the bottom boat through a 1-mm bore Teflon tube inserted through a hole in the end formed by a depression in the ends of the boats at the parting line. These same holes permit access of the arsenic vapor to the gallium. The usual horizontal synthesis was carried out, maintaining an arsenic boiler at 605°C, then the GaAs was allowed to solidify in the boat in which it was produced. When cold, the tube was rotated about 180° so that the cover boat was on the bottom. The charge was then carefully reheated in the arsenic atmosphere so that it melted out of the top boat and drained into the bottom. It was then carefully solidified through a gradient freeze technique. There was a greater tendency for the ingot thus produced to free itself from the boat than in cases where the synthesis and freezing were carried out entirely in a single boat. Nevertheless, there was still sufficient sticking to preclude the formation of single crystals, and, at best, this procedure might again serve only as a means of recovering the GaAs from a boat for subsequent crystal pulling.

It has been observed that the tendency to wet and stick to an AlN boat is very temperature sensitive, and actual soaking of the GaAs into the aluminum nitride structure has been observed when it is considerably superheated. Synthesis as close to the melting point as possible is recommended, but even then complete freedom from sticking cannot be assured. Other aspects of this problem are being investigated.

Manuscript received May 15, 1962; revised manuscript received July 17, 1962. This paper was prepared for delivery before the Los Angeles Meeting, May 6-10, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

The Dehydration of Ammonium Metatungstate

R. W. Mooney, V. Chiola, C. W. W. Hoffman, and C. D. Vanderpool

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

Ammonium metatungstate was allowed to reach equilibrium at temperatures between 55° and 450°C. The products were characterized by chemical analyses, thermogravimetric analyses, and x-ray diffraction patterns. The data confirm the association of one constitutional water molecule with the metatungstate ion. The x-ray diffraction patterns of ammonium metatungstate varied with the water content.

The isomorphism of the metatungstates and the heteropoly tungstates was first suggested by Copaux (1). The determination of the structure of the heteropoly anion, $PW_{12}O_{40}^{3-}$, by Keggin (2-4) provided a basis for more definitive studies, and he suggested that metatungstates contained $H_2W_{12}O_{40}^{6-}$ ions. Subsequent studies confirmed the isomorphism of metatungstic acid with phosphotungstic acid by the aid of x-ray powder photographs (5, 6). The central group in the metatungstates corresponding

to the PO_4 group in phosphotungstic acid was thought by Signer and Gross (5) to be an H_2O_4 group. Jahr (7) contested their hypothesis and instead claimed that the WO_6 octahedra were grouped about an empty hole.

More recent work by Schott and Harzdorf (8) on the metatungstates of lithium, sodium, and potassium confirmed Keggin's hypothesis that two hydrogen atoms were associated with each metatungstate ion, thus favoring the $H_2W_{12}O_{40}^{6-}$ ion rather than the $W_{12}O_{40}^{8-}$ or $(OH_4W_{12}O_{40})^{6-}$ ions. In contrast to the dehydration studies of Schott and Harzdorf who found no distinct chemical hydrates in their metatungstates, Kolli, Pirogova, and Spitsyn (9) in a study of the dehydration of sodium metatungstate reported the existence of hydrates containing 10, 4.5, 2.5, 2, 1.5, 1, and 0.2-0.3 moles water per mole of the anhydrous salt.

The present study of ammonium metatungstate was undertaken to compare the dehydration of this salt to the previous studies of dehydration of alkali metal metatungstates and to determine whether the water associated with ammonium metatungstate at various temperatures was in the form of discreet hydrates or was zeolitic.

Experimental

Preparation.—Ammonium metatungstate was prepared by the digestion of hydrated tungstic oxide with ammonium hydroxide solution. A slurry of 908g of tungstic acid in 2.4 liters of deionized water was agitated and heated to 80°-90°C. While maintaining temperature, 105 ml of reagent grade ammonium hydroxide solution (28%) was added during a period of 1 hr. Digestion was continued for 2 hr, and the mother liquor, ammonium metatungstate solution, was separated by filtration. The yield of ammonium metatungstate crystals was 50-55% of theoretical based on WO_3. The crystalline product was dried at approximately 35°C for 4 hr to get the starting material required for equilibration studies.

Equilibration.—The ammonium metatungstate samples were equilibrated at various temperatures by placing them in an Abderhalden drying apparatus, Fig. 1, for periods of approximately 24, 72, and 128 hr. The temperature of equilibration ranged from 55° to 200°C and was characteristic of the liquid used in the distilling flask of the apparatus. The specific liquids used and the temperatures obtained in the drying chamber of the apparatus were acetone (55°), ethyl alcohol (75°), water (91°), acetic acid (115°), 2-ethoxyethyl acetate (150°), and 2,2-diethoxy ethyl acetate (200°). Differences between the equilibration temperatures and the boiling points of the various liquids as given in the literature were attributed to heat losses in the apparatus. The drying chamber was wrapped with insulating tape to reduce heat losses at temperatures above 100°C. Equilibration temperatures were measured by a thermometer placed in the inner tube of the drying chamber.

For equilibration, two silica boats, 100 x 18 x 11 mm high, and containing 10g of ammonium metatungstate each, were placed inside the inner tube

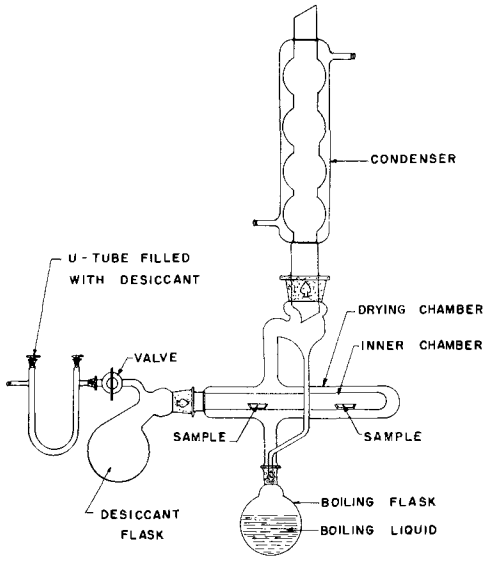

Fig. 1. Abderhalden drying apparatus used for the equilibration experiments.

of the drying chamber. Vapors from the boiling liquid in the distilling flask heated the drying chamber and sample to constant temperature. The moisture released from ammonium metatungstate was absorbed by calcium sulfate (Drierite) drying agent contained in the desiccant flask. The drying chamber and the desiccant flask were open to the atmosphere through a U-tube which also contained drying agent.

From 200° to 450°C the samples were equilibrated at 50°C intervals for 24 hr in a Stanton thermobalance. The weight loss after 24 hr was negligible.

The equilibrated samples were stored in sealed glass tubes until measurements could be made.

Analyses.—To determine the amount of tungsten, the tungstates were ignited at 800°C and the residue weighed as WO_3. Ammonia was determined by the Kjeldahl distillation method. The per cent water was obtained by difference. Thermogravimetric analyses were made on a Stanton thermogravimetric balance at a heating rate of 3°C/min. The sample was contained in a covered quartz crucible in order to employ the "self-generated atmosphere" technique (10) to emphasize changes in rate of weight loss.

The x-ray diffraction patterns were taken on a Philips Norelco unit with a Geiger-counter diffractometer using nickel-filtered CuKα radiation of 1.542Å wavelength. Sample preparations and intensity measurements followed the procedure adopted by the National Bureau of Standards (11). The intensity values of each pattern were measured as peak height above background and expressed as percentages of the strongest line.

Results and Discussion

Crystals formed at room temperature.—Large transparent crystals several centimeters in size were grown from saturated solution. After removal from solution, the crystals lost water rapidly and

became translucent. Therefore, x-ray and thermogravimetric analyses (TGA) were carried out as soon as possible after removal. The crystals were surface-dried with filter paper for the TGA measurements since any heating changed the water content and structure. The water content varied from 22 to 24 waters of hydration per mole of $(NH_4)_6H_2W_{12}O_{40}$. In view of the rapid dehydration the equilibrium form in saturated solution is believed to contain 24 waters of hydration as represented by the formula $(NH_4)_6H_2W_{12}O_{40}\cdot 24H_2O$. Reliable NH_3 analyses could not be obtained on this form. Characteristic low angle x-ray diffraction lines of the 24-hydrate designated AMT22-24, and the other less hydrated metatungstates are given in Table I.

When the evaporation was continued until all of the ammonium metatungstate had crystallized from solution, the product was reduced in water content to between 12.6 and 14.3 waters of hydration by air drying. A typical weight loss curve on this product is shown in Fig. 2. Chemical analyses are given in Table II.

All of the thermogravimetric analysis curves showed a temperature region of little or no weight loss corresponding to the formation of the anhydrous $(NH_4)_6H_2W_{12}O_{40}$. In addition, certain runs including the data of Fig. 2 showed an inflexion point in the curve at a weight corresponding approximately to $(NH_4)_6H_2W_{12}O_{40}\cdot H_2O$. The weight loss above 350°C was relatively slow.

Equilibration results.—The results of equilibration experiments with samples of AMT 12-15 in the Abderhalden drying apparatus are tabulated in Table III. The moles of water were calculated from the thermogravimetric data. A change in structure to the AMT 2-6 form was observed at temperatures from 55° to 91°C with water contents which varied from 1.8 to 5.6 moles of H_2O per mole of $(NH_4)_6H_2W_{12}O_{40}$. A fourth pattern, designated AMT-1, was found on the sample equilibrated at 75°C for 168 hr, which had a H_2O content of 1.1 moles. This latter form is undoubtedly the monohydrate, $(NH_4)_6H_2W_{12}O_{40}\cdot H_2O$ whose presence was indicated by the inflexion point on several TGA curves (see, for example, Fig. 2).

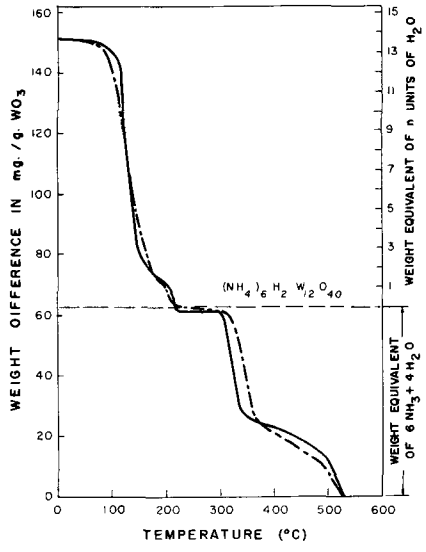

Fig. 2. Thermogravimetric analyses of ammonium metatungstate: solid line, covered crucible technique; dotted line, uncovered crucible.

The sample equilibrated at 91°C for 120 hr and all samples equilibrated at higher temperatures (115°, 150°, and 200°C) in the Abderhalden apparatus were essentially nonhydrated and displayed a common pattern, designated AMT-0, which is characteristic of unhydrated ammonium metatungstate, *i.e.*, $(NH_4)_6H_2W_{12}O_{40}$. The wide region of temperature stability of this unhydrated form is in agreement with the observance of a region of negligible weight loss on the TGA curves at a weight corresponding to the compound $(NH_4)_6H_2W_{12}O_{40}$. This AMT-0 form was very easily hydrated as evidenced by the fact that, if left in the normally humid atmosphere of the laboratory, it hydrated at room temperature changing from AMT-0 to AMT-1 and finally to AMT 2-6, as shown by several series of x-ray experiments.

Above 250°C anhydrous $(NH_4)_6H_2W_{12}O_{40}$ decomposed rapidly to a material of variable composition with respect to both water and ammonia. The x-ray diffraction pattern of this material is designated as X, since it could not be identified as any of the known oxides of tungsten. The pattern was identical to that of material formed at high temperatures from ammonium paratungstates. Finally, at 450°C ammonium metatungstate was completely transformed to tungsten trioxide.

The results are readily seen by a plot of NH_3 and total H_2O content *vs.* temperature of equilibration (Fig. 3). The NH_3 contents were essentially independent of time of equilibration, and therefore average values were calculated (Table III) and used (Fig. 3). On the other hand, the H_2O contents were dependent on time indicating that none of the data represent true equilibrium. It is apparent that from room temperature up to 250°C the NH_3 content is essentially constant at $6NH_3$ per $12WO_3$, de-

creasing only slightly with temperature. The water content, however, decreases steadily with increasing temperature approaching a value of $4H_2O$ per $12WO_3$, which is characteristic of the anhydrous metatungstate $(NH_4)_6H_2W_{12}O_{40}$. Since only three waters are contributed from the six ammonium ions and oxygen, the fourth must be associated with the metatungstate ion itself. Thus the association of two hydrogens with the metatungstate ion is found with the ammonium metatungstates as well as the alkali metal metatungstates (8). A further corroboration of this conclusion and an indication of the tenacity with which that one water is bound are indicated by the fact that when the anhydrous form starts to decompose above 250°C it still retains the one molecule of water up to 400°C until WO_3 is formed.

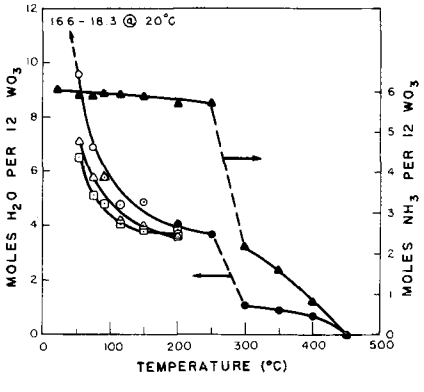

Fig. 3. Water and ammonia content of ammonium metatungstate as a function of equilibration temperature. Equilibrated in Abderhalden apparatus for 24 hr (○), 72 hr (△) and 128 hr (□); equilibrated 24 hr on Stanton thermobalance (●); average ammonia values (▲).

The analytical results as illustrated by Fig. 3 suggest that the water content of the hydrated metatungstates is zeolitic, *i.e.*, the amount of water associated with the structure varies continuously with temperature and relative humidity. Such a finding would be in agreement with Schott and Harzdorf (8). However, evidence for a lattice transition in the anion at 75°C, postulated by them was not observed from the water content *vs.* temperature curve (Fig. 3), although the x-ray data of Table III indicate the possibility of a transition from AMT 2-6 to AMT-1 at that temperature.

These results suggest a fixed anionic structure into which water molecules may be absorbed continuously depending on the relative vapor pressure. Such a model is consistent with the findings of Spitsyn and co-workers (12) who reported no change in the structure of the metatungstate ion or in the coordination of water in a study of the infrared absorption spectra of sodium metatungstates.

The model suggesting zeolitic water is not consistent, however, with the detection of specific x-ray diffraction patterns as a function of water content as found herein or with the existence of specific hydrates of sodium metatungstates reported in the earlier paper (9) by Spitsyn and co-workers. It is suggested that different hydrates of ammonium metatungstate exist and are readily transformed into one another depending on the relative water vapor pressure. The transitions between hydrates proceed so readily, however, that the water content varies continuously with temperature or relative humidity behaving in a manner suggestive of zeolitic water.

Theoretical Analysis of Current Distribution in Porous Electrodes

John S. Newman and Charles W. Tobias

Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

General equations describing the behavior of porous electrodes are developed. These equations are used to determine the initial and the steady-state conditions in one-dimensional porous electrodes of uniform geometry and polarization parameters. In particular, it is shown that the current and reaction distributions in the depth of the electrode are strongly influenced by the type of activation polarization and by mass transport of the reacting ionic species, in addition to the effective conductivities of the two phases. It is found that a linear approximation to a Tafel curve leads to an inadequate description of actual behavior when the reaction is distributed nonuniformly in the depth of the electrode.

A simple electrode has a well-defined interface between the metal electrode and the adjacent electrolytic solution, and the electrode reaction is restricted to this interface, which is often a plane surface. A large class of industrially important electrochemical reactions, however, involves the use of electrodes consisting of porous matrices of a single reactive electronic conductor, or mixtures of solids which include essentially nonconducting, reactive materials in addition to inactive electronic conductors. An electrolytic solution penetrates the void spaces of the porous matrix. This paper is restricted to cases where this penetration by electrolyte is complete or nearly complete. Thus the results are not directly applicable when the penetration by electrolyte is deliberately kept partial, as in most fuel-cell electrodes where the electrode reaction occurs mainly at the three-phase contact between the solid electrode, the electrolyte, and a gaseous reactant.

Relative to solid electrodes, porous electrodes provide much larger contact areas per unit volume between electrolyte, solid (or gaseous) reactant, and electronic conductor. Their use is widespread in primary and secondary batteries and in continuous-feed galvanic cells. At any given time, there will be a large range of reaction rates within the pores. The distribution of these rates will depend on physical structure, conductivity of the matrix and of the electrolyte, and on parameters characterizing overpotential phenomena (1). In galvanic cells this rate distribution directly influences the net power available for external use. A rational understanding of the processes that determine the distribution of reaction rates within porous electrodes is therefore of prime importance, basic to any design or optimization of electrochemical conversion or storage devices.

In order to perform a theoretical analysis of such a complex problem, it is necessary to establish a model which accounts for the essential features of an actual electrode without going into exact geometric detail. Further, the model should be described by parameters which can be obtained by suitably simply physical measurements. For example, a porous material of arbitrary, random structure can be characterized by its porosity, average surface area per unit volume, volume-average resistivity, etc. Similarly, one can use a volume-average resistivity to describe the electrolytic phase in the voids. A suitable model would involve averages of various variables over a region of the electrode small with respect to the over-all dimensions but large compared to the pore structure. In such a model, rates of reactions in the pores will have to be defined in terms of transferred current per unit volume.

Analyses of this type have been developed by Euler and Nonnenmacher (1) and by Ksenzhek and Stender (2). Euler and Nonnenmacher considered the case of a porous electrode flooded with electrolyte and backed by a solid metallic conductor of negligible resistivity (Fig. 1). Solving the equations for a one-dimensional field, uniform concentration, and an assumed linear polarization, these authors showed that, depending on the relative conductivities of the two phases, the current tends to

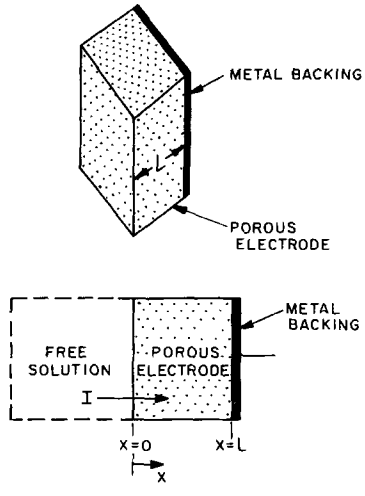

Fig. 1. One-dimensional porous electrode

pass from one phase to the other preferentially near the electrolyte-electrode interface or the electrode-metal backing interface. Although these conclusions represent a significant step forward in our understanding the phenomena occurring in porous electrodes, the model does not adequately resemble real systems. Except in regions of low overpotential, linear polarization is an unrealistic assumption if there is a large range of current densities, that is, if the reaction distribution is quite nonuniform, and, furthermore, concentrations of reacting species may not be regarded as constant except at the instant of closing the circuit.

We next present a general model of porous electrodes which reduces to that of Euler and Nonnenmacher as a special case. However, the subsequent application of the general model takes into account Tafel-type polarization and incorporates concentration variations caused by the charge transfer across phase boundaries.

Macroscopic Description of Porous Electrodes

In this macroscopic treatment of porous electrodes, we shall disregard the actual geometric detail of the pores. The model is an extension of the concepts of conventional electrochemical systems, specifically those of transport phenomena in electrolytic solutions and of the kinetics of electrode reactions. Thus we can define a potential in the solid matrix material, Φ_1, and another in the pore-filling electrolyte, Φ_2. Similarly, two current densities may be defined: $\bar{i}_1$ referring to the current density in the matrix phase and $\bar{i}_2$ to the one in the pore-electrolyte. These current densities will be referred to the projected area of the electrode, rather than to the areas of the individual phases. The flux $\bar{N}_i$ and the concentration C_i of a species will also be expressed relative to this superficial area and to the over-all unit volume of the electrode, respectively. The quantities enumerated are assumed to be continuous functions of time and space coordinates.

The set of equations describing the changes occurring during the passage of current in the porous electrode are as follows:[1]

We apply Ohm's law to the matrix

$$\bar{i}_1 = -\sigma \nabla \Phi_1 \qquad [1]$$

The flux of a mobile ionic species is due to migration, diffusion, and convection

$$\bar{N}_i = -z_i U_i e C_i \nabla \Phi_2 - D_i \nabla C_i + \bar{v} C_i \qquad [2]$$

The fluxes of charged species, when appropriately summed, yield an expression for the current density in the pores

$$\bar{i}_2 = \mathbf{F} \sum_i z_i \bar{N}_i \qquad [3]$$

For expressing the electrochemical reaction occurring in the electrode, we adopt the convention

$$\sum_i s_i M_i^{z_i} \rightarrow n e^- \qquad [4]$$

where s_i may be called the stoichiometric coefficient of species i. Then the conservation law for species i becomes

$$\frac{\partial C_i}{\partial t} = -\nabla \cdot \bar{N}_i + \frac{s_i}{n\mathbf{F}} \nabla \cdot \bar{i}_1 \qquad [5]$$

This equation states that the concentration can change at a point because the species moves away from the point (divergence of the flux $\bar{N}_i$) or because the species is involved in the electrochemical reaction (since $\nabla \cdot \bar{i}_1$ is proportional to the rate of the electrode reaction). We make the reasonable assumption of electroneutrality

$$\sum_i z_i C_i = 0 \qquad [6]$$

The polarization equation

$$\nabla \cdot \bar{i}_1 = af(\Phi_1 - \Phi_2, C_i) \qquad [7]$$

is necessary to express the dependence of the local rate of reaction on the various concentrations and on the potential jump at the matrix-solution interface. This equation, as written, really doesn't help us very much. The appropriate analytic expression depends on the particular chemical system and reaction mechanism involved, and the reader is referred to the specialized literature (3) for details. Since our purpose is not to consider the problems of electrode kinetics in detail, we seek a specific polarization equation which indicates expected behavior and is sufficiently general to cover many cases of practical interest. As an example, we may write

$$\nabla \cdot \bar{i}_1 = a i_o \left[\frac{C_1}{C_1^\circ} \exp\left\{ -\frac{\alpha n \mathbf{F}}{RT} (\Phi_1 - \Phi_2) \right\} - \frac{C_2}{C_2^\circ} \exp\left\{ \frac{(1-\alpha) n \mathbf{F}}{RT} (\Phi_1 - \Phi_2) \right\} \right] \qquad [8]$$

for an "oxidation-reduction" reaction. Here, the forward and reverse reactions are first order with respect to the reactant and product and depend exponentially on the matrix-solution potential jump.

Finally, the equation of conservation of charge is

$$\nabla \cdot \bar{i}_1 + \nabla \cdot \bar{i}_2 = 0 \qquad [9]$$

It should be noted that Eq. [1] to [7] are sufficient to describe the porous electrode, if $\bar{v}$ is specified. Equation [9] can be derived from the preceding equations. However, one may occasionally wish to abandon the assumption of electroneutrality, in which case Eq. [9] should be retained.

Application to One-Dimensional Porous Electrodes

In the following analysis, we consider a one-dimensional porous electrode (Fig. 1), bounded on one side by a metal "electron collector" and on the other by a free electrolytic solution. By "one dimensional" we mean that quantities such as potentials, current densities, and concentrations vary only with depth within the electrode and not with lateral position. This is a worthwhile simplification since it yields results indicative of the general behavior of porous electrodes and since many practical porous electrodes have this geometry.

[1] These equations have been written in vector notation for generality and for brevity.

We shall assume that the shape characteristics and volume percentage of pores are uniform throughout the thickness of the electrode and that the fluid velocity $\bar{v}$ is zero in the electrode. Furthermore, the problems will be posed in such a way that time does not enter in an explicit manner.

Concentration-Independent Polarization Equation

Ordinarily the concentration of species in the pore electrolyte will depend on the position, x, in the electrode. Let us first consider the conditions at the instant of closing the circuit so that the concentrations are uniform and have not had time to change. Then, Eq. [2] becomes

$$\bar{i}_2 = -\kappa \nabla \Phi_2$$

where

$$\kappa = \mathbf{F}e \sum_i z_i^2 U_i C_i$$

is the effective conductivity of the pore electrolyte and is constant. Since the concentrations have been assumed uniform, the polarization equation is essentially independent of concentration, and we may write the problem in one dimension as

$$i_2 = -\kappa \frac{d\Phi_2}{dx}, \quad i_1 = -\sigma \frac{d\Phi_1}{dx}, \quad \frac{di_1}{dx} + \frac{di_2}{dx} = 0, \qquad [10, 11, 12]$$

$$\frac{di_1}{dx} = af(\Phi_1 - \Phi_2) \qquad [13]$$

Here the subscript, x, for components of vector quantities has been omitted. The following boundary conditions are suggested.

At $x = 0, i_2 = I, i_1 = 0, \Phi_2 = 0.$

At $x = L, i_2 = 0.$

These state that at the electrode-solution interface the current is carried entirely by the pore electrolyte while at the metal backing, the current is carried entirely by the matrix. As an arbitrary reference of potential, we choose $\Phi_2 = 0$ at $x = 0$. Somewhere inside the electrode, between $x = 0$ and $x = L$, the current is transferred from the solution to the matrix, and the local rate of the reaction is proportional to di_1/dx.

This problem may be solved analytically for either a linear or a Tafel polarization equation. For Tafel polarization, Eq. [8] becomes in the anodic case ($I < 0$)

$$\frac{di_2}{dx} = ai_o \exp\{\beta(\Phi_1 - \Phi_2)\} \qquad [14]$$

where

$$\beta = (1-\alpha)\frac{n\mathbf{F}}{RT}$$

The cathodic case $I > 0$ can be handled in a completely analogous fashion. By integrating Eq. [12], differentiating Eq. [14], and eliminating Φ_1, Φ_2, and i_2, one obtains

$$\frac{d^2 i_1}{dx^2} = \frac{di_1}{dx}\beta\left[\frac{I}{\kappa} - i_1\left(\frac{1}{\kappa} + \frac{1}{\sigma}\right)\right] \qquad [15]$$

Upon the introduction of the quantities

$$y = \frac{x}{L}, \quad j = \frac{i_1}{I}, \quad \delta = L|I|\beta\left(\frac{1}{\kappa} + \frac{1}{\sigma}\right), \text{ and } \epsilon = \frac{L|I|\beta}{\kappa}$$

a dimensionless, nonlinear differential equation for the current is finally obtained,

$$\boxed{\frac{d^2 j}{dy^2} = \frac{dj}{dy}(\delta j - \epsilon)} \qquad [16]$$

with the boundary conditions

$$j = 0 \text{ at } y = 0 \text{ and } j = 1 \text{ at } y = 1.$$

Since the variable y does not appear in this equation, the latter can be reduced to a first-order equation by introducing

$$p = \frac{dj}{dy}, \text{ so that } \frac{d^2 j}{dy^2} = p\frac{dp}{dj}$$

Then, the first integration is straightforward, and the second integration, somewhat more involved, may be found in standard mathematical tables. The solution is

$$j = \frac{\tan(\theta y - \psi) + \tan\psi}{\tan(\theta - \psi) + \tan\psi} = \frac{2\theta}{\delta}\tan(\theta y - \psi) + \frac{\epsilon}{\delta} \qquad [17]$$

where

$$\tan\theta = \frac{2\delta\theta}{4\theta^2 - \epsilon(\delta - \epsilon)} \text{ and } \tan\psi = \frac{\epsilon}{2\theta}$$

The integration constants θ and ψ cannot be simply related to the parameters δ and ϵ but must be calculated by a trial and error procedure. For a finite current density in the electrode, $0 < \theta < \pi$.

The dimensionless reaction rate is found to be

$$\frac{dj}{dy} = \frac{2\theta^2}{\delta}\sec^2(\theta y - \psi) \qquad [18]$$

and the potential of the metal backing plate is

$$\beta\Phi_1(L) = (\delta - \epsilon)\left[\frac{\epsilon}{\delta} + \frac{2}{\delta}\ln\sec(\theta - \psi)\right] + \frac{2\epsilon}{\delta}\ln\sec\psi + \ln\left(\frac{2|I|\theta^2}{ai_o L\delta}\right) \qquad [19]$$

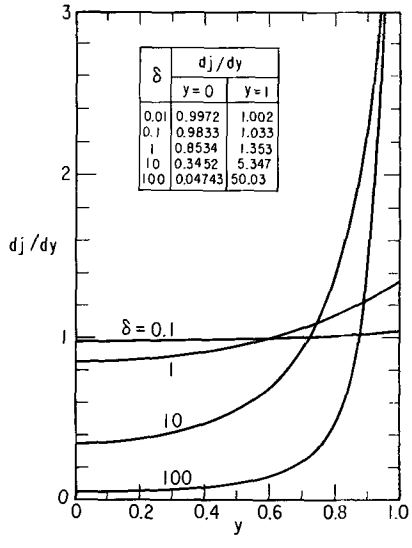

Fig. 2. Reduced current distributions for Tafel polarization with $\epsilon = 0$.

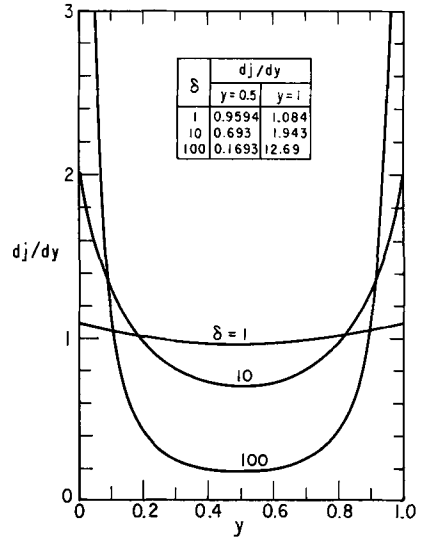

Fig. 3. Reduced current distributions for Tafel polarization with $\epsilon = \frac{1}{2}\delta$.

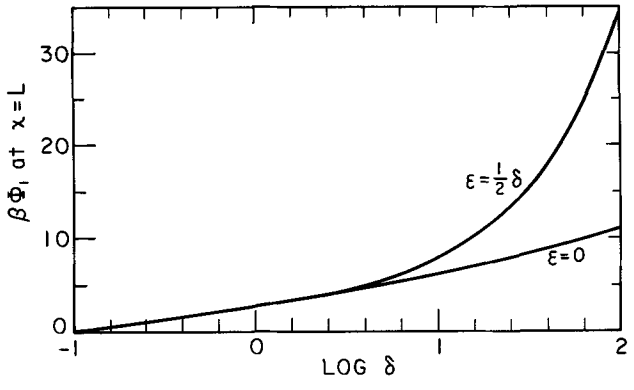

Fig. 4. Potential of the metal backing plate as it depends on δ

Figures 2 and 3 show the reduced reaction rate for $\epsilon = 0$ and $\epsilon = \frac{1}{2}\delta$, while Fig. 4 shows the potential of the metal backing plate when

$$\frac{2\kappa\sigma}{ai_oL\beta(\kappa+\sigma)} = 20$$

From the graphs, we see that for a small value of δ the reaction is uniform, but for large values of δ the reaction takes place mainly at the interfaces. Figure 4 corresponds to a Tafel polarization curve for a plane electrode since δ and ε are both proportional to $|I|$ at fixed thickness, conductivities, and other parameters. The ordinate actually represents the overpotential and should approach zero at small current densities. Instead it approaches ln $|I|/ai_oL$, reflecting the fact that, in using the Tafel polarization curve [14], we have dropped a term in Eq. [8]. This gives us a quantitative criterion for the applicability of the Tafel approximation in porous electrodes, $|I| > ai_oL$.

Euler and Nonnenmacher (4) have solved the constant concentration problem for a linear polarization equation. In this case, Eq. [13] becomes

$$\frac{di_2}{dx} = c\,(\Phi_1 - \Phi_2) \qquad [20]$$

where c is a constant. The solution for the current and the reaction rate is

$$\frac{i_2}{I} = \frac{\kappa}{\kappa+\sigma}\left[1 + \frac{\sigma/\kappa \sinh \nu(1-y) - \sinh \nu y}{\sinh \nu}\right] \qquad [21]$$

and

$$\frac{dj}{dy} = \frac{\nu\kappa}{(\kappa+\sigma)\sinh\nu}\left[\frac{\sigma}{\kappa}\cosh\nu(1-y) + \cosh\nu y\right] \qquad [22]$$

where

$$j = \frac{i_1}{I},\ y = \frac{x}{L},\ \nu = L\sqrt{c\,\frac{\kappa+\sigma}{\kappa\sigma}}$$

For small overpotentials or small current densities, both terms of Eq. [8] must be retained, but under this condition of low polarization, the equation may be linearized to give

$$\frac{di_2}{dx} = ai_o\frac{n\mathbf{F}}{RT}(\Phi_1 - \Phi_2)$$

so that

$$c = \frac{ai_on\mathbf{F}}{RT}$$

Thus, for $|I| < ai_oL$, the linear analysis is better than the Tafel analysis.

However, for $|I| > ai_oL$, the linear analysis requires linearization of the polarization equation. Thus the parameter c is a function of the over-all current density, $c = c(I)$. In order to find the connection between the two models, it is necessary to choose the point about which the Tafel equation is to be linearized. If we choose the midpoint between the extreme rates of reaction (as predicted by the Tafel analysis), we obtain

$$\nu = \theta\sqrt{1+\sec^2(\theta-\psi)} \quad \text{if } \epsilon \leq \tfrac{1}{2}\delta$$

$$\nu = \theta\sqrt{1+\sec^2\psi} \quad \text{if } \epsilon \geq \tfrac{1}{2}\delta$$

On the other hand, if we choose the average reaction rate, we obtain

$$\nu = \sqrt{\delta}$$

The results of the two models are compared in Fig. 5 for $\delta = 2$, $\epsilon = 0.1$ and in Fig. 6 for $\delta = 20$, $\epsilon = 1$. A

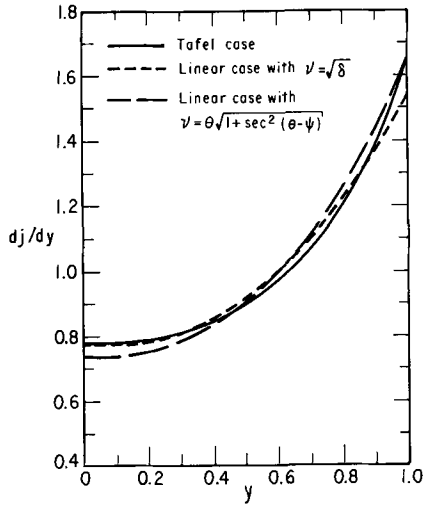

Fig. 5. Comparison of linear and Tafel results for $\delta = 2$, $\epsilon = 0.1$.

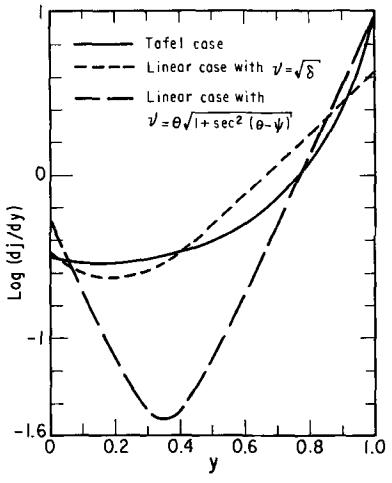

Fig. 6. Comparison of linear and Tafel results for $\delta = 20$, $\epsilon = 1$.

straight line can approximate a curve well over only a short distance compared with the curvature. Therefore the linear case would serve quite adequately where the reaction rate is fairly uniform through the porous electrode. But in Fig. 6 the reaction rate varies by a factor of about 33, and the linear model is not a very good approximation (note the logarithmic ordinate).

Effect of Concentration Variation

The previous analytic results have been obtained by considering concentrations to be constant. Qualitatively, the effect of variations of concentration of the electrolyte would be expected to be the following: The species which react will become depleted in the electrode; this will have the effect of shifting the reaction zone toward the electrode-solution interface where the concentration of the reacting species is greater. With some approximations we may obtain a more quantitative idea of the effect of concentration.

We again consider the one-dimensional, steady-state system described above, and we ignore the structural changes in the electrode as the reaction proceeds. Let us say that the reaction is

$$M_1^{z_1} + ne^- \rightarrow M_2^{z_2}$$

so that $I > 0$. Then we may write the polarization Eq. [8] as

$$\frac{di_1}{dx} = ai_o \frac{C_1}{C_1^\circ} \exp\{-\beta(\Phi_1 - \Phi_2)\} \qquad [23]$$

where $\beta = \alpha n\mathbf{F}/RT$. From the more complete polarization equation we have selected the more important term, both because di_1/dx is positive and because this term contains the concentration of the critical species. We shall assume that the conductivity of the pore electrolyte is unaffected by the concentration of the reacting species. This assumption is well approximated when a large excess of supporting electrolyte is present.

If we neglect ionic migration for the reacting species, then Eq. [2] gives

$$N_1 = -D_1 \frac{dC_1}{dx} \qquad [24]$$

and the continuity Eq. [5] becomes

$$D_1 \frac{d^2C_1}{dx^2} = \frac{1}{n\mathbf{F}} \frac{di_1}{dx} \qquad [25]$$

In addition, we need Eq. [10], [11], and [12]. The boundary conditions are

$$\text{at } x = 0,\ i_1 = 0,\ i_2 = I,\ \Phi_2 = 0,\ C_1 = C_1^\circ$$
$$\text{at } x = L,\ i_2 = 0,\ dC_1/dx = 0$$

The two new boundary conditions on the concentration state that at the solution-electrode interface, the concentration is maintained constant, while at the metal backing the flux is zero. By integrating Eq. [12] and [25], differentiating Eq. [23], eliminating i_2, Φ_1 and Φ_2, and introducing the additional dimensionless quantities

$$\xi = \frac{C_1}{C_1^\circ}, \quad \gamma = \frac{|I|L}{n\mathbf{F}D_1C_1^\circ}$$

we obtain

$$\boxed{\frac{d^2j}{dy^2} = \frac{dj}{dy}\left(\delta j - \epsilon + \frac{d\ln\xi}{dy}\right), \quad \frac{d\xi}{dy} = \gamma(j-1)} \qquad [26], [27]$$

with boundary conditions

$$\text{at } y = 0,\ j = 0,\ \xi = 1, \text{ and at } y = 1,\ j = 1.$$

An exact solution to this problem has not been obtained. Instead, as a first approximation we let

$$\xi^\circ = e^{-Ay} \qquad [28]$$

This reduces Eq. [26] to the form of Eq. [16], which we have already solved. Then Eq. [27] is used to obtain a second approximation for ξ and to select the best value of A. This was done by requiring that the average concentration in the electrode be the same for the two approximations. This is a somewhat involved calculation, for which we shall not give the details here (5). The effect of concentration variations is shown in Fig. 7 for $\delta = 2$, $\epsilon = 0.1$. The results in the form of dj/dy and ξ are given for $\gamma = 1$ and $\gamma = 2.8$, while the corresponding results

for $\gamma = 0$ have already been presented in Fig. 5. Indeed, we see that the depletion effect does shift the reaction toward the electrode-solution interface. Table I shows how the approximate results compare with a numerical solution of Eq. [26] and [27], in the case $\gamma = 1$. This approximation probably becomes less accurate at higher values of γ.

Deposition from a Binary Electrolyte

A problem involving deposition from a binary electrolyte can be handled in a manner similar to that of the preceding section. From the treatment of the binary electrolyte in an electrolytic solution (6), we can expect some simplification here. This manifests itself in two ways. It is not necessary to assume that the conductivity of the electrolyte is constant, and migration of the reacting species can be accounted for. The assumptions which are retained are that one term of the exponential polarization equation is sufficient and that the approximate method of solution used in the last section is accurate enough. Although the diffusion coefficients and transference numbers vary with concentration, they are taken to be constant in the following treatment.

The electrode reaction may be written

$$M_+^{z+} + ne^- \rightarrow M_o^\circ$$

When the solution concentration

$$C = -\frac{C_+}{z_-} = \frac{C_-}{z_+}$$

is used, the equations describing the binary electrolyte in the porous electrode are

$$\overline{N_+} = z_+z_-U_+eC\nabla\Phi_2 + z_-D_+\nabla C$$

$$\overline{N_-} = -z_-z_+U_-eC\nabla\Phi_2 - z_+D_-\nabla C$$

$$\frac{\bar{i}_2}{z_+z_-\mathbf{F}} = (z_+U_+ - z_-U_-)eC\nabla\Phi_2 + (D_+ - D_-)\nabla C \quad [29]$$

$$\frac{\partial C}{\partial t} = D\nabla^2 C - \frac{t_-}{z_+z_-\mathbf{F}}\nabla\cdot\bar{i}_2 \quad [30]$$

where

$$D = \frac{z_+U_+D_- - z_-U_-D_+}{z_+U_+ - z_-U_-} \quad \text{and} \quad t_- = \frac{-z_-U_-}{z_+U_+ - z_-U_-}$$

Now the one dimensional, steady-state problem becomes

$$D\frac{d^2C}{dx^2} = \frac{t_-}{z_+z_-\mathbf{F}}\frac{di_2}{dx} \quad [31]$$

$$\frac{i_2}{z_+z_-\mathbf{F}} = (z_+U_+ - z_-U_-)eC\frac{d\Phi_2}{dx} + (D_+ - D_-)\frac{dC}{dx} \quad [32]$$

$$i_1 = -\sigma\frac{d\Phi_1}{dx}. \quad \frac{di_1}{dx} + \frac{di_2}{dx} = 0 \quad [33], [34]$$

$$\frac{di_1}{dx} = ai_o\frac{C}{C^\circ}\exp\{-\beta(\Phi_1 - \Phi_2)\} \quad [35]$$

where $\beta = \alpha n\mathbf{F}/RT$ and where the second term in the polarization equation has been dropped ($I > 0$). The boundary conditions are

$$\text{at } x = 0,\ i_1 = 0,\ i_2 = I,\ C = C^\circ,\ \Phi_2 = 0$$

$$\text{and at } x = L,\ dC/dx = 0,\ i_2 = 0$$

The condition that dC/dx is zero at $x = L$ is implied by the requirements that $N_+ = N_- = 0$ at $x = L$.

By integrating Eq. [31] and substituting the result into Eq. [32], we obtain

$$\frac{d\Phi_2}{dx} = -\frac{D_-}{z_-U_-e}\frac{d\ln C}{dx} \quad \text{or} \quad \Phi_2 = -\frac{D_-}{z_-U_-e}\ln\frac{C}{C^\circ}$$

By integrating Eq. [34], differentiating Eq. [35], and eliminating i_2, Φ_1, and Φ_2, the problem is reduced to

$$\frac{d^2i_1}{dx^2} = \frac{di_1}{dx}\left[\frac{\beta}{\sigma}i_1 + \left(1 - \frac{D_-\beta}{z_-U_-e}\right)\frac{d\ln C}{dx}\right],$$

$$\frac{dC}{dx} = \frac{t_-}{z_+z_-\mathbf{F}D}(I - i_1)$$

By defining $j = i_1/I$, $\xi = C/C^\circ$, $y = x/L$, $\delta = \beta IL/\sigma$

$\epsilon = 1 - \dfrac{D_-\beta}{z_-U_-e}$, $\gamma = -\dfrac{t_-IL}{z_+z_-\mathbf{F}DC^\circ}$, one obtains

$$\frac{d^2j}{dy^2} = \frac{dj}{dy}\left[\delta j + \epsilon\frac{d\ln\xi}{dy}\right], \quad \frac{d\xi}{dy} = \gamma(j - 1) \quad [36], [37]$$

with boundary conditions

$$\text{at } y = 0,\ j = 0,\ \xi = 1, \text{ and at } y = 1,\ j = 1.$$

This binary electrolyte problem is similar to problems treated earlier. We can obtain an approximate solution by assuming that

$$\xi = e^{-Ay}$$

Then with $f = \epsilon A/\delta$ we have

$$\frac{d^2j}{dy^2} = \frac{dj}{dy}[\delta j - \epsilon A] = \delta(j - f)\frac{dj}{dy} \quad [38]$$

whose solution has been discussed before. The adjustment of A will not be significantly different.

Although this problem has been stated in terms of deposition processes, the binary electrolyte treatment applies to many reactions occurring in batteries. For example, in the lead-acid battery, lead sulfate is quite insoluble and the electrolyte is essen-

tially a solution of sulfuric acid in water, *i.e.*, a binary electrolyte.

Limitations and Interpretation of the Basic Equations

For a plane electrode, the electrode reaction is restricted to the plane interface between the metal and the solution. In a porous electrode, on the other hand, the interface between the solid and the solution is not so simple, but extends throughout the depth of the electrode. Thus one is interested in the rate of reaction per unit volume rather than the rate of reaction per unit of surface area. To be sure, there is still a well-defined interface between the solution and the solid, but now the geometry is quite complicated.

One might begin an analysis of porous electrodes with exact considerations of this geometry. This would become extremely complicated, necessitating crude approximations, and one would probably be forced to consider several specific geometrical arrangements. This could be designated a microscopic approach. Another point of view has been adopted here. In order to obtain results which might be of practical significance, a model is proposed which describes the macroscopic features of porous electrodes. It represents, then, some average over the random and complicated geometry of the porous electrode. Accordingly, it contains parameters which are difficult to predict, but which could perhaps be estimated satisfactorily from a more detailed consideration of a specific system or more likely from some cleverly devised experimental methods. (Among such parameters we find σ, D_i, and U_i, which are the effective conductivity of the matrix material and the effective diffusion coefficients and mobilities of species in the pore electrolyte. Also there are the parameters in the polarization equation.)

Thus, the equations presented at the beginning of this paper should describe reasonably well the macroscopic features of a porous electrode in which there is no gas evolution. This model assumes that, while the porous electrode consists of two phases, it may be described by a combination of equations which treat the porous electrode as a continuum or a superposition of two continua. The microstructure of the electrode is assumed to be sufficiently fine that the various functions, such as the potentials, may be considered to be continuous. If, on a microscopic level, one were in a particular phase, the corresponding potential would be assumed to exist there, so that the actual variation of potential across a pore is not described. This means that the length of a pore is assumed to be long compared to its diameter. The superficial current densities and species fluxes must be corrected for the areas involved in order to obtain the current density or flux in a particular phase. The concentrations must be corrected for the volumes involved, but, as with the potential, concentration variations across the diameter of a pore are not accounted for. From this, we should expect the model to fail when a length characteristic of the microstructure, say the diameter of a pore or of a matrix particle, becomes comparable to a length characteristic of the size of the electrode, say its thickness.

Let us interject a few comments here about the structure of the general Eq. [1] to [9]. Equation [1] describes the matrix phase while Eq. [2], [3], and [6] describe the solution phase. Equations [7] and [9] represent boundary conditions between the phases, although Eq. [9] can be derived from the preceding equations, just as, in the case of a free electrolytic solution, the analogous equation $\nabla \cdot \bar{i} = 0$ follows from the electroneutrality assumption. Equation [5] describes the solution phase, but, while in a free electrolytic solution the bulk production of a species is normally zero, here we have a term from the electrode reaction. It is interesting that relationships like Eq. [7] and [9] are no longer boundary conditions, but, in the macroscopic model, apply throughout the volume of the electrode.

We shall now cite some limitations of the model. There is no consideration of the capacitive effects of the double layer, which means that certain time dependent processes, such as alternating current behavior and interruptor techniques, may not be accurately explained by the model.

More serious is the failure to discuss the complicated phenomena in the solid phase. In the discharge of a battery, the reactant is consumed, products may be deposited, and there are changes in the structure and properties of the electrode. The framework of Eq. [1] to [9] is sufficiently general to describe such processes. The amount of nonmobile reactants and products is already given by the continuity equation. The parameters in the polarization equation and in Eq. [1] and [2] will depend in some complicated way on the local electrode structure or, equivalently, on the local extent of reaction. Before we can satisfactorily predict the discharge curves of batteries, we must obtain a better understanding of this dependence and of the phenomena occurring. It is already quite difficult to determine the values of these parameters at the beginning of the discharge.

Thus, the special cases considered earlier were idealized. The first could apply to any uniform electrode at the beginning of discharge. That involving concentration effects corresponds to the steady state of a redox reaction in a porous metal. The results do not apply strictly to a primary or storage battery since no steady state is possible in these cases.

Finally we should note that Eq. [1] to [9] are limited to dilute solutions of the reactant in the electrolyte phase. In the special cases we have set $\bar{v} = 0$ which would not be the case if there were an appreciable flux of the reactant. In more concentrated solutions we must be more careful in defining the "mass average" velocity. We may also note that fuel cells often use porous electrodes. In one type, a gaseous fuel is dissolved in the electrolytic solution, which is then forced to circulate through the electrode. Here, of course, we should not set $\bar{v} = 0$. If the circulation is sufficiently rapid, concentrations may be uniform through the electrode, and the first special case would apply.

Discussion

Let us now consider the more positive significance of the results obtained. In general, the reaction rate

is not uniformly distributed in the electrode. In fact, with no polarization, that is, when $\Phi_1 - \Phi_2$ is independent of $\nabla \cdot \bar{i}_2$ and of the concentrations, the reaction occurs only at the surfaces of the electrode and is divided between the two interfaces according to the ratio of the effective conductivities of the two phases. Thus, the reaction rate at the electrode-solution interface is $I\sigma/(\kappa + \sigma)$. In this limiting case, the current entering the electrode immediately distributes itself between the phases so that the ohmic drop is the same in each phase.

The effect of polarization is to distribute the reaction more uniformly through the electrode. In the absence of concentration effects, the nonuniformity of the reaction distribution is determined by the parameter $\delta = L|I|\beta(1/\kappa + 1/\sigma)$ for the Tafel case. Increasing the value of this parameter increases the nonuniformity. An interesting feature of this Tafel analysis is that the reaction distribution is independent of the exchange current density i_o and of the specific interfacial area a.

In order to investigate the limit approached at low current densities, it is necessary to use the linear analysis. Here the nonuniformity of the reaction increases with increasing values of the parameter

$$\nu^2 = L^2 c \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right)$$

The linearization of the polarization equation in this region yields

$$c = \frac{a i_o n \mathbf{F}}{RT}$$

or

$$\nu^2 = \frac{L^2 a i_o n \mathbf{F}}{RT} \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right)$$

Now, in the Tafel range we found that the relationship between the parameters of nonuniformity could be expressed as

$$\nu^2 = \delta$$

and since $|I| > a i_o L$ in the Tafel range, we find

$$\nu^2 > L^2 a i_o \beta \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right) \approx \frac{\alpha L^2 a i_o n \mathbf{F}}{RT} \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right)$$

Closer analysis reveals that the reaction distribution is the most uniform when

$$I \approx a i_o L \frac{1 - 2\alpha}{\alpha^{2\alpha} (1 - \alpha)^{(2-2\alpha)}}$$

In this way, we can arrive at a fairly general conclusion. For uniform concentration, the reaction distribution becomes less uniform as one increases the magnitude of the current density, the thickness of the electrode, or the sum of the effective resistivities of the two phases, but the point of most uniform distribution will not occur at zero current unless $\alpha = \frac{1}{2}$.

Mass transport of a reacting mobile species has a significant effect on the steady-state reaction distribution. In the analysis given here, this effect is measured by the value of the additional parameter

$$\gamma = \frac{|I|L}{n\mathbf{F}D_1 C_1^o}$$

which indicates the magnitude of the consumption rate relative to the mass-transfer rate. Here we conclude that the steady-state reaction distribution will be shifted more or less strongly toward the electrode-solution interface as a result of hindered movement of the reactant. The generality of this conclusion is indicated by the following considerations: For a redox reaction, reversing the current means that the other species will become critical, and the other term in the polarization equation will be retained. We have shown that this conclusion holds for deposition, while, for dissolution, the higher concentration will suppress the reaction in the depth of the electrode. However, the effect will be small compared to the cathodic case and would not show up in the Tafel analysis since we retain the other term of the polarization equation.

There are many problems which must still be solved. For a given system it is necessary to determine the parameters in the porous-electrode models. Euler and Nonnenmacher (1) have indicated procedures for measuring several of these. Methods of experimental measurement and theoretical prediction of these parameters should be improved.

Experimental verification of porous-electrode analyses will be attempted in this laboratory. There are great difficulties, but a direct determination of current distribution by using sectioned electrodes shows promise. Some quite crude measurements of this type have been made by Coleman (7). It should also be mentioned that Daniel'-Bek (8) has tried to measure potential distributions in porous electrodes by using probes. However, these probes destroy the pore structure and would require a double differentiation of experimental data in order to obtain the reaction distribution.

In this laboratory, the validity of the macroscopic approach will also be tested theoretically and experimentally by considering models of the pores themselves.

Another important area for further work is in transient phenomena, that is, the transition from the initial conditions to the steady state. It may be necessary to rely on numerical solutions here. However, approximations could yield useful analytic results. First note that time enters explicitly into only the continuity equation. In many cases this can be written as

$$\frac{\partial C}{\partial t} = D\nabla^2 C + B\nabla \cdot \bar{i}_2 \qquad [39]$$

where $B = 1/n\mathbf{F}$ for the supporting electrolyte case.

$$B = \frac{1}{z_+ z_- \mathbf{F}} \left(t_+ + \frac{z_+ s_+}{n} \right)$$ for a binary electrolyte.

Thus the potential can often be removed from the continuity equation.

This equation is of the form of the heat conduction equation, which has been studied extensively in mathematical physics. Furthermore, the last term

representing sources or sinks is known initially and at steady state. Thus, since the total current density I is specified, it should be possible to guess a first approximation for the reaction distribution and to solve Eq. [39]. Then the potential across the electrode (and a second approximation to the reaction distribution) can be calculated for any particular time from the concentration distribution.

Finally, for practical systems it will be necessary to account for changes in the electrode properties as the reaction proceeds (see preceding section) and to combine the analytic description of detailed processes in order to allow the prediction of the dynamic performance of complete systems.

a	specific interfacial area per unit volume, cm^{-1}.
A	constant used in approximation to concentration distribution.
c	slope of polarization curve in linear model, mho/cm^3.
C_i	concentration of species i, g-mole/cm^3.
C_i°	reference concentration.
D	molecular diffusion coefficient of binary electrolyte.
D_i	diffusion coefficient of species i, cm^2/sec.
e	magnitude of the electronic charge, coulomb.
e^-	symbol for electron.
f	used to denote function in polarization equation.
F	Faraday's constant, coulomb/g-equivalent.
i_o	exchange current density in Tafel polarization, amp/cm^2.
$\bar{i}_1$	current density in matrix phase, amp/cm^2.
$\bar{i}_2$	current density in pore electrolyte, amp/cm^2.
I	over-all current density in one-dimensional porous electrode.
j	i_1/I.
L	thickness of one-dimensional porous electrode, cm.
M_i	symbol for chemical formula of species i.
n	number of electrons in equation for electrode reaction.
$\bar{N}_i$	flux of species i, g-mole/cm^2-sec.
R	universal gas constant, joule/mole-deg.
s_i	stoichiometric coefficient in equation for electrode reaction.
t	time, sec.
t_-	transference number of negative species in binary electrolyte.
T	temperature, degrees absolute.
U_i	mobility of species i, cm/sec-dyne or cm^2/m-sec-newton.
$\bar{v}$	fluid velocity, cm/sec.
x	distance through the one-dimensional porous electrode, cm.
y	x/L.
z_i	valence of species i.
α	transfer coefficient in Tafel polarization equation.
β	convenient reciprocal potential, *e.g.*, $\alpha n\mathbf{F}/RT$.
γ	$\lvert I\rvert L/n\mathbf{F}D_1C_1^\circ$ or $-t_-IL/z_+z_-\mathbf{F}DC^\circ$ for binary electrolyte.
δ	$\beta\lvert I\rvert L(\kappa+\sigma)/\kappa\sigma$ or $\beta IL/\sigma$ for binary electrolyte.
ϵ	$\beta\lvert I\rvert L/\kappa$ or $1 - D_-\beta/z_-U_-e$ for binary electrolyte.
θ	integration constant for Tafel polarization.
κ	conductivity of pore electrolyte, mho/cm.
ν	$L\sqrt{c(\kappa+\sigma)/\kappa\sigma}$ for linear polarization.
ξ	C_1/C_1°.
σ	conductivity of matrix, mho/cm.
ϕ_1	potential of matrix phase, volts.
ϕ_2	potential of pore electrolyte, volts.
ψ	integration constant for Tafel polarization.

Technical Notes

Feasibility of Electrolyte Regeneration in Al Batteries

S. Zaromb[1] and R. A. Foust, Jr.

Scientific Laboratory, Philco Corporation, Blue Bell, Pennsylvania

In a concurrent paper (1) an Al battery is discussed, based on the reaction

$$Al + \tfrac{3}{4}O_2 + OH^- + \tfrac{1}{4}H_2O \rightarrow Al(OH)_4^- \quad [1]$$

followed by an electrolyte regeneration reaction

$$Al(OH)_4^- \rightarrow Al(OH)_3\,(solid) + OH^- \quad [2]$$

The occurrence of reaction [2] at a sufficiently fast rate is, of course, an essential requirement for maintaining the electrolyte concentration within a satisfactory range over prolonged periods of heavy current drain.

Reaction [2] has already been studied exhaustively in connection with the Bayer process for the manufacture of purified Al_2O_3 for use in the production of Al (2-5). However, these experiments involved various fixed initial starting conditions (temperature, NaOH and $NaAl(OH)_4$ concentrations, and $Al(OH)_3$ seed surface) with the experiments completed upon decomposition of the excess concentration of $Al(OH)_4^-$ ions.

In Al-air batteries, on the other hand, the $Al(OH)_4^-$ ions are to be continuously replenished by reaction [1] and removed by reaction [2] over

[1] Present address: Research and Advanced Technology Department, Electronic Systems and Products Division, Martin-Marietta Corporation, Baltimore, Maryland.

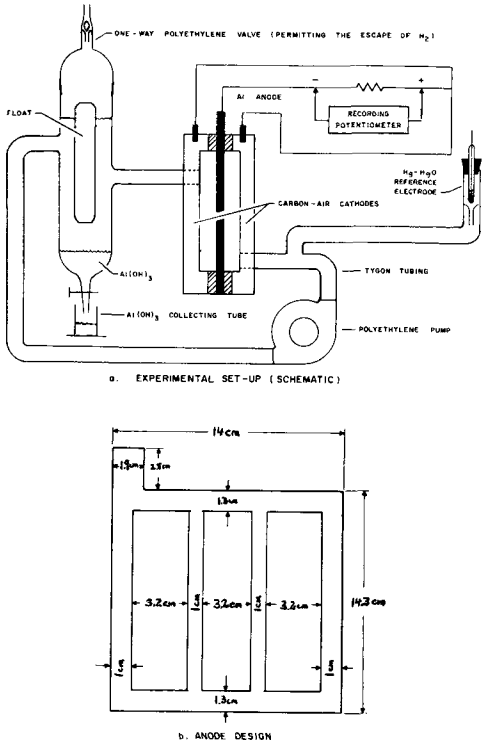

Fig. 1. Experimental setup for the electrolyte regeneration experiment. The cell components (cathodes, gaskets, and anode) were clamped together between two 0.6 cm steel plates (not shown).

long periods of time. These processes introduce a number of favorable and unfavorable factors.

Continuous current drain experiments aimed at proving spontaneous self-regeneration of the electrolyte had been impeded initially by accumulation of the $Al(OH)_3$ reaction product near the Al electrodes. The formation of this product is, in itself, a proof of the fast occurrence of the desired reaction [2]. However, to prove the feasibility of long lasting Al-air cells, it still remained necessary to achieve continuous satisfactory current and voltage outputs for longer periods of time. Utilizing an improved circulating and $Al(OH)_3$ collecting system, a steady current of about 2 amp (corresponding to a current density of at least 20 ma/cm^2) at approximately 1½v was withdrawn from an experimental cell for a period of 30 hr. Clogging of the anodes by the $Al(OH)_3$ product was again responsible for the subsequent decrease in current voltage outputs. This clogging was further reduced by the improved anode design and $Al(OH)_3$ collecting setup shown in Fig. 1 .

Finally, the feasibility of electrolyte regeneration was conclusively proved by a continuous current-drain experiment of more than 100-hr duration. The initial electrolyte consisted of 120 cc 3.0M KOH solution. The total current-drain amounted to more than 80 amp-hr (at around 1.5v and 20 ma/cm^2), which is equivalent to more than 3 times the discharge expected without electrolyte regeneration.

To make up for appreciable accidental losses of electrolyte at several stages of the experiment, a total of 330 cc of H_2O was added. This resulted in dilution of the remaining electrolyte to less than 0.5M total KOH. Nevertheless, appreciable current could still be drawn for a number of hours even with this low alkali concentration thanks to continuous circulation of the electrolyte. However, with the lowest alkali concentrations, a slow build-up of an adherent $Al(OH)_3$ layer at the anodes gradually reduced the current and voltage outputs to nearly zero. Addition of H_2O should therefore be confined to KOH concentrations exceeding 2-3M.

Silicon Dioxide as Dielectric in Solid Electrolyte Capacitors

W. Haas

Philco Scientific Laboratory, Blue Bell, Pennsylvania

The present work is a preliminary study of silicon as a new candidate as basic material for solid electrolyte capacitors. Such a capacitor consists of the following functioning parts: (*a*) an anode of silicon doped to achieve the necessary conductivity; (*b*) a film of silicon dioxide covering the anode and serving as dielectric; and (*c*) a coating of conducting MnO_2 (1), making contact over the outer surface of silicon dioxide. In order to produce the high capacity per unit volume which characterizes solid electrolyte capacitors, pellets of sintered silicon powder were used as anodes. Such structures provide the necessary large available surface area for dielectric and counterelectrode.

The dielectric is formed on the pellets by a step of thermal oxidation. This step, usually performed in moist O_2 at 1200°C for 16 min, produces an oxide about 1500Å thick, yielding a clear interference color. Silicon is capable of being oxidized anodically, but it is recognized that the thermally produced oxide is electrically superior (2).

Experimental

It was initially determined that the surface treatment of the silicon is of great importance in achiev-

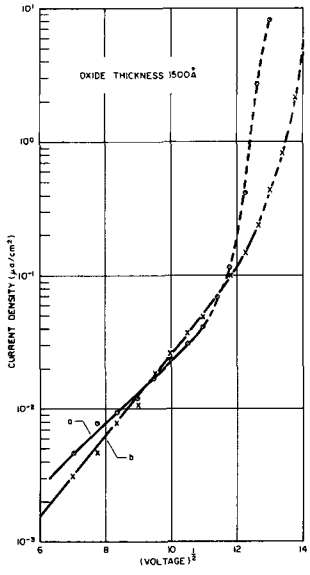

Fig. 1. I-V characteristics of an oxidized silicon crystal in NMA

ing high insulation resistance of a thermally grown oxide, and that the insulation resistance could be improved by anodically biasing the oxidized silicon in an electrolyte of NMA (a solution of 0.04*N* KNO_3 in N-methylacetamide (3).

The importance of the surface treatment is illustrated in Table I by the leakage values of the same silicon crystal (oxidized under the same conditions), first after a brief cleaning with acetone and then after an etch with 1:2 of $HF:HNO_3$.

In Table II, leakage values of a thermally oxidized silicon crystal (oxide thickness about 1500Å) after different lengths of time under bias are recorded along with the values obtained after 48 hr without bias. The insulation resistance was increased by a factor greater than 100 by the anodic bias.

The mechanism of this improvement is not clearly understood but we think that pores, channels, or fissures are plugged during the process. The oxide thickness does not increase under the chosen bias. If a sufficiently higher voltage is applied, the oxide starts to increase in thickness; at the same time, the current increases drastically, and luminescence of the anode can be observed in a darkened room.

As said before, the leakage current through thermal oxides decays under anodic bias. The precise effect of bias was illustrated on a polished crystal slab (n-type, 6 ohm-cm) covered with a thermal oxide of 1500Å thickness. After 2-hr bias at 150v in NMA, a I-V plot was taken (plot a, Fig. 1). The bias was varied by 10-v steps and current measured after 1 min. After a further hour bias at 200v a second I-V plot was recorded (plot b, Fig. 1). Clearly, the linear range on a log I *vs.* $\sqrt{V}$ plot extends to higher voltages as observed also with anodic oxides (3).

The absolute leakage values for silicon dioxide are, in fact, lower than leakage current densities reported for tantalum (4) and niobium (5) pentoxides at equal field strengths (Table III).

The leakage values depend to a certain extent on the testing electrolyte as already pointed out by Hand *et al.* (5); to illustrate this better we compared the I-V characteristics taken in NMA and in 10% H_3PO_4 of a silicon crystal which had been oxidized and subsequently biased for 30 min in NMA (Fig. 2).

It should be noted that the ratio of leakage values of silicon dioxide in H_3PO_4 and NMA is higher at lower voltages. This trend is still more pronounced on sintered pellets, as also shown in Fig. 2. For oxide thicknesses of 1500Å measurements had to be carried out below 200v in H_3PO_4 because of the onset of violent sparking at this voltage.

Planar Capacitors

Several sample capacitors were prepared on single crystal silicon wafers by thermal oxidation

and subsequent anodic bias at 150v in NMA. Manganese dioxide counterelectrodes were applied by pyrolysis of $Mn(NO_3)_2$, reformed in NMA, and capacitors were finished with Aquadag and silver paste. The area varied from 3-8 cm² (capacitance between 65-175 nf).

To achieve low leakage values, as said before, the preoxidation treatment is very important. In Fig. 3, line (a) illustrates the leakage values of a finished capacitor using a mechanically polished silicon crystal etched in HF for a short time; line (b) shows the leakage values of another sample, not previously polished, and only cleaned with acetone. Even though the values differ by a factor of 10, the slope of both lines is the same.

The capacitance of the finished samples corresponded to the values calculated from the oxide thickness. The dissipation factor of all capacitors was high (0.1 at 1000 cps) due to high series resistance of the silicon tabs. Low resistivity crystals only became available later and were used for the preparation of pellets.

Preliminary life tests still in progress show that a bias of 47v, at room temperature decreases the leakage current from ≈ 0.7 to ≈ 0.08 μa/μf after 500 hr.

Sintered Pellets

Silicon powder of mesh −100 +200 for the preparation of pellets was prepared from n-type silicon crystals (ρ = 0.006-0.010 ohm-cm). Using benzene as lubricant disks ¾ in. in diameter and ⅛ in. thick were pressed with a single-action single-punch press at 6.8 tsi. The green strength was just sufficient to allow careful handling. Each pellet was cut into smaller pieces of about ⅛ x ⅛ x ¼ in. Pellets were sintered in an argon atmosphere for 60 min at 1300°C or 1400°C. After sintering, the pellets had a density of ≈ 1.4 g/cc, *i.e.*, about 60% of the bulk value.

Since it was necessary to attach an integral lead to the pellets, as a first approach, tabs 1/16 x 1/16 x 1/2 in. were cut from crystals of the same type used for the powder preparation. These tabs were welded to the sintered pellet using an oxy-hydrogen flame.

The surface area of the pellets was calculated from the weight increase after oxidation since the oxide thickness was known approximately from its refraction index (1.46 for amorphous silica) and interference color. Values of about 1100 cm²/cm³ were obtained.

The wet capacitance measured in dilute H_2SO_4, however, was about 25% lower than expected from the calculated surface area and assumed oxide thickness.

It is possible that this discrepancy is explained by cumulative errors in the oxide thickness and small weight increases recorded. The possibility that the pores were incompletely contacted was ruled out by remeasuring the capacitance after removing any air bubbles by a low-pressure treatment.

After thermal oxidation, samples were biased at 125v and the leakage current allowed to decay at room temperature for 17 hr (Table IV). Leakage current characteristics were subsequently improved by the use of certain techniques prior to the thermal oxidation. Table V shows results obtained with two different cleaning techniques (A and B) and

28	6.5	A

* No treatment.

for comparison the results obtained at 150v with two nontreated pellets.

Technique A consisted in dipping the sintered pellets with silicon contact for 5-10 sec in a 2:1 mixture of HNO_3 and HF. The reaction is violent and rapidly reduces the size of the pellet. Technique B consisted in oxidizing the sintered pellet for 16 hr in air and removing the thick oxide with HF.

The average leakage value of chemically treated pellets was 5.9 $\mu a/\mu f$ at 150v against 113 $\mu a/\mu f$ at 125v for pellets described in Table IV. Leakage values could be further improved by the use of pellets prepared from powder etched in a mixture of 5% HF 95% HNO_3, prior to the sintering.

So far, we were only concerned with oxide thicknesses of 1500Å. Some pellets were oxidized for longer periods and, in consequence, voltages well over 400v could be applied in NMA without excessively high leakage currents. From capacitance *vs.* time measurements, we suspected, however, that the oxidation did not proceed uniformly throughout the pellet. This suspicion was confirmed by the appearance of different interference colors inside the pellet.

Several sample capacitors were finished by application of two coats of MnO_2 and an outer electrode of Aquadag and silver paste applied after the last reforming step. Typically, such units have at room temperature a capacitance per unit volume of 270 $\mu f\text{-}v/cm^3$ (calculated on the basis of anode volume), a leakage parameter of about 0.1 $\mu a/\mu f$ at 20v and a dissipation factor of 0.15 at 1000 cps.

Conclusions

Thermally formed silicon dioxide improved by anodic bias is a dielectric film which can be used in solid electrolytic capacitors. Judging from the low leakage currents at high field strengths of single crystals in NMA, the relatively low dielectric constant might be partially compensated by using thinner oxides for a given working voltage. Therefore, a better capacitance-to-volume ratio than the one given by the dielectric constants can ultimately be expected for sintered pellets. The preoxidation treatment is of utmost importance in achieving good results.

Acknowledgments

The author wishes to express thanks to Dr. Basil J. Nicholson for many useful discussions and to Dr. Paul F. Schmidt for suggesting a method of improving thermally formed silicon dioxide.

Surface Photovoltage Studies of Silicon-Electrolyte Systems

Richard S. Muller[1]

Pacific Semiconductors Inc., Lawndale, California

The space-charge region at the surface of a semiconductor will, if illuminated, be the seat of a photovoltaic effect. This photovoltage may be detected by measurements made between a nonrectifying contact, affixed to the semiconductor, and an electrode having a potential difference with the semiconductor surface that is independent of illumination.

The theoretical behavior of the surface photovoltage has been analyzed by Garrett and Brattain (1). The feasibility of the determination of surface potential through measurements of the surface photovoltage was demonstrated for germanium in gaseous ambients by Johnson (2) and for germanium in liquid ambients by Garrett and Brattain (3). Harten has reported some use of the technique for silicon in Na_2SO_4 solutions (4, 5). In the work to be reported here, surface photovoltage measurements were employed to test the effects of electrolytic environment on both n- and p-type silicon having a range of resistivity values. The electrolytes chosen were those used in various phases of the chemical processing of silicon for commercial use.

[1] Present address: Department of Electrical Engineering, University of California, Berkeley, California.

Experimental Technique

The experimental apparatus used to make the photovoltage measurements is sketched in Fig. 1. Light from a 300w tungsten filament lamp was passed through a crossed polaroid modulator and a rotating disk shutter. It was then partially deflected by a mirror to shine through a specified depth of

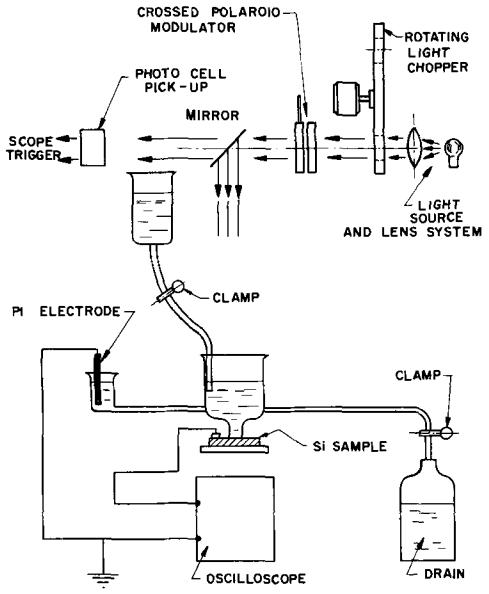

Fig. 1. Apparatus used to measure the surface photovoltage. The reservoir and drain system permit holding the silicon surface in a continuously liquid ambient.

liquid onto the surface of the test specimen. A portion of the light was gathered at a photocell, which served as a synchronizing trigger for the oscilloscope used to measure the photovoltage. The photocell also served to calibrate the light source.

The silicon specimens were cut in the (100) plane and lapped, chemically polished in a CP-4 solution, and dried in air. The over-all thickness of each wafer was about 10 mils. The specimens were then glued with an epoxy cement to the lip of an inverted polyethylene bottle, the bottom of which had been removed. Clamp arrangements between electrolyte reservoir and drain facilitated flushing the sample surface with distilled water between changes of the electrolyte. The photovoltage was measured between an ohmic contact made to the silicon sample and a platinum counter-electrode situated in a remote reservoir which was connected by a liquid-filled tube to the test sample bottle. The platinum electrode was used after trials showed it to give readings consistent with those of a calomel standard which had been used initially. The photovoltage was detected in a-c fashion by an oscilloscope (one megohm input impedance) and its polarity checked by comparison with the synchronizing trigger from the photocell.

Table I lists the resistivity values of the three p-type and three n-type specimens which were used in the experiments. To check the consistency of the results, some of the measurements were duplicated on a second set of three n-type samples which had resistivities equal to those of the first set.

Table I. Resistivity values

Sample	Resistivity, ohm-cm
N-1	0.56
N-2	19.5
N-3	48.0
P-1	2.8
P-2	26.0
P-3	58.0

The photovoltage was measured first in three different solutions which are fairly inactive with the silicon surface: these were 0.1M solutions of $PdCl_2$, $SnCl_2$, and NaCl. A solution of 0.5M NaH_2PO_2, which was capable of a partial reduction in the silicon surface oxide, was used next. Finally, readings were taken in a 0.1M HF solution. The HF was sufficient to remove all the silicon surface oxide coating.

Results

Typical behavior of the photovoltage in the absence of HF is shown in Fig. 2 for three n-type samples. The electrolyte used for the data in this figure was 0.5M NaH_2PO_2. The data for p-type material in the same electrolyte plot as a reflection of the curves of Fig. 2 in the $y = 0$ plane, with the measurements showing the same relative dependence on resistivity as does the n-type. Actual magnitudes of the photovoltage in p-type material were, however, less than 0.25 kT/e. In the electrolytic environments not containing hydrofluoric acid, the silicon consistently became the positive terminal for p-type material and the negative terminal for n-type material in the measured surface photovoltaic effect. Consistency with the data trend of Fig. 2 was obtained with a series of identical resistivity-value silicon samples, measured under the same conditions. Actual photovoltage values did, however, differ by about 10% of the magnitudes given in Fig. 2 in the second set of data.

Figure 3 indicates the dependence of the photovoltage on the electrolytes tested. The data for this curve were taken for sample N-3 (19-ohm-cm material); qualitatively similar curves were obtained for all other n-type samples. An HF environment is seen in Fig. 3 to reverse the polarity of the observed photovoltage, as well as to change the character of the illumination dependence. For p-type samples, an HF solution maintained the positive polarity of the photovoltage, while increasing its magnitude by a tenfold factor. About 30 sec in the HF solution were necessary to reach an equilibrium condition for the

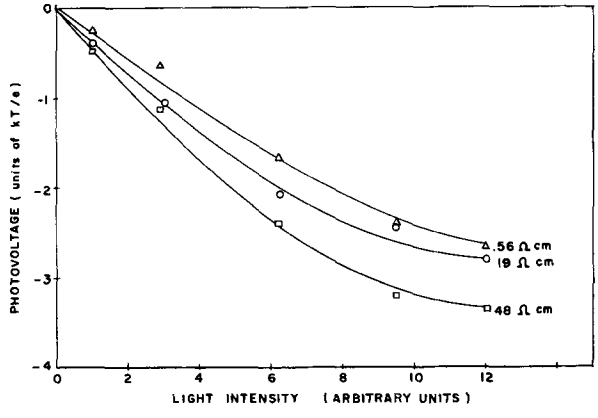

Fig. 2. Measured photovoltage vs. light intensity for three samples of n-type silicon in 0.5M NaH_2PO_2 solution. An intensity of 12 corresponds approximately to one lumen. The polarity of the photovoltage is that of the silicon with respect to the Pt electrode immersed in the electrolyte.

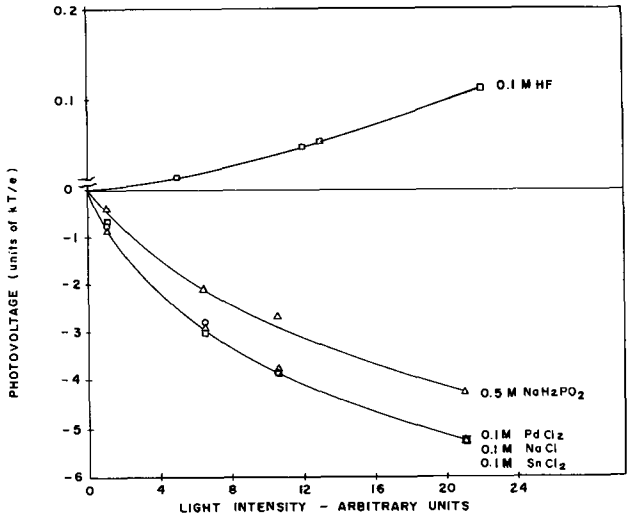

Fig. 3. Measured photovoltage vs. light intensity of sample N-3 (19 ohm-cm resistivity) in three electrolytes. Note the change in the ordinate scale for positive photovoltages.

photovoltage. The *p*H of the HF solution was varied over a wide range. The only effect on the photovoltage was a shortened time to reach an equilibrium as *p*H was decreased. In solutions other than HF, the p-type samples showed a low value for the positive photovoltage, which increased slightly in changing from a NaCl electrolytic environment to a NaH_2PO_2 environment.

The apparent source resistance for the photovoltage measurements was monitored by observing the loading resistor which halved the output voltage. This resistance was always less than 100 kilohms and varied in a way which was not directly related to the silicon resistivity.

Discussion

The polarity of the measured photovoltage indicates that both n- and p-type silicon assume a depletion-layer surface in an electrolytic environment free of HF. Thus, the immobile surface charge is negative for n-type material and positive for p-type material. The addition of NaH_2PO_2, which partially removes the surface oxide layer, tends to make both surfaces increasingly positive. This suggests that the oxide complexes formed in the dissolution carry off surface electrons. A completion of the oxide stripping of n-type material results in an accumulation-layer surface. For p-type silicon, HF acts to increase the magnitude of the depletion layer at the surface and thereby to increase the photovoltage. The dependence of photovoltage on material resistivity is not a very strong one, as is evident in Fig. 2.

The difference in the photovoltage polarity in a given electrolyte with a change in conductivity type suggests that a predominant part of the energy interchange resulting in an equilibrium at the liquid-silicon interface is through electron transfers. The other possible mechanism for this energy transfer, ionic adsorption and dissolution, would not depend on the position of the Fermi level in the material, or, therefore, on conductivity type (6).

An independent measurement of the photon-injected carrier density would be necessary to make a quantitative comparison of the general theory of the surface photovoltage as developed by Johnson (2) with the results described here. Following the suggestion of Harten (5), an attempt was made to obtain this quantity by monitoring the change in sample resistance with illumination. This technique led to nonreproducible results apparently due to variations in the current flow through the electrolyte in parallel with the surface. In Harten's work this component of current was considered to be negligible.

Qualitatively, the rapidly rising curve followed by a saturation for the depletion-layer photovoltage and the slowly rising curve for an accumulation-layer photovoltage, as seen in Fig. 3, match the predictions of Johnson's theoretical analysis. However, Johnson's theory predicts a stronger dependence on material resistivity and a smaller light sensitivity than is actually observed.

Dislocation Cracks in Abraded Germanium Surfaces

E. N. Pugh and L. E. Samuels

Defence Standards Laboratories, Australian Defence Scientific Service, Sydney, Australia

Dislocation cracks were first reported by Allen in indium antimonide (1); they are dislocation arrays which usually occur as extensions to true cracks and which have the same morphology. The present authors have shown that dislocation cracks can be produced in germanium by local impact and have suggested that their formation is an intermediate stage in the fracture process (2). If this is so, dislocation cracks should be associated with cracking irrespective of the method of stressing. However, while damaged layers in abraded germanium surfaces have been shown to contain large numbers of true cracks, no dislocations were detected (3, 4). Abraded surfaces were therefore re-examined in the light of the more recent observations.

The problem of distinguishing between fine cracks and arrays of closely spaced dislocations when both have the same morphology arises from the fact that

etching reagents which reveal dislocations also attack cracks. This difficulty can be overcome by using the ferricyanide reagent developed by Billig (5), which has been shown to make fine cracks readily visible in short etching treatments (2-3 sec) whereas longer times (5 min) are required to reveal dislocations (3).

Experimental

Studies were confined to {111} surfaces of germanium single crystals which were abraded unidirectionally with silicon carbide particles, used both in abrasive papers and as slurries on a glass plate. Etching studies with the ferricyanide reagent require flat surfaces. Accordingly, the abraded surfaces were polished with a relatively fine diamond abrasive used on a napless cloth, polishing being continued to the stage when the surface irregularities were just removed; damage cracks then still remained. The surfaces were finally polished metallographically using fine magnesia abrasive. The polishing operation itself produced some damage, and on etching this gave rise to background "scratches." These scratches were visible at high magnifications (see Fig. 3), but could readily be distinguished from the damage introduced by the original abrasion process.

Observations and Conclusions

Etching with the ferricyanide reagent for short times (less than 10 sec) resulted in attack at the damage cracks. Figure 1 illustrates these cracks in a surface abraded with 220-grade papers. It must be emphasized that these features are true cracks which could be detected before etching. Further etching caused the cracks to become more pronounced and produced a number of additional markings (cf. Figs. 1 and 2) which have the characteristics of dislocation cracks, as described in the earlier paper (2). The dislocation cracks are shown at higher magnification in Fig. 3; they can be readily distinguished from the fissures formed at true cracks (indicated by arrows in Fig. 3) since the closely spaced dislocations give rise to shallow v-sectioned grooves. Dislocation cracks were observed to accompany cracking in all the abrasive treatments investigated.

Fig. 1. Surface originally abraded with 220 grade paper (abrasion direction horizontal) after etching for 3 sec with the ferricyanide reagent. Magnification 250X.

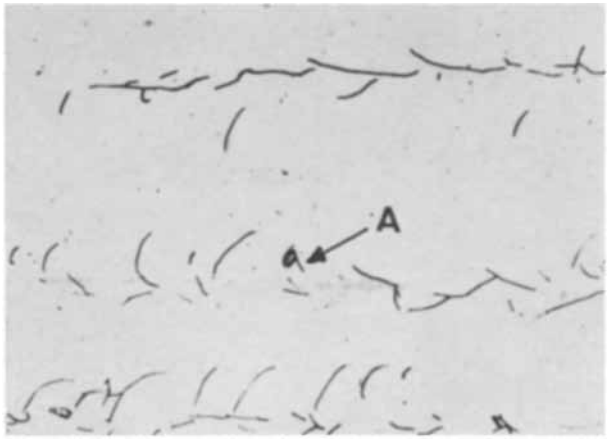

Fig. 2. Same field as in Fig. 1 after etching 5 min. Magnification 250X.

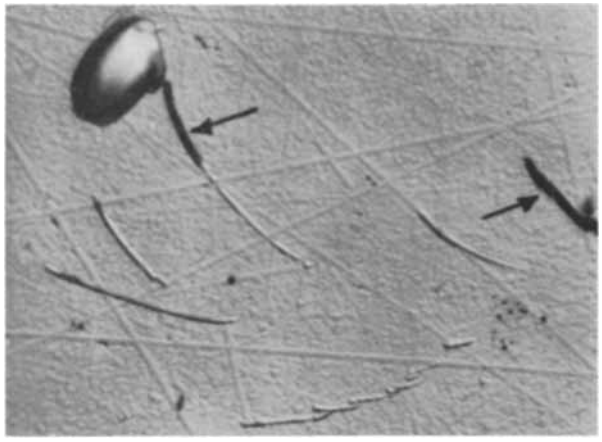

Fig. 3. Region A of Fig. 2 showing two cracks (marked with arrows) and several dislocation cracks. Magnification 1500X.

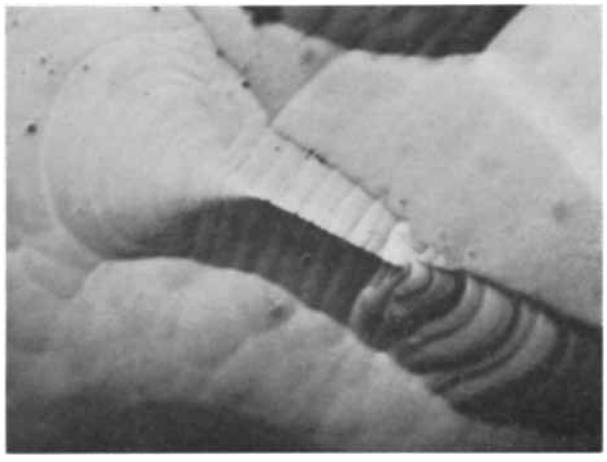

Fig. 4. Dislocation crack in a surface abraded with 220 grade silicon carbide slurry and etched with CP4. Magnification 750X.

Etching with CP4 has previously been shown to produce characteristic grooves at dislocation cracks (2). When abraded surfaces were etched with this reagent dislocation cracks were detected. Figure 4 illustrates a typical example. However, they were observed only in specimens in which the dislocation cracks were relatively large, *i.e.*, in surfaces treated with coarse abrasives. Further, the number of dislocation cracks revealed in these specimens was small compared to the number produced by the ferricyanide reagent. This suggests that the difference between the rate of etching along dislocations

and the rate normal to the surface is small, so that the smaller dislocation cracks were removed before they produced detectable grooves.

It is concluded that arrays of dislocations, in the form of dislocation cracks, are present in damaged layers in abraded germanium surfaces. However, the dislocation cracks are minor features of the damaged layers, their area being less than 10% of that of the true cracks which constitute the bulk of the damage.

The Effect of Dissolved Germanium on the Surface Tension of Molten Indium

A. A. Bergh

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

Molten indium has been observed to spread and contract during alloying on (111) oriented single crystal germanium (1). This was explained by the variations in the surface tension of the melt during alloying (2). The surface tension of indium was assumed to decrease with the temperature rise and to increase with the concentration of the dissolved germanium, the two competing forces thus resulting in spreading and contraction. While the first assumption is substantiated by experimental data (3, 4), the second is contradictory to the generally observed behavior of mixtures. In general, the surface tension of liquid metals follows approximately a linear mixture law (linear in the surface fraction) unless the components form intermetallic compounds, and the surface tension of the liquid is likely to be dominated by the component with the lower value of γ (5). No intermetallic compounds are formed between germanium and indium (6) and Table I shows how close the respective surface tension values are, those of the indium being smaller by about 20%. Hence, in view of the empirical rules, very little effect of the dissolved germanium can be expected on the surface tension of indium. In order to resolve the above contradiction, experiments were carried out to collect quantitative data on the effect of dissolved germanium on the surface tension of molten indium.

Experimental

All surface tension values were measured by the maximum bubble pressure method. The principle of the method along with an application for a liquid metal system is given, *e.g.*, in Taylor's paper (9). A schematic diagram of the apparatus is shown in Fig. 1. A quartz or alundum crucible (A) contained the indium or indium-germanium sample of about 10 ml in volume; 99.999% pure indium and 5 ohm-cm n-type germanium were heated to 800°C in a hydrogen furnace for 30 min and then rapidly cooled to about 100°C to establish a nearly homogeneous distribution of germanium composed of small crystallites within the indium. Next the crucible was placed into a stainless steel vessel (B) equipped with bellows to lift or lower the sample with respect to capillary (D). Quartz cylinder (G) was connected to the stainless steel vessel with the help of a Buna gasket. Coaxial with the capillary was tube (C) to protect the orifice tube during handling. The pressure was affected by means of a polyethylene bellows compressed by a micrometer screw, and it was measured by following the change of the meniscus in the smaller limb of the manometer with a high precision

Table I. Surface tension of molten indium and germanium

	γ, dynes/cm	Temp, °C	Method of determination	Atmosphere	Ref.
In	515	600	Max. bubble pressure	H_2	(3)
	518	600	Drop volume	H_2	(4)
	514 ± 4	600	Max. bubble pressure	H_2	Present work
Ge	600	Mp	Drop weight	Ar	(7)
	600	1000	Sessile drop	Vac	(8)

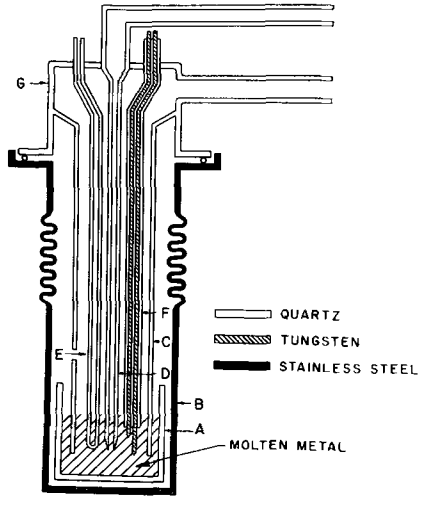

Fig. 1. Schematic diagram of the maximum bubble pressure apparatus.

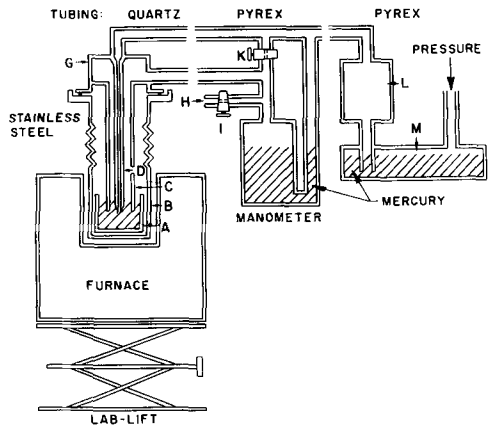

Fig. 2. Part of the maximum bubble pressure apparatus containing the capillary.

cathetometer. The system was flushed with hydrogen through tube (H) for 30 min when stopcock (I) was closed and stopcock (K) was opened and the sample heated to the desired temperature. The accurate positioning of the orifice in the liquid was facilitated by a simple electrical circuit. An indicator lamp was turned on when the upper tungsten wire (Fig. 2, F) got into contact with the liquid metal surface. The orifice at this point was immersed 4.07 mm deep. The bath temperature was recorded by a thermocouple carried in sheath (E).

Since the contact angle of indium on quartz is unknown, the orifice of the capillary was ground extremely thin (less than 0.1 mm) thus equalizing the internal and external radii for any practical conditions. For the effect of the gravitational distortion, Sugden's correction method was applied making use of the Bashforth's and Adam's tables as shown, *e.g.*, in Taylor's paper (9).

Results

The surface tension of pure indium and that of alloys containing different atomic per cents of germanium has been determined at 600°C. Each value in Table II represents the average of at least five measurements with the corresponding mean deviations.

Table II. Surface tension of indium-germanium alloys at 600°C in hydrogen atmosphere

Atomic % In	Atomic % Ge	γ, dynes/cm
100	0	514 ± 4
96.54	3.46	511 ± 3
91.98	8.02	510 ± 6
83.02	16.98	516 ± 5

Measurements are in good agreement with the generally observed behavior of mixtures and lead to the conclusion that the dissolved germanium does not affect the surface tension of indium to any greater extent than the accuracy of our measurements and can by no means be responsible for the contraction of the indium at higher temperatures.

Acknowledgment

The author wishes to acknowledge the help rendered by Mr. T. S. Miller in carrying out surface tension measurements.

Brief Communication

Structure of Electroless Nickel

A. H. Graham, R. W. Lindsay, and H. J. Read

Department of Metallurgy, Pennsylvania State University, University Park, Pennsylvania

Ever since the first extensive studies of electroless nickel were published in 1944, the as-plated deposits have been regarded as amorphous because of the appearance of only one broad diffraction peak in their x-ray spectra. This belief, supported by intensive investigations by Goldenstein *et al.* (1), has posed difficulties in understanding the hardening of the deposits when they are heat-treated at temperatures above 200°C. Explanations such as one by Ziehlke, Dritt, and Mahoney (2) attributing the first stage of hardening to the formation of "an interim crystal lattice in the initially amorphous deposit" are not attractive because all the hardening mechanisms familiar to metallurgists are based on the existence of a crystalline structure at the start of the hardening process.

The x-ray evidence for the amorphous structure reported in the literature does not exclude the possibility that the as-plated deposits may be extremely fine-grained, supersaturated, solid solutions of phosphorus in crystalline nickel. The transmission electron diffraction pattern that we offer in Fig. 1 for a

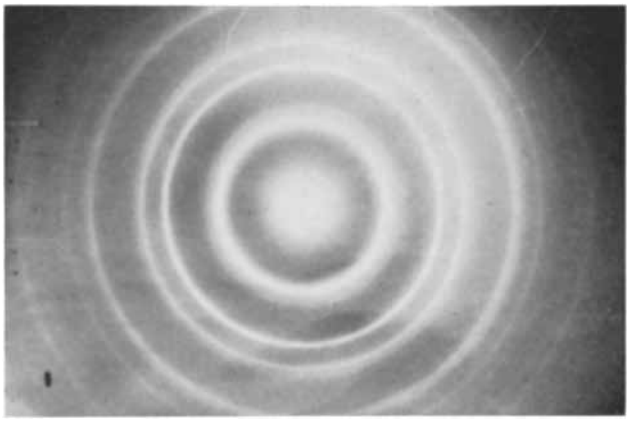

Fig. 1. Transmission electron diffraction pattern of as-plated electroless nickel, 5 weight per cent phosphorus; accelerating voltage 75 kv.

specimen plated on a thin copper substrate in a conventional alkaline nickel-chloride bath and thinned by electropolishing is one of many patterns that appear to us to be convincing evidence that as-plated electroless nickel is crystalline. On the negative for this pattern eleven rings were distinct enough that their diameters could be measured.

The composition and operating conditions for the bath used in making the specimen for Fig. 1 are as follows: nickel chloride hexahydrate, 45 g/l; ammonium chloride, 50 g/l; sodium citrate dihydrate, 82 g/l; sodium hypophosphite, 16 g/l; pH, 8.5; temperature, 90°C; agitation, stirrer. The as-deposited film was about 25μ thick on copper foil and had the lustrous matte appearance typical of deposits from this bath. Phosphorus content was determined by wet chemical analysis. A solution of chromic acid (500 g/l) and sulfuric acid (50 g/l) served for removal of the copper substrate. Extensive experience with this stripping solution has shown that there is neither chemical attack nor mechanical disturbance of nickel or nickel-phosphorus films. The deposit was thinned by electropolishing until it would transmit an electron beam. Although the exact thickness was not determined, it must have been less than 0.1μ. Diffraction patterns were produced by impinging the electron beam vertically on the plane of the film, and appropriate precautions were taken to prevent heating by the electron beam that could have caused crystallization of an initially amorphous deposit.

Although difficulties were encountered in the determination of the lattice type and in the indexing of the pattern, all the reflections could be attributed to nickel regardless of the lattice type assumed. Therefore it is probable that the deposit is primarily a supersaturated solid solution.

Figure 1 can be reasonably indexed according to either a hexagonal-close-packed (hcp) or a face-centered-cubic (fcc) structure. The most important factor in attempting to distinguish between the two possible structures is the {200} reflection for the fcc structure. The presence of this reflection would be indicative of a fcc structure, whereas its absence would indicate a hcp structure. In the large majority of the electron transmission diffraction patterns observed, the {200} reflection was either absent

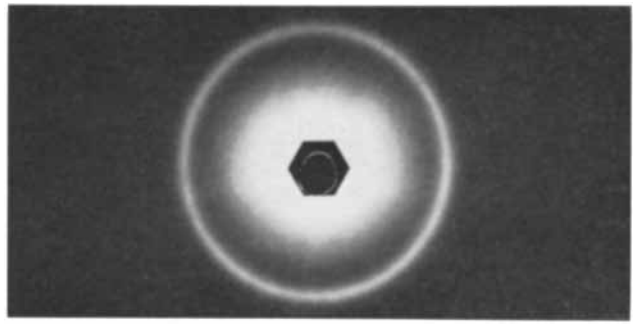

Fig. 2. Transmission x-ray diffraction pattern of as-deposited electroless nickel, 5 weight per cent phosphorus; unfiltered copper radiation.

or extremely weak. The difficulties in indexing can be attributed to stacking faults in the structure of fcc nickel. Paterson (3) has shown that stacking faults not only shift the {200} reflection toward a lower Bragg angle, but also greatly diminish its intensity. The diffraction pattern in Fig. 1 is compatible with the effects of stacking faults on the other reflections.

The fact that x-ray diffractometer patterns and x-ray transmission photographs of electroless nickel (see Fig. 2) give a definite indication of an amorphous structure was confirmed for the same specimens that yielded electron diffraction patterns that were evidence for a crystalline structure. This apparent contradiction between electron and x-ray results can be explained by a consideration of the effect of grain size. Lines in x-ray patterns are broadened and become less intense as the grain size decreases to diameters less than 10^{-3} cm. In electroless nickel the apparent grain size as indicated by transmission electron micrographs is of the order of 10^{-6} cm; therefore, only the most intense x-ray lines would appear. The amount of broadening of diffracted radiation from a fine-grained material is directly proportional to the wavelength of the radiation. Because the wavelength of electrons accelerated through a potential of 75 kv is almost two orders of magnitude smaller than the wavelengths of x-rays used in diffraction work, the fine grain size of electroless nickel does not preclude the production of electron diffraction lines. Although the x-ray spectrum of a crystalline material with a particle size of 10^{-6} cm should probably contain more than one line, the added effects of internal stress, solid solution, and stacking faults on diminishing the intensities of reflections can reasonably account for the destruction of all but the most intense x-ray reflection from electroless nickel.

It is anticipated that a future contribution will contain a detailed account of this and other work on the metallurgical properties and structure of electroless nickel.

Oxidation of Iron-Nickel Alloys

VI. A Survey of Kinetics and Mechanism

R. T. Foley[1]

General Electric Company, Schenectady, New York

ABSTRACT

The oxidation of Fe-Ni alloys in the 500°-1100°C range has been the subject of many investigations. These observations are summarized, and an attempt is made to generalize on the kinetics and mechanism of oxidation. The composition of the oxide film over the entire composition range can be explained in terms of the thermodynamic stability of the oxides of Fe, of NiO, and of $Ni_xFe_{3-x}O_4$. In alloys of all compositions that have been investigated the first reaction is one of selective oxidation, creating a Ni-rich metal layer at the alloy-oxide interface. The growth of a Ni-containing spinel is promoted and formation of FeO is suppressed. This explains the reduction of oxidation rate to about 1000 times less than that of pure iron. The short-time kinetics of oxidation appears to be governed by diffusion through this Ni-rich metal layer or by diffusion through the Ni-containing spinel. Only at the Ni-rich end of the Fe-Ni system is NiO observed, and this exists next to the alloy interface under a layer of spinel. The reaction between NiO and Fe_2O_3 is rapid at these temperatures, thus explaining why these two oxides are not observed together. On prolonged reaction, subscale oxidation and intergranular attack is observed. Because of the stratification of oxide layers and these secondary effects, the development of a general rate law would be difficult.

Since 1916 and particularly during the last decade, a number of investigations have been carried out on the kinetics and mechanism of oxidation of Fe-Ni alloys. From the practical standpoint the need to acquire knowledge of the high-temperature behavior of these alloys is obvious, as various compositions are used in industry because of their magnetic behavior, their thermal expansion properties, their ability to participate in glass-to-metal seals, and their corrosion resistance. From the theoretical viewpoint the Fe-Ni system is of significance. Thermodynamically the system, consisting of a continuous series of solid solutions, is almost ideal (1) in the sense of obeying Raoult's law. Both Fe and Ni are oxidizable, and in addition, the oxides of iron are known to undergo solid state reactions with nickel oxide.

The investigations carried out in a number of laboratories have dealt with compositions over the entire phase diagram, varying from high-purity vacuum-melted preparations to commercial alloys containing several per cent of various alloying elements. The oxidizing atmospheres have included laboratory air of unknown moisture content as well as rigorously controlled atmospheres. The duration of the experiments have been such as to produce, in some cases, thin films, while in others thick scales and considerable subscale formation.

[1] Present address: Melpar, Inc., A Subsidiary of Westinghouse Air Erake Company, Falls Church, Virginia.

The objective of this paper is to organize these rather extensive observations and to develop the generalizations that would summarize the oxidation behavior of Fe-Ni alloys. This report will restrict itself to film formation beyond the nucleation stage. The concepts that the reaction product appears first at special points on the metal surface and that the number and form of these nuclei is related to the crystallographic orientation (2) of the surface, will be accepted.

For the sake of organization the whole Fe-Ni system is divided into three parts: the Fe-rich part of the system, 0-30% Ni; the intermediate section, 30-75% Ni; the Ni-rich part of the system, 75-100% Ni. The observations relative to kinetics of oxidation, composition, and nature of oxide film, as well as secondary effects, *e.g.*, subscale oxidation, will be discussed on this basis.

Oxidation of Fe-Rich Alloys (0-30% Ni)

In interpreting some of the results reported in the literature distinction should be made between "equilibrium" compositions and those compositions actually observed during an oxidation at elevated temperature. The oxide species observed on the alloys in the latter case are those growing under the particular conditions of temperature and gaseous environment that exist during the experiment. The "equilibrium" results were achieved (3, 4) by a technique involving strenuously oxidizing the alloy

Table I. Fe-Rich alloys (0-30% Ni)

Composition, % Ni	Temperature range, °C	Duration investigated	Kinetics	Film composition	Comments	Ref.
2.08, 6.40, 10.36, 15.06	1050-1095	7-20 days (equilibrium)	Reaction decreases considerably with increase in Ni content.	External layer of wüstite free of Ni.	"Equilibrium" studies. No spinel is found on alloys containing 15% or less Ni. Magnetite does form on cooling.	(3)
5.10	675-950	5-100 hr (in some cases 300 hr)	$y^n = kt$ (y = total O_2 picked up) where $n \neq 2$ always	Fe_2O_3 Fe_3O_4 FeO + Fe_3O_4 (alloy)	High-purity alloys. Extensive internal oxidation in low nickel range.	(6)
20	675	up to 14 hr	$n \cong 2$. (parabolic)			
	800	up to 5 hr	$n = 2.4$

and then equilibrating the sample for an extended period of time (about 1000 hr) in an inert atmosphere. In this way sections of the equilibrium diagram for the Fe-Ni-O system were obtained. The kinetic tests would reach this end point if the reaction were allowed to proceed indefinitely in an oxygen partial pressure equal to the dissociation pressure of the oxide with the lowest dissociation pressure.

The experimental investigations bearing on the oxidation of the Fe-rich alloys are summarized in Table I.

In the oxidation of these alloys the first reaction involves selective oxidation of Fe, and in the very thin layers it appears that no Ni is contained in the oxide. The fact that the surface is enriched with Ni seems well established for all alloys in this region. Moreau and Bénard (5) measured this Ni enrichment occurring on the surface of the 30% Ni alloy. After a 1-hr oxidation time the Ni content of the surface approximates 50% at 850°C, 60% at 950°C, and 82% at 1050°C. As oxidation proceeds there is developed a composite layer with Fe_2O_3 (on the atmosphere side), a spinel structure, and FeO (in contact with the metal). FeO, which represents the "equilibrium" oxide (3), is found only with the very low Ni content alloys and probably exists in a layer mixed with Fe_3O_4 as observed metallographically (6). At oxygen pressures of about 0.2 atm Fe_2O_3 is a major reaction product at these temperatures (600°-1000°C). At 1 mm O_2 pressure no Fe_2O_3 was observed on the 4.89% alloy (7). The spinel observed even on the low Ni alloys contains appreciable Ni. Thus Gulbransen, Phelps, and Hickman (7) reported a spinel with a = 8.34Å, which conforms to $NiFe_2O_4$, in the body of the oxide film formed by oxidizing at 4.89% Ni alloy at 500° for up to 60 min in 1 mm O_2 pressure. The existence of a high Ni content in films grown on alloys containing 25% Ni is well established (8). It has also been noted (8) that when an alloy contains a few per cent of Mn, this Mn appears to concentrate in the spinel. The concentration of Ni dissolved in the Fe_3O_4 structure exists in a gradient with the high concentration next to the alloy, which itself is nickel rich at this interface.

The phenomenon of nickel enrichment either on the metal surface or in the innermost layer was observed during metallographic investigations of

specimens which had been severely oxidized (21-23). These studies revealed that metallic Ni was segregated during these extended oxidations as a result of the alloy-oxide interface moving into the sample.

Usually the oxidation rate of these alloys approximates a parabolic law for short periods of time (1-2 hr), and the rate seems to be determined by diffusion of cations, either through the Ni-rich metallic zone or through the Ni-containing spinel. The Ni has the outstanding effect of suppressing the formation of FeO, probably by decreasing the thermodynamic activity of Fe at the alloy surface (3). FeO is the fastest growing phase of the three possible oxides; it is the major oxide formed on pure Fe and accounts for the high oxidation rate of Fe. The effect of Ni on the oxidation rate appears at very low contents of Ni in the alloy. Thus, the rate of oxidation of a 2.08% alloy is appreciably less than that of pure Fe, and the rate of a 10.38% alloy is less by many orders of magnitude. The early part of the oxidation is made complex by continual change in alloy composition at the surface. After oxidation times of several hours and the build-up of appreciable scale it is likely that the rate-determining step is diffusion across the oxide film. At these longer times the growth law deviates from a simple parabolic relationship because layers of different composition are growing. Actually there is not a great deal of quantitative data available to evaluate the effect of small percentages of Ni on the oxidation rate. However, it is apparent that the Ni effect is considerable, reducing the oxidation rate of Fe by a factor of 10^2-10^3 as measured by parabolic rate constants determined for 1 hr oxidations. At 30% Ni the effect is established in the sense that further addition of Ni has little effect on the rate. The oxidation rate of the 30% alloy is approximately the same as that of the 40.9%, and the activation energy is about the same, 40.5 kcal/mole inferring a similar mechanism.

Oxidation of Fe-Ni Alloys Containing 30-75% Ni

The first-formed film on alloys in this intermediate range is an oxide of Fe which results from selective oxidation. Thus lines for FeO (12) and Fe_2O_3 (11) are observed in the vacuum of the high-temperature electron diffraction camera. As a consequence there is an early enrichment of Ni at the alloy-oxide interface. However, upon oxidation at times longer than 1 min at 600°C, a spinel structure is obtained. This spinel has a formula $Ni_xFe_{3-x}O_4$ wherein x approaches unity close to the alloy-oxide surface, as established by lattice parameter measurements and chemical analysis (13, 14). For example, the oxide produced on the 41% alloy after 1 min at 800°C contained 31.8% Ni (average value) (13). For oxidation times up to about 3 hr at temperatures in the 500°-1100°C range the predominant oxide was this nickel-containing spinel. In addition a layer of Fe_2O_3 was formed at the oxide-atmosphere interface. Continued oxidation followed by equilibration in an inert atmosphere (4) yields external scales composed of nickel-containing spinel with wüstite. In addition there is extensive subscale formation, the product in this case being wüstite and spinel. While this subscale would penetrate completely a normal oxidation strip during runs of several hundred hours, for runs up to 1 or 2 hr this secondary phenomenon does not appear to play an important part in the kinetics, at least insofar as quantitative data are available to us. During the extended equilibration periods hematite disappears and FeO appears. The equilibrium procedure is carried out at the oxygen pressure established by the dissociation pressure of FeO.

The enrichment with respect to Ni at the alloy-oxide interface is observed for long time oxidations (13 days at 1000°C). The development of an "inner layer" containing 52% Ni on an original 36% Ni alloy was interpreted by Pfeil as due to the movement outward of Fe through the Fe-Ni metallic zone in contact with the oxidizing atmosphere (20).

The kinetics of reaction for alloys in this range is governed primarily by the formation and growth of the Ni-containing spinel. As has been pointed out (4), the high Ni content of the alloy has made the fastest growing phase on Fe, namely FeO, thermodynamically unstable. The growth rate of magnetite on Fe is only about one-twentieth that of FeO on

Table II. Fe-Ni alloys (30-75% Ni)

Composition, % Ni	Temperature range, °C	Duration investigated	Kinetics	Film composition	Comments	Ref.
48.5	1050	1000 hr equilibrium		Spinel + wüstite with spinel containing up to 10% Ni	"Equilibrium" studies—Extensive subscale composed of wüstite and spinel	(4)

Fe. The diffusion rate in the Ni-containing spinel is still lower as evidenced by the rate data given in Table II. Because of differences in testing atmospheres, surface preparation, and other factors, a comparison of rate data in the literature can only be semiquantitative. However, with this limitation in mind, a comparison with data on the oxidation of pure Fe (15) yields a factor of improvement from alloying of 10^2-10^3. The apparent energy of activation for the rate-determining diffusion process in the spinel structure is about 41,000 cal/mole (10). This value does not hold at elevated temperatures or in atmospheres that contain H_2O vapor, presumably because of solid-state reactions influencing the morphology of the oxide film (16).

Oxidation of Nickel-Rich Alloys, 75-100% Ni

The oxide film formed on an 80% Ni alloy during the first hour of oxidation in the 600°-1100°C range is essentially the nickel-containing spinel with a lattice parameter 8.35-8.37Å (14, 17) (Table III). The result of the preferential oxidation is a composition closer to $NiFe_2O_4$ than to Fe_3O_4. FeO is not observed as it was on the alloys of lower nickel content. On extended oxidation the system Fe_2O_3: Spinel: NiO (traversing the scale from the outside to the inside) is developed. The thermodynamic activity of Fe is low, and thus only a thin layer of Fe_2O_3 is observed. Fe_2O_3 should not exist in contact with NiO at temperatures of 800°C and above because of the tendency for solid-state reaction to occur as previously discussed (16), and where these two species are observed in the oxide scales they are separated by a layer of spinel. Following depletion of Fe at the surface because of outward diffusion and reaction, the surface, which is essentially Ni, reacts to form NiO which occupies about 50% of the scale after oxidation for 1 hr at 800°C. The only short-time data available for high nickel alloys (10) approximate the oxidation rate data for Ni (18), which presumably is controlled by the diffusion of Ni cations through the NiO layer (19).

Discussion

The composition of the oxide films developed over the whole range of Fe-Ni alloys in the 500°-1100°C range may be explained by consideration of the thermodynamic stability of the oxides of Fe, of NiO and $NiFe_2O_4$ (actually $Ni_xFe_{3-x}O_4$). The dissociation pressure of NiO is large compared with that of the Fe oxides. Above 600°C, Fe_2O_3 and NiO react rapidly to form the spinel.

In the Fe-rich part of the system the first reaction involves the selective oxidation of Fe. The alloy-oxide interface is enriched in Ni, and Fe must diffuse through this metallic layer for further reaction. The concentration and hence the thermodynamic activity of Fe at the interface is greatly reduced; the growth of Fe_3O_4 is promoted and that of FeO is suppressed. This directly bears on the kinetics of reaction as the oxidation rate is reduced by a factor of 1000 as the Ni content increases to 30% Ni. Fe_2O_3 is produced at the atmosphere interface on prolonged oxidation. As the nickel content of the alloy increases, the kinetics and the mechanism of reaction are governed by the formation and growth of the Ni-containing spinel in contact with an alloy interface which has become enriched in Ni. A definite concentration gradient of Ni exists in this spinel, which approaches stoichiometric $NiFe_2O_4$ next to the alloy and Fe_3O_4 in contact with Fe_2O_3 or the oxidizing atmosphere.

The Ni-containing spinel is observed in thin films produced on alloys containing as much as 80% Ni. As oxidation continues, the alloy adjacent to the reaction interface is depleted in Fe and the Ni activity rises; NiO then grows next to the alloy. The fact that NiO and Fe_2O_3 are not seen in contact is due to the rapid rate of reaction of these two species at elevated temperatures.

With oxidation times of many hours there is a considerable subscale formation and grain boundary attack as viewed metallographically. In addition, the usual situation involves stratification of various oxide layers. Therefore, the formulation of a general rate law covering all alloy concentrations would be difficult. For short periods of time (less than 60 min) a single parabolic relationship appears to represent adequately the experimental observations. The kinetics suggest diffusion through the Ni-containing spinel or through the metallic layer enriched with Ni as the rate-determining step. A simple rate law does not hold for longer times or even for shorter times if there is a change in the morphology of the oxide film as a result of solid-state reaction.

Measurement of Thickness and Refractive Index of Oxide Films on Silicon

G. R. Booker and C. E. Benjamin

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Optical interference methods for determining the thickness and refractive index of oxide films on silicon are described. The treatment is confined to those methods in which a portion of the film is dissolved with HF, and measurements are made on the height of the step thus created. For thick films (>3000Å) two-beam interference is used, and for thin films (<3000Å) multiple-beam interference is used. The different types of fringes are explained, and the accuracies of the methods are given. The emphasis is on the development of simple, practical procedures which can be applied in a routine manner.

Oxide films on silicon surfaces are widely employed during the fabrication of semiconductor devices. Relatively thick films (3000-20,000Å) are used for masking against epitaxial growth and certain elements during diffusion, while thin films (50-1000Å) are useful in other device fabrication operations. These thicknesses are equivalent to a few wavelengths of light or less, and hence it is not surprising that the two standard methods used to measure such thicknesses are optical methods.

In the first of these methods the specimen is viewed by reflected white light, and the film thickness is deduced from the color of the film. The color arises because of interference occurring between the light beams reflected from the upper and lower surfaces of the oxide film. Reflections of specific wavelengths interfere destructively, and the remaining wavelengths combine to give a characteristic color. The method consists of comparing the color of the unknown film with the colors of a set of standard films of different thicknesses. However, this method can be applied only to films in the thickness range of approximately 500-4000Å and hence does not fully cover either of the above practical thickness ranges. Moreover the accuracy is limited to approximately ±200Å.

In the second of these methods the film is completely removed from a portion of the specimen so that a step is created equal in height to the film thickness. The step height is then determined by measuring the displacement of monochromatic light interference fringes on crossing the step. The method is direct and can be applied to films of any thickness. The accuracy is dependent on the particular procedure used to obtain the interference fringes. For thick films the two-beam interference technique, which produces relatively broad fringes, is generally sufficiently accurate. A commercial two-beam interference microscope is often used for such measurements because of its convenience and versatility. On

the other hand, the multiple-beam interference technique, which produces narrow sharp fringes, is almost essential for reasonable accuracy with thin films. A noncommercial type of apparatus is usually employed for this purpose.

The present paper is concerned with the second, *i.e.*, step height, method of measurement. In particular, the various types of interference fringes associated with a step or a wedge in a surface oxide film on silicon are demonstrated, the methods used to obtain such fringes are described, and the equations for calculating the film thicknesses are given. In many practical applications of both white light and monochromatic light interference methods of measurement the refractive index of the surface film enters directly into the step-height calculation. A simple technique is described for determining this index with satisfactory accuracy.

The principles underlying the methods described are not new. The purpose of the paper is rather to explain the methods briefly and to indicate how they may be used in a practical manner.

Thick Films

The following procedure is convenient for forming shallow wedge-shaped steps in surface oxide films on silicon. A solution of Apiezon W wax in toluene is applied with a brush to a portion of the silicon specimen surface possessing the oxide film (Fig. 1a). The toluene rapidly evaporates, leaving a hard wax surface film. The specimen is immersed for 60 sec in HF (48%) to dissolve the unprotected portion of the oxide film (Fig. 1b). The specimen is then thoroughly rinsed, and the wax is removed (Fig. 1c) with trichloroethylene. Undercutting of the wax layer by the HF produces a relatively uniform wedge-shaped oxide film step, the angle of the wedge being approximately 1°.

The different types of interference fringes associated with such a specimen can readily be demonstrated if a portion of a specimen possessing a relatively thick oxide film is metallized (Fig. 1d), and the specimen is examined with a two-beam interference microscope (Fig. 2). This instrument produces interference fringes which may be considered as occurring between the surface of the specimen and a nearby image of the surface of a reference plane. Typical fringes for such a specimen which was oxidized in wet argon at 1200°C are shown in Fig. 3. The fringes have been adjusted to be perpendicular to the wedge and of a convenient spacing. This occurs when the reference plane of the interference microscope intersects the plane of the silicon surface along a line perpendicular to the wedge and at a suitable angle. Monochromatic thallium green light ($\lambda = 5350$Å) was used throughout the investigation.

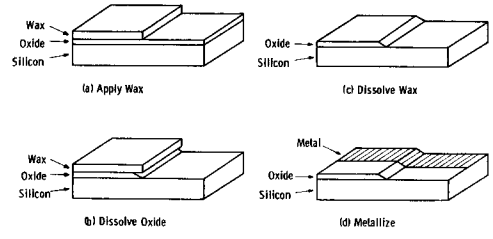

Fig. 1. Preparation of the oxide film step and subsequent metallizing.

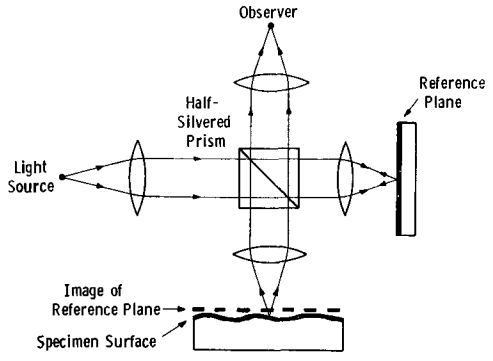

Fig. 2. Optical system of the interference microscope for forming two-beam interference fringes.

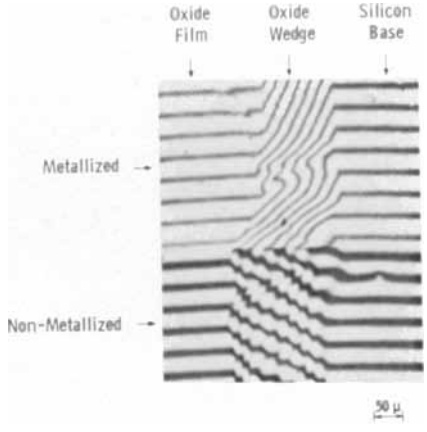

Fig. 3. Interference fringes associated with a relatively thick oxide film on silicon. The specimen was prepared as in Fig. 1 and examined with a two-beam interference microscope.

In the metallized portion of the specimen (Fig. 3, top) a single fringe system occurs, and the displacement of the fringes on going from the silicon base to the oxide film corresponds to a step up. In the nonmetallized portion of the specimen (Fig. 3, bottom), the fringes are more complex. Thus, in the oxide wedge area more than one fringe system occurs. However, a single fringe system predominates, and the displacement of these fringes on going from the silicon base to the oxide film corresponds to a step down.

The origin of these fringe systems is as follows. In the metallized portion (Fig. 4) the interference takes place between the beam reflected from the reference plane of the interference microscope and the beams reflected from the metallized surface of the silicon base, the metallized upper surface of the oxide wedge, and the metallized upper surface of the oxide film in their respective areas. The film thickness d is given by

$$d = p\frac{\lambda}{2} \qquad [1]$$

where p is the fringe displacement and λ is the wavelength of the light. Hence, measurement of fringe displacement on a metallized specimen provides an absolute determination of the film thickness. The

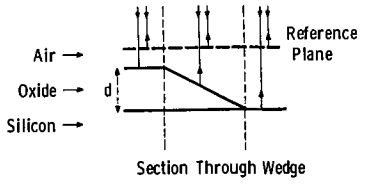

Fig. 4. Origin of the interference fringes in the metallized portion of Fig. 3.

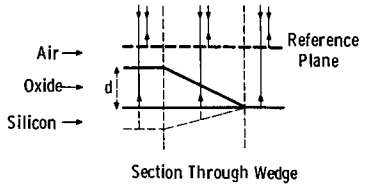

Fig. 5. Origin of the main interference fringes in the nonmetallized portion of Fig. 3.

accuracy is estimated to be ±0.1 fringe, corresponding to ±270Å. The displacement for the film of Fig. 3 is 6.0 fringes, corresponding to a film thickness of 16,000Å.

In the nonmetallized portion (Fig. 5) the interference mainly takes place between the beam reflected from the reference plane of the interference microscope and the beams reflected from the surface of the silicon base, the lower surface of the oxide wedge, and the lower surface of the oxide film in their respective regions. The oxide film of refractive index n has the effect of increasing the optical path length in the film, the oxide/silicon interface thereby being apparently lowered. The amount of lowering in the oxide film area is $d(n-1)$, and the film thickness is given by

$$d = q\frac{\lambda}{2(n-1)} \qquad [2]$$

where q is the fringe displacement. Hence, measurement of fringe displacement on a nonmetallized specimen enables the film thickness to be determined if the refractive index of the film material is known. The accuracy is again estimated to be ±0.1 fringe, but this now corresponds (assuming $n = 1.50$) to ±540Å.

If measurements are made on metallized and nonmetallized portions of the same specimen, then equations [1] and [2] hold simultaneously and so

$$n = 1 + q/p \qquad [3]$$

Hence, the refractive index of the oxide film can be determined simply by measuring the two fringe displacements q and p. The accuracy for a 15,000Å film is estimated to be 1-2%. The values obtained to date for oxide films on silicon have been in the range 1.48-1.50. This method for determining the refractive index of surface oxide films can presumably be applied to materials other than silicon.

Returning to Fig. 3, the wedge area in the nonmetallized portion of the specimen exhibits a complicated fringe array.[1] In addition to the main fringe system crossing the wedge obliquely, there is a weaker system crossing the wedge obliquely in the opposite direction. Comparison with the metallized portion of the specimen identifies this system as being associated with the reference plane of the interference microscope and the upper surface of the oxide film. There is also a third system, seen as a perturbation associated with the main system, running in a direction parallel to the wedge. This system arises from interference occurring between the upper surface and lower surface of the oxide wedge. Hence, it should be possible to examine this latter system without using an interference microscope. The result of removing the reference plane of the interference microscope, equivalent to using a metallurgical microscope equipped with a monochromatic light source, is shown in Fig. 6. In the metallized portion of the specimen no fringes occur, while in the nonmetallized portion of the specimen the third fringe system occurs alone. The origin of this fringe system is shown in Fig. 7. The film thickness is given by

$$d = r\frac{\lambda}{2n} \qquad [4]$$

where r is the number of fringes within the wedge area. The number of fringes r is counted from the silicon base toward the oxide film, the silicon base being considered as the center of a bright fringe. The fractional fringe is estimated by interpolation assuming the slope of the wedge to be uniform. When the wedge terminates with a dark fringe, as for example in Fig. 8b, d, and f, the fractional fringe can also be estimated from the degree of grayness of the oxide film away from the wedge area. Hence, counting the number of wedge fringes on a nonmetallized specimen enables the film thickness to be determined if the refractive index of the film is

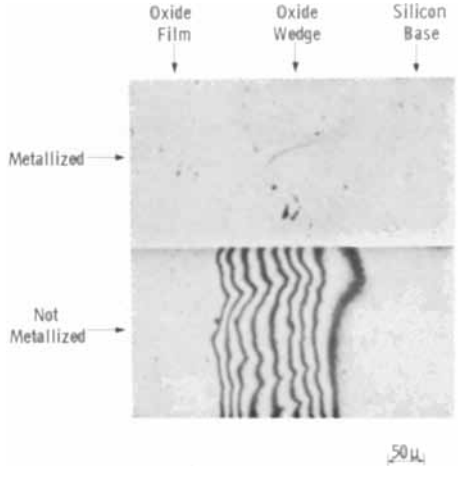

Fig. 6. Result of removing the reference plane of the interference microscope while observing the fringes of Fig. 3. Only wedge fringes in the nonmetallized portion remain.

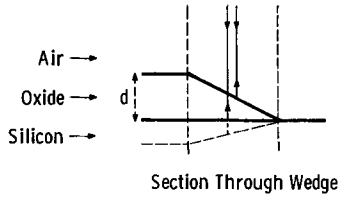

Fig. 7. Origin of the wedge fringes of Fig. 6

[1] A somewhat similar array associated with oxide films on uranium was recently reported by Stebbins and Shreir (1). However, no photographs of the fringes were shown.

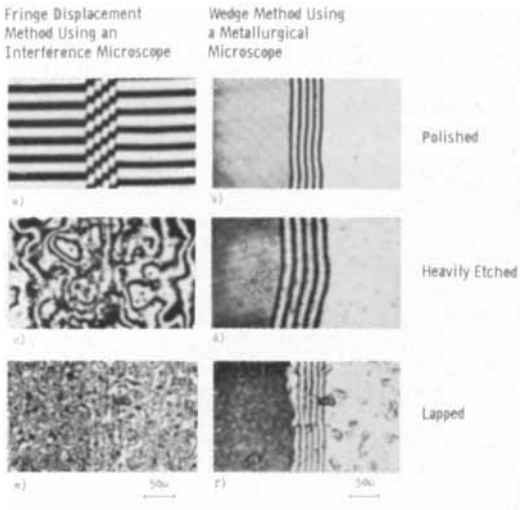

Fig. 8. Influence of surface finish on the fringe displacement and wedge methods for determining film thickness. The wedge method can be used for smooth and rough surfaces.

known. The accuracy is estimated to be ± 0.2 fringe, corresponding (assuming $n = 1.50$) to ± 350Å. Alternatively, by making measurements on metallized and nonmetallized portions of the same specimen according to Eq. [1] and [4], respectively, the refractive index of the oxide film can be calculated from

$$n = r/p \qquad [5]$$

For the derivation of Eq. [3] and [4] it was assumed that any phase changes occurring at the air/silicon, oxide/silicon, and air/oxide interfaces could be disregarded. The assumption is justified by the following. Referring to the nonmetallized portion of Fig. 3, the fringe system associated with the silicon base is dependent on a phase change occurring at the air/silicon interface. On reaching the oxide wedge this fringe system splits into two systems. The main system, proceeding toward the top of the photograph, is dependent on a phase change occurring at the oxide/silicon interface. The secondary system, proceeding toward the bottom of the photograph, is dependent on a phase change occurring at the air/oxide interface. Figure 3 and other similar photographs show that these three fringe systems all meet without any abrupt discontinuities at the boundary where the oxide wedge begins. Hence, it can be deduced that these phase changes are all the same, at least within the accuracy of the measurements discussed here, and can therefore be disregarded. The assumption is further supported by the good agreement obtained in measuring thicknesses by more than one of the interference methods described above.

In the calculation of the accuracies from Eq. [2] and [4], no account was taken of possible errors due to uncertainty in the value assumed for the refractive index n. The additional error which would result may be readily calculated. For example, for Eq. [4] a 1% error in n corresponds to an additional 1% error in d, and for a film 10,000Å thick this amounts to a further ±100Å. This error is small compared with the error given above arising from the fringe measurement, ±350Å, indicating that a knowledge of n to 1% is usually adequate for such measurements.

The wedge method for determining film thickness has a number of practical advantages over the fringe displacement method. The time and equipment involved in metallizing are eliminated. The fringes can be observed readily with a standard metallurgical microscope equipped with a monochromatic light source, so that an interference microscope is not required. Moreover, the only adjustment necessary in order to see the fringes is to focus the microscope.

The wedge method has a further practical advantage, namely, that measurements can be made equally well on specimens whose original surfaces are relatively uneven. This has been demonstrated by applying the fringe displacement and the wedge methods to specimens with three different types of surface finish: polished, heavily etched, and lapped (Fig. 8). The photographs in column 1 were obtained using the interference microscope, and fringe displacements can only be measured on the polished specimen. On the other hand, the photographs in column 2 were obtained using a metallurgical microscope, and the fringes are uniform and clearly discernible for all three specimens. The polished and etched specimens were thermally oxidized at the same time, and it can be seen that the number of fringes within each of these two wedge areas are the same even though the angles of the two wedges are slightly different. The number of fringes for the films of Fig. 8b, d, and f are 4.7, 4.7, and 5.5, respectively, corresponding (assuming $n = 1.50$) to film thicknesses of 8400Å, 8400Å, and 9800Å, respectively. For an additional check on the film thickness of the polished specimen, the fringe displacement of Fig. 8a is 1.6 fringes. Substituting this value into Eq. [2] gives (assuming $n = 1.50$) $d = 8500$Å, in good agreement with the value obtained by the wedge method.

It may be noted that many of the surface irregularities associated with the lapped specimen (Fig. 8e) are of the same order of magnitude as the thickness of the oxide film (Fig. 8f), and yet relatively uniform wedge fringes are still obtained (Fig. 8f). The reason for this is that during the oxidation process an oxide film of uniform thickness is formed, the upper surface of the film following the irregularities of the surface of the silicon specimen. During the step-forming process a certain proportion of this thickness is dissolved depending on its distance from the edge of the wax coating. Hence, although the upper surface of the oxide wedge is also irregular, the thickness of the wedge still varies in a relatively uniform manner.

Because of the simplicity and practicability of the wedge method, it has been found advantageous to use the method as a routine laboratory procedure for determining the thickness of oxide films on silicon. In particular, the method has been extensively applied to films thicker than 3000Å with an accuracy of ±350Å.

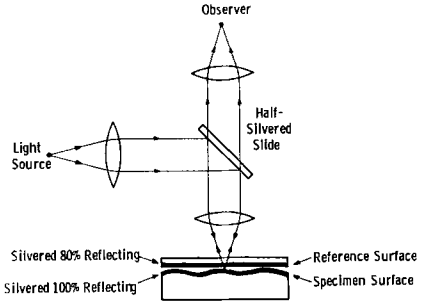

Fig. 9. Optical system using a silvered glass slide for forming multiple-beam interference fringes.

Thin Films

In order to determine the thickness of thin oxide films on silicon, such as those produced by anodic techniques, the methods described in the last section are not sufficiently accurate, and it is necessary to use multiple-beam interference (2). The standard method for obtaining multiple-beam fringes is shown in Fig. 9. One surface of a glass slide is silvered to be approximately 80% reflecting, and the surface of the specimen is silvered to be approximately 100% reflecting. The two silvered surfaces are placed close together with the glass slide uppermost, and the combination is examined with a metallurgical microscope equipped with a monochromatic light source. Light entering the combination undergoes a series of multiple reflections, giving rise to narrow sharp fringes. The silvered surface of the glass slide acts as a reference plane, and the fringes reveal the irregularities associated with the surface of the specimen. The orientation and spacing of the fringes are adjusted by slightly altering the position of the glass slide. Silver is generally used for the metallizing because of its low absorption of light. The value of 80% reflection given above for the glass slide surface is a practical value, being relatively easy to achieve and not critical. Good quality fringes occur only if the two silvered surfaces are very close together.

Multiple-beam fringes obtained by this method for a silicon specimen with a thin oxide film are shown in Fig. 10. The wedge-shaped step in the oxide film was formed by the standard procedure. In this instance the silvered surface of the glass slide was placed directly in contact with the silvered surface of the specimen, and the orientation and spacing of the fringes were adjusted by moving three small weights resting on top of the glass slide. Since the material between the two silvered surfaces is air, the film thickness is given by Eq. [1], where p is the fringe displacement. However, because of the narrowness of the fringes the accuracy here is estimated to be 0.02 fringe, corresponding to ±55Å. The displacement for the film of Fig. 10 is 0.14 fringe, corresponding to a film thickness of 370Å. However, it is difficult when using this method to achieve a routine accuracy much better than ±55Å. This is because of difficulties in positioning the reference surface at an appropriate angle only a few wavelengths away from the specimen surface, and in maintaining the silvered surfaces in good condition, *i.e.*, free from tarnish and surface damage.

Fig. 10. Multiple-beam interference fringes obtained by the silvered glass slide method. The specimen is a step in a thin oxide film on silicon.

A multiple-beam method capable of greater accuracy than the standard technique given above was recently described by Tolansky (3), and Joshi and Tolansky (4). In this method the specimen surface is silvered to be 100% reflecting, and a dilute solution of collodion in amyl acetate is applied to the surface. The specimen is held vertically so that the solution drains and subsequently dries to give a thin wedge-shaped collodion film. The upper surface of the collodion film is then silvered to be approximately 80% reflecting and acts as the reference plane, and the combination is examined in the standard manner.

This method has several advantages compared with the standard technique. First, extremely thin collodion films with very small wedge angles can be formed. Second, the two silvered surfaces between which the reflections occur are protected from the atmosphere, and so do not tarnish. Third, no mechanical adjustment of the two silvered surfaces is performed, so that no surface damage results. Hence, the conditions are ideal for multiple-beam interference, and extremely high quality fringes result. On the other hand, the orientation and spacing of the fringes cannot be adjusted after the collodion film has been formed. Consequently, it is necessary to apply the collodion solution and allow it to drain in such a way that the resulting fringes possess the required configuration.

Fringes obtained using this method for a specimen with a relatively smooth surface are shown in Fig. 11. The fringes are extremely narrow compared with the fringe spacing. If this method were used to measure oxide film thicknesses, the thickness would be given by Eq. [4] where r is the fringe displacement and n is the refractive index of collodion (1.40). It is estimated that fringe displacements could be measured to ±0.002 fringe, corresponding to ±4Å. However, for the method to be successful it is nescessary that the upper surface of the collodion film be smooth.

Fig. 11. Multiple-beam interference fringes obtained by the collodion film method. The specimen is a glass slide with a relatively smooth surface.

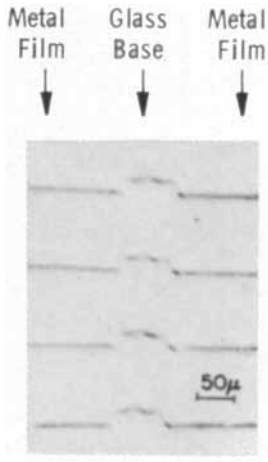

Fig. 12. Multiple-beam interference fringes obtained by the resin film method. The specimen is a double step in an evaporated metal film.

When this method was used to determine the thickness of a number of surface films by measuring step heights, the results were unsatisfactory because the upper surface of the collodion film tended to follow the contour of the step rather than remain smooth. This was ascertained by examining the metallized upper surface of the collodion film with a two-beam interference microscope. Consequently, the indicated fringe displacement was not a true measurement of the film thickness.

The lack of smoothness of the upper surface of the collodion film on crossing the step is thought to arise from the following mechanism. When the collodion solution is applied, the lower surface of the liquid film closely follows the contour of the specimen surface, and the upper surface of the liquid film is smooth. As the solvent evaporates the film becomes thinner and more viscous, and before solidification is complete the film is so viscous that no further lateral movement of the liquid is possible. Consequently, the remaining solidification occurs by a fractional reduction of the remaining liquid film thickness, with the result that the upper surface of the final collodion film follows to some extent the contour of the specimen surface. This behavior presumably occurs whenever a film is formed by a method in which a volume change occurs during solidification.

In order to overcome this difficulty a number of films were prepared using materials exhibiting an insignificant volume change during solidification, *e.g.,* resins which solidify by polymerization and waxes. In all instances the upper surfaces of these films remained smooth on crossing steps on the specimen surface. Consequently, if such materials are used instead of collodion to form the required film, the measured fringe displacement correctly corresponds to the step height.

However, when clear resins with such properties were used to form the wedge-shaped films, the films tended to possess large wedge angles and to be thick. Consequently, the fringes were closely spaced and not of the high quality obtainable with a collodion film. The reason for this is that the viscosities of the liquid resins were approximately the same as the viscosity of the collodion solution. Hence, the liquid films formed on draining a surface vertically using the resins exhibited approximately the same profile as the liquid film formed using collodion. However, after solidification the resin films had substantially the same form, whereas the collodion film possessed a much shallower wedge angle and was much thinner because of the appreciable volume reduction caused by the evaporation of the solvent. Consequently, although a film material which does not significantly change in volume on solidification is required to give valid step height measurements, such a material is less suitable for forming the wedge-shaped films.

A practical application of this method using an epoxy film is shown in Fig. 12. The specimen is a metal film evaporated onto glass rather than an oxide film on silicon, but nevertheless serves to illustrate the method. A strip of the metal film approximately 0.1 mm wide was in this instance removed by lightly scribing the surface with a needle point; the specimen was then silvered to be 100% reflecting. An epoxy resin was applied with a small brush, one stroke being made perpendicular to the strip. When the resin had solidified the upper surface was silvered to be 80% reflecting, and the combination was examined in the standard manner. In the area shown in Fig. 12 uniformly spaced fringes cross the strip approximately perpendicularly and undergo symmetrical displacements at the two steps. The straight part of the displaced fringe corresponds to the thickness of the metal film, while the central V-shaped part corresponds to the depth of the scratch mark made on the glass by the needle point. The film thickness is given by Eq. [4], where r is the fringe displacement and n is the refractive index of the epoxy resin (1.49). The accuracy of measurement is estimated to be 0.02 fringe, corresponding to ±35Å. The displacement is 0.18 fringe, corresponding to a film thickness of 320Å. Accuracies as good as ±20Å have been obtained occasionally by this method.

Summary and Conclusions

Optical interference methods for determining the thickness of oxide films on silicon have been investigated. In all instances a portion of the film was dissolved with HF, and the height of the step thus created was measured. For thick films (>3000Å) two-beam interference was used, and for thin films (<3000Å) multiple-beam interference was used.

Three different methods were employed for the thick films. First, the specimen was metallized and the fringe displacement on crossing the step was measured. Second, the procedure was the same, except that the specimen was not metallized. Third, a shallow wedge-shaped step was formed, the specimen was not metallized, and the number of fringes within the wedge area was counted. The routine accuracies of the three methods were approximately ±270, ±540, and ±350Å, respectively. The first and third methods are the most important. Thus, the first method is an absolute method, *i.e.*, is independent of the refractive index of the oxide film, and is most accurate. The third method has a number of practical advantages that make it valuable as a routine laboratory procedure, and it is only slightly less accurate than the first method. For those oxide films whose refractive index is not known, the refractive index can be deduced simply from fringe measurements made on any particular film by either the first and second methods, or the first and third methods. The accuracy is ±1-2% for a film 15,000Å thick.

Two different methods were used for the thin films. First, the specimen was silvered to be 100% reflecting, a glass slide was silvered to be 80% reflecting, and the slide was placed close to the surface of the specimen (2). The routine accuracy was approximately ±55Å, and the method is an absolute method. Second, the specimen was silvered to be 100% reflecting, a thin liquid film was applied to the specimen surface and allowed to solidify, and the upper surface of the film was silvered to be 80% reflecting. When solutions which dried by evaporation of a solvent were used for the liquid films, *e.g.*, collodion in amyl acetate (3, 4), extremely high-quality fringes were obtained. However, step height measurements were not valid because the upper (reference) surface of the dry collodion film tended to follow the contour of the specimen surface rather than remain flat. When clear resins which solidified by polymerization were used for the liquid film the fringes were not of such high quality. However, step height measurements were valid because the upper surface of the solidified resin was flat. The routine accuracy using resins was approximately ±35Å. Further development of this method, and in particular procedures for applying thin resin films to specimens, should enable this accuracy to be significantly increased.

Acknowledgments

The authors wish to thank Doctors H. F. John, G. Mott, and R. Stickler for useful discussions, and Mr. D. Sealer and Mrs. E. M. Black for valuable assistance with the experimental work. The work was sponsored in part by The Wright Patterson Air Force Base.

Manuscript received June 11, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1963 JOURNAL.

discussion. It was found that the ratio of hydrogen to oxygen uptake was essentially constant over both the pretransition and post-transition corrosion region and independent of heat treatment conditions.

It would be of interest to know if the plateau in the hydrogen to oxygen uptake ratio for Zr-2 Nb-0.5 Sn in 500°C-1 atm steam (Fig. 12 of the discussed paper) has been observed at lower temperatures and/or higher pressures or for other Zr-Nb-Sn alloys.

B. Cox: The primary difference between the results obtained at A.E.R.E.[2] and those of Fisch[3] was the observance at A.E.R.E. of an increased rate of hydrogen uptake by a Zr-Nb-Sn alloy in the post-transition oxidation region at 500°C, and not the occurrence of a "plateau" (since the results at low weight gains, if extrapolated, give a line of similar gradient to that through the K.A.P.L. results). More recent results of hydrogen absorption by Zr-Nb(-Sn) alloys have been presented in an A.E.R.E. report,[4] and the difference

[2] B. Cox, *This Journal*, **109**, 6 (1962).

[4] B. Cox, P. G. Chadd, and J. F. Short, AERE-R 4134, Aug. 1962.

between these results and those obtained at K.A.P.L. has been discussed. At temperatures of 400°C and below, results obtained here for a range of Zr-Nb (-Sn) alloys were in good agreement with those reported from K.A.P.L.; at higher temperatures, however, an increase in the rate of hydrogen uptake during post-transition oxidation was generally observed.

Rösler[5] and Klepfer[6] have also observed increases in the hydrogen uptake rate following transition, whereas Dalgaard[7] and Boulton[8] have not. In many instances, the alloys used in these experiments differ somewhat in composition and heat treatment, and it is not possible to eliminate either of these as the cause of the divergence of results. However, both Boulton and ourselves have used specimens from the same billet, in the same metallurgical condition, with different results. Thus, the observed differences result, probably, from small variations in experimental technique, the oxygen content of the steam being the most likely variable to affect the results. Recent work at Hanford[9] has shown that even small variations in the oxygen content of the steam can result in profound changes in the hydrogen uptake behavior of Zircaloy-2 and Zircaloy-4. We currently are performing experiments to test this hypothesis, with respect to Zr-Nb alloys.

Electrodeposition of Gallium on Liquid and Solid Gallium Electrodes in Alkaline Solutions

J. O'M. Bockris and E. Enyo
(pp. 48-54, Vol. 109, No. 1)

J. D. Corbett[10]: The authors' purpose and technique for studying the electrolysis of basic gallate solutions at gallium electrodes are well taken. However, the suggested electrode mechanisms should be made compatible with more recent knowledge of the solution chemistry of gallium. The principal evidence cited regarding the stability of lower oxidation states of gallium in aqueous solution is Latimer's[11] conclusion that $Ga_2O(s)$ is unstable with respect to disproportionation into gallium metal and Ga_2O_3. However, the evidence for this is tenuous and, moreover, it is stated to apply to *acidic* systems. The same source also estimates that the gallium (II) state is similarly unstable in *alkaline* solutions, the evidence in this case being the behavior of the so-called gallous chloride $GaCl_2$. It is now known that neither statement is entirely correct. First, the gallium dichloride has amply been shown to be a salt of gallium (I), $Ga^+(GaCl_4^-)$,[12,13] and there is no evidence for salts of Ga^{2+}. Secondly, the principal reaction of such gallium(I) salts with aqueous acid or base is the formation of hydrogen [plus gallium (III)] and not disproportionation,[12,14] contrary to Latimer and to Eq. [7] of this paper.

Equally pertinent to this discussion is the observation in this laboratory[15] that alkaline solutions of gallium(I) salts are relatively stable, in contrast to the rapid reaction found with acids. Solutions of Ga ($GaCl_4$) in aqueous NaOH decompose solely *via* the homogeneous reduction of water in a reaction that is first order in both gallium(I) and hydroxide concentrations over the range of 1 to 4M OH^-; a maximum of −1.39v for the Ga(I)—Ga reduction potential can be derived from the reducing capabilities of such solutions. Since the half life of the decomposition reaction is 5.2 hr in 1M OH^-, the possible formation of this intermediate should certainly be considered in the oxidation of gallium metal or in the reduction of alkaline galate(III) solution. It is difficult to assess the rate of the subsequent, nonelectrolytic oxidation of gallium(I) by solvent in the present paper, however, as the concentration of free (or total) hydroxide utilized does not appear to be given.

Insofar as macroscopic reactions can be related to the mechanisms under consideration here, the production of significant amounts of gallium(I), either by equilibration of 0.05M $Ga(OH)^-_4$ in 1M OH^- with the liquid metal or as a by-product of the deposition of the metal by electrolysis of gallate (III) solutions 1 to 3M in OH^-, has not been detected. On the other hand, the anodic oxidation of metal into 1M NaOH has been found to yield reduced gallium as well as the normal gallate at least in the range of 17-170 ma/cm². Although the authors note that the anodic overpotential-current density relationship (Fig. 7 of discussed paper) shows deviations suggestive of Ga(I), the mechanism applied still involves the unknown disproportionation reaction. It would seem more appropriate to consider instead either the disproportionation of or a rapid reduction of water by the less stable gallium(II) in both the anodic and the cathodic processes.

Anodic Polarization Studies in Neutral and Alkaline Solutions Containing Corrosion Inhibitors

K. S. Rajagopalan, K. Venu, and K. Balakrishnan
(pp. 81-87, Vol. 109, No. 2)

J. E. O. Mayne[16]: The authors conclude from the current density/NaCl conc relationship, Fig. 3, that a current density of 290 μa/cm² should distinguish between a corrosive and inhibitive solution. However, this conclusion is not in accordance with their experimental results since the correlation between the polarization tests given in Fig. 5 and the results of the corrosion tests recorded in Table III cannot be regarded as satisfactory. The bias toward passivity shown in the anodic polarization test carried out at 290 μa/cm², Fig. 5, is to be expected at such a high current density; much better correlation has been obtained in similar solutions at 10 μa/cm², although a similar bias toward passivation in the polarization experiments has been experienced at this low current density in the presence of certain corrosive ions such as perchlorate.[17]

It is felt that in order for anodic polarization to be of use in making predictions the current density should be kept low; furthermore, the period of immersion in the solution before the application of the current should be carefully controlled.[18]

K. S. Rajagopalan, K. Venu, and K. Balakrishnan: We have shown that when one plots the current density required to reach the desired potential (of oxide film formation or oxygen evolution) against concentration of sodium chloride, a very sharp increase in the current requirement is observed after a given chloride concentration is reached. This would indicate that at higher chloride concentrations there is little likelihood of the oxide film being kept in repair by local

action. The choice of 290 μa/cm^2 was made as it was rational to take the current represented by the region where the change in the current density requirement was steepest with respect to sodium chloride concentration. In other words, experiments were carried out under the most favorable conditions of repair of oxide film that can at all be met with in the actual system to study the inimical effect of aggressive anions. The authors have shown later in the paper that a study of the time taken for potential to fall back to a corroding potential in relation to concentration of sodium chloride would be more significant than an experiment based on the criterion of a rise in potential on application of current as suggested by Dr. Mayne. It appears to be quite reasonable to carry out such a study under the most favorable conditions, as failure under these conditions may be taken to be a clear indication of failure in natural conditions.

A more detailed investigation may reveal the exact relationship that exists between the time of breakdown and concentration of sodium chloride. This would help in defining the conditions for breakdown of the oxide film. Even then the conditions for breakdown of an oxide film that is not kept under efficient repair would differ somewhat from those inferred in this way. The lack of complete correlation between results obtained in direct tests (Table III) and the conclusions drawn earlier from polarization measurements is, therefore, not unexpected. But the point to be remembered here is that the actual system is a more difficult system for making predictions about the Cl: OH concentration ratio which will cause breakdown of the oxide film.

The Effective Duration of a Linear Slow-Cool

D. R. Killoran (pp. 170-171, Vol. 109, No. 2)

E. D. Fabricius[19]: There are two major types of impurity diffusion mechanisms, interstitial and substitutional. Impurities that diffuse interstitially are characterized by a small diffusion activation-energy, and a very temperature-dependent solid solubility; while those that diffuse substitutionally exhibit a large diffusion activation-energy and a relatively temperature-insensitive solid solubility. Below the maximum solid solubility of impurities in germanium and silicon, the temperature dependence of the solid solubility may be approximated quite closely by an expression of the form[20]:

$$C_s = A \exp(BT) \qquad [1]$$

Table I

Diffusion type	Element	B (°K^{-1})[a]	H/k (°K)
Interstitial	Ag	0.0100	14,300[b]
Interstitial	Li	0.0100	5,800[b]
Substitutional	Sb	0.0020	28,600[c]
Substitutional	In	0.0011	42,400[c]

[a] Calculated from Solid Solubility graphs of: F. A. Trumbore, *B.S.T.J.*, 39, No. 1, 208 (1960).
[b] B. I. Boltaks, *Zhur. Tekh. Fiz.*, 28, 996 (1958), and G. A. Ratcliff, Private communication.
[c] W. C. Dunlap, *J. Phys. Rev.*, 94, 1531 (1954).

Table I of this discussion lists some representative values of the activation energies of diffusion and the approximation of Eq. [1] for impurities in germanium.

On cooling, a material will tend to reject impurities in excess of the solid solubility, thus forcing the diffusion near the surface where the concentration of impurities is greatest.

The general equation for a slow-cool when both the solid solubility and the diffusion coefficient are changing with temperature cannot be solved in a closed analytical manner. However, an arbitrary distribution of impurities, $C_1(x)$, in an infinite slab of material, if allowed to redistribute itself by diffusion, will diffuse according to the following equation[21]:

$$C(x,t) = \int_{-\infty}^{\infty} (4\pi Dt)^{-1/2} C_1(\xi) \exp[-(x-\xi)^2/4Dt]\, d\xi \qquad [2]$$

where D is the diffusion coefficient, and t is the time of diffusion. Eq. [2] can be approximated for a slow-cool by replacing the integral by a series and using the constant-temperature diffusion data for the initial profile, yielding:

$$C(x,t) \approx \sum_i (4\pi Dt)^{-1/2} C_1(\xi_i) \exp[-(x-\xi_i)^2/4Dt]\, \Delta\xi \qquad [3]$$

Due to a lack of data on both rate limitations at surfaces[22,23] and the reactions involved when the concentration at the surface exceeds the solid solubility of a material, one approach would be to assume that the material rejects everything in excess of the solid solubility, limited by the rate of diffusion, and that on the vapor side of the interface the concentration is given by the solid solubility.

Eq. [3] has been programmed on an IBM 650 digital computor under the above assumptions, for the case of an interstitial diffusor, Ag, and a substitutional diffusor, Sb, with the results as shown in Fig. 1 and 2 of this discussion. A comparison with Killoran's equation shows that, except very near the surface, both methods yield almost the same concentration profile for substitutionals. Thus, due to its simplicity, Killoran's approach is the more useful.

For interstitials, a better solution would be to calculate Eq. 3, assuming $[D]$ is a constant, given by the mean value over the temperature interval. While tedious, the equation can be calculated in a reasonable time in this manner, with an accuracy within about 5% of the programmed values. This is due to the fact that, since D appears in the argument of an exponent and under a radical sign, Eq. [3] is relatively insensitive to small change in D.

The validity of Eq. [3] has been verified by measurements of sheet resistivity (yielding the area under the curve), and junction-depth measurements [yielding the value of $C(x)$ at various depths] for several impurities in germanium, the calculated values being within the limits of error in measurement in all cases.

Acknowledgments.—The discussor is indebted to Fred Barson of IBM for directly suggesting this method of attack, to Ray Zachary for arranging the equation in a manner amenable to programming, to Charles Ratliff for programming the equation, and to Gordon Ratcliff for data on the diffusion coefficient of Ag in Ge, as well as many valuable discussions of the problem.

Daniel R. Killoran[24]: The validity of the method used in my paper depends on the assumption that all other parameters remain the same during the slow-cool as during the previous diffusion. However, these results are applicable to the problem considered by Fabricius in the sense that they constitute a limiting case. In particular, it will be shown that

$$U(x,\tau) = C_o \operatorname{erfco}\left[\frac{x}{\sqrt{4\lambda}}\right] - |\epsilon| \qquad [1]$$

where C_o is the initial surface concentration, x is the distance from the surface, $U(x,\tau)$ is the exact solution of the problem when the surface concentration is allowed to decrease during the slow-cool, and

$$\lambda = D(\theta_o)\{\text{duration of initial diffusion}\} \qquad [2]$$

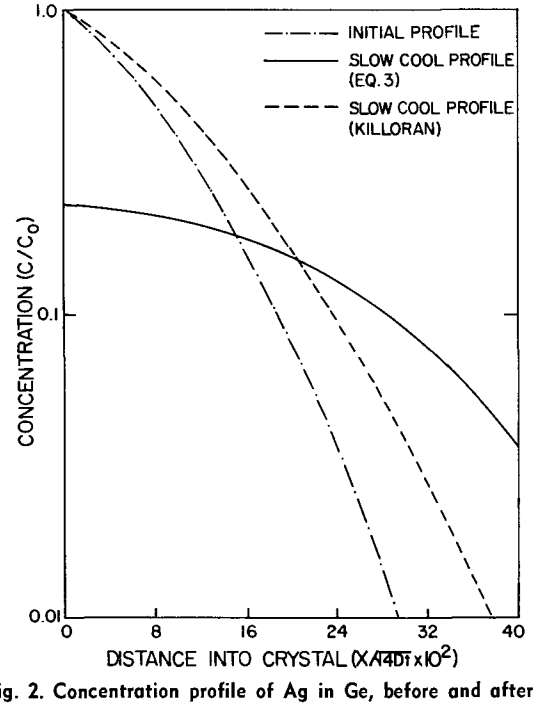

Fig. 2. Concentration profile of Ag in Ge, before and after slow-cool, comparing Eq. [3] with Killoran's equation.

Throughout the analysis we will use the effective time (τ) defined by the equation

$$\tau = \int_0^t D(t)\,dt \qquad [3]$$

where $D(t)$ is the diffusion constant expressed as a function of time.

The expression for the surface concentration as a function of tau is exceedingly complicated, but we only need to know that it is everywhere positive, differentiable, of exponential order, and monotonic decreasing. These facts can be verified by inspection.

Let

$$\frac{\partial^2 C}{\partial x^2} = \frac{\partial C}{\partial \tau} \qquad [4]$$

subject to the boundary conditions

$$C(O,O) = C_o \qquad [5]$$

$$C(x,O) = C_o \operatorname{erfco}\left[\frac{x}{\sqrt{4\lambda}}\right] \qquad [6]$$

$$C(\infty,\tau) = 0 \qquad [7]$$

$$C(O,\tau) = F(\tau) \qquad [8]$$

where $\mathbf{F}(\tau)$ is to satisfy the stated conditions on the surface concentration.

Then, by Duhamel's Theorem

$$C(x,\tau) = \int_0^\tau F(\tau-s)\frac{\partial}{\partial s}\left[\operatorname{erfco}\left(\frac{x}{\sqrt{4(\lambda+s)}}\right)\right] ds \qquad [9]$$

Integrating by parts

$$C(x,\tau) = F(O)\operatorname{erfco}\left[\frac{x}{\sqrt{4(\lambda+\tau)}}\right] - F(\tau)\operatorname{erfco}\left[\frac{x}{4\sqrt{\lambda}}\right] - \int_0^\tau \operatorname{erfco}\left\{\frac{x}{\sqrt{4(\lambda+s)}}\right\}\frac{\partial}{\partial s}F(\tau-s)\,ds \qquad [10]$$

But $F(O) = C_o$ by condition [5] and

$$F(\tau) > 0 \text{ for all } \tau$$

$$\operatorname{erfco}\left\{\frac{x}{\sqrt{4\lambda}}\right\} > 0 \text{ for all } x$$

$$\operatorname{erfco}\frac{x}{\sqrt{4(\lambda+s)}} > 0 \text{ for } x \text{ and } s$$

$$\frac{\partial F(\tau-s)}{\partial s} > 0 \text{ for all } s \text{ and } \tau$$

Therefore,

$$F(\tau)\operatorname{erfco}\left\{\frac{x}{\sqrt{4\lambda}}\right\} > 0 \text{ for all } x \text{ and } \tau \qquad [11]$$

and

$$\int_0^\tau \operatorname{erfco}\left\{\frac{x}{\sqrt{4(\lambda+s)}}\right\}\frac{\partial}{\partial s}F(\tau-s)\,ds > 0 \qquad [12]$$

for all x and τ. It then follows that

$$C(x,\tau) = C_o \operatorname{erfco}\left\{\frac{x}{\sqrt{4(\lambda+\tau)}}\right\} - |\epsilon| \qquad [13]$$

which was to be shown. This means that the solution obtained by ignoring the decrease in surface is an upper bound for the exact solution, as physical intuition would suggest. In particular, the exact solution cannot cross the curve

$$C(x,\tau) = C_o \operatorname{erfco}\left[\frac{x}{\sqrt{4(\lambda+\tau)}}\right] \qquad [14]$$

and, consequently, Fabricius' equation is not valid for large values of $\left(\frac{x}{\sqrt{4\,Dt}}\right)$ in his Fig. 2.

The reason for this is not quite obvious, but the assumption that D is constant is certainly suspect.

By expanding the error functions in Eq. [10] in asymptotic series in x, it can also be shown that

$$\frac{|\epsilon|}{\operatorname{erfco}\left[\frac{x}{\sqrt{4(\lambda+\tau)}}\right]} \to O \text{ as } x \to \infty \qquad [15]$$

and therefore Eq. [14] is also the asymptote for the exact solution for large values of x.

It is interesting to compare these results to those obtained by Waring,[25] although his problem is slightly different.

Solution and Diffusion of Corrosion Oxide Film in Zircaloy

R. M. Treco (pp. 208-211, Vol. 109, No. 3)

Richard E. Westerman[26]: The author states (p. 209) that "if the entire weight gain of the oxygen in the film were to be dissolved and diffused uniformly throughout the Zircaloy-2, it would increase the oxygen concentration by 270 ppm."

The increase in oxygen concentration must depend on the geometry of the Zircaloy-2 piece, yet this is nowhere specified. In any case, the system is implied to be finite.

The author has calculated the time required to dissolve completely and uniformly distribute the film throughout the Zircaloy-2 (Eq. [7], p. 209). This equation, as derived by Barrer, gives the time dependence of the solute concentration existing at the surface of a *semi-infinite solid*. The equation has been applied to a finite system, where $C_f = 1270$ ppm. Infinite time is required in a classical diffusion system to effect uniform distribution of a solute, yet an answer of 7.8 days has been obtained by specifying $(C_f - Co)$ and Q in a dimensionless yet finite system, using an equation developed for semi-infinite media. What has been found is simply the approximate time required to attain an arbitrary surface concentration of 1270 ppm oxygen for a Zircaloy-2 specimen of reasonable thickness. A uniform distribution of oxygen throughout the specimen cannot be implied.

The author then applies the same relation to determine the time required to make the corrosion film just disappear from the surface of the specimen, and obtains a value of 1.8 min (p. 210). This time is erroneously short, as the equation does not take into account the terminal solubility of the solute, which will interfere with the establishment of the predicted concentration gradients during solute redistribution. A rigorous method of finding the time required makes use of Pemsler's formulas[27]:

$$X' = 0.676\,\Delta L \qquad [1]$$

where ΔL = decrease in ZrO_2 film thickness

X' = displacement of oxide-metal boundary during solution of ZrO_2 film.

$$t = \frac{X'^2}{4b^2D} \qquad [2]$$

where $b = 0.126$

D = diffusivity of oxygen in Zircaloy-2

t = time

Substituting $\Delta L = 6.180 \times 10^{-5}$ cm, we obtain a value of 3.8 min for film disappearance.

Use of Pemsler's formulas requires that the oxygen initially present in the Zircaloy-2 is initially uniformly distributed or negligible; the latter is a good assumption under the conditions cited in the paper, and the value of the constant "b" has been derived for these conditions. Though it may appear that the difference between 1.8 min and 3.8 min is trivial, only the (fortuitously) high terminal solubility of oxygen in Zircaloy-2 allows Eq. [7] to yield an approximately correct answer. The author states that the time of 1.8 min has been experimentally verified for complete film dissolution. It would be interesting to know if the limits of experimental error are such that the time of 3.8 would be satisfactory also.

In Eq. [9], $\sqrt{X}$ should be replaced with $\sqrt{t}$.

[26] Chemical Metallurgy, Hanford Labs. Operation, General Electric Co., Richland, Wash.

[27] J. P. Pemsler, "The Diffusion of Oxygen in Zirconium and Its Relation to Oxidation and Corrosion," NMI-1177 (May 1957).

R. M. Treco: Correction is to be noted for Eq. [9] on p. 210 as follows:

$$C - C_o = \left(\frac{0.7}{\sqrt{t}}\right) \exp\left(-1.32 \times 10^{+10} X^2_{\text{in.}}/t\right)$$

Respecting Mr. Westerman's first comment, it should be stated that the original work for this paper was based on a finite section which would lead to a concentration of 270 ppm oxygen for that section. Unfortunately, it was necessary to delete actual dimensions from the paper but this in no way alters the diffusion equations presented. The application of Eq. [7], p. 209, was in fact to a semi-infinite solid, the semi-infinite referring to the diffusion path rather than the time for diffusion. In considering the terminal solubility of the solute, it is also necessary to take into account the classical problem of the moving boundary condition. This has also been pointed out in a private communication of J. P. Pemsler who has derived a relationship which is theoretically correct. When this relation is applied to the present problems, *e.g.*, diffusion during corrosion, the calculated results are very similar. Experimentally, the difference between 1.8 and 3.8 min is difficult to rectify on the basis of experimental error, and for the work described was not significant.

An Electron Optical Study of the Effect of Temperature and Environment on the Growth of Oxide Whiskers on Cold-Rolled and Annealed Copper

W. R. Lasko and W. K. Tice (pp. 211-215, Vol. 109, No. 3)

Axel Rönnquist[28]: In the paper of Lasko and Tice it is shown that the lower temperature limit for the appearance of whiskers is about 300°C and that the number of whiskers per unit area in the temperature range 300°-500°C is higher on the preannealed samples than on the cold-rolled ones. This is also in good agreement with the results obtained by the discussor in a kinetic and morphological study of the initial stages of the oxidation of copper.[29]

Lasko and Tice explain their results by assuming that the whiskers are nucelated at dislocations in the base metal. However, another plausible explanation is that the nucleation of whiskers takes place at stress-induced dislocations in the oxide layer. With this assumption the appearance of oxide whiskers at 300°C is readily explained, since at this temperature the ratio CuO/Cu_2O in the outer oxide layer increases[29, 31] sharply, favoring a high stress—the stress in the outer layer will be larger, the larger the proportion of this less dense oxide.[30]

The higher density of whiskers on the preannealed samples than on the cold-rolled ones in the range 300°-500°C is explained by the authors as differences in the movement of dislocations in the metal. A more attractive explanation which favors a higher stress in the oxide layer may be based on the higher oxidation rate of the preannealed samples. The higher oxidation rate depends upon the anisotropic oxidation of copper and the crystallographic transformation taking part during annealing.

Copper when strongly cold-rolled has the well-defined texture (110) $<111>$—the $<111>$ direction of the face-centered cubic crystals is aligned approximately in the cross-rolling direction and the (110)-faces lie approximately in the rolling plane. When the rolled copper has been completely annealed, the preferred orientation changes to (100) $<100>$.[32] Many

[28] Swedish Institute for Metal Research, Stockholm, Sweden.

[29] A. Rönnquist, *J. Inst. Metals*, In press.

[30] W. Jaenicke and S. Leistikow, *Z. physik. Chem. (Frankfurt)*, 15, 175 (1958).

[31] R. F. Tylecote, *Metallurgia*, 53, 191 (1956).

[32] B. F. Decker and D. Harker, *Trans. Am. Inst. Mining, Met. Petrol. Engrs.*, 188, 887 (1950).

authors[33] have pointed out the high oxidation rate of the (100)-face or the preannealed copper sheets.[29]

At temperatures of 500°C and above, it seems somewhat difficult to give an explanation of the higher density of whiskers on the cold-rolled copper. The situation will be rather complicated because of not only oxidation going on, but even recrystallization and grain growth of the metal.

W. R. Lasko and W. K. Tice: The proposed explanation by Dr. Rönnquist that whisker growth takes place at stress-induced dislocation sites in the base oxide layer, although plausible, has not been confirmed experimentally. In order to demonstrate that whiskers originate at defect sites, as proposed in the paper, either in the oxide layer or base metal, it is suggested that the thin foil technique be adopted. Through the controlled oxidation of thin foils it should be possible to establish a correlation between the nature of the growth site and the points at which dislocation lines emerge.

Similarly, Dr. Rönnquist's explanation might be tested by removing the oxide layer from the base metal by means of selective etchants and subsequently observing it, using standard transmission microscopy. If the hypothesis proposed in the paper is correct then one might see structural detail from the whisker continue through the basal oxide. Conversely, if whisker growth emerges from dislocation sites in the basal oxide layer then one may observe the relationship between dislocations and whiskers using "dark field" techniques. Further emphasis using this approach is under way.

Dr. Rönnquist further indicates that the higher density of whiskers observed on the preannealed sample than on the cold-worked material can be accounted for by the higher stresses setup in the oxide layer, the higher oxidation rate depending on the anisotropic oxidation of the copper and the changes in crystallography resulting from the annealing step. This is an interesting hypothesis and one we have previously considered. In fact, we have made studies using the direct carbon replica technique and have observed the anisotropic oxidation of copper. The results of this study will be published shortly.

Transport Numbers in Pure Fused Zinc Chloride

Arnold Lundén (pp. 260-267, Vol. 109, No. 3)

Richard C. Pinkerton[34]: In order to assign transport numbers in the manner described by the author it was assumed that the rates of association and dissociation of the possible complex ions were very small when compared with the time of transit of an ionic species through the membrane. One would expect that the opposite is true, both because the length of the diffusion path must necessarily be large (10^6 times the average interatomic distance), and because any ionic equilibria should be reached very rapidly. The temperature is high. Exchange studies of zinc complexes at room temperature show that over 90% exchange is complete within the time of separation, which is less than a minute in many cases.[35]

After finding that t_c^+ and t_c^- are apparently very small, the author concludes that "no transport by complex ions has been detected in any part of the investigated temperature range" (p. 265). Rather, it should be concluded that, if complex ions are present, equilibrium is reached rapidly. Large proportions of these ions could be present, without affecting the values as they are assigned by the author.

For experiments of Type I (p. 262), tagged M is placed in the anolyte. The catholyte is examined after the run for activity. Assuming that equilibrium is slow, the author concludes that the sum of t^+ and t_c^+ is obtained, corresponding to transport by M^{2+} and MX^+. If the equilibrium is rapid, on the other hand, one should obtain $t^+ + t_c^+ - t_c^-$. This accrues because any M finding itself in the transport region, or membrane, by virtue of being in the cationic state, will eventually spend a fraction of its life as MX_3^-. While in that state, it will be transported in the reverse direction. This can be shown in more detail by defining the transport numbers in terms of the velocities of the individual ions and their mole fractions. As a result, one observes transport which depends on an averaged velocity.

In experiments of Type II, the author finds t_c^-, whereas the rapid equilibrium case would give $t_c^- - t^+ - t_c^+$. This is seen to be just the negative of the value obtained in Type I. However, for the radiotracer experiments performed, a negative value could not possibly be expected. By definition, no tracer is placed in the anolyte in Type II experiments. Instead, it can only be observed that the net transport of M tracer is not positive. Similarly, for the rapid equilibrium case in experiments of Type III and IV, one should obtain $t_c^+ - t^- - t_c^-$ instead of t_c^+, and $t^- + t_c^- - t_c^+$ instead of $t^- + t_c^-$.

Since the results of experiments of Types II and III indicated to the author that the values of t_c^+ and t_c^- would be small, a value for the sum of t^+ and t^- was found by adding the results from experimental Types I and IV. In the fast equilibrium case, this operation would still give $t^+ + t^-$, but it is also seen that this sum is

$$(t^+ + t_c^+ - t_c^-) + (t^- + t_c^- - t_c^+) = t^+ + t^- + t_c^+ + t_c^- - t_c^+ - t_c^- = 1 - t_c^+ - t_c^-.$$

The author is surprised that the sum of t^+ and t^- is not unity. However, the significant result obtained from this very carefully performed series of experiments is precisely that this sum is less than unity. It may be taken to mean that complexed ionic forms do indeed transport a measureable fraction of the current in molten zinc chloride.

Arnold Lundén: In the original paper it was concluded (p. 265) that "if complex ions exist in molten $ZnCl_2$, their lifetime must be considerably less than the time it takes for an ion to traverse the membrane." Dr. Pinkerton has shown that it should be possible to estimate the contribution to transport also from complex ions with lifetimes of the order of 1 sec or less, since $t_c^+ + t_c^- = 1 - t^+ - t^-$, which would give $t_m^+ + t_m^- < 1$. He suggests that the existence of such short-lived complex ions is the cause of the apparently low values of t_m^+ and t_m^-. However, in this case the obtained transport numbers would be independent of the duration of the runs, and the spread in the results should not be larger than corresponding to a probable error of about ± 0.02. There remains a discrepancy with the experimental results in these two respects, unless diffusion inside the disk as well as in the surface layer is taken into account, as was done in the original communication.

While the results for the runs below the melting point of zinc (420°C) are too uncertain for this purpose, the measurements at higher temperatures can be used to estimate an upper limit for Pinkerton's $t_c^+ + t_c^-$. An extrapolation of t^+ and t^- to "infinite running time" gives a sum that might well be unity as stated in the original communication, but if the experimental error is considered there might instead be a slight deficit, and one might write $t_c^+ + t_c^- = 0.03 \pm 0.03$. Thus the existence of short-lived complex ions is neither proved nor excluded, and it seems difficult to do this with the present type of experiment.

Mechanism of Stress Corrosion Cracking in Stainless Steels

R. Stickler and S. Barnartt (pp. 343-344, Vol. 109, No. 4)

J. C. Scully[36]: The work reported by Stickler and Barnartt represents a most welcome extension of

studies of the stress corrosion of stainless steel by use of electron microscopy. The results, however, must be interpreted with care.

The observation, that nonsusceptible stainless steels exhibit a "cell structure" of dislocations while susceptible stainless steels do not, does not necessarily mean that the restricted slip theory of Forty[37] is applicable. He did not originally propose it for austenitic stainless steels, and what evidence there is suggests that it does not apply to them.

Although the rapid mechanical/slow chemical type of propagation has been reported for other systems of stress corrosion, *e.g.*, Cu 4% Al/NaCl + $NaHCO_3$,[38] mild steel in nitrate,[39] the same experimental techniques have failed to indicate that this type of propagation occurs in stainless steel. Nor is this surprising. Austenitic stainless steel is a highly ductile material and it is difficult to see how it can sustain a stage of brittle crack propagation. When 18-8 is strained at 10^6%/sec at −193°C, brittle failure does not occur.[40] For a brittle crack to run under stress corrosion conditions, the strain-rate at the tip of the crack must be higher than this, yet simple calculation shows that it is several orders of magnitude lower.

In a face-centered cubic lattice there are 12 slip directions. A brittle crack will propagate only if the initial tensile stress in the notch is applied in a shorter time than it takes for the critical resolved shear stress of the material to be reached on the nearest conveniently oriented slip plane. It must be pointed out that no time delay has been detected in stainless steel between the application of a stress and the production of a stress.[41] Furthermore, since the postulated chemical embrittling stage is a slow one, a very sharp notch will probably never form since there will be adequate time for plastic relaxation to occur at the tip.

While an alternating mechanism of propagation can explain certain types of intergranular cracking or transgranular cracking associated with precipitates, I fail to see how it can be applied to the transgranular cracking of austenitic stainless steels.

R. Stickler and S. Barnartt: It is true that some of the attempts to detect sudden fracture steps during crack propagation in 18-8 stainless steels have been negative. Sudden jumps in the potential or elongation of wire specimens were not observed in 42% $MgCl_2$ solutions,[42,43] and acoustic detection of mechanical fracture steps was also negative.[43] Only one positive detection (direct microscopic observation) has been reported [Ref. (4) of the paper]. It is possible that, where negative results were obtained, the sensitivity of the method used was not sufficiently high to show up very short fracture steps.

We do not agree that sharp notches would not occur when the over-all anodic reaction which reinitiates the brittle fracture step is slow. The reinitiation process may be pictured as one in which slow anodic metal dissolution takes place over a relatively large area along the edge of the arrested crack; the brittle step does not occur until a small active area is uncovered, at which both the rate and direction of metal dissolution are favorable for development of a microcrack capable of brittle propagation. The latter propagation takes place immediately, but soon stops when the nearest soft region (such as a slip band) is encountered. Meanwhile, there may have been a large number of embryo microcracks developed by the anodic dissolution process. These would be inactive if they were misoriented or if they developed too slowly, so that as Dr. Scully indicated there would be adequate time for plastic relaxation to take place. A more detailed review of the evidence favoring the restricted-slip model, and of related factors such as stacking fault energy, has been given recently by one of the authors.[44]

The Effect of Pressure on the Electroless Deposition Process

J. S. Sallo, J. I. Swenson, and J. M. Carr
(pp. 389-392, Vol. 109, No. 5)

G. Gutzeit[45]: The authors of this paper appear to have neglected the effect of *p*H decrease inherent in the chemical ("electroless") nickel deposition process, and, consequently, to have misunderstood the reasons for the modification of the Brenner and Riddell bath[46] as reported by Gutzeit[47]—which had precisely for its main purpose the elimination of *p*H variations.[48]

The gross equation for chemical nickel deposition has been written[46] as follows:

$$Ni^{++} + (H_2PO_2)^- + H\,O \rightarrow Ni^{\circ} + 2H^+ + H(HPO_3)^-$$

Obviously, a high concentration of hydrogen ions in the bath favors the formation of nickel ions and will, therefore, slow down or stop the reaction from left to right.[49]

The following test data[47] show the effect of initial *p*H in a moderately buffered plating solution (optimum buffering range *p*H 4.0) on the rate of deposition, specifically the weight of the coating deposited in 15 min.

Initial *p*H	Final *p*H (after 15 min)	Avg wt of deposit (3 tests)
5.5	4.55	0.1047
5.0	4.45	0.0918
4.5	4.21	0.0858
4.0	3.90	0.0448
3.5	3.45	0.0223

Furthermore, regardless of the initial *p*H of the plating bath, the hydrogen ion concentration constantly increases as the reaction proceeds, due to the fact that, for each mole of nickel deposited, two hydrogen ions are formed. As a result, the rate of deposition steadily declines while deposition takes place.

As the hydrogen ions are formed at the catalytic surface, the *apparent* reaction rate in an unbuffered or moderately buffered bath is primarily controlled by a diffusion process (*i.e.*, the transfer of H^+ away from said surface). This masks the effect of any other rate determining factors.

Unpublished data[50] show that by increasing the velocity of turbulent agitation in the bath, the rate of nickel deposition is also increased up to a maximum (roughly equal to twice the original rate), then starts decreasing steadily. The first phase is interpreted in relation to hydrogen ion transfer; while the second phase is believed to be due to the rapid translation of the nickel ions past the catalytic surface.

However, if, in order to study the mechanism of reduction of nickel ions by hypophosphite anions, experimental conditions are selected so that the *p*H remains substantially constant (*i.e.*, a strongly buffered

[49] G. Gutzeit and A. Krieg, U.S. Pat. 2,658,841, Nov. 10, 1953.

[50] Obtained several years ago by D. E. Metheny in General American Transportation's Research & Testing Lab.

bath with a large liquid volume to solid area ratio), it has been shown that the reduction rate (and, consequently, the rate of deposition) is essentially a function of hypophosphite concentration. Thus, we agree that the data reported by Gutzeit[47] indicate a pseudo-first-order reaction in a static system, *i.e.*, in a batch operation.

The practical value of these findings resides in the fact that, in modern industrial "electroless" plating systems (KANIGEN® process), the pH shift is continuously corrected by addition of hydroxyl ions to the buffered bath; in other words, the pH value is kept practically a constant, so that the rate of deposition becomes only a function of hypophosphite anion concentration.

In the light of these remarks, the results obtained by the authors of the above captioned paper could have been expected.

J. S. Sallo, J. I. Swenson, and J. M. Carr: We find the comments by Dr. Gutzeit to be in general agreement with the findings and conclusions reported in our paper. It is of particular interest to note that his unpublished data on the effect of agitation agree with our data.

Although this paper was not concerned with the practical aspect of electroless deposition we do not feel that we neglected the effect of pH decrease inherent in the process, or misunderstood the reasons for the modification of the Brenner and Riddell bath. In the text of the paper we state, "It is probable that the main difference between the systems studied in this work is that bath 2 is highly buffered and bath 1 is not."

It is true that certain of our theoretical conclusions could have been anticipated, particularly since Brenner had previously suggested that in his system the rate is controlled by diffusion of hydrogen ions from the active surface. We have attempted to supply experimental data to support these previous conclusions. Our conclusions dealing with the interplay of active surface area and hydrogen gas, and with the effect of the evolved gas, are results of our new data and, to the best of our knowledge, had not been anticipated in the literature.

We do not believe that any available data, including the discussion presented here, could have led to an anticipation of our experimental results. The fact that small applied pressures can alter the rate of the process was completely unanticipated and unexpected.

Etching of Abraded Germanium Surfaces with CP-4 Reagent

E. N. Pugh and L. E. Samuels (pp. 409-412, Vol. 109, No. 5)

A Metallographic Investigation of the Damaged Layer in Abraded Germanium Surfaces

E. N. Pugh and L. E. Samuels (pp. 1043-1047, Vol. 108, No. 11)

T. M. Buck[51]: The two recent papers by Pugh and Samuels[52,53] have presented an interesting metallographic study of the nature of abrasion damage in germanium. In the more recent paper[53] the microscopic observations are used as a means of determining the depth of damage, and it is concluded that the microscopic method is more reliable than the photomagnetoelectric (PME) method[54] and a number of other methods[55,57] which have agreed essentially with the PME method.

While agreeing that the metallographic method appears to be a convenient and useful one, I do not feel that the published information leads to the conclusion that it is the most reliable method. This conclusion was drawn from measurements reported by Pugh and Samuels[52] in which depth values for three different abrasive treatments were obtained by the metallographic method and by the PME method; the depth values by the PME measurements were about 10% smaller in two cases, and 30% smaller in the third case for every deep damage produced by a coarse abrasive, 220-mesh silicon carbide. These discrepancies do not seem very serious since one does not expect great precision in this type of work and is usually able to leave some safety margin in a practical application, such as etching of devices or research specimens. But, beyond this, it should be noted that comparisons with some of the other data in the literature might lead to the opposite conclusion regarding reliability of the methods, if larger depth

		Etch-rate	5-7	Camp (56)
		Etch-rate	8-10	Faust (57)

values, *i.e.*, sensitivity, are to be taken as the criterion of reliability. It may be that the PME method was not used with its greatest possible sensitivity in the results of Pugh and Samuels. Thus, in Table I of this discussion, it can be seen that for 600-mesh SiC depths of damage obtained in earlier work by three different methods range from 15 to 19μ as compared with values of 8.7-11.5μ obtained from Pugh and Samuels. For abrasion with 305 alumina (3200 mesh) we obtained values of 5-7μ by the PME, photoconductivity decay (PCD), and field-effect mobility measurements; by the etch-rate method Camp[56] got 5-7μ, and Faust reported 8-10μ. But Pugh and Samuels reported a depth of only 5.5μ for 303-½ (1200 mesh) alumina which is a coarser abrasive than 305. It might be argued that we used a rougher method of application but we do not believe this to be the case. As we pointed out[55], our values refer to very gentle hand lapping; rougher methods of application can cause deeper damage, but the values quoted represent the smallest obtained for a given abrasive.

The largest discrepancy found by Pugh and Samuels was for deep damage, with 220-mesh SiC. For very deep damage the slope of the curve of PME response vs. depth removed is more gradual and there is, of course, more uncertainty in choosing the point or region where the response ceases to change. Greater sensitivity might have been obtained with the PME method than apparently was achieved in the work of Pugh and Samuels, by using a thinner specimen with higher resistivity. Their highest PME responses were only 7-8 mv, whereas we had values of 100-240 mv which would afford greater sensitivity in the region where response levels off.

The criteria for reliability and sensitivity, and the definition of "damage" itself, are of course related to the properties of the material in which one is interested. We have always been primarily interested in the electrical properties and have, therefore, used the most sensitive electrical property we could find—the surface recombination velocity, measured by both the PME and PCD methods—to estimate the "depth of damage." The etch-rate methods[56, 57] agree well with the electrical methods. The metallographic method now also seems to correlate reasonably well with surface recombination velocity. It is true that the metallographic method would seem to offer the advantage of detecting isolated spots of damage whereas the other methods measure an average property over a large area, as we have pointed out before.[55] However, this advantage does not seem to have resulted in greater sensitivity for the finer abrasive treatments which are of the greatest interest in semiconductor technology.

The metallographic method certainly provides a nice way of studying the nature of surface abrasion damage. At least two models for this damage have been considered in the past. One[58, 59] involves a cracked layer plus a deeper layer containing a high dislocation density. In another study[55] only the cracked layer was found; no evidence for dislocations was found, nor were cracks found as deep as the electrical effects were felt. Pugh and Samuels now find deeper cracks, extending well below the surface irregularities, and it appears that the damage consists of many fine cracks rather than a high density of dislocations. This still seems to leave an unanswered question about the nature of the recombination centers. Why are recombination centers associated with a crack? If it is just a case of a freshly cracked surface having a high density of recombination centers, then it is rather surprising but true that chemical treatments which lower S on an etched surface but which do not dissolve germanium have no apparent effect on the minority carrier lifetime at an abraded surface. It might be interesting to forcing nonetching solutions or gases into the cracks under pressure to see if this would lower the recombination velocity by acting on more of the cracked surface area.

In summary, it is suggested that the differences in sensitivity between the metallographic method and the lifetime methods are small and probably insignificant, but that if a comparison is to be made most of the data in the literature seems to favor the lifetime methods.

E. N. Pugh and L. E. Samuels: We thank Dr. Buck for his comments and for his interest in the work. However, we cannot accept his arguments on the relative sensitivities of the metallographic method and other methods. Our conclusions that the metallographic method was the most reliable were based on comparative tests carried out on specimens abraded under the same conditions. We do not consider that measurements made by different methods on surfaces abraded in different laboratories can be compared. Thus, the differences discussed by Buck could be due simply to differences in the abrasion conditions. This view is supported by the observations reported in our first paper that the depth of damage was greater in specimens abraded unidirectionally than in those abraded with a random motion.

The Influence of Residual Stress on the Magnetic Characteristics of Electrodeposited Nickel and Cobalt

R. D. Fisher (pp. 479-485, Vol. 109, No. 6)

V. Zentner[60]: The author states that "very little attention has been given to the effects of the internal stress on the magnetic characteristics of electrodeposits."

In 1952 we published a report[61] which contains significant information on this subject, thus anticipating Mr. Fisher's recent contribution. Figure 53 of our publication shows a general relation between stress on the one hand and the magnetic properties of coercive force and maximum permeability on the other for 15 nickel deposits obtained from eight different baths. This figure contains essentially the same information as Fisher's Fig. 7. The latter's Fig. 6, showing the effect of the nickel chloride concentration on stress and on the coercive force, is covered in our Fig. 18 and 46.

Table II of Fisher's paper shows that heat treatment at 440°C causes the coercive force of nickel deposits to decrease and the ratio B_r/B_m to increase. Our Table XXI shows the same effects for deposits from five different types of baths; our heat treatment temperature was 400°C.

The effect of stress on the magnetic properties of nickel was also discussed from a different angle on p. 915 of our publication, and data were given in Table XVIII. It was shown that simply removing the basis metal from a nickel deposit relieved the stress and changed the magnetic properties.

Mr. Fisher's paper is of value since it contains information on the magnetic properties of electrodeposited cobalt in addition to nickel coatings. Furthermore, the latter were not deposited under the same conditions as those used by us. However, the conclusions are very similar. If the author had been familiar with our work, he could have used his efforts to enlarge the general knowledge of the magnetic properties of these coatings, rather than to reconfirm data previously published.

R. D. Fisher: I would like to thank Dr. Zentner for calling my attention to his most comprehensive report on the physical properties of electrodeposited metals.

[59] J. W. Faust, Jr., "The Surface Chemistry of Metals and Semiconductors," H. C. Gatos, Editor, p. 130, John Wiley & Sons, Inc., New York (1960).

[60] Materials Technology Dept., Hughes Aircraft Co., Culver City, Calif.

[61] V. Zentner, A. Brenner, and C. W. Jennings, *Plating*, 39, 865 (1952).

Dr. Zentner's results in regard to nickel deposits are similar to mine despite the difference in solution composition, deposition conditions, and methods of measurement. It is significant to note that the influence of the internal stress on the hysteresis properties of nickel deposits appears to be independent of the solution composition and deposition conditions.

The cobalt deposits were heat-treated at 440°C in an attempt to convert some of the cubic cobalt obtained from solutions at low salt concentration to hexagonal cobalt. This was partially successful as indicated in the paper on page 481. Consequently, the nickel deposits were also heat-treated at 440°C.

Diagrammatic Representation of the Thermodynamics of Metal-Fused Chloride Systems

R. Littlewood (pp. 525-534, Vol. 109, No. 6)

K. E. Johnson[62]: The idea of potential $-pO^{2-}$ diagrams for fused salt systems is attractive in principle. However, the significance of the numbers given by Littlewood is questionable because they are determined solely from free energy data for pure chlorides and oxides (some liquid and some solid). For example, the solubility product of NiO in KCl is really given by:

$$\log K_{sp} = \frac{\Delta G_s}{2.303\,RT}$$

and not

$$\log S \frac{\Delta G^\circ}{2.303\,RT}$$

where ΔG_s and ΔG° are the free energy changes accompanying the reactions

$$NiO\ (s) + KCl\ (l) \rightarrow (NiCl_2 + K_2O)$$

in KCl solution and

$$NiO\ (s) + KCl\ (l) \rightarrow (NiCl_2\ (S) + K_2O\ (?)$$

respectively.

The difference, $|\Delta G_s - \Delta G^\circ|$ represents the free energy of solution of the products. Some measure of this quantity has been given for solutions in NaCl-KCl[63] but the problem arises of an appropriate definition of a standard state. For solution (*e.g.*, $NiCl_2$ in KCl) it seems preferable to define the standard state of the solute as when it is at infinite dilution, whereas for a mixed solvent (*e.g.*, $NiCl_2$-KCl) it is appropriate to refer to the pure salt ($NiCl_2$) as the standard state.

If $|\Delta G_s - \Delta G^\circ|$ is small compared with ΔG° then the author's conclusions regarding solubility products would be qualitatively correct and, indeed, there is some further experimental evidence in support of them.[64] However, the author's data[65] give $S = 10^{-4.46}$ for Na_2O in KCl at 800°, yet he prepared a 5% solution of Na_2O in NaCl-KCl at 700°! Would he elaborate on this point.

R. Littlewood: I thank Dr. Johnson for his comments. He is quite correct in saying that the formal treatment presented in this paper makes the assumption that the free energies of solution of oxides in chlorides are negligible. This fact is not mentioned specifically in the paper but, from the expressions used, it should have been clear that this was an implicit assumption. Its validity has not yet been directly established experimentally, and the scant data available are somewhat conflicting. There is now some evidence that the activity solubility products calculated by the methods suggested in the paper have some physical significance, but, on the other hand, the behavior of the oxygen (on platinum) electrode in contact with chloride melts containing oxide ions cannot at present be explained quantitatively. The latter effects might be due to irreversibility of the electrode processes (in which case the subject is not relevant to the present discussion), or they might indicate that hydroxide ions are important.

In his remarks about the solubility of Na_2O, Dr. Johnson has fallen into the common physicochemical trap of confusing activities with concentrations. It should be emphasized that the parameters "*S*" is an *activity* solubility product and the standard states must always be borne in mind. The activity solubility product of Na_2O in KCl at 700°C may be calculated to be about $10^{-5.67}$, relative to K_2O as standard state for oxide ions. This means that for Na_2O at unit activity in contact with a chloride melt we have the expression:

$$S = (Na^+)^2(O^{2-}) = 10^{-5.67}$$

For example, in equimolar NaCl-KCl (writing ion fraction of Na^+ as activity of Na^+, after Temkin), this gives $(O^{2-}) = 10^{-5.67}$ or $pO^{2-} = 5.07$. The meaning of these figures is that if we immersed a reversible oxygen electrode half-cell in the melt, its potential *vs.* a reference electrode would be about 0.6v higher than a similar electrode immersed in pure K_2O. The figure of $10^{-5.67}$ alone does not tell us what concentrations to expect, unless we know something about the ideality of the system.

On the question of standard states it is pertinent to point out that in fused salt solutions a standard state for solutes of infinite dilution does not have the same significance as in aqueous solutions. Infinite dilution in water is equivalent to isolated ions in a dielectric medium, predominantly molecular in character; in fused salts the mixture is still ionic, even at infinite dilution. Standard states referred to infinite dilution in fused salts thus appear to be both cumbersome and irrelevant; where difficulties arise when the pure salt is taken as a standard state, an arbitrary concentration, say 1 mole %, might be used, as is already common in many systems of metallurgical interest. (For references pertinent to this discussion, *see* Footnotes 66-68.)

June 1963 Discussion Section

A Discussion Section, covering papers published in the July-December 1962 JOURNALS, is scheduled for publication in the June 1963 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1962 Discussion Section will be included in the June 1963 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 30 East 42 St., New York 17, N. Y., *not later than March 1, 1963*. All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

that the problems confronting the world today desperately need the broad outlook of the natural philosopher with his familiarity with many fields of knowledge, including the physical, life, and social sciences. In the professional area he posed the question: "Dos Industry want Electrochemists?" Now, eleven years later, greatly needing electrochemically trained people for fuel-cell research and industrial electrolytic operations, many companies wish they had had the foresight to have given encouragement and support to the teaching of electrochemistry.

In his address as the Society's president Professor Uhlig has treated the subject of creativity. He attributes the progress of science to the emphasis placed on creative thinking and intellectual honesty and suggests that the problems of diplomacy and international relations would be greatly benefited by emphasis on these same qualities.

Professional Society Activities

Professor Uhlig is a member of ten professional societies. His participation in the affairs of The Electrochemical Society has been continuous since he became a member in 1937. He is a past chairman of both the Corrosion and Theoretical Divisions. He was for two years editor of the "Journal" and during that time established the high standards that characterize this publication and that have led to its wide acceptance in the scientific world. He has been chairman of the Publication Committee, vice-president, and in 1955-1956 was President of the Society. He helped organize and served as the Society's representative at the First International Conference on Passivity held at Jugenheim, Germany in 1957, and is now assisting in the organization of the Second International meeting on this subject to be held in Toronto next September.

Uhlig has been chairman of the Gordon Research Conference on Corrosion and of the Intersociety Corrosion Committee. He has been a member of the Advisory Committee for the Prevention of Deterioration Center of the National Research Council and of the Corrosion Research Council.

Professor Uhlig is a member of Sigma Xi and of Tau Beta Pi. In 1951 he received the Willis R. Whitney Award of the National Association of Corrosion Engineers given in recognition of outstanding scientific contributions to corrosion knowledge.

The foregoing account has given some evidence of the manner of man we honor this evening. It should be added that he is soft-spoken and considerate of the views of others, yet firm and persistent in his own opinions; that he is unassuming and reserved, yet articulate and convincing, and finally, that he is gentle, gracious, and an altogether delightful human being.

Ladies and gentlemen: I give you Herbert Henry Uhlig, scientist, scholar, and dedicated teacher who has enriched the lives of his fellow men!

Conquering the Outer Space of Corrosion Science[2]

Herbert H. Uhlig

To attempt to tell you about the outer space of corrosion science is somewhat optimistic, as you well realize, because no one knows the details of outer space, real or imagined. Yet we have some concept of the great expanse of the physical universe, and also in the figurative sense of our subject. And the challenge of exploring what we do not know is equally real in either rocket experiments or corrosion studies.

The value of space exploration of any kind is sometimes questioned on economic grounds. This should be less a factor in evaluating corrosion experiments than in launching rockets which are extremely costly per unit, but perhaps we should remind ourselves that the value of all basic investigations including rocket research lies in the facts which are made available and the use of such facts to fulfill the varied needs of mankind. Not to be overlooked is the additional value of such facts interacting with the minds and attitudes of men. In the long range, accumulated truth of whatever kind elevates mental horizons and provides background and preparation for greater things that lie ahead. The world was first proved round before Newton achieved an audience who appreciated his new ideas regarding the solar system. And only after Newton's ideas were digested did Einstein succeed in presenting his concept of relativity. Purely on the side, as a result of logical deductions concerning relativity, he also concluded that mass and energy are equivalent. It was not many years later that we were brought into the nuclear age. One has the impression that if we succeed in solving all the problems which this age has thrust forth, we shall be strong indeed. And succeed we must.

The greatest things that lie ahead in corrosion science on the short range view are the savings of billions of dollars now lost annually by interaction of metal structures with their environments, plus the avoidance of accidents by sudden failure through stress corrosion cracking or corrosion fatigue. Considering the long-range view, our metal resources, of which there is only a limited supply, will be conserved. Purely on the side, our fuller understanding of the corrosion process itself will raise our mental horizons with regard to the nature of metal surfaces and metal fracture, the kinetics of heterogeneous reactions, the basic electrochemistry of composite electrodes in contact with liquid or solid electrolytes, and the structure of semiconductors at metal- or electrolyte-semiconductor interfaces. What more in addition might result from a well thought-out fundamental program is not predictable; the outer space of corrosion science is a vast area, and undoubtedly many surprises await us as we send man-guided rockets farther and farther into the unknown.

Anode and Cathode Reactions

The basic reactions that occur when a metal corrodes in an aqueous electrolyte involve a simultaneous oxidation and reduction reaction on different sites of the surface. Ions of the metal lattice are not soluble, but they become so if they first interact with water thereby acquiring a sheath of water molecules in accord with

$$M^+(s) + nH_2O(l) \rightarrow M(H_2O)^+_n(l) \qquad [1]$$

where n is not well defined; for the alkali metal ions n apparently ranges from 3 to 5 (1). The solvated complex $M(H_2O)_n^+$ still cannot easily escape the metal surface, however, unless the attracting force between the positive ion and a corresponding free negative electron of the metal is neutralized. This neutralization can occur by a reduction reaction elsewhere on the metal surface (cathodic site) which absorbs the elec-

[2] Palladium Medal Address delivered on Oct. 3, 1961, at the Detroit Meeting of The Electrochemical Society.

tron belonging originally to the positive ion of the metal. Typical reactions at cathodic sites are

$$2H^+ \rightarrow H_2 - 2e \quad [2]$$

and

$$1/2\ O_2 + 2H^+ \rightarrow H_2O - 2e \quad [3]$$

supplemented in many instances by

$$O_2 + 2H^+ \rightarrow H_2O_2 - 2e$$

Because of the neutralization process, or stated another way, because electric charge cannot accumulate anywhere in the system without tremendous energy imbalance, both anode and cathode reactions proceed at the same rate. The slower reaction of the two determines the over-all rate of corrosion. If H^+ discharge controls, for example, the corrosion rate becomes sensitive to factors which catalyze or impede H^+ discharge. Good catalysts correspond to values of low hydrogen overvoltage, whereas poor catalysts correspond to high hydrogen overvoltage. Bonhoeffer (2) showed some time ago that catalytic properties of a metal for the reaction $H + H \rightarrow H_2$ approximately parallel hydrogen overvoltage values (Table I). His experiment consisted of measuring the temperature rise of a thermometer, the bulb of which was coated with one of various metals, on exposure to a stream of gaseous hydrogen atoms. He noted that the temperature rise accompanying combination of H atoms in presence of a good catalyst like Pt was higher than for a poor catalyst like Hg. The parallel behavior of temperature rise with hydrogen overvoltage does not mean that the slow step of H^+ discharge is always H atom combination on the cathode surface, but it does indicate that the controlling reaction, whatever it may be, is sensitive to catalytic properties of the electrode material. We find in fact that many corrosion reactions, and also the so-called passive properties of metals and alloys, are frequently related to catalytic properties. This suggests that the detailed electron transfer steps accompanying formation of adsorbed films entering catalytic properties may also occur in corrosion reactions and in establishing passive films (3).

Platinum is a good catalyst for either reaction [2] or [3], and Cu or Ni is effective for reaction [3]. Other metals may behave less effectively for O_2 reduction because of either inherently poor catalytic properties, or because of interposing surface films. Along these lines, copper when coupled to iron in sea water accelerates corrosion of iron by favoring the O_2 reduction reaction and absorbing electrons which otherwise prevent hydrated Fe^{++} from leaving the iron lattice. The reduction of O_2 proceeds so rapidly that within wide limits all dissolved oxygen reaching the copper surface is reduced, and the increased corrosion is proportional to the total surface of copper exposed. Expressed quantitatively, the penetration rate p through corrosion of iron having area A coupled to copper of area B is

$$p = p_o\left(1 + \frac{B}{A}\right) \quad [4]$$

where p_o is the penetration rate of iron uncoupled. Note that if the ratio B/A is large as when iron rivets are placed in a copper sheet, the ensuing corrosion rate of iron in a good conducting medium can be very large. This equation holds in addition for platinum, nickel, and other good catalysts, but for metals such as titanium or lead, which are poor catalysts, the increased corrosion of iron by reason of galvanic coupling is less than the calculated value. Many data have been published which illustrate this point. LaQue (4), for example, reported values in flowing sea water for various iron couples which show greater galvanic corrosion using Ni and Cu compared to Ti and 18-8 (Fig. 1). These results correlate with parallel data on cathodic polarization of the more noble component of the couple in sea water, good catalysts polarizing less than poor catalysts. Tomashov (5) and Delahay (6) also reported polarization data for the O_2-reduction reaction on various metals which can be interpreted in the same way.

Table I. Relation of catalytic activity for $H + H \rightarrow H_2$ to hydrogen overvoltage

Decreasing catalytic activity (Bonhoeffer)	H_2 overvoltage, v 1N HCl, 10^{-3} amp/cm^2
Pt	0.09
Pd	0.12
W	0.27

Passivity

When an uncoupled metal corrodes, reaction [3] proceeds quantitatively at cathodic sites up to an O_2 concentration at the metal surface which reaches or exceeds a critical value. At such a concentration, particularly for transition metal, excess O_2 forms a monolayer of oxygen atoms adsorbed on the surface, resulting in an expanding cathodic and a shrinking anodic area. A layer of this kind excludes H_2O molecules from the metal surface and hence reaction [1] corresponding to dissolution of metal ions is impeded except at residual exposed anodic sites. Hence metal ions no longer enter solution at their usual rate and the metal is said to become passive. Looked at in other terms, adsorbed oxygen decreases the exchange current density i_o (increases anodic overvoltage, O.V.) attending metal ion dissolution in accordance with the Tafel equation

$$O.V. = \beta \log \frac{i}{i_o}$$

Passivity of metal M can also result from anodic polarization at current densities sufficiently high to discharge OH^- or oxidize H_2O in accord with the reactions:

$$M + OH^- \rightarrow O(\text{adsorbed on M}) + H^+ + e \quad [5]$$

$$M + H_2O \rightarrow O(\text{adsorbed on M}) + 2H^+ + 2e \quad [6]$$

where O(adsorbed on M) represents chemisorbed oxygen on the metal surface. The amount of oxygen adsorbed corresponds in some measurements, *e.g.*, stainless steels, to a monolayer of atoms over which a layer of O_2 molecules is chemisorbed (7-9). The critical current density at which reactions [5] and [6] take place is a function of H^+ activity in accord with the following relation:

$$i(\text{crit.}) = K(H^+)^\lambda \quad [7]$$

where λ and K are constants. This relation is derived (10) from first principles and is confirmed by experiment.

Hence for a metal exposed to an aerated solution, the mechanism of passivation may involve a cathodic current in accord with Eq. [3] equal to or in excess of the critical current required for passivity. Since i(crit.) usually increases with H^+ activity (λ is positive), the critical partial pressure of O_2 for passivity also increases with H^+ activity. The quantitative relation between the critical oxygen concentration c for passivity of a metal and *p*H of the solution in which the metal is immersed is obtained by equating the diffusion current for dissolved O_2 to Eq. [7]

$$p\text{H} = \frac{1}{\lambda}\log\left(\frac{K\delta}{4D\mathbf{F}}\right)\frac{1}{c} \quad [8]$$

where D is the diffusion constant of O_2, δ is the thickness of the stagnant liquid diffusion layer at the metal surface (about 0.05 cm), and **F** is the Faraday.

Consequently iron, for example, becomes passive in air-saturated alkaline solutions (*p*H > 10), but only at higher partial pressures of O_2 in neutral water. For chromium or the stainless steels, which have higher affinity for oxygen than does iron and for which i(crit.) is much lower, the passive film forms at a lower critical partial pressure of oxygen, and hence these metals become passive in air-saturated water, or even in dilute acids. For 14% Cr-Fe alloy, as an example, the critical *p*H above which passivity can establish itself in aerated sulfuric acid is 3-4.

For nontransition metals, *e.g.*, Zn, Sn, Pb, which escape from the metal lattice more readily than the transition metals having characteristically higher sublimation energies, excess dissolved oxygen at the cathode, or alternatively anodic polarization beyond i(crit.) may lead to immediate formation of an oxide film instead of an adsorbed film. The oxide film then impedes further corrosion and accounts for passivity by the mechanism of a relatively thick surface diffusion barrier rather than by the mechanism described above. Since chemisorbed films are only metastable intermediates in the formation of surface compounds, an oxide forms eventually on all metals, both transition and nontransition, and hence in many instances of passivity both kinds of films act jointly.

Critical experiments in this area are very difficult to devise, and for this reason investigators of passive phenomena continue to debate whether the adsorbed films described here are really nothing more than thin oxide films. The vast literature on properties of metal surfaces in contact with gases, beginning with the classic investigations of Langmuir, and continued by many investigators more recently (11), speak against this possibility. The evidence is quite clear to anyone willing to look into the matter that adsorbed films have properties distinct from those of thin oxide films. In addition, it can be said that supposed oxide films equivalent in thickness to a measured 0.003-0.01 coulomb/cm² of apparent surface for passive Cr, Fe, and the stainless steels can be no more than 5-20Å thick based on true surface area, and films of this thickness are not likely to be effective diffusion barrier layers. Thermodynamic interpretation of the Flade potential particularly for iron (8) indicates that oxygen comprising the passive film is adsorbed and is not part of any known iron oxide. Furthermore, capacitance and resistance measurements of Kolotyrkin (12) support the view that the passive film on iron is similar to the oxygen film on Pt which is known to be adsorbed.

Effect of Complexing Agents

Returning to reaction [1], the rate at which this reaction proceeds appears to be sensitive to surface complex formation probably involving OH^-. The overvoltage for the anodic dissolution reaction, therefore, is found in the case of iron to increase with decrease in *p*H (13). The details and quantitative relations, however, are not well understood, and much more information is needed, particularly for the transition metals. The complexity of the problem has been discussed by several investigators (14-17). Complexing agents in general, of course, are known to play a part in the tendency for reaction [1] to go. Any complexing agent which reduces the activity of Fe^{++}, for example, simultaneously changes the potential for the reaction $Fe \rightarrow Fe^{++} + 2e$ in the more active direction. Accordingly, under these circumstances, the potential difference between anodes and cathodes of a corroding metal increases, accounting for an increase in the corrosion current. Iron therefore, corrodes much more rapidly than is normal in ammonium salts, in sodium ethylene diamine tetra-acetates, or in concentrated sodium polyphosphate solutions, all of which form complexes with Fe^{++}. When a good oxidizing anion is also present to stimulate the cathodic reaction, as in the case of NH_4NO_3, the rate can be catastrophically high as is well known to those handling fertilizer solutions. Unusually high rates of corrosion for iron in NH_4NO_3 solutions have been measured by several investigators including Heyn and Bauer (18), and still higher rates in concentrated solutions containing excess NH_3 by Weitz and Muller (19), Libinson, Kukushkin, and Morozova (20) and by Hackerman, Hurd, and Snavely (21). Typical examples of such rates obtained recently by Schick at the M.I.T. Corrosion Laboratory (22) for mild steel in an aqueous solution of 44.4% NH_4NO_3, 5.9% NH_3 at room temper-

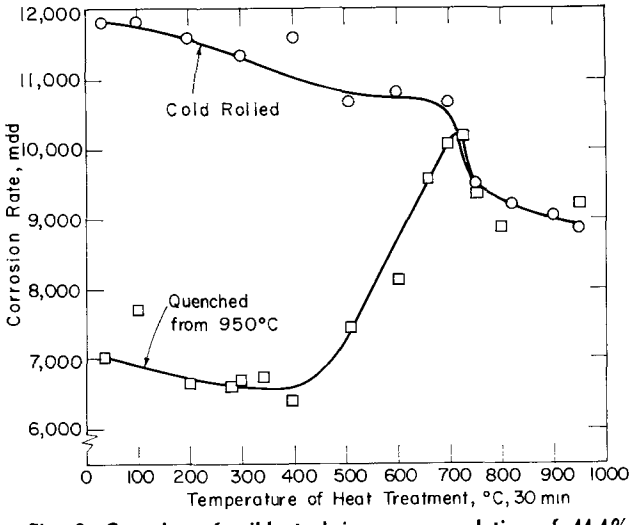

Fig. 2. Corrosion of mild steel in aqueous solution of 44.4% NH_4NO_3, 5.9% NH_3, room temperature.

ature are given in Fig. 2. The highest rates correspond to a penetration of over 2 in. (5 cm) per year. By chemical analysis it was shown that the complex forming in this case has the structure $[Fe(NH_3)_6](NO_3)_2$. Since coupling iron to an equal area of Pt has no effect on the rate, control of the reaction is assumed to be at anodic sites. The rate of dissolution at the anode is sensitive to metallurgical structure as shown by data of Fig. 2, a cold-worked steel corroding more rapidly than one that is quenched from 950°C. However, increased residual energy of the cold-worked metal is not the cause as shown by additional experiments in which cold-worked pure iron, zone refined, corroded at a somewhat lower rate than the same iron quenched from 950°C. Instead, the state of subdivision of carbides and the grain orientation appear to be important, both factors reaching comparable states on heat treatment of mild steel, either cold worked or quenched, for ½ hr at 700°C or above. The corrosion rate can be retarded to the extent of 99 or more % by small additions of SCN^- or various high molecular weight organic substances. These inhibitors probably adsorb on the metal surface interfering with either complex formation, NO_3^- reduction, or both. We have already seen how effectively an adsorbed oxygen film on a passive metal surface can interfere with dissolution of metal ions.

Unusual Valence States

Reaction [1] is complicated for some metals by the tendency to form ions of more than one valence. Which particular valence ion predominates is determined in the usual case by the equilibrium existing at the metal-solution interface. For example for copper, which forms both Cu^{++} and Cu^+, the equilibrium is $Cu + Cu^{++} \rightleftarrows 2Cu^+$ and the corresponding equilibrium constant $(Cu^+)^2/(Cu^{++})$ as calculated from thermodynamic data equals 6×10^{-7}. This value indicates, as observed, that copper usually dissolves predominantly as the divalent ion, Cu^{++}. In a solution which complexes Cu^+, *e.g.*, in HCl, the situation may, of course, change. For other metals, particularly those active in the emf series, it has been proposed that an ion of lower valence may predominate initially, even though it is unstable in water. Unstable ions of this kind are reported to form, for example, during anodic dissolution of Al (23), Mg (24, 25), and Be (26, 27). For Mg, the initially dominant ion, Mg^+, quickly reduces water, one possible reaction being the following

$$2Mg^+ + 2H_2O \rightarrow Mg^{++} + Mg(OH)_2 + H_2 \qquad [9]$$

Additional lesser side reactions may also take place at the same time. In any event, when Mg is polarized anodically, it is observed that hydrogen is evolved at the anode to the extent of about half that at the cathode, and the electrochemical equivalent for magnesium is almost half that usually assigned to magnesium based on formation of Mg^{++} ions. It is not surprising, therefore, that magnesium anodes used for cathodic protection produce only about 500 amp-hr/lb, whereas calculated on the basis of Mg^{++} they should produce 1000 amp-hr/lb instead. The actual output is altered somewhat by local action cells operating on the metal surface, and hence the current efficiency of a magnesium anode also depends to some extent on composition of environment and on the alloy or impurity content of the metal. Some investigators believe that the output of magnesium anodes, so much lower than the calculated value based on Mg^{++}, is accounted for entirely by local action currents. Others (28, 29) propose that a contributing factor resides in metal particles dislodged during the anodic dissolution process. Metallic residues, in fact, are sometimes detected by x-ray as a constituent of anodic reaction products. Other than the possibility that they may also form by dissociation of lower valence ions to a mixture of metal and normal valence ions, it is not yet clear to what extent metallic particles are released during anodic dissolution of metals. For metals like Ag and Cu, some metallic product is detectable, but the total amount is very small and Faraday's law applies, by and large. The fact is significant that the calculated apparent valence of magnesium ions in anodic dissolution experiments for varying current density, temperature, and electrolyte within wide limits always falls between 1 and 2, and that analogous relations are noted for Al and Be. This plus the fact that portions of anolyte obtained from these metals while current flows, temporarily reduce various substances, *e.g.*, $KMnO_4$, lends weight to the conclusion that a state of unusual lower valence exists. After all, multiple valence ions are well known for most of the transition metals, and it is perhaps to be expected that similar ions although unstable may occur in the case of some nontransition metals. But more experiments are undoubtedly necessary to bring this matter into proper focus. Should the existence of lower valence ions receive further confirmation as seems likely, it will probably become necessary to revise the present standard potentials of metals like Al, Mg, and Be as listed in the emf series to bring them into line with equilibria involving the valence of ions actually present at the metal surface.

Oxidation and Tarnish

In presence of a reactive environment but in absence of excess water, metal ions may escape from the metal lattice to form the new lattice of a surface oxide or other type compound such as chloride or sulfide. In this event, electrons enter the film substance along with ions, but along different paths. The initial rate of oxidation, therefore, is controlled either by metallic ion escape, or by electron transfer. In the general case, because of differing electron affinities of metal and film substance, a space charge builds up within the film first forming, which greatly influences the rate of both processes (Fig. 3). The space charge density, in turn, is sensitive to the density of defects within the film substance at which electrons are trapped, and hence impurities and other factors which affect defect density influence the reaction rate.

Under conditions of continuing growth of space charge, the logarithmic equation usually expresses the rate of oxidation, such that thickness of surface film substance y is a linear function of the logarithm of oxidation time t or: $y = k \log (t/\tau + 1)$ where τ and k are constants (30, 31). Under some conditions, the inverse logarithmic equation $1/y = k \log (t/\tau + 1)$ has

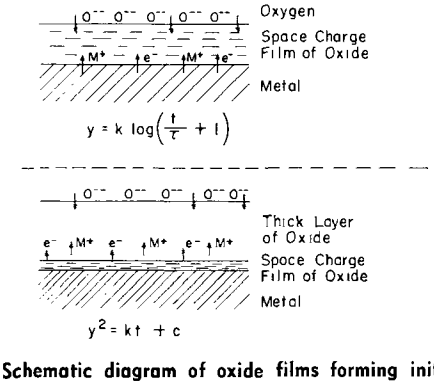

Fig. 3. Schematic diagram of oxide films forming initially (top) and during thick film conditions (bottom).

been found to apply (32, 30) indicating that the mechanism of initial reaction rate is not always the same.

Beyond thin film thickness, the oxidation rate is controlled by diffusion of cations or anions, as described by Wagner (33), and the so-called parabolic equation $y^2 = kt + \text{constant}$ holds. The rate of diffusion, in turn, is now dependent on concentration of lattice defect sites within the film substance. Impurity atoms, in line with semiconductor theory, influence defect concentration; hence impurities also sensitively affect the rate of reaction. Indeed several experiments have demonstrated, in accord with expectation, a major effect of impurities in surface oxides on the oxidation rate of zinc (34) and of nickel (35, 36).

There are many questions that remain regarding the general relationship of kinds of impurities, their concentration and their position within the lattice to initial and thick film oxidation of metals. Also, heat treatment and quenching, for example, which alter the defect structure of semiconductors should have an effect on oxidation rate. An interesting phenomenon as yet unexplored concerns the general properties of surface films in contact with metals accounting for the tendency of protective films to spall off during cooling and heating cycles. In this way, otherwise protective films are destroyed, and the oxidation process continues at higher rates than are normal. Tendency to spalling is an important factor in the general application of all oxidation resistant metals and alloys.

Effect of Stress

The effect of stress on corrosion is important because of catastrophic failures that continue to take place through fretting corrosion, corrosion fatigue, and stress corrosion cracking. Fretting corrosion is damage that occurs when two surfaces, one or both of which are metals, rub against each other. Corrosion products form which in the case of mild steel consist mostly of αFe_2O_3 accompanied by deep pitting at the interface. The pitting is a result of the large volume of oxide compared to the metal from which it forms exerting extra stress at local areas of the surface and accelerating damage. Ultimately, these pits act as nuclei for fatigue or corrosion fatigue cracks. In practice, fretting corrosion causes failure of bearings including jewel bearings, riveted flanges, variable pitch propellers on planes, shrink-fits, steering knuckles of automobiles, and various metal parts subject to vibration in high-speed machinery. The mechanism is not electrochemical; both moisture and higher temperatures reduce fretting damage of steel instead of increasing it. The mechanism appears to be one of mechanical activation of a chemical reaction between the metal and adsorbed oxygen on its surface to form an oxide which is rubbed off by further relative motion. Damage is supplemented by a mechanical wear process, but the latter is not always important as shown by experiments in a nitrogen atmosphere in which a much smaller amount of metal damage results compared to damage in air (37). The assumption that chemical damage and mechanical wear are additive is in reasonable agreement with a limited number of experiments that have been reported so far using mild steel (38). The question arises as to whether the same situation applies to other metals as well. Is the increased damage at lower temperatures caused by more rapid or more complete adsorption of gases on tracks of metal rubbed clean by abrasion? Some investigators propose that the increased damage results from freezing of moisture thereby removing a source of natural lubricant. But this is unlikely in view of the increased damage observed in our experiments at low temperatures using dried air. Does moisture lubricate in any case, or does it soften abrasive metal oxide by forming hydrates? Does the increased damage by fretting noted for stainless steels or titanium result from their increased affinity for oxygen? Is there support in any metal system for the proposal that all the damage is in the form of wear and that small wear particles subsequently oxidize? Considering the importance of this problem to the aircraft, railroad, automotive, and to all industry using high-speed machinery, it is surprising that so little research has been supported aimed at understanding the nature of the damage. Large amounts of money have been spent on empirical approaches to the problem which have provided only temporary relief or which have proved wholly inadequate.

The same situation prevails more or less in the subject of corrosion fatigue. Very little is known at present about the mechanism of metal fatigue itself, and still less is known about corrosion fatigue. In the meantime, airplanes crash, axles break, and machines grind to a halt when components crack. The mechanical engineer redesigns the failed part, but is this the only or the best approach? No one knows. Fundamental factors of metal and environment entering the corrosion fatigue of metals are known to only a limited extent. D. J. McAdam, Jr., at the National Bureau of Standards appears to be one of the few investigators who has systematically surveyed the field, but his excellent work appeared 20-35 years ago, and many unanswered questions remain. The mechanism appears to be at least in part electrochemical, as shown for example by the fact that cathodic protection and corrosion inhibitors reduce damage. But how does the mechanism of corrosion fatigue using repeated or alternate stresses compare with that of stress corrosion cracking requiring a constant stress? Is the effect of metal composition and interstitial impurities the same? Present data indicate they are not, but why? Also why are specific ions required for stress corrosion cracking but presumably not for corrosion fatigue? Some present theories are based on rupture of protective films at the base of cracks in both types of failure. But metals on which naturally formed films are not particularly protective, such as copper or brass, are more resistant to corrosion fatigue than metals with highly protective films such as the stainless steels, which in turn are more resistant than carbon steels, again having less protective films. Also pure metals whether naturally covered or not by protective films do not stress corrosion crack.

Dr. Z. Foroulis recently showed in my laboratory that zone-refined iron corrodes in deaerated hydrochloric acid at the same rate whether cold worked or annealed. Only when small amounts of nitrogen or carbon are present does cold work increase rate of attack, and the effect is then large. Polarization measurements show that the reaction is cathodically controlled. We have interpreted these facts to mean that cold working of iron produces lattice defect arrays at which nitrogen or carbon segregates, and that these areas have lower hydrogen overvoltage than iron itself. Any increased energy of a disarrayed lattice has apparently little effect, contrary to intuitive statements appearing in various textbooks and in the literature. But why do such arrays of interstitial atoms have lower hydrogen overvoltage? What other alloyed elements behave similarly? How does iron differ in this respect from other metals, if indeed it does differ?

Significantly, zone-refined iron does not stress corrosion crack in hot nitrate solutions, whereas iron containing small amounts of nitrogen or carbon is very susceptible. The attack is along grain boundaries. It is

reasonable to suppose that nitrogen or carbon atoms segregate at grain boundaries and thus form the paths along which high corrosion rates prevail. But why are NO_3^- or OH^-, which are specific in causing stress corrosion cracking, the only anions to increase corrosion along such paths? Certainly Cl^-, SO_4^{--}, ClO_4^-, or acetate ions, which do not cause cracking, form good conducting salts and should provide equal local action at the apex of any crack that forms. Is the cracking phenomenon one of surface energy reduction? Do metal atoms at the crack apex, the mutual affinities of which are reduced through adsorption of NO_3^- or OH^-, no longer have the ability to hold on to each other, allowing the metal to separate under stress? This seems to be a reasonable interpretation of the experimental evidence (39). And does the responsible adsorption depend on potential difference between metal at the apex and at the walls of the crack? Is the increased concentration of nitrogen or carbon atoms diffusing to the highly deformed metal at the apex sufficient to account for preferential adsorption of ions? Or the absence of preferential adsorption in the case of pure iron?

In the stable austenitic stainless steels, our experiments (40, 41) show that nitrogen is the major impurity accounting for susceptibility to stress corrosion cracking in boiling $MgCl_2$ solutions. Carbon, to the contrary, decreases susceptibility. Why is this? Susceptibility to cracking is also decreased by alloying nickel with Cr-Fe austenitic stainless steels in the amount of 45-50% or more (42). There have been suggestions that perhaps the dislocation arrays of high-Ni alloys differ from those of other metals, but recent measurements by J. Sava in my laboratory indicate that increasing the nickel content is accompanied by a continuously decreasing solubility of the alloy for nitrogen. Perhaps the critical nitrogen content below which stress corrosion cracking does not occur is reached at about 50% nickel. But additional questions similar to those that were raised regarding carbon steels also enter here. For example, for austenitic stainless steels only Cl^- or OH^- are specific in causing cracking, all other ions apparently having no effect, and it would seem that here too reduction of surface energy through adsorption of specific anions is a likely contribution to failure.

Outlined Program of Fundamental Corrosion Research

It is fair to state, I believe, that we have barely gotten off the ground in our initial search for basic facts in the outer space of corrosion science. For many reasons, fundamental information has accumulated only slowly during the past 10 years, despite the tremendous gains that are promised by any well-directed, adequately supported corrosion program. One of the difficulties is that fundamental corrosion research requires the best scientific talent available among those well trained in both chemistry and in metallurgy. Students having aptitudes in both fields are found only among our best students.

The several questions I have touched on during my discussion in themselves suggest the outline of a serious basic research program in corrosion science. With the thought that a summary of these questions may be worthwhile, I have also included a few subjects deserving of attention, but for which time and space do not permit further discussion.

Outline of Basic Research Program in Corrosion Science

1. Electrochemical problems.
   - A. Anodic overvoltage constants; effect of pH, temperature, nature of anion.
   - B. Unusual valence ions.
   - C. Ratio of anodic to cathodic areas; how to measure them, their values for typical cases.
2. Kinetics of tarnish and oxidation.
   - A. Relation of space charge to initial reaction. Effect of deficit structure, including heat treatment and impurity content of surface films.
   - B. Effect of specific trace impurities and heat treatment of surface films on thick film rates. Effect of impurities on path of oxidation. (For example, Ca additions to 20% Cr, 80% Ni alloy allegedly avoid preferential grain boundary attack.)
   - C. Factors of metal and film substance accounting for spalling of protective films.
3. Mechanism of stress corrosion cracking.
   - A. Relative importance of electrochemical action within cracks compared to specific adsorption of ions and accompanying reduction of surface energy (stress sorption cracking). Effect of potential on specific adsorption within cracks.
   - B. Effect of dislocation patterns and resultant segregation of impurities or alloying components as source of crack paths.
   - C. Factors affecting intermetallic compound formation and rate of formation at grain boundaries and at slip planes as sources of crack paths.
   - D. Effect of metal heat treatment on susceptibility. Similarly effect of impurities and metal composition.
4. Mechanism of corrosion fatigue.
   - A. Effect of metal composition and heat treatment; relative susceptibility of zone-refined metals.
   - B. Effect of environment, (pH, anions, dissolved O_2, etc).
   - C. Effect of temperature.
5. Mechanism of fretting corrosion.
   - A. Effect of frequency and temperature on fretting corrosion of typical metals.
   - B. Relation of susceptibility to rate at which gases adsorb on metal surfaces.
   - C. Effect of magnitude of relative slip.
6. Mechanism of corrosion inhibition, *e.g.*, polyphosphates, benzoates.
7. Mechanism of protective $CaCO_3$ deposition from potable waters. Effect of natural colloids, temperature, and flow rate.

Many other subjects could be added. A small part of the above program is already underway in various laboratories but most of it still waits for attention by those competent to undertake programs of this kind. The above outline does not include service tests nor engineering programs which are also extremely important to progress in corrosion control but which have different objectives. It has already been stated many times by others that engineering programs soon reach a dead end as basic information is used up, and no attempt is made to replenish such information. As a consequence, more than one applied program currently underway stares at a blank wall. New ideas are needed, and although these are sometimes stumbled on, there is merit in paying the price for searching them out systematically. In addition, new ideas often become available through research in understanding corrosion reactions which are wholly unexpected, and which may have even greater importance than the initial program itself. Finally, not least of the benefits to be derived from carrying out a fundamental research program is the training of young minds in the basic sciences and in research techniques. Such minds represent the most

valuable asset of any university, of any industry, or of any nation. Climbing on the shoulders of those who have gone before, young men and women adequately trained can see far more of outer space than do any of us. To them belong the future and it behooves us to give them a good start.
