The postulate of hole traps to account for this peculiar phenomenon in silicon nitride film necessitates models that can explain minor structural changes in a high electrical field. One interesting postulate speculated is as follows: normally, three silicon atoms are hinged together with a nitrogen atom. If there is a nitrogen atom vacancy, then the three unpaired electrons might become quite unstable and a three-centered two-electron bond could be formed to bridge the three silicon atoms together directly. The extra electron would then be expelled; in other words, the unit trapped a hole. If this occurred in the vicinity of the Si_3N_4-Si interface, it would cause a surface N-shift. When a sufficiently high electrical field of the order of 2-4 x 10^6 v-cm^{-1} is applied, irreversible polarization takes place through minor structural change, and the three-centered electron pair is shifted to two of the silicon atoms to make a regular bond bridging the two atoms. The remaining silicon atom could now regain an unpaired electron, or it could serve as an electron trap for an extra electron. This would cause the surface to become neutral or negative.

This is only one of the possible mechanisms. There are insufficient data at present for any definite assertion of a particular model.

If the postulated annealing process was fully irreversible, one would expect the surface to be stable under voltage stress at elevated temperatures up to at least 400°-500°C, since the usual cause of an unstable surface of the system Si-SiO_2 is regarded as ion migration and is excluded in this case. It appeared that, after initial room temperature bias treatment, the surface became more stable and drifted only a small amount under later voltage stress treatment at elevated temperatures. This observation is only exploratory, and more extensive investigation of this subject is being carried out (15). Some preliminary

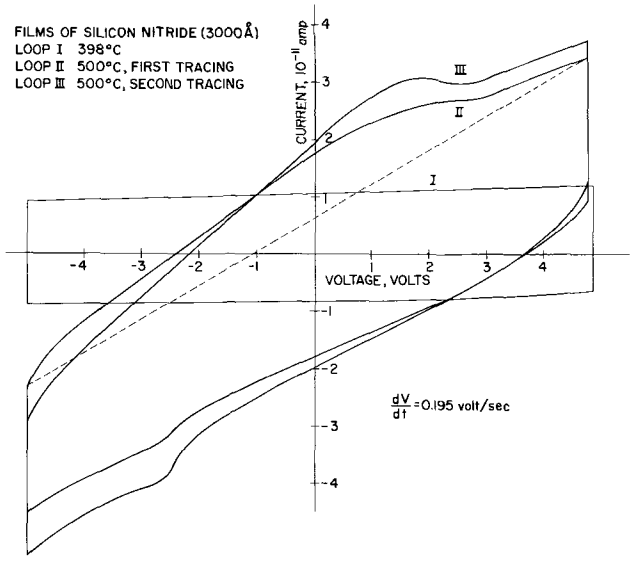

Fig. 7. I-V loop for a pyrolytic silicon nitride film at elevated temperatures.

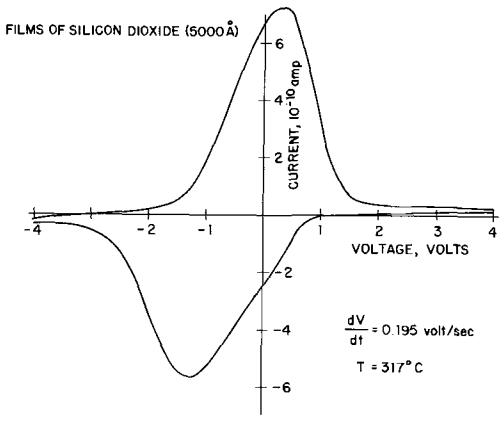

Fig. 8. I-V loop of an ordinary thermal SiO_2 film

results show that under a voltage stress of 1 x 10^6 v cm^{-1} at a temperature of 500°C, a surface p-shift of +10v (for the film thickness of 3000-3600Å) was produced, apparently as a result of further annealing. Compared to the far larger n-shift (opposite direction) at lower temperatures in a slightly lower field usually observed in SiO_2 passivated silicon surface, the results are remarkable.

Ion Migration and Polarization

Since ion migration and related polarization are two important causes affecting surface stability, preliminary experiments have been done on the nitride film. The I-V loop method employed by Yamin (16, 17) for the study of SiO_2 films was used for this investigation. The method consisted of placing an MIS type of device, similar to that used in the surface varactor measurement, in a thermostat chamber, and applying a slow d-c triangular wave at a speed of 0.195 v/sec. The current flux to the electrodes was recorded against voltage. One or more complete loops were traced for each sample at each temperature level; a typical result is shown in Fig. 7.

Loop I is essentially a rectangle, indicating that the MIS structure with silicon nitride film is a simple capacitive element. At a constant rate of voltage change, dv/dt, the electrode current is simply $i = c(dv/dt)$. This loop was traced at 398°C. No detectable amount of ionic polarization was observed. However, precise analysis could separate a conductive element also in the MIS structure, which is the slope of the slight inclination, giving an electrode current of

$$i = \pm 0.195\ C + GV \text{ amp}$$

where C is the capacitance in farad, G the conductance in mho, and V the voltage in volt. At 500°C, ionic migration and polarization became appreciable. This is seen in loop II and III of Fig. 7.

The humps in both the upper part ($dv/dt > 0$) and the lower part ($dv/dt < 0$) of the loop represent the polarization of some unknown species of ions in the film. Each hump consists of a depolarization and polarization of half the complete cycle, and the area bounded by the hump and the dotted line, multiplied by a factor converting voltage to time scale (the voltage used was a linear function of time), gives the total amount of ions polarizable at the temperature. Thus, the polarizable ions at 500°C is about 3 x 10^{16} charges/cm^3. It was also observed that the conductivity of the film seemed to be modified under the voltage stress at the relatively high temperature of 500°C. Sufficient data have not been obtained as to whether there exists any correlation between this conductivity modification and trap reduction.

For comparison, an I-V loop of a typical thermal SiO_2 is shown in Fig. 8. Notice that the current scale has been increased 20 times in this case, and that the temperature is 317°C.

Barrier vs. Diffusion Impurities

A silicon nitride film of 1000Å was shown to block completely diffusion of gallium, oxygen, steam, and phosphorus into the underlying silicon substrate, at a temperature of 1050°C for 40 min. However, quantitative data regarding diffusivity are not available at this time.

Conclusion

From the evaluated characteristics, silicon nitride appears to be an excellent material for semiconductor surface passivation, especially for its resistance to ion migration. Improvements remain to be made in the direction of reducing the surface charge density in the silicon-silicon nitride system.

Diffusion of Arsenic in Germanium from a Germanium Arsenide Source

Prediffusion and Diffusion

G. F. Foxhall and L. E. Miller

Bell Telephone Laboratories, Incorporated, Laureldale, Pennsylvania

ABSTRACT

This paper reports on the diffusion of arsenic in germanium from a germanium arsenide source. This versatile source is suitable for prediffusion over a temperature range of 475° to 725°C, and produces sheet resistances varying from 3000 to 0.5 ohms/□. Techniques for diffusion at temperatures up to 900°C have also been developed. Loss of dopant through outdiffusion has been eliminated even for high-resistivity layers. Background resistivity is maintained by rigorous cleaning prior to diffusion and annealing after diffusion. The closed box technique is used in both cases.

This paper presents results of an investigation of diffusion of arsenic in germanium. The closed box technique is used for both prediffusion and diffusion.

A germanium arsenide alloy (1) is used as a diffusant source for prediffusion. This compound has proved to be quite versatile in that it is suitable for use over a temperature range of 475° to 725°C. Layers varying in sheet resistance from 3000 to 0.5 ohms/□ are obtained.

Techniques have been developed for diffusion at temperatures as high as 900°C. Loss of dopant through outdiffusion, even in high-resistivity layers, has been eliminated by the use of a tightly closed diffusion boat. Background resistivity is controlled by rigorous cleaning prior to diffusion and an annealing process after diffusion.

Prediffusion

The diffusion boat assembly, shown in Fig. 1, is of high-purity, optical grade quartz. The mating surfaces between boat and lid are ground flat to effect a tight seal. Three shelves are fitted into the boat to provide space for 18 slices. The source lies in the bottom of the boat.

To minimize thermal conversion effects (2), a rigorous cleaning procedure is followed. Purified hydrogen is used for the diffusion ambient.

The variation of prediffusion sheet resistance with time and temperature is shown in Fig. 2. Control is good as indicated by the 3σ limits shown for the 1-hr runs. These vary from 30% at 500°C to 2% at 725°C. At a given temperature, the sheet resistance varies reasonably in accordance with the inverse square root of time except at the lower temperatures. Also in this low-temperature region, the sheet resistance begins to increase rapidly as temperature is decreased. Several effects combine to cause this divergence from square law dependence. First, the thermal inertia of the diffusion assembly is sufficient to introduce uncertainty into the diffusion times; second, at these low temperatures, temperature dependent surface rate limitation may be expected. Berman, for example, has reported a surface rate limitation on the diffusion of antimony into germanium in this temperature range.

The dependence of junction depth on temperature and time is shown in Fig. 3. These curves exhibit two distinctive slopes, the smaller of which is associated

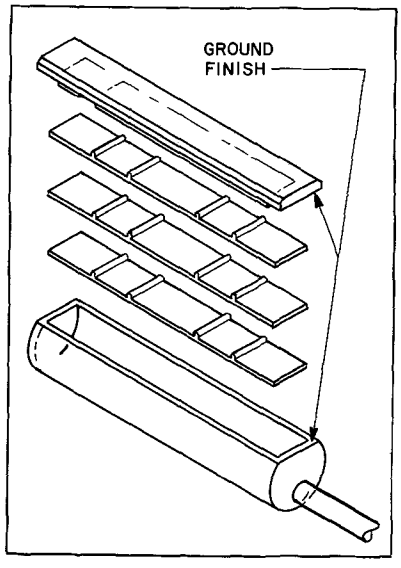

Fig. 1. Diffusion assembly

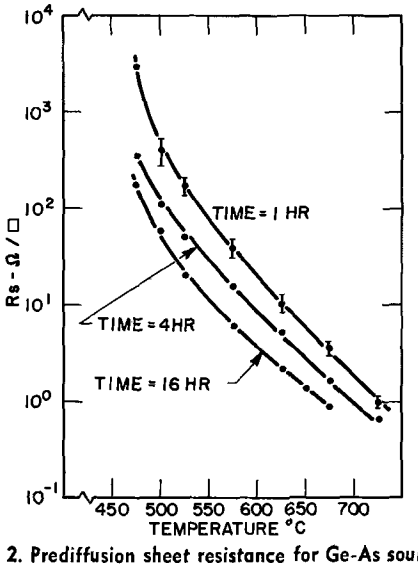

Fig. 2. Prediffusion sheet resistance for Ge-As source

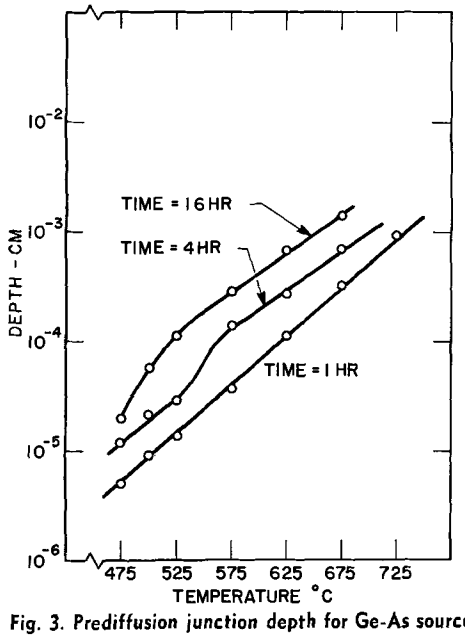

Fig. 3. Prediffusion junction depth for Ge-As source

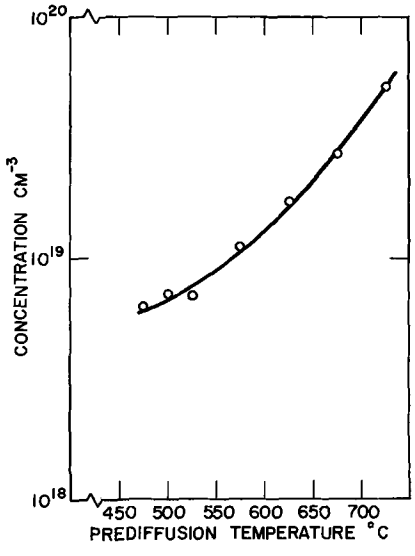

Fig. 4. Dependence of surface concentration on prediffusion temperature for Ge-As source.

with long time and high temperature, and the larger with short time and low temperatures. One notes that in the former region the depth varies nicely with the square root of time, whereas in the latter region it does not. Again one can explain this behavior by thermal inertia and surface rate limitation, which tend to reduce junction depth disproportionately for short times and low temperatures.

Variation of surface carrier concentration with prediffusion temperature is shown in Fig. 4. These values were measured by successively etching and measuring sheet resistance to give a differential conductance and subsequently the effective resistivity of the layer which had been removed. It will be seen later that the actual concentration of arsenic atoms may be considerably in excess of the values shown here.

In connection with this, a typical profile for a prediffused layer is shown in Fig. 5. The distribution is non-Fickian in a manner typical of prediffused layers as has been reported elsewhere (4). The dip in measured concentration adjacent to the surface is common to these prediffused layers over the whole temperature range. This cannot be due to outdiffusion and rather is believed to be due to the formation of a germanium arsenic compound at the surface. The values of surface concentration are taken by extrapolating the profile to the surface as indicated by the dashed line.

Diffusion

Prior to diffusion, the slices are cleaned again. Here the procedure serves to remove a small amount of arsenic which condenses on the surface during the cooling cycle of the prediffusion. Failure to remove this condensate will result in uncontrollably low sheet resistance. At the end of the designated diffusion time, the furnace is reset to progressively lower temperatures without removing the boat from the furnace. This process has been named step annealing.

Success of these diffusions depends on the control of two fundamental factors. The first of these is outdiffusion. For high-resistivity diffused layers, unlimited outdiffusion as in the case of open tube diffusion, for example, would result in an unconverted surface with perhaps a band of n-type in the bulk.

The closely fitted lid traps arsenic which outdiffuses initially in the box. When the surface concentration is high from the prediffused layer, the arsenic outdiffuses until its vapor pressure rises to the point where it is in equilibrium with the concentration of arsenic in the slice. Data by Lee and Speeney (5) indicate that this is on the order of 10^{-6} mm Hg. A simple calculation shows that there is abundant arsenic in the prediffused slice to provide this pressure.

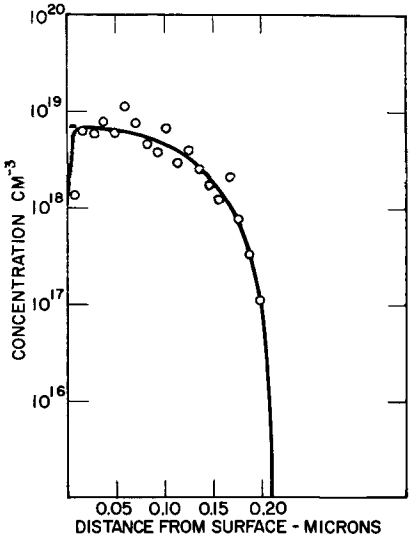

Fig. 5. Impurity profile for prediffused layer 16 hr at 475°C with Ge-As source.

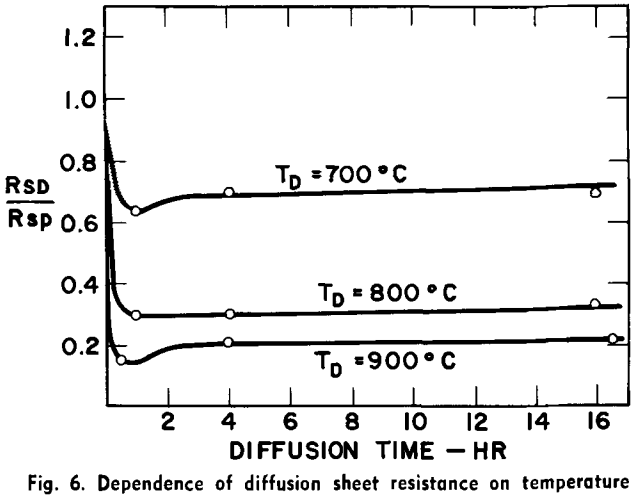

Fig. 6. Dependence of diffusion sheet resistance on temperature and time. R_{SP} = 170 ohms/□.

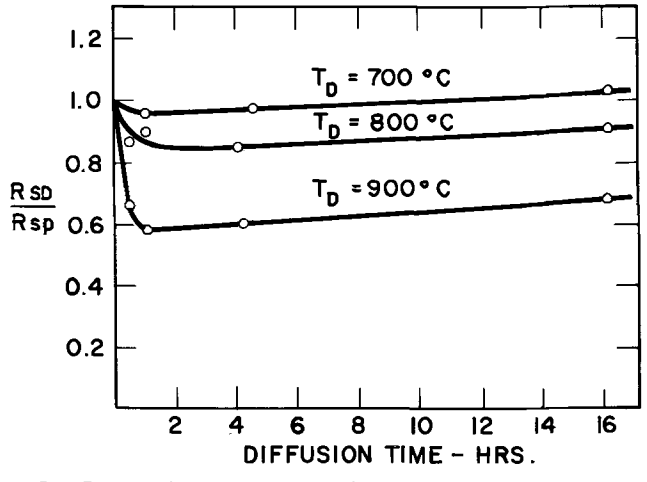

Fig. 7. Dependence of diffusion sheet resistance on temperature and time. R_{SP} = 10 ohms/□.

As the arsenic in the bulk diffuses into the slice, thereby dropping the surface concentration, arsenic in the gaseous state is taken back into the slice to maintain equilibrium between gaseous and solid phases. Prediffusion sheet resistance of 3000 ohms/□ has been observed to drop to about 100 ohms/□ during a 22-hr diffusion at 900°C. This indicates that: (*A*) Loss of dopant through outdiffusion has been significantly

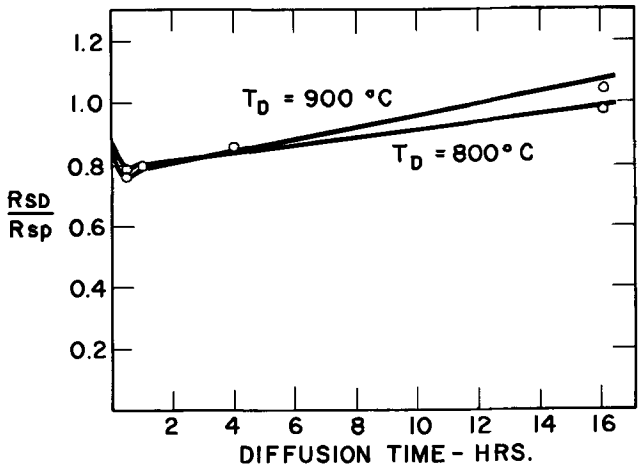

Fig. 8. Dependence of diffusion sheet resistance on temperature and time. R_{SP} = 1.0 ohm/□.

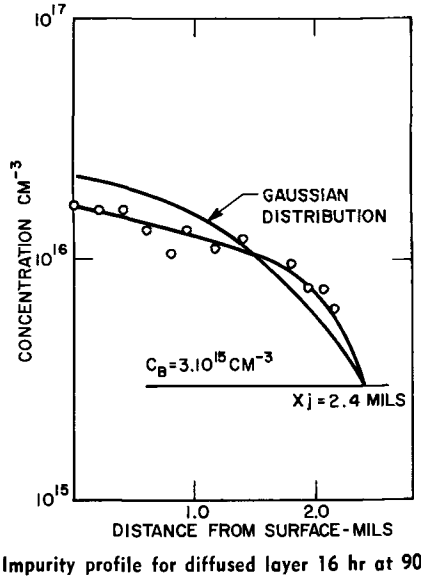

Fig. 9. Impurity profile for diffused layer 16 hr at 900°C. R_{SP} = 170 ohms/□; R_{SD} = 35.8 ohms/□.

limited. (*B*) There is a large amount of arsenic in or on the prediffused slice which is not ionized. This is indicated by the fact that, when the prediffused samples are diffused, a significant reduction in sheet resistance occurs. A factor of eight reduction in sheet resistance is predicted as a result of drive-in diffusion because of the change in mobility which results from a decrease in impurity concentration (6). The observed reduction is significantly greater than that predicted, equaling as much as thirty. This effect is typical of non-Fickian diffusions, and has been reported for the silicon-phosphorus system (4).

The ratio of diffusion sheet resistance, R_{SD}, to prediffusion sheet resistance, R_{SP}, is shown in Fig. 6 as a function of time with temperature as a parameter. All prediffusion sheet resistances were 170 ohms/□. An initial rapid drop in sheet resistance, representing the effects of redistribution of the impurities, is followed by a gradual increase in sheet resistance. This increase represents a loss of impurity atoms from the diffusion boat assembly and is seen to be independent of temperature, being limited, apparently, by the leakage rate from the diffusion boat. This being so, one would expect that at the higher diffusion temperatures, where diffusion into the slice is more rapid, a lower net loss of impurity, and consequently lower sheet resistance, would result. The curves verify this temperature dependence of diffusion sheet resistance.

A similar system of curves is shown in Fig. 7, the difference being that all prediffusions were in this

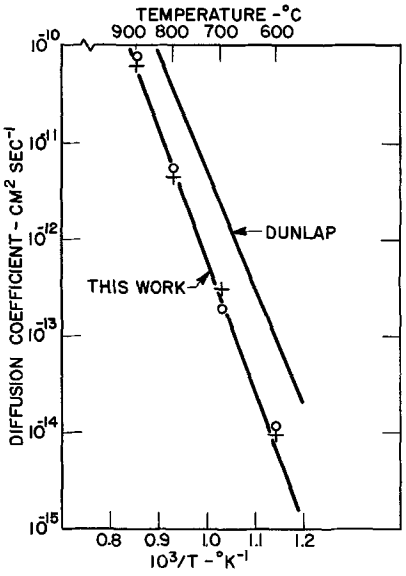

Fig. 10. Diffusion coefficient of arsenic in germanium: + 4-hr runs; ○ 16-hr runs.

case 10 ohms/□. In the presence of the higher concentrations, the rate of loss of impurities is more rapid. It is still independent of temperature, however. Sheet resistance also decreases with diffusion temperature as before.

In Fig. 8 the same type of curves is shown with prediffusion sheet resistance now down to 1.0 ohm/□. Under the influence of these very high concentrations, the rate of loss is now temperature dependent and considerably greater. The behavior of sheet resistance with temperature is also changed.

A profile typical of the diffused layers is shown in Fig. 9. Of particular note is the absence of a dip in concentration at the surface, indicating that outdiffusion has been reduced significantly. Also of importance is the fact that the profile very nearly matches the Gaussian distribution drawn for the same junction depth and sheet resistance.

In calculating the diffusion coefficient, the diffused layers were assumed to be Gaussian. Values are shown in Fig. 10. On all the samples measured, prediffused layers had sheet resistance of 170 ohms/□ and junction depth of about 1300Å. Diffusion times of four and sixteen hours were used at each temperature. The results obtained are seen to be considerably smaller than those of Dunlap (7). The values from this work are believed to represent the concentration independent diffusion coefficient, while the values given by Dunlap are in the concentration dependent range. Diffusion coefficients calculated from the prediffusion data do, in fact, agree generally with Dunlap's work. This work may represent the first data on the diffusion coefficient of arsenic in germanium without concentration enhancement effects.

The second factor which must be controlled is thermal conversion. This is achieved by the step annealing process described above. In spite of rigorous cleaning, some thermal conversion appears to be inevitable. Tweet (8) showed that copper precipitates from the germanium lattice on dislocations according to the relationship

$$\psi = e^{-t/\tau_p(T)}$$

where ψ is the fraction of copper remaining after time t and τ_p is the temperature (T) dependent relaxation time for precipitation. Since τ_p decreases with increasing temperature, it is possible to remove most of the added acceptors at a rapid rate at the higher temperatures of the annealing cycle, while only small amounts are left to be removed at the lower temperatures where the precipitation rate is low. The step anneal reduces the added acceptor level to less than 2×10^{14} cm^{-3} after diffusion at 900°C.

Conclusion

A closed box, two-step system for the diffusion of arsenic into germanium has been developed. Prediffusions have been done over a temperature range of 475°-725°C producing sheet resistances from 3000 to 0.5 ohms/□. Prediffused slices can be diffused at temperatures as high as 900°C with layer depths of 2.5 mils and surface concentrations of 2×10^{16} cm^{-3}. The system offers the advantages of simplicity, flexibility, and controllability.

This work was motivated by demand in the Bell System for high breakdown voltage germanium diodes. The diffusion assembly is currently being used by the Western Electric Company for routine diffusion at 900°C. This produces diodes having breakdown voltages of 350-400v.

Acknowledgments

The authors wish to thank Messrs. T. R. Robillard and W. J. Frankfort for suggesting the use of the germanium arsenide source. They are also indebted to Mr. R. A. Kiehl for assistance in implementing the diffusion.

The Effect of Ion Bombardment on the Photoelectric Threshold of Single Crystal Cuprous Oxide

Richard J. Komp

Research Division, Xerox Corporation, Webster, New York

and Dan Trivich

Department of Chemistry, Wayne State University, Detroit, Michigan

ABSTRACT

Samples of single crystal cuprous oxide prepared by quenching after equilibration at various oxygen pressures at high temperature were subjected to bombardment by argon ions and hydrogen ions, and the photoelectric emission was then measured. The curves for the photoelectric quantum yield Y *vs.* the photon energy E were characterized by the presence of a double shoulder indicating the presence of two thresholds. The data could be fitted to the equation $Y^{1/n} = k\ (E-E_0)$ with n usually having the value of 2, and this was used to evaluate the threshold energy E_0. The high energy threshold was relatively constant at 5.1 ev regardless of the amount of ion bombardment, but the low energy threshold was much more variable, often starting at ~4.0 ev and increasing to 4.6 ev with bombardment. It is proposed that the high energy threshold represents the process of direct excitation with scattering from the valence band. The lower values of the low energy threshold are presumed to represent excitation from surface impurities which are gradually removed by bombardment. The limiting value of the low energy threshold is assigned to excitation from states similar to the bulk acceptor states usually found in Cu_2O at 0.4 ev above the valence band.

The semiconducting properties of cuprous oxide have been known and studied for several decades, notably by Wagner and co-workers (1). Recently with the development of methods in this laboratory (2) and elsewhere (3) for the production of single crystals of the material, it has been possible to provide more definitive information on the electrical properties. Recent investigations on the high temperature (600°-1100°C) thermoelectric effect (4) and the low temperature Hall effect (5) have confirmed that cuprous oxide is a p-type semiconductor under all attainable conditions of temperature and environmental oxygen pressure. The results of these experiments together with measurements of the electrical conductivity at high temperatures (6, 7) and a study of the weight variation (8) with changes in the environmental oxygen pressure have substantiated a modified Wagner model in which an excess of oxygen in the crystal lattice produces copper atom vacancies which can act as electron acceptors. The excess oxygen is in equilibrium at high temperature with the oxygen gas surrounding the crystal.

However the results of measurements on quenched samples at low temperatures are rather complex (5) so that the Wagner model can be applied only in a grossly qualitative fashion. Also in the vicinity of room temperature, one can observe progressive changes in the electrical conductivity and Hall effect if the samples are allowed to stand at slightly elevated temperatures (40°-100°C). These changes may be due to changes in the character of certain bulk acceptor states or may be due to changes in surface states. One possible approach to the study of states at or near the surface is by means of photoelectric emission, and this paper is an initial report of such measurements on cuprous oxide.

The photoelectric emission from compound semiconductors has been measured by several workers. Apker and Taft (9) have carried out an extensive series of investigations on alkali halides. The work by Smith and Dutton (10) on lead sulfide and that by Spicer (11) on alkali antimonides indicate that the majority of photoemitted electrons comes from the valence band of the material. Using a set of theoretical predictions by Kane (12) on the nature of the quantum yield relation as a guide, Allen and Gobeli (13) have made a detailed study of the excitation mechanisms and surface states present in clean silicon.

Allen and Gobeli have also studied the effects of positive ion bombardment and subsequent annealing on silicon surfaces (14). These treatments were developed by Farnsworth (15) and others as a cleaning technique and have been extensively employed to produce clean, well ordered surfaces, notably on silicon and germanium. Although sufficient ion bombardment will remove adsorbed impurity atoms, the treatment leaves a large amount of disarray and some implanted bombardment atoms which may be removed by heating the sample. Cuprous oxide cannot be heated to high temperatures without changing the amount of excess oxygen present in the crystal, so that annealing cannot be used in this case. However, the changes in the photoelectric emission of surfaces upon annealing are not usually found to be as large as those produced by bombardment of a contaminated surface.

In the present investigation most of the ion bombardment was done using argon, but the work was extended to bombardment by hydrogen ions since some interesting special effects might be expected. Muller (16) sputtered copper onto cuprous oxide in a hydrogen atmosphere and produced rectifying and photovoltaic junctions on the top surface of the sample. Waibel (17) also subjected cuprous oxide to a hydrogen glow discharge and produced similar effects. Some preliminary work in our laboratory indicated that proton bombardment causes reduction of the top surface of the cuprous oxide to copper.

Experimental

Sample preparation.—Polycrystalline cuprous oxide sheets were prepared by the oxidation of 99.999+% pure copper plates (purchased from Johnson Matthey and Company Ltd., England) at 1020°C in air. Large crystals of cuprous oxide were then produced in the plates by a grain growth method developed in this laboratory (2).

Portions of the Cu_2O plates were equilibrated at high temperatures and known oxygen pressures to es-

tablish the equilibrium concentration of copper atom vacancies in the crystal. This process was carried out in an apparatus designed by Wright (5). The samples were hung in the center of a 12 in. long tube furnace by a long platinum wire. The desired partial pressures of oxygen were obtained by flowing calibrated mixtures of oxygen and nitrogen through the system, usually at atmospheric pressure, but sometimes at moderately reduced pressures. The lowest oxygen pressure used, 2.4×10^{-7} Torr, was obtained by pumping the closed system and assuming that oxygen comprised 20% of the ultimate pressure. Table I gives a summary of the equilibration conditions for the samples studied.

After the sample had come to equilibrium with the surrounding atmosphere and temperature, the composition was frozen by dropping the sample out of the furnace and quickly cooling the sample with a stream of helium at liquid nitrogen temperature. The resulting samples showed no trace of cupric oxide on their surfaces.

The crystals were then ground on one side using No. 400 alundum abrasive until one half of the thickness was removed, assuring that the disordered region in the center of the crystal was not present in the final sample. The other side was ground lightly to remove the top surface and both sides were then ground using No. 305 emery to remove pits and scratches. The samples were then cut into squares 1 cm on a side, etched in 0.5*N* sodium cyanide for 5 min, washed in distilled water, and air dried. A gold contact was applied on the back of the sample by vacuum evaporation and the sample was left in the metallizing chamber under vacuum until it was to be placed into the measuring system.

Measurement system.—During the bombardment of the sample and the measurement of the photoemission the sample was kept in a bakable, ultrahigh vacuum system, capable of reaching 5×10^{-10} Torr. During most of the photoemission measurements the pressure was maintained below 10^{-8} Torr. Because cuprous oxide cannot be heated much above room temperature without causing changes in its properties, the system could not be baked with the sample in place. To avoid this difficulty, the clean system was backfilled with purified helium and quickly opened. The sample was inserted into the holder while a slight positive pressure in the system kept helium streaming out the open flange. After the system was once more sealed tight and pumped down, the molecular sieve trap was baked. This procedure usually resulted in the attainment of a pressure of 10^{-9} Torr after pumping overnight.

The samples were bombarded with positive ions from an ion source similar to that designed by Moak, Reese, and Good (18). The ion source was separated from the main system by a small capillary tube, and this arrangement allowed the pressure around the sample to remain at 10^{-5} Torr during the bombardment in addition to producing a controllable low current density. The gas used for bombardment was fed into the ion gun by means of a bakable variable leak and was ionized by a 25 mc rf field produced by an external coil. An accelerating voltage of 1500v was applied between a tungsten rear electrode and the source exit nozzle, which was grounded. The sample was kept at ground potential. The ion currents used were usually 0.07 μa/cm^2 for argon and 2 μa/cm^2 for hydrogen.

The light source used for the photoemission experiments was a Hanovia Model 7606 medium high pressure mercury lamp illuminating a Bausch and Lomb 250 mm effective focal length monochromator with entrance and exit slits set at 0.5 mm. An image of the square ruled portion of the monochromator grating was focused by means of an auxiliary quartz lens through a 4 mm square hole in the collecting anode to illuminate the sample. The spectral output of the entire optical system was measured using a sodium salicylate fluorescent plate and a 1P28 photomultiplier detector (19). An absolute calibration of the output of the system was performed using an Eppley thermopile and National Bureau of Standards standard lamp, and the absolute output of the optical system is estimated to be known to ±10%. A quartz window in the vacuum system allowed measurements to be made down to 2000Å.

The photoemitted electrons escaping from the sample were collected by a platinum plate anode placed parallel to the sample and 3 mm from its front surface. The current produced was measured with a Beckman Instruments RXG-2 Micromicroammeter. To reduce electron emission from sources other than the sample, only the sample and sample holder were biased (at —90v with respect to the anode). All other parts of the vacuum system were grounded. All measurements were made at room temperature.

The photoemission from the samples was measured before any bombardment and remeasured after each bombardment period. These periods ranged from 1 min to 1 hr with most samples being subjected to a series of bombardments of 15 min duration. After

* Argon gas was introduced at 10^{-3} Torr for 30 sec before 173.

several periods of argon ion bombardment produced no further change in the photoemission spectral response, the sample was bombarded with protons for several periods.

Experimental results.—Typical results of photoemission quantum yield (electrons per incident photon) *vs.* photon energy are shown in Fig. 1. The experimental conditions used to obtain these results are given in Table II. The various curves are for measurements on a single sample after different amounts of ion bombardment and various times between bombardment and measurement. A prominent feature of the results is the presence of a double shoulder in the photoemission yield curves thus indicating the existence of two energy thresholds. Figure 2, which is a collection of curves from several samples after similar treatments, indicates that these features are a normal result for such samples of cuprous oxide.

The dependence of the yield on photon energy above the high energy threshold obeys a relation of the form

$$Y = k(E - E_o)^n$$

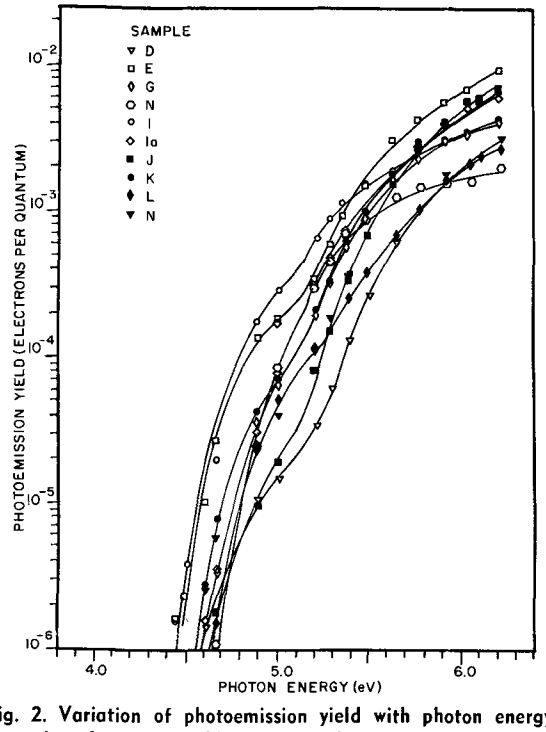

Fig. 2. Variation of photoemission yield with photon energy for all samples after comparable amounts of argon ion bombardment.

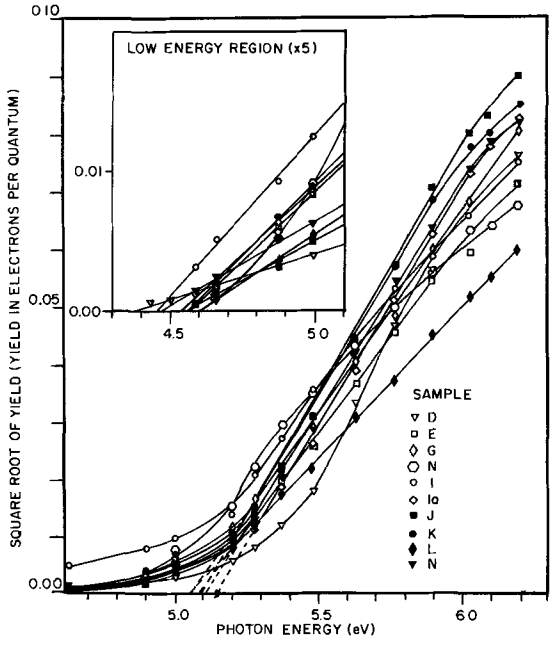

Fig. 3. Plots of the squore root of the photoemission yield vs. photon energy for all samples treated with argon.

where Y is the yield, E is the photon energy, E_o is the threshold energy, and k is a constant. The exponent, n, was found to have a value of 2 for almost all of the samples tested as can be seen in the plots of the square root of the yield *vs.* photon energy shown in Fig. 3. These curves are for all the samples under equivalent conditions and are representative of those used in the extrapolations to determine the threshold energies. The data for two of the samples could be fitted with yield relations with $n = 1$ while a third is best represented by $n = 3/2$, but for all other samples n is very close to 2. The high energy threshold was normally calculated by plotting the square root of the photoelectric yield *vs.* the photon energy and extrapolating to zero yield to obtain the threshold.

The high energy threshold values were remarkably stable for any particular sample and could be reproduced to within 0.02 ev even after treatment of the sample had greatly modified the apparent form of the yield curves. For the various samples measured, these values for the high energy threshold ranged from 5.01 to 5.15 ev. The absolute magnitude of the yield at energies above the high energy threshold varied by as much as a factor of three with changes in the surface condition of the sample, even when the contribution due to the low energy shoulder was subtracted. The yield decreased as a result of bombardment and increased slowly with time of standing after bombardment.

In contrast to the behavior above the high energy threshold, the results in the low energy region varied widely both in the value of the threshold and in the absolute yield. The variation in results from one sample to another was large but also the change in the behavior of any one sample with even a slight amount of treatment was great. However, the samples showed a characteristic general behavior. In spite of the large variation in the results of the measurements on the samples before any bombardment, the curves for the different samples had the same general appearance after only 15 microcoulombs of argon bombardment. As can be seen in Fig. 1, additional bombardment raised the low-energy threshold and decreased the yield until with sufficient argon bombardment the portion of the yield due to the low energy shoulder almost completely disappeared and a limit was reached in the threshold. This limiting value of the low energy threshold was approximately 0.4 ev below

the high energy threshold and was the same for all samples. If the samples were allowed to stand undisturbed in the vacuum system, the low energy threshold slowly decreased and the yield increased correspondingly. The same effect was observed but after a much shorter time if hydrogen gas was introduced into the system to raise the pressure to approximately 10^{-4} Torr. From this evidence it was concluded that the variation in low energy threshold was an effect associated with surface impurity atoms.

Proton bombardment had a much greater effect on cuprous oxide than did argon bombardment, but this effect was not apparent until after considerable total bombardment. At first, as can be seen from Table II and Fig. 1, the low energy threshold behaved as it did for argon and the high energy threshold remained unchanged; but, after approximately 0.015 coulombs of proton bombardment, a sudden change occurred in the yield relation. The low energy threshold usually disappeared completely and the high energy threshold shifted to 4.85 ev.

Argon bombardment had no apparent effect on the appearance of the sample surface, but proton bombardment produced a gold sheen on the sample which further bombardment developed into a definite copper color. After removal from the vacuum system, the samples were found to have what appeared to be a thin deposit of copper on the bombarded surface.

Neither the temperature nor the oxygen pressure surrounding the sample during the high temperature equilibration had any obvious effect on the observed threshold values. If an effect does in fact exist, the variations in the thresholds and yields due to other factors make it impossible at the present time to discuss its nature.

Discussion

The experimental results show the presence of two thresholds, a relatively constant one lying at about 5.1 ev and another one at lower energy which can vary from 3.95 to 4.66 ev depending on the initial conditions and the amount of bombardment. While the present measurements are apparently the first to be done on single crystal cuprous oxide, even the literature on polycrystalline Cu_2O is relatively scanty in regard to photoemission measurements and most of the studies precede the time of a clear understanding of the difference between work function and photoelectric threshold for semiconductors. These earlier studies deal with only a single threshold which is the more obvious higher energy threshold. Ioffe (20) quotes without reference a value of 5.15 ev, which may have been derived from the data of Fleischmann (21). A more recent substantial work by Wasser (22) yields a value of 4.80 ev. A brief communication by Cashman (23) gives a value of 5.34 ev and mentions the existence of a small "tail" in the results at low energies, which was assigned to impurity levels. Other earlier literature is reviewed in Gmelin (24).

The simplest way to explain several features of the present results is with a model having at least two simultaneous but independent mechanisms producing the photoemission and yielding the two thresholds observed experimentally. Because of the large yield associated with the high energy threshold and because of its relative constancy, this threshold most likely represents excitation of electrons from the valence band. According to the general theoretical treatment by Kane (12), the possible mechanisms for the escape of an electron from the valence band are direct excitation, direct excitation with scattering, and indirect excitation. Direct excitation either with or without scattering apparently is the most likely mechanism in the case of cuprous oxide because of the magnitude of the yield, but also because the yield varies as the first or second power of the photon energy above the threshold in accordance with the relations derived by Kane. Since for most of our samples the yield relation has a value of $n = 2$, it is likely that the usual process responsible for the high energy threshold in Cu_2O is one of direct excitation with scattering. Sample H which obeys a yield relation with $n = 1$ may represent the case of direct excitation with no scattering. Sample I, for which $n = 3/2$, may represent an intermediate case with some scattering of the excited electrons so that the total process in the case of this sample is a composite of the two mechanisms. The threshold energy for a direct excitation process without scattering should be greater than that for the process with scattering. Sample H does have the largest value observed, 5.15 ev, in a comparison of all samples under similar conditions. The thresholds for the remaining samples tend to be somewhat lower, averaging 5.05 ev. Taking the value for the band gap in Cu_2O to be 2.3 ev, it is estimated that the electron affinity of Cu_2O is about 2.8 ev. If band bending due to surface states is present, this may affect the high energy to a certain extent. However, in view of the relative constancy of the high energy threshold, at least as compared with the large variations in the low energy threshold, it has been assumed in the preceding discussion that the electrons emitted after excitation from the valence band come from depths below the surface which are small compared with the space charge region.

In the case of the low energy threshold, it becomes necessary to deal with surface states more explicitly. Because of the large variation in the low energy threshold and its dependence on surface conditions as affected by ion bombardment, it is probable that the low energy threshold is strongly affected by the presence of surface states. The fact that the experimental value for the exponent n in the yield relation is normally 2 indicates a mechanism similar to Kane's case of surface imperfections with a continuous distribution in energy in the vicinity of the Fermi level. The variation of the threshold energy with surface conditions indicates that the Fermi level at the surface can vary relative to the vacuum level and thus lead to bending of the bands at the surface as illustrated in Fig. 4. It is assumed that when band bending occurs the bands are bent downward at the surface as shown.

From the model, one can infer that the effect of ion bombardment is to remove gradually some of the surface impurity species and that this causes the drastic lowering of the yield with increased amounts of ion bombardment. As the surface species are removed, the amount of the band bending decreases so that the value of the low energy threshold increases.

With large amounts of bombardment, the energy threshold increases to a limiting value of 4.66 ev, which differs from the high energy threshold by

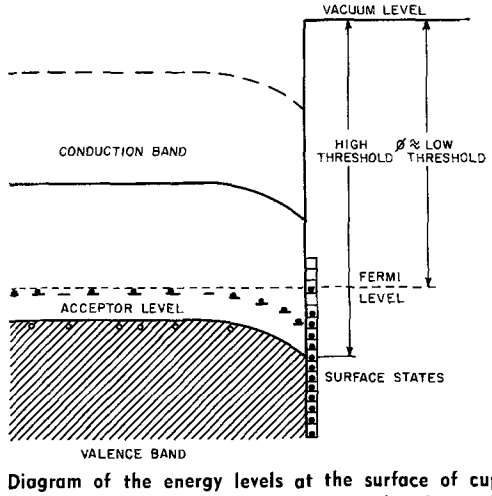

Fig. 4. Diagram of the energy levels at the surface of cuprous oxide indicating the effects of band bending on the photoemission threshold.

about 0.45 ev. This approaches the value of 0.4 ev observed from the temperature coefficient of the Hall effect (5) and which can be assigned to the energy separation between the valence band and the bulk acceptor levels. The photoemission for this limiting case can be assigned to excitation from bulk acceptor levels under conditions where very little band bending is present.

Kinetics of Thermal Growth of Silicon Dioxide Films in Water Vapor-Oxygen-Argon Mixtures

Takashi Nakayama and F. C. Collins

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The kinetics of growth of silicon dioxide films in mixtures of water vapor, oxygen, and argon have been studied in the range of water partial pressures from 4.6 to 355 Torr and the temperature range 850° to 1217°C. A combined linear-parabolic law of growth adequately represents the data over the complete region of temperatures and partial pressures studied. In the absence of oxygen, the linear and parabolic growth constants have first order dependence on the water vapor pressure at low pressures. In the case of the parabolic constant a saturation effect is evidenced by strong negative deviations from the first order law at higher water vapor pressures. This deviation is explained in terms of an adsorption isotherm at the oxide surface. The adsorption calculated from the growth behavior accurately fits the Langmuir adsorption isotherm. The apparent activation enthalpies of the parabolic and linear rate constants are 1.1 ev and approximately 3.3 ev, respectively, over the region of linear dependence upon the water vapor pressure. The enthalpy change calculated from the temperature dependence of the Langmuir adsorption isotherm is near zero. The measured enthalpies correspond to a superposition of the enthalpies of adsorption, desorption, generation of active sites for adsorption, and diffusion through the oxide film. The data do not enable the resolution of these several enthalpies. In the mixed water, oxygen argon ambient, the effect of introducing small vapor pressures of water at fixed oxygen partial pressure is to catalyze that part of the total growth rate due to the presence of oxygen. Higher vapor pressures of water repress the oxygen contribution to the growth rate at 850°. The latter effect was not observed at 1000°C over the partial pressure range investigated.

The kinetics of growth of thermally grown silicon dioxide films on silicon in both dry and wet oxygen and in steam ambients have been intensively investigated (1-24). The process is, at least in part, diffusion controlled as is shown by the generally parabolic form of the law of growth. Departures from the parabolic law which have been observed at temperatures below 1000°C have been interpreted on the basis of the Wagner (25) and Mott (26, 27) theories which predict linear or logarithmic behavior in the initial stage of oxide film growth depending on conditions. The observed values of the activation energy for growth quoted in the cited literature vary widely. There is a small trend in the literature to lower values in the case of wet oxygen as has been pointed out by Lieberman and Averkion (22), but it is not conclusive in view of the large discrepancies in the published values. Because of the fairly high permeability (28) and solubility (29) of water in fused quartz, the existence of a water catalyzed growth process in the case of growth in oxygen presumed dry can not be ruled out where growth is carried out by conventional techniques in a fused quartz furnace tube.

The present detailed investigation of the kinetics of the thermal oxidation of silicon in water-oxygen-argon ambients was undertaken in order to assess the separate roles of water and of oxygen in the oxidation process.

Experimental

The oxidations were carried out on a quartz boat in a 2.6 cm ID quartz tube with 2 mm wall thickness in a three zone diffusion type furnace with the central

zone temperature maintained within ±1°C. The fixed water vapor pressures were provided by a quartz humidiostat using deionized water maintained at a constant temperature. The argon gas used as the inert diluent was 99.998% pure. Tank oxygen of a purity of 99.60% was used in those runs in which oxidation in water-oxygen ambients was studied. The ambient flow rate was maintained at a constant rate of 150 ml/min corresponding to a linear velocity of 1.25 cm/sec within the furnace tube. The exit port of the furnace tube was closed by a silicone oil bubbler to prevent entrance of atmospheric moisture in the runs at low humidities.

The oxide films were grown on single crystal silicon slices doped to $5x10^{13}/cm^3$ with phosphorus. The oxidation studies of Deal and Sklar (21) indicate that phosphorus doping below $10^{19}/cm^3$ has no effect on the oxidation rate. The ingots were grown by the Czochralski method, sliced along the (111) planes, lapped, and polished to mirror smoothness by a vapor etching method (31). Immediately before being placed in the furnace, the slices were treated with HF to remove any oxide film and then successively rinsed in deionized water and methyl alcohol.

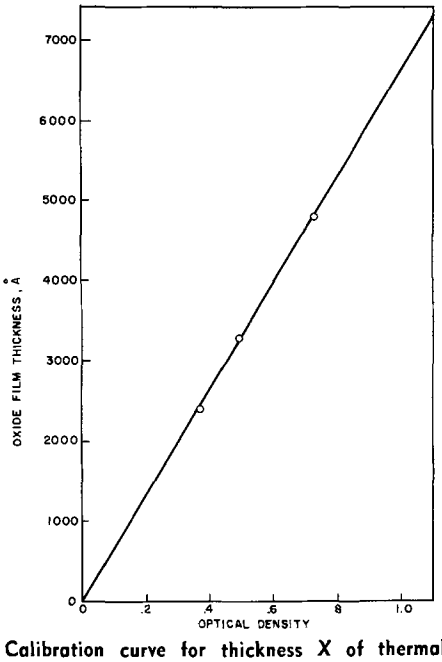

Fig. 1. Calibration curve for thickness X of thermally grown silicon dioxide films relative to optical density at 9.25μ.

The determinations of oxide film thickness were made by infrared absorbance measurements, a method suggested by Pliskin (30). The measurements were made at 9.25μ, the absorbance peak of the Si-O bond in thermally grown amorphous silica. A Perkin-Elmer Model 21 double beam recording spectrophotometer was used with two sample holders exposing equal 0.197 cm^2 areas to the two beams. An unoxidized portion of the same silicon slice which had received the same preliminary treatments was used as a blank in the reference beam. The optical density measurements of film thickness were found to be rapid and quite reproducible. They were calibrated against the Vamfo interference method (32). A linear interpolation was employed between 2400Å and zero. The validity of the interpolation was investigated by comparing the optical density at 9.25μ of a slice thinly oxidized on both sides with the optical density of the slice having the oxide from one side removed. Lambert's law was obeyed down to at least 400Å within an error of ±30Å. The calibration curve for optical density *vs.* oxide film thickness is shown in Fig. 1. At the humidity levels studied in the present investigation, there were no significant differences in the structure of the band in the 9.25μ region from that obtained for specimens thermally grown in pure oxygen. The same calibration curve was found to hold for the lowest and highest humidities studied here.

Data and Discussion

The primary data obtained for growth in water vapor and argon are presented in Fig. 2, 3, and 4. It will be observed that the data fit the purely parabolic law of growth only at temperatures of 1000°C and above. At the lower temperatures the data are consistent with a combined linear-parabolic law of the form

$$AX + BX^2 = t \qquad [1]$$

where X is the thickness of the oxide film at the time t and A and B are constants. The combined linear-parabolic law of the growth of silicon dioxide on silicon has been previously observed (17, 18, 24). The use

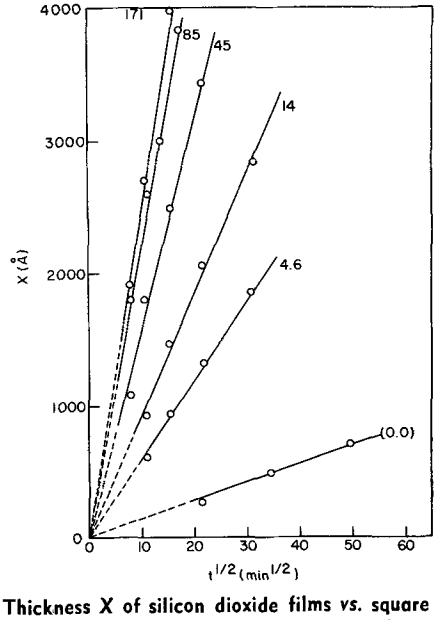

Fig. 3. Thickness X of silicon dioxide films *vs.* square root of the growth time $t^{1/2}$ at 1000°C at various pressures of water vapor as indicated in Torr.

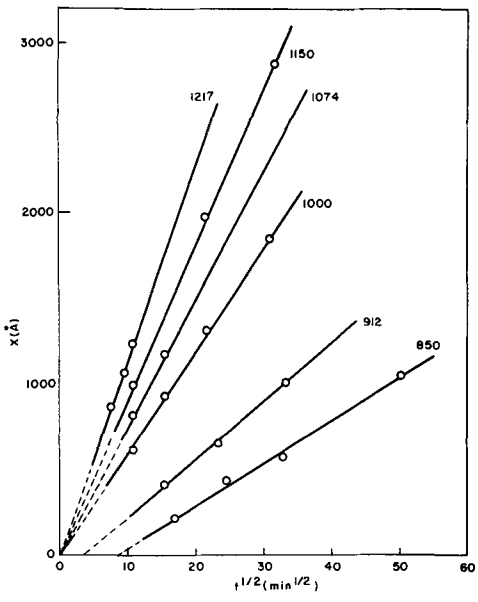

Fig. 4. Thickness X of silicon dioxide films vs. square root of the growth time $t^{1/2}$ at a water vapor pressure of 4.6 Torr at various temperatures as indicated in °C.

of this growth law is discussed theoretically in a subsequent section of this paper where it is shown that A and B are the reciprocals of rate constants for surface controlled and diffusion controlled reactions. Numerical values of these constants are found from the intercept and slopes of linear plots of t/X *vs.* X, as in Fig. 5.

The data illustrating the dependence of the parabolic rate constant k_2 on the partial pressure of water vapor at 850° and 1000°C are shown in Fig. 6. The rate law is first order in water vapor pressure, as expected, over the lower vapor pressure range but displays a marked departure from law at higher water vapor pressures.[1] This saturation effect is to be explained by existence of an equilibrium for the adsorption of water vapor on the surface of the growing oxide. The adsorption isotherm is clearly of the Langmuir type as shown in Fig. 7 in which the experimental points P_{H_2O}/k_2 are well represented by a curve linear in P_{H_2O}.

[1] This observation is not in agreement with the conclusions drawn by Deal and Grove (23) from the data of Flint (11) that the rate law is first order in partial pressure of water vapor up to 760 Torr. However, examination of the experimental points given in their Fig. 8 indicates a systematic negative deviation at higher partial pressures from a straight line drawn through the points at low vapor pressures.

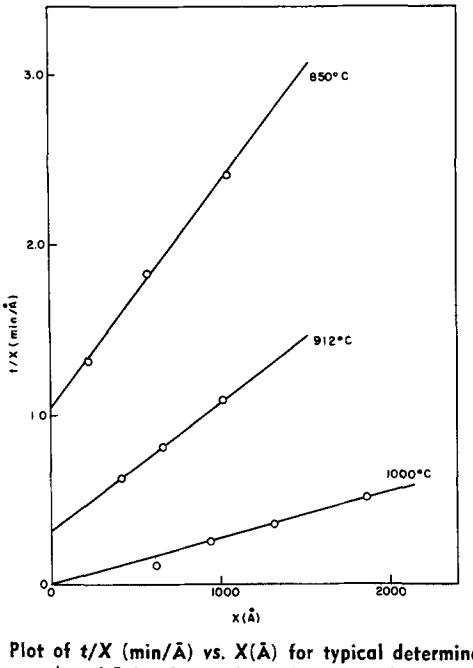

Fig. 5. Plot of t/X (min/Å) vs. X(Å) for typical determination of the constants A and B for the combined linear-parabolic law.

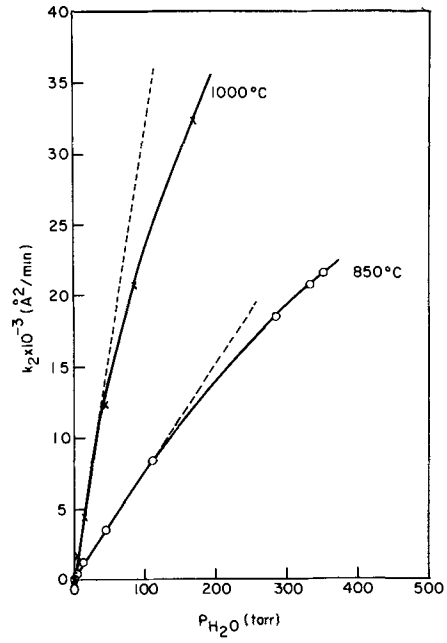

Fig. 6. Dependence of the calculated parabolic rate constant k_2(Å^2/min) on the partial pressure of water vapor P_{H_2O} at 850° and 1000°C.

The linear rate constant k_1 is first order in the water vapor pressure P_{H_2O} over the full range of water vapor pressures studied as is shown in Fig. 8. This is an expected result from the Langmuir adsorption behavior as will be later shown in detail.

Figure 9 presents a plot of the logarithm of the parabolic rate constant k_2 at water vapor pressure of 4.6 Torr against the reciprocal of the absolute temperature $1/T$. The activation enthalpy for the diffusion process calculated by least squares from the plot is 1.14 ev (26.3 kcal). It will be later shown that the activation enthalpy is necessarily independent of the water vapor pressure over the range in which the parabolic rate constant is first order in the water vapor pressure. In the region in which the parabolic

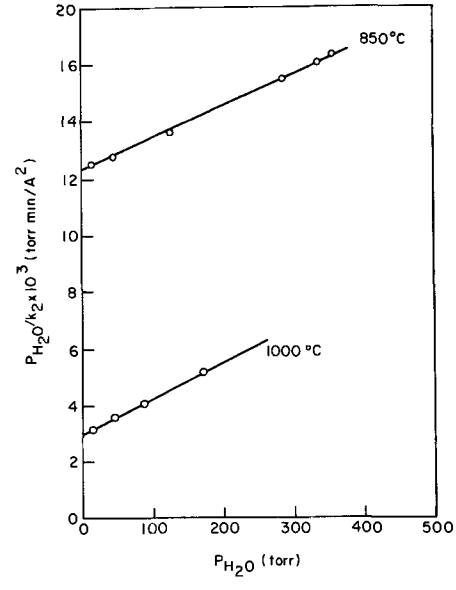

Fig. 7. Plot of k_2/P_{H_2O} vs. P_{H_2O} confirming Langmuir-type adsorption of water in growth mechanism.

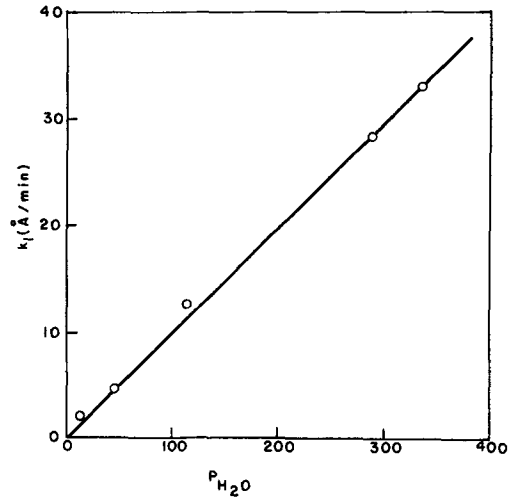

Fig. 8. Dependence of the calculated linear rate constant k_1 (Å/min) on the partial pressure of water vapor P_{H_2O} at 850°C.

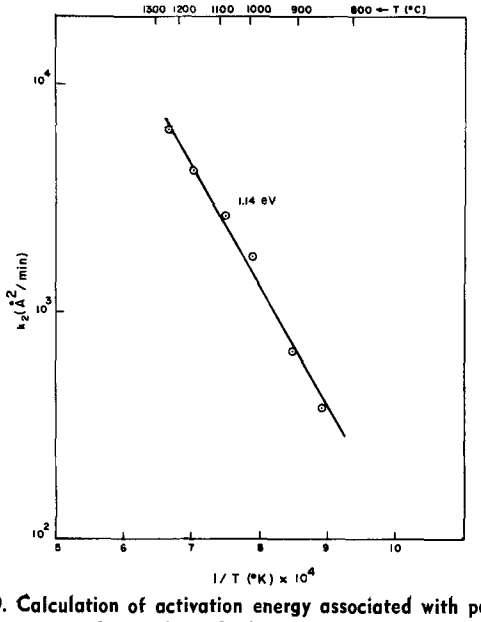

Fig. 9. Calculation of activation energy associated with parabolic growth pressure from plot of the logarithm of the parabolic growth rate constant k_2 vs $1/T$.

rate constant departs from this law, it is apparent from Fig. 6 that the calculated variable activation enthalpy will be lower than that in the linear region of the curves of Fig. 6. The numerical values of the varying activation enthalpy which might be calculated in the nonlinear region of the water vapor pressure dependence are not particularly revealing of the underlying processes. A more definitive quantity is the over-all enthalpy change involved in the Langmuir adsorption process. This is found from Fig. 7 and is zero within the precision of the measurements.

The activation enthalpy for the linear growth rate constant calculated from the linear growth rate constants at 850° and 912°C is 3.3 ev. As this value rests upon only two points, it is probably not of high accuracy, but it is apparently much larger than that for the parabolic rate constant.

The dependence of the parabolic growth rate constants on the partial pressure of water vapor for three oxygen isobars are given in Fig. 10 and 11 at temperatures of 850° and 1000°C. The behavior is obviously quite complex. For the purpose of detailed study, we shall here assume that the gross parabolic rate constant may be written as a superposition of two terms

$$k_2 = k'_2 P_{H_2O} + k''_2 (P_{O_2}; P_{H_2O}) \qquad [2]$$

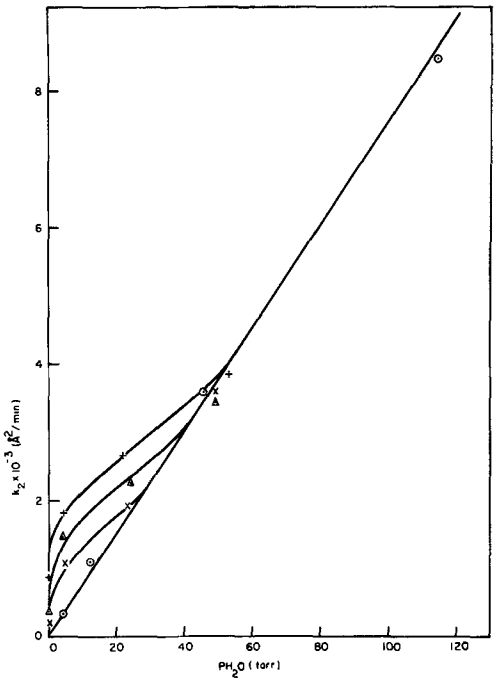

Fig. 10. Dependence of the calculated parabolic growth rate constant k_2 at 850°C on the water vapor pressure P_{H_2O} at various fixed oxygen partial pressures as indicated in Torr in water-oxygen-argon ambients. + P_{O_2} = 500 Torr; △ P_{O_2} = 200 Torr; × P_{O_2} = 100 Torr; ⊙ P_{O_2} = 0 Torr.

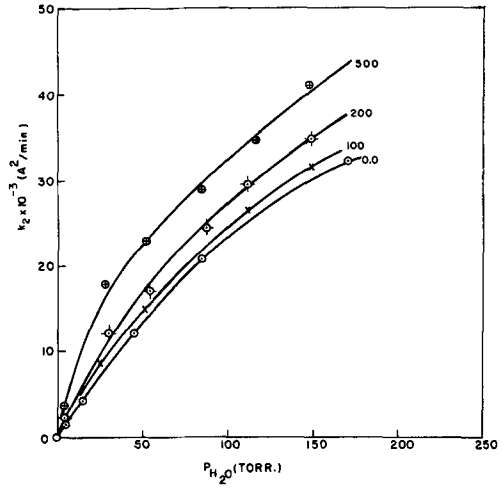

Fig. 11. Dependence of the calculated parabolic growth rate constant k_2 at 1000°C on the water vapor pressure P_{H_2O} at various fixed oxygen partial pressures as indicated in Torr in water-oxygen-argon ambients.

where k'_2 is the parabolic rate constant in the absence of oxygen and k''_2 is a new parabolic rate constant which depends on both the partial pressure of oxygen and that of the water vapor. The behavior of the incremental rate constant k''_2 with respect to the partial pressures of oxygen and water is quite different at 850° and 1000°C.

Figures 12 and 13 show the dependence of the incremental parabolic rate constant k''_2 on the water vapor pressure at fixed oxygen partial pressure at 850° and 1000°C. It will be seen from these figures at both these temperatures that the presence of small amounts of water vapor strongly catalyzes the oxidation of silicon by oxygen. This effect is well known in the oxidation of certain metals. At 850°C, however, additional partial pressure of water vapor, beyond a certain point, inhibits the contribution of oxygen to the oxidation of silicon. This inhibition at higher water vapor

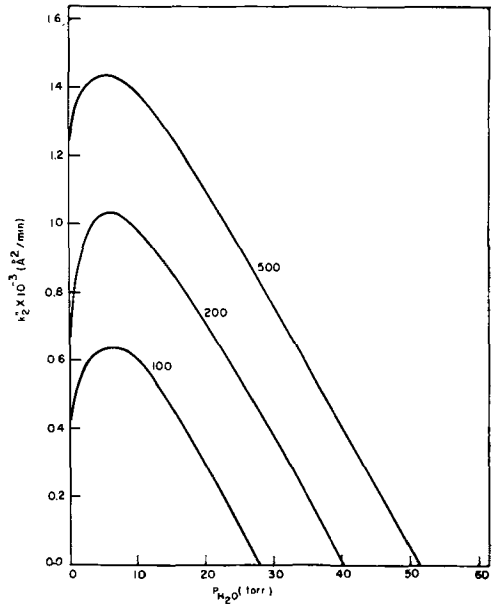

Fig. 12. Dependence of the incremental parabolic rate constant k''_2 at 850°C on the water vapor pressure P_{H_2O} at various fixed oxygen pressures as indicated in Torr.

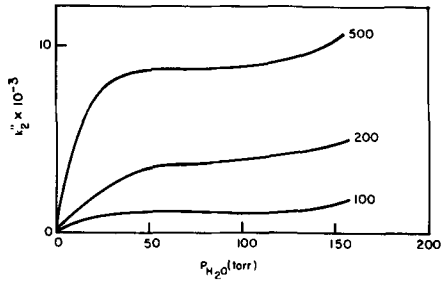

Fig. 13. Dependence of the incremental parabolic rate constant k''_2 at 1000°C on the water vapor pressure P_{H_2O} at various fixed oxygen partial pressures as indicated in Torr.

pressures is not apparent at 1000°C, at least over the range of vapor pressures investigated in this research.

Chemisorption of Oxidants

The saturation effect at high water vapor partial pressures suggests that the water vapor is taken up only at certain active sites at the surface of the growing oxide film. Applying the reasoning of the Langmuir adsorption isotherm, we have

$$c = c_0\theta \qquad [3]$$

where c_0 is the concentration of active sites at the surface and θ is the fraction of these sites which are occupied by adsorbate. For convenience c_0 is here expressed as a volume concentration. The fraction of occupancy is given by the well-known equation

$$\theta = \frac{K P_{H_2O}}{1 + K P_{H_2O}} \qquad [4]$$

where K is the equilibrium constant for the adsorption process. As will be later discussed in more detail, the parabolic rate constant may be assumed to be proportional to the concentration of the adsorbed oxidant species

$$k_2 = mc \qquad [5]$$

where the proportionality constant m contains the mobility of the diffusing species. Combining the last three equations, we have

$$k_2 = mc_0 \frac{KP_{H_2O}}{1 + KP_{H_2O}} \qquad [6]$$

Table I. Graphical values of mc_0 and adsorption equilibrium constant K

Temperature, °C	mc_0, Å²/sec	K, Torr⁻¹
850	8.3×10^4	0.93×10^{-3}
1000	7.7×10^4	4.3×10^{-3}

which may be put into the form

$$\frac{P_{H_2O}}{k_2} = \frac{1}{mc_0K} + \frac{P_{H_2O}}{mc_0} \qquad [7]$$

The last equation is the basis of the linear plots of Fig. 7 and establishes the observed adsorption process to be of the Langmuir type. The quantities mc_0 and K may be evaluated from Fig. 7 and are given in Table I.

The increase with temperature of the adsorption equilibrium constant per site corresponds to an endothermic process with $\Delta H^0 = 0.78$ ev. This is rather unexpected, but it does not necessarily lead to the conclusion that the total adsorption process is endothermic. The adsorption equilibrium also involves the formation of active sites. The lack of temperature dependence of the quantity mc_0 indicates that the formation of active sites is an exothermic process in view of the certainly endothermic activation energy of the diffusion coefficient contained in the constant m. The present data are not sufficient to calculate separately the latter two energies. Two firm conclusions which can be drawn from the region in which the parabolic rate constant is linear in the water vapor pressure.

1. The activation energy for film growth must be independent of the water vapor pressure in this linear region. In this region, the parabolic rate constant assumes the limiting form

$$k_2 = m(T)c_0(T)K(T)P_{H_2O} \qquad [6a]$$

so that at any two temperatures

$$\frac{k_2(T_2)}{k_2(T_1)} = \frac{m(T_2)c_0(T_2)K(T_2)}{m(T_1)c_0(T_1)K(T_1)} \qquad [8]$$

which is independent of the water vapor pressure. It follows that the activation energy must likewise be independent of the water vapor pressure in the linear region. The product mc_0K at 850° and 1000°C may be determined from the slopes of the linear portions of the curves in Fig. 6. The activation energy calculated from the ratio of Eq. [8] is 1.12 ev in close agreement with that calculated from Fig. 9.

2. The activation energy for growth is not uniquely determined by the activation energy for diffusion of the migrating species although the growth process is clearly diffusion-controlled in the parabolic growth law region. The temperature dependence of the parabolic rate constant and its apparent activation energy is determined by the separate temperature dependencies of the three quantities in Eq. [6a]. It may be remarked that the separate factors tabulated in Table I enable a third independent determination of the activation energy connected with the parabolic rate constant k_2. The activation energy so determined from the ratio mc_0K at 850° and 1000°C calculated from Table I is 1.15 ev in agreement with the values more directly obtained from the growth data in the foregoing. It provides a further indication of the general consistency of the data with the interpretation in terms of the Langmuir adsorption isotherm.

The growth rate data at 1000°C do not indicate any inhibition of the oxygen contribution to the parabolic growth rate constant by higher water vapor pressures. It is likely that an inhibition effect would have become evident if the present investigation had been extended to still higher water vapor pressures. Deal and Grove (23) find that the substitution of oxygen by argon produces no change in the growth rate when the partial pressure of the water vapor is *ca.* 640 Torr.

Table II. Representative values of activation energy in ev for parabolic rate growth constant calculated between 850° and 1000°C in water-oxygen-argon mixtures at various partial pressures of water vapor and oxygen

Water, Torr / Oxygen, Torr	4.6	10	25	50	100	150
0	1.12	1.12	1.12	1.12	0.93	0.86
100	0.57	0.93	1.23	1.12	0.97	0.87
200	0.41	0.74	1.13	1.24	1.05	0.92
500	0.86	1.11	1.39	1.44	1.20	1.08

The upward trend of the incremental parabolic rate constant k''_2 in the higher water vapor pressure region of Fig. 13 may be due to enhancement of the water contribution to the parabolic rate constant. This would be contrary to the assumption embodied in Eq. [2] which states that the water vapor contribution is quite independent of the oxygen partial pressure. The possible enhancement of the water vapor contribution by oxygen has some plausibility as indicated in the next section of this paper.

The irregular behavior of the incremental rate constant k''_2 at 850° and 1000°C prevents the calculation of significant activation energies connected with the variation of this rate constant between these two temperatures. Table II gives a few representative values of the activation energy for the combined parabolic rate constant at various partial pressure of water vapor and oxygen. The calculated values of the activation energy are possibly not of high accuracy but there do appear to be significant trends with respect to the ratios of water vapor to oxygen.

Chemical Species Involved in Film Growth

The Wagner-Mott electrochemical theory of oxide film growth (25-27) implies an ionic diffusing species. Jorgensen (14) has demonstrated that this is indeed the case by showing that the growth could be stopped by applying an external electrical potential counter to that of the postulated electrochemical cell. Marker experiments (7, 14, 33) show that the oxidant is the diffusing species. Jorgensen (14) concluded that the diffusing species is an oxygen anion. Seraphim and co-workers (34) have suggested that the oxide ion vacancies could be mobile species in amorphous silicon dioxide films.

The data existing at the present time do not enable a firm conclusion to be reached as to the identity of the diffusing species. However, all of the data are consistent with the hypothesis that the diffusing species is hydroxyl ion. If this hypothesis is correct, the following reactions presumably take place on the opposite sides of the film: At the outer surface

$$2H_2O \rightleftarrows 2\ OH^- + 2H^+ \qquad [R\text{-}1]$$

and at the $Si\text{-}SiO_2$ interface

$$2\ OH^- + Si \rightleftarrows SiO_2 + 2H^+ + 4e \qquad [R\text{-}2]$$

The protons and electrons could combine either at both faces or at the outer surface only. This process may be represented by

$$4H^+ + 4e \rightleftarrows 2H_2 \qquad [R\text{-}3]$$

In any event, the transport of an equivalent number of electrons across the oxide film is required in order to balance the charge carried by the diffusing anions. The mechanism of the electron transport across the silicon dioxide film is not known at present.

The strong catalysis by water of the oxygen oxidation of silicon as evident from Fig. 10, 11, 12, and 13 lends support to the hypothesis that the hydroxyl ion is also the diffusing species in the oxidation by oxygen. This suggests that the adsorption of oxygen is attended by the reaction

$$O_2 + 2H^+ + 4e \rightleftarrows 2\ OH^- \qquad [R\text{-}4]$$

the protons being furnished by the adsorbed water. As the reaction at the silicon-silicon interface [R-2] will remain unchanged, it provides a source of protons for the reaction [R-4] thus establishing a chain process. Accordingly, the presence of only a very small amount of water may be sufficient to set up the hydroxyl ion diffusion mechanism.

Christie (28) has found appreciable amounts of water in the gas efflux from conventional fused quartz furnace tubes under ordinary operating conditions. In the present investigation, a non-zero growth rate was found in pure argon which had been dried by passage through a cold trap refrigerated with dry ice and acetone, see Fig. 2 and 3. The growth rate under these conditions implies the presence of 0.22 Torr of water vapor at 850°C and 0.35 Torr at 1000°C. For the oxidation behavior of silicon in very dry oxygen, reference may be had to the forthcoming paper of Burkhardt and Gregor (24).

The suggested role of protons in facilitating the adsorption of oxygen and catalyzing the oxidation of silicon by oxygen also provides a possibility that it also facilitates the adsorption of water in that it removes one of the products of the latter adsorption, *i.e.*, protons. This could account for the anomalies in the behavior of the incremental parabolic constant k''_2 at 1000°C as it would invalidate the superposition relation, Eq. [2], upon which the significance of the k''_2 depends.

Electrochemistry of Film Growth

In a companion paper (36), the basic electrochemistry of film growth is formulated in a way somewhat different from that originally presented by Wagner (25). The effective electrostatic potential difference ΔV across the film is given by

$$\Delta V = -E^\circ + \Delta\phi \qquad [9]$$

where E° is the potential of the electrochemical cell representing the oxidation process, and $\Delta\phi$ is the Fermi potential difference across the film. The latter quantity is shown to be[2]

$$\Delta\phi = \frac{4q\rho}{M}\frac{k_2}{\sigma_e} \qquad [10]$$

where $M/4$ is the equivalent weight of SiO_2, ρ its density, σ_e the purely electronic (or hole) conductivity of the oxide, k_2 the parabolic rate constant, and N_o Avogadro's number.

Where space charge is absent from the film, the ionic flux J may be put into the form

$$J = -\frac{Dq\Delta V}{kTX}\frac{[c(X)e^{-q\Delta V/kT} - c(O)]}{[e^{-q\Delta V/kT} - 1]} \qquad [11]$$

The value of the electrostatic potential difference ΔV depends on the value of the electronic conductivity σ_e in Eq. [10] and the electrochemical cell potential E°.

Table III gives the calculated cell potentials for the two oxidation reactions relevant to the present work

$$Si + O_2 \rightarrow SiO_2 \qquad [R\text{-}5]$$

$$Si + 2H_2O \rightarrow SiO_2 + 2H_2 \qquad [R\text{-}6]$$

The data for the free energies of formation of quartz silicon dioxide and water were taken from the JANAF

[2] The derivations of Eq. [10] and [11] are given in the companion paper (36).

Table III. Standard free energy changes and cell potentials for oxidation of silicon by oxygen and by water at various temperatures

Temperature, °C	Oxygen ΔG°, kcal	Oxygen E°, V	Oxygen qE°/kT	Water ΔG°, kcal	Water E°, V	Water qE°/kT
850	−169.35	1.84	19.0	−88.81	0.37	9.0
1000	−163.15	1.77	16.1	−84.77	0.85	7.7
1150	−156.99	1.70	13.9	−80.70	0.82	6.7

Tables (35). The free energy changes so calculated are probably somewhat greater than those actually taking place in the above reactions in the present study as amorphous silica rather than quartz is produced. The difference however, should not be large. The standard cell potentials E° are obtained by use of the well-known equation

$$E^\circ = -\Delta G^\circ/nF \qquad [12]$$

where $n = 4$ is the number of electrons transferred in the cell reaction and F is the Faraday.

Where $q\Delta V >> kT$, Eq. [11] assumes the limiting form

$$J = \frac{Dq}{kT} c(X) \frac{\Delta V}{X} \qquad [13]$$

where the concentration of the diffusing species $c(X)$ is proportional to the concentration of the ions adsorbed at the outer surface. The growth rate may then be cast into the form

$$\frac{dx}{dt} = \frac{M}{\rho} J = \frac{k' c}{X} \qquad [14]$$

where c is the concentration of the adsorbed ions. Equation [14] is applicable in both the linear and the parabolic regions of film growth as may be readily demonstrated by combining the adsorption and diffusion equations.

The time dependence of the concentration c in the zone of thickness δ at the surface of the oxide film is

$$\delta \frac{dc}{dt} = k_a(c_o - c)P - k_d c - \frac{k'}{X} c \qquad [15]$$

where k_a and k_d are the specific rate constants for adsorption and desorption, respectively, c_o is the concentration of active sites, and P is the partial pressure of the oxidizing species. We now introduce the usual steady state hypothesis of chemical reaction kinetics

$$\frac{dc}{dt} = 0 \qquad [16]$$

Upon solving Eq. [19] for c and introducing it into Eq. [14] we obtain

$$\left(\frac{k_a P}{k'} + \frac{k_d}{k'}\right) X \frac{dX}{dt} + \frac{dX}{dt} = k_a c_o P \qquad [17]$$

Introducing the boundary condition $X = X_o$ at $t = 0$ and integrating lends to

$$\frac{1}{2}\left(\frac{k_a P}{k'} + \frac{k_d}{k'}\right)(X^2 - X_o^2) + (X - X_o) = k_a c_o P t \qquad [18]$$

The thickness of native oxide X_o at the commencement of the thermal oxidation is small, generally of the order of 20Å for a surface which has been freshly treated with HF. As $X_o << X$ for the region of the measurements of this investigation, it has been dropped in the present analysis.

The linear rate constant may now be identified as

$$k_l = k_a c_o P \qquad [19]$$

corresponding to adsorption rate control of the growth process at small values of X.

The parabolic rate constant is given by

$$k_2 = k' \left(\frac{k_a}{k_a P + k_d}\right) c_o P \qquad [20]$$

in the linear region of dependence upon the pressure P. Thus comparison with Eq. [6] provides

$$m = k' \qquad [21]$$

$$K = \frac{k_a}{k_d + k_a} \qquad [22]$$

Acknowledgments

The participation of one of the authors (T. N.) in this research was made possible by a Fellowship under NSF Grant No. GP 1246. L. V. Gregor, D.P. Seraphim, P. J. Burkhardt, K. J. Zaininger, and A. Revesz are to be thanked for a number of very helpful discussions concerning the research. L. V. Gregor furnished the vapor polished silicon slices. The authors are particularly indebted to W. A. Pliskin for the suggestion of infrared absorbance for the determination of silicon dioxide film thickness and for making the determinations of the thickness of reference samples by the Vamfo technique for the calibration of the infra-red absorbance method.

Manuscript received Feb. 15, 1966. This paper is taken from the dissertation of one of the authors (T. N.) submitted to the Faculty of the Polytechnic Institute of Brooklyn in partial fulfillment for the Ph.D. degree, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

GaSb Prepared from Nonstoichiometric Melts

F. J. Reid, R. D. Baxter, and S. E. Miller

Columbus Laboratories, Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Gallium antimonide single crystals have been prepared from melts ranging in composition from nearly stoichiometric to Sb/Ga atom ratios of about 3/1. P-type GaSb and, by suitable impurity additions, n-type GaSb have been produced with superior electrical properties. The residual acceptor concentration has been reduced to the order of $2 \times 10^{16}/cm^3$ by the growth of crystals from antimony-rich melts. Hole mobilities at 78°K of 6000 cm^2/volt-sec and electron mobilities of over 10,000 cm^2/volt-sec have been realized.

Gallium antimonide is a III-V compound semiconductor with a melting point of 706°C and a forbidden band gap of about 0.7 ev at 300°K. The compound is not difficult to prepare in single-crystal form, but it has been a particularly trying material from the standpoint of obtaining low carrier concentrations. Studies on GaSb (1-5) had revealed the highest purity material to be p-type, containing 1 to 2×10^{17} free holes/cm^3. Analysis for chemical impurities (6) indicated that there were none present, with the possible exception of carbon and oxygen, in sufficiently high concentrations to account for the residual acceptor concentration. In addition, studies by the authors (7), using lithium additions to produce ion pairs between lithium and the residual acceptor and also using additions of donor impurities to produce compensated p-type GaSb, have fairly well established the residual acceptor to be at least a doubly ionizable defect. Therefore, many possible chemical impurities, including carbon and oxygen, can be ruled out as the troublesome residual acceptor, leaving only elements, such as copper, silver, and gold and the alkali metals, which, with the possible exception of sodium, would readily be detected by spark-source mass spectrographic analysis. Thus, the possibility of the residual acceptor in GaSb being a stoichiometric or lattice defect received substantial support. In view of Effer and Etter's first report (5) of success in reducing the residual acceptor concentration in GaSb by a preparation from an antimony-rich melt, the investigation which forms the basis of this paper was undertaken.

Experimental Techniques

Crystals of GaSb were grown from melts ranging in composition from nearly stoichiometric to Sb/Ga atom ratios of about 3/1. High-purity gallium (99.9999%) and antimony (99.9999%) or zone refined GaSb were used as the starting materials. Two crystal growing techniques were used: zone freezing in which the molten zone contained the excess antimony, and crystal-pulling in which a GaSb seed was dipped into a nonstoichiometric, antimony-rich melt. In the first case (zone freezing) the composition of the antimony-rich melt remained constant because nearly stoichiometric GaSb was added by the melting of the crystal at one end of the zone and was removed at the same rate at the other end of the zone by crystallization. In the crystal pulling case, the melt composition changed as the nearly stoichiometric crystal of GaSb grew; however, crystal pulls were concluded after only a small portion of the melt was crystallized, corresponding to about 1/3 of the gallium content. The calculated maximum gradient of hole concentration along the length of our pulled crystals is about ¼ of 1% per mm of crystal pulled. Most of the electrical data pertain to the pulled single-crystal samples.

The electrical properties of interest are the Hall coefficient R and the conductivity σ. The carrier density n was calculated from the equation $R = \pm \gamma/ne$, where e is the electronic charge and $\pm$ indicates the presence of positive carriers (holes) or negative carriers (electrons). The factor γ was taken to be unity; however, the magnitude of the error introduced by this procedure at 78°K will be discussed for p-type GaSb in the section on "Results and Discussion." Another property of interest is the mobility of the charged carriers, which can be specified as a conductivity mobility μ [$\equiv \sigma_o/ne = R_{H\to\infty}\ \sigma_o$] or as a Hall mobility μ^H [$\equiv R_o\ \sigma_o$] (8), where σ_o is the zero magnetic field conductivity and R_o and $R_{H\to\infty}$ are, respectively, the weak- and strong-field Hall coefficients.

Current and potential leads were attached to the Hall samples with indium solder after the surfaces had been etched in a 10:1:90 mixture of HNO_3:HF:H_2O. The samples were placed in a Pyrex tube and measured in an ambient of helium gas or a vacuum. Hall coefficient and conductivity measurements were made at temperatures in the range 25°-400°K, using a L&N type K-3 potentiometer. In making electrical measurements, the sample current and magnetic field were reversed independently and voltage readings averaged to eliminate thermomagnetic and thermoelectric voltages.

Results and Discussion

Figure 1 shows the hole concentrations at 298° and 78°K for GaSb samples prepared from antimony-rich melts. The melt compositions are shown on the abscissa in terms of the antimony content in atomic per cent. The circles represent data for GaSb prepared by zone freezing and crystal pulling techniques in which the freezing rate was 0.16 cm/hr. The triangles represent data for crystals pulled at a rate of 0.72 cm/hr. For all pulling experiments the seed and melt were rotated in opposite directions, giving a net rotation rate of 12 rpm.

In the case of the growth of GaSb from antimony-rich melts, the controlling feature regulating the melt composition at the freezing solid/liquid interface is the segregation of excess antimony at this interface. In most elementary treatments of segregation in a freez-

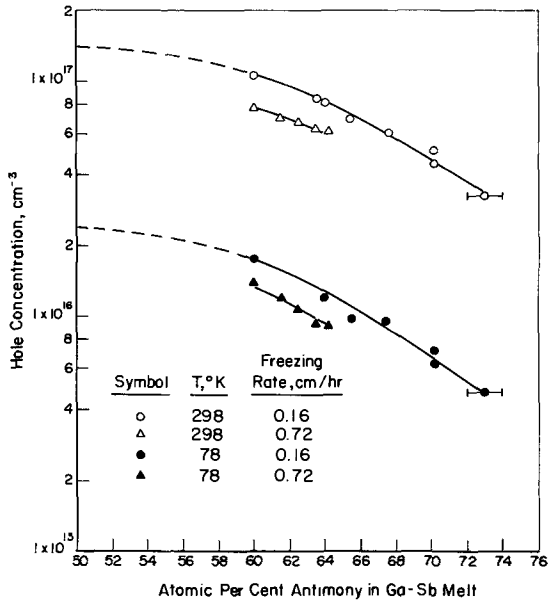

Fig. 1. Hole concentration in GaSb as a function of gallium-antimony melt composition.

ing process, it is assumed that no diffusion occurs in the solid and that the liquid remains completely mixed. Although solid-state diffusion generally can be neglected, complete mixing in the liquid is an idealized condition that is attained only in the limit as a zero freezing rate is approached or as an infinitely rapid rotation rate, and hence thorough stirring, is realized. The boundary-layer treatment of Burton *et al.* (9) for prediction of segregation in crystal growth from the melt has been extended recently by Wilcox (10). Our results are in qualitative agreement with this work, *i.e.*, a finite boundary layer having a larger antimony content than the average of the melt appears to be present particularly at the larger freezing rate. Hence, the data for samples prepared at the two freezing rates could be made to coincide if one assumed the hole concentration to be determined by the composition of a boundary layer, which is more antimony rich than the bulk of the melt.

The dashed portion of the curves in Fig. 1 represent extrapolations between nominal values of hole concentrations for GaSb prepared from nearly stoichiometric melts and data for melts containing greater than 60 a/o antimony. It is to be noted that it is not worthwhile to make a "half-hearted" attempt in investigating antimony-rich melts because even at 60% antimony only a small reduction in hole concentration is observed. This small reduction could easily be overlooked without the supporting data at larger Sb/Ga ratios.

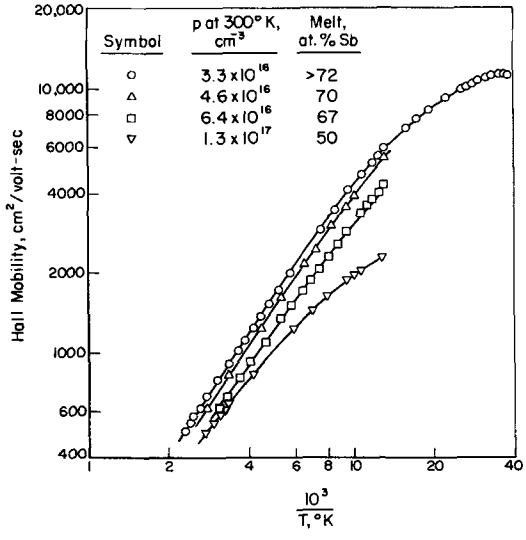

Fig. 2. Hall mobility as a function of temperature for several specimens of p-type GaSb.

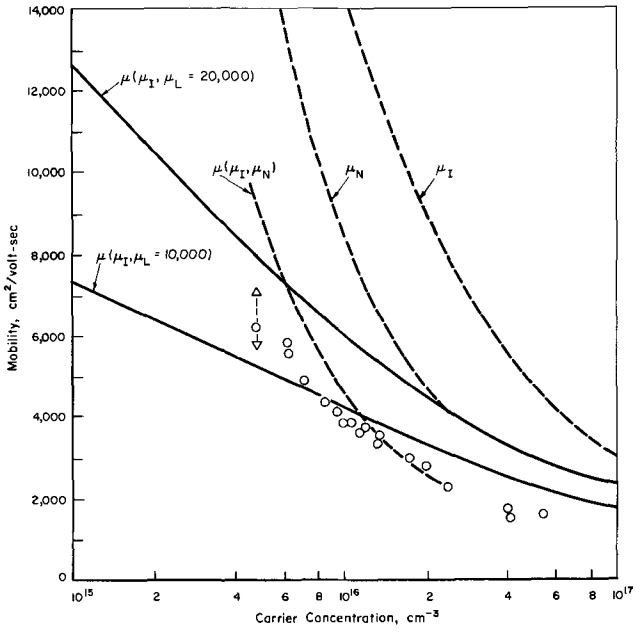

Fig. 3. Mobility at 78°K as a function of carrier concentration for p-type GaSb. △, $\mu^H[\equiv \sigma_0 R_0]$; ▽, $\mu[\equiv \sigma_0 R_{H\to\infty}]$; ○, $\sigma_0 R_{H=5.7kg}$.

Figure 2 shows the hole mobility of four p-type GaSb samples as a function of temperature. The hole concentration, p, and melt composition from which the crystal was prepared are shown. It is noted that the mobility, which is sensitive to the density of ionized defects, becomes progressively larger as hole concentration is reduced by growing from melts containing progressively larger antimony excesses. These data verify that the reduction which has been achieved in hole concentration is truly a decrease in ionized defect concentration and not the result of increased compensation. Hole mobilities reported for GaSb prepared from nearly stoichiometric melts have been in the range 2000-4000 cm²/v-sec at 78°K. Effer and Etter (5) obtained mobilities of about 5000 cm²/v-sec, and the present work has realized mobilities of about 6000 cm²/v-sec at 78°K with a value of about 12,000 cm²/v-sec at 30°K.

Figure 3 presents some data on the hole mobility in p-type GaSb as a function of the hole concentration at 78°K. Some idea of the magnetic field dependence of the Hall coefficient in p-type GaSb is revealed from the points indicative of the lowest carrier concentration sample. It is seen that μ^H/μ is about 1.2 for this sample, which is much the same as for p-type germanium (11). The open circles represent mobilities from Hall measurements done at 5700 gauss and are about 7% higher than the strong field limit (H > 15 kilogauss) in the worst case. Theoretical curves were obtained, using appropriate equations in the references cited, for an ionized-impurity scattering mobility μ_I (12, 13), a neutral-impurity scattering mobility μ_N (14), a combination of μ_I and μ_N (15), and a combination of μ_I and μ_L (16), the acoustic mode lattice scattering mobility. A dielectric constant of 15 and a hole effective mass m^* of 0.5 m_o were assumed for all cases. Values in the literature for m^* range from 0.23 to 0.5 m_o. Use of the smaller effective mass increases the theoretical mobility for the combination of μ_I and μ_L and decreases it slightly for the combination of μ_I and μ_N.

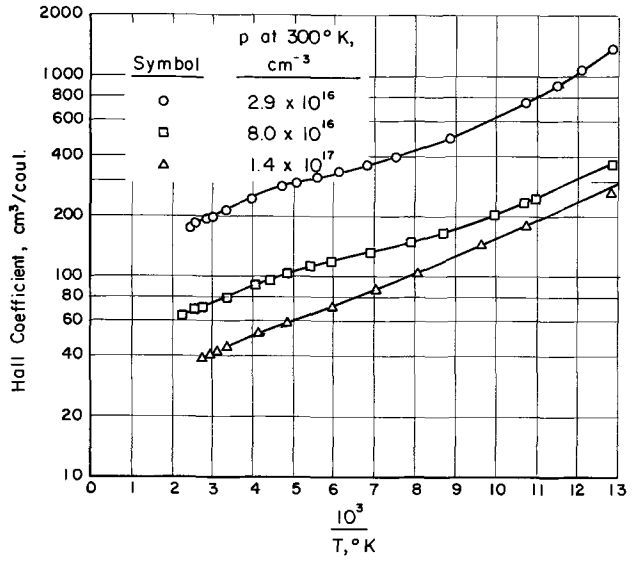

Fig. 4. Hall coefficient as a function of temperature for three different specimens of p-type GaSb.

It appears that neutral-impurity effects are significant, particularly at large carrier concentrations, because the combination of μ_I and μ_L predicts much larger mobilities than are observed at large carrier concentrations. Introducing polar mode lattice scattering only makes this situation worse. The neutral impurities are seen to arise from the deionization of acceptors as the temperature is lowered. One may appreciate this by considering the temperature dependence of the Hall effect as shown in Fig. 4. Of course, the combination of μ_I and μ_N becomes unrealistic at the smaller carrier concentrations because lattice scattering becomes controlling in this range. An integral form to combine all three scattering processes is available; however, the effort to evaluate this integral is hardly justified for present purposes.

Figure 5a shows the phase diagram for the gallium-antimony system after Greenfield and Smith (17). The solidus is, of course, so narrow in this illustration that it appears as a solid line. What one accomplishes by using nonstoichiometric melts is to lower the freezing point of GaSb by going out on the liquidus to high antimony concentrations. Hence, since the reduction in the residual acceptor concentration was shown to result from a reduction in a lattice defect concentration, it follows that the defect in question is characteristic of gallium-rich material as shown in Fig. 5b, where the abscissa scale is greatly magnified and the solidus curve was obtained from a detailed analysis of Hall effect as a function of temperature on the basis of a doubly ionizable defect model (7).

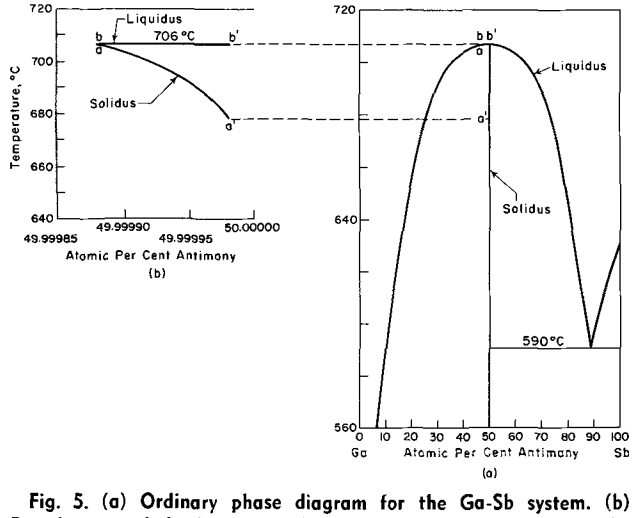

Fig. 5. (a) Ordinary phase diagram for the Ga-Sb system. (b) Greatly expanded abscissa scale revealing fine structure in the solidus aa'. Due to the narrowness in over-all composition now covered by the expanded abscissa, the deviations in the liquidus from horizontal are too small to be seen. The data sensitive enough to delineate the fine structure were obtained by analysis of electrical measurements.

Now, with the maximum melting point of GaSb lying on the gallium-rich side, and because of the existence of at least a doubly ionizable type of lattice defect, it appears likely that the nature of the defect is a gallium atom substituted on an antimony site. This follows, inasmuch as a gallium interstitial would be expected to be a donor. Also, it is unlikely that a simple antimony vacancy could act as an acceptor, especially one capable of double ionization. Actually the antistructure defect mentioned above might involve other rearrangements of the lattice in the vicinity of the suggested antistructure defect and be quite complex in reality.

One of the more interesting avenues that this investigation has opened is the possibility of obtaining relatively low carrier concentration n-type GaSb that does not contain a large concentration of compensating acceptors, particularly doubly ionized acceptors. Theoretical predictions (18) indicate that the electron mobility should be considerably higher than has thus far been realized experimentally. Figure 6 shows the electron mobility of some Te-doped samples of GaSb prepared from antimony-rich melts. The lowest curve (inverted triangular data points) is for a sample from a melt containing 68% antimony and the open-circle data points for a sample, from the same melt, when it contained 73% antimony. The increase in carrier concentration from 2.0 to 3.7 x 10^{17} per cm^3 results partly from an increase in tellurium content and partly from a reduced concentration of the doubly ionized acceptor defect. The observed increase in mobility is considerably greater than has been observed for samples of comparable carrier concentrations but with no reduction in the concentration of compensating defects.[1]

The two curves with triangular data points are illustrative of results before (inverted triangles) and after lithium diffusion into a sample of n-type GaSb. The higher carrier concentration, higher mobility sample contains lithium, which apparently pairs with acceptor defects, resulting in reduced compensation and less ionized impurity scattering (7, 20-22). Finally, the top curve is for a lithium-diffused sample which was prepared from a melt containing about 66% antimony with a smaller addition of tellurium than was used for doping the other crystals.

[1] For n-type GaSb in this carrier concentration range, the electron mobility is observed to increase with increasing carrier concentration (19).

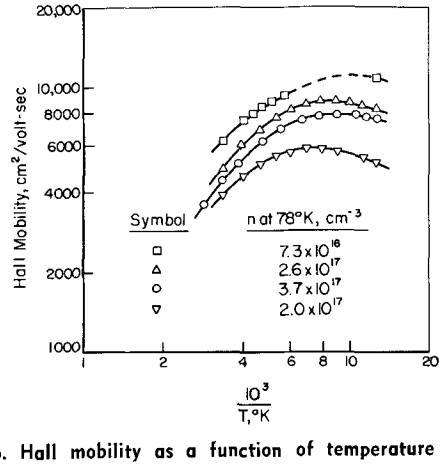

Fig. 6. Hall mobility as a function of temperature for several specimens of n-type GaSb.

Summary

It has been shown that a reduction in the residual acceptor concentration, with a corresponding increase in the hole mobility, can be effected by growing GaSb crystals from antimony-rich melts. In the improved material, with carrier densities of 2 x $10^{16}/cm^3$, it appears that the residual acceptor is still the dominant source of free carriers. Further reduction by the present techniques will be hampered by the existence of a gallium-antimony eutectic which has a Sb/Ga atom ratio composition of about 87/13. The maximum melting point of GaSb has been found to be on the gallium-rich side of the exact 1 to 1 composition. It appears that the dominant stoichiometric defect present in material prepared at the maximum melting point is not a simple vacancy defect. The most straightforward model suggested for the defect consists of gallium atoms substituted for antimony atoms on the antimony sublattice. The actual defect may be considerably more complicated involving other rearrangements of the lattice in the vicinity of the antistructure defect. However, the antistructure defect model is in good agreement with experimental observations.

The findings of this work have made it possible to produce p- and n-type GaSb with electrical properties superior to those previously attainable. The availability of such materials should permit investigations in the areas of fundamental transport properties under conditions of decreased impurity scattering, and studies of impurity behavior and device feasibility under conditions of decreased contributions from residual acceptors. An important feature of the work in growing GaSb from nonstoichiometric melts is that this is the first III-V compound in which fairly complete and convincing evidence of the importance of stoichiometric defects has been developed. It is interesting to note that, because of the very narrow width of the apparent solidus region of GaSb, analyses of electrical properties is the only method sensitive enough to delineate this region.

The Epitaxial Growth of Silicon on Silicon Webs and Silicon Slices

T. L. Chu

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Silicon webs with flat principal faces of {111} orientation are ideal substrates for the epitaxial growth of silicon, and this growth has been carried out by the pyrolysis of silane and the thermal reduction of trichlorosilane in a flow system. Epitaxial layers of good structural perfection have been grown on web substrates and accurately oriented {111} substrates at relatively low temperatures (1080°C) and high growth rates (1.5 μ/min). The exact {111} surface of the substrate has no effect on the macroscopic perfection of the epitaxial layer, in contrast with the commonly observed growth pyramids. The thermal reduction of trichlorosilane has been used for the epitaxial growth of silicon on individual silicon slices with main faces of various crystallographic orientations. The growth rate has been found to be independent of the crystallographic orientation of the substrate surface, due to the fact that the diffusion of reactants to the substrate surface is the rate-determining step of the growth process. However, when a substrate has two or more adjacent faces of different crystallographic orientations, the growth rate on these faces becomes orientation-dependent.

Silicon web consists of an extended sheet with flat faces of {111} orientation bounded by two dendrites; the sheet portion is usually much wider and thinner than the supporting dendrites (1-3). The web grows along a <211> direction, and the sheet and dendrites are of the same crystallographic orientation. Although the presence of twin planes in dendrites is essential for their growth, the twin structure of dendrites may or may not continue through the sheet. Twin planes in the sheet do not impair its usefulness for device purposes since {111} twin boundaries in silicon have been shown to have no unusual diffusion properties and no influence on p-n junction characteristics (4), and twin structures in germanium have been shown to have no detectable effects on the recombination of minority charge carriers (5). Furthermore, in contrast to dendrites, microsegregation of dopants is not observed in the sheet even in highly doped materials. Both n- and p-type webs of good crystalline perfection and of resistivities over a wide range have been prepared in long lengths. When desirable, the supporting dendrites in the web can be removed readily by using aqueous sodium hydroxide as a preferential etchant (6) or by mechanical stripping processes (7). These facts indicate that silicon webs are ideal substrates for the preparation of epitaxial devices, offering many advantages. For example, the mechanical and chemical operations involved in the preparation of substrates from conventional ingots are eliminated, and the preparation of very large area devices or continuous processing is also possible. Large area solar cells have been prepared by the epitaxial growth technique using web substrates (8).

The epitaxial growth of silicon on web substrates has been carried out to study the structural perfection and morphology of these epitaxial layers. Silicon slices with main faces of various low-index orientations, prepared from conventional crystals, were also used as substrates for comparison. The use of the thermal reduction of trichlorosilane or the pyrolysis of silane in a flow system has produced epitaxial layers of good crystalline perfection at rates of 0.5-1.5μ/min on silicon webs, the same as the growth of silicon on conventional substrates. The fact that the surface of the silicon sheet is of exactly {111} orientation has no observable influence on the structural perfection of the grown layer. Furthermore, the growth rate has been found to be independent of the crystallographic orientation of the substrate surface under conditions used in this work. These results are discussed in this paper.

Experimental

The epitaxial growth of silicon was carried out in a flow system using the thermal reduction of trichlorosilane with hydrogen or the pyrolysis of silane in a hydrogen atmosphere. Doping of the grown layer was accomplished by using diborane or phosphine as a dopant. Semiconductor grade trichlorosilane, purchased from the Union Carbide Corporation, was purified by fractional distillation through a quartz column. Semiconductor grade silane, purchased from Gray Chemical Company, was used without further purification. Commercial grade hydrogen was purified by diffusion through a palladium-silver alloy.

Silicon webs used in this work, grown at the Westinghouse Research Laboratories and the Westinghouse Semiconductor Division (1,2), had dislocation densities of 0-10^2 cm^{-2} and 10^2-10^4 cm^{-2} on the main faces and across sections, respectively. When the webs had been exposed to the laboratory atmosphere over a period of time, they were cleaned successfully with organic solvents, hydrofluoric acid, and deionized water, or etched briefly in a hydrofluoric acid-nitric acid mixture. In some cases, the dendrites were removed by using a 30% sodium hydroxide solution at 95°C as a preferential etchant (6) in which the dendrites exhibited considerably faster dissolution rate than the sheet portion. The silicon substrates prepared from Czochralski crystals were of {111}, {110}, {100}, and {211} orientations; x-ray goniometric measurements indicated that the surfaces of {111} oriented substrates deviated no more than 15 min from a {111} orientation. They were mechanically lapped with American Optical Company No. 305 abrasive and chemically polished with CP_4. To minimize foreign contaminants on the substrate surface, the subsequent operations such as rinsing, drying, assembly, etc., were carried out in a laminar flow ultraclean bench where the air was filtered with Cambridge absolute filters.

The growth process was carried out in a horizontal fused silica tube, and the substrates were placed on a silicon or silicon-coated graphite heater in this tube. To determine the dependence of growth rate on the crystallographic orientation of substrate surfaces, silicon webs and conventional substrates of various orientations were used in the same experiment so that the growth on each substrate proceeded under almost

identical conditions of temperature, reactant composition, etc. The temperature variation among all substrates in a given experiment was less than 10°C. Prior to the growth process, the substrates were further etched in the reaction tube with anhydrous hydrogen chloride (9) or water vapor (10). Both techniques were found to yield the same results. During the growth process, the substrate temperature was varied from 1050° to 1180°C, and the reactant contained 0.07-0.5% silane or 0.5-2% trichlorosilane. The deposition rate was 0.5-1.5 μ/min. The thickness variation of the epitaxial layer among substrates in a run was usually less than 10%.

The structural perfection of epitaxial silicon layers was evaluated by chemical etching using the Sirtl etch[1] (11). The thickness of the grown layer was determined either by cross-sectioning technique or from the dimensions of the etch figures of stacking faults on the as-grown surface (12). The growth thicknesses determined by these techniques were in good agreement.

Results and Discussion

Growth on silicon webs.—Epitaxial silicon layers were deposited on silicon webs at 1080°C by the pyrolysis of silane in a flow system using hydrogen as a diluent. The reactant mixture contained 0.07-0.5% silane, yielding deposition rates in the range of 0.5-1.5 μ/min. Similar deposition rates were obtained by the thermal reduction of trichlorosilane on silicon webs at 1170°-1180°C. In these experiments, accurately oriented {111} silicon slices were also used as substrates for comparison. The as-grown surfaces of all epitaxial layers prepared under proper cleanness conditions were planar and followed the topography of the substrate.

The absence of triangular pyramidal defects on these epitaxial layers is in contrast with the commonly observed effects of accurately oriented {111} substrates on the surface morphology of epitaxial germanium and silicon. For example, triangular growth pyramids were observed invariably on epitaxial germanium deposited on accurately oriented {111} substrates by the transport technique in a closed or an open system (13, 14). However, the growth on substrates misoriented from a <111> direction appeared to be free of pyramids. Pyramids were also observed frequently on {111} oriented epitaxial silicon layers prepared by the thermal reduction of silicon tetrachloride, depending on the deposition rate and the degree of misorientation of the substrate surface (15). At a given temperature, pyramids were found to form when the deposition rate for a particular substrate orientation exceeded a certain value, about 1 μ/min at 1200°C for a substrate with a 0.5° misorientation from the <111> direction. Thus, the pyramidal growth has been attributed to the effects of the substrate orientation, and the use of substrates misoriented 0.5° or more from a <111> direction has long been a general practice. On the other hand, it was found in this work that the grown layer on webs or on {111} oriented substrates always had high concentrations of growth pyramids over the entire surface when foreign impurities were present on the substrate surface or in the growth system. Since planar growth was achieved at relatively low temperature (1080°C) and high growth rates (1.5 μ/min) by using proper *in situ* etching and growth techniques, foreign impurities must be one of the factors governing the pyramidal growth. Other growth parameters such as the substrate temperature and the nature of the chemical reaction also play important roles. It is believed, however, that the growth on webs and accurately oriented {111} substrates is more susceptible to the effect of impurities than that on substrates slightly off from a {111} orientation. A misoriented {111} plane may be considered as consisting of many steps with nominal {111} faces, and the region along these steps will facilitate the nucleation process thus minimizing the effects of impurities.

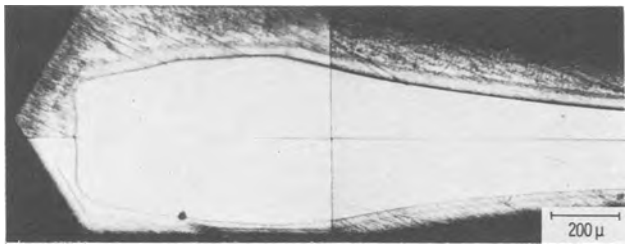

Fig. 1. Portion of the cross section of a specimen perpendicular to the long dimension of the silicon web showing the epitaxial growth of silicon on the web, Sirtl etch, 1 min.

The morphology of the cross section of epitaxial silicon deposited on silicon webs is of interest. Figure 1 shows a portion of the cross section of a specimen with an epitaxial layer of approximately 120μ in thickness prepared by the thermal reduction of trichlorosilane. This cross section was made perpendicular to the long dimension of the web; its surface is therefore of {211} orientation. The substrate-deposit interface and the twin plane in the web and supporting dendrite were brought out by chemical etching. The growth on the bottom surface of the web was due mainly to the transfer of silicon from the heater surface. It is noted that the grown material has a hexagonal cross section. This hexagonal geometry is a result of the dependence of growth rate on the crystallographic orientation of the substrate surface. Since, on the vertically cross-sectioned surface, the side faces make an angle of approximately 118° and the angle between a side face and a grown surface is approximately 121°, these side faces are therefore of {311} orientation. The {311} side faces were also found in the silicon ribbon prepared by the iodine transport of silicon in a closed tube containing impurities (16). Furthermore, when a single crystal silicon filament with its axis oriented in a <211> direction was used as the substrate, the crystal developed to a slightly irregular hexagon with two sets of adjacent {311} faces separated by {111} faces (17, 18). The development of the {311} faces presumably arises from the fact that the {311} planes are the lowest energy planes perpendicular to the {211}.

Epitaxial silicon was also grown on silicon sheets after the supporting dendrites were removed from the web. Figure 2 shows the cross section of a specimen consisting of four epitaxial layers of different resistivities deposited on a silicon sheet by the thermal reduction of trichlorosilane. The left-hand photograph shows the growth near the edge of the sheet, and the right-hand photograph shows the growth at the center of the sheet. Although the cross section of the specimen still has a hexagonal geometry, the growth thickness along the thickness direction of the sheet is highly uniform.

Structural imperfections in epitaxial silicon layers on silicon webs were mostly inherited from the web. The imperfections in the web are mainly the twin lamella and dislocations. The twin lamella have no effect on the perfection of the epitaxial layer except

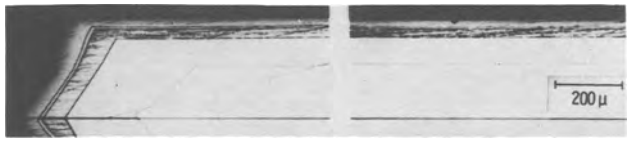

Fig. 2. Two regions of the cross section of a specimen perpendicular to the long dimension of the silicon sheet, showing the uniform growth of silicon on the sheet, Sirtl etch, 30 sec. The regions of different resistivity in the grown layer are delineated by chemical etching.

when the twin plane terminates at the principal surface of the web. Under this condition, random growth always occurred at this region. Silicon webs may have dislocations with axes perpendicular and parallel to the main face; only the former propagated into the epitaxial layer. Under proper growth conditions, the epitaxial layers were essentially free from process-induced imperfections such as stacking faults, growth pyramids, polycrystalline inclusions, etc. Results indicate that p-n junctions prepared by depositing n- or p-type silicon on webs of opposite conductivity type exhibited good electrical characteristics (19).

Dependence of growth rate on crystallographic orientations of substrates.—The dependence of the growth rate of epitaxial germanium and silicon on the crystallographic orientation of the substrate surface has been of general interest. In the epitaxial growth of germanium on a {110} oriented germanium substrate by the closed-tube transport technique, the variation in the growth thickness around the periphery of the substrate indicated that the growth rate increased with crystallographic direction in the following order <100>, <111>, <110> (20). During the epitaxial growth of silicon on a silicon rod with its axis in a <111> direction, {$\bar{1}$10} and {$\bar{2}$11} faces were developed initially (17, 18). A nearly regular hexagonal habit with six {$\bar{2}$11} faces resulted after prolonged growth, indicating a higher growth rate along the <$\bar{1}$10> directions. When individual silicon slices of various crystallographic orientations were used as substrates for the growth of silicon by the thermal reduction of silicon tetrachloride at 1200°C, the deposition rate was found to increase as the substrate surface deviated from the {111} orientation, and the growth rate on the {110} oriented substrates, about 1.3 μ/min, was more than twice of that on the {111} oriented substrates (15).

In this work, the growth rate of silicon on individual slices with main faces of {111}, {110}, {100}, and {211} orientations and on silicon webs was compared using the thermal reduction of trichlorosilane at 1170°C. The growth rate was in the range of 0.5-1.5 μ/min, and the duration of each experiment was adjusted to yield epitaxial layers of approximately 100μ in thickness to minimize measurement errors. The results of many experiments under these conditions indicated that the growth rate was independent of the crystallographic orientation of the substrate surface. These results are in contrast to those obtained by the tetrachloride process (15) and will be discussed in relation with the growth process.

In the growth process under consideration, the formation of silicon by the chemical reaction takes place predominately on the heated substrate surface since no silicon is deposited on the cooler walls of the reaction tube. Most probably, the growth process involves the following consecutive steps: the diffusion of reactant molecules to the substrate surface, the adsorption of one or more reactant species on the surface, the chemical reaction on the surface and the incorporation of silicon atoms into the crystal lattice, the desorption of by-products and their diffusion away from the surface. The over-all rate of the growth process is controlled by the slowest of these steps. If epitaxial layers of good perfection are to be obtained, the rate of chemical reaction must be equal to or slower than the rate of incorporation of silicon atoms into the crystal lattice. Otherwise, silicon atoms not incorporated into the crystal would yield polycrystalline deposits since they cannot evaporate at appreciable rates at temperatures used in the growth process. Thus, the addition of silicon atoms to the crystal lattice is not the rate-determining step of the growth process. Furthermore, under growth conditions used in this work, the growth rate was found to be independent of substrate temperature in the temperature range 1150°-1220°C, similar to the findings of Glang and Wajda concerning the trichlorosilane process (21). Since the chemisorption of reactants on the substrate surface and their subsequent reaction have appreciable activation energies, these processes cannot, therefore, be the rate-determining steps of the growth process. Thus, the rate of the growth process must be limited by the rate of diffusion of the reactant molecules to the substrate surface, and the diffusional resistance is concentrated predominately in a laminar layer in the immediate vicinity of the substrate surface. When individual silicon slices are used as substrates in the epitaxial growth process, each substrate has a main face of one crystallographic orientation exposed to the reactant mixture. All substrate surfaces are maintained at the same temperature and are subjected to the same flux of reactants. Since the diffusion of reactants is the rate-determining step in the trichlorosilane process, the diffusion, adsorption, and chemical reaction at all substrate surfaces takes place at the same rate irrespective of the crystallographic orientation of the substrate surface. Consequently, the same number of silicon atoms deposit on a unit area of each substrate surface, and the growth thickness or growth rate is the same. It should be noted that, although the number of atomic layers grown on substrate surfaces of various orientations and the density of atoms on these crystallographic planes are different, their product is a constant. For example, the average spacings of atomic layers parallel to {111}, {110}, {100}, and {211} planes are of the ratio $1 : \sqrt{\frac{3}{2}} : \frac{\sqrt{3}}{2} : \frac{3\sqrt{2}}{4}$, and the average density of atoms on these planes also have the same ratio.

The kinetics of the epitaxial growth of silicon by the tetrachloride process has been studied by several authors; however, their results on the variation of growth rate with substrate temperature have not been consistent. While a linear relation between the logarithm of the growth rate and the reciprocal of the absolute temperature was observed over the temperature range 900°-1300°C by Theuerer (22), the growth rate was found by Bylander to be relatively temperature-independent at substrate temperatures higher than 1100°C (23). When the growth rate is temperature-dependent, the surface processes, chemisorption, and chemical reaction, become the rate-determining steps of the growth process. Since substrate surfaces of various crystallographic orientations possess different structure and consequently different chemical reactivity, the growth rate may depend on the orientation of the individual substrate as reported by Tung (15).

When a substrate with two or more adjacent faces of different crystallographic orientations is used for epitaxial growth, the growth rate could become orientation-dependent even when the growth process is governed by the diffusion process. The difference in the growth rate of silicon on adjacent {111} and {311} planes of the web by the trichlorosilane process is shown in Fig. 1 and 2. This is again related to the different chemical reactivity associated with surfaces of different orientation. After the reactant molecules diffused through the laminar layer, the various faces of the substrate compete for these molecules resulting in the orientation dependence of the growth rate.

Summary and Conclusions

Epitaxial silicon layers of good structural perfection have been deposited, at rates of 0.5-1.5 μ/min, on silicon webs at 1080°-1180°C by the pyrolysis of silane and the thermal reduction of trichlorosilane in a flow system. Contrary to the common belief, the use of substrates of exactly {111} orientation, such as the main faces of the web, had no observable influence on the structural perfection of the epitaxial layer when the layer was grown at relatively low temperatures (1080°C) and high deposition rates (1.5 μ/min). How-

ever, good *in situ* etching and growth techniques were found to be necessary for obtaining planar surfaces. Dislocations with axes perpendicular to the main face of the web were continued into the web, and twin planes terminating at the principal face of the web promoted the random growth. However, these imperfections in the web are easily eliminated, and silicon webs are ideal substrates for the preparation of epitaxial devices.

When individual silicon slices of various low-index orientations were used as substrates, the growth rate of silicon at 1170°C, obtained by the thermal reduction of trichlorosilane at rates up to 1.5 μ/min, was found to be independent of the crystallographic orientation of the substrate surface. This is due to the fact that the diffusion of reactant molecules to the substrate surface rather than the incorporation of silicon atoms into the crystal lattice is the rate-determining step of the growth process. However, when a substrate has two or more adjacent faces of different crystallographic orientations, the growth rate on these faces is orientation-dependent because of their difference in structure and bonding requirements.

Effect of Dry Oxygen on Conductivity of Fluoridated Silicon Surfaces

M. Yamin and R. Lieberman

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

When high resistivity silicon surfaces are heated in dry nitrogen at temperatures below 350°C, a marked rise in surface conductivity may occur. When the surface is subsequently exposed to dry oxygen at room temperature, a rapid decrease in surface conductivity occurs. The magnitude of the effect was found to depend on the chemical treatment of the surface prior to heating and on the subsequent thermal history of the surface. The greatest effect was found on surfaces which had been exposed to HF vapor. Exposure of the surface to water tended to decrease the magnitude of the conductivity changes.

This paper describes a study of changes in surface conductivity which occur on gas baking of unpassivated silicon surfaces. The material used was 700 ohm-cm n-type silicon, cut into bars about 0.015 x 0.060 x ¾ in. Ohmic gold-antimony contacts were alloyed to either end, and the bars were etched bright in 10 HNO_3:1 HF. The resistance of the bars was about 10^5 ohms and was essentially constant at measuring voltages from −10 to +10v. The samples were mounted by their gold leads in a glass cell through which dry gases could be passed. The cell, which also contained an iron-constantan thermocouple, could be surrounded by either a small resistance furnace for heating or a thermostated water jacket for measurement. All resistance measurements were taken in this cell at 30° ± 0.1°C in the dark, using a General Radio No. 650A impedance bridge, the measuring voltage being 1v d.c. The gases used were dry nitrogen and dry oxygen. The oxygen was passed through a freshly regenerated Lectrodryer; the nitrogen came from a dry nitrogen line whose moisture content was generally less than 5 ppm. The gas handling system was all metal, except for a short length of polyethylene tubing. A flow rate of 0.5 to 1.0 l/min was used through the 150 ml glass cell.

The fundamental effect with which this paper is concerned will be referred to as the "oxygen effect." The oxygen effect of a typical specimen is illustrated

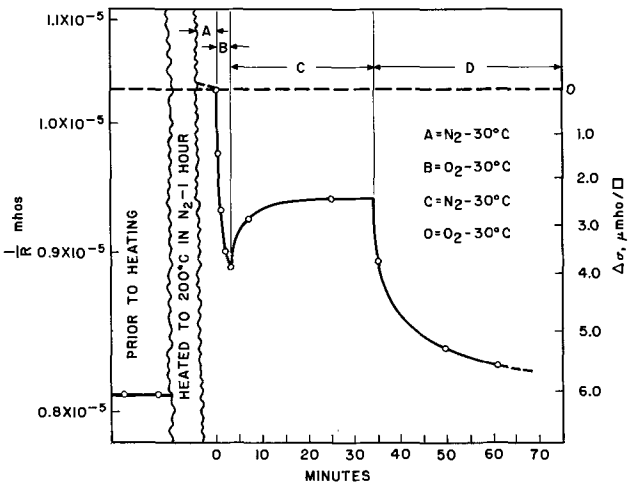

Fig. 1. Oxygen effect. Conductance (1/R) is initially 0.81×10^{-5} mho. After heating in dry nitrogen and cooling to 30°C, the conductance is 1.03×10^{-5} mho. Exposure to dry oxygen causes a rapid decrease in conductance. Changing of the gas back to nitrogen halts this decrease, but it resumes on restoring oxygen. This cycle can be repeated by reheating the specimen in dry nitrogen. The values of $\Delta\sigma$ (decrease in surface conductivity) are referred to the value immediately before the exposure to oxygen.

in Fig. 1. The scale at the left is measured 1/R; that on the right is the surface conductivity relative to that when the oxygen was first applied to the specimen. The conductance 1/R of the specimen is measured at 30°C in dry nitrogen. The specimen is then heated in dry nitrogen in the 150°-300°C range. On cooling to 30°C, a significantly higher value of conductance than that prior to the heating cycle may be observed. This value of conductance will show only a slow downward drift in nitrogen. If the ambient is now changed to oxygen, a rapid decrease in conductance will occur. If, while the conductance is decreasing in oxygen, the ambient is switched back to dry nitrogen, the rapid drop in conductance will be interrupted, and the conductance may even rise a little. Restoring oxygen will cause the drop in conductance to resume, eventually leveling off, usually at a value slightly lower than that before the hot nitrogen-cold oxygen cycle. Reheating the sample in dry nitrogen will restore the high conductance value, and the oxygen effect can then be repeated. No such effect is observed if the heating phase is conducted in oxygen; in fact, this treatment destroys the subsequent reactivity of the sample. The conductance changes can correspond to a rise in surface conductivity after nitrogen baking, and a subsequent drop on exposure to cold oxygen, as high as 20 μmho/□; the measured resistance of the specimens used can actually double in a few minutes on exposure to oxygen.

This effect is not obtained invariably on a given silicon surface, and its magnitude is subject to considerable variation. In this work, the magnitude of the oxygen effect is used to measure the reactivity of the surface to the hot nitrogen-cold oxygen cycle after various chemical and thermal treatments. A standard measurement routine was used. The sample was dried at room temperature for 30 min in flowing dry nitrogen after a chemical treatment, then heated in dry nitrogen for 30 min at the desired temperature. The cycling cell was next surrounded by the 30°C water jacket and let stand with nitrogen flowing for 20 min. At this point the resistance was measured, giving a value R_1, and the gas flow was changed to dry oxygen. Resistance measurements were made for 30 min, at which time the resistance had virtually ceased to rise. This final resistance was R_2. Resistance measurements were related to the surface conductivity change, on the assumption that the bulk resistivity remained unchanged, by the following equation

$$\Delta\sigma = \frac{L}{P}\left(\frac{1}{R_1} - \frac{1}{R_2}\right) \qquad [1]$$

where L is the distance between the gold contacts and $P = 2t + 2w$, where t is the thickness of the sample and w its width.

Effect of Surface Fluoridation

The first requirement for investigation of the effect was to determine a chemical treatment which would invariably produce a reactive surface as a starting point for further investigations. It was observed that re-etching an unreactive surface in HNO_3-HF mixtures restored its reactivity, but considerable variation was introduced as a result of the necessary rinsing operations which followed etching. Eventually it was found that exposure of the specimen for 15 min to the vapor over 48% aqueous HF solution at room temperature would produce surfaces which were most reactive to the hot nitrogen-cold oxygen cycle, and that this treatment would regenerate the reactivity of a surface whose reactivity had been destroyed as described below. For example, one specimen showed a value of $\Delta\sigma$ (determined as defined in Eq. [1], following nitrogen baking at 267°C) of 5.22 μmho/□ when freshly etched; subsequently, its $\Delta\sigma$ was reduced to 0.20 μmho/□ by thermal treatment as described below, but exposure to HF vapor restored a $\Delta\sigma$ of 5.89 μmho/□.

Effect of Temperature of Heating

The oxygen effect obtained is a function of the temperature at which the hot nitrogen phase of the cycle is carried out, and also of the thermal history of the sample. The behavior of a specimen on many repetitions of the hot nitrogen-cold oxygen cycle is illustrated in Fig. 2, in which $\Delta\sigma$ for each of 26 consecutive hot nitrogen-cold oxygen cycles is represented by a vertical line. The initial $\Delta\sigma$ for this specimen after HF activation was 8.3 μmho/□ with a heating temperature, T_H, of 150°C. On subsequent cycles, with T_H = 150°C, $\Delta\sigma$ declined to about 4 to 5 μmho/□, but after the 5th cycle remained relatively constant. Increasing T_H to 200°C again produced a $\Delta\sigma$ in this range, and so did going to 250°C (cycle 15) and to 300°C (cycle 18). Cycle 19, with T_H = 200°C, however, produced a much lower $\Delta\sigma$ of 1.1, and cycle 21, with T_H = 250°C, produced a $\Delta\sigma$ of 2.0. The interspersed cycles, 20 and 22, with T_H = 300°C nevertheless produced $\Delta\sigma$'s of 3.7 and 3.6, nearly as high as the

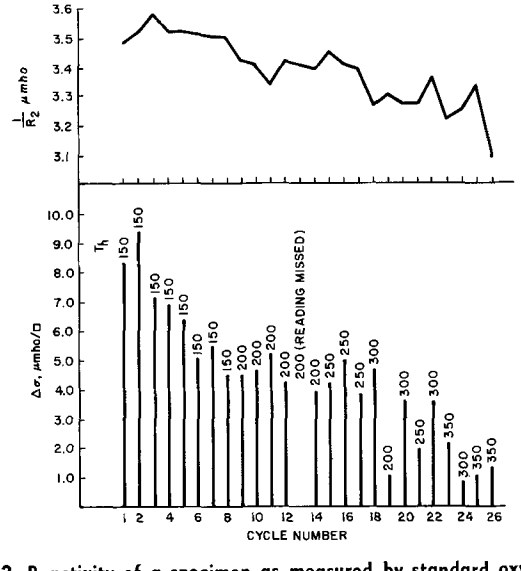

Fig. 2. Reactivity of a specimen as measured by standard oxygen effect $\Delta\sigma$ on many repetitions of the hot N_2-cold O_2 cycle. Upper diagram shows that final conductance, $(1/R_2)$, in oxygen tends to decrease with many repetitions of the cycle.

previous 200° and 250°C results. Going to $T_H = 350°C$ on cycle 23, we see that we destroy the subsequent reactivity of the specimen at 300° and also at 350°C. Some apparent increase in the reactivity on 400°C cycling is observed, but since this is above the eutectic temperature of the gold-silicon alloy contact, other influences than that of temperature on the silicon surface may be present.

This pattern of behavior, which is typical of that observed with a number of specimens, seems to lead to the following generalization. After the initial decline of $\Delta\sigma$ on the first few cycles, a relatively constant value will be observed for T_H between 150° and 300°C, so long as any cycle is performed at a temperature equal to or greater than all previous T_H. However, heating to any temperature in this range destroys reactivity at any lower temperature. Heating at 350°C destroys reactivity at any temperature including 350°C.

Also plotted in Fig. 2 is $1/R_2$ for the specimen, that is, its final stable value of conductance in dry oxygen subsequent to each cycle. It will be observed that this value creeps slowly downward during the experiment.

As mentioned earlier, the reactivity of this specimen is entirely restored by exposure to HF vapor.

Effect of Water Soaking

In order to investigate the effects of chemical treatments on the reactivity of silicon surfaces to the hot nitrogen-cold oxygen cycle, the values of $\Delta\sigma$ were compared for two silicon specimens which were given identical treatment except for the chemical process under investigation. The two specimens were mounted together in the glass cycling cell, activated together by exposure to HF vapor, heated together to a standard temperature (which was fixed at 250°C for such investigations), and exposed to dry oxygen after cooling to 30°C. The chemical treatment being investigated was applied to one of the specimens prior to the heating cycle. As Fig. 2 shows, the magnitude of $\Delta\sigma$ changes from one heating cycle to the next, presumably as a result of variations in temperature and time of heating as well as of changes in the silicon surface. It is assumed that for two similarly treated specimens essentially the same cycle-to-cycle variation of $\Delta\sigma$ will occur, and that therefore the ratio of $\Delta\sigma_t$ (for the treated specimen) to $\Delta\sigma_c$ (for the control specimen) will be constant. If one of the specimens is subjected to a chemical treatment, any change in the ratio $Y = \Delta\sigma_t/\Delta\sigma_c$ must reflect this treatment; even if random variations of Y occur, repeated chemical treatment of one specimen should produce a constant variation in Y which is distinguishable from random change.

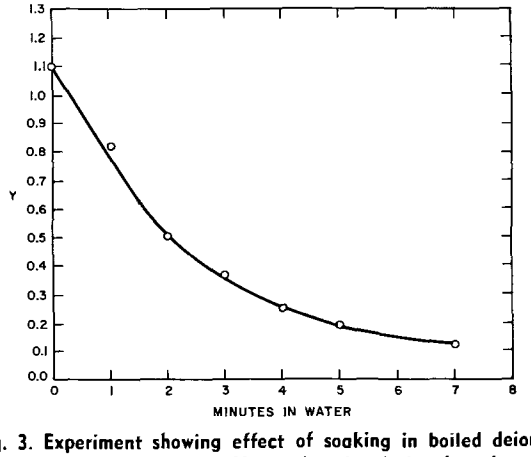

Fig. 3. Experiment showing effect of soaking in boiled deionized water at room temperature. $Y = (\Delta\sigma_t/\Delta\sigma_c)$ is plotted against total time of soaking of the test specimen in water; test and control specimens are subjected to identical hot N_2-cold O_2 cycle after each period of water treatment.

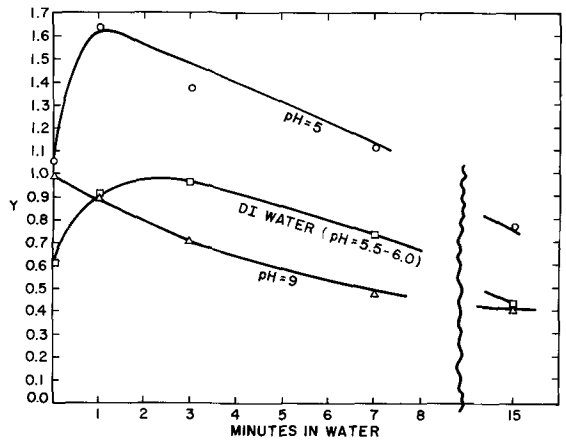

Fig. 4. Effect of soaking in water at three pH levels

The particular treatment investigated was water soaking at 30°C. The test specimen would be immersed in water for a measured interval, usually 1 or 2 min, and dried; the hot nitrogen-cold oxygen cycle would then be performed on both test and control specimens; then the water treatment would be repeated. Figures 3 and 4 show the results of such an experiment. In Fig. 3, the ratio Y is plotted against total minutes of soaking of the test specimen at room temperature in deionized water which had been boiled and cooled in flowing nitrogen to remove dissolved oxygen and carbon dioxide. It is seen that the effect of water is to reduce the reactivity of the treated specimen far below that of the control specimen; after about 7 min, the ratio Y has been found to level off at some value generally between 0.1 and 0.4. (In some cases, the initial value of Y is not 1.0, as a result, presumably, of variations in the HF activation procedures.) The presence or absence of oxygen in the water does not seem to be significant. In Fig. 4, similar plots are shown for three samples of water: one, as obtained from the deionizing system, whose *p*H was measured with a Beckman *p*H meter as 5.5-6.0 (this acidity probably resulting from dissolved carbon dioxide); one whose *p*H had been adjusted to 5.0 with HCl; and one whose *p*H had been adjusted to 9.0 with NaOH. The basic solution is seen to have a different initial effect on the reactivity of the silicon surface than the acidic ones.

Discussion

It appears from the experimental results described above that five reactions occur on silicon surfaces, all of which affect the surface conductivity. They are:

1. The reaction of HF with the surface (activation reaction).
2. The reaction of the activated surface on heating in nitrogen, which produces a large increase in surface conductivity.
3. The reaction of the above conductive surface with oxygen at room temperature.
4. The reaction that causes the activated surface to lose its reactivity on heating to elevated temperatures in nitrogen.
5. The reaction that causes the activated surface to lose its reactivity on exposure to water at room temperature.

Buck and McKim (1) have studied the effects of chemical treatments on the surface conductivity of silicon. Figure 5, in which surface conductivity is plotted against the position of the Fermi level at the surface, U_s, for 425 ohm-cm n-type silicon, is adapted from their Fig. 1. This figure was constructed using the data of Kingston and Neustadter (2). The curve for 700 ohm-cm material would not be significantly different for the purposes of this discussion. Buck

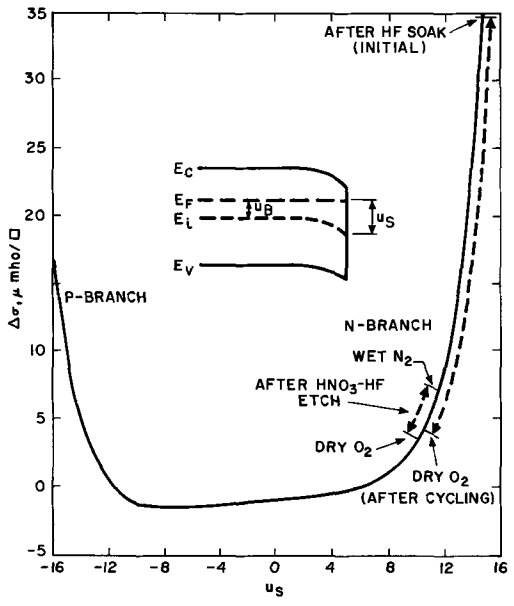

Fig. 5. Surface conductivity (referred to flat band condition) of 425 ohm-cm n-type silicon vs. surface potential. Adapted from ref. 1, Fig. 1 by courtesy of the authors.

and McKim (1) found that soaking in HF produced a very strong n-shift; Brattain-Bardeen cycling of this surface resulted in a decrease in surface conductivity in dry oxygen and an increase in wet nitrogen, but this was superimposed on a steady downward trend in surface conductivity. Etching in HNO_3-HF also produced an n-type surface as shown. It is likely that reaction 1 in our listing above produces a surface similar to that resulting from HF soaking; we may assume that the effect of HF treatment is to remove any oxide present and to produce a surface on which many of the free valence bonds of surface silicon atoms are satisfied with fluorine. It is also likely that reaction 5 is the hydrolysis of Si-F surface groups to Si-OH by water; this would be similar to the irreversible decrease in surface conductivity found by Buck and McKim on repeated wet-dry cycling. We may further speculate that reaction 4 also results in the elimination of fluoride from the silicon surface, in this case perhaps by the condensation of a number of surface fluorine atoms on a single silicon atom causing eventual bond rupture and volatilization as silicon tetrafluoride. It is seen from Fig. 2 that this reaction also causes an irreversible decrease in surface conductivity. Thus, our hypothesis is that the activation reaction is fluoridation; the deactivation reactions result from the removal of fluoride and the conversion of the silicon surface to its normal oxidized (or hydroxylated) condition.

This leaves reactions 2 and 3: those which constitute the oxygen effect. Reaction 2, which occurs on nitrogen baking, raises the surface conductivity; we may assume that this treatment produces an n-shift in surface potential, and that reaction 3, on exposure to dry oxygen, reduces the potential in the p-direction. (If the effect of nitrogen baking were to transfer the potential to the p-branch, we might expect a minimum in conductivity with time during exposure to oxygen; this is not observed.) The simplest way to discuss these reactions is to assume that a fluoridated silicon surface which has been exposed to air is covered with a layer of adsorbed oxygen; reaction 2 would then be the desorption of the oxygen layer and reaction 3 its readsorption. Hall, Baird, and Williams (3) have observed, by gas chromatography, an enhancement of oxygen adsorption on an HF treated surface.

It is interesting that a fluoridated silicon surface reversibly adsorbs oxygen; if the surface were not fluoridated, it would of course immediately and irreversibly react with the oxygen to form the first layer of oxide; in fact, part of the loss of reactivity to the hot nitrogen-cold oxygen cycle on repeated cycling may result from some of the adsorbed oxygen penetrating the fluoride layer to form such oxide. The ease of desorption probably indicates that the adsorbed species is molecular oxygen. The binding force may be of a van der Waals type, but it is interesting to speculate whether there may be some sharing of electrons in the conduction band of the n-type silicon with orbital levels in the oxygen molecule, producing a weak binding. Such a mechanism would help to account for the p-type shift of the surface potential on adsorption of oxygen.

The effects observed have important implications regarding the stability of silicon semiconductor devices which have not been passivated by the growth or deposition of insulating films. Many devices receive, in the final stages of manufacture, an etch which leaves their surfaces partly fluoridated; they are subsequently baked and encapsulated in vacuum or in dry inert gas. This work shows that the bakeout may result in a shift of surface potential comparable with that observed on wet-dry cycling, and that subsequently the surface will be sensitive to traces of oxygen. Such instabilities could easily be eliminated (*a*) by assuring that the device surface is effectively freed of fluoride, prior to encapsulation, by water soaking or by baking at a temperature of 350°C, and (*b*) by encapsulation in an ambient containing sufficient oxygen that the desorption leading to n-type surface potential shifts cannot occur. The latter technique was successfully used by Buck *et al.* for surface stabilization of p-n junction radiation detectors (4).

The Preparation and Properties of Vapor-Deposited Epitaxial $GaAs_{1-x}P_x$ Using Arsine and Phosphine

James J. Tietjen and James A. Amick

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Single crystal $GaAs_{1-x}P_x$ layers have been grown epitaxially from the vapor phase in a novel apparatus, using gaseous arsine and phosphine as sources of arsenic and phosphorus. These layers exhibit the highest quality, and the widest range of controlled resistivity yet reported for solid solutions in this system. Vegard's law is obeyed over the entire composition range. At room temperature, the change from a direct to an indirect transition across the band gap occurs at the value, $x = 0.44$. Electron mobilities in these layers are high; a sample containing 27% GaP, for instance, had a room temperature mobility of 4900 cm^2/v-sec, and a 69% gallium phosphide alloy had a mobility of 700 cm^2/v-sec at room temperature. Both n- and p-type doping have been obtained, with hydrogen selenide gas and zinc vapor as the sources of donor and acceptor impurities, respectively. In this apparatus it is also easy to prepare multilayered structures incorporating layers of different resistivity and/or composition.

The preparation of homogeneous solid solutions of gallium arsenide-gallium phosphide, $GaAs_{1-x}P_x$, is of both fundamental and practical importance. Throughout most of the composition range, the band gap for this system corresponds to energies associated with the visible region of the spectrum. These materials are therefore potentially useful for the fabrication of luminescent devices, such as electroluminescent diodes and injection lasers. This system also affords opportunity to study changes in band structure with composition, especially in the region of the cross-over from a direct to an indirect (phonon-assisted) band-gap transition. Further, it is desirable to control the electrical characteristics of these crystals by the controlled addition of donor or acceptor impurities. Although it is possible to prepare these compositions from the melt (1), vapor deposition techniques have been more commonly employed (2-6). In both sealed tube and continuous gas flow apparatus, epitaxial growth has been obtained by means of a single transporting agent, such as water vapor or a hydrogen halide. Such techniques, however, do not allow for the independent, precise control of the partial pressure of two volatile species, such as arsenic and phosphorus. Furthermore, if one provides liquid or solid sources of arsenic and phosphorus, their vapor pressures are exponentially dependent on the temperature of the reservoirs. While this dependence may not be critical for the growth of the pure compounds, it becomes extremely critical for the preparation of homogeneous solid solutions.

The epitaxial growth of gallium arsenide layers by direct synthesis from arsenic vapor and gallium chloride was recently reported (7). The apparatus has been redesigned to permit the introduction of arsenic and phosphorus independently in the form of their gaseous hydrides, arsine (AsH_3) and phosphine (PH_3). On heating, these hydrides decompose to form the respective elements, with hydrogen as a by-product. As in the earlier apparatus, gallium is transported as its subchloride, prepared by passing hydrogen chloride over gallium. Since the epitaxial growth is carried out in an excess of hydrogen, the substitution of arsine and phosphine for the elements does not substantially alter the chemistry of the growth. This substitution offers the following advantages, however: (*i*) The partial pressure of arsenic and of phosphorus in the growth region is determined by the rate of introduction of arsine and phosphine, respectively. Since both of these compounds are gases at room temperature, their vapor pressure is not a strong function of the temperature. (*ii*) These gases can conveniently be obtained commercially, diluted in hydrogen to any desired concentration, and stored in pressurized cylinders for indefinite periods of time. (*iii*) They can be metered into the apparatus through flowmeters, allowing the introduction rate to be held constant and measured with precision. (*iv*) The rates of introduction of arsine and phosphine can be changed independently, permitting gradual or rapid changes in the composition of the growing layer. (*v*) Since no temperature control of these gases is necessary, the apparatus is simplified; only three critically controlled temperature zones are required.

Still another feature of the new apparatus is that n- and p-type doping over a wide range of resistivities can be obtained easily. Selenium is added as the n-type dopant by introducing gaseous hydrogen selenide; zinc is introduced directly in the vapor form to provide p-type doping. Because of the characteristics of the flow apparatus, doping can be initiated and discontinued at any time, at almost any rate, and during any stage of the crystal growth.

These features have made possible the epitaxial growth of single crystal $GaAs_{1-x}P_x$ solid solution layers of unusually high purity and homogeneity over the entire compositional range. In addition, crystals having a wide variety of resistivities, both p- and n-type, have been prepared. Finally, multilayer structures have been prepared sequentially within the growth apparatus, the samples not being removed from the apparatus until all growth operations are completed.

Experimental

Apparatus.—The apparatus consists principally of a single 2.5 cm ID quartz tube 80 cm long; it is shown schematically in Fig. 1. The three heated zones are surrounded by conventional temperature controlled, resistance heated furnaces. A large bore (35 mm) stopcock separates the growth portion of the apparatus from a forechamber. As described previously (7), substrates mounted at the end of a precision ground (Trubore) rod can be inserted into the forechamber. This chamber can then be purged with hydrogen before the samples are inserted through the stopcock into the growth portion of the apparatus. In this manner, contamination of the growth region during insertion and withdrawal of the samples is minimized. Furthermore, the substrates may be etched or heat-treated in this forechamber prior to their insertion into the growth region. Finally, following

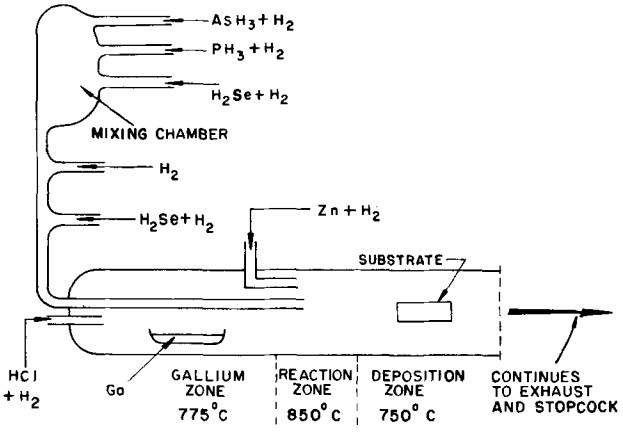

Fig. 1. Schematic representation of vapor-deposition apparatus

deposition, the substrates can cool to room temperature in this chamber in a controlled atmosphere before being withdrawn into the laboratory.

Arsine, phosphine, and hydrogen selenide are introduced through flow meters into a 2-liter ballast vessel which empties into the hydrogen carrier gas stream. This permits these reagents to be thoroughly mixed before they enter the reaction zone, and helps to smooth out small sporadic fluctuations in the individual gas flows. If desired, the hydrogen selenide can be made to by-pass the mixing bulb if abrupt gradients in donor impurity concentrations are required. As shown in Fig. 1, the arsine-phosphine-hydrogen mixture is introduced into the reaction zone through a long quartz tube which extends beyond the gallium. Through a shorter quartz tube a mixture of hydrogen chloride and hydrogen is injected. This mixture, passing over gallium in a quartz boat, provides the gallium subchloride. It is a significant feature of this method of introducing the different vapor phase constituents that at the gas stream velocities used in this investigation only the hydrogen chloride and hydrogen come into contact with the gallium. Since the equilibrium for the reaction between gallium and hydrogen chloride is rapidly attained, and since the contents of the boat are essentially pure gallium throughout the entire deposition, the composition of the gas phase components can be maintained constant during the entire growth cycle. In addition, abrupt changes in the crystal composition can be introduced during the growth period, since the crystal growth at any time does not depend on the previous history of the growth apparatus. In contrast, when arsenic trichloride and phosphorus trichloride are used as transport agents, the contents of the gallium boat change as the run proceeds. As a result, it is difficult, with these transport agents, to start and stop the growth abruptly. P-type doping is obtained from a small amount of metallic zinc held in a quartz "bucket" attached to a Trubore rod. This zinc can be inserted into a heated side arm adjacent to the growth region of the apparatus, and the zinc is transported into the growth region in hydrogen carrier gas. The temperatures of the three zones shown in Fig. 1 are selected so that deposition is emphasized in the vicinity of the substrate and minimized on the long quartz tube through which the arsine-phosphine mixture passes. The concentrations of the reactant species are controlled by adjusting the flow rates of the gaseous species entering the apparatus.

Materials.—The gases employed in this work were obtained commercially and used without further purification. Typically the arsine is obtained diluted in H_2 to a concentration of 10%,[1] the PH_3 as a 5% dilution in H_2,[1] and the H_2Se diluted to 500 ppm in H_2.[1] A typical mass spectrometric analysis of the impurities present in the arsine is presented in Table I. It should be noted that, at the levels present here, the three primary impurities apparently do not affect the growth characteristics or electrical properties of the layers. The hydrogen chloride is obtained in standard cylinders.[2] The hydrogen employed as the carrier gas is purified by passage through a standard palladium-alloy diffuser. The manufacturers reported purity for the gallium[3] and zinc[4] is 99.9999 and 99.9998%, respectively.

Both germanium and gallium arsenide substrates were employed in this study. Germanium substrates nominally had {111} surfaces, while gallium arsenide wafers having {111}, {110}, and {100} surfaces were used. Although it was demonstrated that epitaxial layers of $GaAs_{1-x}P_x$ can be successfully deposited on {111} germanium surfaces or on gallium arsenide surfaces oriented normal to the <110> and <111> directions, gallium arsenide wafers having {100} surfaces, about 1 cm^2 in area and 0.5 mm thick, were almost exclusively used in this work. These were mechanically polished to a flat, mirror-smooth finish and then chemically polished in a mixture of sulfuric acid, hydrogen peroxide, and water in the ratio, 4:1:1 (Caro's acid). As substrates, a wide variety of n-type, gallium arsenide wafers oriented normal to the <100> direction were employed, having electron carrier concentrations in the range, 1×10^{16} to $2 \times 10^{18}/cm^3$, with the major impurities including silicon, selenium, tellurium, and tin.

Procedure.—Freshly etched substrates are first mounted on the substrate support. Since growth is usually required on only one surface of a substrate wafer, two wafers are usually mounted in a common slot, back to back. In this manner, two substrates having essentially identical growth history can be obtained in one run. When inserted into the apparatus, the surfaces of these substrates are parallel to the direction of gas flow. With no further treatment, the substrates are introduced into the growth region of the apparatus, the entire apparatus being at room temperature. After purging the system with hydrogen, the furnaces are turned on, and the temperature rises at about 20°C per minute. When the substrate temperature reaches 600°C, the arsine flow is started in order to establish an arsenic atmosphere in the deposition zone and to prevent decomposition of the substrate. When all three zones have reached the operating temperature, the hydrogen chloride flow over the gallium is started; at this time, gallium arsenide begins to deposit epitaxially on the substrate. The phosphine flow is then initiated to produce a gas phase mixture of arsine and phosphine appropriate to the desired gallium arsenide-phosphide composition. Because of the 2-liter ballast vessel in the gas introduction system, the composition of the epitaxial growth on the substrate changes slowly from pure gallium arsenide to the selected alloy composition. It is believed that this gradual transition aids in minimizing strain arising from differences between the lattice constants of the substrate and of the deposited alloy.

Typically, the sum of the flow rates of pure arsine and pure phosphine are about 15 cc/min. The hydrogen chloride flow rate is approximately 5 cc/min. An additional 2.5 liters/min of hydrogen is employed as a

carrier. With these flow rates, with a substrate temperature in the range 725°-775°C, a reaction zone temperature of 850°-875°C, and a gallium zone temperature of 775°-800°C, growth rates of approximately ½ μ/min are obtained under steady-state conditions. With these growth conditions, the contents of any of the gas cylinders permits at least 60 hr of continuous crystal growth.

To determine the electron carrier concentrations and mobilities in the deposited layers, a technique was developed which permits Hall coefficient and resistivity measurements to be made on layers as thin as 50μ. Indium contacts are alloyed to the grown layer in a hydrogen atmosphere. The temperature required to alloy ohmic contacts ranges from 450°C for GaAs to 850°C for GaP. The sample is then fastened to a quartz lapping plate with glycolphthalate and the substrate is lapped off. Final contacts and measurements are made while the sample remains supported on the quartz lapping plate. In this way the measurements are made on layers that have been completely removed from the substrate but are otherwise unaltered. To test this procedure, several bulk samples of gallium arsenide were measured first by conventional techniques and then, using this procedure, after being lapped to about 100μ thickness. In all cases, the second set of measurements produced identical results to the first.

Results and Discussion

Crystallinity and Homogeneity

X-ray analysis by the Debye-Scherrer technique shows that these layers are single phase, cubic, solid solutions which have a very high degree of homogeneity, as revealed by the sharpness of the diffraction lines. The width of the diffraction lines, for 15 specimens of different alloy compositions, is identical to those for pure gallium arsenide and pure gallium phosphide. Thus, any variation in composition was below the detection limit. This result is in agreement with electroluminescent data obtained from diodes fabricated from selenium-doped alloys containing up to 30% gallium phosphide. For these diodes, the width of the incoherent emission peak at 77°K is equal to that of pure gallium arsenide. Since the maximum experimental error associated with this measurement is approximately 5%, this result indicates that compositional variations are less than 0.1 mole %. Also, the threshold current densities of laser diodes fabricated from specimens containing as much as 20% gallium phosphide is the same as that for pure gallium arsenide (8). In addition, there is no drop in electron mobility with alloying up to 30% gallium phosphide (9). Moreover, the room temperature electron mobilities of undoped layers, presented in Table II, are high for all alloy compositions. Note especially the values of 4900 and 700 cm^2/v-sec for alloys containing 27 and 69% gallium phosphide, respectively. These results are also attributed to the high degree of homogeneity of these materials.

X-ray analysis by the Laue back-reflection technique reveals that the layers are epitaxial. In Fig. 2 the lattice constant is presented as a function of alloy composition showing that Vegard's law of solid solutions is obeyed in this system. This result is in agreement with those of Pizzarello (4) and Rubenstein (6). The compositions were determined by chemical analysis (10) with an accuracy of ±0.5%. It was also demonstrated by chemical analysis that compositions can be reproduced in sequential runs to within ±1%.

Growth Morphology

As a result of a novel etchant (11) developed by Abrahams and Buiocchi of the RCA Laboratories, it is now possible to observe dislocation densities on the major low index faces of $GaAs_{1-x}P_x$ alloys. Etch pit densities were obtained (12) using this etchant, which reveal that the density of dislocations in the grown layers are determined almost exclusively by the dislocation densities of the substrates. Practically all dislocations which lie in the substrate, and intersect the plane of the substrate-grown-layer interface, propagate into the grown layer. The additional dislocations which originate in the grown layer are much smaller in number by at least an order of magnitude than those originating in the substrate. Typical dislocation densities for the substrates employed in this study, and therefore for the grown layers, are usually of the order of 10^3/cm^2, but have ranged up to 10^6/cm^2.

Electrical Properties

The epitaxial layers were examined by Hall coefficient measurements. Typical electron carrier concentrations for undoped specimens are in the range, 5×10^{15} to 1×10^{16}/cm^3. The high values of the electron mobility at 77°K of alloys containing up to 20% gallium phosphide, as shown in Fig. 3, attest to the high quality of the undoped samples and demonstrate that this material is noncompensated.

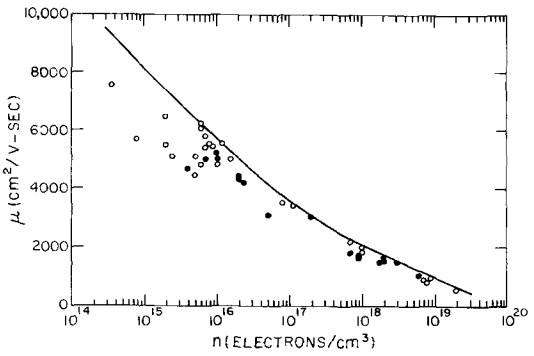

Fig. 4. Dependence of the electron mobility on electron carrier concentration in selenium-doped $GaAs_{1-x}P_x$ at 300°K; symbols are the same as in Fig. 3.

Doping

Attempts were made to dope the layers using hydrides of various donor impurities as the source of the n-type dopant. These included hydrogen sulfide, hydrogen selenide, germane, and silane. However, it was found that the best results were obtained with hydrogen selenide, and it was, therefore, used almost exclusively. The primary advantage of hydrogen selenide is that a lower gas phase concentration of this hydride is required. Apparently, selenium is incorporated into the growing layer much more efficiently than the other doping agents. As compared with the other hydrides, as much as 100 times less hydrogen selenide is needed to produce a given electron carrier concentration in the deposited crystal. This has the inherent advantage of introducing less unknown contamination to the growth system. Using hydrogen selenide diluted in hydrogen in the concentration range 5-5000 ppm allows for doping from 5×10^{16} to 2×10^{19} electrons/cm^3 with a reproducibility of ±25%.

Selenium-doped samples containing up to 20% gallium phosphide were prepared having electron carrier concentrations as high as 2×10^{19}/cm^3. The dependence of the electron mobility on the carrier concentration is shown in Fig. 3 and 4 for 77°K and room temperature, respectively. The relatively high values for the electron mobility of heavily doped samples imply that the crystals are extremely homogeneous and contain few defects. In addition, the dependence of the mobility on electron carrier concentration is the same for the alloy specimens as for pure gallium arsenide. It is concluded that doping to these high donor levels does not interfere with the preparation of homogeneous material.

The investigation of acceptor doping with zinc has been carried out to a lesser extent. However, it has been demonstrated that hole concentrations in the range 2×10^{18} to 4×10^{19}/cm^3 can easily be attained with mobilities varying from 120 to 60 cm^2/v-sec for this doping range.

In addition to the preparation of single epitaxial layers doped with donor or acceptor impurities, multilayered structures have been fabricated by varying the introduction of the doping agents at different times during crystal growth. Figure 5 shows a section of a gallium arsenide multilayered structure in which an N^+, N, P^+ arrangement has been grown on a {100} surface of a gallium arsenide substrate. The P^+ region has a hole concentration of about 2×10^{19}/cm^3 while the N^+ and N regions have electron concentrations of about 4×10^{18} and 5×10^{15}/cm^3, respectively. Because of the low growth rates that can be realized in this system, the thickness of the individual layers can be controlled to about 1μ. This method of preparing multilayered structures during the growth of the alloy crystal has been used to fabricate several types of semiconductor devices having superior electrical characteristics (13).

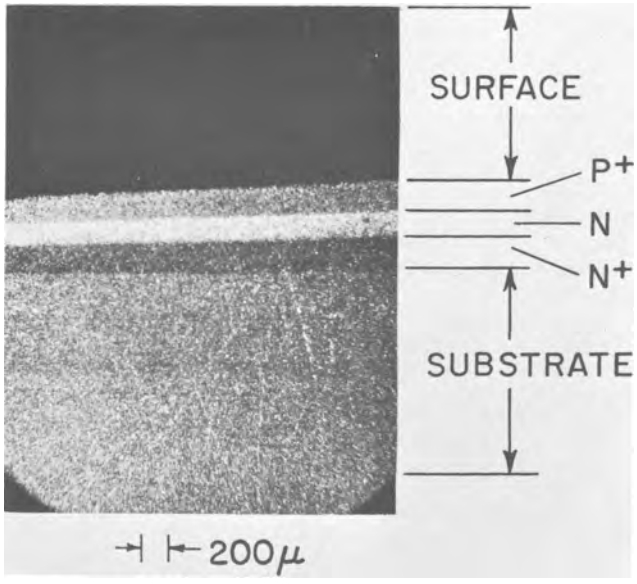

Fig. 5. Cross section of a P^+, N, N^+ GaAs structure, angle-lapped at 3° and chemically stained to reveal the individual regions. The geometric magnification introduced by angle-lapping increases the vertical dimension by a factor of approximately 20. Therefore, the actual thickness of each layer is about 10μ.

Optical Band Gaps

Optical absorption measurements were made in a Cary model 14R spectrophotometer on the same epitaxial films used for the Hall coefficient measurements. These measurements revealed that, on the high energy side of the absorption edge the absorption coefficient, α, obeys the relationship

$$\alpha = \alpha_o (E - E_o)^n$$

where E is the photon energy and E_o is the energy of the band gap (14). For alloys containing greater than 50% gallium phosphide n is equal to 2, while for alloys containing less than 45% gallium phosphide n is approximately unity. A value of n equal to 2 is indicative of an indirect (phonon assisted) band gap transition while values of n less than unity have been associated with a direct band gap transition (15). The dependence of E_o on alloy composition at room temperature and 77°K is presented in Fig. 6. It is apparent that a distinct transition occurs at $x = 0.44$ (at room temperature) as the slope of the curve changes abruptly. This is undoubtedly due to the change from a direct to an indirect band gap transition. These data are in excellent agreement with the results of Pilkuhn and Rupprecht (16), Fenner (17) and Cusano, Fenner, and Carlson (18), but are in par-

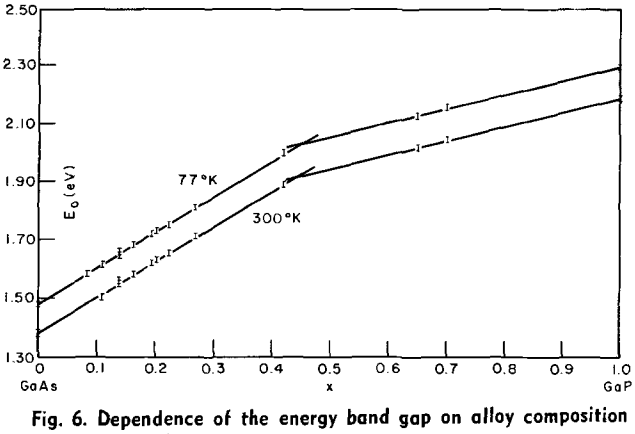

Fig. 6. Dependence of the energy band gap on alloy composition in the system, $GaAs_{1-x}P_x$.

tial disagreement with the results of Pizzarello (4) and Ku (3).

Conclusions

The superiority of this vapor-growth method for the preparation of homogeneous $GaAs_{1-x}P_x$ alloys has been demonstrated. Furthermore, very homogeneous alloys are obtained for a wide range of doping concentrations as both p- and n-type material. In addition, the versatility of this method has been explored in terms of growing a multilayer structure incorporating this high-quality material.

Measurements on the material prepared by this technique reveals that very high mobilities can be attained in this alloy system. It is especially striking that an alloy containing 27% gallium phosphide had a room temperature mobility of 4900 cm^2/v-sec, while a 69% gallium phosphide alloy had a mobility of 700 cm^2/v-sec at room temperature. Vegard's law of solid solutions was found to be obeyed, and optical absorption data showed that the change from a direct to indirect band gap transition occurs at $x = 0.44$ at room temperature.

This technique should also be useful for the preparation of any semiconducting compound or alloy system where volatile halides and/or hydrides occur.

Acknowledgments

The authors wish to express their sincere appreciation to H. F. Gossenberger for his valuable assistance throughout the course of this study, and to D. Richman and L. R. Weisberg for many very helpful suggestions and discussions. Thanks are extended to G. W. Neighbor, R. Paff, and R. Smith for performing the x-ray analysis, to S. Ochs for measuring the electroluminescent spectra, and to I. J. Hegyi and A. Salerno for mobility data. The research reported in this paper was sponsored by the Advanced Research Projects Agency, Materials Sciences Office, under Contract No. SD-182.

Manuscript received Jan. 17, 1966; revised manuscript, received March 21, 1966.

The Epitaxial Growth of Silicon Carbide

V. J. Jennings,[1] A. Sommer,[2] and H. C. Chang

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A method for growing SiC epitaxially on the (0001) plane of 6H SiC is described. The SiC is grown from the vapor phase by the reaction of hydrogen with silicon and carbon tetrachlorides. Cubic SiC grows at temperatures between 1600° and 1775°C. In order to grow hexagonal SiC, the substrate surface must be polished mechanically and the temperature must be greater than 1725°C.

This work was undertaken as part of a program for the development of a SiC active device. Hexagonal SiC crystals in the form of platelets, with basal plane areas up to 1 cm^2, may be prepared by the sublimation of polycrystalline SiC. However, it is dfficult to control the purity of the crystals obtained by this method. An epitaxial growth technique, where SiC is formed by the hydrogen reduction of silicon and carbon containing gases, would permit a greater control of purity. In the present work, an epitaxial layer was grown by the hydrogen reduction of silicon and carbon tetrachlorides.

Apparatus and Substrate Preparation

Apparatus.—Figure 1 shows a schematic diagram of the epitaxial growth reactor. This was a water-cooled 1-in. ID quartz tube. The heater was a graphite pedestal, which was heated with a 450 k/c generator.

The brightness temperature of the SiC substrate was measured with a "Pyro" micro-optical pyrometer. The true crystal temperature is estimated to be 100°-150°C higher than the brightness temperature, by making corrections for the absorption of radiation by the quartz water jacket and the emissivity of SiC.

Tank hydrogen (Ultrapure-Matheson Company, East Rutherford, New Jersey) was purified by passing it through a liquid nitrogen cold trap containing Linde 5A molecular sieves, and was filtered through a 0.22μ millipore filter. The purified hydrogen was metered into two saturators held at 0°C which contained silicon tetrachloride (Electronic Grade, Anderson Chemical Division, Stauffer Chemical Company) and carbon tetrachloride (Analyzed Reagent, Baker Chemical Company), respectively. The saturation obtained was 30% at 0°C. In experiments, the normal hydrogen flow through each saturator was fixed to give a 0.1% mole concentration of both silicon and carbon tetrachlorides to the hydrogen. The total hydrogen flow was 4×10^{-2} g moles/min.

Substrate preparation.—The substrates were 6H SiC and were grown in these laboratories. Prior to growth, most substrates were etched for 2 min in a 3:1 mixture

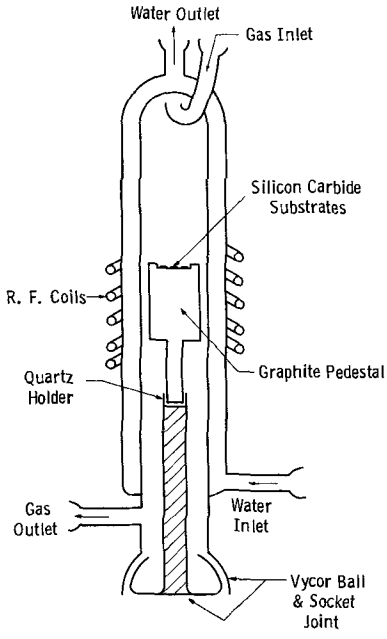

Fig. 1. Schematic diagram of epitaxial growth reactor

of sodium hydroxide to sodium peroxide at 700°C. After etching, one basal plane face of the substrate was shiny [the (0001) face], and the other was dull [the (000$\bar{1}$) face] (1, 2). Sometimes after the (0001) face was identified, it was then mechanically lapped successively on 600, 800, and 1000 grit boron carbide and polished with 1 and 0.25μ diamond paste.

All substrates were cleaned by immersion for 15 min in 48% hydrofluoric acid and washed in deionized water. They were then washed ultrasonically in trichloroethylene followed by methanol and dried.

Experimental Results

Figures 2 and 3 are the surfaces of layers grown at 1650°C on natural[3] (0001) and (000$\bar{1}$) faces of SiC substrates. A similar result was obtained for each face in the temperature range 1600°C to 1775°C. Below 1600°C, growth on the (0001) face became polycrystalline. Above 1775°C, the growth rate was much reduced and by 1800°C the substrate was etched. There was no significant difference in the type of mosaic line patterned growth obtained on either a natural or an etched natural (0001) surface. When the mole ratio of tetrachloride gases to hydrogen was increased from 0.1 to 0.3% the layer consisted of many intergrown yellow crystals, frequently with triangular facets growing parallel to the (0001) face of the substrate, as may be seen in Fig. 4. When growth occurred on a mechanically polished substrate at a temperature between 1725° and 1775°C the layer was colorless and showed no mosaic lines. Below 1725°C, the layer was yellow in color.

[3] A natural crystal face is defined here as the condition of the crystal face after growth in the sublimation furnace.

Fig. 3. Growth at 1650°C on natural (000$\bar{1}$) SiC surface

Layer Evaluation

Temperature dependence of growth rate.—The growth rate was determined by growing a layer for a period of 1 hr at a known temperature. The thickness of the layer was obtained by cross-sectioning the specimen either by scribing and breaking or by bevelling at an angle of a few degrees. The growth rate as a function of temperature is plotted in Fig. 5. The reaction to produce SiC was too complex to per-

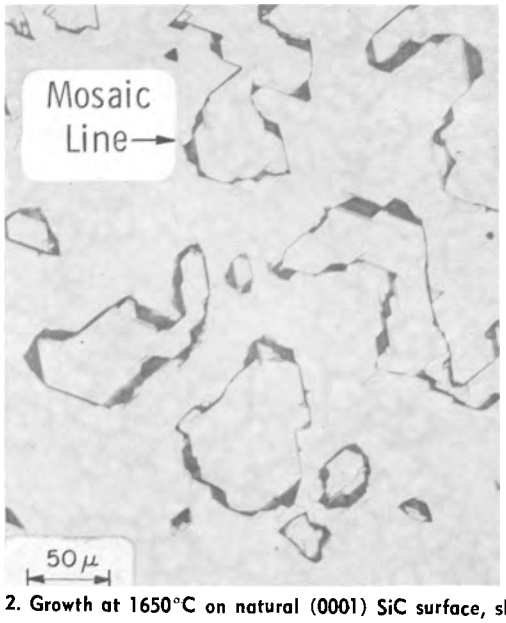

Fig. 2. Growth at 1650°C on natural (0001) SiC surface, showing mosaic.

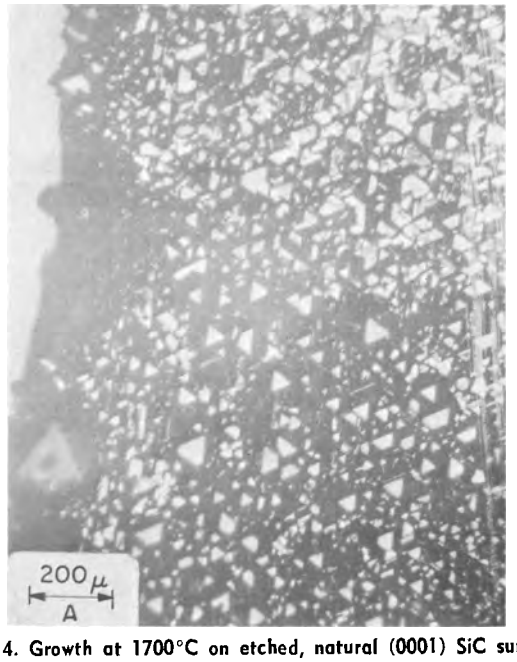

Fig. 4. Growth at 1700°C on etched, natural (0001) SiC surface when mole ratio was 0.3%.

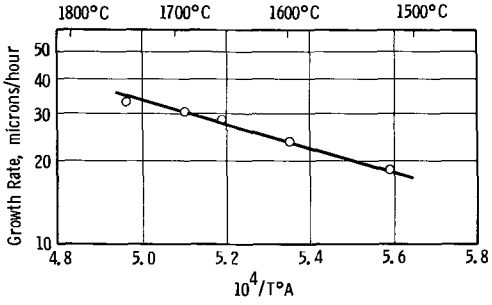

Fig. 5. Temperature dependence of SiC growth rate

mit the determination of its true activation energy. The apparent value was 20 kcal/mole.

Structure of SiC *layer.*—The structure of the layer was examined by molten salt etching. All yellow colored layers gave triangular shaped etch pits. Although these layers seemed homogeneous, after etching, colorless lamellae could be seen intergrown with the yellow material. Figure 6 shows the etched surface of the yellow material. It may be seen that there was a twin relationship between the orientation of the etch pits on each side of the mosaic line. Colorless layers, after etching gave a surface showing hexagonal etch pits (see Fig. 7).

Some substrate 6H crystals were subjected to Laue transmission x-ray analysis in order to confirm the polytype (3, 4). Transmission photographs of colorless layers after growth were found to be identical with those before growth, thus showing that the layer was also of the 6H polytype.

Purity of the SiC *layer.*—The purity of the colorless layers was evaluated by the capacitance method in which the room temperature capacity of a tantalum-SiC epitaxial layer rectifier was measured as a function of d-c voltage. It was found that the layer was not doped uniformly. The method of Anderson and O'Rourke (5) was used to calculate the impurity density distribution in the layer. The results showed that the purest SiC layers contained 10^{14} to 10^{15} ionized acceptors per cubic centimeter at room temperature.

Discussion

The yellow colored layer grown on the (0001) face of a 6H SiC substrate was predominantly cubic SiC, since triangular etch pits were obtained on etching.

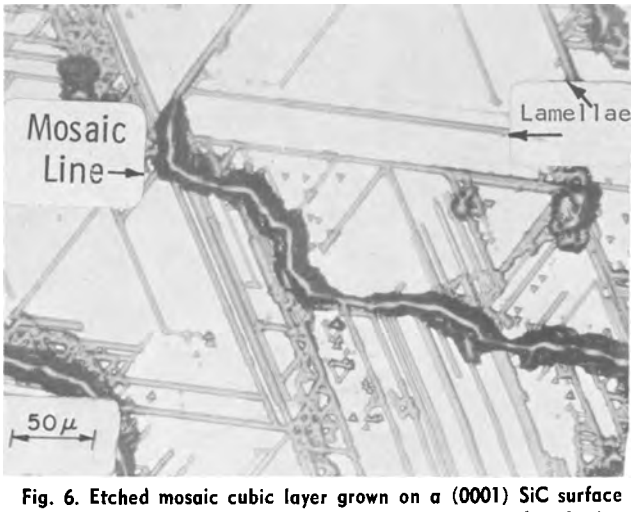

Fig. 6. Etched mosaic cubic layer grown on a (0001) SiC surface showing twinning by means of the orientation of trigonal etch pits.

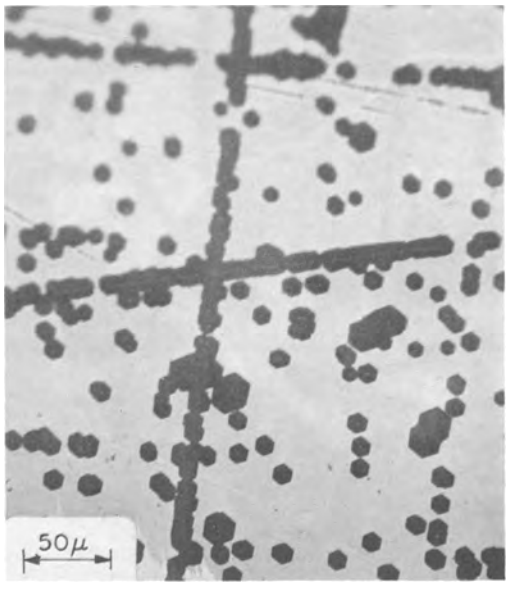

Fig. 7. Etched hexagonal layer grown on 0.25μ diamond polished (0001) SiC surface.

However, the colorless lamellae revealed by etching suggested that a mixed cubic and hexagonal layer had been grown, similar to those grown by Knippenberg using a sublimation process (6). Such yellow layers could be grown at temperatures between 1600° and 1775°C. At temperatures higher than 1800°C, the substrate was etched. At the latter temperature, SiC has an appreciable dissociation pressure (7), and the hydrogen gas used may act as an etchant.

An epitaxial 6H SiC layer could be grown on a mechanically polished substrate at temperatures between 1725° and 1775°C. The layer was p-type in conductivity when grown on a p-type substrate. Electrical measurements of the layer showed it to be of high purity although inhomogeneously doped. The inhomogeneity was due probably to diffusion and/or vapor transport of impurities from the substrate into the growing layer.

The fact that cubic SiC grows over a wide range of temperatures and substrate conditions, whereas hexagonal SiC does not, may be explained by Knippenberg's theory on the stability of SiC polytypes (8). According to this theory, cubic SiC is an unstable modification at all temperatures and not just at low temperatures. Thus, random crystallographic imperfections on natural and etched natural substrates could act as favored nucleation sites for initial deposition of cubic SiC.

Acknowledgment

The authors would like to thank Dr. R. Armstrong for his evaluation of the x-ray data, Mr. R. Yut for able assistance in the laboratory, and Dr. G. Della Pergola for his evaluation of the purity of the hexagonal layers. They also thank Dr. D. R. Hamilton and Mr. J. C. Castle for helpful discussions.

Absorption, Degassing, and Solution Equilibrium in the Nitrogen-Niobium System at Ultrahigh Vacuum and High Temperature

R. A. Pasternak, B. Evans, and B. Bergsnov-Hansen
Stanford Research Institute, Menlo Park, California

ABSTRACT

In the nitrogen-niobium system, sorption at high constant temperature and low pressure follows approximately the parabolic rate law

$$\frac{S}{S_o} = 1 - \left(\frac{c}{c_e}\right)^2$$

where S is the sticking probability at the nitrogen concentration c in the metal, S_o the initial sticking probability, and c_e the saturation concentration. This rate law can be explained by a reversible reaction mechanism: Nitrogen is adsorbed atomically on the essentially clean metal surface at a rate which is proportional to pressure but independent of temperature; it then transfers rapidly into the bulk and distributes itself uniformly by fast diffusion. In the reverse reaction nitrogen recombines on the surface at a rate which is proportional to the square of the nitrogen atom concentration in the bulk. The observed degassing rates at both constant and variable pressure can be explained by the same mechanism.

The refractory metals of group 5a and 6a of the periodic table show low resistance to corrosion and embrittlement at elevated temperatures because they dissolve oxygen, nitrogen, and hydrogen easily. Extensive research has been carried out to elucidate the solution mechanisms involving oxygen. In most of these studies the pressures and temperatures employed were such that oxide layers were formed on the metal surface; only rarely were experimental conditions approached which permitted studying the primary reaction step between the gas and the essentially clean metal surface (1-3). The kinetics of solution of nitrogen in refractory metals has been studied less extensively; again, data on the primary surface reaction are meager (4, 5).

In a recent paper the mechanisms of adsorption and of the early stages of absorption at very low pressures were discussed for the nitrogen-niobium system (6). The present investigation, which extends that study, is concerned with the solution equilibrium and with the kinetics of absorption and of degassing at such low pressures and high temperatures that only the primary reaction between the gas and the essentially clean metal surface occurs. A similar study of the low pressure interaction of nitrogen with niobium-1% zirconium alloy is in progress elsewhere (7). (7).

Experimental

The sorption kinetics was investigated in an ultrahigh vacuum flow system by a constant pressure technique which has been described in detail elsewhere (6, 8). In this approach, the pressure in the sorption cell is kept constant by varying the gas flow into the cell; the flow rate is adjusted by means of a servo-controlled, motor-driven valve to compensate for gas pumping or release by the sample. This flow rate, which is recorded continuously, is a measure of the sorption rate and can be converted to the latter by simple arithmetic manipulations.

The solubility of nitrogen in niobium was determined by a modification of this approach: Nitrogen was dissolved in amounts well defined by absorption runs; then, at a controlled pressure in the cell the sample temperature was adjusted to a value at which gas was neither absorbed nor released. Such steady-state points in the solubility diagram were determined over a wide range of the three parameters, pressure, temperature, and concentration. The relative change in solute concentration during the adjustment of pressure and temperature was negligible, since steady state was established virtually instantaneously. Also, the same steady-state temperature-pressure pair was observed, within the precision of the measurements, from whichever direction it was approached. Since throughout this study the gas phase was at ambient temperature (300°K), the measured pressures p were multiplied by the factor $\sqrt{T/300}$; the resulting equivalent pressures P at temperature T of the sample are assumed to be equal to the true equilibrium pressure (9).

Information on the sorption mechanism was also obtained by degassing the sample without admitting gas; the pressure p in the system then decreased with time t. If the volume term $V(dp/dt)$ is small compared with the gas flow out of the cell, the degassing rate is given by $(dM/dt) = -f_o v p$, where f_o is the effective area of the valve opening to the pump.

The samples used were ribbons, about 0.004 x 0.1 x 25 cm, rolled from a zone-melted ingot with a total impurity level of less than 50 ppm. The samples were chemically cleaned and, after mounting in the unit, degassed thoroughly in ultrahigh vacuum at about 2200°K. At these temperatures, dissolved oxygen is removed as a volatile unsaturated oxide (10). A more detailed description of the preparation and properties of such samples has been given elsewhere (6). The gas used was Research Grade nitrogen (total impurity less than 50 ppm) which was dried over liquid nitrogen.

The ribbons were heated electrically using lead storage batteries and high-wattage resistors in series. Brightness temperatures were measured with an optical micropyrometer; they were corrected for absorption by the walls, and for emissivity which has been shown to be independent of solute concentration (11). No correction was applied for the temperature variation along the sample (about ±50°C at the highest temperatures), or for end effects, which are, however, rather small because of the length of the sample. Approximately constant temperature was maintained during sorption runs by applying a constant voltage. A small temperature correction, required when a run covered a wide concentration range, was derived from the correlation between resistivity, temperature, and nitrogen concentration established previously in calibration runs (12).

The data presented here were obtained mainly with two samples; less extensive measurements with additional samples agreed with the over-all pattern.

Results

Equilibrium measurements.—A series of equilibrium curves at concentrations between 0.05 and 0.5 a/o (atom per cent) are shown in Fig. 1; log P is plotted *vs.* $1/T$. The data cover a pressure range of about 10^{-5} to 10^{-8} Torr and a temperature range of 1900°-1400°K. The experimental points define a series of parallel straight lines. The heat of solution ΔH_{sol}, calculated by a least-squares treatment of the data for each concentration, is 53.5 ± 1.5 kcal/g atom. No systematic variation in ΔH_{sol} with concentration was found.

Figure 2 is a plot of log P *vs.* log c_e at 1600°K, derived from the curves in Fig. 1. The points lie, within the precision of the measurements, on a straight line drawn with the slope 2; thus, Sieverts' law is obeyed, and the solution equilibrium can be described by the equation

$$c_e = 1.2 \times 10^{-5} \exp [53{,}500/RT] P^{1/2} \text{ a/o}$$

The pre-exponential factor was derived from the plot in Fig. 2. Equilibrium runs with other samples resulted in heats of adsorption agreeing within 2 kcal/g atom with the value given here. However, variations by a factor of about three in the pre-exponential factor were found which undoubtedly arise from the systematic errors in pressure and temperature measurements.

Absorption and degassing at constant pressure.—In the preceding low-pressure study of nitrogen adsorption by niobium (6), the initial sticking probability S_o of nitrogen on a thoroughly degassed sample was found to be approximately constant over a wide range of high temperatures and low pressures; however, S_o varied for different samples between 0.05 and 0.09. In the present study the kinetics of solution of nitrogen beyond this initial adsorption state was investigated in detail. The rates of solution were measured at temperatures from 1650° to 2000°K and pressures from 6×10^{-7} to 6×10^{-6} Torr. They all exhibit the same dependence on the nitrogen concentration in the sample, as illustrated by the curves in Fig. 3 and 4(a). These plots of sticking probability S *vs.* nitrogen concentration c in the sample have an initial slope close to zero, then bend over and exhibit an approximately linear approach to the saturation concentration c_e. The rate curves for all the experiments when normalized in terms of S/S_o and c/c_e coincide within the precision of the measurements.

Rates of degassing were determined at pressures of 9×10^{-7} and 2×10^{-6} Torr, and temperatures of 1640° to 1830°K; (a wider range of the parameters was inaccessible for experimental reasons). Figure 4 shows the method used and the internal consistency of the measurements. After the sample absorbed nitrogen at 2×10^{-6} Torr almost to saturation (a), a pressure increase to 4×10^{-6} Torr led to additional gas uptake (b); reduction in pressure to 2×10^{-6} Torr resulted in degassing (c) which returned the sample to the same equilibrium concentration origi-

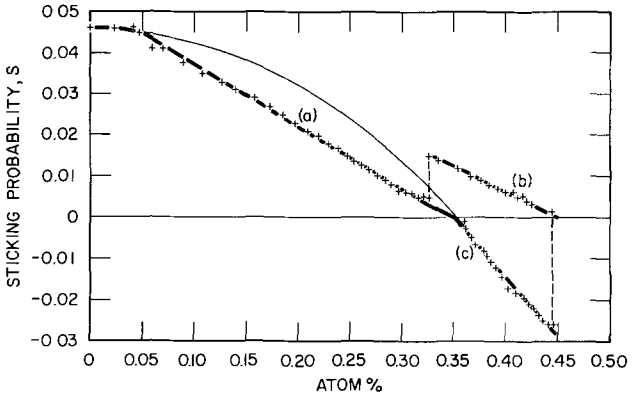

Fig. 4. Absorption and degassing at constant pressure and temperature. Nitrogen concentration in atom per cent. (a) Absorption at 2 x 10^{-6} Torr; (b) absorption at 4 x 10^{-6} Torr; (c) degassing at 2 x 10^{-6} Torr; T = 1640°K. The thin line is a parabola.

nally approached by absorption at this pressure. The experimental conditions for other degassing runs and the slopes of the rate curves expressed as S/S_o *vs.* c/c_e are listed in Table I.

The data presented so far cover only homogeneous solutions of nitrogen in niobium. When the solubility limit is exceeded, the sorption pattern is modified. This is illustrated by the absorption run at 2 x 10^{-6} Torr and 1470°K in Fig. 5. Both the sticking probability and the sample resistance are plotted *vs.* total concentration in the sample. During the earlier stages of sorption, the sticking probability exhibits a similar concentration dependence as in runs at higher temperatures; however, at about 0.8 a/o it approaches a constant value insensitive to further uptake of nitrogen. Similarly, the linear resistance curve changes its slope at about the same concentration. Both curves indicate formation of a new phase. This is suggested also by the equilibrium pressure over the sample which was measured at the end of the absorption run; this pressure was equal to that over a homogeneous solution at a concentration of about 0.6 a/o, although the over-all total concentration was 1.6 a/o.

Degassing at variable pressure.—Degassing rates were measured as a function of temperature and of conductance f_o to the pump when no gas was leaked into the cell. In such degassing runs the pressure p decreased with time according to the equation $p^{-1/2} = a + bt$, as illustrated in Fig. 6. It will be shown in the Discussion that this relationship is equivalent to a second order rate law in respect to nitrogen concentration, and the slope b is a rate constant of degassing. The Arrhenius plot of the rate constants measured at different temperatures results in a straight line as shown in Fig. 7. Curve (a) represents the data of Fig. 6 for a conductance f_o = 0.1 cm², curve (b) data of another series for f_o = 0.18 cm². From the slopes and intercepts of these plots, activation energies ΔH_a of 56 and 54 kcal/g atom and pre-exponential factors of 7 x 10^5 and 1.2 x 10^6 Torr$^{-1/2}$ sec^{-1} are derived.

Finally, the dependence of the degassing rates on conductance is shown in Table II.

Discussion

Solution equilibrium.—The close fit of the experimental equilibrium data to the equation

$$c_e = KP^{1/2} = K_o \cdot \exp\left[\Delta H_{sol}/RT\right] \cdot P^{1/2} \qquad [1]$$

is convincing evidence that within the temperature and concentration range of this study (1400 < T < 1900°K, c_e < 0.5 a/o) nitrogen dissolves atomically

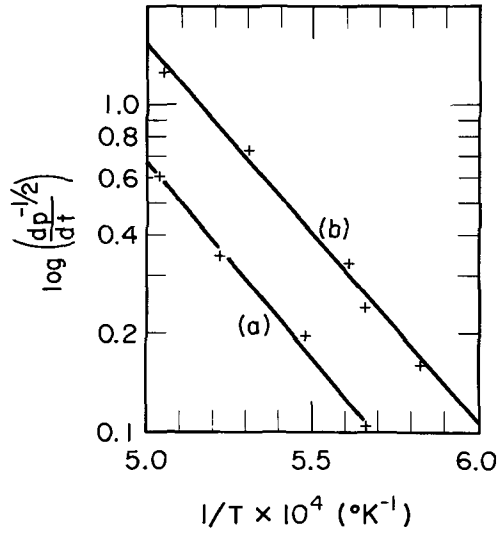

Fig. 7. Activation energy for degassing at variable pressure. Plots of log $[d(p^{-1/2})/dt]$ *vs.* $1/T$. (a) Conductance f_o = 0.1 cm²; (b) f_o = 0.18 cm².

Table II. Experimental slopes $d\,(p^{-1/2})/dt$ ($Torr^{-1/2}$ sec^{-1}) for degassing curves at variable pressure as function of conductance. $T = 1685°K$

f_o, cm^2	0.22	0.15	0.10	0.05
$\frac{d\,(p^{-1/2})}{dt}$	0.14	0.11	0.08	0.04(5)
$\frac{1}{f_o}\cdot\frac{d\,(p^{-1/2})}{dt}$	0.64	0.73	0.80	0.90

in niobium to form a homogeneous, regular solution. This result is in agreement with two earlier studies (11, 12) of the nitrogen-niobium system; close adherence to the same functional relationship had been found in a temperature range between 1800° and 2500°K. The constants fitting these earlier data were $K_o = 6.2 \times 10^{-4}$ and 7.7×10^{-4} a/o $Torr^{-1/2}$ and $\Delta H_{sol} = 46.0$, and 42.4 kcal/g atom (11, 13). A heat of solution of 51 kcal/g atom has been observed by Inouye (7) for low concentrations of nitrogen in niobium 1% zirconium alloy. The values derived in the present study are 1.2×10^{-5} a/o $Torr^{-1/2}$ and 53.5 kcal/g atom. Although the reported entropies and enthalpies found in these studies differ considerably, the free energies are rather close. It is not possible to ascertain on the basis of the present data whether the observed differences have thermodynamic significance or are artifacts due to systematic errors, particularly in the determination of absolute temperature. The tantalum-nitrogen solution equilibrium also obeys Sieverts' law (4) as would be expected in view of the general similarity of the two metals.

Absorption and degassing at constant pressure.—The over-all sorption process can be logically separated into three reversible, sequential processes: dissociative adsorption, transfer of adsorbed atoms from surface to bulk, and diffusion of atoms in the bulk.[1]

A clean surface is maintained at least during the earlier stages of absorption; this is indicated by the approximate constancy of the sticking probability over a wide pressure and temperature range and a significant concentration range. Thus, transfer of the adsorbate into the bulk must be a much faster process than adsorption. Furthermore, an estimate based on the known diffusion coefficient of nitrogen in niobium (15) showed that for our experimental conditions the diffusion rates are sufficiently high to distribute the dissolving nitrogen virtually instantaneously and uniformly throughout the bulk (6). Finally, high rates of transfer and diffusion relative to the rate of desorption are suggested by this observation: on flash-heating a well-degassed sample which is covered with a monolayer of nitrogen, no gas burst is observed; nevertheless the sample, after cooling, again adsorbs a monolayer of nitrogen.

For the formulation of a quantitative rate law we assume that the opposing surface reactions

$$(N_2)_{gas} + 2\ \text{sites} \rightleftarrows 2\,(N)_{ad} \qquad [2]$$

are the rate-determining steps, since diffusion is so fast that surface and bulk are at all times in virtual equilibrium with each other. If we in addition assume that the surface concentration is small as is the bulk concentration, the two concentrations are proportional to each other

$$(N)_{ad} = K_D c \qquad [3]$$

and K_D, the distribution constant, is of the order of unity or smaller, when both concentrations are expressed in comparable units.[2] Consequently, the rate of adsorption is at all times proportional to the impingement rate of molecules on the surface, *i.e.*, to the pressure, since the impinging molecules see always an essentially clean surface; and the rate of desorption is proportional to the square of the bulk concentration.

The resulting over-all rate of sorption, per unit area, is given by

$$\frac{1}{a}\left(\frac{dM}{dt}\right)_{p,T} \equiv Svp = S_o vp - k\,(N)^2_{ad} = S_o vp - k'c^2 \qquad [4]$$

where S is the normalized net rate of sorption, and S_o the constant rate of adsorption; a is the sample area and v the incidence rate per unit area at unit pressure. Since the net sorption rate becomes zero at equilibrium, the constant k' can be expressed in terms of S_o and the equilibrium concentration c_e, and one obtains the simple parabolic rate law, after dividing by vp

$$\frac{S}{S_o} = 1 - \left(\frac{c}{c_e}\right)^2 \qquad [5]$$

The observed sorption kinetics is described reasonably well by this rate law. In particular, the rate curves expressed as S/S_o *vs.* c/c_e are found to be independent of pressure and temperature, and their slopes at $c/c_e = 0$ are approximately zero (Fig. 3, 4, 5). Moreover the degassing curves fit the parabola well, as illustrated in Fig. 4c. (The precision of the measurements is not sufficient to detect the predicted slight curvature.) This good fit is also shown in Table I; the slopes of the experimental degassing curves agree closely with the calculated slopes of the parabola at the mid-point of the concentration range of each degassing run. However, the sticking probabilities for adsorption deviate significantly from the parabola (Fig. 3, 4a). We suspect that this deviation is an experimental artifact; this is suggested by the discontinuity in the slope of the experimental rate curves at saturation concentration (Fig. 4a and c).

The kinetics of gas uptake extending beyond the solubility limit (Fig. 5) can be explained by the same basic mechanism. In the one-phase region the sticking probability curve again may be fitted approximately by a parabola which now passes through the hypothetical equilibrium point for a homogeneous solution at the pressure and temperature of the particular experiment. In the two-phase region, where the concentration of the solute in the metallic phase remains constant, the sticking probability is constant also; apparently the new phase, probably Nb_2N (11) does not segregate as a surface layer.

Degassing at variable pressure.—When no gas is admitted into the cell, the rate of degassing is equal to the rate at which the gas is leaving the cell, and the pressure is now a function of time; moreover, if we assume that rate Eq. [5] also applies in this case, the conditions hold

$$-\left(\frac{dM}{dt}\right)_{T,f_o} = -\alpha\left(\frac{dc}{dt}\right)_{T,f_o} = f_o vp \qquad [6a]$$

and

$$-\alpha\left(\frac{dc}{dt}\right)_{T,f_o} = avpS_o\left[\left(\frac{c}{c_e}\right)^2 - 1\right] \qquad [6b]$$

where α is a conversion factor proportional to the sample volume, a the area of the sample, and f_o the conductance to the pump; c is the concentration and p the pressure at time t, and c_e is the concentration if the sample was in equilibrium with the gas phase at pressure p. At any time during degassing $c_e < c$.

Equation [6b] can be expressed in terms of the experimental parameters c and p by the substitution

[1] Physisorption has been proposed as the step preceding chemisorption even at high temperatures (3): it has little physical meaning in the temperature range of interest here for the following reason. An adsorbed molecule has a residence time on the surface of about 10^{-13} exp $[\Delta H_d/RT]$ sec, where ΔH_d is the heat of desorption, and the associated jump frequency for surface diffusion is about 10^{13} exp $-[\frac{1}{4}\Delta H_d/RT]$ sec^{-1} (14). For example, a rather high heat of physisorption of 5 kcal and a temperature of 1500°K result in a residence time of about 10^{-12} sec, and the molecular undergoes only 3 surface jumps in this time interval.

[2] A large value of K_D implies the existence of an energy barrier for the transfer of adsorbate into the bulk. This important case will not be treated here, since the formalism given appears to be sufficient for the interpretation of the data.

$$c_e = KP^{1/2} = K\left(\frac{T}{300}\right)^{1/4} p^{1/2}$$

By elimination of p from Eq. [6a] and [6b] the second order rate law is obtained

$$-\left(\frac{dc}{dt}\right)_{f_o,T} = k'_2 c^2 \qquad [7a]$$

The time dependence of the pressure is derived from Eq. [7a] and [6a] by elimination of c and dc/dt, and integration

$$p^{-1/2} = p_o{}^{-1/2} + k_2 t \qquad [7b]$$

where

$$k_2 = \frac{\nu}{\alpha}\left(\frac{300}{T}\right)^{1/4} f_o\left(\frac{S_o a}{f_o + S_o a}\right)^{1/2} K^{-1} = \beta K^{-1} \qquad [8]$$

and $K = K_o \exp[\Delta H_{sol}/RT]$ is the solubility constant.

A second order rate law would have been arrived at simply by assuming that the rate of degassing was proportional to the square of the solute concentration in the bulk. Our treatment, however, correlates the degassing process with the solution equilibrium and with the mechanism of sorption: The rate constant is inversely proportional to the solubility constant K, and thus the activation energy of degassing is equal to the heat of solution (if one disregards the factor $T^{-1/4}$). For $S_o a >> f_o$, degassing takes place at quasi-equilibrium, and

$$\beta = \frac{\nu}{\alpha}\left(\frac{300}{T}\right)^{1/4} f_o$$

the rate constant is proportional to f_o, and is independent of S_o. For $S_o a << f_o$, only an insignificant fraction of the gas released in readsorbed, and

$$\beta = \frac{\nu}{\alpha}\left(\frac{300}{T}\right)^{1/4} a^{1/2} S_o{}^{1/2} f_o{}^{1/2}$$

the rate is now proportional to the square root of both f_o and of S_o.

The derivation of the rate law for sorption contains the assumption that no significant energy barrier exists for the transfer of adsorbate from the bulk to the surface. If, however, the energy barrier is significant, the observed activation energy of degassing becomes a function of f_o: for small values of f_o (*i.e.*, for degassing at quasi-equilibrium), it is equal to the heat of solution, whereas for large value of f_o (*i.e.*, for rapid degassing), it approaches the true activation energy.

The experimental degassing data support the simple model. The linear dependence of $p^{-1/2}$ on time is closely obeyed over a reasonably wide temperature and pressure range (Fig. 6). Also, the experimental slopes of the curves increase less than linearly with the conductance f_o (Table II); however, the limited range of conductance values achievable in these experiments does not permit a quantitative test of the relationship given. Finally, the activation energies of degassing, 56 and 54 kcal/g atom found for the two series at conductances of 0.1 and 0.18 cm^2 (Fig. 7) are, within the uncertainty of the measurements, equal to the heat of solution (53.5 kcal). Also, the pre-exponential factors K_o of 3.4 and 3.2 x 10^{-5} a/o Torr$^{-1/2}$ calculated from the degassing experiments and from the parameters of the sample (α = 2.0 x 10^{18} molecules, a = 4.6 cm^2, S_o = 0.05) are close to the value of 1.2 x 10^{-5} obtained directly from equilibrium measurements. As satisfactory as this agreement is, it does not rule out an energy barrier for transport of solute from surface to bulk, since the accessible pumping speeds were too small to displace the system far from equilibrium; only 30 and 44% of the released gas were removed in these runs. The data, however, show that the solubility of gases in metals can be determined from degassing experiments alone, without information about the actual solute concentration in the sample.

Liquidus Curves for Aluminum Cell Electrolyte

IV. Systems NA_3AlF_6 and Na_3AlF_6-Al_2O_3 with MgF_2, Li_3AlF_3, and K_6AlF_6

David A. Chin and E. A. Hollingshead

Aluminium Laboratories Limited, Arvida, Quebec, Canada

ABSTRACT

Liquidus curves have been determined from cooling curves and by sampling melts saturated with alumina. The latter technique was used to redetermine the alumina-rich liquidus of the binary Na_3AlF_6-Al_2O_3 system and yielded a eutectic point at 10.0% Al_2O_3 and 962°C. The binary systems of Na_3AlF_6 with Li_3AlF_6, MgF_2, and K_3AlF_6 gave respectively: eutectic point at 62.0% Li_3AlF_6 and 716°C; pseudobinary eutectic point at 18.0% MgF_2 and 924°C; and a minimum melting point at 40% K_3AlF_6 and 945°C. (Compositions are given in weight per cent). Diagrams are given for Na_3AlF_6-Li_3AlF_6, Na_3AlF_6-K_3AlF_6, and the Na_3AlF_6-rich side of the systems Na_3AlF_6-Al_2O_3, Na_3AlF_6-MgF_2, Na_3AlF_6-Al_2O_3-MgF_2, Na_3AlF_6-Al_2O_3-Li_3AlF_6, and Na_3AlF_6-Al_2O_3-K_3AlF_6.

Previous reports (1-3) from this laboratory have given liquidus curves for aluminum cell electrolytes now employed industrially. This paper gives similar data for Na_3AlF_6-Al_2O_3 with MgF_2, Li_3AlF_6, or K_3AlF_6, which are considered to be possible alternate electrolytes.

The only previously reported liquidus diagram of the ternary Na_3AlF_6-Al_2O_3-MgF_2 system is that by Vatslavik and Belyaev (4). The ternary systems with Li_3AlF_6 and K_3AlF_6 were reported in the book by Belyaev *et al.* (5). Rolin and Muhlethaler (6) more recently reported on the solubility of Al_2O_3 in Na_3AlF_6-Li_3AlF_6 melts and Mashovets and Petrov (7) on the Na_3AlF_6-Li_3AlF_6-Al_2O_3 system. Since other results by cooling curves for melts in the alumina phase field have been proven (1-3) to be in error, these ternary systems were redetermined.

Materials

Sodium cryolite was specially hand picked natural cryolite. The freezing point by cooling curves was 1009±1°C. Aluminum fluoride (99+% by difference) was the product of vacuum distillation of commercial grade (90%) AlF_3. The major impurities were Al_2O_3 (0.12%), Fe (0.06%), and Si(0.05%). Alumina was a special low-soda product produced experimentally, and the impurities detected were 0.01% Na, 0.03% Fe, and 0.01% Si. Lithium fluoride was reagent grade from J. T. Baker Chemical Company. Potassium fluoride (dried at 105°C before use) was reagent grade from General Chemical Division of Allied Chemical and Dye Corporation. Magnesium fluoride (99%) was spectroscopic grade from A.D. MacKay Inc.

Method

Primary freezing points were determined by cooling curves on melts from which the cryolites were the primary crystalline phase. Cooling curves were determined on 150g samples weighed out, mixed, and heated to 1060°C. The stirred melts were held until clear and then cooled at 1-3°C/min until the primary freezing point was registered.

The visual method (1), which consisted essentially of determining the temperature at which crystals could be first seen to separate from a slowly cooling melt, formerly used for the points in the alumina phase field has been replaced by a saturation method. For saturation measurements, melts containing an excess of alumina were stirred at the saturation temperature for 20 min, the alumina was allowed to settle out, and the supernatant melt was sampled with a preheated rhodium spoon. The quenched samples were analyzed for free Al_2O_3 by the $AlCl_3$ method (8).

The Pt, 10% Rh-Pt thermocouples were guaranteed by the manufacturers (Johnson Matthey and Mallory Ltd.) to be within 1°C. They were checked periodically at the freezing point of reagent grade NaCl, 801°±0.5°C.

Accuracy

The error in the cooling curve determinations was not greater than 3°C (2). The analysis for free Al_2O_3 was found to be accurate to ± 0.3% Al_2O_3, compared with ±0.25% reported by Henry and Lafky (8) for values in the range of 0 to 12% alumina. The presence of MgF_2 or Li_3AlF_6 did not affect the accuracy of the determinations. However, in the presence of K_3AlF_6 or KF, the $AlCl_3$ method yielded very low values for the alumina content of the melts. In this case, analysis of the quenched melt was made for total aluminum and the alumina content calculated after correcting the total aluminum figure for the weighed-in K_3AlF_6 and Na_3AlF_6 proportions. The standard error of the mean of duplicate analyses was calculated to be 0.5% Al_2O_3.

Results and Discussion

The eutectic point in the binary Na_3AlF_6-Al_2O_3 system has been determined by the saturation method to be at 10.0% alumina and 962°C. (Compositions are given in weight per cent.) The values by Fenerty and Hollingshead (3) for primary freezing points on the cryolite side of the eutectic were employed. The binary diagram together with previous results (1, 3, 9) is given in Fig. 1. The results of the present work for the solubility of Al_2O_3 agree with those at 975° and 1000°C reported by Henry and Lafky (7). They are as much as 1.0% lower than found previously by the visual method (1). Above 1030°C, good agreement was obtained with Foster's results (9) by the quenching method; below this temperature, alumina solubilities lower by 0.3-0.6% were detected.

The liquidus diagram of the Na_3AlF_6-MgF_2 system which was determined up to 45% MgF_2 is shown in Fig. 2 together with the reproduced diagram of previous workers (5). It was found that this is not a true binary system. X-ray diffraction analysis of crystals from a partially crystallized melt originally containing 26% MgF_2 yielded patterns for both $2NaF \cdot MgF_2 \cdot AlF_3$ (weberite) and $NaF \cdot MgF_2$. It was not determined which of these two compounds was the primary phase.

In the Na_3AlF_6-Al_2O_3-MgF_2 system, sections were determined at 2, 5, 10, 14, 15, 16, and 20% MgF_2 (compositions expressed on Al_2O_3-free basis), and the results are shown in Fig. 3. (To avoid confusion in the diagram, the results for 14, 16, and 20% MgF_2

were not plotted). The cryolite corner of the diagram (Fig. 4) is based on these results (Fig. 3) and on the revised diagrams for Na_3AlF_6-MgF_2 and Na_3AlF_6-Al_2O_3. A pseudoternary eutectic point was found at 3.0% Al_2O_3, 14.5% MgF_2, 82.5% Na_3AlF_6, and 912°C. Previously a ternary eutectic at 4.5% Al_2O_3, 15.5%

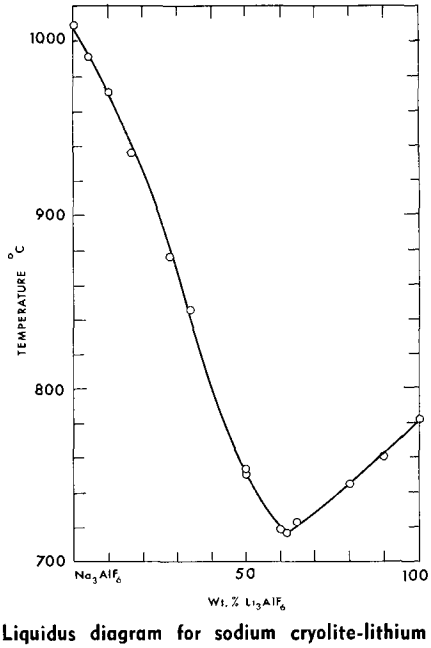

Fig. 5. Liquidus diagram for sodium cryolite-lithium cryolite

MgF_2, 80.0% Na_3AlF_6, and 919°C was reported by Vatslavik and Belyaev (4).

The eutectic line separating the crystallization fields of cryolite and alumina and the isothermal contour indicating the alumina solubility (Fig. 4) show a fairly steep drop for the addition of the first 5% MgF_2 and then a gradual decrease up to 14.5% MgF_2. The eutectic line from 18% MgF_2 in Na_3AlF_6 to the pseudoternary eutectic point separates the Na_3AlF_6 field from a $2NaF \cdot MgF_2 \cdot AlF_3$ (or $NaF \cdot MgF_2$) field. No attempt has been made to determine the extent of this field.

The binary system Na_3AlF_6-Li_3AlF_6 (Fig. 5) has a eutectic point at 62.0% Li_3AlF_6 and 716°C. This agrees with the work of Mashovets and Petrov (7).

In the ternary Na_3AlF_6-Al_2O_3-Li_3AlF_6 system, sections were determined at 5, 10, 15, 20, 25, and 30% Li_3AlF_6 (compositions expressed on Al_2O_3-free basis) and are shown in Fig. 6. The ternary diagram based on these and the present diagrams for the two binary systems Na_3AlF_6-Li_3AlF_6 and Na_3AlF_6-Al_2O_3 is plotted in Fig. 7. The eutectic line separating the fields of crystallization of sodium cryolite and alumina shows a fairly steep decrease for up to 10% Li_3AlF_6, but on

the other hand the isothermal contours indicating the alumina solubilities show a gradual reduction in alumina content. Rolin and Muhlethaler (6) reported larger Al_2O_3 solubilities in Na_3AlF_6-Li_3AlF_6 melts, but it must be noted that their binary eutectic for Na_3AlF_6-Al_2O_3 at 11.2% Al_2O_3 is also high (see Fig. 1).

The liquidus diagram for Na_3AlF_6-K_3AlF_6 is depicted in Fig. 8. With addition of increasing amounts of K_3AlF_6, the primary freezing points decrease to 945°C at 40% K_3AlF_6 and then rise to 955°C at 60-70%. This is interpreted as the tendency toward the formation of the compound elpasolite ($2KF \cdot NaF \cdot AlF_3$) which can be shown by x-ray diffraction analysis to be present in frozen Na_3AlF_6-K_3AlF_6 melts. The present liquidus diagram does not agree with that of Belyaev and Studenzov (10) in the range 30-70% K_3AlF_6; there is good agreement with the form of the liquidus diagram, *i.e.*, a somewhat flat portion between 50 and 75% K_3AlF_6, attributed to Lundina (11).

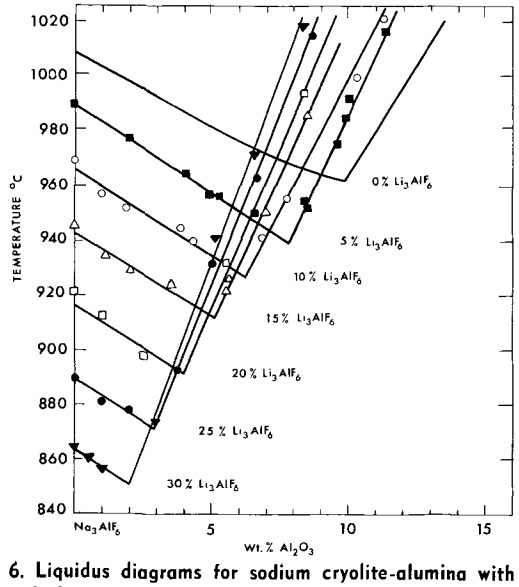

Fig. 6. Liquidus diagrams for sodium cryolite-alumina with 0, 5, 10, 15, 20, 25, and 30% lithium cryolite; weight per cent Li_3AlF_6 given on alumina-free basis.

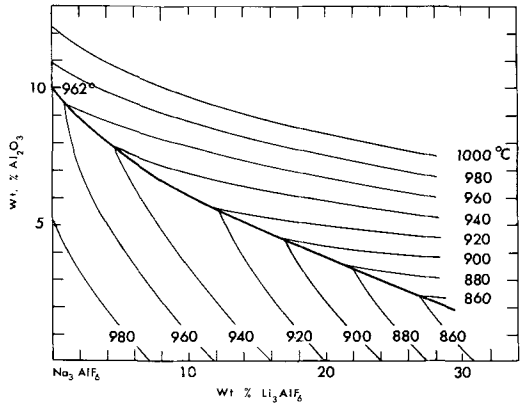

Fig. 7. Liquidus diagram for sodium cryolite-alumina-lithium cryolite: % Na_3AlF_6 + % Al_2O_3 + % Li_3AlF_6 = 100.

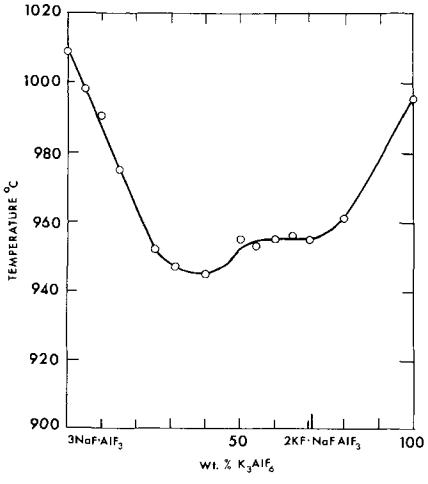

Fig. 8. Liquidus diagram for sodium cryolite-potassium cryolite

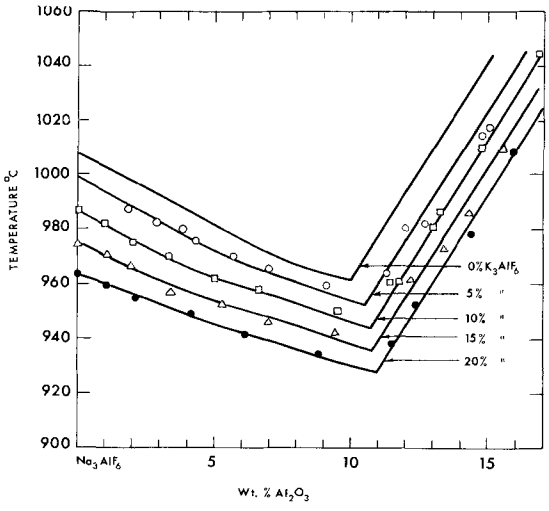

Fig. 9. Liquidus diagrams for sodium cryolite-alumina with 0, 5, 10, 15, and 20% potassium cryolite; weight per cent K_3AlF_6 given on alumina-free basis.

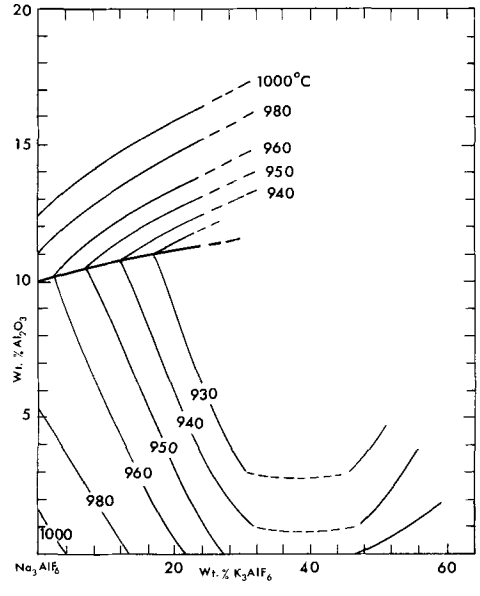

Fig. 10. Liquidus diagram for sodium cryolite-alumina-potassium cryolite: % Na_3AlF_6 + % Al_2O_3 + % K_3AlF_6 = 100.

Figure 9 shows sections across the Na_3AlF_6-Al_2O_3-K_3AlF_6 system, and the ternary diagram (Fig. 10) was constructed from these and other sections determined at 1, 2, and 3% Al_2O_3 (not shown). Addition of K_3AlF_6 increases the Al_2O_3 solubility, as reported by Baimakov and Batashev (12).

It is not clear why the Al_2O_3 in quenched melts containing potassium cryolite should be soluble in $AlCl_3$ solutions; possibly it is present as some kind of oxyfluoride. Leach water is not alkaline to phenolphthalein, showing the absence of aluminate, and no unusual x-ray diffraction pattern was obtained from a quenched melt containing 10.5% Al_2O_3 in K_3AlF_6 even though only 3.7% Al_2O_3 was insoluble in $AlCl_3$ solution. Possibly there is a connection between the change in form of the Al_2O_3 and the substantially higher solubility in K_3AlF_6.

Manuscript received Dec. 20, 1965.

Electrode Kinetics of Oxygen Evolution and Dissolution on Rh, Ir, and Pt-Rh Alloy Electrodes

A. Damjanovic, A. Dey,[1] and J. O'M. Bockris

John Harrison Laboratory of Chemistry, Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

Cathodic and anodic Tafel parameters, stoichiometric numbers, and decay kinetics have been determined on rhodium, iridium, and platinum-rhodium alloy electrodes. Two regions of constant $\partial \ln i_{anodic}/\partial V$ for a given substrate were observed. The catalytic activity of the substrates in acid solution above about 1.4v (*vs.* N.H.E.) was $i_{Pt} < i_{Pt\text{-}Rh} < i_{Rh} < i_{Ir}$. On the anodic side, the alloy substrate tends to behave as Rh, on the cathodic side as Pt. Time decay behavior was conventional except for the alloy surface, where the decay from the anodic side behavior resembled that on Pt. The stoichiometric number on Rh, Ir, and Pt-Rh was about 2. Rate-determining steps have been determined unambiguously by the criteria mentioned because of the existence and helpful diagnostic nature of two distinct values for $\partial \ln i/\partial V$ on the anodic side, and because of the availability of stoichiometric numbers. After anodic polarization, Pt-Rh electrodes behave as if the substrate were an individual area of Pt and Rh oxides. A model which rationalizes this deduction is suggested.

Recently, the situation concerning the mechanism of oxygen dissolution and evolution on platinum electrodes has been the subject of increased study (1-30). The desire for enhanced electrocatalysis, and hence efficiency and power in electrochemical converters, is the origin of much of this work, but it cannot be fulfilled easily if there is not comprehensive knowledge of the mechanism of the reaction on a sufficient number of electrode catalysts. Consequently, in this paper, a study is reported of the oxygen electrode reactions on rhodium, iridium, and on a platinum-rhodium alloy in acid and in alkaline solutions. Data on the kinetics of O_2 reaction on these electrodes are scarce (30-32).

Experimental

Experiments were carried out in highly purified acid and alkaline solutions. Since the experimental procedure in this work was basically the same as described in a previous publication (10), it is given here only briefly.

Cell, solution, and chemicals.—An all-glass cell with three compartments separated by stopcocks used in these experiments was previously described (1, 9, 10).

Oxygen, which was bubbled through the test and the counter electrode compartments of the cell, was purified by passing through a purification train (10).

Solutions were prepared from conductivity water directly redistilled into the cell which had already been cleaned by acids and rinsed with conductivity water (see below). A known amount of perchloric acid, which was twice recrystallized in an auxiliary vessel (10), was introduced along the closed glass tubing system (including the measuring buret) into the cell. Concentration of the solution was adjusted to 1*N* $HClO_4$ by redistilling more conductivity water into the cell. The solution was further purified by anodic pre-electrolysis for about 20 hr or more at a c.d. (current density) of 1 ma/cm^2 on an auxiliary electrode of 4 cm^2.

Alkaline solutions were made from Baker Analyzed Reagent Grade potassium hydroxide. Concentration was adjusted to 1*N* KOH. Alkaline solutions were anodically pre-electrolyzed longer than the acid.

Rh and Ir, and Pt-Rh alloy in the form of wires were obtained from A. D. Mackay, Inc. Alloy composition was 40 at. % Rh.

Electrode treatment.—Wire electrodes (diameter 0.5 mm) of known geometrical area (~0.50 cm^2) were sealed to a true bore ground glass tubing fitting the bore on the cap of the test electrode compartment of the cell. In order to ensure a leak-proof seal, one end of the test wire is spot welded to a narrow (~1 mm), thin (0.001 mm) platinum foil (length about 5 mm), the other end of which was spot welded to a piece of platinum wire (d $\approx$ 0.5 mm or less) serving for contact. The platinum foil with the welded portions of the test electrode and of the contact wire are sealed into a glass bead which is then joined to a true bore ground glass tube.

Electrode pretreatment includes washing with organic solvents, chromic-sulfuric, and nitric sulfuric acid, and finally thoroughly with conductivity water.[2] After the electrode was introduced into the test electrode compartment which itself was washed with acids and conductivity water, it was washed once again inside the cell in freshly redistilled conductivity water. The cell was all the time under slight (~5 -10 mm of H_2O) overpressure of purified O_2

[1] Present address: Hooker Chemical Corporation, Niagara Falls, New York.

[2] Electrodes treated in different ways (10) yielded the same results.

Measurements.—The electrical circuits were described elsewhere (33).

After an electrode had been anodized with 10^{-3} amp/cm^2 for 20 min, anodic Tafel lines were taken by reducing c.d. in steps of half decade. Once the lowest c.d. was reached, anodic lines were retraced by increasing c.d. In the range of the c.d. usually studied (10^{-8} to 10^{-2} amp/cm^2), bubbling of oxygen through the test electrode compartment had no effect on potential. Bubbling caused the potential to decrease (10) only at current densities less than 10^{-8} amp/cm^2, and for that reason oxygen bubbling was disconnected for measurements at lower ($<10^{-8}$ amp/cm^2) c.d. Cathodic lines were obtained on electrodes which had been first anodized, and then a constant cathodic current was applied. Steady state was observed as a plateau on a recorder. At current density of 10^{-4} amp/cm^2, the plateau established in about 1 sec, after which time the potential changed less than 10 mv/min in the next few minutes. Readings were taken at the initial part of the plateau (*e.g.*, for this c.d. after about 5 sec). At lower c.d., steady-state potentials are more stable, and readings are taken at correspondingly longer times. This change of the potential with time at high cathodic c.d. was interpreted as being due to the gradual (but far from complete) reduction of oxides. It is now established (34) that when a Pt electrode, for instance, is reduced, reduction of O_2 proceeds along a path different from that on the oxide covered electrode. Fast measurements at the highest cathodic c.d. used in the present work ($\sim 10^{-4}$ amp/cm^2) are taken so that the effect of the gradual reduction of oxide (which at the potential of the measurements proceeds at a far lesser rate than the reduction of O_2) is minimized.

Coverage with oxygen-containing films on potentiostated electrodes was determined by cathodic reduction with a constant current. Electrodes were potentiostated for 1 min at a given potential after which the potentiostating circuit was broken and a constant ($\sim$30 ma/cm^2) cathodic current was applied immediately (33) ($\sim 10^{-5}$ sec). The change of potential with time during the cathodic pulse was followed on an oscilloscope. All experiments were carried out in the oxygen saturated solutions (10).

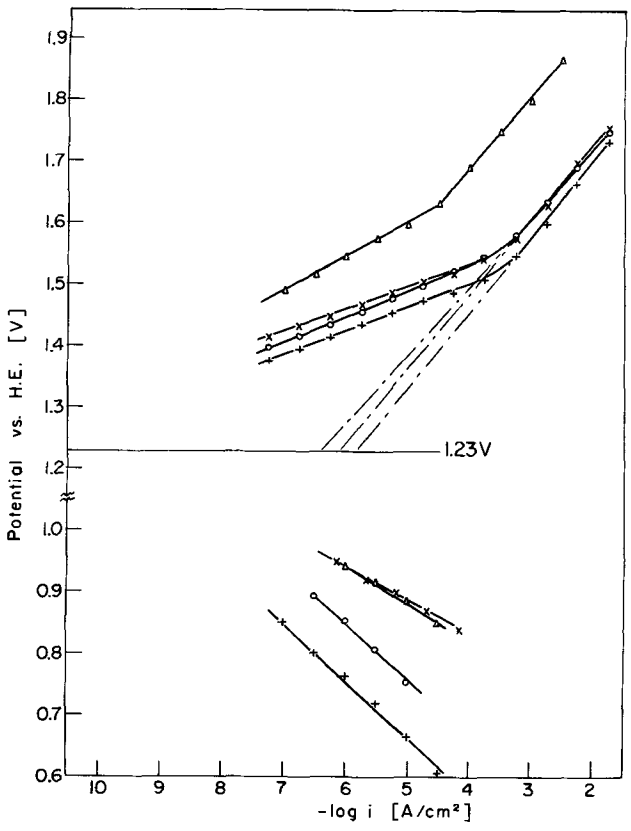

Fig. 2. *V*-log *i* plots for Rh(○), Ir (+), and Pt-(40 at. %) Rh (x) alloy electrodes in 1*N* KOH. Data (10) on Pt (△) are included.

Results

Potential current density relations.—Rh and Ir, and Pt-Rh alloy electrodes, in acid and in alkaline solutions, show two distinct linear *V*-log *i* anodic regions with different slopes. Transition from one region to another is rather sharp; it occurs in less than 1 unit of log *i*. On the cathodic side, only one linear region on each of these electrodes was observed, except for Rh in acid solution where, at lower c.d., another linear region appears to exist. In Fig. 1 and 2, these relations are shown for 1*N* $HClO_4$ and 1*N* KOH solutions, respectively; data are summarized in Table I. In these figures and in Table I data (10) for Pt are included for comparison.

At high anodic η, both in acid and in alkaline, $\partial V/\partial \ln i \simeq 2RT/\mathbf{F}$ for all electrodes. At low η, it is either close to $2RT/3\mathbf{F}$, as for Ir in both solutions and for Rh and Pt-Rh in alkaline, or to $RT/\mathbf{F}$, as for Rh and for Pt-Rh in acid (and for Pt in alkaline) solutions. On the cathodic side, $\partial V/\partial \ln i$ approach the ideal $2RT/\mathbf{F}$ on all electrodes except for Pt-Rh, and Pt in alkaline solution ($\sim RT/\mathbf{F}$). On Rh in acid solution, in addition to the $2RT/\mathbf{F}$ slope, a second slope close to the ideal $RT/\mathbf{F}$ appears at lower cathodic η.

The change of anodic slopes in acid solution[3] occurs at a constant current density ($\sim 10^{-4}$ amp/cm^{-2}) rather than at a constant η. In alkaline, in contrast to the acid case, *V*-ln *i* curves (almost) overlap for all electrodes except for Pt, which behaves more like Rh or Pt-Rh in acid solution. Ir in acid and in alkaline solution has the same η-ln *i* relation in contrast to all other electrodes.

[3] Including also Pt in KOH.

* At current densities below 10^{-7} amp/cm^2.
** From cathodic Tafel slope at low η.
*** Calculated with the cathodic slope at high η.

At any given potential above about 1.4v (*vs.* H.E.), the activity in acid solution is in the order

$$i_{Pt} < i_{Pt\text{-}Rh} < i_{Rh} < i_{Ir} \qquad [1]$$

Similar trend holds also in alkaline, although, at higher η, alloy electrodes almost overlap with Rh.

At low c.d. ($<10^{-8}$ amp/cm^2), Tafel lines of Rh and Ir electrodes often tend to deviate from linearity, and η approaches[4] (not shown in Fig. 1 and 2) a rest potential between 1.25 and 1.45v (*vs.* H.E.). These potentials probably correspond to the mixed potential of an oxide reaction with the reversible oxygen reaction.

When the experiments were carried out on Pt-Rh alloy electrodes in highly purified acid solution below about 10^{-7} amp/cm^2, the Tafel line appears to reassume the slope of $2RT/F$ (Fig. 3).

Reproducibility of results.—Anodic V-ln i curves are well reproduced at current densities above about 10^{-7} amp/cm^2. Positions and slopes of anodic Tafel lines above 10^{-7} amp/cm^2 were not affected by the rest potentials established at zero c.d. At lower c.d. ($<10^{-8}$ amp/cm^2) it was often difficult to reproduce results. Cathodic lines are, in general, less reproducible than anodic lines. The degree of reproducibility depends on the time an electrode was kept at a potential below about 1v (*vs.* H.E.). The longer the time and the lower the potential, the poorer was the reproducibility. This is attributed to the change on the electrode surface due to the partial reduction of the surface oxides below certain potential. On an oxide free electrode surface, the mechanism and rates for O_2 reduction are, in general, different than on oxide covered electrode surface (34). This is illustrated in the case of prereduced and preanodized Rh electrodes in Fig. 4. With the present technique of measurement [fast measurement on preanodized electrodes (10)] dissolution was certain to occur on the same type of electrode surface as the evolution, namely, on oxide covered electrodes. For this reason, current density range on the cathodic side over which a linear relation was established is shorter than on the anodic side.

Exchange current densities.—For Ir (and Pt), both in acid and in alkaline solution, and for Rh and Pt-Rh alloy in alkaline solutions, cathodic and anodic (at low c.d.) Tafel lines when extrapolated intercept close to 1.23v *vs.* H.E. (±0.035v). For Rh and Pt-Rh alloy in acid, however, cathodic line with $\partial V/\partial \ln i \approx 2RT/F$ intercepts $\eta = 0$ axis at $i_o \approx 6 \cdot 10^{-10}$ and 10^{-9} amp/cm^2, respectively, while the anodic lines (at low η) intercepts this axis at about $3 \cdot 10^{-11}$ amp/cm^2 for both electrodes. If experimental points on Rh at low cathodic η are considered only, cathodic line with slope corresponding to RT/F extrapolates to $\eta = 0$ at $i_o = 10^{-11}$ amp/cm^2, hence close to the point where the anodic branch intercepts the axis (3.10^{-11} amp/cm^2). This appears to justify the interpretation of the experimental points on Rh in acid at low cathodic η in terms of a linear V-log i with $\partial V/\partial \ln i \approx RT/F$. Similarly, in acid solution extrapolation of the anodic Tafel line of Pt-Rh alloy electrode from the lowest

[4] This is particularly so if an electrode was anodized for longer (30 min) time at high (10^{-2} amp/cm^2) c.d.

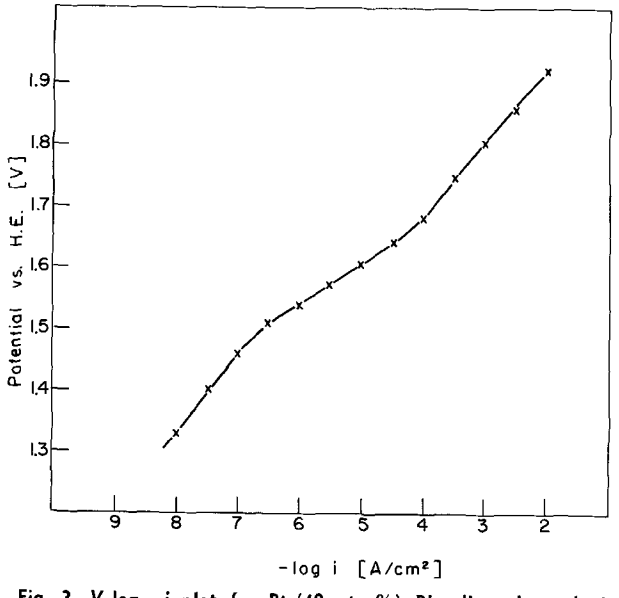

Fig. 3. V-log i plot for Pt-(40 at. %) Rh alloy electrode in highly purified acid (1N $HClO_4$) solution. At lowest current density additional linear relationship appears with the slope close to $2RT/F$ (compare with Fig. 1).

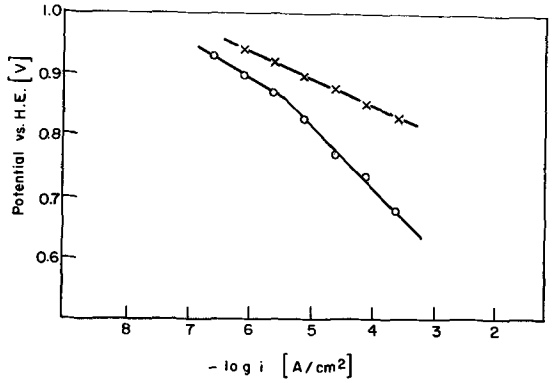

Fig. 4. V-log i plot for O_2 dissolution on Rh electrodes in 1N $HClO_4$. (○): preanodized electrode; (x) prereduced electrode by potentiostating at 0.2v (*vs.* H.E.) for 20 sec. Different mechanisms are operative on these electrodes.

Table II. Idealized stoichiometric numbers and Tafel slopes

Electrode		Anodic		Cathodic		Stoichiometric number	
		low η	high η	low η	high η		
Rh	Acid	RT/F	$2RT/F$	(RT/F)	$2RT/F$	(2)**	2.5***
	Alkaline	$2RT/3F$	$2RT/F$	$2RT/F$	—	2

	Alkaline	$2RT/3F$	$2RT/F$	RT/F	—	1-2	
Pt	Acid	$2RT/F$	—	$2RT/F$	—	4	
	Alkaline	RT/F	$2RT/F$	RT/F	—	2	

* At the lowest measured current densities.
** On the basis of cathodic slope at low η (RT/F).
*** On the basis of cathodic slope at high η ($2RT/F$).

current densities (Fig. 3) leads to the exchange c.d. of 10^{-9} amp/cm^2, in agreement with that extrapolated from the cathodic side.

The exchange c.d. obtained by extrapolation of linear Tafel regions both at low and at high η's are given in Table I.

Open-circuit potential decay.—Plots of potential decay after anodic polarization in acid solution are shown in Fig. 5 for times longer than 1 sec.[5] Similar plots were obtained for alkaline. Data on $\partial\eta/\partial \ln t$ are summarized in Table I. Decay potential data agree with $\partial V/\partial \ln i$ data, except for Pt-Rh alloy in acid solution with $\partial V/\partial \ln t$ being higher (average 95 mv) than $\partial V/\partial \ln i$ ($\simeq RT/F$). However, at the lowest potentials, $dV/d \ln t$ for the alloy corresponds closely to $2RT/F$.

Using these potential decay data and those from V-ln i curves, idealized diagnostic criteria are summarized in Table II.

Stoichiometric number.—The stoichiometric numbers, calculated by the equation (35)

$$\nu = \frac{n\mathbf{F}}{RT}\left[\frac{1}{b_a} - \frac{1}{b_c}\right]^{-1} \qquad [2]$$

[5] Because of the low exchange c.d., the electrodes are still in the linear region.

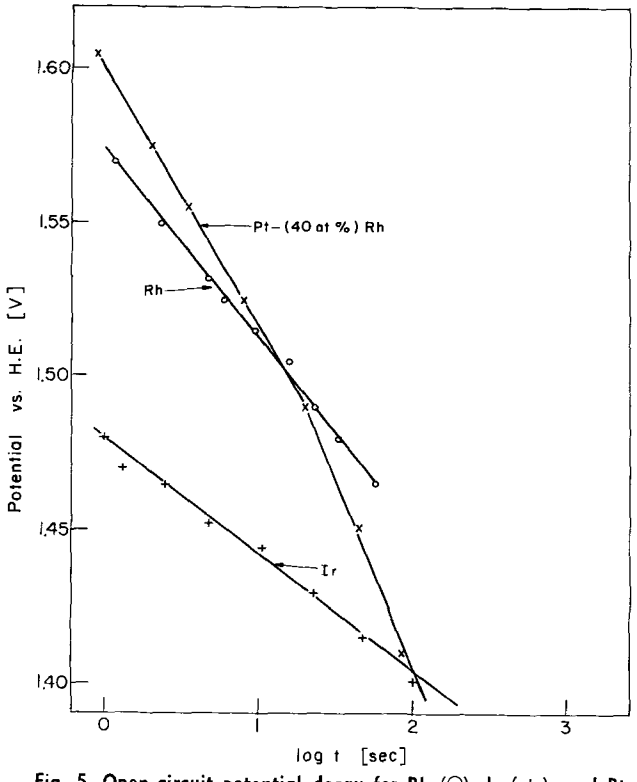

Fig. 5. Open-circuit potential decay for Rh (○), Ir (+), and Pt-(40 at. %) Rh alloy (x) electrodes in 1N $HClO_4$. On the Pt-Rh alloy electrode at low potentials slope increases to about 115 mv.

where b_a and b_c are anodic and cathodic Tafel slopes, respectively, are given in Table I. Only b_a's at low anodic η were used. For Rh in acid, η was calculated with both cathodic slopes ($RT/\mathbf{F}$ at low, and $2RT/\mathbf{F}$ at high η).

Coverage by oxygen-containing film.—Galvanostatic cathodic transients of Rh and Ir electrodes, after potentiostating in acid solution at a potential above 1v (*vs.* H.E.), differ significantly between themselves (Fig. 6). Ir electrode shows a prominent "flat" region in the V-t transients at relatively high potentials. In alkaline solutions, transients on Rh and Ir are much alike and are similar to that of Ir in acid solution.

A similar dependence exists of coverage by oxygen containing species on the potential (at which electrodes were potentiostated for 2 min) for both Rh and

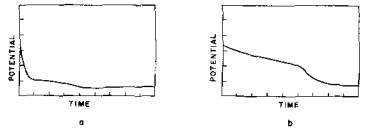

Fig. 6. Typical constant current transients in reduction of oxides on Rh (a) and on Ir (b) electrodes. Electrodes were potentiostated at 1.4v (vs. H.E.) in 1N $HClO_4$. Reduction current density 30 ma/cm^2; time scale 20 ms/cm; potential scale 0.5 v/cm.

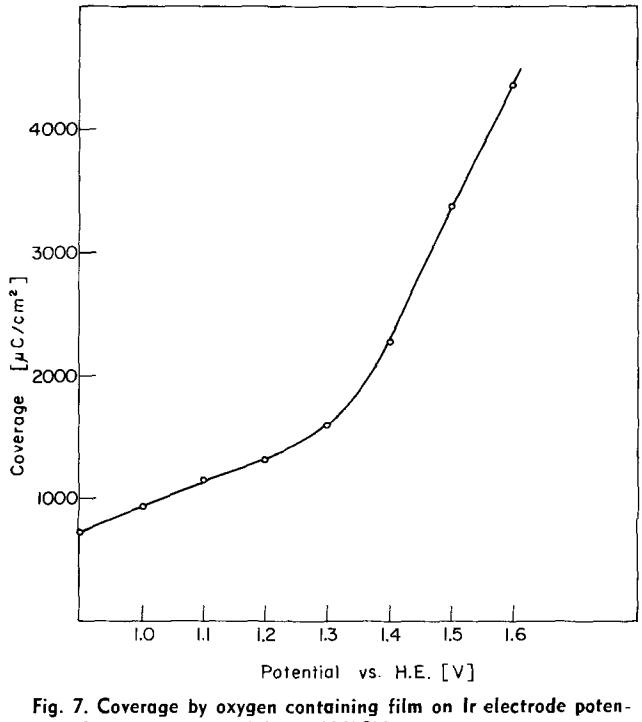

Fig. 7. Coverage by oxygen containing film on Ir electrode potentiostated at various potentials in 1N $HClO_4$.

Ir electrodes in acid or in alkaline solutions. In Fig. 7, the relation for Ir electrode in $HClO_4$ is shown. Two distinct and to a first approximation linear regions are apparent. They intercept at about 1.3v (*vs.* H.E.).

Some irreproducibility in coverage measurements was observed, particularly if an electrode was used for some time, in which case, the electrode, for the same potential, has a higher coverage than it had initially. This was attributed to gradual roughening of the electrodes in successive anodic and cathodic pulsing. New electrodes were used for these measurements.

Discussion

Mechanism on Ir *in acid and alkaline solutions.*— The intercepts of the extrapolated cathodic and anodic Tafel line at low η, which are close to 1.23v (*vs.* H.E.), show that the mechanisms for the over-all reaction

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad [3a]$$

for acid, or

$$4\,OH^- \rightarrow O_2 + 2H_2O + 4e^- \quad [3b]$$

for alkaline solution, are the same both in evolution and in dissolution. $\partial V/\partial \ln i$ of $2RT/3F$ at low anodic, and $2RT/F$ at cathodic η's, imply[6] that the rate of the over-all reaction (3) is controlled by an electrochemical step which occurs twice ($\nu = 2$) while the over-all reaction occurs once.[7] For the anodic direction of the reaction, two charge transfers precede the rate-controlling step.[7] Three reaction paths, which satisfy this requirement are given in Table III. They are paths A, B, and C. Path A is the "electrochemical oxide" path of Bockris (36), path B was recently suggested by the present authors as a possible path for O_2 reaction on Pt electrodes in alkaline solutions (10), and path C is that given by Krasilshchikov (37) for the same reaction on Ni electrodes. For path A, the second step, and for paths B and C, the third step in the anodic direction would be rate-controlling.

High value of $\partial V/\partial \ln i$ at high anodic η's ($\sim 2RT/F$) can be explained by either of these three paths. Two possibilities exist. First, at high anodic η, coverage by intermediates becomes high, the result of which is that for the same path and the rate-controlling step potential current density relationship changes and second, higher slope, appears at higher η's. This case was discussed first by Bockris (36) and more recently by the present authors (10). The second possibility is that for the same path the rate-controlling step at high anodic η's changes, and the first step (in either of these paths) becomes rate-controlling (10).

*p*H dependence of overpotential in acid solution could discriminate between the electrochemical path (A) and the other two (B and C). $\partial\eta/\partial$ *p*H at low and at high η's is positive for the former and negative for the latter two (see Table III). No such distinctions could be made in alkaline solution. For the electrochemical oxide path, the *p*H dependence of η for each step reverses its sign when the solution changes from acid to alkaline. This, and the fact that for Ir,

[6] Langmuirian type of adsorption assumed [cf. ref. (10)].

[7] This can be shown using Eq. [4].

Table IV. Summary of the mechanisms of O_2 reaction on various electrodes

		Anodic low η	Anodic high η	Cathodic low η	Cathodic high η

	Alkaline	A(2)	A(2) or A(1)	B(2) or D(2)	—
Pt (10)	Acid	1(1), 3(1) or 4(1)**	—	1(1), 3(1) or 4(1)**	—
	Alkaline	B(2) or D(2)	B(1) or D(1)	B(2) or D(2)	—

* At lowest overpotential the mechanism is 1(1), 3(1) or 4(1).
** These are the "oxide" path, "hydrogen peroxide" path, or "metal peroxide" path, respectively. Symbolism here corresponds to that in ref. (10).

V-log i curves overlap in acid and in alkaline solutions (and, hence, over-all $\partial\eta/\partial$ pH = 0) would favor the electrochemical oxide path over the other two. However, it is possible that the path in acid is different from the path in alkaline solution.[8]

Mechanism on Rh *in alkaline solution.*—Rh in alkaline solution behaves in the same way as the Ir electrode. Correspondingly, the discussion for Ir holds also for Rh. In Table IV, mechanisms for each electrode are tabulated.

Mechanisms on Rh *electrode in acid solution.*—Observed $\partial V/\partial \ln i$ close to $RT/\mathbf{F}$ at low anodic η's required a chemical rate-controlling step which follows an electrochemical step(s). This can be shown with the Eq. [4] (10, 18, 39, 40).

$$\frac{\partial V}{\partial \ln i} = \frac{RT}{\mathbf{F}} \left[\beta_k n_k + \sum_{i=1}^{k-1} \frac{\nu_i n_i}{\nu_k} \right]^{-1} \qquad [4]$$

where ν_i and ν_k are "stoichiometric numbers" (11),[9] and n_i and n_k are the numbers of electrons transferred in the single step i, and in the rate-controlling step k, respectively. Thus,[10] is $n_k = 1$ (a rate-controlling step involving charge transfer), and to satisfy the condition $\partial V/\partial \ln i = RT/\mathbf{F}$ at low anodic η's, Σ is ½. Two possibilities might be thought to satisfy this requirement: $\nu_i = 2$ and $\nu_k = 4$; or $\nu_i = 1$ and $\nu_k = 2$. If $\nu_i = 1$ and $\nu_k = 2$, only one electron is transferred before the rate-controlling step, but two are needed to form (at least) two identical intermediates required as reactants for the rate-controlling step ($\nu_k = 2$). If $\nu_i = 2$ and $\nu_k = 4$, then six electrons would be transferred in the over-all reaction. In general, an electrochemical rate-controlling step in O_2 evolution with the parameters given is therefore not possible.

With $n_k = 0$ (a chemical rate-controlling step), ν_k could be any integer from 1 to 4, but must be equal to the total number of electrons transferred before the rate-controlling step ($= \sum_{i=1}^{k-1} \nu_i n_i$). Four paths which satisfy this condition, B, C, D, and E, are given in Table III. Path D is the alkaline path of Hoar (2), and E was introduced by the present authors in a previous publication (10). The second step in this anodic direction in all these paths would be rate-controlling for the reaction.

With the anodic $\partial V/\partial \ln i$ of $RT/\mathbf{F}$ (and, hence, $n_k = 0$, and $\sum_{i=1}^{k-1} \nu_i n_i = \nu_k$), and, since in this case (see above) $\sum_{i=1}^{k-1} \nu_i n_i$ is equal to the number of electrons transferred before the (chemical) rate-controlling step, the number of electrons transferred before the (same) rate-controlling step in O_2 dissolution is $n - \nu_k$, where n is the number of electrons for the over-all reaction. It follows from Eq. [4] that, for this cathodic reaction, $n - \nu_k = \nu_k\, \alpha_{\text{cath.}}$, where $\alpha_{\text{cath.}}$ is the transfer coefficient for the cathodic direction of the reaction. $\alpha_{\text{cath.}}$ in this relationship cannot have value of ½, and, hence, (for the given conditions: anodic $\partial V/\partial \ln i = RT/\mathbf{F}$) cathodic slope of $2RT/\mathbf{F}$ at low η's must be excluded.

The observed value of $2RT/\mathbf{F}$ on the cathodic side must, therefore, reflect the change of the Tafel slope in the cathodic direction with increased η. This is supported by the fact that the observed Tafel line with $2RT/\mathbf{F}$ intercepts the $\eta = 0$ axis at c.d. higher than does the anodic Tafel line. Short and apparently linear range of V *vs.* ln i observed on the cathodic V-log i curves at low η's does intercept in extrapolation the anodic branch close to $\eta = 0$ axis. Hence, this short region of V-ln i at low η's represents a true linear relation of V *vs.* log i. Its slope is close to $RT/\mathbf{F}$. This is a permissible cathodic slope for the condition $(\partial V/\partial \ln i)_{\text{anodic}} \simeq RT/\mathbf{F}$, the only other permissible slope being $RT/3\mathbf{F}$. With the latter slope, the extrapolated exchange c.d. would be far less than that obtained from the anodic extrapolation, and, hence, this slope is impossible.

With the cathodic slope at low η's of $RT/\mathbf{F}$, the stoichiometric number $\nu_k = 2$ and the possible paths reduce to B, C, and D. It remains, however, to explain the appearance of the $2RT/\mathbf{F}$ slope of high cathodic η. The change of the slope from $RT/\mathbf{F}$ at low η's, to $2RT/\mathbf{F}$ at high cathodic η's, is most probably due to the change in the rate-controlling step with potential. Path D can now be eliminated, as there is no $2RT/\mathbf{F}$ cathodic slope required for high η (cf. Table III). For the remaining two paths, B and C, the third steps (in the anodic direction) are the only possible rate-controlling steps at high cathodic η. (The first three steps in these two paths differ only in the "hydration" of intermediates and are indistinguishable by present electrochemical criteria.)

Finally, the change of slope in the anodic V-ln i from approximately $RT/\mathbf{F}$ at low η, to $2RT/\mathbf{F}$ at high η, is due either to a change in mechanism from B(2)[11] to B(3), or from B(2) to B(1)[12] (see Table III). One point here favors the change in mechanism from the second to the first step. Extrapolation of the anodic Tafel line at high η gives the exchange current density of $3 \cdot 10^{-8}$ amp/cm^2. Extrapolation for the cathodic side at high η gives to the exchange current density of $6 \cdot 10^{-10}$ amp/cm^2. This shows different mechanisms at high anodic and at high cathodic η. Since on the cathodic side at high η the mechanism can be only B(3), at high anodic η it is B(1).

Mechanism on Pt-Rh *alloy electrodes.*—Pt-Rh alloy electrodes behave in a peculiar way. In acid solution, $\partial V/\partial \ln i$ of $RT/\mathbf{F}$ at low anodic η excludes $2RT/\mathbf{F}$ as a slope on the cathodic side. The reasoning for this conclusion is given in the discussion of Rh in acid solutions. However, in contrast to the behavior for Rh, plot of V-log i of the alloy does not show or indicate another cathodic slope at low η. The cathodic Tafel line intersects the $\eta = 0$ axis at higher values of (exchange) current density than does the anodic branch, and so it is possible that the linear V-ln i relationship with a slope of $RT/\mathbf{F}$ exists at still lower cathodic current densities. If so, the arguments advanced for the case of Rh in acid solution would hold here, too, and the mechanism would be (see Table III) either B(2) [or C(2)], at low anodic, or cathodic η, B(1) [or C(1)] at high anodic η, and B(3) [or C(3)] at high cathodic η.

In alkaline solution, the anodic slope at low η of $2RT/3\mathbf{F}$ excludes (the observed) cathodic slope of $RT/\mathbf{F}$. The only acceptable slopes are $2RT/5\mathbf{F}$ and $2RT/\mathbf{F}$. Almost the same exchange current densities are extrapolated from the anodic (10^{-12} amp/cm^2) and the cathodic ($3 \cdot 10^{-12}$ amp/cm^2) side. Were the cathodic slopes to be $2RT/5\mathbf{F}$ or $2RT/\mathbf{F}$, the extrapolated exchange current density from the cathodic side would be either lower or higher, respectively, than that extrapolated from the anodic side and, consequently, the latter two slopes are also impossible. This apparent inconsistency of the experimental results may be rationalized in the following way.

From Fig. 1 and 2, it can be seen that the reaction, both the oxidation to O_2 and the reduction to H_2O, follows the kinetic characteristics corresponding to the individual metals, whichever has the faster

[8] Recently, Wong (38) has shown that for O_2 evolution on Ir electrodes in acid solution $(\partial\eta/\partial \text{pH})_i \approx +20$ mv at low η's, and about +40 mv at high η's. These results are consistent with the electrochemical path.

[9] ν_i is the number of times the step i occurs for one act of the over-all reaction; it is here called a stoichiometric number although, formally, this term applies only to the rate-controlling step.

[10] In this analysis, it is taken that no more than one charge can be transferred in any single reaction step.

[11] B(2) means the second step in the anodic direction of the path B is rate-controlling.

[12] Since the first three steps in paths B and C are indistinguishable by electrochemical means only path B is considered here.

rate. The likely interpretation of this is that the homogeneous alloy substrate has become a heterogeneous mixture of a platinum oxide and a rhodium oxide.[13] Although the reaction takes place on both oxides, the over-all rate is determined by the rate for that oxide on which the reaction at the given potential proceeds faster. Thus, on the anodic side, the reaction at higher potentials occurs predominantly on rhodium oxides. At lowest anodic η's in acid solution, Tafel line of the alloy (Fig. 3) deviates toward lower potentials. This is exactly what would be expected on the basis of the proposed hypothesis: the rate of the over-all reaction at these lowest overpotentials is determined by the rate on platinum oxides (cf. Fig. 1, 2, and 3). The cathodic reaction occurs in alkaline solution (Fig. 2) predominantly on Pt oxides, on which the rate is faster than on Rh oxides. In acid, in the potential range examined, both oxides are equally active, and the reaction occurs on both of them. At the lowest cathodic η (in acid solution), Tafel line for alloy does not show additional slope as does the line for Rh. This additional slope on alloy electrodes is not expected since, according to the advanced hypothesis, the rate of the reaction at low cathodic η (in acid solutions) would be controlled by the rate with which the reaction occurs on a Pt electrode.

A reason for this situation may be suggested tentatively as follows. When a platinum-rhodium alloy surface undergoes anodic oxidation, it is probable that the platinum and the rhodium atoms alternatively (since there is almost an equal atomic composition of the alloy) leave the kink sites and diffuse across the surface of the metal. Nucleation at individual patches containing platinum and oxygen and those containing rhodium and oxygen must occur, respectively, on the surface, to form platinum oxides and rhodium oxides effectively. On each of these oxides, the reaction mechanism and the rates of the reaction may be different. Such an electrode would behave as a mixed electrode,[14] and the over-all rate of the reaction would be given by

$$i_a = F_A i_o^A \exp\left[\frac{\alpha_a{}^A F\eta}{RT}\right] + F_B i_o^B \exp\left[\frac{\alpha_a{}^B F\eta}{RT}\right] \quad [5]$$

where i_o^A and i_o^B are the exchange current densities for the corresponding oxide. F_A and F_B are the fractional surface areas of these oxides. Subscript a stands for anodic. Similar equation would hold for the cathodic reaction. If $\alpha_a{}^A = \alpha_a{}^B = \alpha_a$, the same linear dependence of V on ln i holds for both oxide phases, and the over-all reaction proceeds with the rate

$$i_a = [F_A i_o^A + F_B i_o^B] \exp\left[\frac{\alpha_a F\eta}{RT}\right] = (i_o)_{Ap} \exp\left[\frac{\alpha_a F\eta}{RT}\right] \quad [6]$$

where

$$(i_o)_{Ap} = F_A i_o^A + F_B i_o^B \quad [7]$$

is the apparent exchange current density. In general, one term in the sum (7) would be expected to be larger than the other, and the over-all rate of the reaction will be controlled by the rate of the reaction corresponding to one oxide. If $\alpha_a{}^A \neq \alpha_a{}^B$, the rate of the over-all reaction in different potential range may be controlled by the rate of different oxides. In general, if

$$i_o^A \exp\left[\frac{\alpha^A F\eta}{RT}\right] > i_o^B \exp\left[\frac{\alpha^B F\eta}{RT}\right] \quad [8]$$

the rate is controlled by the phase A.

Additional support for the hypothesis advanced to account for the behavior of Pt-Rh alloy electrode comes from the analysis of the open-circuit potential decay curve for the alloy. At lowest potentials, this curve for acid solution has a slope corresponding to $2RT/\mathbf{F}$ (cf. Fig. 5), as expected for a pure Pt electrode.

Hence, the behavior of Pt-Rh alloy electrodes, both in acid and in alkaline solutions, is fully accounted for by the advanced hypothesis. Appropriate mechanisms are given in Table IV.

Nature of electrode surfaces.—Cathodic transients on an Ir electrode after it was potentiostated at 1.4v for 2 min in acid solution show prominent "flat" region between two inflections at relatively high potentials. On Rh electrodes (acid solution) this region is far less prominent and the reduction occurs at higher overpotential than on Ir (Fig. 6). In alkaline solutions, transients of both Rh and Ir are almost identical and are similar to that of Ir in acid solution. If the potential at which an oxide is reduced is a measure of the exchange current density for oxide formation (or reduction), it appears that the oxides on Rh in alkaline and on Ir both in acid and in alkaline solutions behave similarly, but are different from that on Rh in acid solution. There is, hence, a correlation between the "type" of oxides on an electrode surface and the reaction mechanism for the oxygen evolution reaction.

High coverage values (Fig. 7) on all these electrodes at potentials above about 1v can only be accounted for if phase oxides form. The existence of phase oxides has been proved unambiguously by the ellipsometric technique on Pt electrodes potentiostated above 1v (*vs.* H.E. in the same solution) in acid solution (11). Phase oxide also forms in alkaline solution (41). It is expected, on this basis, that on an alloy electrode oxides also form.

At potentials below about 1v (*vs.* H.E.) oxides reduce and, hence, O_2 dissolution, in contrast to the evolution which always occurs on oxide covered electrodes, may occur either on oxide covered or oxide free electrode surfaces. Mechanisms, and hence activity at a given potential, may differ on oxide covered and on oxide free electrodes. This was already shown for Pt electrodes (34), and here it is illustrated on Rh electrodes in acid solutions (Fig. 4). In the present experiments, measurements have been conducted so that electrodes remained oxide covered in O_2 dissolution also.

In contrast to Pt electrodes, where oxide coverage increases linearly with potential up to about 1.7v with no change of slope (5, 10, 11) on Rh, and on Ir electrodes (Fig. 7), initially (from 1 to about 1.35v) oxide coverages increase slower with potential, but above about 1.35v, the coverage increases sharply with potential. The change in the slope is not, however, related to the change in the slope of V-ln i curves. The latter change occurs at potentials above 1.5v (at about 1.6v).

Conclusions

The present paper is an example of a situation in which the mechanism criteria of the steady-state Tafel line slope may be applied to give mechanism information. The effectiveness of the criteria in this instance is associated with the presence of knowledge of the stoichiometric number and the existence in the experimental data of changes of slope at certain potentials. The slope values are in all cases (*a*) constant and (*b*) simply related to $RT/\mathbf{F}$.

The mechanisms discussed in this paper (summarized in Table IV) are derived largely from the criteria: Tafel slopes in cathodic and anodic direction; stoichiometric numbers; pH dependence of rate; and some knowledge concerning the nature of the substrate. Mechanism deductions in this manner can be made only when the exchange current densities are sufficiently low and when the change of the substrate with potential and time is negligible in the potential region of the kinetic analysis.

[13] The electrodes under conditions at which the reactions occur are covered with a layer of a few angstroms of oxides (10).

[14] Mixed electrodes here should not be confused with polyelectrodes at which two or more different reactions occur simultaneously to establish a mixed potential.

Some recent papers use the term "mechanism" to apply to knowledge of the number of electrons used in the over-all reaction. It is desired to stress that this is only a preliminary stage of a mechanism analysis; the path and rate-determining step are the goal. In so far as they can be known, or at least number of alternative paths and rate-determining steps reduced, so is the contribution of the work to the electrocatalysis situation for the reaction increased.

The Application of Irreversible Thermodynamics to the Thermogalvanic Behavior of Copper-Copper Sulfate Systems

Paul D. Miller, Arch B. Tripler, Jr., and J. J. Ward

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Experiments with the thermocells $Cu(T_2)/CuSO_4(T_2)/CuSO_4$ Bridge/ $CuSO_4$ (25°C)/Cu (25°C) are described. The cell potentials were quite dependent on the *p*H of the 0.01*M* solution. Experimental results were in fairly good agreement with data obtained from a physicochemical model using procedures of irreversible thermodynamics. Procedures used to calculate ionic entropy values for copper are described.

Thermogalvanic corrosion is one form of metal deterioration of great practical importance which has not been extensively studied experimentally. The action is one in which an area of a metal surface wet by an electrolyte becomes anodic (corrodes) while another becomes cathodic as a result of a temperature difference. Thus, the different electrode reactions result in a potential difference which can be measured.

It is possible to treat such nonequilibrium systems by the techniques of the Onsager thermodynamics of irreversible processes. The present paper illustrates the use of irreversible thermodynamics to interpret the experimental data obtained from a thermogalvanic cell (thermocell) composed of copper immersed in 0.01*M* copper sulfate. The treatment relies quite strongly on the theoretical approach suggested by two fairly recent papers by de Bethune (1, 2).

The cold copper electrode is anodic in the cell being discussed while the hot one is cathodic. On the other hand, copper, as well as most other metals studied, is anodic when it forms the hot section of a thermocell with sodium chloride as electrolyte. Thus, it can be seen that metal dissolution can occur at

either hot or cold areas depending on the system. The treatment which follows, however, is devoted entirely to the copper sulfate thermocell.

Experimental Work

Thermogalvanic cells and circuitry.—Figure 1 is a schematic diagram of the apparatus and circuitry used in this study. The basic portion of the experimental setup consists of two individually isothermal electrolytic half-cells operating at different temperatures and connected by a liquid bridge to form a thermal cell. Each half-cell consists of copper dipping into a copper sulfate solution. The cells are kept at the desired temperatures (left cell 25°-100°C, right cell 25°C) by suitable thermostatic equipment. The Pyrex containers hold about 750 ml of solution and are flanged at the top to fit covers containing four 24/40 standard taper openings. Electrodes, gas sparge tubes, connecting bridge, and thermometers are introduced through these openings. The connecting bridge is made from 14 mm diameter Pyrex tubing.

The metal specimens are solid cylinders about 25 cm^2 in area which have been drilled out and tapped on the upper end. A threaded rod of the same material is screwed into the specimen and is protected from contact with the solution by a glass tube surrounding it. Leakage of the solution is prevented by a Teflon washer placed between the glass tube and the top of the metal cylinder. Pressure is applied on the seal by means of a nut at the top end of the metal rod which extends beyond the glass tube. Copper wires were used in all connections and circuitry.

High-purity copper, 99.999+, was used in most of the experiments. Oxygen-free high-conductivity (OFHC), 99.96% copper was used in some instances. Reagent grade copper sulfate was used for preparing the solutions.

Cell potentials were read primarily with a L&N type K-2 potentiometer using an electronic ammeter-voltmeter having a high input resistance as a null indicator. Some readings were made with an electrometer with an input impedance of 10^{13} ohms. The zero resistance ammeter was not used when thermogalvanic potentials were being read. That is, cell currents were measured in separate experiments.

Hg-Hg_2SO_4 reference electrodes were prepared from triply distilled mercury and mercurous sulfate. Hg_2SO_4 was wetted with the $CuSO_4$ solution. The readings with reference electrodes were made primarily to furnish data under isothermal conditions.

Thermogalvanic potential measurements.—Thermogalvanic potentials of copper in 0.01, 0.1, and 1.0*M* copper sulfate solutions were measured over a ΔT of 70°C. It was found that in the most dilute solution the potentials were dependent on the solution *p*H. Results

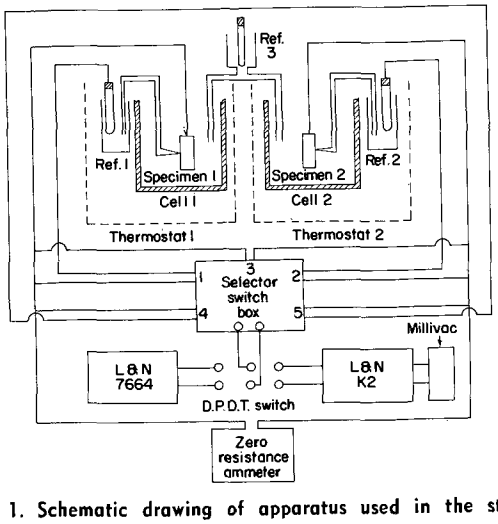

Fig. 1. Schematic drawing of apparatus used in the study of thermogalvanic potentials and currents.

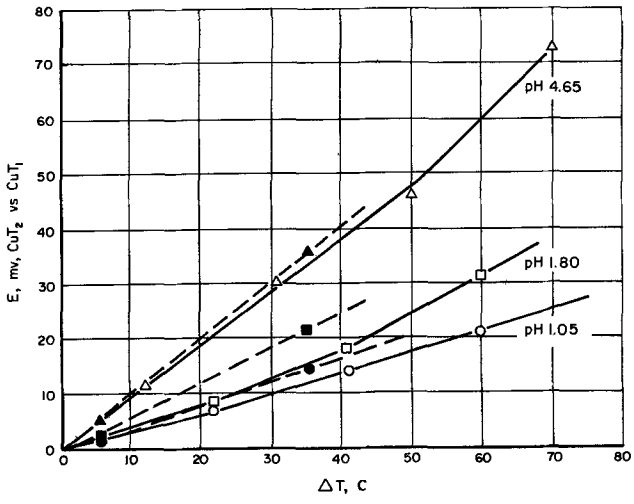

Fig. 2. Effect of *p*H on the thermogalvanic potentials of copper in 0.01M $CuSO_4$. ——— and open points, experimental values; — — — and solid points, calculated values.

at three *p*H levels reached by additions of H_2SO_4 are illustrated in Fig. 2 for 0.01*M* solutions. Note that the slope of the line decreases with decreasing *p*H. The data obtained in 0.1 and 1.0*M* solutions at all *p*H values could be expressed by lines somewhere in the area near the line for *p*H 4.65 in Fig. 2.

In all instances the cold electrode was negative (anodic) in these thermal cells. The reproducibility of voltage readings was sometimes good to only ±5 mv although frequently it was better than ±1 mv. Accordingly, it was assumed that the Soret effect in these cells was small.

Application of irreversible thermodynamics to copper-copper sulfate thermal cells.—A mathematical treatment for interpreting the data obtained from the experiments with thermogalvanic cells is given in the following paragraphs. The development is based largely on that presented by deBethune (1, 2). The thermal cell can be expressed by:

$$M(T_1)/\text{Electrode}(T_1)/\text{Electrolyte}(T_1)/$$
$$\text{Electrolyte}(T_2)/\text{Electrode}(T_2)/\text{Electrode}(T_1)/M(T_1) \quad [1]$$

The thermogalvanic potential of such a cell can be expressed by

$$\left(\frac{dE^*}{dT}\right)_{th} = \frac{S^*}{nF} \quad [2]$$

where $nF = 46.12$ mv/deg.

According to de Bethune, the transported entropy can be considered to be moved by a threefold mechanism according to the following equation

$$S^* = S^*_E + S^*_M - nS^*_{(\text{electrons})} \quad [3]$$

where the three terms on the right are defined as follows: (*i*) $S^*_E = Q^*_E/T$, called the entropy of electrochemical transport, results from the electrode reactions. (*ii*) $S^*_M = Q^*_M/T$, called the entropy of migration transport. This entropy comes from the migration of non-reversible ions which carry heat. A consideration of this term leads to the conclusion that it is required to satisfy the Onsager principle of microscopic reversibility (6). (*iii*) $nS^*_{(\text{electrons})}$, called the entropy of electron transfer. This entropy comes from the migration of electrons from the anode to the

cathode in the external circuit. Since this term is small it is neglected in all calculations.

The thermal temperature coefficient $(dE/dT)_{th}$ is defined as positive when the hot electrode is the (+) terminal of the cell.

Equation [2] was then used to calculate the thermal temperature coefficients so that a comparison could be made with experimental values derived from the slopes of the lines in Fig. 2 in the following manner.

The term S^*_E, entropy of electrochemical transport, in Eq. [3] depends basically on the reaction which takes place at the hot electrode. The experiments in the copper-copper sulfate system showed that copper was plated out on the hot electrode and that this electrode reads (+) on the electrometer. Accordingly the hot-electrode reaction can be expressed as

$$Cu^{++} + 2e \rightarrow Cu^{\circ} \qquad [4]$$

the reverse reaction takes place at the cold electrode. The entropy of electrochemical transport can then be expressed as

$$S^*_E = S^{\circ}_{Cu^{\circ}} - (\bar{S}_{Cu^{++}} + 2S^{\circ *}_{H^+}) \qquad [5]$$

where $S^{\circ}_{Cu^{\circ}}$ = entropy of metallic copper, $\bar{S}^{\circ}_{Cu^{++}}$ = partial molal entropy of transport for Cu^{++} ion, $2S^{\circ *}_{H^+}$ = standard ionic entropy of H^+ ion (introduced to correct term to standard state).

It can be seen that the proper placing (in hot or cold compartments) of reaction [4] is quite important since it helps to determine the sign of S^*.

The second term S^*_M, entropy of migration transport, is sometimes related to transference numbers for the ions involved as in

$$S^*_M = t_- S^*_M (SO_{4^=}) - t_+ S^*_M (Cu^{++}) \qquad [6]$$

However, in the system under discussion it was found experimentally that the H^+ was quite important in the cell potentials. Furthermore the ionic mobility of this ion is much greater than for the sulfate ion. The proposed model therefore was selected to permit the transfer of entropy by the H^+ moving in the opposite direction as the copper ion. It should be noted that this transfer also satisfies the principle of microscopic reversibility. The equation expressing this concept is

$$S^*_M = 2S^*_{H^+} \qquad [7]$$

Three other possible explanations for the large effect of pH on thermogalvanic potential were also considered. These were: (*i*) ratio of HSO_4^-/SO_4^{--}, (*ii*) effect of Cu^+; (*iii*) the reaction of the copper ion with water to form a cupric oxide film and hydrogen ions.

Calculations showed that none of these explained the effect of pH on the potential. Therefore, the assumption that the hydrogen ion migration accounted for the change of thermogalvanic potential as the pH varied is quite reasonable.

It should also be mentioned that a model assuming transference of the sulfate ion to satisfy microscopic reversibility does not provide agreement between calculated and experimental values.

The over-all entropy summations can then be expressed as

$$S^* = S^{\circ}_{Cu^{\circ}} - (\bar{S}_{Cu^{++}} + 2S^{\circ *}_{H^+}) + 2S^*_{H^+} - 2S^*_{(electron)} \qquad [8]$$

As was mentioned before, the entropy contribution from the electron flow is small and is considered zero.

In Tables I and II the individual entropy contributions in Eq. [8] are listed separately for the systems at 30° and 60°C, respectively. Note in particular the large entropy contribution furnished by the H^+ ion. From these individual entropy contributions, the Peltier heat transferred from one compartment to the other can be calculated. This calculation was made by multiplying the temperature of the compartment by the entropy transferred to it, and the product is listed as TS^* in the table. The pH values and temperature are chosen to agree with experiments so that a direct comparison can be made between calculated and experimental results.

The entropy values for metallic copper (Cu°) were taken from Kelley (7). The tables also include the temperature coefficients $(dE/dT)_{th}$.

The calculated results required an entropy value for the partial molal entropy of the copper ion at 30° and 60°C. The values used are presented in Table III and are based on experimental results from Wetmore and Gordon (3). Their data were confirmed in this laboratory by isothermal cell measurements. In these experiments the potentials between copper and a $Hg\text{-}Hg_2SO_4$ reference electrode were measured under reversible conditions at 25° and 60°C in 0.01, 0.05, 0.1, and 1.0*M* solutions.

The model also requires the entropy of transport of H^+ at various pH values in 0.01*M* copper sulfate solution. These data were not available. An approximation of these values was obtained by calculating the entropy of transfer of the H^+ ion by a method similar to

Table I. Entropy and thermal temperature coefficient values for the copper-0.01 *M* copper sulfate thermogalvanic cell at 30°C

one described by de Bethune and co-workers (1). The results of these calculations for the entropy transfer of H^+ in the absence of Cu^{++} are given in Table IV. Results are based on the data presented by Bates and Bower (4) and Fales and Mudge (5).

Discussion of Results

The implications of the results of the research just described are brought out by a comparison of values calculated from theory with those obtained from experiment. The individual entropy terms, S^*, $(dE/dT)_{th}$, and TS^* can be compared in Tables I and II and also in Fig. 2. The solid points and dotted lines in this figure were obtained by calculating the thermogalvanic potentials assuming the hot electrode was at 30° or 60°C while the cold one was at 25°C and using Eq. [2]. The agreement between calculated and experimental values is very good over a range of temperature and at several pH values. Thus, the results confirm that the coupling of entropy terms as suggested by theory in Eq. [8]

$$S^* = S^\circ_{Cu^\circ} - (\bar{S}_{Cu^{++}} + 2S^\circ_{H^{+*}}) + 2S^*_{H^+} - 2S^*_{(electron)}$$

is reasonable. It is significant that this agreement has been reached for solutions greatly removed from ideality and that both cell polarity as defined by de Bethune and cell potential are essentially correct. Continuing studies have shown a similar agreement between theory and experiment for 0.1 and 1.0*M* copper sulfate solutions. The hydrogen ion plays a much less significant role in these more concentrated solutions.

The electrochemical model on which Eq. [8] is based predicts that copper is reduced at the hot electrode and oxidized at the cold one. Experiments carried out separately under conditions to permit large thermogalvanic currents to develop showed that metallic crystals of copper were indeed deposited at the hot electrode.

The work has also been carried over to the nickel-nickel sulfate system where the proper cell polarity was predicted by theory and fair agreement was obtained for the value of the thermogalvanic temperature coefficient for pure nickel electrodes in 0.1*M* nickel sulfate.

Attempts are currently being made to carry this type of analysis to the zinc-zinc sulfate system as well as to thermal cells in high conductivity water. Some progress has been made along these lines and final results could be the subject of a future paper.

Technical Notes

Charge-Discharge Mechanisms in Electrolytic Capacitors

Walter J. Bernard

Research and Development Center, Sprague Electric Company, North Adams, Massachusetts

The use of aluminum wet electrolytic capacitors as energy storage devices, as in the "photoflash" application, is dependent on the ability of the capacitor to tolerate a very large number of charge-discharge cycles without damage to its physical and electrical properties. Since the current within the capacitor is carried by an electrolyte subject to the laws of electrochemical change at the electrodes, some questions may be raised concerning the physical and chemical mechanisms operating within the capacitor.

The circuit shown in Fig. 1 is applicable to the process under discussion. The capacitor C is charged from the d-c source by closing S_1; S_1 is then opened and the capacitor is discharged through R by closing S_2. It is an observed fact that, for capacitors subject to this type of cycling, one must use etched aluminum cathode foil of large effective surface area or suffer loss of capacitance in the capacitor as a consequence of oxide formation at the cathode. Evolution of gas, as evidenced by pressure increase, may be encountered as well.

If one considers the electrochemical reactions which must occur on charge-discharge cycling, the consequences of nonetched foil use should be anticipated.

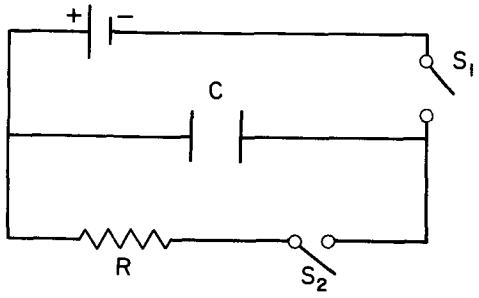

Fig. 1. Circuit for capacitor energy storage applications

During charging, a charge q, equal to C_AV, where C_A is the anode capacitance and V the voltage, is built up on the anode; an equivalent charge migrates to the cathode and brings about an electrochemical change. If the cathodic reaction is the expected one of reduction of hydrogen ion, then C_AV/F (F = 96,500 coulombs) equivalents of hydrogen must be generated at the cathode surface. On discharge of the anode, electron transfer from the solution to the aluminum cathode, and thence to the external circuit, can be achieved by the discharge of hydroxyl ion to produce either molecular oxygen or anodic aluminum oxide.[1]

These observations suggest that, under any circumstance, one would observe excessive gas evolution, cathode formation, and eventual electrolyte depletion. However, it is a fact that with a well-constructed capacitor of etched cathode design, it is possible to get in excess of 10^6 cycles of service without the occurrence of these predicted modes of failure. The following explanation is advanced to account for this behavior.

On charging the anode, hydrogen ions are first discharged on the cathode surface as hydrogen atoms, and then undergo combination to form molecular hydrogen. Each hydrogen atom is bound to the metal by surface valence forces and only combines with another hydrogen atom when its concentration becomes too large for a given metal surface. Although it is not known what the maximum concentration of atomic hydrogen would be on aluminum under any given set of conditions, it is not difficult to imagine that incomplete coverage could result since a relatively small amount of electrochemical change occurs during a single charging cycle of a capacitor. (For example, under the conditions described in the experimental part of this paper, it may be calculated that a full charge on the anode corresponds to the deposition of 2.3 x 10^{-8} equivalents of hydrogen at the negative electrode. For smooth foil cathodes the average surface density of hydrogen would then be approximately one atom for each seventy square angstroms, but for etched foil the density would be at least one order of magnitude less than this.) Therefore, if a capacitor plate is charged and hydrogen ions are discharged at the cathode to form only hydrogen atoms, with little or no combination to give rise to molecular hydrogen, then on capacitor discharge the anions impinging on the aluminum surface will have available two modes of discharge: the usual anodic reaction which, for convenience and simplicity, may be written:

$$6\,OH^- + 2Al \rightarrow Al_2O_3 + 3H_2O + 6e^- \qquad [1]$$

leaving the previously adsorbed H undisturbed; or

$$OH^- + H_{Adsorbed} \rightarrow H_2O + e^- \qquad [2]$$

Reaction [2] would be expected to be favored over [1] since [1] requires that aluminum atoms overcome barrier effects at the interface in order to react, whereas in [2] the hydrogen atoms are already on the surface of the metal and available for combination with OH^-.

This approach would suggest that all that is required for successful energy storage operation is an aluminum cathode, but in fact plane foil (nonetched) does not behave ideally, whereas etched foil does. Apparently then, the etched surface enhances the effect of hydrogen adsorption, but the question which is raised is whether it is due to the greater surface area or to some induced surface activity brought about by the etching process.

[1] The electrolyte must obviously contain not only OH^- but other anions as well. However, with conventional electrolytes, the only important anodic reaction is the production of oxygen.

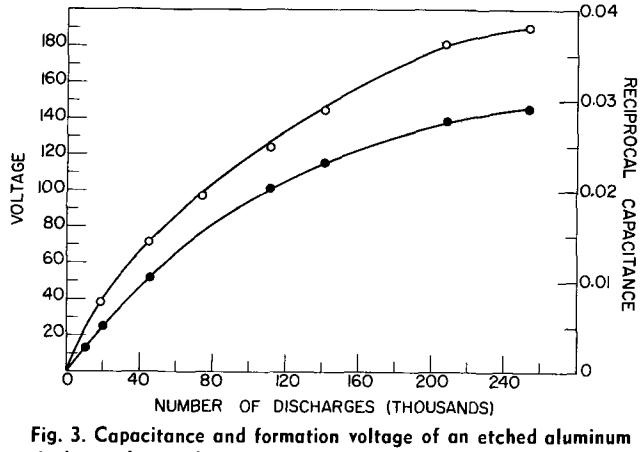

Fig. 3. Capacitance and formation voltage of an etched aluminum cathode vs. the number of capacitor discharges. Platinum electrode used as cathode during charging. ○ Reciprocal capacitance; ● voltage.

Experimental

In order to choose between these alternatives, the experimental arrangement shown in Fig. 2 was devised. The d-c source is a well-regulated constant voltage power supply. Switching is controlled by means of a relay connected to a variable electronic timer, permitting between 30 and 200 charge-discharge cycles/min; an electric counter is connected in parallel with the relay. During charging S_1 is closed and S_2 is open; cathodic discharge of hydrogen occurs at the platinum electrode and the aluminum anode, C_A, is charged. S_1 is then opened and S_2 is closed, discharging C_A through C_C, the aluminum cathode. Since there is no hydrogen at the aluminum cathode under these conditions, the only reactions which can occur there are the evolution of oxygen and the formation of Al_2O_3. Oxygen is not expected to be a product since the electrolyte used was a borate-glycol solution known to have a high current efficiency of oxide formation (1). This arrangement effectively separates the two electrochemical reactions which occur at the

cathode during the charge-discharge cycles and enables one to determine the true effect of etched surfaces.

During discharge the two aluminum surfaces, C_A and C_C, act as parallel capacitors; when no hydrogen is on the surface we expect C_C to become charged to the maximum voltage which may be impressed before ionic current can flow. Charge from C_A will continue to flow to C_C until the voltages across the two capacitors are equal. If there is an oxide film on C_C, a residual charge will remain on C_A and thus, during subsequent charging of C_A, something less than the charge q ($= C_A V_C$) will be required for each cycle. As the cycling continues, the oxide film on C_C will continue to grow and its thickness will approach a limiting value, at which point the two capacitors will be permanently charged to V_C. Thereafter no further current will flow, assuming that the leakage currents are negligible. This effect should occur for both plain and etched foil; the only difference expected would be the time required to bring this about because of the greater surface area of the etched metal.

For the experiments described here, etched foil anodes of 100 cm² area and anodized to 200v were used. The capacitance was 14.8 mfd and the charging voltage was 150v. The course of reaction was followed both by measuring the cathode capacitance and by measuring the d-c voltage which could be impressed on the cathode before causing a rapid rise in current (2).

Results

Figure 3 shows the increase in reciprocal capacitance and voltage on an etched aluminum specimen of 100 cm² (geometrical) area used as the "cathode" during the discharge portion of the cycle. These curves clearly demonstrate that the oxide film on this electrode increases to a thickness that will eventually accommodate the charging voltage on the anode.[2] Gas was also observed at the platinum electrode during the experiment, in accord with prediction.

The aluminum cathode was then replaced with a fresh etched specimen and the platinum electrode was removed from the circuit, giving essentially the circuit of Fig. 1 (the energy storage application). There was no discernible increase in the oxide film on the cathode by either of the two methods of measurement, even after 280,000 cycles. This effect is the same as that observed in capacitor use, and corresponds to the explanation advanced above, *i.e.*, hydrogen adsorption on the aluminum surface and subsequent reaction with hydroxyl ion.

Some experiments with smooth aluminum foil also serve to demonstrate this effect in a slightly different manner. Figures 4 and 5 show the change in reciprocal capacitance and formation voltage, respectively, of specimens with and without the presence of the platinum electrode. Because of the much smaller surface area, as compared to etched foil, oxidation of the aluminum cathode occurs in both instances, but is markedly faster when a platinum electrode is available for the discharge of hydrogen. It should also be noted that in the absence of the platinum electrode, formation of oxide on the cathode ceases well below the total charging voltage. For the specimens in Fig. 4 and 5 no further growth in oxide thickness was observed by increasing the total number of discharges to 160,000. The reason for this behavior is simply that, as the oxide layer increases on the cathode, the amount of charge transferred from the anode continually decreases, until the point is reached where even a nonetched aluminum surface can accommodate the hydrogen atoms deposited during the charging part of the cycle. Subsequent discharge of the anode then results in the usual depolarizing reaction observed on etched cathodes.

One additional experiment was run to show that the total surface area (and not the nature of the etched surface) is responsible for the difference in behavior between etched and nonetched cathodes. A specimen of etched aluminum with a geometrical area of 5.0 cm² was used for the cathode. Even though this foil was etched it would be expected to form an oxide film since the charge density during cycling would be approximately the same as smooth foil of 100 cm² area. Figure 6 shows that, as expected, oxide formation occurred, gas evolution at the cathode was also observed and, as in the case of smooth foil, a limiting thickness of oxide is reached.

[2] Continued cycling is equivalent to prolonged aging of the electrode at constant applied voltage, and therefore the so-called formation voltage, since it is measured effectively at constant field, will tend to exceed the charging voltage.

Solubilities of GaAs in Metallic Solvents

M. Rubenstein

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Liquidus solubilities of GaAs in gallium have been reported for temperatures from 1237° down to 450°C (1-3). The phase diagram for the GaAs-Ge system has also been reported (4). Liquidus solubilities are reported here for GaAs in solvents gallium, tin, bismuth, and lead. The liquidus solubility data reported here were obtained using a high-temperature filtration technique (5).

This technique involves a quartz tube which is divided into two compartments by a quartz disk which has 1 mm diameter holes. GaAs fragments and the metal in question are placed in the bottom compartment; the ampoule is sealed under a pressure of less than 10^{-5} Torr. A quartz rod is attached to the top of the ampoule. The ampoule is placed in a furnace with the quartz rod projecting out of the furnace. The temperature of the furnace is raised to the desired temperature and maintained at temperature for 16 hr. By means of the quartz rod the ampoule is turned 180°C about the axis of the quartz rod, and, by gentle tapping, the solution is filtered so that the solution of GaAs in a metal is separated from the undissolved GaAs.

The furnace is then cut off so that the ampoule and contents are cooled to room temperature. In some cases the ampoules are air quenched after filtration.

The ampoule is then opened and the filtrate and residue are quantitatively analyzed to ascertain how much GaAs and metal are in the filtrate and the residue. All of the solution (at the elevated temperature) does not have to enter the filtrate. If one can assume that the solution of GaAs in the metallic solvent is at equilibrium after 16 hr at the elevated temperature, any portion of this solution which enters the filtrate is representative of the entire solution. The size of the solution should be large enough so that weighing errors become unimportant to the calculation of the solubility measurement.

In the systems reported here, gallium, tin, bismuth, and lead were separated from GaAs using three different techniques. Gallium metal was separated from GaAs by using concentrated hydrochloric acid. Tin was separated from GaAs by using concentrated hydrochloric acid with a platinum wire in contact with the tin. Bismuth and lead were dissolved using 30% H_2O_2 and glacial acetic acid in the ratio of 1:1. If the high-temperature filtration samples were cooled slowly from the elevated temperatures, the crystallite size of the GaAs was much larger than if the samples were air quenched. The larger crystallite size allowed one to have a more quantitative recovery of GaAs when the metal was being dissolved.

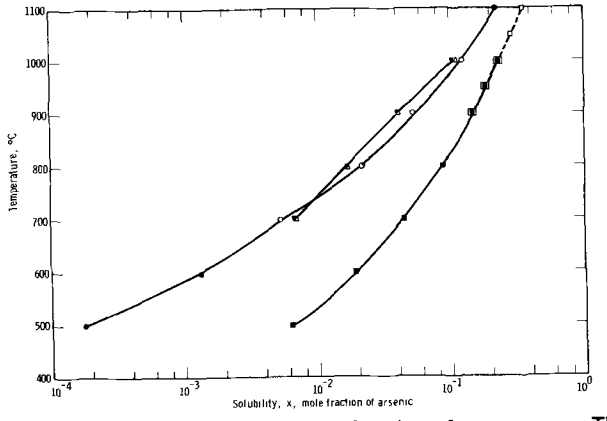

Fig. 1. Solubilities of GaAs as a function of temperature. The solvents are gallium, tin, bismuth, lead and germanium. ○ Gallium as solvent; ● gallium as solvent (3); ■ tin as solvent; ▼ bismuth as solvent; △ lead as solvent; □ germanium as solvent (4).

X-ray diffraction studies on the GaAs recovered from the filtrates showed no change in lattice constants (no change in the fourth significant figure of the lattice constant of GaAs) when the solvent was gallium, tin, bismuth, or lead. Figure 1 shows the solubility data of GaAs in the four solvent systems: gallium, tin, bismuth, and lead. This figure also shows the solubility data of GaAs in germanium recalculated from ref. (4). The curves for lead and bismuth are virtually superimposable. The precision of the solubility measurements presented in this note is ± 0.001 for solubility measurements for $x > 0.010$ and ± 0.0005 for $x < 0.0100$. Table I presents the solubility data from ref. (1) and (3), together with data presented in this paper. The comparison demonstrates the reliability of the data obtained by the high-temperature filtration technique.

Similar measurements were made on the systems GaAs-In, GaAs-Te, and GaAs-Se. These three systems are not pseudobinaries. They have been investigated in ref. (6-9): GaAs-InAs (6, 7), GaAs-Ga_2Te_3 (8), and GaAs-Ga_2Se_3 (8, 9).

In the case of GaAs-In, the solid recovered from the filtrates indicated the formation of GaAs-InAs solid solutions from 22 mole % indium for the filtrations at 500°C to 7 mole % indium for the filtrations at 1200°C. The GaAs-Te system is also not a pseudobinary one, and there is evidence to believe that some Ga_2Te_3 was formed. The same is true of the GaAs-Se system (some Ga_2Se_3 was formed). When filtrations were performed on the GaAs-Se system at 650°C, crystals were left behind with the undissolved GaAs which were analyzed as Ga_2Se_3 (by x-ray fluorescence analysis). Of two samples investigated, one had an arsenic concentration less than 0.1 mole % and the other 2 mole %. These crystals were red-brown in color and tetragonal with $a = 5.47$Å, $c = 5.41$Å ($c/a = 0.989$). X-ray diffraction showed the same tetragonal dimensions for these two samples and other samples. Ga_2Se_3 is reported in the literature (10) as being reddish-black in color and cubic, with $a = 5.418$Å.

Manuscript received Jan. 21, 1966; revised manuscript received March 28, 1966. Portions of this paper were presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Microplasma Observations in Silicon Junctions Using a Scanning Electron Beam

John W. Gaylord

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

It has been shown (1-2) that signals induced in junctions by a scanning electron beam can be helpful in device failure analysis. This technique has now been used to locate and study certain microplasma sites (areas which emit visible light) in an effort to determine the cause of low collector-base breakdown voltage in silicon junctions. A scanning electron beam microscope was used to produce micrographs of p-type base regions diffused into an n-type substrate. N-type spikes were observed extending from the substrate up into the p-base region at locations corresponding to areas of optical light emission. In addition, these areas were shown to be the avalanche sites which limit the collector-base breakdown voltage characteristic of the junction.

An optical micrograph of a typical junction is shown in Fig. 1. The junction was formed by diffusing boron in a teardrop pattern into n-type silicon. A round hole has been etched in the oxide over the center of the junction to permit contact by a probe as shown. External bias was applied to the junction by means of this probe and a conducting support for the wafer. Figure 2 illustrates the circuit used. The junction region was scanned by an 18 kv, 0.4 na electron beam approximately 5μ in diameter. Electron-hole pairs generated by this scan were collected at the junction producing a reverse current that modulated the beam current of a cathode ray tube. The cathode-ray tube was made to scan in synchronism with the electron beam. Typical micrographs obtained by photographing the screen of the cathode ray tube

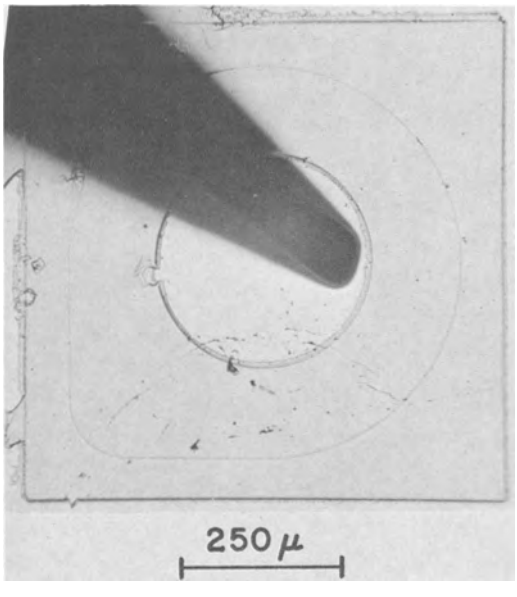

Fig. 1. Optical micrograph of junction

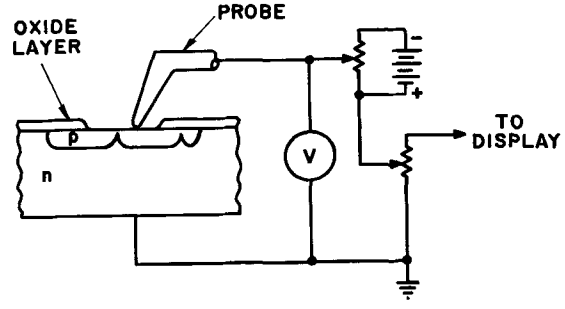

Fig. 2. Video signal sensing circuit

are shown in Fig. 3 and 4. Current flow is such that enhanced reverse current either from electron-hole pairs or from an avalanche induced by the beam appears as bright areas in the micrographs. Streaks in these pictures running from right to left after an abrupt change in brightness are caused by the recovery characteristics of the electronics and are not related to physical properties of the junction. The center area where oxide has been removed is brighter than the surrounding junction region because the electron beam intensity has not been reduced during travel through the oxide layer prior to reaching the junction region.

Figure 3 is made without any external reverse bias ($V = 0$). The area around the bottom edge of the oxide hole shows several bright spots, labeled A, B, and C. These areas constitute sites in the junction where increased currents are generated during scanning. It was deduced that this increase in current is caused by the junction coming closer to the surface as illus-

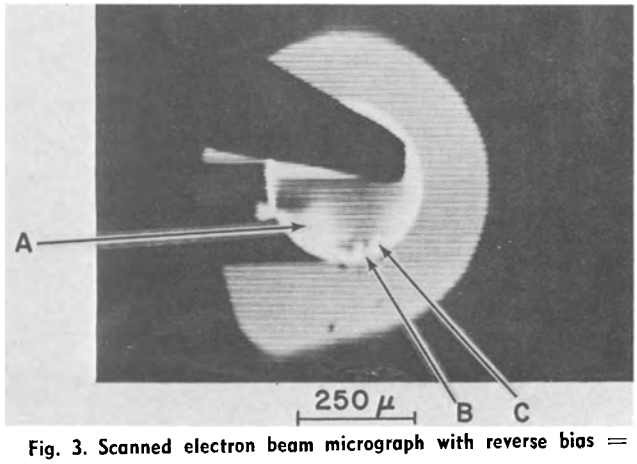

Fig. 3. Scanned electron beam micrograph with reverse bias = 0v.

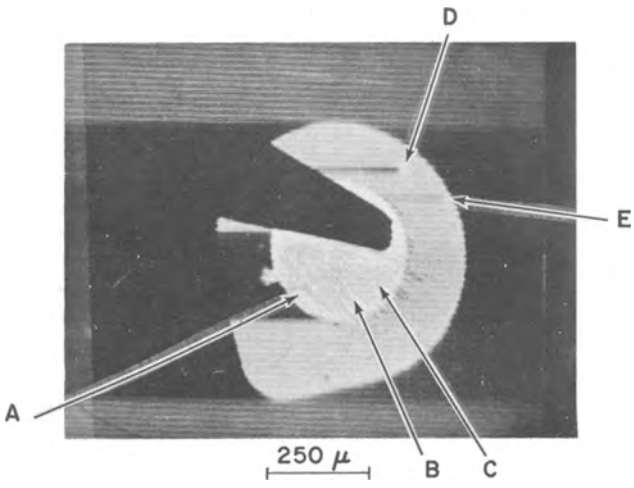

Fig. 4. Scanned electron beam micrograph with reverse bias = 20v.

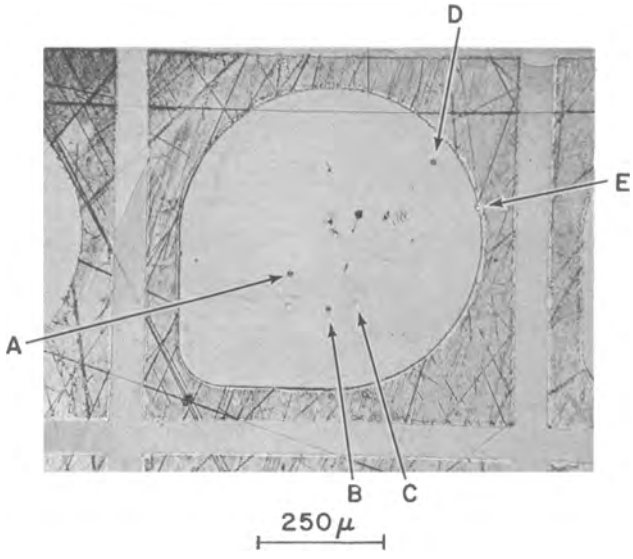

Fig. 5. Optical micrograph of lapped and stained junction

trated in Fig. 2 where the flux of electrons from the beam is greater because of reduced scattering and absorption in the silicon. Figure 4 shows the effect of applying a reverse bias of $V = 20$v to the junction. Two additional bright spots now appear labeled D and E as well as enhanced brightness from spots A, B, and C. These spots indicate that a localized avalanche (multiplication) is being excited by the electron beam as it injects carriers in regions of high field. Such high fields would be expected from the geometry of the junctions as seen in Fig. 2. As the bias increases, the avalanche effect increases at each of the sites until complete breakdown can be initiated by scanning a single site at a reverse bias slightly less than the static breakdown limit. It was thus deduced from the micrographs that the cause of low collector-base breakdown voltage is the presence of these avalanche sites and that the sites are spikes or columns of n-doped material extending through the p base region to or near the silicon surface.

The most pronounced avalanche sites, A, D, and E are sources of relatively strong "microplasma" light emission as can be observed optically when a reverse bias greater than breakdown is applied. This phenomenon is also to be expected for the enhanced field produced at the tips of n-type spikes extending into the p-region.

To verify completely the junction model deduced from electron beam scanning the sample was successively lapped and stained. Figure 5 is a micrograph of the sample taken during this operation. The oxide has been removed and enough of the surface lapped away to reveal the spikes by conventional copper staining techniques. Continued lapping revealed the spikes to be quite narrow, and it was observed that they coincide with the avalanche sites shown by electron beam scanning and by light emission.

Conclusion

The scanning electron beam technique combined with conventional electrical tests provides a means of nondestructively locating and analyzing a source of low breakdown voltage in semiconductor junctions. The possibility now exists of coupling this technique with conventional microprobe analysis to locate and determine the presence of foreign impurities in a manner heretofore impossible.

Acknowledgments

The author is indebted to Mr. H. R. Meisel of RCA EC&D Division, Somerville, for supplying the samples analyzed, A. W. Fisher for staining and lapping the junctions, and F. E. Heiselmann for assisting in the operation of the scanning electron microscope.

A Reference Electrode for Use in Dimethyl Sulfoxide: Thallium Amalgam–Thallous Chloride

William H. Smyrl and Charles W. Tobias

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

The measurement of thermodynamic properties of electrolytes and the study of electrode processes in dimethyl sulfoxide (DMSO) requires a suitable reference electrode of the second kind. Solubility studies (1-4) have shown the chlorides, bromides, iodides, nitrates, and perchlorates to be the most soluble salts in DMSO. Sulfates, fluorides, and carbonates were found to be generally insoluble. For practical reasons the choice of a halide couple would be most advantageous since it affords the establishment of con-

centration cells without transference.

The silver-silver chloride electrode was explored for use in DMSO by Kolthoff and Reddy (5), who found that silver chloride is quite soluble in excess chlorides. In this laboratory silver iodide and silver bromide were found to dissolve in excess iodide and bromide, respectively, thereby eliminating the silver-silver halide electrodes from consideration as reference electrodes.

The other obvious choices, the analogues of the calomel electrode, were shown to be unsuitable because mercurous chloride, bromide, and iodide each disproportionate in DMSO. After the salts have been in contact with the solvent for a short time, small droplets of mercury appear in the bottom of the vessel. Analysis of the solution has not been made to confirm the presence of the Hg^{+2} ion. However, since $HgCl_2$, $HgBr_2$, and HgI_2 are highly soluble in DMSO, these products of disproportionation would promise to be quite stable in solution.

Among the metals which form amalgams and are stable with respect to the solvent, thallium appeared promising. Hills (6) discussed the use of the thallium amalgam-thallous chloride reference electrode in liquid ammonia. Since the thermodynamic properties of thallium amalgams are well known (7), this electrode couple looked promising. Solubility studies were initiated, and thallous iodide and chloride were found to be sparingly soluble in dimethyl sulfoxide. Excess iodide precipitates thallous iodide from solution. From visual observations, excess chloride does not precipitate TlCl, nor does any more solid TlCl dissolve. Further, experiments have shown the solubility product of TlCl in DMSO to be of the order of 10^{-6}.

On the basis of this information exploratory measurements were initiated with a thallium amalgam-thallous chloride reference electrode. Manipulations were carried out in a dry box. The liquid amalgam, containing approximately 10^{-2} mole fraction thallium, was introduced into each one of three special cups, to which electrical contact was made by platinum wires isolated from contact with the electrolyte solution by glass tubes. A 1-2 mm layer of thallous chloride was sprinkled on the amalgam surfaces, the three electrodes were placed into the cell, and the electrolyte was introduced. In the tightly sealed cell an argon atmosphere of 1 atm pressure was maintained over the solution throughout the measurements. The cell was thermostated at 25° ± 0.01°C.

The solvent, purified by distillation, contained less than 50 ppm moisture as determined by Karl Fischer titration. Measurements were made with four different 10^{-2}M solutions, containing one of LiCl, RbCl, $MgCl_2$, $InCl_3$. [Mercury, Baker's Analyzed "reagent"; thallium, Cominco "69's Grade"; thallous chloride, Electronic Space Products "Analytical Grade"; lithium chloride, Baker and Adamson "Reagent Grade", dehydrated by treatment with thionyl chloride (8); rubidium chloride, City Chemical Corporation "Reagent Grade"; magnesium chloride, K & K Laboratories "99.9% Purity"; indium chloride, Indium Corporation of America "99.99% Purity".]

The bias potential between the electrodes was measured by a L&N K-3 potentiometer, using a galvanometer of 4.5 x 10^{-10} amp/mm sensitivity to determine balance. The difference in potential between any two of the three electrodes was always found to be less than 0.03 mv, and less than 0.01 mv in the case of solutions containing LiCl. Equilibrium was established rapidly and maintained for at least one week, after which a particular test run was discontinued.

The equilibrium was offset by the application of 0-10 mv potential between electrode pairs, also with reversed polarity. The current passed in either direction ranged up to 2 x 10^{-7} amp. This was repeated for all combinations of the three electrodes. The current was always found proportional to the applied potential, and on no occasion was a hysteresis effect observed. The current was applied by an Electronic Measurements Model C 612 constant current power supply, and was measured by a Sargent Model MR Recorder. The voltage was measured by a Keithley Model 610R electrometer.

On the basis of these findings, the thallium amalgam-thallous chloride electrode appears suitable for thermodynamic measurements in DMSO solutions, and may be recommended for a practical reference electrode. Care must be taken to protect the amalgam from oxidation, and workers should be aware of the toxicity of thallium and its compounds.

(Editor's Note: Dimethyl sulfoxide is readily absorbed through the skin and has certain physiologic effects on the body. While it has shown promise as a therapeutic agent, tests on humans have been discontinued for the present because of possible undesirable side effects.)

Brief Communication

Hydrothermal Attack of Silver and the Formation of Silver Crystals

Solomon Levinson and Forrest Lee Carter

United States Naval Research Laboratory, Washington, D. C.

Silver has been found to be unattacked by NaOH at 538°C under a dry forming gas atmosphere (1). Under hydrothermal conditions (temperature unspecified) Laudise and Nielsen (2) have found silver to be inert to a 4-5*M* alkaline solution while Lux and Niedermaier (3) have found enhanced silver corrosion with NaOH at 410°C in the presence of oxygen (and water) above the melt. In the course of a program to grow ruby for laser use hydrothermally, we first studied the growth of α-Al_2O_3 without Cr addition. Small crystals of silver were observed when a heliarc-welded fine silver liner containing α-Al_2O_3 nutrient and seeds in a 4*M* NaOH solution was employed at 46% fill. With the exception of copper (4), we have found no previous reference to the growth of other metal crystals by this technique. The autoclave containing the liner was pressure balanced with water. It had been maintained for three weeks at a bottom temperature of 500°C. The top of the liner was cooler by about 50°C.

Two liquid layers were observed after opening the liner; the lower was considerably more viscous. The largest crystals of silver had formed in the vicinity of the two-liquid interface although smaller ones could be found higher up on the seed rack. The sum total of impurities as determined by spectrographic analysis was found to be about 0.003%.

The deposited silver was in intimate contact with a mass of transparent material (not identified). The very soft and fragile nature of the deposited silver necessitated the removal of the imbedding matrix by means of a 6*N* HCl solution. The deposited silver occurred predominantly in the form of very thin platelets, the largest of which was 5 mm across and 0.01 mm thick and also in the form of fine three-dimensional filigree. In addition a few thicker rhombus shaped crystals were observed, unusual examples of which are indicated by the two spears in Fig. 1.

An isolated rhombus (hollow)) was examined by x-rays using a G. E. single crystal orienter (CuK_α radiation) and a precession camera (MoK_α radiation). The rhombus face of the single crystal was the (111) plane and was related to the cubic axes as indicated in Fig. 2a. The majority of the thin platelets had forms as in Fig. 2b and 2c. It appears that most of the silver was epitaxially deposited on substrate crystals subsequently removed by the HCl treatment. The unit cell edge was 4.086 ± 0.001Å.

Charging the Silver Oxide Electrode with Periodically Varying Current

II. Repeated Open-Circuit Periods

Charles P. Wales

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

Sintered silver electrodes were oxidized anodically in 35-50% KOH at 25°C, usually at the 20-hr rate, sometimes at faster rates. Length of charge plus open-circuit periods varied from 8 hr to 1/60 sec. A particular charge length and open-circuit length was repeated until oxygen evolution occurred. In 50 or 45% KOH this charge method gave either the same capacity as a constant d-c charge or less capacity, but in 35% KOH the improvements averaged as high as 40% under certain conditions. Best results were obtained when the preceding discharges were at low rates.

The discharge capacity of AgO electrodes is strongly influenced by conditions of the preceding charge (anodic oxidation). It has been shown that capacity of AgO electrodes can be increased by charging with a periodically varying current if pulses of charge current are added to the normal charging current using the proper conditions (1). Polarization decreases during a short pulse of increased current, perhaps as a result of breaking or roughening the oxide film which covers the electrode. Thus the surface area increases, and a larger amount of oxide can form before oxygen evolution begins. There may also be an increase in conductivity during a pulse if there is appreciable activation of the semiconductors Ag_2O or AgO (2, 3). Pulses of increased charging current must be short or else concentration gradients become so large that polarization increases greatly and resultant capacity is less than normal.

In general, both the total amount of AgO that forms on a silver electrode and the AgO crystal size vary inversely with the charging current density that is used (4). When charging storage batteries that contain silver electrodes it is often impractical to use rates requiring a day or more for completion, even though these low rates give a high capacity. As a compromise, sometimes a high charging current is used at first, followed by a lower current after potential begins to rise to the oxygen evolution value. This usually gives less capacity than if a lower current had been used for the entire charge, because the fine AgO crystals that form when using high current densities may make a tight coating on the electrode surface and limit further oxidation (4).

Capacity can be increased somewhat by putting a silver oxide electrode on open circuit for a time, when charging potential approaches the gassing value. The present work was undertaken because it was believed that there may be benefit from periodically interrupting the charge current throughout a charge.

Experimental Procedure

The test cells contained sintered silver plaques that had been manufactured for use in commercial silver-zinc storage batteries. The silver plaques were 30.5 x 63.5 x 0.8 mm or 41.5 x 38.0 x 0.8 mm. Neglecting the grid of expanded silver metal, the plaques had an average weight of 7.9 or 5.8g, respectively, for a theoretical capacity of 3.9 or 2.9 amp-hr. Porosity of unused electrodes, as determined by liquid absorption, was 50-56%. The silver plaques were wrapped in cellulosic separator material of a type normally used in commercial silver-zinc cells. Similar silver electrodes were used for both the cathode and anode. The test cells contained an excess of 35 or 50% KOH.

A constant current which gave an average discharge length on the order of 20 hr following a charge using this same current was defined as the 20-hr rate of charge and discharge. This 20-hr rate was taken as the standard or "normal" charge current. Charges were continued until potential stopped changing rapidly after reaching oxygen evolution (about 510 to 530 mv positive to the Ag/Ag_2O reference electrode). This resulted in a charge input which was usually 101-102% of the following discharge. Discharges were done with a controlled constant current and ended at a final potential 300 mv negative to the Ag/Ag_2O reference. Normal charges (as defined above) alternated with charges using interrupted current. All discharges used the 20-hr rate except where noted otherwise. The work was done at 25° ± 1°C.

Some charges by interrupted current were repeated with commercial silver-zinc secondary cells using 35 or 45% KOH. These cells were rated at 5 amp-hr, and each cell contained four silver electrodes. These electrodes were the same size as the test electrodes which had a theoretical capacity of 2.9 amp-hr. The test electrodes had been manufactured for use in this size of silver-zinc cell. The silver-zinc cells were charged to 2.05v and discharged to 1.10v using the 20-hr rate of constant current (as defined above). The electrolyte supplied with these cells was analyzed and found to be 45.0% KOH and 0.6% K_2CO_3. The "35%" KOH was prepared from reagent grade KOH. Analysis of this solution gave 34.7% KOH and 0.9% K_2CO_3. When the electrolyte was used in the cells the carbonate concentration probably increased from degradation of the cellulosic separators.

There were four types of charge regime using interrupted current. In each of the four a particular length of charge and open circuit was repeated until strong oxygen evolution occurred. In one type, a cell was charged for 3 hr at the normal (20-hr) rate of constant current. This was followed by a stand period ranging from 12 min to 5 hr before resuming the charge. In the second type the charge periods began every 60 min, with the cell being charged at the normal (20-hr) rate for periods ranging from 59 to 45 min and the remaining 1-15 min being the stand period. In the third type the charge periods began every 10 min, with the cell being charged at the normal (20-hr) rate for periods ranging from 9.5 to 4 min and the remaining 0.5-6 min being the stand period. The fourth type of charge was derived from rectified 60-cycle alternating current, using unidirectional currents that were equivalent in coulombs per unit time to either the 20-hr or 6-hr charge rate.

Several sources of controlled d.c. were used. When stand times were under 1 min, a power source was

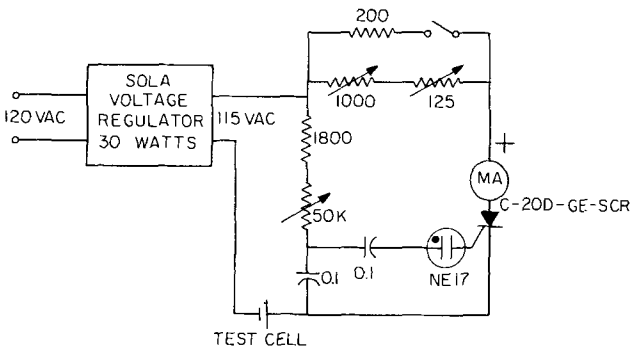

Fig. 1. Circuit for obtaining rectified a.c. with current interrupted for more than half of the a-c cycle.

used that had a recovery time of less than 50 μsec for reaching the preset current value. For longer stand times, a d-c source having a recovery time of several seconds was used also. Half-wave and full-wave rectified a.c. were obtained from 60-cycle a.c. by typical rectifier circuits. Rectified a.c. in which the current flowed less than half of the a.c. cycle was obtained by using a silicon-controlled rectifier (Fig. 1). These forms of current were used rather than the customary square wave, because they were easily obtained and seemed more practical for possible widespread use.

Rectified a.c. which consisted of approximately the last half of an a-c half-wave was called "quarter-wave rectified a.c." for simplicity. Current rose rapidly to a maximum value and then fell more slowly to zero, with no current flowing for ¾ of the time (upper part of Fig. 2). Similarly the last quarter of an a-c half-wave was called "eighth-wave rectified a.c." (Fig. 2). Average current in these examples was 80 ma including the time in which no current flowed.

Results

Each new test cell was charged and discharged at the 20-hr rate of constant current several times until capacity stopped changing rapidly, before charging with periodically interrupted current. The initial or second cycle often gave as much as 70-80% of theoretical capacity for the sintered silver. Capacity dropped in the next few cycles. After about 12 cycles

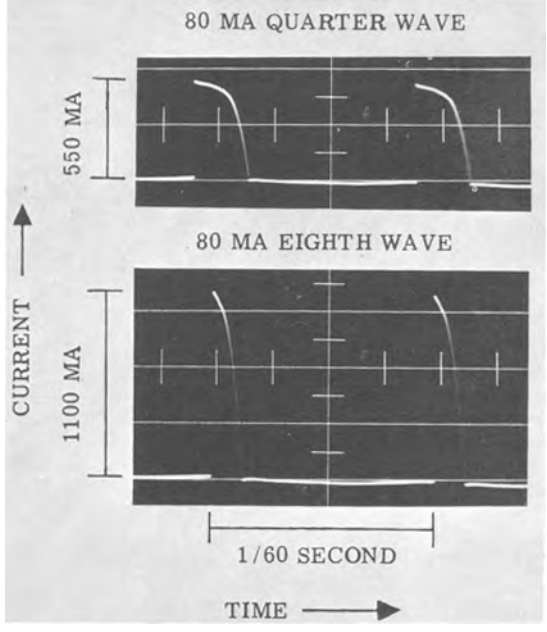

Fig. 2. Oscilloscope traces showing wave form of quarter-wave and eighth-wave rectified a.c. with approximate current calibration. Average current was 80 ma.

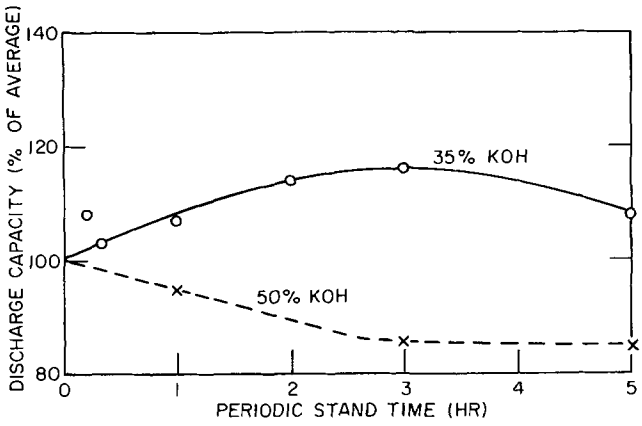

Fig. 3. Change in discharge capacity following charges at 20-hr rate with stand periods after each 3 hr of charge. Plotted points are averages of several discharges.

capacity showed no further loss but varied irregularly, with the capacity of normal cycles in 35% KOH usually falling in the range 44-57% of theoretical capacity and averaging 50-55% of theoretical. In 50% KOH the capacity was usually in the range 36-48% of theoretical.

Variations in cell capacity were minimized by calculating the average discharge capacity of the four normal cycles (20-hr constant current charge and discharge) nearest to each discharge. This average was then taken as the "normal" capacity at that point in the cycle life of the cell. Capacity of each discharge was expressed as a per cent of this normal capacity. These calculations also improved comparison between cells having different capacities. Throughout this paper the results are presented as being a certain per cent of normal capacity. Normal capacity always means the average discharge capacity that was measured when using a constant current at the 20-hr rate for both charge and the following discharge.

Although capacity of individual normal cycles varied irregularly, 135 normal cycles in 35% KOH that alternated between the charges with repeated stands had a discharge capacity which averaged 100.1% of normal capacity and had a standard deviation of 7.1. The center half of these normal capacities fell in the range 96.1-103.4%. In 50% KOH there was less variation, the average of the discharge capacities of 27 normal cycles being 99.6% of normal capacity (standard deviation = 2.4) and the center half falling in the range 98.2-100.8%.

When stand periods followed each 3 hr of charge, most charge-stand combinations gave increased capacity in 35% KOH, and decreased capacity in 50% KOH (Fig. 3). The plotted points for 50% KOH were the average of two discharges and were very reproducible. In 35% KOH the plotted points were averages of 3 to 7 discharges with individual capacities varying widely. For example, the 115.7% shown for 3-hr stands repeated every 3 hr in 35% KOH is the average of 5 discharges, divided between two cells, with individual capacities varying from 99.7 to 131.8% of normal capacity. Potentials of a charge having stand periods of 1 hr alternating with charge periods of 3 hr are given in Fig. 4.

Higher charge currents in 35% KOH also could give beneficial results. When there were 3-hr stands after every 3 hr of charge at the 6-hr rate, the capacity averaged 90% of the normal 20-hr value and about 9 hr (total of charge time + stand time) was required. This should be compared to the 83% of normal capacity that was obtained when using uninterrupted constant current at the 6-hr rate. When using 1-hr stands repeated after every 1 hr of charge at the 6-hr rate, a charge required about 13 hr (total) and 5 of these cycles gave an average 110.3% of normal capacity. When 1-hr charges at the 3-hr rate alternated

Table I. Effect on commercial silver-zinc cells of stands after each 3 hr of charge using 20-hr charging current

Periodic stand time, hr	Average discharge capacity, %	
	35% KOH	45% KOH
1	97.8[4]	96.3 [3]
3	114.2 [3]	99.8 [2]
5	105.8 [3]	95.9 [2]

Values in brackets give the number of measurements made.

with 1-hr stands, there was 83-93% of normal capacity obtained in about 6 hr.

This charging method was tried at the 20-hr charge rate with commercial silver-zinc cells (Table I). Although results were not identical with test cell results, trends were similar.

Stand periods of 1-15 min repeated every 60 min during a charge gave discharge capacities that differed little from capacities following an uninterrupted charge at the 20-hr rate (Fig. 5). This type of charge was not tried in 50% KOH.

Stands repeated every 10 min during a charge could be beneficial or harmful, depending on conditions (Fig. 6). Although the averages fell close to a smooth curve, individual charges in 35% KOH gave widely varying capacity, particularly when using stands of 2, 3, or 4 min. There were 6 to 9 charges for these three times and at least one of the following discharges varied more than 36% from each of these three averages (Fig. 6).

Selected portions of potentials that were measured during a charge having 2-min stands repeated every 10 min are given in Fig. 7. The first excerpt is at hour 4.33 as potential rose to the peak value that started the Ag_2O/AgO plateau. Potentials rose to a maximum value in 0.4-0.8 min after the charge was resumed following most of the 2-min stands at the

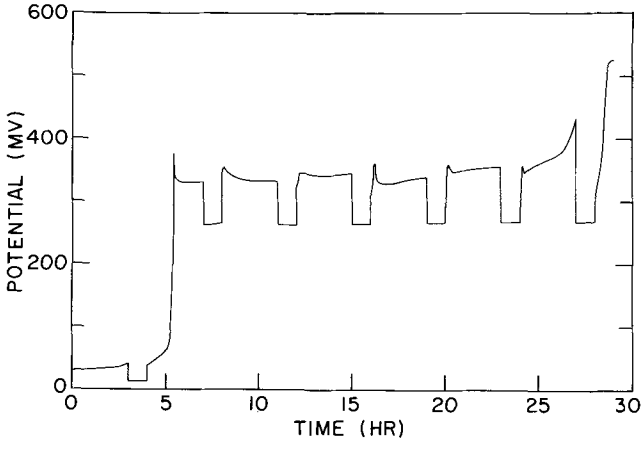

Fig. 4. Potentials during charge at 20-hr rate in 35% KOH with 1-hr stands after each 3 hr of charge. Potentials are given with respect to Ag/Ag_2O reference electrode.

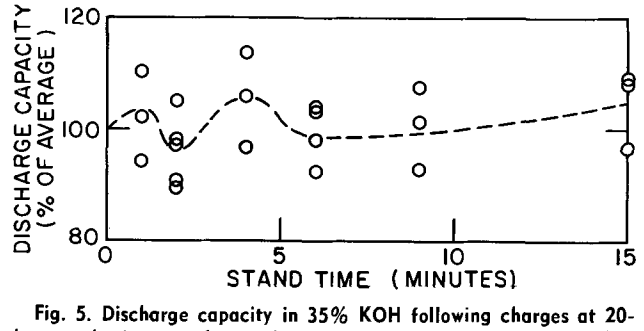

Fig. 5. Discharge capacity in 35% KOH following charges at 20-hr rate having stand periods repeated every 60 min. Dashed line connects averages of plotted values.

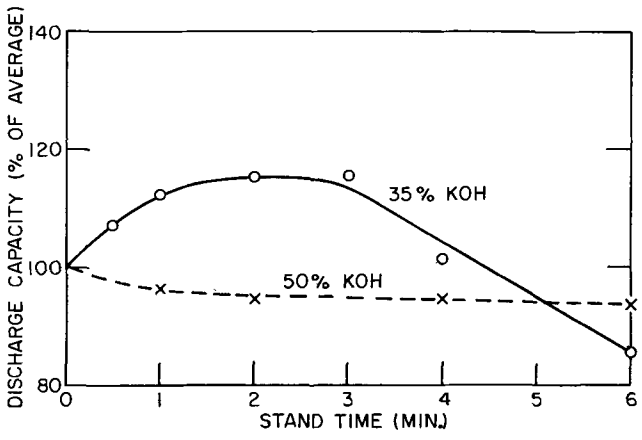

Fig. 6. Discharge capacity following charges at 20-hr rate having stand periods repeated every 10 min. Plotted points are averages.

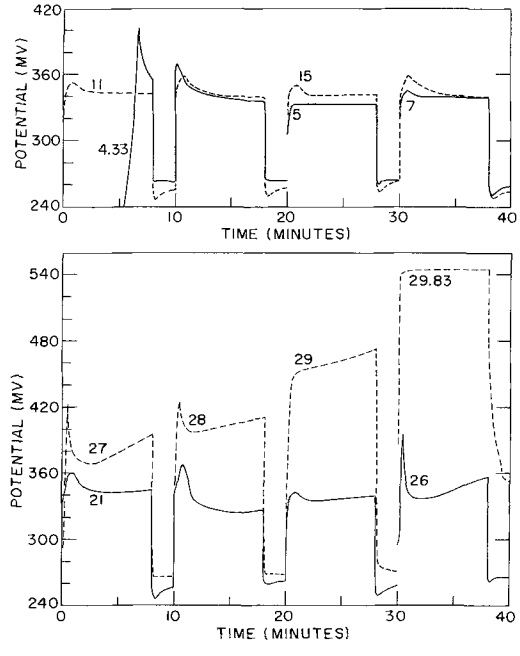

Fig. 7. Some brief excerpts taken from charge in 35% KOH having stand periods of 2 min every 10 min. Numbers indicate total elapsed time in hours at beginning of the particular 8-min charge excerpt that is shown. Lack of number indicates charge was continuous from previous stand shown. Potentials are given with respect to Ag/Ag_2O electrode.

Ag_2O/AgO plateau. After the third 8-min charge period at this plateau, stand potential fell to a minimum value in 0.2-0.3 min and then rose more slowly. This behavior continued throughout most of the charge after hour 5 (Fig. 7 and 8). There was a marked tendency for the charge and stand potentials to be relatively low during one 10-min period but higher the next, beginning about hour 11. This is shown more clearly in the 20-min excerpt at hour 15 (Fig. 7). After the electrode was two-thirds charged the potential patterns usually repeated themselves every 30 min instead of 20 min (hour 21 Fig. 7 and 8).

The same type of charge in 50% KOH gave potentials that were more steady. Until the electrode was half charged, potentials in 50% KOH lacked a maximum when charge was resumed following the brief stands. After the electrode was half charged there was a small maximum in charge potential following the brief stands but this maximum was usually less than 10 mv. Stand potentials did not show a minimum in 50% KOH, but did fall to increasingly lower values as

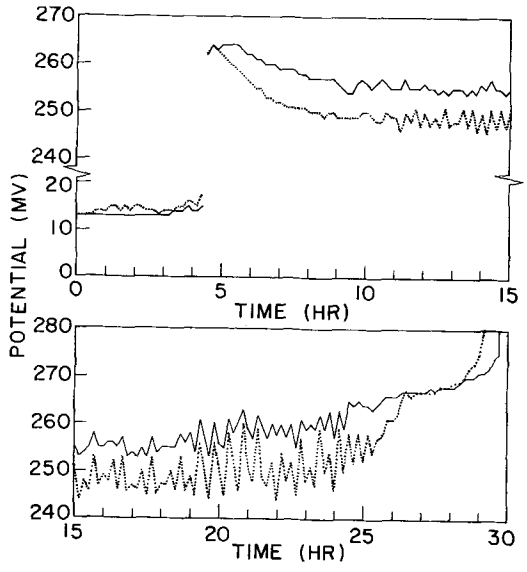

Fig. 8. Open-circuit potentials after standing 0.25 min (dotted line) and 2.0 min (solid line) during charge shown in Fig. 7.

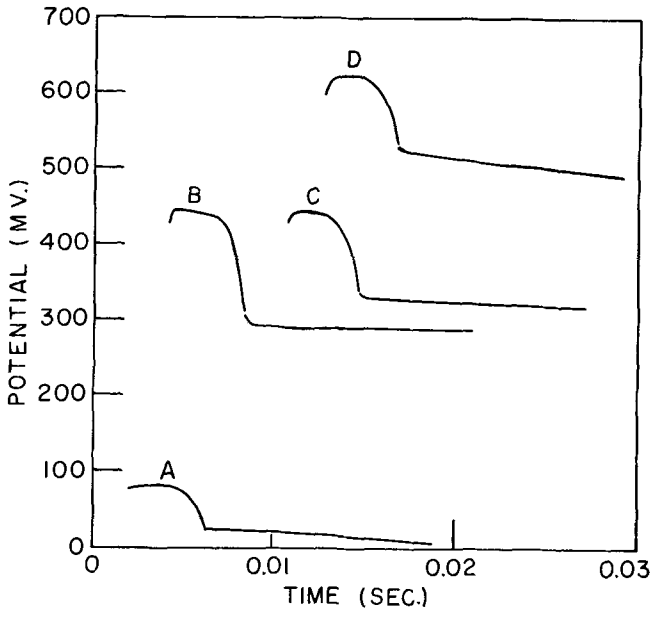

Fig. 9. Some potentials during quarter-wave charge at 20-hr average current in 35% KOH. Potentials are given with respect to Ag/Ag_2O electrode. A, half charged at Ag/Ag_2O potential plateau; B, ⅛ charged at Ag_2O/Ag plateau; C, ⅞ charged at Ag_2O/AgO plateau; D, while strong oxygen evolution occurred.

the charge progressed until the electrode was 80% charged. This charge in 50% KOH gave a capacity slightly below normal. Six-minute stands repeated every 10 min in 35% KOH, a charge that gave relatively low capacity, had similar weak maxima in the charging potentials.

Two-minute stands every 10 min were also tried when using the 6-hr charge rate in 35% KOH. Two cycles gave an average 98% of normal (20-hr rate) capacity, instead of the 83% average obtained using constant current at the 6-hr rate. This charge was tried with the commercial silver-zinc cells at the 20-hr rate, but it gave no significant change in capacity.

A charge current that was interrupted 60 times a sec resulted in improved capacity when using 35% KOH, but had no particular effect in 50% KOH (Table II). Included in Table II are normal constant current cycles which alternated with the cycles using rapidly pulsating charge current that was derived from 60-cycle a.c. Although there was variation in capacity during the life of the cells, the variation did not conceal the beneficial effects that could be obtained, even when actual discharge capacity was considered. This is shown in Table II where discharge capacity is given both in terms of average normal capacity at a particular point in the cycle life of the cells and also as a per cent of capacity that was theoretically possible for the sintered silver of the six test electrodes that were used here.

A few typical potentials drawn from oscilloscope photographs of a quarter-wave charge are given in Fig. 9. The average current was the 20-hr rate, but peak current was about 7 times larger. This current wave-form was shown in the upper part of Fig. 2. The same types of charge current were used at the 6-hr rate (Table III) and using commercial silver-zinc cells (Table IV).

During a discharge following a normal charge at the 20-hr rate, 26-32% of the capacity was obtained before reaching the Ag_2O/Ag potential plateau. The same proportion was obtained after a charge with repeated stand periods, with but few exceptions. The proportion of discharge at the upper potential plateau was often 5-10% longer than normal following charges having stands of 2 or more hours after each 3 hr of charge. After charging with the various forms of rectified 60-cycle a.c. at the 20-hr rate, the dis-

Table II. Effect of 20-hr charges using current pulsating 60 cps

Values in brackets give the number of measurements made.

charge at the upper plateau was at a lower potential and the proportion was usually 5-10% shorter than normal. Capacity obtained at this plateau had not increased as much as total capacity had increased. The discharge capacity at this plateau was practically unchanged following a charge of 50% constant current with 50% superimposed a.c., although total discharge capacity was considerably increased. This resulted in the proportion of discharge being about 20-25% less than the normal proportion.

For one series of cycles a cell was charged at the 20-hr rate and was then discharged at the 1-hr rate, instead of the 20-hr rate. The initial discharge at the 1-hr rate gave a capacity that was about the same as normal capacity, but on repetition the capacity of discharges at the 1-hr rate was increased by an average of 10%. Under these conditions full-wave rectified a.c. or repeated 8-min charges followed by 2-min stands gave about the same capacity at the 1-hr discharge rate as did constant current charges. Quarter-wave rectified a.c. gave about 5% additional improvement in discharge capacity.

Discussion

The experimental results showed that significant improvements in capacity were possible through the use of repeated open-circuit periods during charge when using 35% KOH as the electrolyte. The largest capacity increases were obtained by using a rapidly fluctuating current, with or without stand periods (Table II). All of these rapidly pulsating currents that were tried at the 20-hr rate improved capacity in 35% KOH. There was no marked change in capacity when stand length and pulse current both increased, with net current remaining equivalent to the 20-hr rate (Table II). Superimposing a charge current that was pulsating 60 times per second onto a constant charge current, the smoothest type of current used except for constant current, could give a large improvement. This type of current is related to that used earlier, in which current was increased for a few seconds every 10-60 min and an increase in capacity up to 30-40% was obtained (1). Lack of improvement in 50% KOH was also noted in this earlier work.

Constant current at the 6-hr rate gave only about 5/6 of normal capacity in 35% KOH but close to normal capacity could be obtained by using rapidly pulsating currents (Table III). Here again a relatively large improvement resulted from superimposing a charge current that was half-wave rectified a.c. onto a steady charge current. Benefits at the 6-hr rate of charge were less in proportion than they were at the 20-hr rate.

Comparison of Fig. 3, 5, and 6 showed that neither stand length nor charge length nor ratio of these lengths determined whether or not a particular charge-stand combination was beneficial. A disadvantage to some of these types of charge with repeated stands was that total charge time increased greatly. Higher capacity was not just an effect of this increase in total charge time. Charging at the 6-hr rate with 1-hr stands after every hour of charge required only two-thirds of normal charge time but gave 10% more capacity than a normal charge. Charging at the 20-hr rate with charge periods of 3 hr alternating with stands of 3 hr required approximately the same total time as the 40-hr rate of uninterrupted constant current but averaged about twice as much capacity improvement, comparing both types of charge to a normal charge. The use of low charging currents may be preferable for some applications, however, because the following discharge will have a shorter AgO/Ag_2O potential plateau and thus give a more constant discharge potential. Although more AgO is present after charging with a low current than is present after using a high current, the surface area is smaller when the oxide is formed slowly, and this smaller surface is covered more rapidly with Ag_2O during a discharge (4). Therefore the discharge shows less capacity at the AgO/Ag_2O potential level even though total discharge capacity has increased. This initial potential plateau lasted 17-25% of the total time for a discharge immediately following a 40-hr charge, and 7-16% when discharged immediately following an 80-hr charge. As mentioned earlier, 26-32% was obtained following a 20-hr charge or most charges using stand periods.

The wide scatter of individual measurements in 35% KOH that were averaged for the points shown in Fig. 3 and 6 indicated that all factors were not under control. If all factors could be controlled consistently, there is possibility of an improvement larger than that shown by these figures because many individual measurements were much better than the averages. The scatter could not be attributed to different cells nor to whether a measurement was made early or late in the cycle life of a cell.

Potentials gave an indication of electrode conditions. When using stands repeated after 3 hr of charge or stands repeated every 10 min, the largest capacity followed a charge showing strong potential maxima soon after many of the open-circuit periods at the Ag_2O/AgO plateau. A charge lacking these maxima, or having but slight maxima, gave only normal capacity. When a silver electrode is oxidized anodically with constant current, the potential rises sharply to a maximum value after the silver surface is covered with Ag_2O. The first reaction following this potential peak or maximum is Ag_2O oxidizing to AgO. Little or no additional silver oxidizes until a large part of the Ag_2O has oxidized (4, 5). With some charge-stand combinations the open-circuit potentials began to have a minimum value as the charge continued to form more AgO (Fig. 7, 8). The potential minimum tended to reach increasingly lower values as the AgO layer thickened, for approximately the first half of this type of charge (Fig. 8). The potential minima were probably the result of nonuniform distribution of oxygen and silver in the oxide layer (6).

When the electrode was about one-third charged using 2-min stands every 10 min, potential patterns began to be repeated every 20 min (hour 11 Fig. 7, 8). The low stand potential and the following high charging potential both indicated that ion movements were retarded under these conditions. Then a change must have occurred that decreased concentration gradients in the electrode. It is believed that the oxide coating cracked, allowing electrolyte to penetrate nearer to the silver, and this decreased the concentration gradients in the oxide layer. Decreased concentration gradients were indicated both by the lowered charge potentials and by the potentials of the next stand being nearer to equilibrium values, close to values measured earlier when only a small amount of AgO was present. The process was repeated as the film built up again. It is likely that development and removal of concentration gradients in the electrode were also at least partly responsible for the potential maxima observed after stands of 1-5 hr. These comparatively slow changes within the electrode probably did not take place to any great extent when using current pulsating 60 times per second because of the short time between successive current pulses.

An additional factor during the long stands was formation of a thin Ag_2O film on the silver as a result of the reaction between silver and AgO (3). During short stands the formation of Ag_2O was not appreciable. When charge was resumed after 1-hr stands, potential often did not rise to a peak immediately (Fig. 4) as it should have done if the maximum were caused entirely by Ag_2O resistance. The reaction between silver and AgO can result in slightly deeper oxidation and slightly increased capacity. Benefit would be limited because the reaction rate probably decreased as the Ag_2O film thickened and separated the reactants. In earlier work Ag_2O was not definitely

visible to x-ray diffraction even after 2½ days stand of a charged electrode, although x-ray diffraction patterns of AgO had weakened in this time (4). It should be noted that Ag_2O was more likely to form deep in the electrode where silver was available than at the electrode surface where Ag_2O could be detected more readily by x-ray diffraction.

It is unlikely that enough Ag_2O was formed in the longer stand times used in these charging methods for the Ag_2O to cause sufficient resistance to account for the entire potential rise. If there were a high internal resistance due to Ag_2O, there would be a large potential gradient in the electrode as current passed. Although grid or terminal potential could be quite high the surface potential would not be expected to rise beyond the potential necessary for oxidation of Ag_2O to AgO. But potentials rising to the oxygen evolution value have been observed after long stands (2). It may be that as conducting paths to the surface are formed, when a charge is resumed after very long stands, concentration of charge current along these conducting paths allows the surface to reach the gas evolution potential. Oxidation of Ag_2O and oxygen evolution could then take place simultaneously until potential fell as more or better paths to the surface are formed.

A more important factor to be considered is changes in AgO crystallinity under the different charge conditions. It has been established that there is an exchange of oxygen between a KOH solution and AgO (7). It would not be surprising if there is also an exchange between dissolved silver and AgO. These exchange reactions would allow perfection of the AgO crystallinity and smoothing of the surface when time was sufficient, such as during long stand periods or during low-rate charges. Thus true current density following a long stand would be higher at the surface of the electrode and the increased current density could account for high charge potentials as well as the low discharge potentials that have been observed at the AgO/Ag_2O level after very long stands. Results in 50% KOH, although not improved by a charge with repeated stands, usually were much more reproducible than in 35% KOH. This was probably at least partly caused by physical differences between the AgO coatings that formed on silver in 35% KOH and the coating in 50% KOH. Perhaps AgO crystallizes in a physical form in 50% KOH that retarded passage of oxygen through the AgO. There is no reason to assume that a cubic AgO forms initially and that this AgO converts to monoclinic AgO at low current or during long stands as has been suggested (2). Monoclinic AgO can actually be detected quite soon after anodic potential reaches the Ag_2O/AgO plateau (4) and the compound originally reported as cubic AgO has since been shown to be a different material (5).

The most important cause of increased capacity in the charges that were beneficial was believed to be an increased surface area. Increased surface area allowed more AgO to be formed during a charge before slow diffusion through the AgO caused sufficient polarization that potential rose to the oxygen evolution value. When the charging potential increased to a relatively high value after a stand, oxygen from the surface layers could penetrate deeper into the oxide layer under the influence of the high charging potential, thus oxidizing silver that was under the oxide coating.

There is a large expansion when a certain quantity of silver is oxidized to an equivalent amount of Ag_2O. There is only a slight additional increase in volume when Ag_2O is oxidized to an equivalent amount of AgO. If the reactions take place entirely in the solid state, with each single crystal of Ag_2O changing into a single crystal of AgO, then an oxide film may also be broken by distortion of the crystal lattice. Two cell dimensions expand, one contracts and one angle changes as a face-centered cubic crystal of Ag_2O is oxidized to monoclinic AgO. Expansion of the crystal lattice as AgO formed from Ag, most likely through Ag_2O as an intermediate, probably cracked the oxide coating which covered the electrode and allowed electrolyte to penetrate nearer to the silver under these conditions. The increased porosity resulted in decreasing current density and decreasing concentration gradients within the oxide layer. For this reason the charge potential fell to its lowest value in the same 8-min period that had the highest potential (for example see curve at 21 hr 10 min in Fig. 7).

Thus the potential drop after the maximum was probably caused by breaking of the smooth oxide layer and, after long stands, also partly caused by oxidation of resistive Ag_2O to AgO. If the drop in potential were merely the result of activation of the semiconductors Ag_2O (3) or AgO (2), conditions after activation would be the same as they were before interrupting the current, and there would be no reason to expect increased capacity after a series of potential maxima, but the best discharge capacity usually followed charges that showed irregular potentials. It is proposed here that the capacity increase was mainly the result of deeper oxidation of the silver, caused by breaking of the surface as AgO formed below the electrode surface.

The increased amount of oxide that formed when using current pulsating 60 times per second in 35% KOH was probably also the result of surface area increasing as the oxide film on the electrode broke or roughened when current was high. Stresses may be set up as a result of fast formation of the oxide film or layer and then be relieved by cracking. Stand time was not important or even necessary when using these rapidly pulsating currents (Tables II, III). Current being high for only a brief time prevented harmful formation of large concentration gradients, such as would have occurred if curernt had remained high for longer times. Charges at the 6-hr rate were less beneficial than charges at the 20-hr rate because the faster charge resulted in larger concentration gradients in the electrolyte and smaller crystals of AgO were formed (4). Both of these effects could limit further oxidation.

The mobility of the hydroxyl ion is an important factor in the oxidation process (8). Lack of hydroxyl ion at the electrode can seriously impair charges. This can occur in concentrated KOH solution, or when using high current densities, or at low temperatures. A combination of these is more harmful than any one singly. For example, capacity decreased more rapidly with increasing charge current in 50% KOH than it did in 35% KOH (9). Thus one would expect that a current pulsating 60 times per second (and momentarily reaching higher current densities than a normal charge) would not necessarily give as good results in 50% KOH as it does in 35% KOH, especially when using faster charges (Tables II, III). The limited amount of free electrolyte in the commercial silver-zinc cells, due to tight packing in the cell cases, probably resulted in increased concentration gradients in the electrolyte near the electrode surface compared to test cell conditions. This may be the reason for the commercial cells usually not showing the improvement that test cells showed, but no experimental work was done to prove this.

As mentioned earlier, the rate at which a cell was discharged in 35% KOH had a large effect on the results of a charge using pulsating current. It has been shown that a charge following a high-rate discharge gave more capacity than a charge following a low-rate discharge because of differences in chargeability of the forms of silver that resulted under these conditions (4). Therefore when a cell was given a series of complete discharges at low current density, capacity tended to decrease at least to a point. If a cell was then given a series of complete high-rate discharges, capacity tended to increase back toward the original value. As a result of this, although a single

discharge at the 1-hr rate might give less capacity than the preceding discharge at the 20-hr rate, after several discharges at the 1-hr rate (and recharges at the 20-hr rate) the capacity increased to a value larger than it was after a series of discharges at the 20-hr rate. Charge acceptance at the Ag/Ag_2O plateau had doubled, but charge at the Ag_2O/AgO plateau was only 90% of its normal length. Under these conditions, where the capacity was high already, a constant current charge gave about the same capacity as the pulsating charges.

Several phenomena were involved in the results reported here and no single explanation will adequately cover them all. Further work is obviously necessary for a more definitive explanation and will be undertaken after determining the effect on capacity of current reversals during a charge. In particular a microscopic examination of the electrodes at various steps in the different types of charge is expected to be useful.

Conclusions

The charge methods described can be beneficial or harmful, depending on specific conditions. Faster charges or greater capacity after slow charges could be obtained by these charging methods. Results in 35% KOH were always better than in 45 or 50% KOH. The charge methods worked best when a cell had previously been discharged at low currents.

The Photogalvanic Disruption of Cuprous Oxide Films on Copper

E. J. Duwell

Minnesota Mining and Manufacturing Company, St. Paul, Minnesota

ABSTRACT

The cuprous oxide film normally present on copper is disrupted by photogalvanic action. Partial illumination of an oxidized copper surface in an electrolyte results in reduction of the cuprous oxide to metallic copper in the illuminated areas and oxidation and dissolution of the cuprous oxide in the unilluminated areas. The disrupted film is believed to lead to an observed increase in corrosion rate of copper in an illuminated salt-spray cabinet.

It is well known that a photovoltaic effect characteristic of a p-type semiconductor can be observed on cuprous oxide (1-5). Since the oxide layer on mildly oxidized copper consists essentially of cuprous oxide, it is not surprising that there have been numerous reports of the effect of light on the corrosion of copper (6-10). In general, light has been found to accelerate the corrosion of copper, although it has been shown recently that the rate of initial growth of the oxide film is decreased by light under certain conditions (11), while the dissolution of cuprous oxide to cupric ions is promoted by light.

When the oxide film becomes relatively thick (200Å), it serves to some extent as a protective film against further corrosion. We have found that the effectiveness of this film is greatly decreased by light if the oxide coated surface is covered by a conducting solution. The purpose of this paper is to describe the photogalvanic reactions which take place on oxidized copper surfaces to disrupt the continuity of the oxide film. Using a simple salt-spray corrosion test, the effect of light on the oxidation rate of copper was also evaluated.

Experimental

Because copper is a relatively noble metal, the oxide can be removed from the surface by acid dissolution without appreciable attack of the metal. If a dilute acid such as 2M H_2SO_4 is used, only half of the copper in the cuprous oxide film is dissolved as a result of disproportionation

$$Cu_2O + H_2SO_4 \rightarrow Cu^o + Cu^{++} + SO_4^{=} + H_2O$$

Although this method has been used for oxide film analysis by previous investigators (12), it was felt that total dissolution of the oxide film with concentrated hydrochloric acid would be more suitable for our purposes. In this case the acid dissolves all of the cuprous oxide with formation of the anionic chloride complex

$$Cu_2O + 4HCl \rightarrow 2CuCl_2^{-} + 2H^{+} + H_2O$$

In either case, care must be taken to exclude atmospheric oxygen which would cause further oxidation and dissolution of the metal. Cupric oxide is dissolved by either method, and, therefore, the latter method can be considered an analysis for total oxidized copper, while the former method would result in an ambiguity if the oxide film contained an unknown amount of cupric oxide. The oxide film on copper treated at 300°C for about 10 min has been shown to be essentially all cuprous oxide (13). Analysis of equal areas of an oxide film prepared under these conditions by both the dilute sulfuric acid and concentrated hydrochloric acid dissolution methods resulted in twice the concentration of copper in the hydrochloric acid solutions, thus verifying the self-consistency of the two methods.

Analysis for copper in solution was done spectrophotometrically after formation of the tetraethylene pentamine complex as outlined in the literature (14).

The copper corrosion samples were ASTM B-133 pure copper (99.9+%). Other chemicals used were all reagent grade. Ordinary household tungsten filament incandescent lamps were used for illumination.

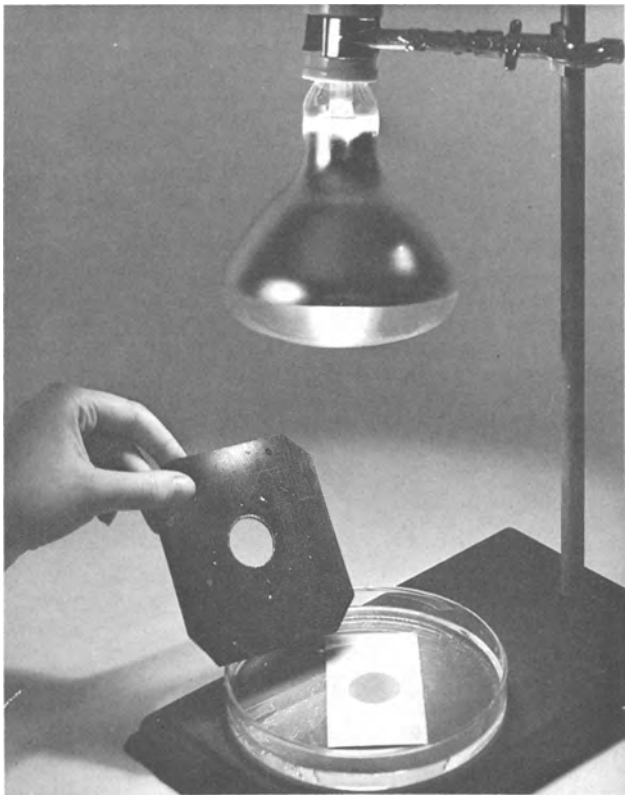

Fig. 1. Photogalvanic action on an oxidized copper panel immersed in saturated KCl solution. The exposed area became black after illumination for 10-15 min at a light intensity of 5000 ft-c.

Experimental Results

A photogalvanic cell reaction on oxidized copper is easily demonstrated. The copper may be heated at 300°-400°C for 30 min or may be simply held in a Bunsen flame until the reddish brown cuprous oxide coating develops but not until an incoherent cupric oxide film is formed. If the copper panel is then immersed in a salt solution and partially illuminated, the illuminated portion of the surface eventually becomes black (Fig. 1). At a light intensity of 5000 ft-c, the discoloration on the illuminated surface just becomes discernible in 1 min. The same area is quite black after 10 min. The blackening is greatest at the periphery of the spot. These areas are, of course, closest to the unilluminated area, and the resistance through the solution is a minimum. Apparently any soluble salt which does not attack the oxide surface will serve as an electrolyte and will permit the photogalvanic reaction to take place. There is no evidence of a surface reaction if the surface is dry or is covered with distilled water. Also, simple qualitative experiments revealed that the rate of blackening depends on salt concentration.

The change in potential of the illuminated surface can be compared through an external circuit with the electrode potential of a similar panel kept in the dark or more simply with a calomel reference cell. In either case, light is noted to make the oxidized copper more positive by a potential as high as 0.12v (Fig. 2). The magnitude of the effect apparently depends on the manner in which the oxide layer is formed. If the oxide layer is grown in a salt-spray cabinet for several days, the change in potential is from 10-25 mv. Short exposures of the copper to higher temperatures generally appears to produce a more photosensitive surface than slow oxide growth at lower temperatures.

A copper cylinder, ⅜ in. in diameter, was oxidized at about 300°C, immersed in saturated KCl solution, and a small portion of the surface illuminated with a tungsten lamp. The illuminated portion of the surface

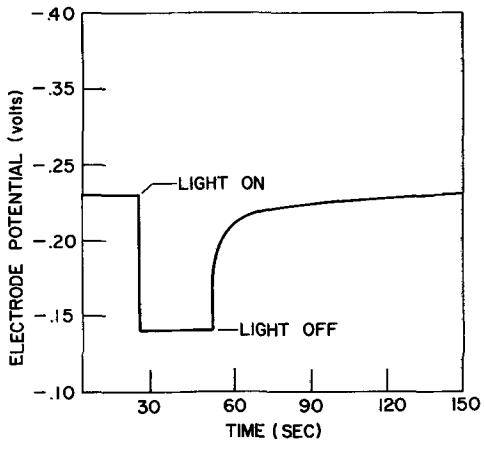

Fig. 2. Photogalvanic response of an oxidized copper panel relative to a saturated calomel electrode. The light intensity was 3000 ft-c.

which became black was compared with the original surface by grazing angle electron diffraction. The original surface gave a diffraction pattern characteristic of cupric oxide, while the illuminated surface gave a diffraction pattern of metallic copper. No diffraction pattern was observed on surfaces adjacent to the illuminated area indicating the formation of an amorphous surface layer. It is not surprising that a cupric oxide rather than cuprous oxide pattern was obtained on the original surface since a thin layer of cupric oxide always appears to form over the cuprous oxide. The same result was obtained by Beck and Pryor (13) who also identified the cuprous oxide layer using a stripping technique and diffraction patterns obtained by electron transmission.

In a photogalvanic cell (Fig. 3) constructed of two copper electrodes oxidized at 360°C for 1 hr, the illuminated electrode was also observed to become blackened with time. Immersion of both electrodes in concentrated hydrochloric acid resulted in complete cleaning of the unilluminated electrode, but an insoluble black sludge consisting of finely divided metallic copper clung to the illuminated electrode. This sludge was easily removed with a rubber policeman and dissolved in dilute nitric acid. Initially, the conversion of the oxide coating appears to proceed linearly with time (Fig. 4). Approximately 0.01 mg Cu/cm^2 is removed without illumination. This is probably a result of air oxidation and mechanical removal of the oxide film. The total amount of oxidized copper available for reduction was about 0.30 mg/cm^2.

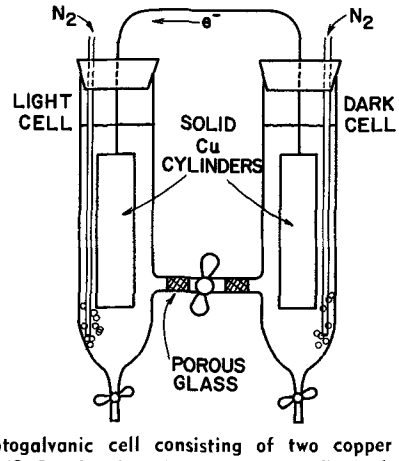

Fig. 3. Photogalvanic cell consisting of two copper electrodes oxidized at 360°C. The direction of electron flow when the left cell is illuminated is from right to left. The cells are kept free of oxygen through the use of nitrogen bubblers.

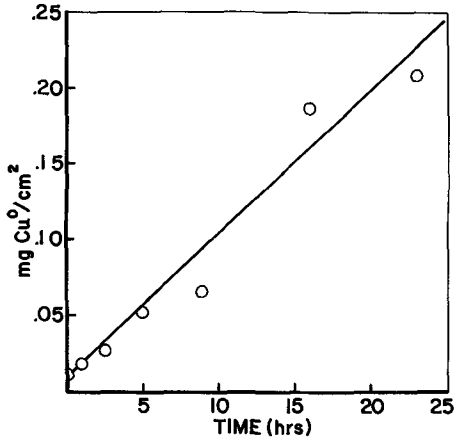

Fig. 4. Reduction of Cu_2O to copper metal as a function of time at a light intensity of 500 ft-c (light cell, Fig. 3).

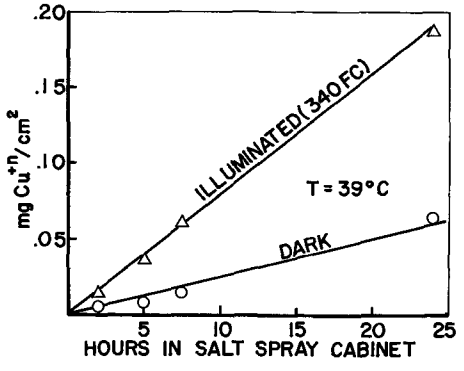

Fig. 5. Corrosion rate of copper as a function of time in a dark and illuminated salt-spray cabinet. Temperature was constant at 39°C.

If the external circuit of the photogalvanic cell (Fig. 3) is opened, reduction of the oxide on the illuminated electrode still takes place but at a slower rate. Despite careful cleaning and uniform illumination, both cathodic and anodic sites must, therefore, be present on the illuminated electrode. Closing the circuit results in dissolution of the oxide film on the unilluminated electrode as evidenced by analysis of the cell solutions after 7 hr of illumination (Table I).

The rate of corrosion of copper in a salt-spray cabinet was increased by a factor of 3.2 when the panels were illuminated on one side with a light intensity of 340 ft-c (Fig. 5). The panels were abraded clean and washed in acetone prior to being placed in the salt-spray cabinet. A further increase in corrosion rate was noted at higher light intensities (Fig. 6). The lamp was kept in an air-cooled container to avoid a temperature increase in the chamber.

Discussion

Although the kinetics of some electrode processes may be affected by photosensitive reaction steps or by photosensitive products of the electrode reaction, the reactions which have been described appear simply to be generated by the photovoltaic effect commonly observed in cuprous oxide. Accordingly, the electrode reactions do not appear to depend on the composition of the electrolyte but only require the presence of a neutral conductive solution. For example, since no electrode reactions occur in distilled water, it can be concluded that light does not directly cause disproportionation of the oxide film. Rather, the illuminated surface undergoes reduction

$$2e^- + Cu_2O + HOH \rightarrow 2Cu^\circ + 2\,OH^-$$

while anodic oxidation of the oxide film takes place on the unilluminated surface

$$4H_2O + Cu_2O \rightarrow 2Cu(OH)_2 + H_2O + 2H^+ + 2e^-$$

The copper initially goes into solution, but prolonged operation of the cell shown in Fig. 3 eventually results in the appearance of gelatinous cupric hydroxide in the dark chamber. The observed polarity can be correlated with the effect of light on the current carrying mechanism in p-type semiconductors (5), of which cuprous oxide is an example.

It is apparent that the introduction of oxygen to the system presents a complex chemical situation. It can probably be assumed that photogalvanic reactions make the surface more susceptible to further oxidation, thus increasing the corrosion rate under conditions such as those encountered in a salt-spray cabinet. To determine if such reactions occur more readily at anodic or cathodic sites and if the subsequently formed oxide surface is also photosensitive, the anodic and cathodic reactions must be isolated in a system in which the oxygen concentration is carefully regulated.

Table I. Effect of illumination on surface and solution composition of photogalvanic cell

A: External circuit open; B: external circuit closed

	Light Chamber		Dark Chamber	
	$Cu_{electrode}$,* mg	$Cu_{solution}$	$Cu_{electrode}$,* mg	$Cu_{solution}$

The Effect of Oxide Volatilization on the Oxidation Kinetics of Cr and Fe-Cr Alloys

C. S. Tedmon, Jr.

General Electric Company, Research and Development Center, Schenectady, New York

ABSTRACT

The oxidation of Cr and Fe-Cr alloys which form Cr_2O_3 scales involves at least two processes: (*i*) the solid-state, diffusive transport of ionic species, with parabolic kinetics, and (*ii*) the oxidation of Cr_2O_3 to a volatile species, probably CrO_3, with linear kinetics. The effects of this second reaction cannot be neglected, either in interpretation of short-term oxidation results, or in predicting long-term oxidation behavior. In this paper equations are derived which describe the oxidation behavior of a system in which both diffusive and gas/oxide interface processes occur simultaneously. According to the model, the oxide scale grows to a limiting thickness which is determined by the parabolic rate constant and the surface-reaction rate constant; as the limiting thickness is approached, a transition from parabolic to linear kinetics takes place. The model is applied to the oxidation of Cr and Fe-Cr alloys, and good agreement with experimental data is found.

When Cr_2O_3 is heated to above 1000°C in an oxidizing atmosphere, it loses weight (1-6). This weight loss cannot be accounted for simply by vaporization of the oxide, since it occurs only when the specimen is exposed to an oxidizing atmosphere (3-5); furthermore, the reported values of the vapor pressure of Cr_2O_3 (4, 7) are too low to account for the observed rates of weight loss. The chemical reaction involved in the Cr_2O_3 weight loss has not been completely identified, but is probably (3, 7)

$$Cr_2O_3(s) + 3/2\ O_2(g) \rightarrow 2CrO_3(g) \qquad [1]$$

Reduction of CrO_3 back to Cr_2O_3 subsequently occurs in cooler parts of the system.

Hagel (4) measured the rate of weight loss of Cr_2O_3 samples exposed to oxygen and found that the weight loss could be expressed by

$$\frac{\Delta M}{A}\left(\frac{g}{cm^2}\right) = -k_v t \qquad [2]$$

where the "volatilization rate constant," k_v, has the temperature dependence

$$k_v = 0.214 \exp(-48{,}000 \pm 3000/RT)\ g\ cm^{-2}\ sec^{-1} \qquad [3]$$

Although Hagel (4) corrected his highest temperature (1350°C) Cr oxidation data for such weight loss, the large effect that this surface reaction has on the parabolic oxidation kinetics of Cr and alloys which form Cr_2O_3 scales has not been generally recognized. It will be seen in the following discussion that unless this surface reaction is taken into account in oxidation studies, two significant effects can appear: (*i*) short-time oxidation kinetic data may be incorrectly interpreted, and (*ii*) estimates of service life will be in error.

That a surface-controlled reaction could alter parabolic oxidation kinetics was pointed out by Loriers (8). Subsequently, Webb, Norton, and Wagner (9) derived more general equations in order to explain their tungsten oxidation data. More recently, Birchenall (10) has discussed various factors which could alter parabolic oxidation kinetics, including the effect of a gas/oxide interface reaction.

Derivation of Rate Equations

Rate of scale-growth.—Consider the case of a metal having an adherent, dense, external scale, of thickness x at some time t. The instantaneous rate of growth of the scale is given by

$$\frac{dx}{dt} = \frac{k_d}{x} \qquad [4]$$

where k_d is equal to one-half of the usual parabolic rate constant, k_p. Because of the oxide-gas interface reaction, the scale will tend to get thinner, and the kinetics for this process are described by

$$\frac{dx}{dt} = -k_s \qquad [5]$$

where k_s is proportional to k_v. Combining Eq. [4] and [5] gives

$$\frac{dx}{dt} = \frac{k_d}{x} - k_s \qquad [6]$$

Integration of Eq. [6] yields

$$\frac{-x}{k_s} - \frac{k_d}{k_s^2}\ln(k_d - k_s x) + C = t \qquad [7]$$

where C is the integration constant. The integration constant may be evaluated applying the boundary condition that $x = 0$ at $t = 0$. Solving for C and rearranging terms gives

$$t = \frac{k_d}{k_s^2}\left[-\frac{k_s}{k_d}x - \ln\left(1 - \frac{k_s}{k_d}x\right)\right] \qquad [8]$$

Since the rate of scale growth decreases with increasing thickness, eventually the rate of growth of the scale will become zero, and a limiting scale thickness is reached. For Cr oxidation, this means that the rate of supply of Cr^{+3} cations to the gas/oxide interface from diffusion through the scale is balanced by the rate of loss of Cr ions, presumably due to reaction [1] or some similar process. The limiting scale thickness may be determined by setting Eq. [6] equal to zero, yielding

$$x_f = \frac{k_d}{k_s} \quad [9]$$

If c.g.s. units are employed then the dimensions of k_d and k_s are $cm^2\ sec^{-1}$ and $cm\ sec^{-1}$, respectively. Obviously Eq. [8] is valid only for $0 \leq x < x_f$.

The logarithm term in Eq. [8] may be expanded in a Taylor series, whereby Eq. [8] becomes

$$t = \frac{1}{2}\frac{x^2}{k_d} + \frac{1}{3}\frac{k_s}{k_d^2}x^3 + \ldots + \frac{1}{n}\frac{k_s^{n-2}}{k_d^{n-1}}x^n + \ldots \quad [10]$$

Equation [10] is useful when either x or k_s is small. It is seen from Eq. [10] that when $k_s = 0$, parabolic kinetics obtain, and $k_d = \frac{1}{2}k_p$.

If the activation energies for the parabolic and linear reactions are Q_d and Q_s, respectively, then the limiting scale thickness x_f will be temperature dependent if $Q_d \neq Q_s$. When the limiting scale thickness is reached, the oxidation reaction is no longer diffusion-limited, and oxidation proceeds with a linear rate.

Rate of metal recession.—It is also of interest to determine the effect of a surface reaction such as that described above on the rate of metal recession, since it is this quantity that is of most interest to the corrosion engineer. Let y be the extent of metal recession at some time t ($y = 0$ is the original metal/gas interface at $t = 0$); the differential equations describing the parabolic and linear contributions to the metal recession rate are then

$$\frac{dy}{dt} = \frac{k_d'}{y} \quad [11]$$

and

$$\frac{dy}{dt} = k_s' \quad [12]$$

respectively. Combining these equations yields

$$\frac{dy}{dt} = \frac{k_d'}{y} + k_s' \quad [13]$$

which is of the same form as Eq. [6]. Integrating and solving with the boundary condition above gives

$$t = \frac{k_d'}{(k_s')^2}\left[\frac{k_s'}{k_d'}y - \ln\left(1 + \frac{k_s'}{k_d'}y\right)\right] \quad [14]$$

The logarithmic term in Eq. [14] may be expanded to give an equation analogous to [10].

Kinetic measurements.—A common method of determining the oxidation kinetics of a metal is to measure the weight-change that occurs when a sample is exposed to an oxidizing atmosphere. Clearly, if two reactions are taking place, such as described above, then the weight-change measured is the difference between the gain due to oxygen pick-up and the loss due to metal escaping in the volatile oxide. The weight change may be predicted by utilizing Eq. [5] and [8]. With Eq. [8], the weight-gain arising from oxygen in the oxide can be accounted for, since the oxide thickness at a given time can be calculated. The weight loss, due to the metal contained in the volatile oxide, can be determined as a function of time, by integration of Eq. [5]. The difference between these quantities, that is, oxygen pick-up in Cr_2O_3 and Cr loss in CrO_3, is what is actually measured in a gravimetric experiment.

Application to Cr, Fe-Cr *Alloys, and Other Alloys Which Form* Cr_2O_3 *Scales*

Since the rate of loss of Cr_2O_3 by reaction [1] ought to be essentially independent of the source of Cr_2O_3, the oxidation kinetics of any alloy which forms an adherent, protective Cr_2O_3 scale will be influenced by the loss. This would include such alloys as the ferritic stainless steels which contain more than about 13% Cr (11, 12). Since both oxidation data (4, 13) and Cr_2O_3 evaporation data (3, 4) are available, the constants k_d, k_s, k_d', and k_s' may be evaluated as a function of temperature.

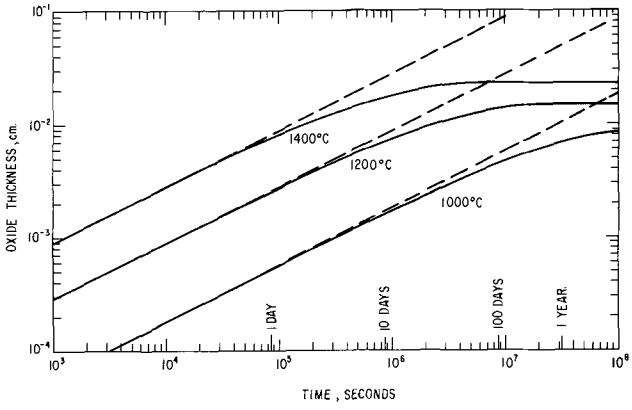

Fig. 1. Calculated oxide thickness as a function of time. The solid curves were calculated from Eq. [8]. — — — Parabolic kinetics.

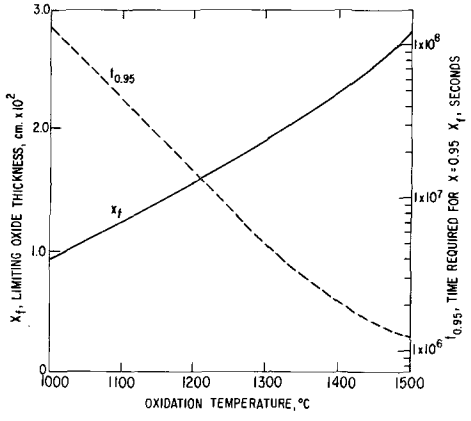

Fig. 2. Temperature dependence of the limiting oxide thickness and the time required for the scale to grow to 95% of its limiting thickness.

Rate of Growth of Cr_2O_3 *Scale.*—Using the data of Hagel (4) to determine the rate constants, Eq. [8] has been evaluated for various temperatures and is plotted in Fig. 1. The dashed lines show the expected growth assuming only parabolic kinetics. For short times, *e.g.*, $t < 10^5$ sec, the growth rate appears to be nearly parabolic. By 10^6 sec, however, significant departures from parabolic behavior are seen at all three temperatures. It is seen that the limiting oxide thickness increases with increasing temperature; however, with increasing temperature, shorter times are required to reach that limiting thickness. The temperature dependence of the limiting oxide thickness is shown in Fig. 2 which also shows the time required for the oxide scale to grow to 95% of its final value, as a function of temperature. By the time the thickness of the scale has reached this value, it is much less than the thickness expected from parabolic kinetics alone.

Metal recession rate.—Metal recession values as a function of time are presented in Fig. 3 for three temperatures. After about 10^7 sec at 1200°C, it is seen that the transformation to linear kinetics is essentially complete. Note that at 10^6 sec, or about 116 hr, the estimated metal-recession is about 20% greater than that expected from parabolic kinetics alone.

Weight-gain rate.—With Eq. [5] and [8], using the data from ref. (4), the net weight-gain (or loss) has been calculated as a function of time for a given temperature. The results of this calculation at 1200° and 1300°C are shown as solid lines in Fig. 4. The dashed curves indicate the weight gain that would be ex-

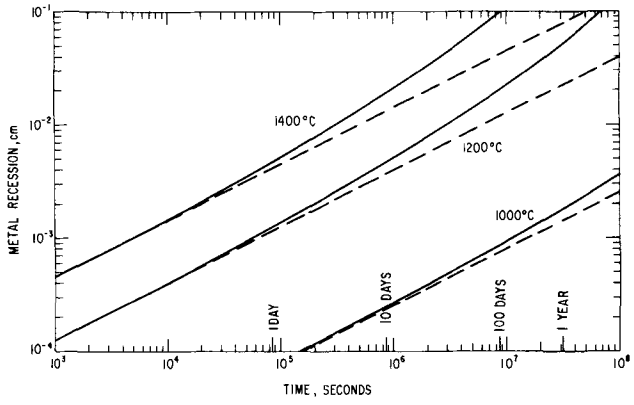

Fig. 3. Calculated metal-recession as a function of time. The solid curves were obtained from Eq. [14]. — — — Parabolic kinetics.

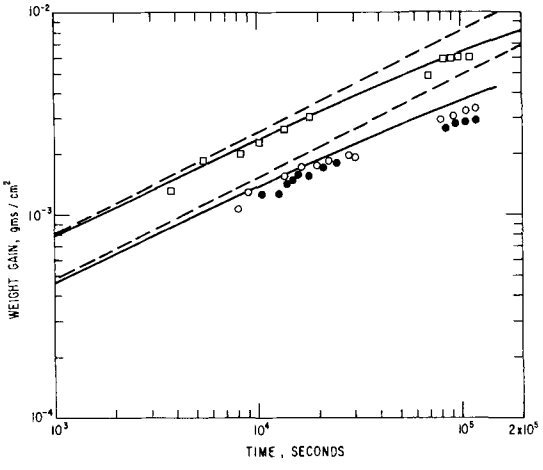

Fig. 4. Calculated and experimental values of weight-gain as a function of time, for short times. P_{O_2} = 100 Torr. □ Fe-70 w/o Cr, 1300°C; ○ Fe-45 w/o Cr, 1200°C; ● iodide Cr, 1200°C. — — — Parabolic kinetics; ——— corrected for loss.

pected from parabolic kinetics alone. Also presented in this figure are some oxidation data for three different alloys which form Cr_2O_3 scales, *viz*, Fe-70 w/o Cr, Fe-45 w/o Cr, and iodide-grade Cr. In spite of the scatter, the data are in good agreement with the calculated curves obtained from Eq. [5] and [8]. The departure from parabolic kinetics for these experiments is not large, because relatively short times are involved. If the data were interpreted in terms of parabolic behavior, the parabolic rate constants thus obtained would be essentially valid when interpreted in terms of ionic transport mechanisms (14, 15). Such data, however, are insufficient to describe the oxidation process fully, especially for extended times. This is shown in Fig. 5, which presents weight-change data for Cr which contained 0.2 w/o Y. This sample was oxidized at 1200°C for almost two weeks. The solid curve is the calculated weight-change evaluated from Eq. [5] and [8]. The dashed curve is the weight change expected from parabolic oxidation kinetics. The circles are experimental gravimetric data; the agreement between calculated values and experimental data may be considered to be quite good.

Summary

The oxidation behavior of Cr and alloys which form Cr_2O_3 scales cannot be accurately described by a parabolic rate law; the effects of a gas/oxide interface reaction, probably $Cr_2O_3(s) + 3/2\ O_2(g) \rightarrow 2CrO_3(g)$ must be recognized and taken into account.

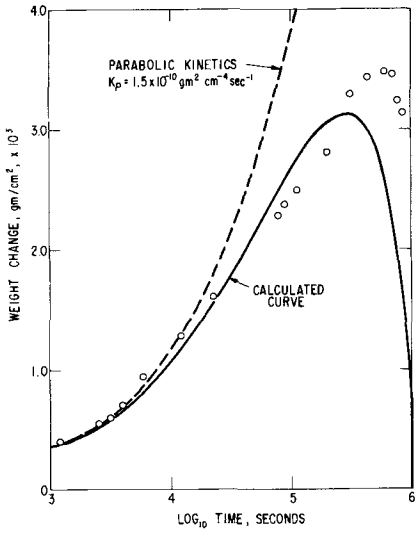

Fig. 5. Calculated and experimental values of weight-gain for extended oxidation. ○ Cr + 0.2Y alloy, 1200°C.

The effect of this surface reaction is to cause a transition from parabolic to linear oxidation kinetics. The oxide scale will grow to a limiting thickness; thereafter, metal-recession will proceed at a linear rate. Also, as the limiting value of oxide thickness is approached, gravimetric data will show departure from parabolic kinetics, and eventually weight loss will ensue at a linear rate. The interpretation of short-time oxidation data and estimated long-term oxidation performance will therefore be in error if based only on a parabolic rate law.

The equations presented herein, while applied to the specific cases of Cr and Cr-alloy oxidation, have completely general applicability to any scaling reactions involving processes possessing parabolic and linear kinetics.

Acknowledgment

Appreciation is extended to Mr. D. E. Broecker, who made the kinetic measurements and to many colleagues who contributed valuable discussion.

The High-Temperature Oxidation of Ductile Cr-Re Alloys

C. S. Tedmon, Jr.

General Electric Company, Research and Development Center, Schenectady, New York

ABSTRACT

The high-temperature oxidation behavior of ductile Cr-Re alloys containing 32 and 44 a/o (atomic per cent) Re has been investigated using thermogravimetric, metallographic, electron microbeam probe, and x-ray analytical techniques. The oxidation reactions taking place include the formation of a Cr_2O_3 external scale, a subscale, and volatile Re oxides. The Cr_2O_3 scale which forms on the Cr-32 a/o Re alloy is an effective barrier to loss of Re; on the Cr-44 a/o Re alloy, the Cr_2O_3 scale is quite porous, and Re loss as volatile oxide ensues, giving rise to linear kinetics. Air-oxidized samples showed essentially the same kinetics as samples exposed to oxygen; Cr_2N did not form.

Cr-Re alloys with Re concentrations near the bcc α-phase solubility limit possess good ductility and high strength (1-3). Since the use of Cr as a structural material has been limited historically by its lack of ductility at low temperature ($T<300°C$) (4-7), the discovery of the Re ductilizing effect has aroused increased interest in ductile Cr-base alloys. Although there is considerable interest in potential applications of Cr-Re alloys at elevated temperatures, an understanding of their oxidation behavior has been lacking.

Over the temperature range of 700°-1300°C, unalloyed Cr oxidizes with parabolic kinetics (8-11). The rate is primarily controlled by Cr^{+3} cation diffusion (8, 12, 13) although other factors such as surface preparation (11), oxide blistering (8, 11) and oxide evaporation (8, 11, 14) can alter the kinetics significantly. Caplan *et al.* have suggested that anion diffusion could also affect the kinetics (11).

The oxidation of Re has been studied by several investigators (15-17). Above about 600°C, linear rates of weight loss are observed due to the formation of volatile Re oxides, probably ReO_3 or Re_2O_7 (17).

The objectives of this investigation were to determine the oxidation behavior of ductile Cr-Re alloys and to identify the factors controlling the kinetics.

Experimental Procedure

Sample preparation.—The melt stock used for the alloys was iodide Cr (99.99%) and Re powder (Chase Brass, 99.99%). The Re powder was vacuum sintered in an electron-beam furnace prior to melting in order to reduce surface oxide and surface area.

The ductility of Cr-Re alloys increases with increasing Re content (3, 18), including Cr supersaturated with Re. Two compositions were studied, *viz.*, Cr-32 a/o Re and Cr-44 a/o Re. Both alloys were prepared by nonconsumable electrode arc-melting under purified argon. Chemical analyses of the alloys are presented in Table I. As prepared, both alloys were single phase, α-bcc structures. The solubility limit of Re in Cr, below about 1400°C, is 36 a/o; above this temperature the solubility increases to 50 a/o at 2280°C (19). The Cr-44 a/o Re alloy, as cast, was supersaturated with respect to Re. Metallographic examination and electron microbeam probe scans showed the alloys to be homogeneous. During oxidation runs at 1100°C and above, the Cr-44 a/o Re alloy transformed to a two-phase $\alpha+\sigma$ structure.

Kinetic measurements.—Samples for kinetic oxidation runs were prepared by cutting slices from the cast ingot, followed by polishing through No. 400 grit SiC paper. Specimens were typically about 4 cm^2 in surface area and about 0.01 cm thick. All samples were degreased and cleaned in toluene and acetone immediately before insertion into the spring-balance furnace.

Isothermal weight-change data were obtained using a quartz helical spring; the sample was hung on a sapphire rod which was connected to the spring. The system was evacuated and the furnace brought to temperature. The desired atmosphere was introduced and the run was commenced. All runs were carried out in a static atmosphere, either dry O_2 at a pressure of 100 mm Hg, or in dry air at 760 mm Hg. Specimen temperature was measured with a Pt/Pt-10 Rh thermocouple located in an Alundum tube, with its junction about ¼ in. from the center of the sample. Temperature control was about ±5°C at the highest temperature (1400°C) and ±2°C in the lower temperature range (1000°C and below). Weight change was determined by following a fiducial mark on the sapphire rod with a cathetometer. Conversion factors for the quartz springs were about 10^5 $\mu g/cm$. Readings were reproducible to about ±0.0005 cm giving a sensitivity of ±50 μg, or for a typical specimen, about ±15 $\mu g/cm^2$. After completing a run, the furnace was shut off and the system was evacuated.

As another means of following oxidation kinetics, isothermal metal-recession measurements were made on the Cr-44 a/o Re alloy as a function of time at 1300°C. The change in sample thickness was determined metallographically.

Auxiliary measurements.—The oxide scales were identified from Debye-Scherrer diffraction patterns. Electron microbeam probe studies of oxidized samples were carried out using a Cambridge Mark II unit.

Following the kinetic runs, oxidized samples were mounted and polished using standard metallographic procedures. Specimens which were to be examined in the microprobe were mounted in an electrically conducting base of copper-filled diallyl phthalate.

Experimental Results

The kinetic data for the Cr-32 a/o Re alloy are summarized in Fig. 1. The data from the 900°C run were quite erratic during the first few hundred minutes. At 1000°C, very little change in weight was observed. Samples run at 1200°, 1300°, and 1390°C exhibited weight gains, with rates decreasing with time, although not in a parabolic manner. The results from two runs at 1300°C are shown; the data represented

by open squares are from a sample exposed to oxygen at 100 mm Hg pressure, and those shown by the open diamonds are from a sample exposed to air at a pressure of 760 mm Hg. Also included in this figure, for comparison, is a plot for pure Cr at 1000°C (8). From the weight-gain data, it would appear that at 1000° and 1200°C, the Cr-32 a/o Re alloy oxidized slower than pure Cr. As a check on this, metal recession measurements were made on these samples. Results are presented in Table II. The last column gives figures for the metal recession that would have occurred on pure Cr during oxidation under the conditions given in the first two columns. These values were calculated from the parabolic rate constant equation for Cr given in ref. (8), and converting weight-gain to metal recession. The metal recession values for the alloy were obtained by comparing the thickness of oxidized samples, as determined by photomicrographs of cross sections, with the original thickness. This is a rather inaccurate measurement, and it is further complicated by the presence of a subscale, as shown in Fig. 2. In determining metal recession, the presence of the subscale was ignored, and the sample thickness was measured from the metal/oxide interface. This means the values in the third column of Table II are somewhat optimistic in describing the extent of oxidation. In any case, it is clear from Table II that the gravimetric data presented in Fig. 1 do not fully describe the oxidation behavior of the Cr-32 a/o Re alloy.

Diffraction analyses of oxide scales from samples run at 1300°C and below showed only Cr_2O_3 to be present. No extra lines were observed, and the lattice parameters of the scales agreed with handbook values (20), within experimental error (±0.001Å).

For the sample oxidized at 1390°C, however, an expansion in lattice parameters was observed, with the a_o and c_o values increasing from 4.954 to 4.960Å, and 13.584 to 13.589Å, respectively.

Scans across oxidized samples with the electron microbeam probe showed a region of Re enrichment and Cr depletion in the metal adjacent to the metal/oxide interface. Figures 3a and 3b present schematically the intensity data for a sample oxidized at 1300°C for 30 hr. The amount of Re enrichment and

Cr depletion increased with increasing temperature. For exposure at 900°C, for 30 hr, the Re-Lα intensity increased about 15% above the bulk value, with a corresponding decrease in Cr-Kα intensity.

Figure 2 is a photomicrograph of a cross section of a sample of the Cr-32 a/o Re alloy oxidized at 1300°C. The external Cr_2O_3 scale is quite dense and well-bonded to the metal. Adjacent to the external scale is a region containing a subscale; intermixed with the subscale are σ-phase particles, which precipitated out of the α-phase as the latter became depleted in Cr. X-ray diffraction results from samples taken near the surface showed only lines characteristic of the metal phases and Cr_2O_3. Therefore, it appears that the subscale is probably Cr_2O_3.

Cr-*44* a/o Re *Alloy*.—The gravimetric oxidation data for the Cr-44 a/o Re alloy are presented in Fig. 4 and 5. Figure 4 shows the weight changes that occurred during the first few hours of oxidation at various temperatures; behavior for extended periods of oxidation is shown in Fig. 5. The data are characterized by a period of rapid weight loss, which may tend to level out with time, depending on the temperature. The data for the 1200°C run, for example, appeared to level out after 300 min of oxidation (Fig. 4), but after 1200 min, there was further loss (Fig. 5).

The results of the isothermal metal-recession experiment are shown in Fig. 6. The open circles are measured values of metal-recession; the dashed line is the metal-recession extrapolated from the 1300°C gravimetric data. In making the calculation, a value of −100 $\mu g/cm^2/min$ was taken for the slope of the weight-change curve (Fig. 5). It was assumed that the weight-change was due only to Re loss; both

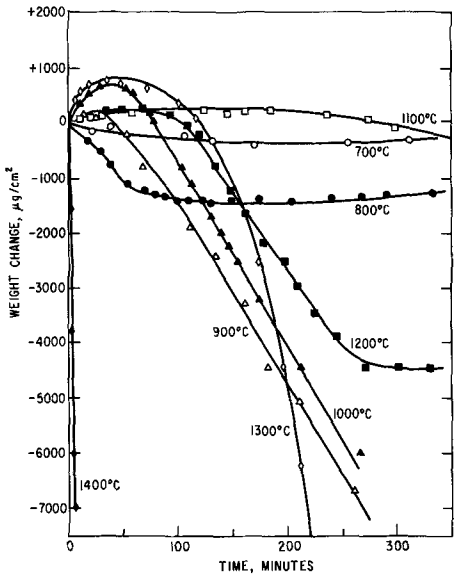

Fig. 4. Short-time oxidation behavior of Cr-44 a/o Re alloy at various temperatures: P_{O_2} = 100 mm Hg.

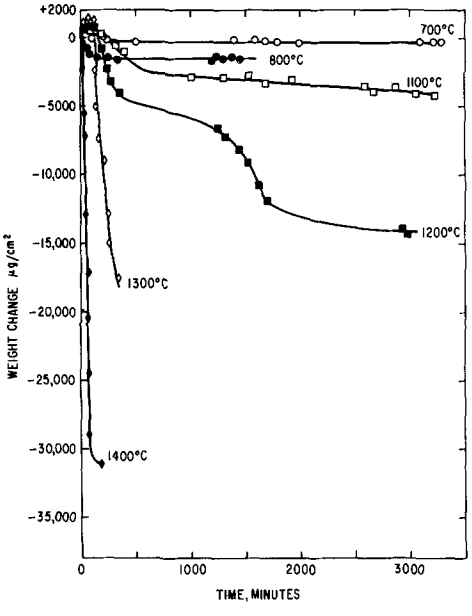

Fig. 5. Extended oxidation of Cr-44 a/o Re alloy at various temperatures. P_{O_2} = 100 mm Hg.

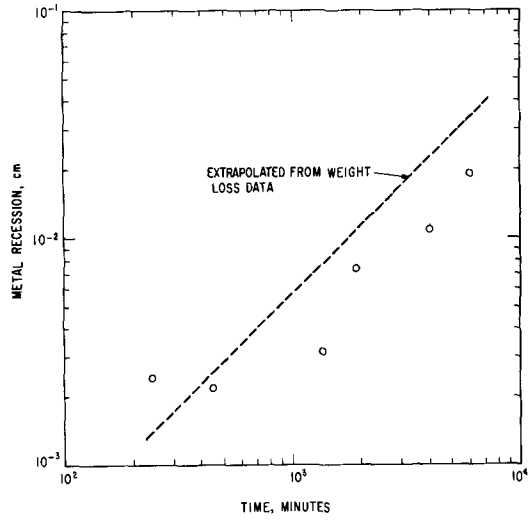

Fig. 6. Isothermal metal recession data for Cr-44 a/o Re alloy. Open circles are experimentally determined data; the dashed line is the extrapolated recession based on a linear rate of weight-loss of 100 μg/cm²min.

weight gain due to oxygen pick-up in Cr_2O_3, and weight losses due to Cr_2O_3 volatilization (8, 14) and metal vaporization were neglected. The density of the alloy is about 13.5 g/cm³. The largest error is in the first assumption; there is of course Cr_2O_3 formation which would tend to offset the weight loss from Re oxide volatilization. The extent of this error is about 20%. At 1300°C, the rate of Cr_2O_3 vaporization is about 2.2 μg/cm²/min (8). The vapor pressure of the alloy is not known. However, since the metal recession data lie within about a factor of two from the calculated curve, certainly the dominant factor influencing the gravimetric data is the rate of loss of Re from the alloy.

It is of interest to compare the rate of weight-loss of this alloy to that of pure Re. At 1300°C, the maximum rate of weight-loss of the Cr-44 a/o Re alloy is about 10^2 μg/cm²/min; pure Re at the same temperature oxidizes to give a linear rate of weight-loss of about 10^5 μg/cm²/min (17).

A few oxidation runs were made in air at atmospheric pressure. The weight-change kinetics were essentially the same as for specimens oxidized in pure oxygen at 100 mm Hg pressure.

X-ray diffraction analysis showed Cr_2O_3 to be the primary oxide product in the external scale. Diffraction results from a sample oxidized at 1400°C indicated that the presence of a small amount of another phase in addition to Cr_2O_3; its Debye-Scherrer pattern could not be indexed.

Electron microbeam probe scans were made on oxidized samples of the Cr-44 a/o Re alloy. The results were qualitatively similar to those obtained from the Cr-32 a/o Re alloy; that is, Cr depletion and Re enrichment occurred in the region adjacent to the metal/oxide interface.

The oxide scale which formed on the Cr-44 a/o Re alloy was adherent and did not spall. The scale was quite porous, as can be seen in Fig. 7(a) and 7(b), taken from a sample oxidized at 1300°C. This porous structure was typical for samples of this composition. The amount of porosity in the scale was somewhat temperature-dependent; at lower temperatures, the scale tended to be more dense. In addition to the porous Cr_2O_3 scale, there is a region of internal oxidation. The morphology of the internal oxide has been strongly influenced by the σ-phase which precipitated from the supersaturated α-solid solution. Metallograpic and x-ray data showed Cr_2N to be absent in samples oxidized in air.

Discussion

Comparison of the gravimetric data with observed metal-recession indicates that with both alloys there are two concurrent processes taking place: (*i*) oxidation of Cr to Cr_2O_3, and (*ii*) oxidation of Re to ReO_3 or Re_2O_7, both of which are volatile at the oxidation temperature (15-17). Since the Cr-32 a/o Re alloy showed weight gains in the gravimetric experiments at 1200°C and above, it appears that in this temperature range the external Cr_2O_3 scale acts as a barrier to further oxidation, and hence linear kinetics do not obtain. The scale is not fully protective, in the usual sense, since some Re loss occurs, as shown by the data in Table II. The formation of the volatile Re oxides could occur by Re diffusing through the Cr_2O_3 scale and reacting with oxygen at the oxide/gas interface, or by reaction with oxygen at the metal/oxide interface, where cracks and similar defects in the scale existed. Since no expansion in lattice parameter was observed, except at 1390°C, and since x-ray fluores-

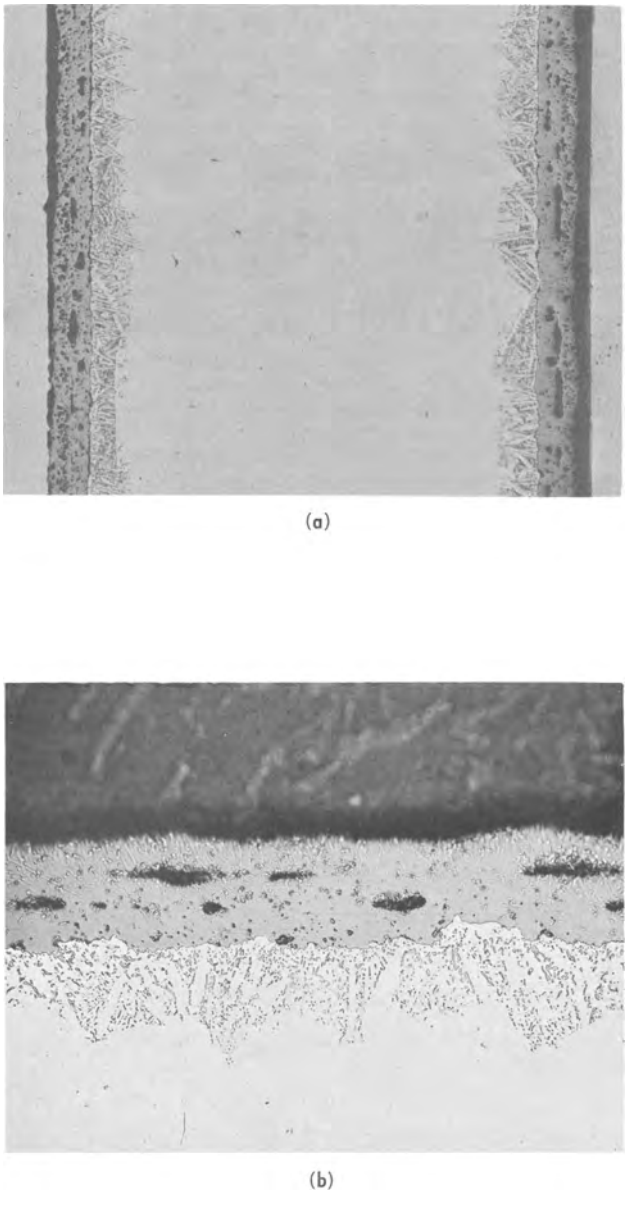

Fig. 7. Micrograph of Cr-44 a/o Re alloy, oxidized at 1300°C. Unetched. (a) Magnification 150X; (b) Magnification 500X.

cence analyses and microprobe scans showed no indication of Re in the Cr_2O_3 scale, there is very little evidence to support the first mechanism. More likely, it would appear that as the external scale grows, mechanical defects form, providing oxygen access to the Re-rich alloy at the metal/oxide interface.

When the Re content is increased to 44 a/o, the Cr_2O_3 scale becomes quite porous, as shown in Fig. 7. Although the scale thickens with time, Re loss continues, and the gravimetric data show weight-loss. The weight-change data indicate that at 1100°C and below, the oxidation rate decreased after several hundred minutes. At 1200°C, the sample showed an increase in rate after about 1000 min of oxidation, apparently due to a mechanical failure in the oxide. At 1300° and 1400°C, the rate of weight-loss was so rapid that the capacity of the spring-balance system was exceeded, after only a few hundred minutes of exposure. The metal-recession data presented in Fig. 6 show that at 1300°C, essentially linear kinetics prevail even after several thousand minutes of oxidation, and at about the same rate indicated from the gravimetric results. Again, as with the Cr-32 a/o Re alloy, the oxidation kinetics appear to be governed by the accessibility of oxygen to the metal/oxide interface.

The subscale which forms on both alloys is apparently Cr_2O_3. It has been suggested that the subscale first forms as a Cr-Re mixed oxide or suboxide, which is stable only in low oxygen partial pressures, converting to Cr_2O_3 and ReO_3 or Re_2O_7 on exposure to oxygen at higher pressures (21). There are however, no x-ray data to support this hypothesis.

The absence of Cr_2N is of interest. It has been postulated that the Re ductilizing effect is a consequence of reduced interstitial solubility (1, 22, 23). In further pursuit of this point, vacuum fusion analyses for total nitrogen content was performed on oxidized and unoxidized samples of the Cr-44 a/o Re alloy. The as-cast, unoxidized sample contained 11 ppm N_2. After oxidation for 28 hr at 1100°C in air, the N_2 content was 28 ppm. This latter figure includes the nitrogen content of the external Cr_2O_3 scale. The inability of Cr_2N to form is probably due to the reduced Cr activity in the Cr-Re alloys (21).

The identity of the volatile Re oxide was not established. During oxidation runs with the Cr-44 a/o Re alloy, a blue condensate formed in cool regions of the furnace, where the temperature was below about 200°C. Opening the system to the laboratory air after a run caused the condensate to become grey-brown. Attempts to identify this were unsuccessful. A blue modification of ReO_3 has been reported in the literature (24).

Conclusions

The oxidation kinetics of ductile Cr-Re alloys containing 32 and 44 a/o Re have been investigated. The oxidation reactions taking place include the formation of a Cr_2O_3 external scale, a subscale, and volatile Re oxides, probably ReO_3 or Re_2O_7.

The Cr-32 a/o Re alloy forms a Cr_2O_3 scale which is compact and adherent. Re loss, as a volatile oxide, takes place by mechanical defects in the scale, such as cracks. The 44 a/o Re alloy forms a porous external scale, which allows direct access of oxygen, resulting in essentially linear kinetics, at least at 1300° and 1400°C.

Air-oxidized samples showed essentially the same kinetics as samples exposed to oxygen; Cr_2N did not form.

Acknowledgments

Appreciation is extended to D. E. Broecker, who carried out a large part of the experimental work. Dr. W. C. Hagel provided much help and advice throughout the experimental program. The author also wishes to thank Dr. C. S. Wukusick, who supplied the Cr-32 a/o Re alloy, and Dr. D. H. Wilkins, who performed the chemical analyses of the alloys.

Manuscript received Feb. 18, 1966; revised manuscript received May 13, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Microsegregation and the Tendency for Pitting Corrosion in High-Purity Aluminum

ABSTRACT

Single crystals of 99.99%, 99.999%, and 99.9999% Al have been grown from the melt under conditions controlled to produce either homogeneous solute distributions, or microsegregation (on the scale ~100μ) of the dominant residual impurities Fe, Cu, and Si. Exposure of samples to NaCl + H_2O_2 resulted in a fine-scale pitting of segregated specimens while homogeneous specimens remained free of such pits. Various mechanical and annealing treatments did not disturb this contrast and, in general, the pitting could be quantitatively related to a previous segregation study in these metals. Polarization measurements showed that the main effect of segregation is to produce a decrease in the cathodic overvoltage which shifts the corrosion potential into a range where pitting occurs. Since the two less pure grades exhibited segregation in the same size scale, and were relatively indistinguishable, it seems that the distribution, rather than the total amount of residual impurity, is more important in producing a tendency for pitting.

Severe microsegregation achieved under conditions of normal solidification in several grades of "pure" aluminum has recently been examined in detail by a combination of an anodic film technique used to locate areas of segregation, and the electron microprobe (1). With the results of this study in hand, it is possible to search for correlation between fine segregation and the initiation of pitting corrosion in purer metals. Although several types of segregation are possible as a consequence of solidification at high impurity levels, in the range of 10 ppm, the cellular substructure is most important. Since much original work and several reviews of the genesis and characteristics of this substructure are available [for example, Chalmers (2)], the following description can be taken as a brief review to accompany Fig. 1 and Eq. [1]

$$\frac{G_L}{V} < \frac{-m_L C_\infty (1-k_o)}{D_L k_o} = \beta \qquad [1]$$

Whenever solidification occurs with solute of concentration C_∞ in the liquid in a binary system of liquidus slope m_L, distribution coefficient k_o, and solute diffusivity in the liquid D_L, such that Eq. [1] holds in unidirectional solidification for growth velocity V, and temperature gradient in the melt G_L, a planar solid-liquid interface is unstable. Equation [1] has been termed the condition for constitutional supercooling; when it is exceeded in progressive degree, various kinetic substructures develop. Extreme conditions lead to dendritic growth but over quite a large

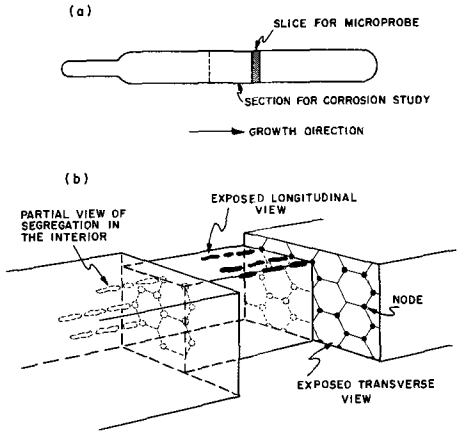

Fig. 1. Schematic diagram showing (a) the location of the samples studied in the as grown crystal and (b) an enlarged (about 100 times) representation of the segregation developed in the cellular substructure. Note that since the regions of high impurity concentrations are discontinuous, a transverse section will not intersect a highly segregated area at every junction of cell walls.

range (3-6) of imposed growth conditions the segregated structure is as depicted in Fig. 1. After solidification is complete there may be a hexagonal net of segregation extending in the direction of crystal growth but it only appears certain that pronounced segregation occurs at nodes, as the junctions of three cell boundaries have been called. The exact configuration of solute in the nodes depends on the solute concentration level and other parameters contained in β; comparative studies have been made in the system Sn-Pb (7-9). At the low concentration levels, which are the most critical test, the nodes display extended, but noncontinuous regions (prolate spheroids), that may be enhanced in concentration by orders of magnitude above C_x. As a result, for many systems such an enhancement must lead to a second phase, that may be quite complex if several residual solutes are concerned in a pure metal, and as solubilities decrease nearer to room temperature, these segregated areas can prove to be indefinitely stable.

Aluminum single crystals already examined quantitatively for the segregation of Fe, Cu, and Si were available for corrosion studies (1). The average quoted purities of the aluminum used are given in Table I. Except for the ultra-pure, zone-refined aluminum, it turns out that segregation can be induced or inhibited at will by manipulation of the growth conditions in Eq. [1]. Thus the zone-refined aluminum which is pure enough to be beyond the range of cellular segregation under normal crystal growth provides an important control and contrast.

Experimental Procedure

In the preceding study, ⅛-in. thick slices were removed approximately halfway along the length of 5 in. crystals of half-inch-square cross section for microprobe study (1). Specimens for corrosion study were taken immediately adjacent to these slices from the single crystals of the two purity levels grown at 1 and 60 cm/hr. The following designation is used: 493-1, 593-1, 493-60, 593-60, and ZR for the 99.993% Al grown at 1 cm/hr, etc., and for the zone-refined aluminum. Investigation of Eq. [1] and Table I shows that the cellular substructure should not appear at the slow growth rate for 493 and 593 nor at all in ZR, but should be present in the other two samples. This was indeed the case (1).

Thus, two sets of samples were available of identical impurity content, differing only in the distribution of impurities. This difference in distribution was revealed by anodizing in sulfuric acid for a short time producing an oxide film whose thickness varied with the nature of the underlying metal, thus giving rise to interference colors that revealed the nodes in the cellular sample (10, 11, 1). Figure 2 shows monochrome prints made from photomicrographs obtained from cellular and noncellular samples of the same composition.

Samples for corrosion study were prepared for all tests by electropolishing in a mixture of two parts acetic anhydride and one part perchloric acid, cooled below 20°C. Several hours at an applied potential of 30v was required for a satisfactory polish, free of pits.

All pitting measurements were carried out by exposing the polished aluminum to 0.5M NaCl containing 0.3% H_2O_2 for 200 min. The *p*H of this solution ranged from 5.6 to 6.0. Cathodic polarization measurements were made galvanostatically in the same solutions. Potential readings were made 1 min after switching on the desired current. Potentiostatic anodic polarization measurements were made in 0.5M NaCl deaerated with nitrogen. Current readings were made 5 min after setting the desired potential.

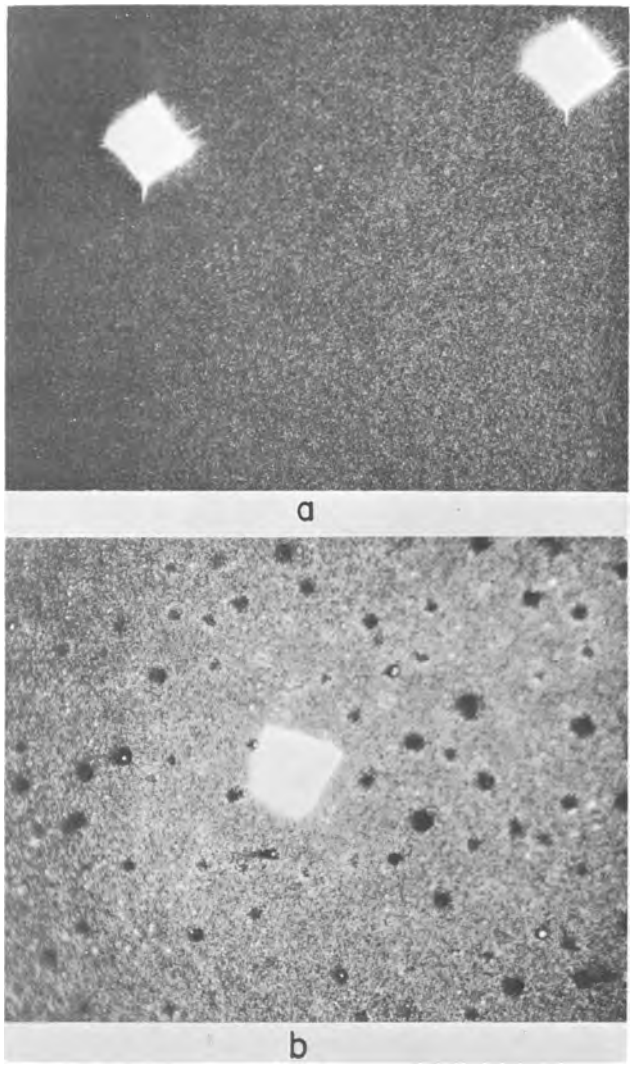

Fig. 2. Anodically filmed aluminum (a) 493-1 (noncellular) and (b) 493-60 (cellular); fiducial marks are visible. Magnification 120X.

Results

Pitting tests.—Exposure of the as-grown specimens in the NaCl-H_2O_2 pitting solution produced pronounced fine-scale pitting in the cellular samples, as shown in Fig. 3, but had little or no effect on the specimens having the more homogenous distribution of impurities (*i.e.*, noncellular). It appears that there is little difference apart from pit size, when pits are visible, in the behavior of the 493 and the 593 samples. This indicates by comparison for the two ranges of impurity levels that the total amount of impurity is less important than the impurity distribution. The ZR aluminum, which has too low an impurity content for development of the cellular structure was not detectably affected by exposure to the pitting solution for periods up to 260 hr.

In order to examine the effect of mechanical and thermal treatments on the behavior of these specimens, samples were cold rolled parallel to the crystal growth direction to 75% reduction in thickness and examined in the as-rolled condition as well as after annealing 1 hr at 200°C or 25 hr at 600°C. Both the as-rolled specimens and the specimens annealed at 200°C retained the pitting characteristics and pit density of

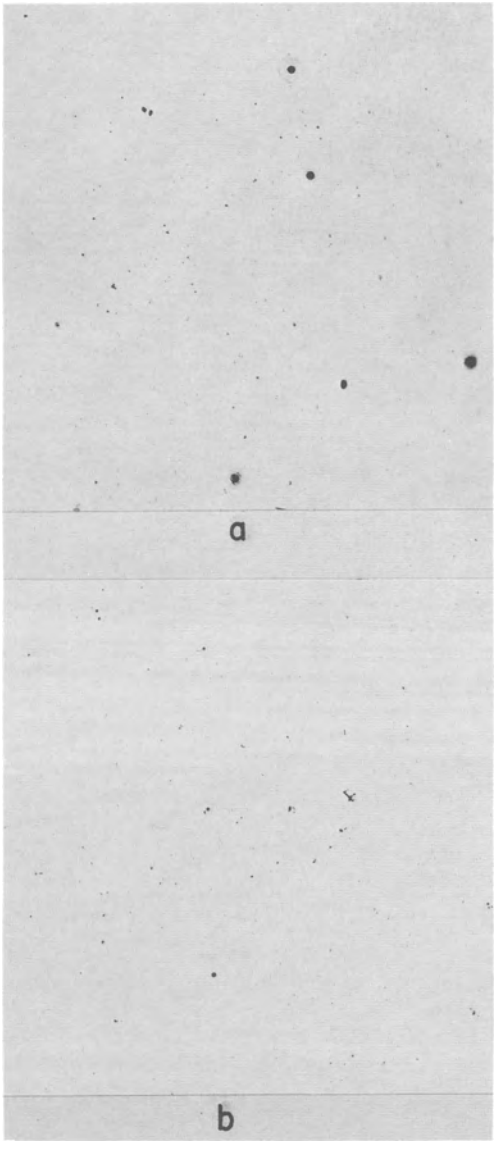

Fig. 3. As-grown aluminum samples exposed to 0.5M NaCl + 0.3% H_2O_2 for 200 min. (a) 493-60; (b) 593-60. Magnification 120X.

the original crystals while the originally noncellular Al remained free of pits after these treatments. This result is not surprising since at these low temperatures diffusion of the principal impurities, iron or copper, over appreciable distances is not possible. The 24-hr anneal at 600°C did affect the behavior somewhat. The pits on the cellular samples became smaller, but more numerous, while very small pits were apparent on the less pure noncellular sample, 493-1. At this temperature there is appreciable solubility of iron and copper in aluminum, and during the anneal sufficient diffusion apparently could take place to redistribute the impurities; however, no pronounced pitting was noted for sample 593-1 after 24 hr at 600°C, indicating that at this low impurity level the driving force for redistribution was too small to produce a noticeable effect in the time allowed.

Finally an attempt was made to extend this examination of the initiation of pitting to the stage of more well developed pits. Samples of 493-1 and 493-60, cold rolled, and cold rolled and aged at 200°C, were exposed for 260 hr to the pitting solution. The over-all contrast between the cellular and noncellular specimens was preserved, although all the specimens exhibited two or three small isolated areas of severe attack (per square centimeter). The pits observed in the 493-60 were generally distributed about as shown in Fig. 3, but were increased nearly five times in diameter after this longer exposure. In contrast, the 493-1 remained free of pits except in the isolated areas mentioned. Since these tests of the worked single crystals and the low temperature recrystallized polycrystals are closer to corrosion practice than those possible on single crystals, there seems to be a basis for attributing a tendency for pitting corrosion to microsegregation.

Electron microprobe results.—Although the preceding results are indicative, they do not establish that the fine-scale pits are definitely associated with the cellular nodes. To do this, two tests were undertaken in 493-60. First a simple counting technique with about 90% reliability showed a density of 165 pits/mm^2 after corrosion compared to 150 nodes/mm^2 before corrosion. Even though this difference is within the experimental error of the pit density determination, a higher number could be expected after pitting since progressive corrosion might reveal regions unaffected previously.

The second test consisted of a microprobe analysis undertaken on 493-60 after pitting. The same technique reported previously (1) was used here, with the exceptions, that an electron beam of 25μ diameter was necessary because of the pitted surface, and that the analysis was limited to the most important element, iron. As a further step, the pitted sample was reanodized to aid in the location of segregated areas and reanalyzed with the electron microprobe. The three analyses are given in Table II. The correlation is better than it appears. The fact that about half the pits as corroded, no longer exhibit high impurity concentration does not necessarily mean that they are not located at or adjacent to node sites. It is quite likely that in the corrosion process the local high impurity concentrations are being destroyed. This is indicated by the increased significance in locating high iron concentration after reanodization.

Polarization measurements.—The results of anodic polarization measurements on these samples, given in Fig. 4, do not show any significant differences for all the samples investigated, but do show a sharp change in anodic current as the potential is shifted from —0.75 to —0.70v *vs.* SCE. A similar result has been

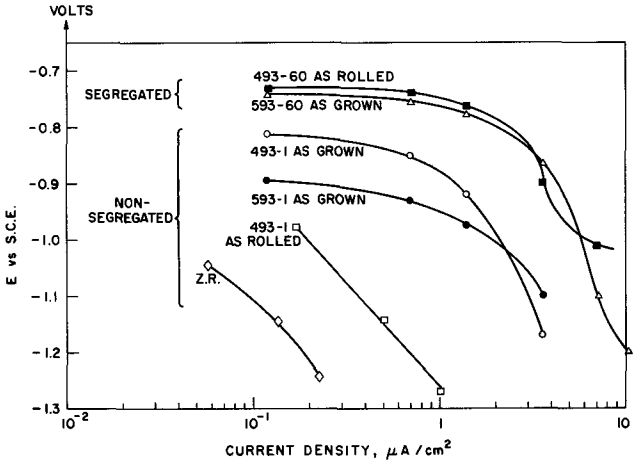

Fig. 5. Cathodic polarization in 0.5M NaCl + 0.3% H_2O_2

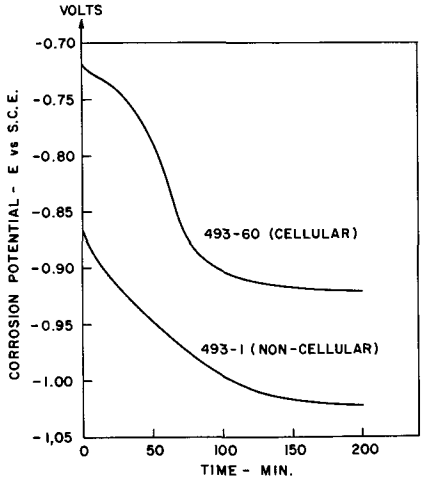

Fig. 6. Typical corrosion potential-time plots for cellular and noncellular samples.

reported by Kaesche (12). The current fluctuates at potential more noble than about —0.72v. This rise in anodic current corresponds to the onset of pitting as can be demonstrated by holding electrodes of zone-refined aluminum in nitrogen saturated 0.5M NaCl at —0.75 and at —0.73v for 90 min; no pitting occurred at —0.75v while definite pitting was observed after holding at —0.73v.

The potential at which pitting first occurred was quite reproducible, but the magnitude of the anodic current at potentials more active than the pitting potential was variable and time dependent, so that no great significance can be attached to the current variation from sample to sample below the pitting potentials. However, it is not surprising that at the more active potentials the zone-refined sample shows the highest anodic currents since the current plotted is the applied current and does not include the contribution of local action corrosion currents. This local action current would be expected to be smallest on the highest purity aluminum while making an important addition to the true anodic current on the less pure samples at the most active potentials investigated.

In the absence of chloride, no pitting occurred in 0.5M Na_2SO_4 even at potentials much more noble than —0.73. This is in accord with the known anodizing characteristics of aluminum in sulfates.

On the other hand, the cathodic polarization characteristics of these samples were strongly affected by impurity content and distribution. Figure 5 gives results of cathodic polarization in 0.5M NaCl + 0.3% H_2O_2. It can be seen that the cellular samples have the lowest cathodic overvoltage at all current densities while the zone-refined aluminum has the highest. From this it must be concluded that the impurity concentrations at nodes provide very favorable sites for the cathodic reaction, presumably reduction of H_2O_2.

It must be noted for strictness, that these results presented in Fig. 5 are not steady-state measurements. In fact, a steady state would require days for establishment. However, it was found that reproducible measurements could be made by placing the electrode in the electrolyte, waiting 5 min on open circuit, then applying the lowest desired current for 1 min, proceeding to the next current, and so on. In this way the measurement can be made before pitting alters the surface of the cellular samples a great deal. Exposure of the cellular sample for long periods led to an increase in the cathodic overvoltage, most probably due to the destruction by pitting of the most active cathodic sites.

Corrosion potential measurements were also made on these samples as a function of time. Figure 6 shows typical results for a cellular and a noncellular aluminum. The potential of the cellular sample starts out near the region indicated by the anodic data to be the area where pitting occurs. The drift of the corrosion potential in the active direction can easily be explained by supposing the destruction of some of the active cathodic node sites as pitting proceeds. (This is consistent with a decreased number of iron rich pits or nodes as shown in Table II.) The corrosion potential of the nonsegregated aluminum remains considerably more active than the pitting potential right from the start of the run. Table III shows the corrosion potential measured 5 min after immersion of the specimen for the types of samples investigated. It can be seen that all the cellular specimens exhibit potentials close to the pitting potential while all the noncellular samples, except 493-1 annealed at 600°C, have potentials much more active than the corrosion potential. The noncellular sample 493-1 annealed at 600°C did pit to some extent so it appears that the

corrosion potential is a reliable indicator of the pitting tendencies of these materials.

Discussion

It is useful to point out that most solidification studies of the cellular substructure have involved observations of the decanted (13) solid-liquid interface. However, as often pointed out, the segregation at a decanted solid-liquid interface is not representative of the steady-state segregation created in a completely solidified crystal. That is, a remnant liquid clings to the decanted interface and freezes rapidly, leading to a more extreme segregation. Therefore, although such studies have been useful in generating an understanding of cellular segregation, a study of decanted interfaces is not germane here. This is emphasized by comparing Fig. 7, a decanted interface of 99.99% Al grown cellularly and corroded similarly to Al 493-60, with Fig. 2 and 3. Indications of cell walls as well as nodes and a more extreme and complex pitting is clearly evident in the singular case of Fig. 7.

The present study of microsegregation and the initiation of pitting corrosion has thus been limited to prepared sections of completely grown crystals. It is possible to conclude that preparation techniques such as cutting and polishing must have had little effect, when it is considered for example, that rolling and lower temperature anneals did not alter the contrasts between cellular and noncellular specimens.

At another point it is possible to question the preparation procedure. The anodic film on aluminum is not homogeneous; otherwise, the location of excess impurity would not be possible. The following observation has been made many times: at the beginning of anodization, a surface viewed under white light first appears to exhibit a blue color, whereas those regions eventually to be recognized as nodes are still colorless. As anodization proceeds, node-free areas progress in the sequence blue-green-red-blue while nodes lag behind as colorless-blue-green-red. A closer investigation might reveal interposing colors elsewhere in the spectrum, but this general observation indicates that the oxide film is thinner in a region of impurity segregation (14). For completeness, we note that the samples examined here were not controlled to have standard oxide films. This must be especially true since materials of two purities were used, and from observation it was noted that more than one sequence of passage through the color spectrum could sometimes be observed.

It is possible to speculate on the effect of impurity concentration on the properties of the protective oxide film. The thinner film near nodes could be an indication that incorporation of the impurity metals in the aluminum oxide leads to a decrease in electronic resistivity. If this effect is carried over in the film formed in the corrosion environment, it is reasonable to correlate improved electronic conductivity with an increase in the cathodic reduction reaction velocity. It is also possible that the oxide film in the regions of high impurity concentration remains thin enough for electron tunneling to occur, thus facilitating the electron transfer involved in the cathodic reaction.

Previous studies have shown that impurities affect corrosion (15-18). However, there is no apparent prior indication that a distribution of impurities in single crystals at such minor levels as those investigated here can be important. An elementary knowledge of solidification processes forces the conclusion that cast materials of the purity level 99.99% or less must all be subject to the same segregation as studied here, unless uncommon precautions are taken. Moreover, since the mechanical and lower thermal treatments undertaken were of no appreciable affect in altering corrosion characteristics, the dominant segregation of iron must be expected to persist in these metals even after treatments subsequent to casting. The correlation with solidification characteristics is emphasized by the unchanged nature of pitting corrosion even as purity level is changed after short-time exposures to the pitting reagent. However, since the 260 hr exposures can also be argued to be "short-time," a correlation between the fine scale and massive pitting must really be deduced not concluded. This is nevertheless reasonable if the observations of Edeleanu and Evans (19) are accepted, *i.e.*, small pits tend to grow, or the pitting corrosion in aluminum is autocatalytic.

The experimental results of the exposure to a corrosive environment are at least a confirmation of the existence of severe microsegregation in aluminum of purity as high as 99.999% after certain growth conditions, and do show a correlation between this segregation and the tendency for pitting corrosion in aluminum. In particular, concentration of iron and copper at nodes in the cellular substructure reduces cathodic overvoltage sufficiently to bring the corrosion potential to the critical value at which chlorides lead to pitting corrosion. That these impurities exert a strong effect on cathodic overvoltage is not unexpected since Hansen and Wetmore (15) have interpreted their work on the hydrogen overpotential on aluminum on this basis. However, the present work does demonstrate that the distribution, rather than the total amount of residual impurity seems more important at very low impurity levels.

Chemical Nickel-Iron Films

A. F. Schmeckenbecher

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Ferromagnetic films, useful for computer applications, have been deposited from a modified Brenner bath by chemical reduction using hypophosphite. The deposits contain about 25% iron, 1-0.5% phosphorus, small amounts of oxygen, carbon, etc. The balance is nickel. The films are well suited for memory applications because of their high creeping threshold and their fast coherent rotational switching. The effects of certain plating parameters on the properties, in particular on the magnetic properties, are discussed.

Nickel films have been deposited on active surfaces by reduction with hypophosphite (1, 2). The technique is widely used mainly because films of uniform thickness and special properties can be deposited on intricately shaped surfaces. Adding an iron salt to the alkaline nickel plating bath under certain conditions results in a nickel-iron alloy deposit. Electroless deposition of nickel-iron alloys seems to have been investigated to a relatively small extent (3-5). Little is known about the properties, in particular the magnetic properties, of such films.

The mechanism of reduction of nickel alone has been discussed in detail (6-8). When plating a nickel-iron alloy, the situation is complicated by the fact that different types of complexes are involved. The nickel ions are mainly bound to nitrogen in an ammonia complex while the iron mainly is bound to oxygen in a chelate (tartrate, citrate, etc.). Also, while the iron is reduced directly from its bivalent state (ferrous ion) to the metal, it can be introduced into the bath in its trivalent state. Therefore, equilibria between both the ferrous, ferric, and nickelous ions and their complexes would have to be considered. Also insoluble compounds such as nickel hydroxide and basic tartrate, etc., may form at *p*H values between 8.5 and about 7 in the deposition zone and might be incorporated in the film. Plating parameters such as temperature, pressure, *p*H value of the plating solution and concentration of bath constituents affect the deposition mechanism and as a consequence the composition and properties of the deposits. For instance, when the *p*H value of the bath is increased from 8 to 11 by adding ammonia, less nickel ions become available for reduction. The iron content of the deposit increases. Similarly, at high *p*H values the deposition of phosphorus, which has hydroxyl ions as a by-product, is slowed down. The phosphorus content decreases.

For the purpose of this discussion we consider the effect of the thickness of the deposit, of the ratio of nickel to ferrous ions, and of the metal and hypophosphite ion concentrations on the composition and properties of the deposits.

Plating Technique and Effect of Plating Time on Film Properties

We plated on beryllium-copper sheets, which had been activated by dipping in a 0.1% palladium chloride solution. The surface being plated was between 2 and 12 in.^{2}/liter of plating bath. The plating bath was newly made up and heated in a water bath to 75°C. The bath was not agitated during plating. A typical plating bath contains 56 mM/liter Ni^{++} as nickelous chloride, 20 mM/liter Fe^{++} as ferrous ammonium sulfate, 100-350 mM/liter sodium potassium tartrate, 10 g/l or 94 mM/liter sodium hypophosphite, and 3.6 mols/liter ammonia.

The potential during plating measured against a saturated calomel electrode was —1.01v. Taking the calomel electrode potential at 75°C as —0.211v, the deposition potential was —0.799v. The potential was measured on a relatively large substrate. If the area being plated is smaller than about 0.1 mm^2, fluctuations of the potential by about 10-15 mv are observed, which occur with a frequency of about 3 per min. Agitation of the bath lowers both the potential and the plating rate: while in baths containing nickel only, agitation increases the potential and plating rate.

The deposits were analyzed for iron and nickel by dissolving them in hydrochloric acid and comparing the intensity of x-ray fluorescence of the solution with standard nickel and iron solutions. The accuracy of the method is within ±3% of the values.

The phosphorus content was determined colorimetrically by the "Heteropoly method," with a precision of ± 15%. Also, radioactive hypophosphite was used in one experiment, with P^{32}, giving a phosphorus content about 30% higher than the colorimetric method. In the charts the colorimetric figures are given. Samples of the deposits were flash heated to 5000° in vacuum; gases set free were qualitatively identified in a mass spectrograph.

For thickness determination, the deposits on a known area were weighed directly, or the weight was determined by the x-ray fluorescence method, and using a density figure of 8.4 g/cm^3 the thickness was calculated. Also, microsection techniques were used to check the thicknesses. The thickness is 10-15% higher with the microsections. In the charts the data obtained with the x-ray fluorescence method are given.

The deposits contain 25% iron, 0.5-1% phosphorus, small amounts of hydrogen, carbon monoxide, oxygen, water, and nickel. Within the first 25 min of plating, in a newly made up bath, very little change of potential, plating rate, or iron content beyond the precision of the analysis was observed. The absorption of the bath of ultraviolet and visible light (at 285 mμ and 575 mμ) did not change within the first 30 min. Changes beyond a plating time of 30 min depend on the ratio of surface being plated to the bath volume and are probably due to consumption of hypophosphite, oxidation of ferrous to ferric ion, and other changes in the bath.

After plating, the films were kept at room temperature for at least 24 hr, without further treatment. Changes occurring with time and temperature are not being discussed here.

The deposits up to about 1000Å thickness are silvery in appearance with a high reflectance (as measured on a Bausch and Lomb "Spectronic 20" spectrophotometer at 525 mμ with a reflectance attachment). When the deposits become heavier, they get a golden brown tinge. On rolled beryllium-copper the thinnest deposits (500-100Å) had a reflectance of about 45% of the magnesium carbonate standard. With increasing thickness of the deposits, the reflectance decreased to level off at 10,000Å to a value of about 30% of the magnesium carbonate standard. Electromicrographs of the surface of deposits of various thickness show an agglomeration of balls, the size of which increases with increasing thickness up to 10,000Å, then levels off to a constant value of about 1000Å diameter (Fig. 1 and 2). Micro-cross-sections of the films show both a columnar and laminar structure similar to the structure known for chemical nickel deposits (1, 10). X-ray data (line broadening technique) indicated a crystallite size in the order of 200-300Å. The sheet resistance of 10,000Å thick films plated on glass and measured using spring loaded metal contacts is about 50 μohms-cm as compared to about 18 μohms-cm for bulk nickel-iron alloy (11). When plated, the films are under considerable tensile stress, which at 10,000Å reaches a value of about 30,000 psi.

For the magnetic measurements, the films were deposited on 3-in. long beryllium copper strips of about 4 mils by 2.5 mils cross section. The strips were photoetched out of beryllium-copper sheet of 2.8 mils thickness. An orienting field of 40 oe was applied along the long axis of the strips during deposition.

The coercive force (H_c) and anisotropy field (H_k) were measured on a 60 cycle BH loop tester, by the usual methods. It is understood that the anisotropy field is a function of the shape of the material. The data are given for the described configuration.

Figure 3 shows that above 10,000Å thickness, the coercive force (H_c) and anisotropy field (H_k) are fairly constant; going below 10,000Å, the coercive force increases rapidly.

Fig. 1. Nickel-iron film 4000Å-thick. Magnification ca 49,000X

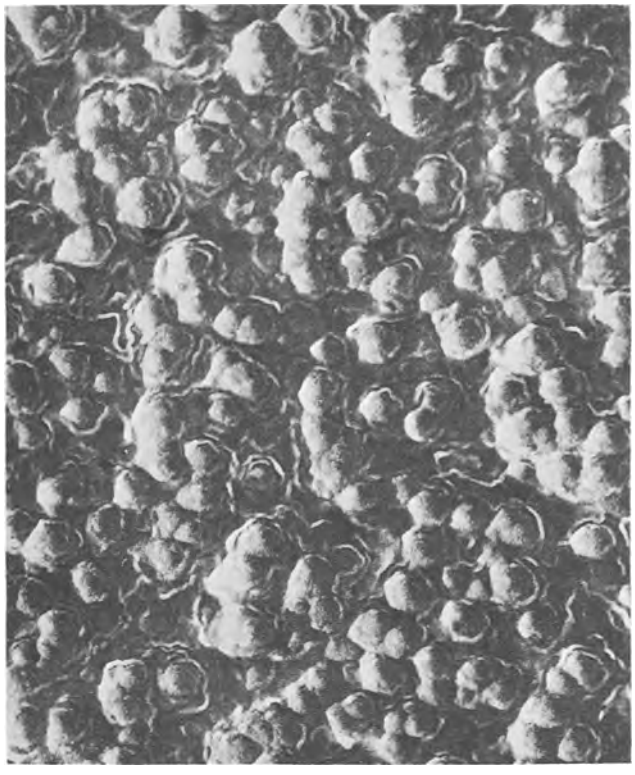

Fig. 2. Nickel-iron film 20,000Å-thick. Magnification ca 49,000X

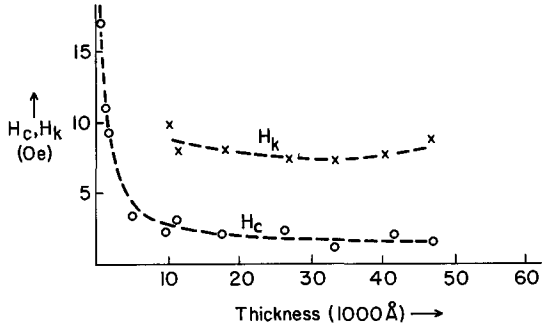

Fig. 3. Coercive force (H_c) and anisotropy field (H_k) vs. thickness of deposit.

Ni^{++}/Fe^{++} *ratio.*—Deposits of 10,000Å thickness were plated from baths with constant nickel content (56 mM/liter) and iron content varying from 0-30%. The plating rate drops almost linearly from 1700Å/min at 0% Fe, to 900 Å/min at 30% Fe. The coercive force (Fig. 4) follows the pattern observed in nickel-iron alloys deposited by other techniques (13). However, the minimum normally observed at 18% iron has been shifted to about 10% iron. The magnetostriction constant is positive in deposits containing considerably less than 19% iron, while in nickel-iron alloys deposited by other techniques it becomes negative at about 19% iron (14). X-ray diagrams show the presence of nickel phosphides and nickel oxide (NiO) and iron oxide (FeO). H_k increases with decreased iron content.

Metal concentration in bath.—The concentration of the heavy metals in the bath (Ni and Fe), with the ratios of nickel to iron and of iron to tartrate kept constant, was varied next. Figure 5, top section, shows that with increasing metal concentration the iron content of the film goes up to a constant level. The plating rate also increases up to a certain point, and then levels

out, at levels depending on the amount of hypophosphite in the bath (Fig. 5, bottom section).

Effect of hypophosphite concentration.—The hypophosphite concentration in the bath affects the composition of the films, as well as the magnetic properties.

In Fig. 6 the percentage of iron in the bath (from the sum of Ni^{++} and Fe^{++} concentration in the range of 0-30% Fe) is plotted against the percentage of iron in the film for various hypophosphite contents.

Above 10 g/l sodium hypophosphite the codeposition is normal (15); *i.e.*, the less noble iron deposits more slowly than the more noble nickel. Below 10 g/l sodium hypophosphite the codeposition is anomalous, while at 10 g/l sodium hypophosphite the codeposition is close to equilibrium over a relatively wide range.

At a given iron content in the bath (such as 25% Fe^{++}) the deposition potential and the deposition rate increase with increased hypophosphite content (Fig. 7).

Figure 8 shows, against the hypophosphite content in the bath, the coercive force (H_c) and the anisotropy field (H_k) of deposits which were 10,000Å thick, and which had 25% iron obtained by adjusting the Ni^{++}/Fe^{++} ratio in the bath with the other parameters kept constant. The phosphorus content of the films increased almost linearly with increased hypophosphite content (from 0.5 to 1.5% P for 2-25 g/l $NaH_2PO \cdot H_2O$).

With lower hypophosphite content the coercive force increases while the anisotropy field stays low.

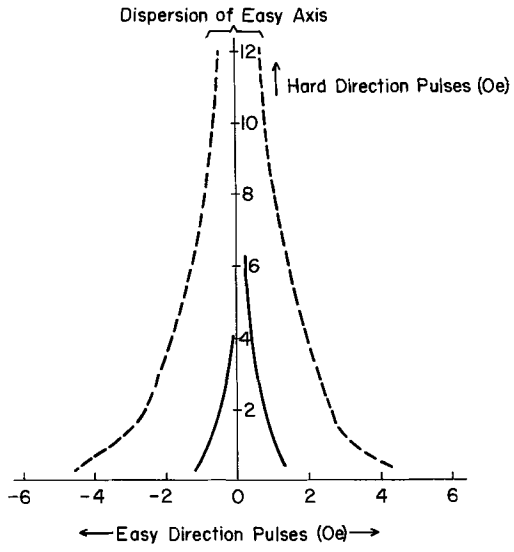

Fig. 10. Memory writing and disturb characteristics, 15 g/l $NaH_2PO_2 \cdot H_2O$.

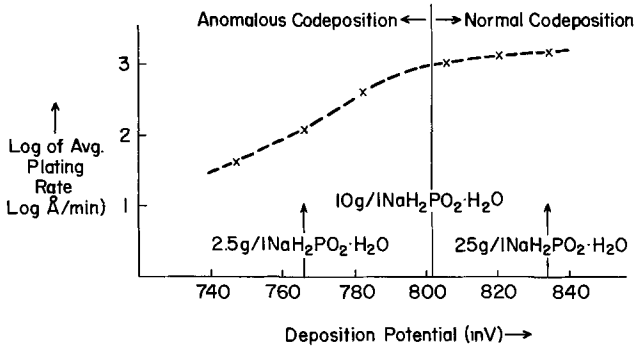

Fig. 11. Deposition potential vs. plating rate

Chemical nickel-iron deposits were tested for use in memory applications, in particular in the orthogonal mode (12), with pulses both in the hard and easy directions.

Figure 9 shows how a deposit of 9000Å thickness performs under such conditions, plated from a bath containing 5 g/l $NaH_2PO_2 \cdot H_2O$ with a H_k/H_c ratio of 1.3.

The dotted lines of the asteroid show the combinations of pulses in the easy and hard directions needed to switch 90% of the deposit; the inner lines show the combinations of a large number of pulses needed to start switching the magnetization (creeping threshold). The pulses used had a rise time of 15 nanosec, duration of 80-160 nanosec. The usual techniques *i.e.*, setting the magnetization of the material by a large number of overlapping easy and hard direction pulses and for the creeping threshold a large number of disturb pulses simulating the conditions in the memory application, have been used (12). The distance between the dotted lines at the top of the asteroid is a measure of the dispersion of the easy axis (12).

There is a wide range of combinations of the easy and hard direction pulses which switch the film, but for which the individual pulses stay below the creeping threshold.

Figure 10 shows similar plots for a deposit from a bath containing 15 g/l $NaH_2PO_2 \cdot H_2O$. The H_k/H_c ratio in this case is 3.5. The creeping threshold is too low for memory applications.

Discussion

A look at Fig. 5, bottom section, shows that the deposition rate appears to be controlled either by the concentration of the metal ions, or if the concentration of the metal ions surpasses a certain value, by the concentration of the hypophosphite ions in the bath.

If we plot the deposition potential at various hypophosphite concentrations against the logarithm of the deposition rate (Fig. 11), we see that at 10 g/l sodium hypophosphite, *i.e.*, at equilibrium codeposition, the curve has a break. At the lower potentials (low hypophosphite concentrations) the deposition rate is controlled by the hypophosphite concentration, at the higher potentials the metal concentration controls the deposition rate. The temperature dependence of the plating rate shows that the logarithm of the deposition rate is inversely proportional to the absolute temperature in the range of 35°-75°C. At the lower deposition potentials (in hypophosphite controlled deposition) the activation energy is smaller than at the higher deposition potentials. Not considering the mechanisms involving the oxidation of the hypophosphite ions (6-8), a number of rate controlling steps involving the metal ions are possible: the diffusion of metal ions or complexes, the dissociation rate of metal complexes, formation of precipitates affecting the catalytic surface, adsorption of metal ions on the surface and re-dissolution of metal. Figure 5 shows that with low metal concentrations, the iron content of the deposit is lower. It is believed that this is caused by different rates of diffusion or dissociation of the iron tartrate complex from that of the hexammine nickel complex.

It is in the hypophosphite controlled baths that we observe the unusual magnetic properties in the nickel-iron films.

Recent investigations (16) indicate that a nonmagnetic layer of about 20Å thickness between two layers of about 250Å of permalloy tends to increase the coercive force and the creeping threshold of the magnetic layers, provided the nonmagnetic layer has irregular phase boundaries. The minimum of the coercive force at 10% Fe, rather than 18%, points to the presence of nonmagnetic material in the deposits. The laminar structure of the deposits possibly consists of magnetic layers of 80-20 nickel-iron alloy interspaced between relatively nonmagnetic layers of nickel phosphide, and/or oxide of the appropriate thickness to raise the creeping threshold of the deposits.

Conclusion

The deposition of chemical nickel-iron films containing up to 30% iron by reduction with hypophosphite is controlled either by the metal ion concentration or, above a certain metal content, by the hypophosphite concentration. The codeposition may be normal or anomalous, depending on the hypophosphite concentration.

Properties, in particular certain magnetic properties, have been discussed. The chemical reduction with hypophosphite offers a simple, internally controlled method to prepare a useful magnetic material for computer memories.

Acknowledgments

The author is grateful to D. W. Hall, J. A. Lindholm, and H. E. Towner for carrying out the plating experiments; Dr. H. O. Leilich, T. R. Scott, H. H. Zappe and others for evaluating the films magnetically; Mary E. Fritsch and R. Flitsch for the chemical analysis; D. P. Cameron for the electron micrographs; Dr. C. L. Masters for P^{32} tracer analysis; and to P. Geldermans, Drs. G. Kahan, K. L. Romankiw, and N. W. Silcox, and many others for helpful discussions.

Manuscript received Jan. 26, 1966; revised manuscript received April 27, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Transport Processes in the Thermal Oxidation of Silicon

Douglas O. Raleigh

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

Previous experiments on the effect of an electric field on the oxidation rate of silicon are reconsidered. It is shown that such experiments do not in themselves prove that oxidation occurs by the diffusion of a charged species through the reaction layer, but may be analyzed in terms of an electrolytic process being superposed on the normal oxidation process. Supplementary data present in the literature are also insufficient to conclude whether a charged species is involved. A theoretical analysis of the transport processes to be expected when oxidation involves a charged diffusant shows that the rate of such a process may be predicted if the electronic conductivity of SiO_2 under the conditions of oxidation is known. Suitable experiments for determining this quantity are suggested.

The kinetics of oxidation of silicon has in recent years become of interest in the fabrication of semiconductor devices (1). Air oxidation of silicon at elevated temperatures yields uniform, compact, adherent films of vitreous silica which are the basis of the well-known MOS structures. Accordingly, there has been considerable effort devoted to elucidating the oxidation mechanism under various experimental conditions and its relation to the characteristics of the resultant devices. Although largely outside this area, in the last few years there has also been considerable study of the electrochemical and transport properties of solids, principally by Wagner and co-workers (2). It is felt by the author that insights from this work, together with Wagner's earlier studies on metallic oxidation (3), can be used to bring into better focus some basic considerations on the mechanism of silicon oxidation. Specifically, it is intended to reexamine the question of the diffusing species involved in the high-temperature oxidation of silicon by dry oxygen.

A large number of investigators (4-10) have found that the rate of oxidative growth of a silica film on Si obeys the parabolic law characteristic of a diffusion-controlled process; that is, $dx/dt = k/x$, where x is the film thickness and k the rate constant. Law (5) has pointed out that a parabolic rate dependence does not necessarily prove diffusion control unless a linear plot of x^2 *vs.* t back-extrapolates through the origin, and found evidence of partial rate control by a phase boundary process for films 100-500Å thick. Deal *et al.* (11) found evidence of partial phase boundary control under some experimental conditions from studies on the oxidation of heavily doped silicon. Deal and Grove (12) recently provided an excellent analysis of the general situation where both diffusion and phase boundary processes are involved. In general, however, oxidation does appear to be diffusion-controlled for film thicknesses in excess of 1000Å under a wide variety of conditions. Jorgenson (8), for instance, obtained a plot of x^2 *vs.* t that was linear through the origin for 2000-5000Å films in normal oxidation at 850°C. Since, at any rate, the question of what is the diffusing species is best examined under conditions of diffusion control, the considerations in this paper relate to experiments carried out under these conditions. Moreover, the discussion is limited to dry oxidation, since the diffusing species involved in wet oxidation is manifestly another question.

In further studies, marker experiments by Jorgenson (8) at 850° and by Karube *et al.* (13) at 1250°C indicated that the oxidation process involves the diffusion of oxygen rather than silicon through the SiO_2 reaction layer, so that oxidation occurs at the $Si|SiO_2$ interface. Karube's studies at 1250° included infrared absorption measurements to show that a 2000Å reaction layer was essentially all SiO_2 rather than other oxides of Si. Motzfeldt (14) has recently compared a wide variety of data on the oxidation of Si and SiC with data on the rate of permeation of oxygen through vitreous silica membranes to show that all three processes follow the same rate kinetics. A master plot of the collective data shows an activation energy of 26.3 kcal/mole for the above rate constant k, in excellent agreement with subsequent data by Deal and Grove (12) in which phase boundary effects were corrected for. Motzfeldt's comparison thus appears to show that the oxygen transport properties of thermally grown SiO_2 and silica glass are the same. In consequence, available measurements (15, 16) of the diffusion coefficient of oxygen ions in silica glass should be applicable to the oxidation process.

There appears to be a fairly widespread conviction (12, 14, 17-22) that the oxygen diffusing through SiO_2 in the oxidation process has been demonstrated to be in the form of oxygen ions. This conclusion rests on experiments by Jorgenson (8) which intended to show that the oxidation rate is influenced by the application of an electric field across the reaction layer. Jorgenson subsequently employed similar experiments to show that oxygen ions are likewise involved in the oxidation of zinc (23). It is felt by the author, however, that there are serious conceptual errors in the interpreta-

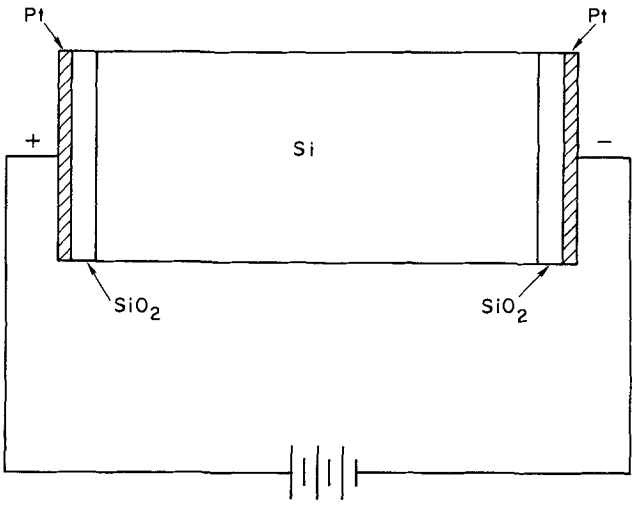

Fig. 1. Jorgenson's apparatus for studying the effect of an electric field on the oxidation of silicon.

tion of these experiments, so it is well to consider the experiments in some detail for the case of silicon oxidation.

Effect of an Electric Field on Silicon Oxidation

In Jorgenson's experiments, porous platinum electrodes were affixed to the opposite sides of a partially oxidized silicon single crystal. The experimental arrangement is shown in Fig. 1. The assembly was heated at 850° in the presence of oxygen, and the SiO_2 film thickness on each side was monitored as a function of time interferometrically. Experiments were carried out in the presence and absence of an applied voltage on the assembly, where the voltage corresponded to an electric field of about 10^4 v/cm across each SiO_2 layer. It was reasoned that, if the oxygen diffusing through the SiO_2 film in normal oxidation possessed a negative charge, the applied field shown would accelerate the process at the film on the right and retard film growth on the left. Plots of x^2 *vs.* t appeared to indicate this was the case. Linear plots were obtained for both the field-free and "accelerated" film growths, the slope being considerably greater for the accelerated case. At the "retarded" side, film growth proceeded at an initially smaller rate than in the absence of a field and came to a halt at about 3000Å in 50 hr, there being no further thickness increase observed in 120 hr.

In subsequent experiments, constant currents in the range 1-4 μa were applied to the assembly and the voltage across each film measured as a function of time. For the accelerated case, a parabolic voltage-time plot was obtained. In the case of the retarded film, the voltage rose to a constant value, corresponding to the halted film growth, which was independent of the current, although achievement of the halt voltage took longer at lower currents. The above experiments were taken as evidence that the oxygen involved in the oxidation possessed a negative charge. The constant voltage obtained across the retarded film was said to correspond to the free energy of formation of SiO_2 at 850°, although a somewhat lower than theoretical value was obtained.

In reinterpreting these experiments, one must begin by asserting that the external application of an electric field *per se* cannot provide a steady-state driving force for a diffusion-controlled process such as the thermal oxidation of silicon. This is because, in any such oxidation, the net process must be the transport of an electroneutral species (elemental oxygen in this instance) through the reaction layer. Regardless of the details of the diffusion mechanism, the transport of elemental oxygen across the film can occur only in response to a gradient in its chemical potential. Since the chemical potential of oxygen is chemically fixed on both sides of the film (by the ambient oxygen pressure on the gas side and by the presence of the phases Si, SiO_2 on the silicon side), its gradient is not accessible to influence by an externally applied electric field.

Microscopically, we may see this as follows. Suppose the transported oxygen were in the form of oxygen ions. Then, to correspond to the transport of electroneutral oxygen, a flow of oxygen ions across the film would have to be accomplished by an equal flow of electronic charge in the opposite direction (3). In consequence, any applied field which accelerated the ionic flow would retard the electronic flow. If the flows were thus unbalanced, the net result would be the transport of uncompensated charge across the film. The steady-state result would inevitably be the accumulation of opposite charges on the two sides of the film until the field generated by them cancelled out the externally applied field. Thereafter, oxygen transport would proceed as in the field-free case.

A sample calculation shows the field-free condition would be reestablished quite rapidly on the time scale of the oxide film growth. Let us consider the field generated by the build-up of one monolayer of uncompensated charge on each side of the oxide film. One monolayer of Si^{+4} or $O^{=}$ ions in SiO_2 corresponds to about 5×10^{-4} coul/cm^2. If we consider the oxide layer as a capacitor with a dielectric constant of 4, such a surface charge density would result in a field of $\sim 10^9$ v/cm within the layer. Thus, the charge accumulation due to a temporary unbalancing of the ion and electron flows in the presence of an applied electric field would be sufficient to cancel out most fields of interest when only a fractional monolayer of mass transport had occurred.

It should be remarked that the term "field-free," as used here, refers only to the absence of an externally imposed field. There are, to be sure, internal fields associated with such oxide films, but, as we shall see later, such fields are uniquely determined by the parameters of the system and are thus inaccessible to external influence. In another point of interest, it is possible at least in principle that the application of an external field, while not changing the gradient of oxygen chemical potential, can alter the basic transport properties of the diffusing entities. If, for instance, an externally applied field exceeded the electronic breakdown voltage of the oxide, the mechanism of electronic transport would be changed. Such effects, however, are in general only relevant to much thinner films than those we are considering in the present study.

The most likely reason why Jorgenson found an apparent effect of an applied field involves the manner in which such a field *per se* can be legitimately applied in a system of this nature. Jorgenson noted that Uhlig and Brenner (24) and, more recently, Cismaru and Cismaru (25) were unable to influence the oxidation rates of copper and zinc, respectively, with an electric field. He attributed this to their use of a condenser to impose the electric field, which he maintained resulted in virtually no field across the oxide. Jorgenson, however, in his use of a battery circuit, not only applied an electric field, but also provided an external circuit for electronic flow. As we have noted above, diffusive transport of oxygen through the reaction layer as oxygen ions would require both ionic and electronic flows, so would depend on both the ionic and electronic conductivities of SiO_2. If an external circuit, however, were provided for the electronic flow, oxygen ion transport would then require only ionic conductivity, so that what may have been only a minor transport mechanism because of a low electronic conductivity might then assume larger significance. In fact, Jorgenson appears to have carried out an electrolysis. The fact that ionic transport can occur under these conditions is no more indicative of ionic transport in the absence of a field than is the

anodic oxidation of a metal in an aqueous solution a proof that normal corrosion of the metal in the solution involves transport of dissolved atmospheric oxygen through the solution as oxygen ions. In fact, as we shall discuss, there is at least some evidence to the contrary for silicon oxidation. Experiments by Schmalzried (26), for instance, have indicated that vitreous silica at 1000°C is a pure ionic conductor. Pressure dependence data on the silicon oxidation rate (12) and on the permeability of vitreous silica to oxygen (27) tend to favor molecular oxygen as the transported species. While none of this data may yet be considered a proof, it does at least show that the question of the nature of the oxygen diffusant in silicon oxidation must be regarded as still unsettled.

Let us now consider the details of Jorgenson's experimental results in terms of an electrolytic process, since it will be seen that we may obtain a reasonable picture of their significance. In view of the fact that electrolytic conduction must occur in the reaction films to account for the effect of an electric field, we may consider Jorgenson's experimental assembly to consist of two electrolytic cells, $O_2(g)$,Pt $SiO_2(s)|Si(s)$, placed back-to-back. Reversible oxygen electrodes of the type $Pt,O_2|$(solid oxide) are well known in the literature of solid-state electrochemistry (2) and reversible $SiO_2|Si$ electrodes have been suggested both explicitly (28) and as an implicit consequence of observed galvanic emfs (21) in MOS structures. If ionic conduction in the SiO_2 is by oxygen ions, the following half-cell reactions may be postulated

$$O_2(g) + 4e \rightleftharpoons 2\,O^=$$

$$2\,O^= + Si \rightleftharpoons SiO_2 + 4e$$

and the total cell reaction will be $Si + O_2 \rightleftharpoons SiO_2$, the direction of the arrow in each case depending on the direction of the cell current. If conduction is partially or entirely by silicon ions, somewhat different half-cell reactions would apply, but the net cell reaction would still be the same. In the experimental assembly shown in Fig. 1, application of the voltage shown would form SiO_2 electrolytically from its elements at the reaction layer on the right and decompose it into its elements on the left. Since passing a particular amount of current would, in accordance with Faraday's law, form the same amount of SiO_2 on the right as is decomposed on the left, there will be zero free energy change in the over-all system and hence no galvanic emf to be surmounted in order for the electrolysis to occur.

Consider now the processes that occur in the assembly at elevated temperatures in the presence of the applied voltage. The normal diffusive or thermal oxidation process must occur on both sides at a rate unaffected by the presence of an electric field, but is augmented on the right side by electrolytic SiO_2 formation and opposed on the left by electrolytic decomposition. The net rate of oxide film growth will be given by

$$\frac{dx}{dt} = \frac{k}{x} \pm \frac{M}{4\rho\mathbf{F}}\, i_{\text{ionic}} \qquad [1]$$

where M is the molecular weight of SiO_2, ρ is its density, $\mathbf{F}$ is Faraday's constant, i_{ionic} is the ionic current density, and the plus and minus signs refer to the right and left sides of the assembly, respectively. In the early stages, the growth process will be dominated by the thermal oxidation process because of the inverse dependence of its rate on the film thickness, apparently being retarded on the left by the electrolytic process and accelerated on the right. Since Jorgenson's data for the accelerated growth showed only a 20% rate increase due to the field, it is not surprising that an apparent parabolic growth rate was observed for it. At the retarded side, however, the oxide film apparently grew sufficiently to reduce the thermal oxidation rate to that of the electrolytic decomposition, resulting in the observed "halt." At this point, where $dx/dt = 0$, one would have under constant-current conditions no further film growth. The differing extents to which the field affected thermal oxidation at the two electrodes may be accounted for by different effective electrode areas, since this would result in different current densities and hence different rates per unit area of the electrolytic processes at the two electrodes.

It must be emphasized that such a balance between thermal growth and electrolytic decomposition would not be a precarious or fortuitously achieved one, but rather a self-perpetuating, dynamic steady state that would inevitably be achieved in such a system at any particular level of current density. This is because the current density defines a particular decomposition rate per unit area toward which the initially faster thermal oxidation rate must approach as film growth proceeds. When a film thickness is reached at which the rates of the opposing processes are equal, there will no longer be any net driving force toward further film growth, and hence the constant film thickness will define a constant thermal oxidation rate equal to the electrolytic dissociation rate. The effect of lowering the electrolysis current will merely be to increase the film thickness required to achieve this balance, so that longer oxidation times will be required, as was found experimentally (8).

It is of interest to consider the significance of the voltage across the retarded film in the experiments where various currents were passed through the assembly and this quantity was measured. It is to be recalled that a halt point voltage was obtained which was the same at each current level. At the halt point, where the rates of oxidative formation and electrolytic decomposition become equal, one may write from Eq. [1]

$$\frac{k}{x} = \frac{M}{4\rho\mathbf{F}}\, i_{\text{ionic}} = \frac{MI_{\text{ionic}}}{4\rho\mathbf{F}A} = \frac{t_{\text{ions}}IM}{4\rho\mathbf{F}A} \qquad [2]$$

where I_{ionic} and I are the ionic and total currents (taking into account the possibility of partial electronic conduction in the SiO_2), t_{ionic} is the transference number for ionic conduction, and A the effective electrode area. In the most general case, the voltage across the film will be given by $V = \epsilon_0 + IR$, where ϵ_0 accounts for any galvanic emf between the voltage-measuring leads and R is the film resistance. If the voltage-measuring leads were made to the Pt electrode and Si crystal, the occurrence of a finite ϵ_0, corresponding to the galvanic couple $Si|SiO_2|O_2$, would depend on whether the contact to the Si crystal was made in the absence of any SiO_2 film and maintained in an oxygen-free environment. Otherwise, an oxygen electrode similar to the one on the gas side would result at this contact and one would have $\epsilon_0 \approx 0$. Since the description of the experiment does not indicate this precaution was taken, it seems likely that there was no galvanic emf involved. Further evidence for this is in the voltage-time data itself, which appears to extrapolate to zero at the start of the experiment (*i.e.*, as $R \to 0$) rather than to some finite voltage.

One has, then, for the voltage across the layer at the halt point

$$V_{\text{halt}} = IR_{\text{halt}} = I\frac{x_{\text{halt}}}{\sigma A} \qquad [3]$$

where σ is the total conductivity of SiO_2. Solving Eq. [2] for I and substituting in Eq. [3], one obtains

$$V_{\text{halt}} = \frac{4\rho\mathbf{F}k}{Mt_{\text{ions}}\sigma} = \frac{4\rho\mathbf{F}k}{M\sigma_{\text{ionic}}} \qquad [4]$$

One sees that a value of the halt voltage is obtained which depends only on transport properties of the SiO_2, being independent of the cell current and unrelated to the free energy of formation of SiO_2. V_{halt} is current-independent because it is the IR drop at the

halt point. When I is lowered, R (which is proportional to x_{halt}) is correspondingly raised, since a thicker film is required at the lower current to reduce the rate of the thermal oxidation to that of the electrolytic dissociation.

A rough estimate of this voltage may be made for comparison with the experimental value. As Motzfeldt (14) has noted, one may derive from Jorgenson's normal oxidation curve a rate constant $k = 1.25 \times 10^{-11}$ cm²/hr, in good agreement with data from other sources. For σ_{ionic}, one notes that Jorgenson's accelerated oxidation curve shows a thickness augmentation of 1.0×10^{-5} cm above that obtained by normal oxidation at the end of 100 hr. It may be calculated from Eq. [1] that this would require an average electrolytic current density of 0.37 μa/cm². With a stated electric field of approximately 10^4 v/cm, this would imply an ionic conductivity of about 3.7×10^{-11} ohm^{-1} cm^{-1}. Using these values for k and σ_{ionic}, one obtains $V_{halt} = 1.25$v. This is within 25% of the value experimentally obtained (1.62v), which is satisfactory agreement considering the approximateness of the calculation. Because of the relation of V_{halt} to k and σ_{ionic}, it would seem that halt voltages such as these would provide useful supplementary data in conjunction with studies on ionic conductivity and oxidation rates.

Oxygen Ions, Atoms, or Molecules? Relevant Data and Experiments

The considerations thus far have had mostly the negative objective of showing that experiments on the effect of an applied electric field on metallic oxidation do not in themselves offer a valid means of determining whether diffusion of a charged species is involved. Rather, no effect of a field *per se* is to be expected, and the use of a field in conjunction with an external circuit yields effects which should properly be considered in the framework of electrochemistry. These latter effects, however, may be of interest in themselves in studying various aspects of transport in reaction films, provided their electrochemical nature is recognized. Jorgenson's experiments, for instance, showed the existence of at least one precondition for oxidative transport by ions, namely, that SiO_2 possesses a measurable ionic conductivity. We ask now whether other information from elsewhere in the literature may offer further insights on this question.

We have noted previously that Motzfeldt's comparison of data on the oxidation rate of Si and SiC and the permeation rate of oxygen through silica glass shows all three processes are apparently rate-determined by the same transport phenomenon, that of oxygen through vitreous silica. The permeability of silica glass to oxygen, as measured by Norton (27) in the range 950°-1100°C, was in fact directly converted to an equivalent oxidation rate constant k, by essentially no more than a change to the units appropriate for k, and showed excellent agreement with values of k obtained from oxidation rate data. Thus, it would appear that not only does this provide further evidence for diffusion control in the oxidation process, but indicates that there is nothing unusual in the oxygen transport properties of "grown" SiO_2, as compared to silica glass.

Norton's experiments included a determination of the diffusion coefficient of oxygen in silica glass by a "lag time" method. A log D *vs.* $1/T$ plot gives an activation energy for diffusion of 27 kcal/mole and an extrapolated value of about 1.6×10^{-9} cm²/sec for D at 850°C. By contrast, Sucov (16) measured the diffusion coefficient of oxygen ions in silica glass in the range 925°-1225°C, using a tracer method, and found an activation energy of 71.2 kcal/mole. The extrapolated D at 850° is about 2.1×10^{-16} cm²/sec. Similar values are indicated in the earlier work of Haul and Dumbgen (15). The expected conclusion, however, cannot be drawn since, as Shewmon (29) has pointed out, the chemical diffusion coefficient, as measured by Norton in a transport experiment, is the diffusion coefficient of the defects responsible for the transport, where tracer experiments would measure the diffusion coefficient of the average oxygen ion in silica glass. Since the latter would be immobile except for the brief periods when it exists in a defect configuration, a much smaller value would be expected than for defects, and the activation energy associated with its diffusion would involve both the activation energy for diffusion and the formation energy of the defect involved. The available D values from tracer studies, however, permit an interesting supplementary calculation. If this D is that of the average oxygen ion in silica, then the ionic conductivity of silica due to oxygen ions should be approximately given by

$$\sigma = 2N\mathbf{F}\mu = \frac{4N\mathbf{F}\mathbf{F}'D}{RT} \qquad [5]$$

where N is the oxygen-ion concentration in silica in moles/cm³, μ is the oxygen-ion mobility, $\mathbf{F}$ and $\mathbf{F}'$ are Faraday's constant in units of coul/eqvt and kcal/volt-eqvt, respectively, and the Nernst-Einstein diffusion-mobility relation has been employed. Using $N = 0.069$, calculated from Jorgenson's reported average density of 2.08 g/cm³ for his silica films, and an average value from the two available references (15, 16) for D at 850°, one obtains $\sigma = 3.5 \times 10^{-11}$ ohm^{-1} cm^{-1}, in fortuitously good agreement with the value previously calculated from Jorgenson's data, considering the possible sources of error. It would appear, however, that we have further evidence for the essentially similar nature of "grown" SiO_2 and silica glass.

More direct evidence regarding the nature of the diffusing oxygen in silicon oxidation could be derived from the oxygen pressure dependence of the oxidation rate. In accordance with the considerations of Motzfeldt and Norton, the flow rate of dissolved oxygen through the reaction film, when this is the rate-determining process for oxidation, will be given by

$$J = \frac{2\rho}{nM}\frac{dx}{dt} = D_c\frac{\Delta C}{x} \qquad [6]$$

where J is in moles oxygen solute/cm²-sec, n is the number of oxygen atoms in the solute species, D_c is the chemical diffusion coefficient as previously discussed, and ΔC is the difference in concentration of dissolved oxygen at the two sides of the reaction film. Since the phase boundary $SiO_2|Si$ defines an extremely low chemical potential of oxygen on this side, we may replace ΔC with C_s, the solubility of oxygen in SiO_2 on the gas side in moles solute per cubic centimeter SiO_2. Comparison with $dx/dt = k/x$ yields from the above expression

$$k = \frac{nMD_cC_s}{2\rho} \qquad [7]$$

Since k should thus vary linearly with C_s, it is apparent from Henry's law that a linear dependence of k on p_{O_2}, the partial pressure of oxygen in the gas phase, would be the case if the dissolved species were O_2, where a $(p_{O_2})^{1/2}$ dependence would imply O as the dissolved species.

In the case where gaseous oxygen would dissolve to form oxygen ions, say, by the formation of an equivalent number of electronic holes

$$O_2(g) \rightleftharpoons 2\,O^{=}(\text{in defect sites}) + 4\oplus$$

the p_{O_2} dependence would be less certain. If SiO_2, however, were a predominant or even an appreciable ionic conductor, as data by Schmalzried (26) indicate, one would expect the hole concentration to be small compared with the total oxygen-ion defect concentration. In this event, mass action considerations would predict a $(p_{O_2})^{1/2}$ dependence. In fact, a vari-

ety of pressure dependence have been noted (5, 7, 27, 30, 31). Data by Norton indicate a linear dependence of the permeation rate on p_{O_2} at 1100°, but data on SiC oxidation at higher temperatures show a square root dependence and, as Motzfeldt has noted, there appears to be little by way of reliable data on the pressure dependence of silicon oxidation under diffusion-controlled conditions. Deal and Grove (12) have recently analyzed unpublished oxidation rate data by Flint (31) to assert that, when correction is made for phase boundary effects, the data show a linear dependence on p_{O_2}. These authors suggested that in view of Jorgenson's conclusions, the diffusing species may be the superoxide ion, O_2^-. In view of the above discussion, however, it would seem that molecular O_2 is also a likely possibility, assuming that a linear pressure dependence has been demonstrated. In the latter respect, it may still be desirable to obtain pressure dependence data under explicitly diffusion-controlled conditions.

Finally, we consider the important question of electronic transport in SiO_2 and its relation to an oxidation process involving oxygen ions. The kinetics of processes of this type have been treated in the metal oxidation theory of Wagner (3). An account of the forms of this theory and its success in matching experimentally observed oxidation rates in various systems has recently been given by Kubaschewski and Hopkins (32). It is felt, however, that previous expositions of the theory, especially in its more exact forms, have been heavily thermodynamic in nature, with resultant difficulties in visualizing the physical processes involved. In what follows, a somewhat different approach has been taken, a suitable kinetic expression being derived for the case of Si oxidation on the basis of essentially flow rate and electroneutrality requirements.

Let us suppose that oxygen is introduced into vitreous silica as oxygen ions and electronic holes, in accordance with the above oxide-gas equilibrium, which then diffuse across the reaction layer to react with the silicon

$$2\,O^{=} + 4\oplus + Si = SiO_2$$

The fluxes of oxygen ions and holes at any point within the SiO_2 in response to their respective concentration gradients dN_O/dx and $dN_\oplus/dx$ and whatever electrostatic field $d\phi/dx$ arises from spacecharge effects should be given by

$$-J_O = D_O \frac{dN_O}{dx} - \frac{\sigma_O}{2\mathbf{F}} \frac{d\phi}{dx} \qquad [8]$$

$$-J_\oplus = D_\oplus \frac{dN_\oplus}{dx} + \frac{\sigma_\oplus}{\mathbf{F}} \frac{d\phi}{dx} \qquad [9]$$

in accordance with Fick's and Ohm's laws. Here, the fluxes are in moles/cm²-sec and σ_O and $\sigma_\oplus$ are the partial specific electrical conductivities in SiO_2 due to oxygen ions and holes, respectively, it being assumed that each migrating oxygen ion possesses two negative charges regardless of its defect configuration. D_O is the average diffusion coefficient of whatever defects are responsible for the oxygen-ion migration. As we have noted previously, fluxes such as the above must be intimately coupled to preserve bulk electroneutrality. Since holes and oxygen ions are being introduced at the gas phase side of the reaction layer on a 2-for-1 basis and being removed on the Si side on the same basis at essentially the same rate,[1] one may define an effective flux J of electroneutral oxygen such that at steady state $J \equiv J_O = \frac{1}{2}J_\oplus$ at any point within the film. Moreover, if holes are the only electronic defects in the film, one must have matching charge gradients due to oxygen ions and holes to preserve bulk electroneutrality, so that we may also define an effective oxygen concentration gradient by $dN/dx \equiv dN_O/dx = \frac{1}{2}dN_\oplus/dx$. Introducing the quantities J and N in the above equations, we now have

$$-J = D_O \frac{dN}{dx} - \frac{\sigma_O}{2\mathbf{F}} \frac{d\phi}{dx} \qquad [10]$$

$$-2J = 2D_\oplus \frac{dN}{dx} + \frac{\sigma_\oplus}{\mathbf{F}} \frac{d\phi}{dx} \qquad [11]$$

If we now eliminate $d\phi/dx$ by multiplying Eq. [10] by $\sigma_\oplus/\sigma_O$, dividing Eq. [11] by 2, and adding, we obtain

$$-\left(1 + \frac{\sigma_\oplus}{\sigma_O}\right) J = \left(D_\oplus + \frac{\sigma_\oplus}{\sigma_O} D_O\right) \frac{dN}{dx} \qquad [12]$$

for the oxygen flux within the film as a function of the local concentration gradient. The special significance of this result is that, in consequence of the coupled ionic and electronic flows, the steady-state oxygen flux depends only on transport parameters of the diffusing entities and on the average value of the oxygen concentration gradient, as established across the film by the chemically fixed oxygen potentials at its boundaries. Thus, as we asserted earlier, no effect of an externally imposed electric field is to be expected. Alternatively, Eq. [10] and [11] could have been solved for the local internal field $d\phi/dx$ to show that it is uniquely established by transport parameters of the diffusants and by the externally imposed oxygen concentration gradient. Again, we are assuming the transport parameters are field-independent, which is believed to be the case for oxide films sufficiently thick to exhibit parabolic growth behavior.

A special case of Eq. [12] is of interest. Since one expects $D_O << D_\oplus$ in view of the generally much larger electronic than ionic mobility in solids, the second term in brackets on the right may be neglected if the electronic conductivity is small compared to the ionic conductivity or even comparable to it. Moreover, if the ionic conductivity is due only to oxygen ions, as we have been assuming implicitly, we may equate the bracket on the left to $1/t_{ions}$, so that we obtain

$$-J = t_{ions} D_\oplus \frac{dN}{dx} = \frac{1}{2} t_{ions} D_\oplus \frac{dN_\oplus}{dx} \qquad [13]$$

This result is quite general, since the same expression with $D_\oplus$ and $N_\oplus$ replaced by $D_\ominus$ and $N_\ominus$ may be derived in like manner if the electronic defects are assumed to be conduction band electrons. In this case, one would be dealing with an oxygen-ion deficient structure, in which diffusion would involve countercurrent flows of oxygen ions and electrons. One further special case of interest is that in which the reaction layer is a strongly predominant ionic conductor. In this case, Eq. [13] becomes

$$-J \approx D_\oplus \frac{dN}{dx} = \frac{1}{2} D_\oplus \frac{dN_\oplus}{dx} \qquad [14]$$

and one has the expected result that the oxygen transport is strictly limited by the field-free diffusion of the electronic carriers. Equation [14] is, in fact, an upper bound to the size of the oxygen-ion flux in relation to the electronic diffusion current, a result which is of interest since, as we shall see later, we may determine the latter directly by a well-known experimental arrangement in solid-state electrochemistry.

We may now evaluate the oxidative rate constant k to be expected when diffusion proceeds by oxygen-ion

[1] There will be a very small divergence of the effective oxygen flux due to solution of oxygen in the growing reaction layer, but this may be ignored for our purposes.

migration. For the relation of k to oxygen flux J, we have, from Eq. [6], $J = (2\rho/nM)(dx/dt) = 2k\rho/Mx$, where we have used $n = 1$ for oxygen ions. Since J is essentially constant across the reaction layer, we may write as an integrated form of Eq. [13], $J = \frac{1}{2}\overline{t_{ions}}\,D_{\oplus}\,\overline{(dN_{\oplus}/dx)} = \frac{1}{2}\overline{t_{ions}}\,D_{\oplus}N_{\oplus}^{\circ}/x$, where the bars represent average values across the film, $N_{\oplus}^{\circ}$ is the equilibrium hole concentration in SiO_2 in contact with the ambient gas phase, and we have assumed negligible hole concentration on the Si side in accord with previous considerations of low oxygen solubility on this side. Comparing these expressions for J gives

$$k = \frac{M\overline{t_{ions}}D_{\oplus}N_{\oplus}^{\circ}}{4\rho} \qquad [15]$$

Then, employing the Nernst-Einstein expression, $D_{\oplus} = \mu_{\oplus}RT/\mathbf{F}'$ and defining the specific hole conductivity of SiO_2 in equilibrium with the ambient gas phase by $\sigma_{\oplus}^{\circ} = N_{\oplus}^{\circ}\mathbf{F}\mu_{\oplus}$, we obtain

$$k = \frac{M\overline{t_{ions}}\sigma_{\oplus}^{\circ}RT}{4\rho\mathbf{F}\mathbf{F}'} \qquad [16]$$

This expression for k is more accurate than a somewhat different one suggested by Motzfeldt (14) on the basis of the Wagner oxidation theory, in that it takes into account the expected variation in electronic carrier concentration across the film, but is arrived at without the rather complex thermodynamic considerations attendant in previous treatments with this refinement. It is still approximate in that an average value of t_{ions} is involved, but the use of such an average should not introduce too much error if ionic conduction in the film predominates or is at least comparable with electronic conduction. In the case of predominant electronic conduction, other forms of the Wagner theory (32) would be more appropriate.

In all the above, the central role of electronic conductivity in oxygen transport by ions is to be noted. We consider now what relevant information is available in the literature or accessible through experimentation. As noted earlier, experiments by Schmalzried have indicated that vitreous silica is a pure ionic conductor. Conduction by impurities, however, could not be ruled out in this work and, at any rate, a quantitative estimate of the electronic transference number, however small, is not available from the data. Moreover, measurements on grown films of SiO_2 on Si would undoubtedly be more convincing, despite the apparent similarity of grown SiO_2 and vitreous silica. Jorgenson suggested $t_{ions} = 0.4$ on the basis of a single voltage measurement, but, by his own admission, the accuracy of the measurement was questionable and may reflect some of the contact problems discussed earlier in connection with measuring the halt voltage.

In recent years there has been considerable success in measuring electronic conductivity in predominant ionic conductors by the use of so-called "polarization cells," first suggested by Wagner (2a). Cells of this type employ an electrochemical arrangement in which ionic conduction is "blocked" and the electronic conductivity is measured from a residual electronic diffusion current. In analogy with previous cell arrangements (33-35), the cell

$$(-)\mathrm{Si}|\mathrm{SiO_2}|\mathrm{Pt},\ \text{inert gas}\ (+)$$

is in principle capable of determining the electronic conductivity of grown SiO_2 films atop silicon. Since the electronic conductivities of such compounds are in general a function of the chemical activities of their elemental components, valuable complementary information could be obtained from the cell arrangement

$$(+)\mathrm{O_2(g)},\mathrm{Pt}|\mathrm{SiO_2}|\mathrm{Pt}(-)$$

with various oxygen pressures. Since, in this cell, the electronic diffusion current (36) existing just below the SiO_2 decomposition potential would be precisely the same as that represented in Eq. [14], its measurement would provide a direct determination of the upper limit of permissible oxygen transport in SiO_2 by oxygen ion diffusion. A similar arrangement has been used by the author (37) to measure bromine-induced hole conductivity in AgBr. Cells such as the above provide data not only on the degree of electronic conduction, but on the electronic carrier involved, and would be of great intrinsic value for an understanding of SiO_2 in addition to the question of the oxidation mechanism.

Conclusion

The question of whether an ionic species is involved in diffusion-controlled oxidation of metals is not directly answerable by experiments on the effect of an electric field *per se*, although associated electrochemical experiments may be of great interest if their electrochemical nature is realized. Ionic oxidation mechanisms have been quite successful in interpreting experimental results in a number of systems, but the open, disordered structure of vitreous silica could also conceivably permit the diffusion of an electroneutral entity such as O_2. Conclusion as to which type of transport process predominates does not appear possible on the basis of data available now. Suggested future experiments include better determination of the pressure dependence of the oxidation rate under conditions where the rate is known to be diffusion-controlled and measurements of the electronic conductivity in such films for use with oxidation rate theory. Studies of this type should be of broader interest than the question of the oxidation mechanism because of the apparent similarity of transport processes in grown SiO_2 and silica glass.

Manuscript received Feb. 16, 1966; revised manuscript received April 26, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Emission Spectra of Impurity Activated (Zn,Cd)(S,Se,Te) Phosphors

II. Silver Activated Phosphors

W. Lehmann

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Silver activated (Zn,Cd)S and (Zn,Cd)Se phosphors are essentially single band emitters. The emission band shifts monotonically to lower quantum energies with increasing replacement of Zn by Cd. In contrast, gradual replacement of sulfur in ZnS or CdS by selenium, or of selenium in ZnSe by tellurium, causes little or no shift of the emission band but gradual replacement by a new band. Silver is a two-band emitter in all intermediate Zn(S,Se), Cd(S,Se), and (to some extent) Zn(Se,Te) phosphors. The dependences are demonstrated in recombination term schemes assuming predominantly ionic crystal bonding and validity of the Schön-Klasens model of luminescence.

Emission spectra due to copper in (Zn,Cd) (S,Se, Te) phosphors as a function of the composition of the binary or ternary host material were reported in a previous paper (1). This present paper deals with a similar investigation on silver activated phosphors. Copper and silver are both well known activator impurities in the II-VI compounds, and a fair amount of knowledge has accumulated in the literature especially on the emission due to silver in ZnS and in (Zn,Cd)S phosphors. However, and also similar to the case of copper, little is known yet on the question of how the Ag-emission depends on the composition of the host material within the rest of the II-VI compounds.

The experimental work was limited to powder phosphors containing Ag in the order of 10^{-4} g-mole/g-mole of Zn and/or Cd. The conditions of preparation, excitation (by ultraviolet, at 77°K) and measurement were identical to those described in ref. (1).

Two complications arose which have to be taken into account when the measured emission spectra are identified. First, all ZnSe and ZnTe used contained copper in the order of 1 to 10 ppm (determined by spectroscopic analysis). This contamination is enough to create also a weak copper emission, besides the stronger silver emission, in all samples containing either ZnSe or ZnTe. Second, silver activated II-VI compound phosphors fairly persistently also show an emission band [called SAL emission by Rotschild (2)] at a relatively high quantum energy (*e.g.*, in the near ultraviolet in ZnS:Ag). This emission was actually assumed to be due to silver by van Gool (3), but it can be observed also in phosphors containing no silver (*e.g.*, in self-activated ZnS:Cl) so that van Gool's assumption probably is in error. Both the weak copper emission and the also relatively weak SAL emission sometimes are hard to differentiate from the silver emission. Nevertheless, a clear correlation between activation and at least the strong emission bands can be observed in the case of silver as well as in the case of copper activation, and questionable identifications will be especially mentioned as such.

Zinc Sulfide

The best known and usually best developed emission band of silver in cubic or hexagonal zinc sulfide consists of a single, structureless band in the blue (4-6). A green emission band (corresponding to the green emission of ZnS:Cu) has also been reported (7, 8) but, if it is real, it is always weak compared to the blue band. The following observations on the blue emission band of ZnS:Ag were made within these investigations:

(*a*) Position and shape of the blue Ag-emission band do not noticeably depend on the quantum energy of the exciting ultraviolet. However, the peak position is slightly uncertain and may vary from sample to sample over a range of approximately 0.03 ev even within phosphors made of identical compositions. Also the width is somewhat uncertain and may vary between about 0.23 to 0.28 ev (measured at half-maximum) at 77°K, analogous to corresponding observations on Cu-activated ZnS (1).

(*b*) The mean peak position of the blue emission band of ZnS:Ag depends on structure, and on the kind of the co-activator used, roughly in the same way as observed for the blue band of ZnS:Cu. The following peak positions were measured (at 77°K) as averages over many samples:

cubic ZnS:Ag, (Cl, Br, or I)	2.78 ev
cubic ZnS:Ag, (Al, Ga, or In)	2.81 ev
hexagonal ZnS:Ag, (Cl, Br, or I)	2.85 ev
hexagonal ZnS:Ag, (Al, Ga, or In)	2.81 ev

Some typical spectra are shown in Fig. 1. It will especially be noted that, on the average, hexagonal

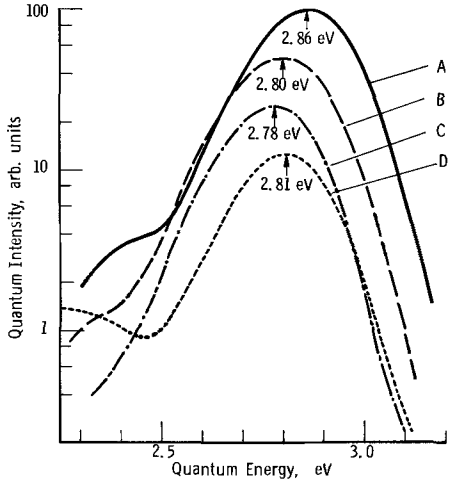

Fig. 1. Emission spectra of four different ZnS:Ag phosphors, all excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K. A: Hex. ZnS:Ag(0.01%),Cl(0.1%), 1100°C, S_2 + argon. B: Hex. ZnS:Ag (0.01%), Al(0.03%), 1100°C, H_2S. C: Cub. ZnS:Ag(0.01%), Br(0.1%), 800°C, S_2 + argon. D: Cub. ZnS:Ag(0.01%),Ga(0.01%), 800°C, H_2S.

ZnS:Ag gives a peak position at roughly 0.07 ev higher quantum energy only in case of halide co-activation, while no such difference exists in cases of co-activation with Al, Ga, or In, and that the blue band of cubic and of hexagonal ZnS:Ag, halide is virtually indistinguishable from the blue band of corresponding copper activated phosphors (1).

(c) A weak green emission band (peak near 2.35 to 2.40 ev) could be observed in several samples of ZnS:Ag (examples Fig. 1). The question whether this green band is due to an accidental contamination with copper (present in the order of 1 ppm) or whether it is the reported green band of silver (7, 8) is as yet undecided.

Hexagonal Zinc-Cadmium Sulfide

Gradual replacement of ZnS by CdS causes the well known gradual shift of the blue emission band of ZnS:Ag toward red and into the near infrared (3, 4, 9-13). Thus, the emission of hexagonal ZnS:Ag,Cl (peak ~2.85 ev at 77°K) corresponds directly to an emission band of similar width and shape with the peak near 1.69 ev (λ = 734 nm) in hexagonal CdS:Ag,Cl. Measured spectra are shown in Fig. 2 and 3. Consideration of the II-VI compounds to be predominantly ionic compounds, so that a variation of the cation means a variation of the conduction band, and application of the Schön-Klasens model of luminescence, yields the recombination term scheme of Fig. 4 where the quantum energies of the peaks of the emission bands are plotted downward from the edge of the conduction band. The resulting points can be connected by a curve approaching a horizontal straight

line at the Zn-rich side but slightly deviating downward at the Cd-rich side [in contrast to the corresponding curves derived for copper which are horizontal straight lines over the whole range (1)].

Cubic Zinc Sulfo-Selenides

Emission spectra of Zn(S,Se):Ag phosphors are published by Leverenz (4) and by Klasens (14). Both agree in the observation that a few per cent of S in ZnS:Ag phosphors replaced by Se causes a strong green emission band, in addition to the common blue band of ZnS:Ag, to appear. Our observations are essentially in agreement with this statement although a closer inspection reveals that the matter is somewhat more complicated. Some spectra are shown in Fig. 5 and 6.

Cubic ZnS:Ag,Cl phosphors emit practically only in a blue band at ~2.78 ev. Replacement of only 1% of ZnS by ZnSe causes a strong green band at ~2.47 ev to appear (Fig. 5) in agreement with Leverenz (4) and Klasens (14). Simultaneously, the peak position of the blue band seems rather abruptly to change from ~2.78 to ~2.73 ev. This "jump" of the peak position is hard to observe because of a too strong overlap of the two emission bands [it was not noted in a previous publication (15)], but it is in accord with a similar, but much stronger, jump observed in corresponding copper activated phosphors (1). Further increase of the ZnSe concentration above 1% then causes only a comparatively weak shift of both emission bands and a gradual increase of the low-energy

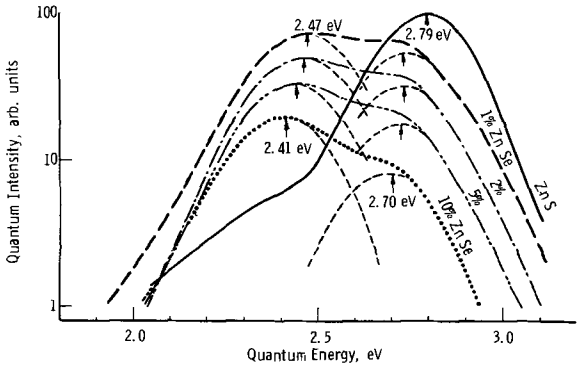

Fig. 5. Emission spectra of cubic Zn(S,Se):Ag(0.01%),Cl phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

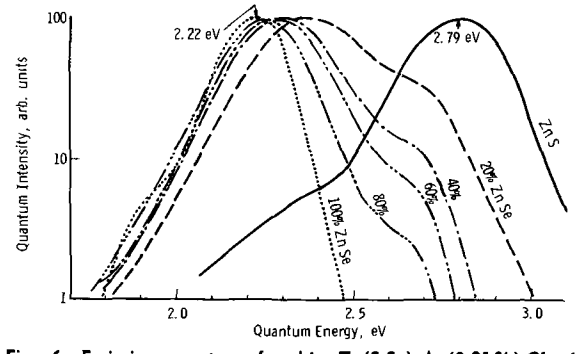

Fig. 6. Emission spectra of cubic Zn(S,Se):Ag(0.01%),Cl phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

band at the expense of the high-energy band until in 100% ZnSe only the former, which is then shifted to ~2.20 ev (yellow) is observed (Fig. 6). The yellow Ag-emission in ZnSe can ordinarily be observed in full intensity only at low temperature, it is more or less thermally quenched at room temperature.

All ZnSe:Ag phosphors made and examined to date showed, in addition to the strong yellow band, also two weak emission bands at ~1.95 ev (red) and at ~2.6 ev (blue-green), respectively. The former most likely is not due to Ag but to unavoidable contaminations with copper. The latter was originally believed (15) to be the remnant of the blue band of ZnS:Ag which, in ZnSe, would be shifted just approximately to that position. However, it might also be the emission band corresponding to the near-ultraviolet SAL-emission frequently observed in ZnS:Ag phosphors. In any case, the questionable emission is weak so that ZnSe:Ag is essentially a single band emitter just as well as ZnS:Ag.

In the ionic picture, a variation of the composition of the host material from ZnS to ZnSe means a variation of the valence band while the conduction band remains unchanged. Using the Schön-Klasens model of luminescence, the measured peak positions are plotted downward from the edge of the conduction band in Fig. 7, and the resulting points are connected by two curves. Neither curve is a perfectly horizontal line, but the deviation from the horizontal is much less than the strong variation of the edge of the valence band observed over the same range. No unsteadiness comparable to the small jump in the lower curve near 100% ZnS is to be observed in the upper curve near 100% ZnSe.

Cubic Zinz Seleno-Tellurides

Replacement of a small amount of Se in ZnSe:Ag phosphors by Te causes little or no change on the position of the yellow emission band at ~2.2 ev but causes a new band at ~1.8 ev (deep red) to build up at the expense of the yellow band, which disappears

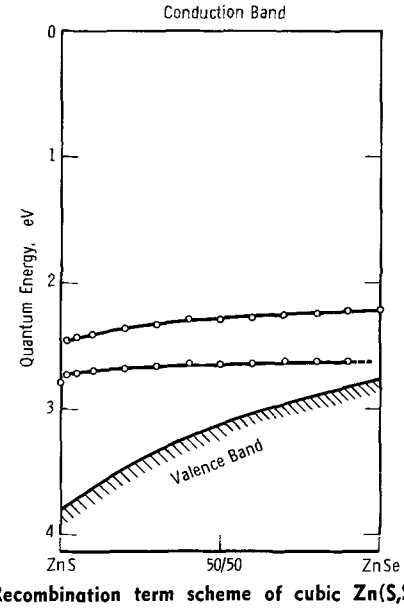

Fig. 7. Recombination term scheme of cubic Zn(S,Se):Ag,Cl at 77°K.

at about 30% Te. The intensity of the red band goes through a maximum and disappears at ~50% ZnTe (Fig. 8). The writer was unable to detect any emission in Zn(Se,Te):Ag containing more than about 50% of ZnTe which unambiguously could be ascribed to be due to silver. If the observed peak positions are plotted downward from the horizontal edge of the conduction band, one obtains the recombination term scheme of Fig. 9. Two points corresponding to an

emission in ZnTe:Ag reported by Halsted, Aven, and Coghill (16) are also shown in Fig. 9, but their correlation to the curves on the ZnSe-side of the diagram is not clear.

Zinc-Cadmium Selenides

Silver activated ZnSe (cubic) emits, predominantly or only, in a single band at ~2.2 ev. The emission spectrum of CdSe:Ag (hexagonal) is reported (17) to consist of a single band at 920 nm (1.35 ev), measured at 77°K. Some emission spectra of (Zn,Cd)Se:Ag phosphors prepared and measured within these investigations are shown in Fig. 10. All consist of a single strong band accompanied by one or two weaker side bands at lower or higher quantum energies, *i.e.*, left or right of the main band in Fig. 10. The left side band most likely is due to unavoidable copper contamination. The right side band probably is the analog of the SAL emission frequently observed in ZnS:Ag phosphors. Only the strong center emission band can be attributed to silver with a reasonable degree of certainty. The band moves steadily to lower quantum energies with increasing concentration of CdSe, completely similar to the shift observed in corresponding sulfide phosphors, so that the 2.2 ev band of ZnSe:Ag corresponds directly to the 1.34 ev band of CdSe:Ag. If the Schön-Klasens model of luminescence is used and the quantum energies corresponding to the peaks of the measured emission bands are plotted downward from the curved edge of the conduction band, one obtains the recombination term scheme of Fig. 11, where all points scatter closely around a horizontal straight line. The slight discontinuity between 40 and 50% of CdSe may be due to the transition of the crystal structure from cubic to hexagonal. Similar to the case of corresponding sulfides (Fig. 2), the points deviate slightly but distinctly from the horizontal

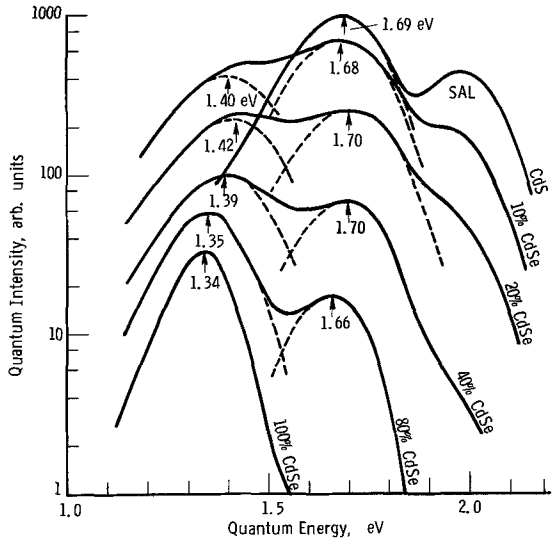

Fig. 12. Emission spectra of hexagonal Cd(S,Se):Ag(0.03%) excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

straight line only near the cadmium-rich side of the diagram.

Hexagonal Cadmium Sulfo-Selenides

Emission spectra of intermediate Cd(S,Se):Ag phosphors, except those of the two end-members CdS:Ag and CdSe:Ag, do not seem to be reported before. Some spectra measured within these investigations are shown in Fig. 12.

The emission spectrum of CdS:Ag frequently consists of two bands at approximately 1.98 ev and at about 1.70 ev, respectively. The writer believes the former to be the SAL emission; only the 1.70 ev band can be attributed fairly certainly to silver. Gradual replacement of CdS by CdSe causes a new emission band near 1.40 ev to appear and develop. The new band requires about 10 mole % of sulfur to be replaced by selenium to be fairly fully developed, and no unsteadiness is observed in the peak position of the 1.70 ev band near the 100% CdS composition, all in contrast to corresponding zinc compounds (Fig. 5). Further increase of the CdSe concentration causes only very little shift of both emission bands, but a gradual increase of the intensity of the 1.40 ev band at the expense of the 1.70 ev band until, in CdSe:Ag, only the former is still present and moved to ~1.34 ev. Hence, CdS:Ag and CdSe:Ag are both essentially single-band emitters (the SAL-emission disregarded) but the 1.70 ev band of CdS:Ag does not directly correspond to the 1.34 ev band of CdSe:Ag.

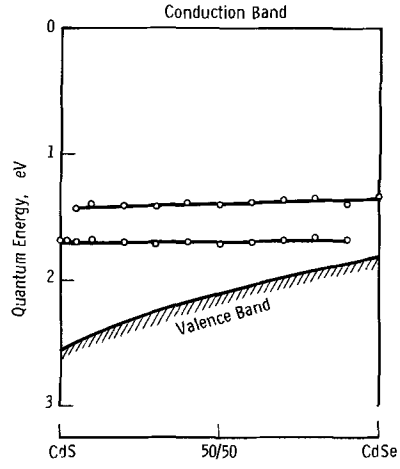

Fig. 13. Recombination term scheme of hexagonal Cd(S,Se):Ag at 77°K.

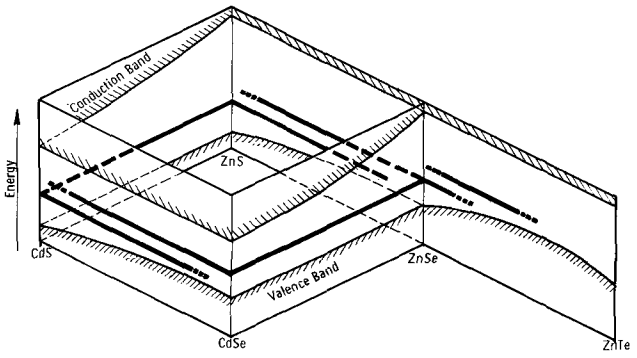

Fig. 14. Simplified recombination term scheme of silver in the binary and ternary (Zn,Cd)(S,Se,Te) phosphors covered in these investigations.

If the quantum energies corresponding to the peaks of the emission bands are plotted downward from the horizontal edge of the conduction band, one obtains the recombination term scheme of Fig. 13, where all points are connected by two curves both almost (not quite) horizontal straight lines, quite in contrast to the pronounced variation of the valence band.

Discussion

The main observations on the emission spectra due to silver in the II-VI compound phosphors can be summarized as follows:

The emission in the binary compounds ZnS, ZnSe, CdS, and CdSe consists essentially of only one band. The exact peak position depends not only on the host material but also on a number of other parameters some of which are still unknown. Gradual replacement of zinc by cadmium either in the sulfides or in the selenides causes a steady shift of the emission band toward lower quantum energies so that the difference between the band gap and the emission peak remains approximately constant. By contrast, gradual replacement of sulfur in ZnS or CdS by selenium, or of selenium in ZnSe by tellurium, causes little or no shift of the emission but the gradual replacement of the one emission band by another one. The consequence is that silver in Zn(S,Se), in Cd(S,Se), and (at least to some extent) also in Zn(Se,Te) is just as much a two-band emitter as copper is (1), and that altogether in the whole system three different emission bands appear to be due to silver. One band requires the presence of sulfur, another the presence of selenium, and the third that of tellurium. The positions of the three recombination terms in the band diagram of the entire system are, highly schematically and neglecting all details, shown in Fig. 14. It is tempting to assume that each one of the three emission bands belongs to a particular recombination center involving, besides silver, either sulfur or selenium or tellurium. This assumption is probably wrong, however, for two reasons.

First, an activator can be considered as a localized center consisting of an impurity cation (silver in this case) surrounded by four anions as next neighbors. Hence, if the compositions of the material varies from ZnS to ZnSe, for instance, there should be some kind of a statistical distribution of impurity cations surrounded by X sulfur and 4-X selenium ions where X = 0,1,2,3,4. Hence, a variation from ZnS to ZnSe should produce a more gradual change of the emission involving five (possibly closely overlapping) emission bands, but not only two bands. The theory of this variation is discussed by Fonger (18) for the case of Zn(S,Se), and probably it holds essentially also for Cd(S,Se) and Zn(Se,Te).

Second, it would certainly be rather arbitrary to restrict a model which correlates the three observed emission bands to three assumed kinds of recombination centers (each containing an impurity ion and either sulfur or selenium or tellurium) to the case of silver activated phosphors only. However, there is open disagreement between the model and the cases of phosphors activated by copper and, as far as known, by gold since copper and gold both produce two emission bands even in the sulfides containing no selenide, and copper also in selenide phosphors containing no sulfide and no telluride.

The only conclusion to be drawn at the moment is that our knowledge of the true mechanism of luminescence in copper or silver activated II-VI compound phosphors is still incomplete. A consideration of the II-VI compounds as predominantly ionic compounds and an assumption of validity of the Schön-Klasens model of luminescence are able to explain the experimentally observed behavior only to some extent, and a considerable amount of it is still open for interpretation.

Acknowledgment

The author wishes to express his thanks to H.F. Ivey and to W. A. Thornton for proof-reading and helpful suggestions, and to H. H. Dorman for much careful work in preparation and measurement.

Manuscript received Feb. 25, 1966; revised manuscript received May 5, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

The Basic Significance of Oxygen Chemisorption on the Photoelectronic Properties of CdS and CdSe

Richard H. Bube

Department of Materials Science, Stanford University, Stanford, California

ABSTRACT

The long-known phenomenon of oxygen chemisorption on CdS and CdSe, more intensively studied recently, is shown to have a basic significance for the photoelectronic properties of thin crystals or layers. It is proposed that every "pure" crystal of CdS or CdSe is of relatively high conductivity [$\geq 10^{-6}$ (ohm cm)$^{-1}$] and high photosensitivity (electron lifetime of 10^{-3} sec) as prepared by standard techniques. If the crystal or layer is thin enough, oxygen adsorption obscures these properties and gives the appearance of a highly insulating insensitive material. Smaller effects are found in crystals containing deliberately incorporated impurities as long as the Fermi level at room temperature lies above the level associated with the surface state for chemisorbed oxygen. Because of the universal presence of oxygen chemisorption effects, every experiment in which the effect of heat, vacuum, or photoexcitation are investigated toward understanding the nature of photochemical changes, must be interpreted in the light of the significant effects associated with the simple desorption of oxygen.

The effect of oxygen on the photoelectronic properties of CdS and CdSe has been known from the early days of research in this area. A common prescription for improving the light-to-dark resistance ratio of photoconducting cells was to bake the cells in air to increase the dark resistance (1). The importance of adsorbed oxygen in determining measured values of dark resistance and photosensitivity in CdS (2, 3) and CdSe (4) was investigated a number of years ago, but it is only in recent years that the general importance of these effects has been realized. The effect of adsorbed oxygen on the photovoltaic effect of CdS has been studied by Williams (5) and by Haas, Fox, and Katz (6), on the lifetime and response time for strongly absorbed light in CdS by Mark (7-9), on the conductivity of CdSe layers by Somorjai (10), on the photoelectronic properties of sintered layers of CdS-CdSe and CdSe by Shear, Hilton, and Bube (11), and on the photo-Hall effect of sintered layers by Robinson and Bube (12). The importance of oxygen chemisorption phenomena in simulating other types of photochemical changes has also been discussed for CdS-CdSe crystals (13), for which the electron lifetime at room temperature could be varied by a factor of 20 by varying the amount of adsorbed oxygen.

It now appears that what was originally believed to be an appreciable effect of importance for only a few specially prepared crystals or for particular excitation conditions is in fact a quite general effect that can have a profound influence on the photoelectronic properties of CdS and CdSe. The effects would be expected to be the most pronounced for thin crystals or layers of these materials for which surface chemisorption of oxygen could have electrical effects extending throughout the volume of the material.

Mark has given a thorough report on the phenomenon of oxygen chemisorption on CdS crystals, both as to its kinetics and its energetics. He has worked with strongly absorbed photoexcitation of CdS crystals without photosensitivity in the red portion of the spectrum and has located the surface level associated with chemisorbed oxygen at 0.91 ev below the conduction band. The largest change in electron lifetime reported by Mark is an increase by a factor of 35; he reports that changes in lifetime of less than 20% are found in all red-sensitive crystals.

It is the purpose of the present paper to indicate that the changes in photoelectronic properties of "pure" crystals (*i.e.*, relatively red-insensitive) due to oxygen adsorption can be surprisingly large, amounting to seven to ten orders of magnitude in dark conductivity and to three to four orders of magnitude in electron lifetime. Effects involving several orders of magnitude in dark conductivity and one order of magnitude in electron lifetime are found even in thin crystals with red sensitivity. Only in crystals in which the Fermi level at room temperature lies at or below the level of the surface state of chemisorbed oxygen does the effect become very small. The realization of the importance that chemisorbed oxygen effects can have on all thin crystals and layers of CdS and CdSe provides the basis for explaining a number of previous observations.

Experimental

Four different types of crystals were used in the present investigation: (*i*) pure crystals of CdS prepared with extreme caution to eliminate impurities, particularly oxygen during the crystal growth, in thin platelet form (14); (*ii*) thin platelet crystals of CdS:Cl:Cu which had been grown with an excess of chlorine and then had been compensated by diffused copper (15); (*iii*) crystals of CdS:Cu grown by sublimation from an initial charge of CdS and Cu_2S (16); and (*iv*) crystals of pure CdSe, used in a previous investigation of the effect of vacuum annealing (17). All these crystals were available through the courtesy of RCA Laboratories.

Ohmic contacts were applied to the crystals by melted indium electrodes applied in air. That the properties of the crystals were not altered by this electrode application process was demonstrated by measuring the properties of crystals with gallium contacts applied without heating at room temperature.

Measurements of dark conductivity and photoconductivity were made in a special cryostat in which flowing atmospheres of helium, oxygen, or air could be maintained. The temperature range covered was from 80°K to the melting point of indium at about 430°K. Photoexcitation was by a Bausch and Lomb monochromator. All currents were directly recorded on a L&N X-Y recorder through a L&N micromicroammeter.

Results

Measurements made on 5 crystals of pure CdS, 2 crystals of CdS:Cl:Cu, and 2 crystals of CdS:Cu are summarized in Table I. In addition to the atmosphere present during the measurement, Table I gives the

activation energy associated with the dark conductivity, the actual value of the dark conductivity at room temperature measured during the run for which it is listed, the initial electron lifetime determined from the steady-state photoconductivity, and the electron lifetime measured after the run for which it is listed.

Similar measurements on 3 crystals of pure CdSe are listed in Table II; all of these measurements were done in a helium atmosphere.

Although in our experience it is only the rare crystal that shows appreciable oxygen desorption upon heating in even a nonoxygen atmosphere to 100°C, a wide variety of crystals show oxygen desorption effects on heating to 125°-150°C regardless of the atmosphere. Insofar as most measurements reported in the literature usually do not involve heating appreciably above 100°C, the purpose of the heating being to eliminate water vapor from the Dewar system, such measurements deal with crystals with chemisorbed oxygen.

Dark conductivity.—Only one of the twelve crystals in this investigation had a measurable dark conductivity at room temperature, the limitation of the instrumentation being about 10^{-10} (ohm cm)$^{-1}$ depending on the exact geometry of the crystal. The initial heating almost always gave an apparent activation energy for all but the CdS:Cu crystals, which was too large to have physical significance as a simple conductivity process (1.6-5.7 ev), but requires interpretation as due to oxygen desorption as well. In the oxygen-free state, the dark conductivity of all 5 pure CdS crystals is between 10^{-7} and 2×10^{-6} (ohm cm)$^{-1}$ (see Table III for summary of parameters from Table I).

Dark conductivity data for the CdS-A-1 crystal are given in Fig. 1. The initial heating has a very steep slope with apparent activation energy of 5.7 ev. The dark conductivity at the upper temperatures was also time dependent, again indicating the importance of thermal desorption of oxygen in the flowing helium atmosphere. Curve 2 in Fig. 1 shows the results of partial

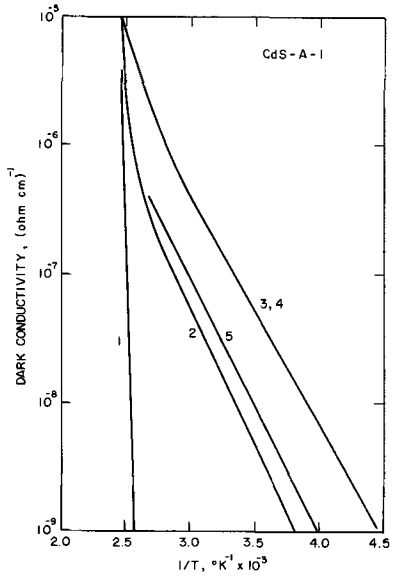

Fig. 1. Dark conductivity of pure CdS-A-1 in flowing helium as a function of temperature 1. Initial heating after long period of exposure to air; 2. second heating after reaching maximum temperature of 127°C; 3, 4, third and fourth heatings after reaching maximum temperature of 146°C; 5, fifth heating after the measurement of photoconductivity and thermally stimulated conductivity vs. temperature.

desorption of oxygen, and curves 3 and 4 indicate the reversible state arrived at by heating to 146°C. Curve 5 was measured later, after the measurement of photoconductivity and thermally stimulated conductivity as a function of temperature, during which time some readsorption of oxygen had apparently occurred. The activation energy for dark conductivity for curves 2 through 5 is between 0.35 and 0.42 ev.

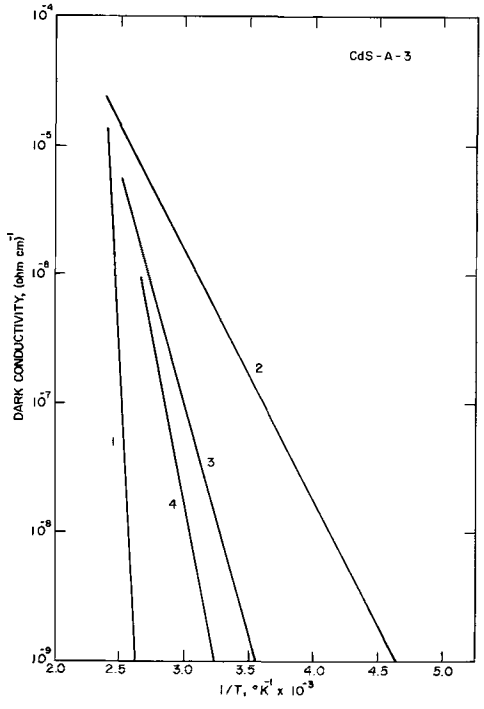

Fig. 2. Dark conductivity of pure CdS-A-3 as a function of temperature. 1, Initial heating in flowing helium after long period of exposure to air; 2, second heating in flowing helium after heating to 144°C; 3, heating in flowing oxygen; 4, heating in flowing oxygen after photoexcitation at elevated temperature and while cooling.

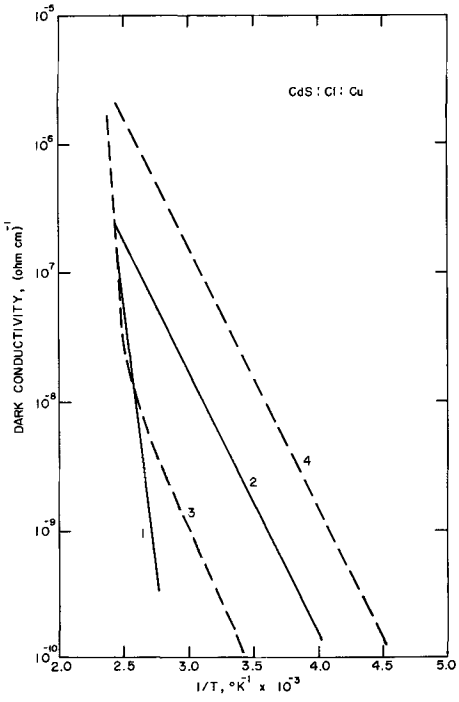

Fig. 3. Dark conductivity of two CdS:Cl:Cu crystals in flowing helium as a function of temperature. 1, Initial heating of CdS:Cl:Cu-1 after long period of exposure to air; 2, second heating of CdS:Cl:Cu-1 after reaching maximum temperature of 144°C; 3, initial heating of CdS:Cl:Cu-2 after long period of exposure to air; 4, second heating of CdS:Cl:Cu-2 after reaching maximum temperature of 147°C.

Similar data for CdS-A-3 are shown in Fig. 2. Curve 2, which represents the dark conductivity in the oxygen-free state, has an activation energy of 0.38 ev. Curve 3 represents the reasonably reversible variation of dark conductivity for this crystal if oxygen is used to replace the helium after the run shown in curve 2. If, in addition, the crystal is photoexcited at the highest temperature reached in curve 3 and is then cooled rapidly continuing photoexcitation, subsequent heating yields curve 4, indicating still greater oxygen adsorption as a result of the photoexcitation.

Such results are not confined to pure CdS crystals. Data for the two crystals of CdS:Cl:Cu are given in Fig. 3. The initial heating is given in curves 1 and 3 and the properties of the oxygen-free surfaces in curves 2 and 4. Once again the activation energy for the dark conductivity in the oxygen-free state is about 0.40 ev. Crystal CdS:Cl:Cu-2 shows a low-temperature conductivity slope of 0.44 ev on the initial heating, indicating the presence of these centers even with adsorbed oxygen.

Values of the dark conductivity activation energy are summarized in the last column of Table III for all measurements made in helium, following a heating in helium to eliminate oxygen adsorption effects. An average value of activation energy of 0.40 ± 0.03 ev is obtained for 9 measurements on the 7 pure CdS or CdS:Cl:Cu crystals.

Very large increases in apparent dark conductivity are found also for the pure CdSe crystals tested, as shown in Table II. The activation energies for the oxygen-free crystals are much lower than in CdS crystals and do not show such constancy from crystal to crystal.

Strikingly different is the behavior of the two CdS:Cu crystals. The activation energy on the initial heating is only slightly larger than on subsequent heatings in helium, and the dark conductivity in the oxygen-free state is probably about 10^{-13} (ohm

Table IV. Ratio of the photoconductivity in the oxygen-free state for several CdS crystals to that with adsorbed oxygen for various wavelengths of photoexcitation

Crystal	Photoconductivity ratio at 4000Å	Photoconductivity ratio at λ_{max}	Photoconductivity ratio for long λ
CdS-A-1	7000	1000	17,000 (5400Å)
CdS-A-2	3000	500	4,500 (5400Å)
CdS-A-3	18,000	4000	10,000 (5300Å)
CdS:Cl:Cu-1	95	10	300 (7500Å)
CdS:Cl:Cu-2	20	3.5	6 (8000Å)
CdS:Cu(3.3%)	25	3	3 (7500Å)

cm)$^{-1}$, the estimated dark conductivity in the initial state being about 10^{-14} (ohm cm)$^{-1}$.

Electron lifetime.—Although the initial electron lifetimes for the 12 crystals measured varies from 2×10^{-8} to 3×10^{-4} sec, the lifetime in the oxygen-free state for all crystals except one lies in the range of 2×10^{-4} to 2×10^{-3} sec. In other words, removing the adsorbed oxygen increases the electron lifetime by a maximum factor of 4×10^4 (CdSe-2) and by a minimum factor of 3 [CdS:Cu(3.3%)], but the final electron lifetime in all cases is essentially of the order of 1 millisec. These results indicate that CdS and CdSe crystals as prepared by a variety of standard methods and, regardless of the kind of impurity incorporation over a wide range, are all highly photosensitive in the absence of adsorbed oxygen.

Spectral dependence of photoconductivity.—The values of electron lifetime used in the previous section and in Table I-III are the values calculated for excitation at the maximum of the photoconductivity spectrum. The change in photoconductivity with oxygen desorption is a minimum for this wavelength, often being appreciably larger for both shorter and longer wavelengths. Results for several of the CdS crystals are summarized in Table IV.

Thermally stimulated conductivity and electron lifetime.—Earlier investigations (7, 8, 18) have reported a much larger increase in response time or in thermally stimulated conductivity on oxygen desorption from CdS crystals than in electron lifetime. Mark, for example, cites an increase in electron lifetime of 35 being accompanied by an increase in thermally stimulated conductivity by a factor of 10^5.

Measurements were made on the temperature dependence of electron lifetime and of thermally stimulated conductivity both with adsorbed oxygen and in the oxygen-free state for crystals CdS-A-2 and CdS-B-2. Results are summarized in Table V. Although attempts to compare these figures in any exact quantitative way are unjustified because of the differences in current levels involved, it does appear that they are of comparable magnitude and that a large discrepancy between changes in free electron lifetime and in thermally stimulated conductivity is not found.

Dynamic behavior.—Some of the changes accompanying oxygen desorption reported above are so large, particularly for the pure crystals, that it may be wondered whether oxygen desorption is indeed the only process involved. In order to provide evidence that the effects are indeed reversible oxygen chemisorption effects, several measurements were made of the dynamic behavior of dark conductivity and photoconductivity with changes of atmosphere.

Table V. Comparison of changes in electron lifetime and thermally stimulated conductivity with oxygen desorption

Crystal	T, °C	Ratio of electron lifetime	Ratio of thermally stimulated conductivity
CdS-A-2	−150	100	250
	−100	60	200
	−50		300
	0		
	25	60	
CdS-B-2	−150	400	10,000
	−100	1200	20,000
	−50	2000	2,000
	0	2500	1,000
	25	8000	700

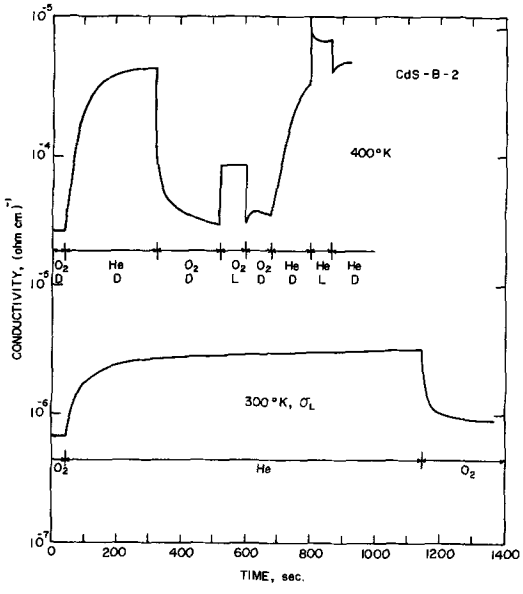

Fig. 4. Dynamic behavior of conductivity in CdS-B-2 crystal. Lower curve shows variation in photoconductivity at room temperature with variation between oxygen and helium atmosphere. Upper curve shows variation in dark conductivity and in photoconductivity with variation between oxygen and helium atmosphere. D represents "dark," and L represents "light."

Figure 4 shows a series of dynamic measurements for the pure CdS-B-2 crystal. The lower curve shows the effect on the photocurrent at 300°K of replacing the oxygen atmosphere around the crystal by a helium atmosphere, and then returning to the oxygen. The upper curve shows a series of measurements at 400°K, demonstrating the reversibility of atmosphere effects on the dark conductivity and on the photoconductivity.

Figure 5 shows the dynamic behavior of CdS-A-3 at room temperature after having been heated in helium to desorb oxygen. Even in helium in the dark there is a slow decay of dark conductivity, evidently associated with readsorption of oxygen present in trace amounts, as mentioned previously. A decrease in lifetime by a factor of about 1000 is observed directly from the data of Fig. 5 on replacement of helium by oxygen, as well as a decrease in dark conductivity.

Reversibility in the oxygen chemisorption effects is also demonstrated by the data given in Table I for CdS-A-2. After desorption of oxygen had increased the dark conductivity and the electron lifetime, the crystal was simply exposed to air at room temperature for 5 days. Subsequent measurements showed that the initial dark conductivity and electron lifetime values were restored.

Discussion

"Pure" crystals.—The results indicate that every "pure" crystal of CdS and CdSe has a relatively low resistivity and a high photosensitivity as prepared by any one of the standard techniques. If the crystal is thin enough, oxygen adsorption obscures these properties and gives the appearance of a highly insulating insensitive crystal.

An immediate explanation is hereby offered for the observation that large crystals of pure CdS invariably have high dark conductivity, whereas thin crystals of pure CdS can be prepared easily with low dark conductivity. How thin a crystal must be for the effect of oxygen adsorption at room temperature to be domi-

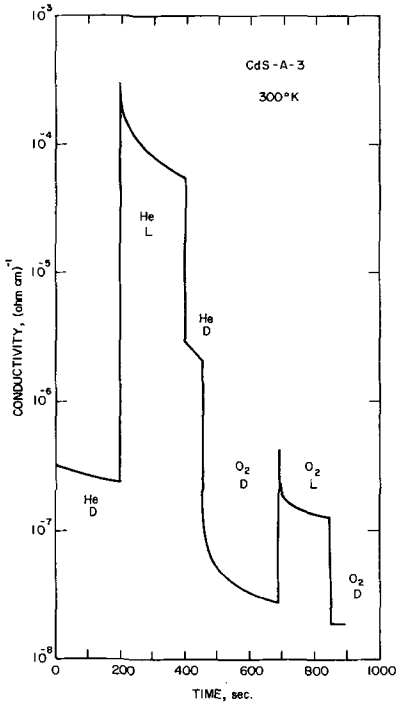

Fig. 5. Dynamic behavior of conductivity at room temperature for crystal CdS-A-3. D represents "dark," and L represents "light."

nant can be estimated from the thickness of the barrier layer associated with chemisorbed oxygen

$$d = \left[\frac{\epsilon\phi_0}{2\pi eN}\right]^{1/2} \qquad [1]$$

If we set $\epsilon = 10$, $\phi_0 = (0.9\text{-}0.4) = 0.5$v, we can calculate d if the value of N, the density of ionized donors, is known. Since the room temperature conductivity of such pure crystals in the oxygen-desorbed state is of the order of 10^{-6} (ohm cm)$^{-1}$, the corresponding value of N is about 2×10^{10} cm^{-3} for an assumed electron mobility of 300 cm^2/v-sec. Under such conditions, $d = 240\mu$. This means that high-resistivity, pure CdS crystals should in general have a thickness of less than a few hundred microns. The thicknesses of the 5 pure crystals used in this investigation were between 12 and 50μ.

Pure, thin crystals of CdS have been generally found to have poor photosensitivity. It has been conventional (19) to ascribe this lack of sensitivity to the absence of compensated sensitizing centers, *i.e.*, particular compensated acceptors with a much smaller capture cross section for free electrons than for free holes. The fact that photosensitive crystals can be produced by the incorporation of trace amounts of halogen impurities (14) has been attributed either to the creation of sensitizing-type defects or to compensation of existing sensitizing-type defects by the incorporated halogen. It now appears probable that the principal effect of the halogen is to supply electrons to reduce the effects of adsorbed oxygen. The fact that pure crystals are highly photosensitive in the oxygen-free state is additional evidence that the sensitizing-type defects are indeed intrinsic crystal defects such as cadmium vacancies.

The dominant donor in the pure CdS crystals in the oxygen-free state appears to have an ionization energy of about 0.40 ev. Since the ionization energy of the donors in highly nonstoichiometric CdS is of the order of 0.03 ev, it is possible that the 0.40 ev activation energy is associated with the second ionization level of an anion vacancy. The fact that the same activation energy of 0.40 ev is found in the CdS:Cl:Cu crystals is additional evidence of its identification with an intrinsic crystal defect. It is possible that the activation energy of 0.40 ev corresponds only to a particular value in a relative continuous distribution of donor levels, this particular value being fixed by the degree of oxygen desorption associated with the experimental conditions that prevented heating above 156°C in order not to melt the indium electrodes. The similarity of activation energy between curves 2 through 5 in Fig. 1, and between curves 2 through 4 in Fig. 3, argues against this possibility.

In the case of CdSe-1, an activation energy of 0.14 ev was found for the dark conductivity in the oxygen-free state. When crystals of this same type are annealed above 500°C in vacuum, dark conductivity with an activation energy of 0.14 ev is found (17). This result indicates that the density of 0.14 ev donors is increased by the vacuum anealing to the point where the effects of oxygen adsorption can be overcome.

Impure crystals.—Oxygen adsorption effects will of necessity be minimized in crystals in which the Fermi level lies near or below the level of the surface state corresponding to adsorbed oxygen. A Fermi level lying 0.91 ev below the conduction band at room temperature in CdS corresponds to a dark conductivity of about 10^{-13} (ohm cm)$^{-1}$, again using an electron mobility of 300 cm^2/v-sec and an electron effective mass ratio of 0.2.

The thin CdS:Cl:Cu crystals have a dark conductivity of about 10^{-8} (ohm cm)$^{-1}$ in the oxygen-free state, and oxygen adsorption effects on dark conductivity and electron lifetime are measurable, although they are not as large as in the pure crystals.

The CdS:Cu crystals, on the other hand, have a dark conductivity at room temperature of about 10^{-13} (ohm cm)$^{-1}$, estimated by extrapolation of dark conductivity data above room temperature. It would be expected that the effects of oxygen adsorption on these crystals would be small. Such is found to be the case.

Thermally stimulated conductivity.—The apparent occurrence of a much larger increase in thermally stimulated conductivity than in electron lifetime with oxygen desorption led Mark (8) to propose that a high density of surface electron traps was compensated by an equally high density of surface hole traps, in order to avoid a barrier field at the surface much larger than the breakdown field of CdS.

Measurements in the present investigation, summarized in Table V, indicate that to a first approximation the increase in thermally stimulated conductivity can be interpreted as a direct result of an equal increase in electron lifetime with no appreciable change in actual trap density. Since this indicates that a high density of electron surface traps is not a necessary part of the oxygen-free surface condition, it suggests that the earlier results (7, 8, 18) may involve an incorrect assessment of the actual trap density in the oxygen-free state. Such an error could result if the electron lifetime in the thermally stimulated conductivity or response time measurements were actually much larger than the electron lifetime for steady-state excitation (20). Mark has also pointed out this possibility (21), but has argued that the increased effective lifetime found for electrons released during a TSC measurement is the result of their having been released from surface traps, recombination becoming possible only after a compensating hole is released into the bulk from a surface trap. Experiments on the effects of adsorbed oxygen on electron lifetime and thermally stimulated conductivity in the carefully studied CdS-CdSe single crystal system indicated a direct correspondence between changes in electron lifetime and in thermally stimulated conductivity (13).

General consequences.—Since the properties of CdS and CdSe crystals and layers can be changed by such large factors by the simple alteration of the amount of adsorbed oxygen, other experiments in which desorption of oxygen may occur must be carefully inter-

preted. This would apply in particular to experiments in which the effect of heat, vacuum, or photoexcitation is investigated to understand the nature of photochemical changes.

Acknowledgments

Helpful discussions in the course of this work were held with G. A. Dussel and with Dr. Guy Marlor and Dr. Victor Serdyuk.

Work on this paper was supported partially by the Army Research Office (Durham) and partially by the Advanced Research Projects Agency through the Center for Materials Research at Stanford University.

Manuscript received March 25, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

The P-T-X Phase Diagram of the System Ga-S

R. M. A. Lieth, H. J. M. Heijligers, and C. W. M. v.d. Heijden

Solid State Physics Group, Department of Technical Physics, Technical University, Eindhoven, The Netherlands

ABSTRACT

The phase diagram of the system Ga-S has been determined. Two maxima are found in the T-X diagram, one at the composition of GaS, the other at the composition of Ga_2S_3. The compound GaS has a maximum melting point of 962° ± 4°C at a sulfur pressure of $0.9 \cdot 10^{-4}$ mm Hg Ga_2S_3 has a maximum melting point of about 1090°C at a sulfur pressure of 1.3 mm Hg. A range of liquid immiscibility exists between about 10 and 48 a/o (atom per cent) S and possibly also between about 65 and >90 a/o S.

Investigations on GaS have revealed that this compound has interesting semiconducting properties (1, 2). In order to grow single crystals of this layer compound under controlled conditions we found it useful to know more about the P-T-X diagram of the system Ga-S.

While the solid-liquid phase equilibria of the system Ga-Te, In-Te, In-S, and In-Se are fully described (3-6), there seems to be no report on a phase diagram of the system Ga-S. Klemm and von Vogel (7) synthesized GaS from the elements and Ga_2S_3 by passing a stream of H_2S over Ga_2O_3 at 1250°C. They report melting points of 965° and 1250°C for GaS and Ga_2S_3, respectively.

Spandau and Klanberg (8) reported the decomposition of GaS when heated at temperatures between 970°-1200°C. Ga_2S, one of the decomposition products, was used in a vapor pressure experiment, and above 950°C Spandau and Klanberg found an inhomogeneous melt containing Ga and GaS, while complete miscibility was found above 1150°C.

On the basis of a comparison of Debye-Scherrer powder photographs Spandau and Klanberg suggested a hexagonal structure for Ga_2S which was almost the same as that of GaS. These authors reported a melting point for GaS of 970° ± 3°C which is in accordance with the work of Brukl and Ortner (9). The same authors also synthesized Ga_2S_3 from the elements. Above 950°C, Ga_2S_3 started to loose sulfur and decomposed into Ga_4S_5 and S_2.

Experimental Procedures

To obtain the phase relations as a function of temperature and composition, use was made of thermal analysis (10) carried out on samples sealed under a vacuum of 10^{-3} mm Hg in vitreous silica tubes which had an axial thermocouple well. As the closed silica tubes were almost completely filled with the substance under investigation and because the equilibrium sulfur pressures at the temperatures involved are low, as discussed later, the uncertainties introduced by evaporation of sulfur from the melt are negligible.

The samples used in these experiments were synthesized by heating the elements[1] for several hours in an electrically heated furnace. Samples with a sulfur content up to 50 a/o were kept at a temperature of 1100°C, those with a sulfur content higher than 50 a/o were heated at 1300°C.

Afterwards, cooling curves as function of time t were taken, the melting points being shown by a change in the slope, or by a horizontal portion of the temperature-time curve.[2] In order to get an indication of the form of the diagram, in the first series of cooling experiments the samples were cooled down from 1100° and 1300°C, respectively. This was repeated several times, and with the information gained a second series of cooling and heating measurements was made on the same samples.

In these experiments the melt was maintained for several hours at a few degrees above its liquidus temperature and then cooled down at a rate of 10°C/min. These measurements were repeated until a difference of less than 2.5°C was obtained between the thermal arrests of the cooling and heating curves of each sample. The Pt-Pt 10% Rh thermocouples were calibrated under identical experimental conditions by cooling curves taken on pure silver and sodium chloride. No supercooling occurred during these experiments.

[1] From Johnson Matthey and Co. Ltd., spectrographically pure.

[2] This was done with a Philips automatic measuring bridge.

Preliminary work had shown that GaS had a maximum sulfur pressure at its melting point of less than 10^{-6} atm. In the case of Ga_2S_3 this was less than 10^{-2} atm.

To obtain the phase relations as a function of pressure and temperature, the following method was used: accurately weighed samples were heated for several hours at various temperatures in sealed silica tubes together with a known volume of hydrogen. This hydrogen had a pressure of 1 atm at room temperature. At the temperatures involved, equilibrium is attained according to the equation

$$H_2 + \frac{1}{2}S_2 \leftrightarrows H_2S \qquad [1]$$

in which the sulfur pressure is the equilibrium sulfur pressure over the sulfide. The values of

$$K_{H_2S} = \frac{p_{H_2S}}{p_{H_2} \cdot p_{S_2}^{1/2}} \qquad [2]$$

at the various temperatures can be obtained from literature (11). Cooling the quartz tubes rapidly to room temperature, the equilibrium is frozen in. After opening the tube the H_2S content can be determined by iodometric titration (12), the hydrogen pressure under equilibrium conditions can be calculated, and this together with the determined H_2S content enables one to calculate the sulfur pressure by using Eq. [2].

In the case of Ga_2S_3 a second method was used as a check on the above mentioned experiments, although it is a time consuming method. Sulfur and Ga_2S_3 were placed in separate quartz bulbs connected by a smaller tube. Both bulbs were equipped with thermocouple holes. The whole system was sealed under a vacuum of 10^{-3} mm Hg and placed in a two-section electrically heated furnace in which each section could be heated independently.

A definite sulfur vapor pressure was created by heating the sulfur-containing part of the system to the appropriate temperature (T_1). The other bulb was maintained at a temperature somewhat higher than the melting point of Ga_2S_3 (T_2). As P_{Ga} and $P_{Ga_2S_3}$ are very low at the temperature T_2,[3] the liquid Ga_2S_3 comes into equilibrium with the sulfur vapor pressure established at T_1. The melting point of Ga_2S_3 was then repeatedly determined by thermal analysis until no change could be detected in this melting point and the corresponding sulfur pressure established at T_1 could be regarded as the equilibrium pressure over Ga_2S_3. These values were in good agreement with those obtained by the first method.

Results

The T-X projection.—In Table I the results of the thermal analysis for the various Ga-S mixtures are given. In column 1 the sulfur contents of the samples are listed; column 2 gives the appearance of these samples. In columns 3, 4, and 5 the temperatures of the first, second, and third thermal arrest points are indicated. Column 2 shows the change in color in going from the Ga-rich side of the system to the S-rich side. Alloys rich in gallium contained inclusions of metallic gallium, which could be seen without breaking the regulus into pieces. The majority of Ga_2S_3 synthesized in the course of our experiments exhibited a dark-red color. It happened occasionally that a batch was ivory colored with a mother of pearl shine on its outer surface. In the literature Ga_2S_3 is reported to be ivory or white (7, 8). Debye-Scherrer photographs showed no difference between the different colored substances. Thermal analysis on the other hand revealed a difference in the melting points. Compared with the yellow and white substances which contain, respectively, 63 and ≈ 65 a/o S, we therefore consider the ivory colored compound with "60" a/o S to be sulfur rich Ga_2S_3. The determined phase diagram is shown in Fig. 1.

[3] P_{Ga} is less than 10^{-5} atm according to the work of Speiser and Johnston and Cochran and Foster (13, 14). $P_{Ga_2S_3}$ is assumed to be very low, since even after several days no sublimation occurred under the above mentioned sulfur pressures.

The compounds GaS and Ga_2S_3 melt at temperatures lying considerably above the melting points of the components. On the gallium-rich side, near pure Ga, no thermal arrest above the melting point of Ga could be detected. The first detectable melting point was at a sulfur content of 10 a/o.

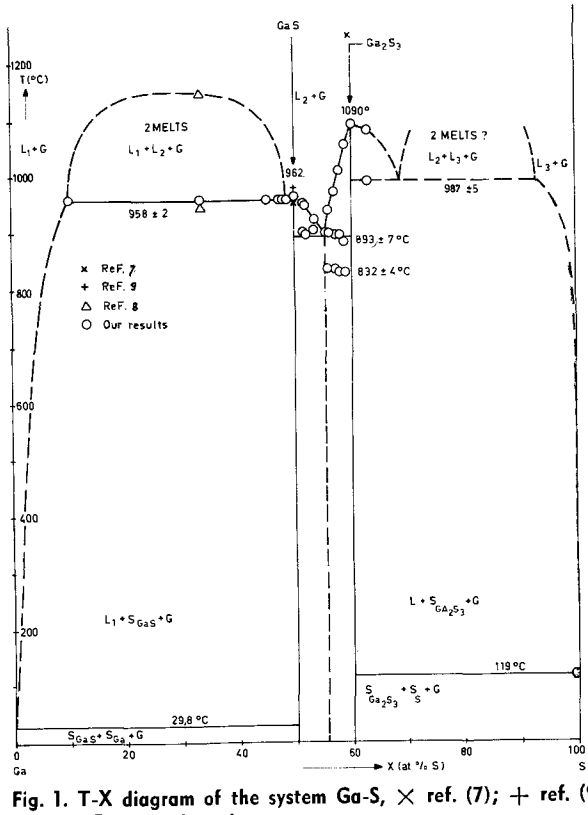

Fig. 1. T-X diagram of the system Ga-S, × ref. (7); + ref. (9); △ ref (8); ○ authors' results.

Between about 10 and 48 a/o S the monotectic at 958°C indicates the existence of a range of liquid immiscibility in good agreement with the work of Spandau and Klanberg (8). Analogous regions of liquid immiscibility are found in the systems Ga-Te (3), In-Te (4), In-S (5), In-Se (6), and Sn-S (15). It is therefore reasonable to suppose that the composition of the eutectic point on the gallium-rich side must be very close to that of pure Ga.

Between GaS and Ga_2S_3 there is a eutectic point at 893° ± 7°C at a composition of about 55 a/o S. Analysis of x-ray powder patterns on samples at 56 a/o S showed lines characteristic of GaS with 4 extra lines and some GaS lines missing. There was no indication of the existence of a compound Ga_4S_5. The effects found at 832° ± 4°C indicate the possibility of a phase transition in the solid state. On the sulfur-rich side of the diagram, thermal analysis, as mentioned above, could not be done on samples with a sulfur content from 65% to about 99.5%. Efforts to synthesize small samples containing more than 65 a/o S at temperatures around 1200°C, in large sealed quartz vessels[4] always resulted in a mixture of Ga_2S_3 and free sulfur, which would have too high a pressure (16) for the silica tubes used in thermal analysis.

The P-T projection.—In Table II the values of the sulfur vapor pressure above various Ga-S samples, as determined by the method described above, are listed. The S_2-vapor pressure values of samples with a sulfur content of 50 a/o were determined at temperatures ranging from 798° to 978°C, and the value P_{S_2} at 962°C as shown in Fig. 2 was obtained from these values by graphic interpolation. The same procedure was followed for samples with a sulfur content of 60 a/o S to determine the pressure at 1090°C. For samples with a sulfur content between 50 and 60 a/o the vapor pressure was determined at the melting points. Every value given in Table II is an average of at least two determinations.

In the P_{S_2} *vs.* 1/*T* projection as shown in Fig. 2, the values of P_{S_2} at the melting points of the various samples are plotted. The line AB presents the vapor pressure of pure sulfur as a function of the temperature (16).

Marked sublimation of GaS at temperatures around 920°C was observed when we tried to grow single crystals. In these experiments GaS powder was sealed in a silica tube under vacuum of 10^{-3} mm Hg and placed in a temperature gradient. After 24 hr sublimed crystals could be seen at the cold end of the tube (850°C). These platelike crystals had the greenish-yellow color of GaS. In the foregoing discussion it was shown that the P_{S_2} at temperatures around 920°C is very low. This fact together with the observed sublimation indicates that the equilibria in the dissociation reactions

[4] These vessels were so large that the total amount of free sulfur could not create a pressure of more than 20 atm.

Table II. Sulfur vapor pressures in the system gallium-sulfur

Sulfur-content of substance, a/o	Heated with hydrogen, temperature, °C	S_2-vapor pressure, mm Hg
50	798	1.0×10^{-6}

The S_2-vapor pressure values of samples with a sulfur content of 50 a/o were determined at temperatures ranging from 798° to 978°C. The value of P_{S_2} at 962°C as shown in Fig. 3 was obtained by graphic interpolation of these values. This was also done for the samples with 60 a/o S. The samples with 55, 57, and 58.5 a/o S were only heated at their melting points and the P_{S_2} corresponding to these temperatures are given in this table and in Fig. 3.

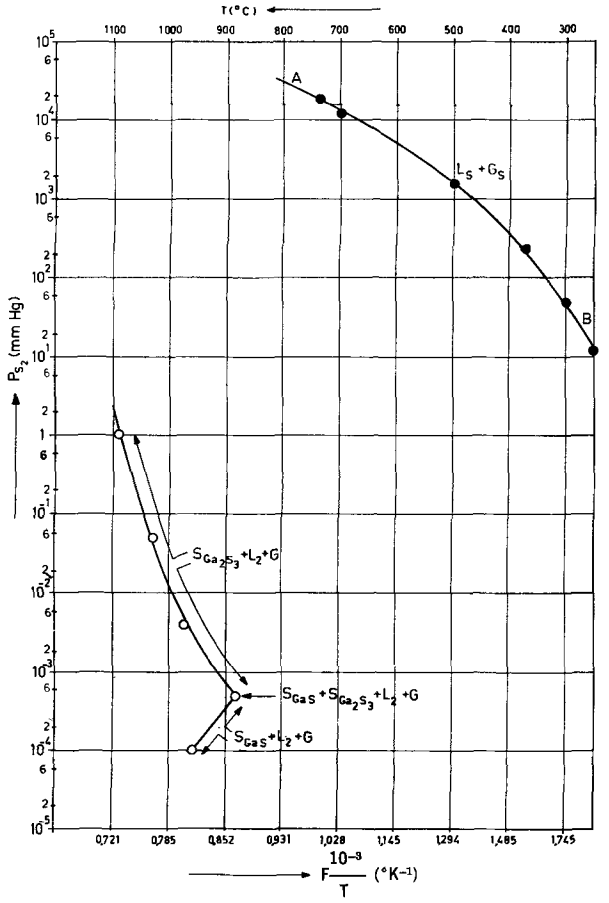

Fig. 2. P_{S_2} *vs.* 1/T diagram of the system Ga-S. The line AB presents the vapor pressure of pure sulfur as function of the temperature.

$$2GaS_{(g)} \leftrightarrows 2Ga_{(l)} + S_2 \qquad [3]$$

and

$$2GaS_{(g)} \leftrightarrows Ga_2S + \tfrac{1}{2}S_2 \qquad [4]$$

lies strongly to the left and sublimation is carried by GaS molecules.

The P-X projection.—From the data of the T-X projection and the P_{S_2} *vs.* 1/*T* projection given in Fig. 1 and 2, the P-X projection of the three-phase lines $S_{GaS} + L + G$ and $S_{Ga_2S_3} + L + G$ can be deduced (see Fig. 3).

This figure shows the steep increase of the sulfur vapor pressure of substances with a sulfur content between 0 and about 10 a/o and between 50 and 60 a/o. Only a very small increase of the sulfur pressure is required to increase the S-content of the substance from 10 to 50 a/o; this results in a horizontal line connecting the regions between 10 and 50 a/o S. With the estimation of a second range of liquid immiscibility for substances with a sulfur content > 65 a/o in the T-X projection, one must assume a continued rise in the sulfur pressure beyond Ga_2S_3 with an increasing sulfur content until a second liquid phase appears. This is the liquid immiscibility region. From here on the P_{S_2} remains constant with increasing sulfur content until the Ga_2S_3 rich liquid (L_2 see Fig. 1) has disappeared. Adding more sulfur will lower the melting point and also the vapor pressure until at 100 a/o S the melting point will be 119°C and the pressure around $3 \cdot 10^{-2}$ mm Hg (16).

Crystal structures.—The crystal structure of GaS has been determined by Hahn and Frank (17). It has a hexagonal layer structure, each layer consists of 4-sublayers in the sequence S-Ga-Ga-S in which every Ga-atom is surrounded tetrahedrally by one gallium and three sulfur atoms. There are three structures for Ga_2S_3 as determined by Hahn and Frank

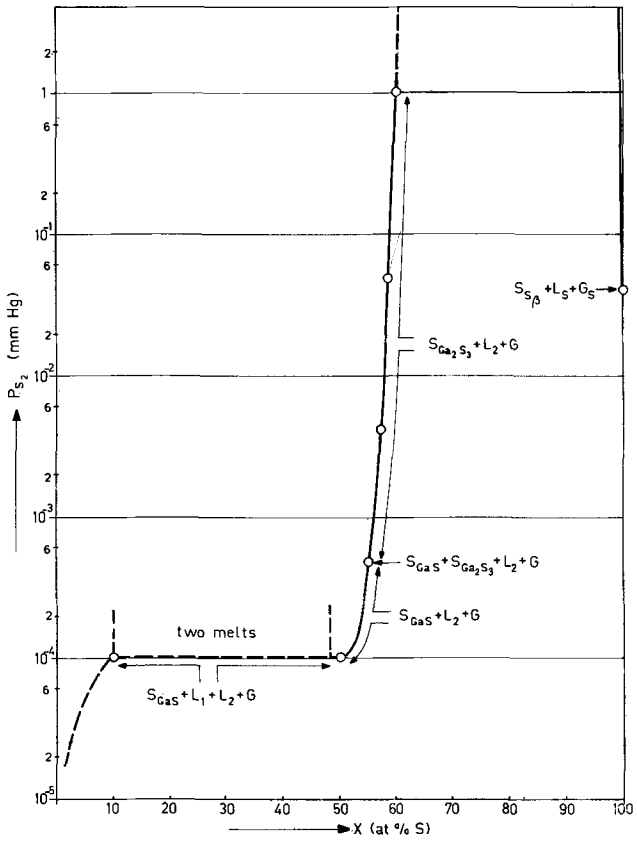

Fig. 3. P_{S_2} vs. X diagram of the system Ga-S. S_β is monoclinic sulfur.

(17), Hahn and Klingler (18), and Goodyear, Duffin, and Steigman (19). These are called α-Ga_2S_3, β-Ga_2S_3, γ-Ga_2S_3. According to Hahn and Klingler Ga_2S_3 can crystallize in one of two modifications, a low-temperature form (the γ-form) or a high-temperature form (the β-form). The inversion temperature is thought to be between 550° and 600°C, and these authors found that the low- and high-temperature phases have structures which are related to the zinc blende and wurtzite structures, respectively, each having a random distribution of vacancies in the sites normally occupied by Zn in the model structures, while α-Ga_2S_3, the ordered low-temperature phase, has a monoclinic symmetry according to Goodyear *et al.* (19).

Acknowledgment

The authors thank Professor F. van der Maesen for his stimulating discussions and his continuous interest in this work.

Manuscript received Feb. 9, 1966; revised manuscript received May 4, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Growth Studies of Silicon Carbide Crystals

L. J. Kroko

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Silicon carbide crystals are commonly grown from the vapor at a temperature of about 2600°C in so called "sublimation" furnaces wherein crystals are grown on the inside walls of a cavity formed within a large porous block of silicon carbide. A model for growth in this system is postulated and growth rate as a function of temperature is calculated. Growth in argon with pulses of nitrogen introduced at regular (7½ min) intervals is shown to produce sharp green lines that define the successive crystal sizes during the entire growth period (~8 hr). Temperature changes are made during growth and the growth rates are measured during successive temperature cycles. Considerable fluctuation in growth rate is revealed by this new measuring procedure. Theory and experiment are in qualitative agreement.

Although single crystals of silicon carbide obtained as an accidental by-product in commercial abrasive production have been known since the early nineteen twenties, it is only since about 1954 (1) that practical methods for producing crystals in the laboratory have been available.

The basic structure used for this purpose is a sintered block of silicon carbide, *ca.* 40% density, with

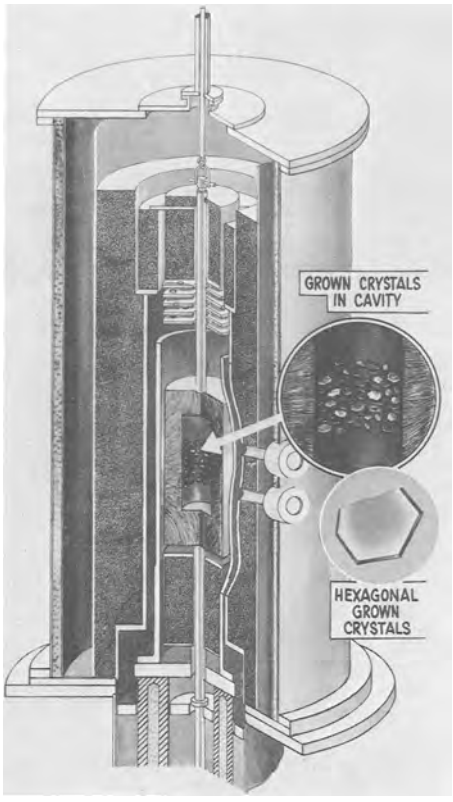

Fig. 1. Schematic drawing of 2600°C silicon carbide crystal growth furnace showing water-cooled envelope, powdered graphite insulation, and crucible with crystals attached to cavity wall.

an internal void or cavity. Crystals grow from the walls of such cavities when certain thermal conditions to be described later are met. In furnaces used for abrasive production, cavities form when the starting mixture of coal, sand, and sawdust shift during combustion; in laboratory furnaces the cavities are formed by deliberate stacking of chunks of pre-reacted silicon carbide or through the use of thin-walled graphite tubes (2). An electrically heated furnace of a type commonly used in the laboratory for this purpose is shown in Fig. 1. The outer container is made of stainless steel and is water cooled. The heating element is a graphite cylinder so slotted that current flows up one half of the cylinder and down the other. Insulation is provided by combinations of graphite powder and machined solid shapes. (No known metals or ceramics can be used in the hot zones because of the extreme temperatures and reactive vapors, particularly silicon vapor.)

The "charge" for the furnace is a circular graphite crucible, in this case 4 in. diameter by 8 in. long overall, filled with silicon carbide grain or with a near stoichiometric mixture of finely divided silicon and carbon. The loose bulk material is kept out of the central portion of the charge by a hollow right circular cylinder made from a graphite tube 2 in. diameter, 3 in. long, 0.004-0.008 in. thick, and 1/16 in. thick end-caps.

Inside the furnace the "charge" is suspended from above by a graphite rod threaded into the lid of the crucible. Usually the crucible is rotated to provide better thermal symmetry. In a typical run, the charge just described is heated to about 2600°C and held there for 5-20 hr, depending on the result desired. In an average run about 10-20% of the silicon carbide mass put inside the charge is lost; the remainder fuses to form a coarse grained porous mass whose structural features will be considered in detail later. Crystals nucleate and grow from the walls of the central cavity in the manner depicted in Fig. 1. Approximately 10% of the runs produce no crystals, 20% produce exceptionally fine large (up to ½ in.) ones, and 70% of the runs produce reasonable yields (>100) of crystals of the order of ¼-⅜ in.

As a basis for the study of this growth process, the following observations may be made:

(*A*) Crystals appear in a zone on the cavity wall. Near the zone center the hexagonal platelets have nearly plane parallel faces and intersect the substrate at right angles; at the zone extremities crystals often have one flat side and one "staircase" side, are usually relatively thick and comparatively small.

(*B*) Cross sections of the furnace charge disclose "lines" of crystallization in the bulk material which closely resemble a trace of what one might expect as heat flow paths in an orthogonal system of flow and isothermal lines.

(*C*) Most crystals, especially the largest, are oriented so that normals to their flat faces are nearly parallel to the long axis of the growth cavity (Fig. 1).

(*D*) Crystals tend to have a thickness-to-width ratio of the order of ⅛, but ratios as large as ½ and as small as 1/100 are not uncommon. Crystals often grow at vastly different rates in the "a" directions on the basal plane as evidenced by the unequal lengths of the hexagonal sides. The perfection of crystals depends strongly on the substrate character and the number of interfering crystals. The best crystals are those which grow with few neighbors. Even these, however, show surface spirals and other physical evidence of dislocations (3).

(*E*) P-type crystals (aluminum doped) are blue in color, n-type (nitrogen doped) green, and pure or compensated crystals are colorless. The greater the impurity concentration, the greater the color density. Degenerate crystals are nearly opaque.

By the study of these features and others, such as growth rates as functions of temperature, considerable progress can be made in understanding silicon carbide growth processes.

Discussion of Growth Features

"Crystallization" lines.—Perhaps the most important clue to the working of this system is the set of curved crystallization lines which form in the bulk material surrounding the cavity. By experience it has been found that the best crystals are grown when conditions are adjusted so that horizontal or vertical planes through the cavity center are mirror planes for the crystallization lines. Some typical forms observed and the resulting crystals are shown in Fig. 2. In Fig. 2a the horizontal crystallization lines intersect the substrate at 90° in the central region of the cavity and deviate from 90° above and below. Only when this pattern is observed are good crystals obtained.

In Fig. 2b the entire line structure is shifted downward and the horizontal crystallization lines intersect

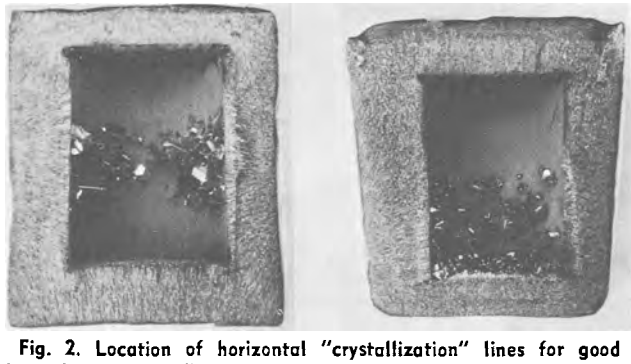

Fig. 2. Location of horizontal "crystallization" lines for good thermal symmetry "a" (left) and poor thermal symmetry "b" (right).

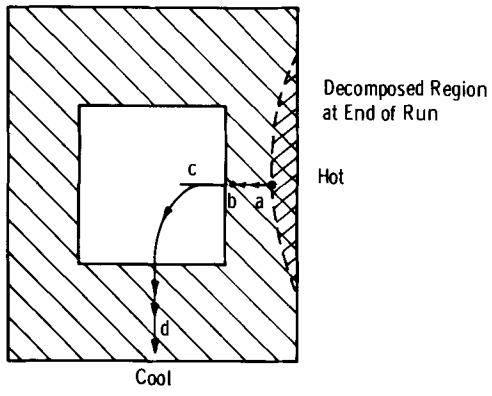

Fig. 3. Transport paths which give rise to "crystallization lines" in a silicon carbide charge.

the end cap. In this case crystals grow from the wall as well as from the end cap and the perfection is very poor.

In searching for an explanation of this structure one is quickly led to a "flow" theory because of the strong resemblance these lines bear to graphical solutions of Laplace's equation. One can easily imagine heat flow in from the right and left and out through the top and bottom in Fig. 2a. This pattern is entirely consistent with the heater geometry, and measurements confirm that the sides of the container (Fig. 2a) are hotter than the top and bottom. With these boundary conditions the origin of the lines follows immediately.

As the furnace is heated, point "a" (see Fig. 3) reaches a temperature T_a where material begins to decompose appreciably (SiC has no liquid phase at reasonable pressures), and the vapors diffuse in all directions. There is some vapor which travels toward "b" where it condenses as a result of the lower temperature T_b there. This results in a concentration gradient which enhances diffusion of the silicon carbide species toward the cavity. At growth temperature material is steadily transported from a to b to c to d along the typical path shown. This steady decomposition and condensation along the temperature gradient results in grain-like patterns which accurately define the flow path (and the associated orthogonal isothermal lines). For very long or very high temperature runs, a realm of decomposition progresses from a along the path shown and after some time there will be silicon carbide only at d; the rest having been decomposed to graphite-like pseudomorphs.

Temperature environment of growing crystals.—In view of the heat flow path and temperature gradient just established, it is apparent that the root of a growing crystal must be at least as hot as the growing faces. Therefore the heat of solidification of the incoming molecules must be discharged somehow into the cavity proper; it cannot be conducted to the substrate. This of course, could be accomplished through conduction by the ambient gas or by radiation. In a later section it will be apparent that conduction is negligible compared with radiation because of the high absolute temperature and the small temperature difference.

Crystal size variations.—The first widely accepted theory for the enormous range of sizes, >100:1, observed in a typical furnace run was based on the notion that the nucleation of crystals was a continuous process. Those crystals which grew to large size were assumed to have nucleated early in the run while those which were small were assumed to have nucleated late. In 1956 this notion was invalidated by unpublished work of the author who showed, by pulse nitrogen doping experiments similar to ones described in the section on Observation of Growth Rates, that all crystals which grew to significant size were nucleated during a short period of about 10 min duration at the beginning of a run. This discovery was quite surprising and gave impetus to studies of temperature and vapor supply as possible causes of growth rate variations.

Temperature differences at least on the scale of physical observations with an optical pyrometer could normally be held to a few degrees and were constant for any given run. Furthermore the location of large and small crystals was completely random. Small crystals sometimes grew alone and sometimes adjacent to very large crystals. It seemed that these conditions required variations in the controlling parameter which were large compared to crystal spacing and therefore the small area properties of vapor supply and temperature variations were considered.

If vapor supply were the controlling factor then one should expect to find no preferred crystal orientation, however such ordering is one of the dominant growth features. The source orientation effects appear also when graphite cloth is substituted for the thin graphite cylinder. The structure of graphite cloth is such that the point-to-point variations in vapor supply are highly improbable. These arguments make it unlikely that vapor supply can be made to account for crystal to crystal size variations.

There is still the matter of growth rate differences along the various "a" directions in any one crystal. With negligible exception crystals have faces flat to within small integral multiples of the basic polytype unit cell. (For the commonest forms, 4H, 6H, 15R, this amounts to several hundreds of angstroms at most.) This flatness can occur only if the surface mobility of the absorbed species is very high. This suggests that the actual source of the vapor must be unimportant and that directional rate variations must be due to something else.

For temperature variations between crystals to be responsible for the observed growth rate differences, one must find a heat transfer mechanism which can support temperature differences of a large enough value. Because conduction to the substrate is ruled out by the direction of the thermal gradient, and differences in conduction through the gas for adjacent crystals are unlikely to be adequate quantitatively, it appears necessary to consider the possibility that radiative effects are the cause of the growth rate differences.

Actually strong evidence for the dominance of radiation comes from many observations and experiments. The most obvious of these is the unfailing habit of grown crystals to be oriented with their largest faces subtending what is known to be the coldest area of the cavity (top and bottom). This is clearly evident in Fig. 2a. When there are massive clusters of intergrown crystals, crystal orientation is less obvious but this is easily accounted for by multiple reflection radiation paths.

A direct measure of the importance of orientation has been obtained by planting fully grown crystals in the thin graphite wall prior to a growth run. In all cases it is found, when the experiment is not complicated by wild profuse cluster growth, that growth is maximum on those samples oriented as in Fig. 1 and minimum (indeed, usually negative) when normal to this direction. For angles between the extremes a smooth progression in rate occurs.

In a variation of the latter experiment a series of crystals all parallel to one another and in a line between top and bottom of the cavity has been used. In this arrangement the crystals on the end subtend the cold sink while each successive crystal is blocked there from by one or more crystals. In these experiments the end crystals grow most on the side toward the end caps. Each succeeding crystal grows less and usually the crystal in the middle of the line decomposes. In these structures the only difference in environment for the separate crystals is their relative radiative shielding from the ultimate sink.

The shielding effect can in fact be carried to the extreme in another experiment. If one considers lines from the vertical midpoint of the cavity wall to the center of the top and bottom of the cavity in Fig. 2a it is possible to visualize 3 or 4 shields evenly spaced between the center and each end such that each shield extends from the substrate to the line so that any point on the substrate sees at least one shield between it and the end cap. When this is done it is found that not only is crystal growth eliminated but nucleation as well. This shows that the supersaturation of vapor required for nucleation as well as for growth is controlled completely by heat radiation to the cold portions of the cavity.

Nuclei formation.—The radiation hypothesis explains the fact that useful nuclei form only during some short interval at the beginning of a furnace run. As the furnace is heated up the thermal capacity of the charge gives rise to larger gradients than those which exist in the steady state. Therefore on the cavity walls supersaturation is highest early in the run, and nuclei of all orientations may form. Once formed they radiate heat and grow. After a short time the gradient becomes less, the supersaturation is reduced, and the probability of forming new nuclei becomes small. The nucleation process is also retarded by the fact that after the initial nuclei grow beyond a certain size they screen the wall from the sink and reduce the supersaturation still further.

Before summarizing the pertinent deductions it is worthwhile to consider temperature profiles within the cavity. A quick glance would tempt one to extend the crystallization lines of the bulk into the cavity and thereby deduce that crystals grow along the gradient so defined. This construction is, however, fallacious since the emissivity of a crystal and of a gas are different and hence the temperature at any point depends heavily on whether or not there is a crystal there. In short, the crystal determines the temperature at its faces by virtue of its radiative surroundings. Its physical location, relative to the extended crystallization lines, is not of fundamental importance.

One other point is worthy of comment here. It is not uncommon for authors to speak of silicon carbide crystals as growing in isothermal cavities. Such a condition is truly impossible since condensation of material on a crystal face requires the rejection of a positive quantity of heat. Indeed the basis of this work is that it is the existence of small but positive temperature gradients which completely governs growth rate.

Summary of observations.—As a result of the preceding discussion, the following qualitative picture of growth can be put forth. Thermal gradients imposed on the growth structure from outside, cause silicon carbide transport through the bulk charge by an evaporation condensation cycle which produces characteristic lines of crystallization. When these vapors enter the cavity, they condense on nuclei in amounts determined by the relative ability of the individual nuclei to radiate away the energy of condensation. Although nuclei of all orientations are originally available only those favorably oriented for heat radiation grow, the others disappear so that in the final system certain orientations are prominent. A fundamental part of the model proposed is that the rate limiting step is heat transfer by radiation. Vapor supply and the nucleation of growth ledges, etc., are found to be of second order importance. The model is developed quantitatively in the section that follows.

Growth Model and Growth Rate Calculations

Figure 4 represents a crystal located in a cavity within a mass of loosely packed silicon carbide. The temperature configuration is such that $T_1 > T_2 > T_3$. T_2 is controlled by radiation to the sink T_3 and hence bears some definite relation to T_1 and T_3. The crystal

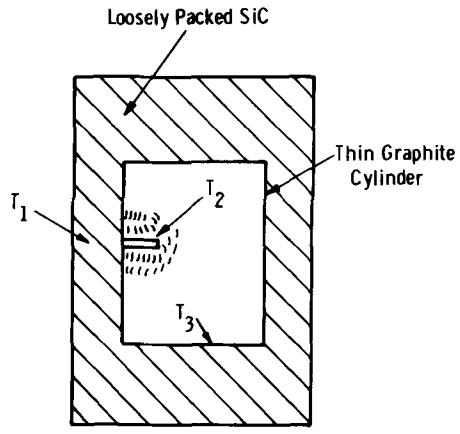

Fig. 4. Model for growth of silicon carbide crystals by the sublimation method.

is assumed to be surrounded by vapor at a temperature T_1. It is further assumed that the processes of condensation and evaporation at the crystal faces do not couple, *i.e.*, are independent of one another.

From kinetic theory the mass of molecules arriving at the crystal surface from the T_1 source is

$$G_i = C_0 T_1^{-1/2} \exp\left[\frac{-\Delta E}{RT_1}\right] \quad [1]$$

where G_i is in g/cm²/sec, T in °K, R is the gas constant, kcal/mole/°K, and ΔE is activation energy for dissociation, kcal/mole. A similar expression for molecules arriving from T_3 should also be written, but it will be seen later that this complication adds little to the results obtainable from the analysis. Similarly an expression for the mass of molecules leaving the crystal surface is

$$G_v = C_0 T_2^{-1/2} \exp\left[\frac{-\Delta E}{RT_2}\right] \quad [2]$$

The net rate is

$$G_i - G_v = C_0 T_1^{-1/2} \exp\left[\frac{-\Delta E}{RT_1}\right] - C_0 T_2^{-1/2} \exp\left[\frac{-\Delta E}{RT_2}\right] \quad [3]$$

It is quite likely that C_0 and ΔE of Eq. [1] are not equal respectively to C_0 and ΔE of Eq. [2] and it would be useful to have separate values appropriate to the two processes. Unfortunately such a determination is very difficult to execute and for the purposes of this study the aforementioned assumptions were made. As will be seen later the temperatures T_1 and T_2 differ by the order of 1°C and $T_1^{1/2}$ and $T_2^{1/2}$ therefore differ by less than 1%. Hence Eq. [3] may be simplified to yield for the net growth rate

$$G = C_1\left[\left(\exp\frac{-\Delta E}{RT_1}\right) - \left(\exp\frac{-\Delta E}{RT_2}\right)\right] \quad [4]$$

C_1 and ΔE in this expression can be determined by direct measurement of the rate of decomposition of crystals. This is presented in the Appendix where the values obtained for 1 atm argon pressure are $C_1 = 3.08 \times 10^7$ g/cm²/sec and $\Delta E = 148$ kcal/mole. However before calculations of growth rate can be made representative values for T_1 and T_2 or more specifically for T_1-T_2 must be known.

Direct experiments to determine T_1 and T_2 by optical pyrometry have shown that any opening big enough to permit visual sighting causes heat leaks sufficient to change the entire heat pattern as evidenced by the altered crystallization pattern of the bulk charge. Even under such extreme conditions temperature differences are less than the resolving capability of optical pyrometers (*ca.* 5°C).

For purposes of defining the range of computation an approximate value for T_1-T_2 may be obtained by making use of the heat of condensation of silicon carbide as follows. Assume that the crystal in Fig. 4 must dissipate heat by radiation at a rate sufficient to dispose of the heat of condensation of incoming molecules only. (For typical size crystals and temperature differences deduced, heat conducted via the ambient gas is small compared with heat lost by radiation.)

The heat per unit area transferred between the crystal at T_2 and the sink at T_3 is

$$P = \epsilon\sigma\,[T_2^4 - T_3^4]\ \frac{\text{watts}}{\text{cm}^2} \qquad [5]$$

where ϵ = effective emissivity of the growing crystal and its sink, and σ = Stephan Boltzmann constant (5.67×10^{-2} w/cm^2/°K^4). Now experiment shows that a typical crystal in a growth run of 6 hr at ~2500°C may have an area of 0.1 cm^2 (*ca.* 0.3 x 0.3 cm), a thickness of 0.025 cm, and a weight of 0.0077g. From the value for ΔE of the Appendix (148 kcal/mole) a crystal of this weight requires 28.5 cal to be dissipated in the 6 hr. Hence from Eq. [5], it is readily shown that for $\epsilon = 1$ T_2-T_3 needs to be only of the order of 0.1°C while for $\epsilon = 0.1$ T_2-T_3 needs to be about 1°C.

It may be further shown that T_1-T_2 is within 10% of T_2-T_3 by assuming an equilibrium situation where the power transfer is constant.

On the basis of these arguments it is reasonable to evaluate Eq. [4] for temperature differences in the range of 1°C for purposes of comparison with experiment. It is possible to argue that it is unrealistic to assume T_1-T_2 is not a function of temperature; however simple computations show that it is not a steep function of temperature and in addition the over-all assumptions are too severe to make this refinement meaningful.

Theoretical curves of growth rate from Eq. [4] are given in Fig. 5 for argon at atmospheric pressure. Roughly a 100°C change in temperature produces a 2.5:1 change in growth rate for a constant ΔT. The effect of ΔT is also seen to be considerable, for example a change of ΔT from 1° to 2°C approximately doubles the growth rate. In view of the absolute growth temperature ~2600°C it may be concluded that the control of growth rate presents serious problems. Furthermore, measurements of growth rate are likewise difficult and a method for doing this is developed in the remainder of this paper. The results of such measurements are rationalized with the discussion of growth already presented.

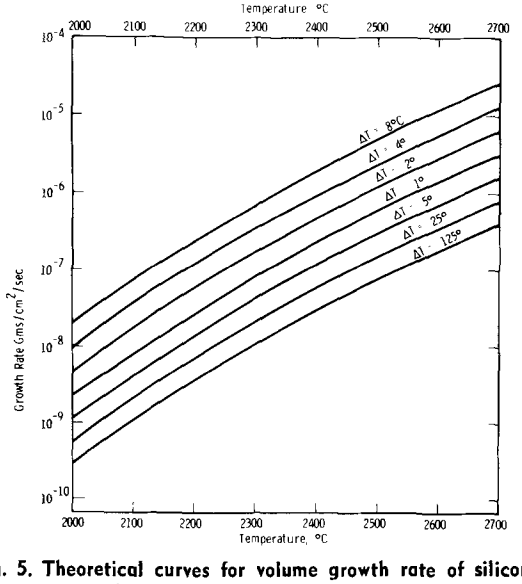

Fig. 5. Theoretical curves for volume growth rate of silicon carbide crystals in "sublimation" furnace.

Observation of Growth Rates

Prior attempts to relate growth rate and temperature compared rates measured in separate experiments in each of which large numbers of crystals of all sizes were produced. From statistical treatment of such data Hamilton (4) concluded that rate increased with temperature but the actual rate was not obtainable from the data.

In this work the growth rate at a minimum of two temperatures was measured in each of the many crystals of a single run. To accomplish this the temperature was alternated between two different values for several cycles during the growth run. Each crystal thus contained several regions grown at each temperature. The different regions were outlined by admitting small quantities of nitrogen each time the temperature was changed. The dark green color thus imparted by nitrogen was limited to small areas by a constant flow of argon which served to purge the furnace and return the atmosphere to one which produced very light green material before temperature was changed again.

Some crystals grown in variations of this experiment are shown in Fig. 6, 7, and 8. These figures show only selected samples from a wide range of the sizes and shapes obtained in each actual run (*ca.* 1000 crystals total). There were many crystals too small to be seen with the unaided eye as well as one or two much larger than those shown. All but the largest show a distribution of band patterns similar to those illustrated. The very largest have bands whose spacing show no effect of temperature. These will not be discussed here, since they represent a negligible fraction of the total and are very imperfect and probably grew fast for this reason.

Fig. 6. Crystals from growth rate experiment. The bands defined by nitrogen doping each represent 1 hr of growth (the temperature schedule is given in Table I).

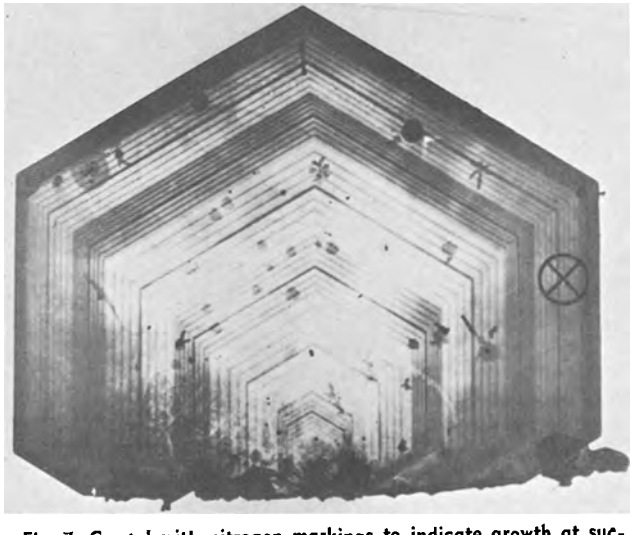

Fig. 7. Crystal with nitrogen markings to indicate growth at successive time intervals, see Table I for details of temperature changes, and the text for particulars of the nitrogen doping. The fine lines occur at 7½ min intervals.

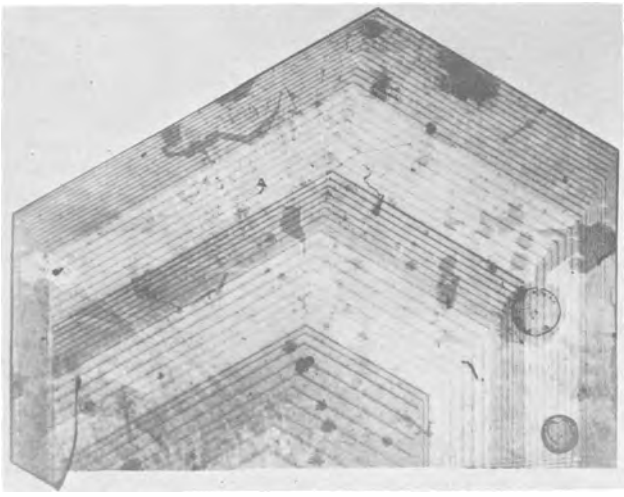

Fig. 8. Silicon carbide crystals with nitrogen markings showing growth rate fluctuations in various directions on the basal plane. Fine lines occur at 7½ min intervals.

Figure 6 was the first experiment of this sort and each band represents 1 hr of growth for the temperature schedule of Table I. Figures 7 and 8 are typical of refinements in the procedure in that each hour period is divided into 8 parts with a fine mark each 7½ min. In the crystal of Fig. 7 the half hour marks were intensified by tripling the nitrogen volume introduced. In Fig. 8 another variation of marking was used. For the outer band (~1½ hr, 12 marks) all marks were of the same density but for the other bands the quantity of nitrogen was varied in equal steps from the first to the eighth band. This was done to disclose any effect of nitrogen on growth rate. The temperatures for the three samples are given in Table I where the first entry is for the last band (*i.e.*, the edge of the crystal).

The crystal of Fig. 7 represents one of the better examples of good hexagonal symmetry to be found among crystals produced by this process. This sample is of uniform thickness, *0.006* in., perpendicular to the illustration, and measures 0.270 in. across from left to right. (Crystals approaching 1 in. across have been grown in other experiments.) Growth rates in all directions tend to be very nearly equal, except for those which intersect the ragged edge where the platelet was attached to the substrate. There is however some asymmetry in the region of small hexagons (early growth).

Comparison of this crystal with that of Fig. 8 shows some important effects. To begin with the extremes of the crystal of Fig. 8 show an asymmetry, but more than that it can be seen that while growth rate was reasonable during the last period along the left side it was near zero for the three preceding periods and normal before that. This has been found to be a rather common occurrence in crystals and can be attributed to a change in the thermal environment of an edge brought about by other crystals and/or changes in the heat input pattern from the heater.

Table I. Time temperature schedule for growth rate experiments

* Note: fourth band has triple quantity of nitrogen.
** Note: all but the outer band have graduated marks.

Another characteristic obvious in Fig. 7 and 8 is the apparent difference in background color density (related to the N_2 content) for the alternate high and low temperature regions. During the growth of the region between marks nitrogen put in to make the mark is depleted to some level which is the same for low and for high temperature regions. Nevertheless the color shows that the amount of nitrogen incorporated is greater in the low temperature regions. This supports the notion that the rate of incorporation of nitrogen increases with decreasing temperature as proposed by Hamilton (4).

Also of interest are the terraces or rings of Fig. 6. It can be seen on crystals B and C that there would appear to be growth ledges spreading out from the faster moving, shorter, edges. This pattern is consistent with the explanations given earlier where it is proposed that the ability of a surface to dissipate heat governs the volume grown. In this instance the limit of progress of a growth ledge defines the extent of the cooled region of the crystal.

Interpretation of Results

As pointed out earlier, crystals from microscopic size to those of Fig. 6, 7, and 8 were obtained in these experiments. All grew for the same length of time and hence there is a tremendous variation in growth rate. As a result one is immediately faced with the problem of deciding which, if any, crystals can be compared with the preceding theory. This question is easily resolved by recalling the assumptions of the theoretical model. Reference to Fig. 4 shows that the crystal considered enjoyed direct radiative access to the heat sink and by the arguments given so far is therefore set to grow at the maximum possible rate. Therefore crystals to be measured should be the largest found in any specific case. The crystals of Fig. 6, 7, and 8 are such samples.

Having chosen the largest crystals there is still a problem associated with crystals like that of Fig. 8 where the growth rate was obviously interrupted along the left side. Here one wonders whether the material not deposited along that direction is to be found elsewhere on the crystal or whether it is lost to the crystal. This cannot be determined directly and therefore growth rate will be presented in two approximate forms, linear rates and volume rates.

In some crystals, such as B in Fig. 6, the growth rates perpendicular to the sample bear the same ratio to the corresponding widths as the final thickness bears to the final width. In others, the crystal of Fig. 7, for example, special account must be made for fluctuations in rate. A schematic of the latter crystal section is shown in Fig. 9. The extra growth in the cross-hatched section occurred in the second band from the outer edge marked X in Fig. 7. It is seen that the linear rate is not unusual although the crystal approximately doubled its thickness in this period. This type of short-term accelerated growth seems to be very common, and there is some evidence for thinking that unbalanced growth rates exist somewhere in every crystal. It is believed that such growth results from temporary increases in thermal gradient for the subject crystal since others in the same run have accelerated growth in different periods. When large seed crystals, properly oriented, are planted in a growth structure they have unobstructed access to

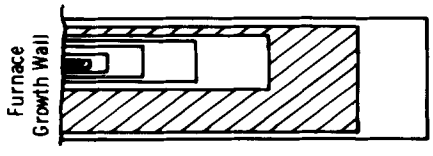

Fig. 9. Schematic cross section of a crystal with thickness growth rate variations. The illustration is representative although not to scale of fluctuations seen in the crystal of Fig. 7.

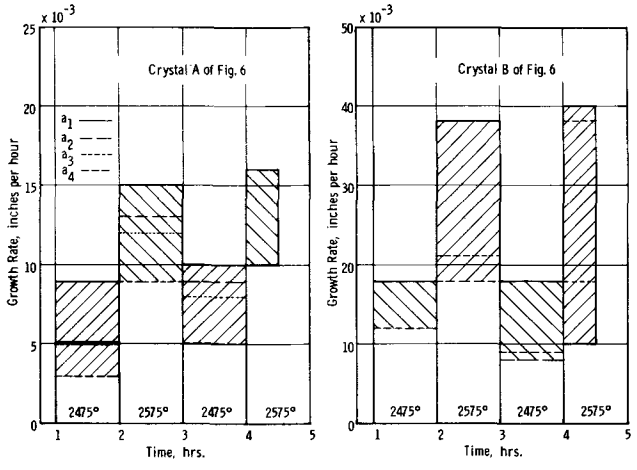

Fig. 10. Silicon carbide linear growth rates vs. temperature (measured).

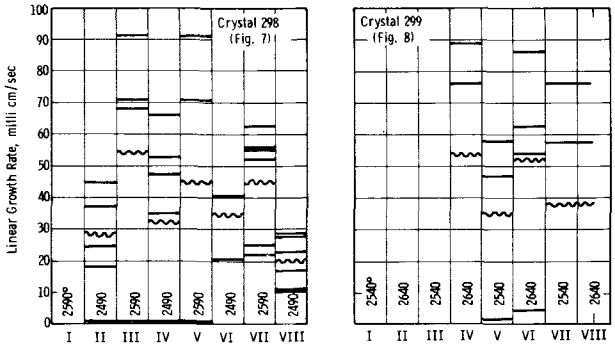

Fig. 11. Linear growth rates for various axes in the crystals of Fig. 7 and 8. Average values are represented by wavy lines.

the col sinks at least for a while and in every case extreme thickness to width ratios are observed. This is taken as evidence that growth in the C direction, as in Fig. 9 cross-hatched, arises from temporary abnormal gradients.

In an aggregation of crystals (Fig. 1, for example) it is unlikely that any one crystal, unless planted as a large seed, ever sees the full gradient of the cavity and therefore it may be impossible to associate a predicted growth rate with any given crystal. In Fig. 10 and 11 linear growth rates for the various "a" directions are presented for the crystals of Fig. 6(A + B), 7, and 8. The growth rates depend on the axes considered. Average values (of all axes measured) are given as wavy lines in Fig. 11. A systematic variation of growth rate with temperature can be seen in this figure. Volume rates are given in Fig. 12 for crystal 298 (shown in Fig. 7). During the seventh growth period abnormal thickening occurred (as discussed with reference to Fig. 9) and this increase is shown separately in the diagram.

Figure 12 shows, during the initial cycles at least, a fall off of growth rate with time. The volume growth rates (not shown here) for the crystal of Fig. 8 show a similar decrease. Although the reason is not known with certainty a consistent explanation for the decrease in rate at the same apparent temperature can be obtained from the radiation hypothesis. For region I in Fig. 12, the crystal was small, the shielding effect of neighbors is correspondingly small, and the sample grew as though it were exposed to nearly the full cavity gradient. As it and its associates grew, shielding became important and the rate at both temperatures decreased until reaching an apparent steady state in periods V, VI, VII, and VIII. During period VII the thickening increment makes the total growth almost equal to that of period I, suggesting that somehow the full gradient was again operative. Figure 13

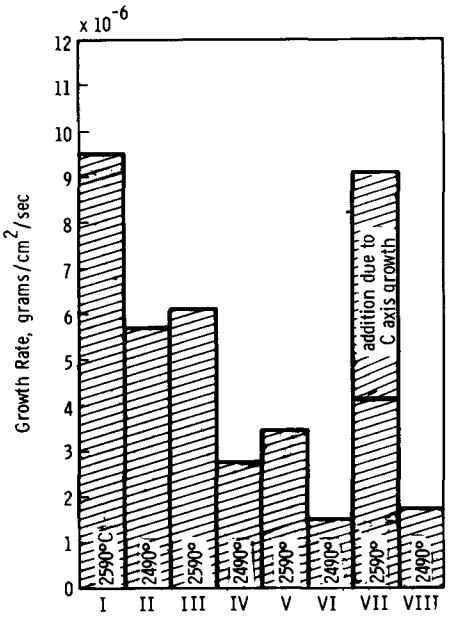

Fig. 12. Measured volume growth for crystal 298 (Fig. 7) each period 1 hr.

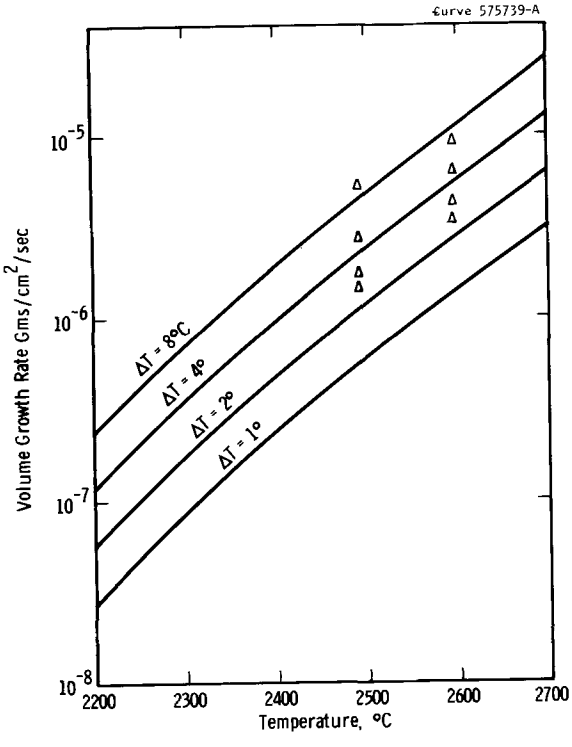

Fig 13. Theoretical volume growth rate (curves) and actual growth rate (triangles) for SiC crystals vs. temperature for crystal to sink ΔT of 1.0°, 2.0°, 4.0°, and 8°C.

presents theoretical lines of growth rate *vs.* temperature from Eq. [4] for temperature differentials of 1°-8°C and measured volume rates of growth for the crystals of Fig. 7.

It is concluded that the theoretical model predicts both the absolute growth rate and its variation with temperature to an accuracy consistent with the resolving power of growth experiments. Furthermore all growth habits are readily explained by the model and none are in conflict with it. Further progress in this work requires better control of experimental conditions and higher accuracy for measurement of local temperature.

APPENDIX

Decomposition Rate for Silicon Carbide

The activation energy for decomposition of silicon carbide was measured by weight loss in argon under conditions simulating the sublimation furnace in which crystals are grown. In the actual arrangement crystals of known area, weight, etc., were mounted in a graphite block (previously outgassed) and surrounded with a graphite enclosure. At least two crystals were used in each measurement; one was a high purity clear crystal and the other was doped to the levels encountered in grown PN junctions ($\sim 10^{19}$ cm^{-3}). Furnace runs varied from ½ to 3 hr and weight losses were measureable to about 3%. After a run, crystals typically had a graphite-like surface which was removed by burning before weighing. The weight of this layer was very low, about 5% of the total weight loss. The existence of this layer did not seem to inhibit decomposition to any observable degree.

The losses exhibited by all crystals, pure and impure alike, were the same within experimental error. The spread in data points is attributed mainly to variations in the decomposition rate of the part of the crystal embedded in the graphite block. The little tab provided for this purpose decomposed at different rates in the different runs presumably depending on the tightness of the fit.

The data was plotted and a mean square line fitted thereto. Calculation of the intercept and slopes of the line yielded $3.08 \times 10^7/cm^2/sec$ and $\Delta E = 148$ kcal/mole.

Impurity Distribution in Single Crystals

II. Impurity Striations in InSb as Revealed by Interference Contrast Microscopy

August F. Witt and Harry C. Gatos

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The nature of impurity striations in InSb grown in the <111> direction was investigated by interference contrast microscopy. Six different types of impurity striations were revealed in the {211} planes parallel to the growth axis. The impurity concentration in the melt, size of the crystal, rate of rotation, pulling rate, temperature gradients, and growth direction were found to affect the density, intensity, and other characteristics of the striations.

The existing uncertainty on the nature and origin of impurity striations in crystals (1-3) can be attributed largely to the fact that their detailed structure cannot be sharply revealed by conventional optical techniques because of lack of contrast. Similarly radiotracer techniques and standard resistivity microprofiles suffer from insufficient resolution. Interference contrast microscopy combined with properly prepared surfaces provided high resolution as well as high contrast and led to the identification of six different types of striations.

Experimental Procedure

Single crystals of InSb containing tellurium as impurity (2-50 mg Te per 50g InSb melt) were grown in a Czochralski-type apparatus. Purified hydrogen was passed over the melt at an approximate rate of 10 cc/min. The melt temperature was controlled to within 0.1°C.

The single crystals grown in the <111> B[1] direction were cut along the growth axis to expose a (211) plane which was subsequently polished with a Linde B abrasive (particle size 0.05μ). For best results in our optical investigation the final polishing was done in a direction perpendicular to that of the striations of interest. In this way any scratch marks could be clearly differentiated from striations. After polishing the specimens were rinsed with distilled water and the still wet samples etched with modified CP4 ($5HNO_3$, $3CH_3COOH$, 3HF, $11H_2O$). The etchant was applied with a piece of cotton so that the formation of gas bubbles on the reacting surfaces could be prevented by rubbing them gently with the cotton. After etching the specimens were again rinsed with distilled water and subsequently dried with hot filtered air after treating them with a mild detergent to prevent stain formation. By properly positioning the specimens under the interference contrast attachment the visibility of scratch marks could be minimized while the striations could be observed with optimum contrast.

Etching characteristics of {211} planes.—By cutting the crystals along the <111> growth direction and parallel to one of the three commonly present peripheral flat regions the (211) and $(\bar{2}\bar{1}\bar{1})$ planes are exposed. If the facet at the crystal-melt interface is indexed as the $(\bar{1}\bar{1}\bar{1})$ plane, then the surface exhibiting optimum etching characteristics is found on the section containing the peripheral flat region parallel to the cut, i.e., $(\bar{2}\bar{1}\bar{1})$. The corresponding (211) plane exhibits etching characteristics which are not suitable for the investigation of impurity striations. The noncentrosymmetric nature of the <211> direction is clearly reflected in the behavior of the {211} planes shown in Fig. 1. Here rotational twinning of the crystal has exposed simultaneously the (211) and $(\bar{2}\bar{1}\bar{1})$ planes.

Results and Discussion

Single crystals grown in a <111> direction exhibit more or less extensive "coring" as well as impurity

[1] It is common practice to denote the {111} surfaces of III-V compounds terminating with group V atoms as {111}B surfaces or simply B surfaces and those terminating with group III atoms as {111}A or just A surfaces.

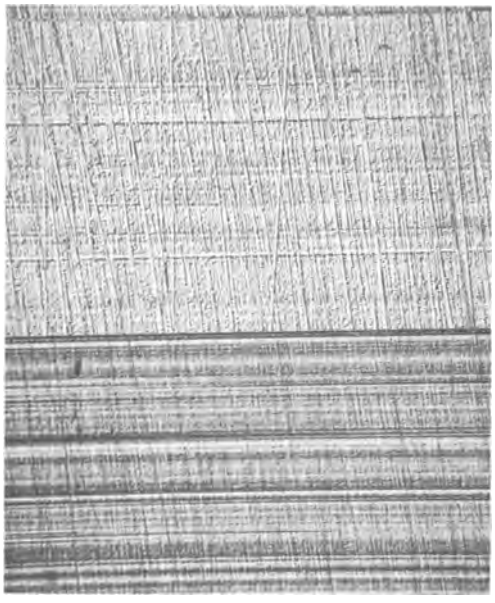

Fig. 1. Impurity striations on a rotational twin; the upper part is a (211) and the lower part a $(\bar{2}1\bar{1})$ plane. The latter one is employed throughout this study for revealing the various types of striations. Magnification 95X.

striations if impurities are present in the melt as shown in Fig. 2. The core results from the presence of the well-known (111) facet at the solid-melt interface and is revealed through its impurity concentration which is significantly different from that of the off core region. The extent of coring (laterally) can vary between zero and 100% depending on the prevailing thermal conditions in the crystal-melt system.

Hulme and Mullin's findings (4) that the extent of coring increases with increasing impurity concentration could not be confirmed in the present experiments. In intrinsic crystals the presence of a core could not be revealed by etching techniques. Its presence can only be presumed from the existence of the (111) facet at the crystal-melt interface. Depending on the specific experimental conditions prevailing during growth, several different types of striations were encountered. Since all of these striations may coexist

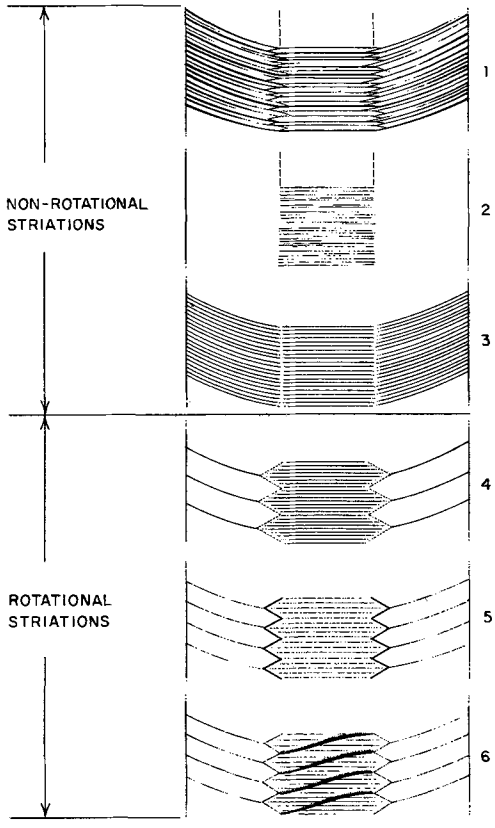

Fig. 3. Schematic diagram of impurity striations encountered in InSb single crystals.

very complex patterns were frequently observed which are extremely difficult to analyze.

For convenience and clarity the different striations will be discussed individually with the aid of the schematic diagram shown in Fig. 3.

Nonrotational striations.—Striations observed in crystals without rotation are generally attributed to growth rate variations caused either by temperature fluctuations occurring at the solid-melt interface during growth or by irregular variations of the pulling

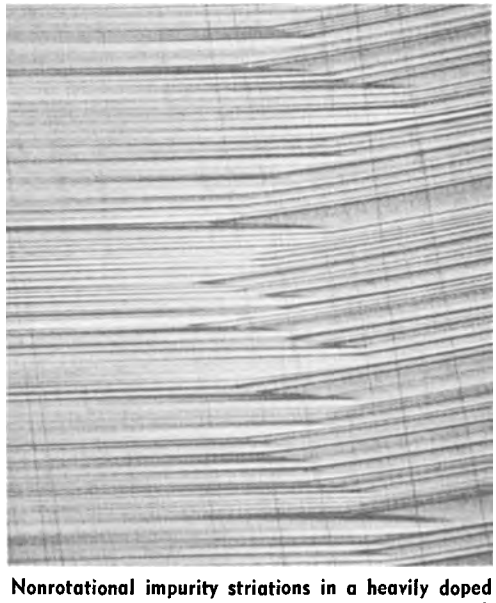

Fig. 4. Nonrotational impurity striations in a heavily doped crystal (60 mg Te in 50g melt). The striations are straight in the "on core" region on the left and exhibit curvature in the "off core" region on the right hand side of the photograph. The on core-off core interface is corrugated in appearance. Compare with striations No. 1 in Fig. 3. Magnification 95X.

rate originating in the mechanical arrangement (5). This type of striations is very common in crystals grown with Czochralski type techniques and can be observed in various forms under virtually any experimental conditions.

Striations of type 1 in Fig. 3 exhibit several distinctive features (see Fig. 4). Their shape always reflects the configuration of the crystal-melt interface at the time of their formation. The width, density (frequency), and intensity (sharpness) as revealed by etching were found to vary, generally increasing, with increasing impurity concentration. Their intensity frequently decreases toward the center of crystal. Accordingly, faint striations near the periphery of the crystal often become completely invisible toward the center of the crystal as shown in Fig. 5. This change in intensity of striations most likely reflects corresponding changes in impurity concentration in the melt.

These striations do not exhibit a long-range periodicity although short-range periodicity can frequently be observed. They are continuous through the core of the crystal at high impurity concentrations. This type of striations is invisible in dark field illumination because of their diffuse nature.

Striations of type 2 in Fig. 3 are much less common and differ significantly from the previously discussed nonrotational striations (see Fig. 6a). They appear only in the core region, and apparently their formation is associated with the (111) growth facet which is responsible for the crystal core. Being extremely sharp they can be individually investigated in dark field illumination in which standard nonrotational striations are invisible (see Fig. 6b). In this way it was observed that the striations are of limited and varying length, usually terminating somewhere within the core. Their intensity is not significantly sensitive to variations in impurity concentration. The fact that these striations can still be observed after successive polishings to a depth of several millimeters indicates that they are planar in nature and not line defects. The frequency of their appearance is a function of the growth direction and increases sharply with deviation from the <111> direction. On the basis of all aspects considered it is concluded that the mechanism of their formation is basically different from that of all other striations. They are tentatively considered as a planar defect structure associated with slip planes or stacking faults.

Striations of type 3 in Fig. 3 can only be observed under high magnification following highly controlled

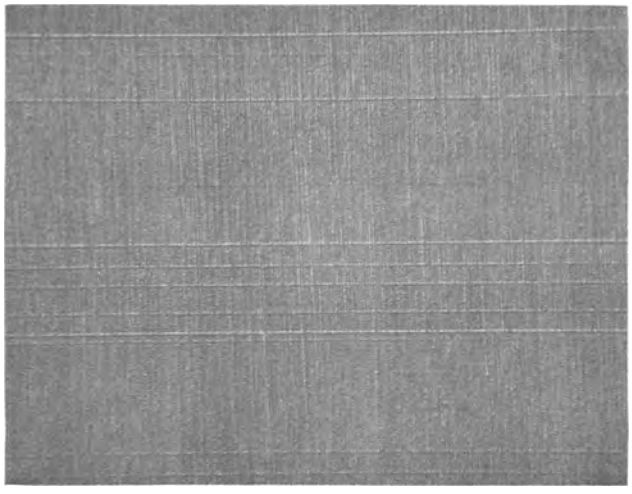

Fig. 6a. Sharp on core striations in bright field illumination. Compare with striations No. 2 in Fig. 3. Magnification 390X.

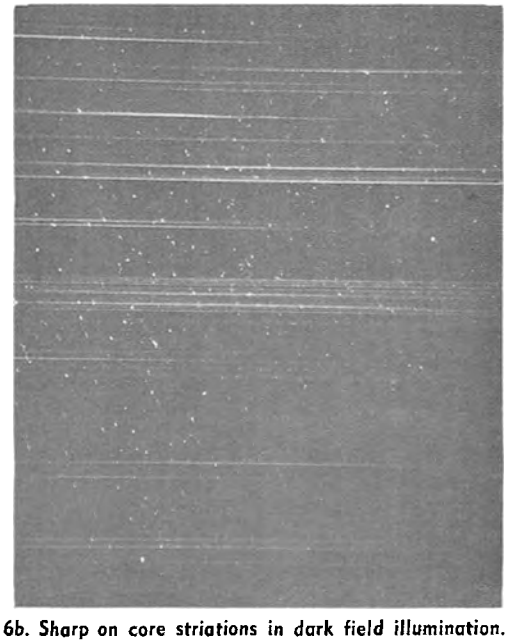

Fig. 6b. Sharp on core striations in dark field illumination. Magnification 275X.

polishing and etching (see Fig. 7). The spacing of these rather faint striations is around 1μ and their frequency of formation is between 1 and 20 per sec. They were observed on core and off core with a discontinuity at the core boundary. The fact that they were found throughout the crystal suggests that their formation is associated with the over-all solidification process rather than with some specific aspect of solidification kinetics; the solidification kinetics is presumed to be significantly different for the core and the off core region. The observed high frequency of formation on the other hand makes it rather difficult to associate their origin with temperature fluctuations due to convection as was the case with the striations of type 1 and 2.

These striations are most likely associated with pulling rate fluctuations or vibrations of the melt surface. Indeed precise measurements of the pulling rate by means of a velocity transducer (sensitivity 500 mv/in./sec) revealed pulling rate fluctuations having frequencies between 1 and 10 per sec. (see Fig. 8). These values are in the range of the observed striations. Furthermore, low-frequency vibrations were observed on the surface of the melt.

The close spacing of these striations delineates short time changes of the crystal-melt interface. Such

changes could be valuable in investigating crystal growth kinetics.

Rotational striations.—All crystals pulled under rotation exhibit the so-called "rotational" striations in addition to the previously discussed nonrotational striations (see Fig. 9). Since they are more pronounced than the nonrotational striations they can be observed at lower impurity concentrations where the previously discussed types of striations are absent (see Fig. 2).

Striations of type 4 in Fig. 3 are intense and in crystals of constant diameter exhibit short- as well as long-range periodicity (see Fig. 10). The long-range periodicity can be calculated from the pulling and rotation rates after correcting for the continuous change of the melt level. In crystals of varying diameter the short-range periodicity was not observed. An increasing crystal diameter resulting from a decrease in the melt temperature is associated with an increased growth rate which at constant pulling rate is accommodated by a shift of the solidification front into the melt. Conversely an increase in the melt temperature results in a decreasing rate of solidification (or even back melting) and thus in a rise of the crystal-melt interface.

Rotational striations in the off core region differ only by their increased intensity from nonrotational striations. Their penetration into the core region is complex and very difficult to analyze. Thus, each striation appears to split and to develop a substructure which changes continuously across the core region (see Fig. 11 and 12). The component striations of the substructure are straight and reflect the (111) facet growth. The complexity of the substructure increases with increasing deviation of crystal growth from the <111> direction (see Fig. 13).

Striations of type 5 in Fig. 3 delineate the off core-on core interface and reflect the sudden change of impurity concentration in this transition region (see Fig. 14). The corrugated nature of this interface and therefore of the core is believed to be caused by the fact that the rotation and thermal axis of the growing crystal do not coincide. Under such conditions the (111) facet is being continuously relocated with respect to the over-all crystal in order to conform with the solidification isotherm. The extent of relocation depends on the rate of rotation and the separation of the rotation and the thermal axis. Thus, the extent of penetration of the off core region into the core reflects the lack of thermal and rotational symmetry of the growth system. The irregularities observed within

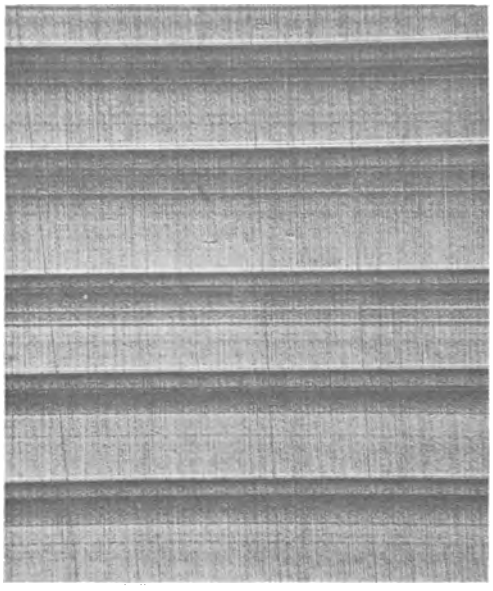

Fig. 11. Substructure of rotational striations in the on core region grown in the <111> direction. Magnification 95X.

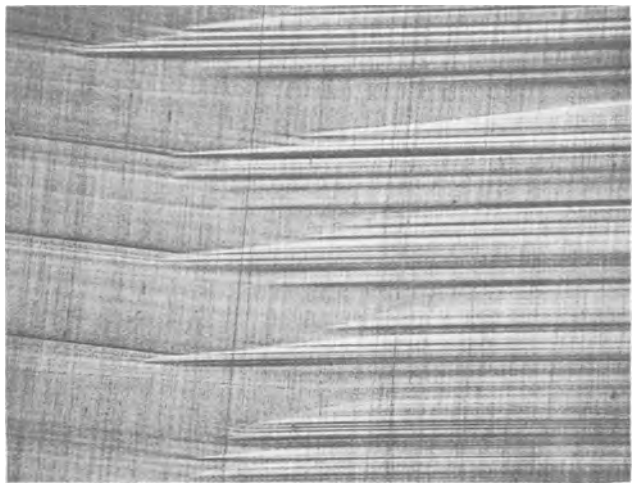

Fig. 13. Rotational striations in the off core-on core transition region of a crystal grown 9° off the <111> direction (impurity concentration 6 mg in 50g melt). Compare with Fig. 10. Magnification 95X.

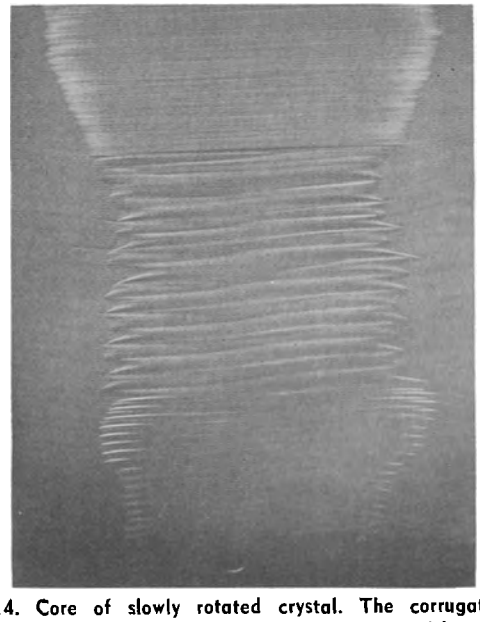

Fig. 14. Core of slowly rotated crystal. The corrugated off core-on core interface is clearly visible. Compare with striations No. 5 in Fig. 3. In addition we observe helical striations which are not parallel to the (111) facet. Compare with striations No. 6 in Fig. 3. Magnification 7X.

the corrugated structure are believed to result from the irregular (noncircular) shape of the (111) growth facet.

Striations of type 6 in Fig. 3 are directly associated with rotation and consequently have a helical structure as seen in Fig. 14. They are encountered in the on core region of crystals pulled under slow rotation. Their intensity decreases with increasing rotation rate, and they could not be observed in crystals rotated at rates greater than 5 rpm. These striations do not lie in the (111) growth facet. In most instances they were found to cross the on core striations at varying angles. Accordingly they are not considered to be regular (111) facet growth striations.

If we assume that a striation of a given intensity reflects a constant impurity concentration, then the formation of these striations can be explained on the basis of varying impurity concentration on the (111) growth facet as follows. The (111) facet moves laterally when the thermal and rotation axes do not coincide (see above) so that the region of a given concentration on the facet forms a helical pattern resulting from the combined lateral and vertical motion. Thus, these striations are essentially the locus of points of the same concentration in consecutive growth layers. A decrease in impurity concentration in the direction of the center of the core was indeed measured in nonrotated and slowly rotated crystals by resistivity measurements using a four point microprobe.

Although the various types of impurity striations have been discussed individually, they are often encountered simultaneously developing rather complex striated structures which cannot be fully analyzed.

Summary

Interference contrast microscopy in conjunction with special polishing and etching techniques was employed for the investigation of impurity striations under conditions of high optical contrast. Individual striations were studied with a spacing of less than 1μ. Six different types of impurity striations were identified. It was furthermore observed that under conditions of incomplete stirring, the crystal core generally exhibits a concentration gradient along the (111) growth facet which is reflected in the apperance of

helical striations. Impurity striations and the associated defect structure are believed to be powerful tools in studying crystal growth kinetics.

Preparation and Properties of Boron Arsenides and Boron Arsenide-Gallium Arsenide Mixed Crystals

S. M. Ku

General Telephone and Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Both cubic and rhombohedral forms of boron arsenides were made by the vapor-phase technique. Energy gaps of the cubic and rhombohedral forms were estimated to be 1.46 and 1.51 ev, respectively, by the optical transmission technique of powdered samples. Mixed crystals of boron arsenide-gallium arsenide were also prepared by vapor-transport reaction. Variation of energy gaps from 1.36 to 1.27 ev was observed within the mixed crystal composition range containing 0.8 to 2.8 w/o (weight per cent) of boron. Measurements of effects of temperature and injection level on the emission of diodes prepared from these mixed crystals indicate that all compositions up to 2.8 w/o of boron are direct semiconductors.

The advent of injection-luminescent diodes and lasers and of Gunn effect devices has prompted extensive studies of the composition ranges available in mixed crystals produced by solid solution of two III-V compounds and of the resulting variation in semiconducting properties. In spite of the potentially attractive properties of III-V boron compounds, such as relatively high energy gaps and high mobilities (1-3), these materials remain relatively unexplored because of the formidable difficulties involved in the synthesis of reasonably pure and large single crystals (4). It is the purpose of this paper to report on an investigation of a new III-V mixed crystal system, BAs-GaAs. This work was primarily concerned with preparation of boron arsenide-gallium arsenide mixed crystals and the determination of their electrical and optical properties. It also included preparation of boron arsenides by various techniques, and measurements of some of their optical properties.

Preparation and Properties of Boron Arsenides

Preparation methods.—The boron arsenides were prepared by a method similar to that described by Williams and Ruehrwein (5). A weighed amount of finely powdered amorphous boron of 99.99% purity was placed at one end of a quartz capsule, and an amount of 99.9999% pure arsenic in excess of that required to react with the boron was inserted at the other end of the capsule. The entire ampoule was evacuated to 10^{-5} Torr and then baked at 250°C for at least 4-6 hr to remove any residual gases that were adsorbed on the surface of the micron-size boron powder. After the baking cycle, the capsule was sealed off and inserted into a two-zone resistance furnace, where the boron was kept at a temperature in the range of 850°-1100°C and the arsenic was held at 640°C in order to maintain 1 atm arsenic pressure in the capsule. Since the equilibrium vapor pressure of solid arsenic has an exponential dependence on temperature, precise temperature control is required to obtain the stability required for vapor synthesis. The arsenic cold-sink temperature was usually controlled within ±1°C during the entire operation. At 1 atm arsenic pressure over 100 hr were usually required to complete the reaction.

Boron arsenide was also prepared by reacting finely powdered AlAs with BI_3. Hydrogen was bubbled at a rate of 0.5 liter/min through BI_3 held between 120°-150°C and was then carried over AlAs powder which was held at 750°C. Boron arsenide was deposited downstream in the cooler parts of the furnace tube. Boron arsenides prepared by the double displacement reaction of AlAs and BI_3 were found to be a mixture of boron monoarsenide, subarsenides, residual AlAs, aluminum silicate, and other compounds. Layers deposited on the wall of the quartz tube were less than 1μ in thickness after 6 hr of reaction, and the color of these layers varied from deep amber to dark black. No further attempt was made to characterize these layers.

Structure.—Two distinct microcrystalline forms of boron arsenide were prepared by the direct vapor synthesis technique described above. With the arsenic pressure in the range of 1-2 atm, the product at a reaction temperature of 875° ± 25°C was of dark brownish color; at 1000°C or above, the product was of amber color. X-ray powder diffraction pattern analysis identified the lower temperature product as cubic boron monoarsenide BAs, and the high-temperature material as rhombohedral boron subarsenide with lattice parameters of 4.7778 and 5.3177Å ($\alpha = 70° 32'$), respectively. The compositions of the synthesized materials were determined by both chemical and x-ray fluorescence analysis. The structures and compositions confirm those assigned by Matkovich (6) and LaPlaca and Post (7). When the boron monoarsenide was heated above 1000°C under arsenic pressures varying from a few tenths of an atmosphere to 3 atm, the BAs transformed into the subarsenide. However, the reverse transformation of the rhombohedral form to the cubic structure did not take place at 850°C even under arsenic pressures as high as 5 atm.

Impurity content.—Spectrographic analysis indicated that the boron compounds synthesized by direct

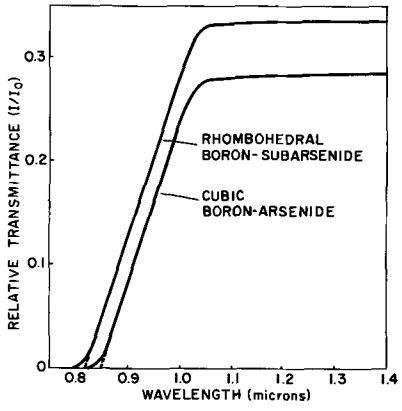

Fig. 1. Comparison of optical transmission vs. wavelength (300°K) of rhombohedral and cubic forms of boron arsenides.

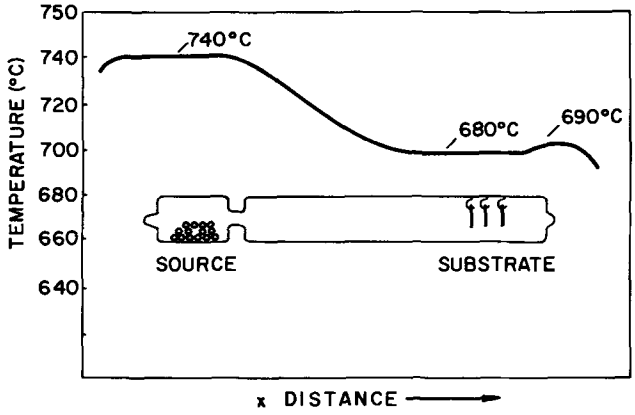

Fig. 2. Furnace temperature profile for epitaxial growth and relative position of the reaction tube in the furnace.

vapor reaction contained impurities such as Mg, Ag, Al, and Pb at levels below 50 ppm. These impurities can be traced to the starting materials used in the preparation. Copper and silicon were the only two impurities detected in more than 50 ppm concentration in the boron arsenides. The silicon content increased with the duration and temperature of the run and presumably came mainly from the quartz tube. In subarsenides (synthesized near 1100°C) silicon concentrations as high as 1% were observed. In monoarsenides (synthesized near 870°C) the silicon content was usually less than 100 ppm. The fact that the copper concentration (50-100 ppm) was independent of the synthesis conditions indicates that the boron arsenides do not effectively leach copper from quartz within the temperature range used for synthesis.

Optical energy gaps.—Transmission *vs.* wavelength measurements were made to estimate the optical energy gaps for the monoarsenides and subarsenides. Since large specimens of these two compounds were not available, the transmission samples were prepared in the following manner. Boron monoarsenide and subarsenide microcrystallines were ground to —300 mesh, mixed with KBr powder of the same particle size, and pressed into 0.025 in. thick pellets ½ in. in diameter. These pellets were then lapped and polished down to 0.007-0.010 in. wafers in a dry nitrogen atmosphere to prevent absorption of moisture by the KBr. The optical absorption of the specimen was measured in the wavelength range 0.55-1.50μ using a DF-2 prism spectrometer (Perkin-Elmer 112). Figure 1 is a plot of the optical transmission *vs.* wavelength measurement at room temperature. The optical energy gaps estimated from the extrapolation of the slope of these curves to zero transmission were 1.46 ev for monoarsenide and 1.51 ev for subarsenide. However, the 1.51 ev value might be considerably less than the actual optical gap of subarsenide since the subarsenide samples were heavily contaminated with Si and the absorption coefficient of Si is extremely high in this region.

Boron Arsenide-Gallium Arsenide Mixed Crystals

Preparation.—The apparatus for growing monocrystalline boron arsenide-gallium arsenide mixed crystals from the vapor phase consisted essentially of a 2 in.-diameter quartz tube extending through two separately controlled constant-temperature regions, the lower-temperature region for the substrate and higher temperature zone for the source. The temperature profile and the capsule placement in the furnace is illustrated in Fig. 2. Oriented gallium arsenide single crystals cut perpendicular to the <110> or <111> direction and etched in sulfuric acid-H_2O_2 solution were used as substrate. The transporting agents were either BI_3 + H_2 or I_2 + H_2. The BI_3 was presynthesized by reacting amorphous boron under I_2 vapor at 1000°C; the white BI_3 was collected in a side tube which was controlled at a temperature of 200° ± 1°C. Crushed gallium arsenide pieces and free arsenic were used as source materials when the transport agents were BI_3 and H_2; otherwise, vapor synthesized microcrystalline boron monoarsenide and gallium arsenide were the source materials. If n-type doping was desired in the epitaxy, SnI_4 was added to the transport agents.

Composition and structure.—Mixed crystals were prepared by the iodide vapor transport reaction with various predetermined source compositions ranging from 10 to 75 mole % of cubic boron-monoarsenide. The compositions of the mixed crystals were determined by several analytical methods: x-ray fluorescence, electron-beam (E-B) probe, "wet" chemical, and lattice-constant determination. The first two methods give the boron composition only indirectly by measuring the gallium-to-arsenic intensity ratio of the sample. Although the third method gives an independent direct measurement of the weight per cent of each of the three elements, B, Ga, and As in the mixture, the inherent disadvantages of this technique are: first, it is destructive analysis, and second, large samples are needed in order to achieve a high degree of accuracy (within ±0.25 w/o). The fourth method relies on the assumption that Vegards' law of solid solution holds for this mixed system; thus with the known lattice constants of the two terminal compounds one can determine the composition.

The analytical results of the boron arsenide-gallium arsenide mixed crystals obtained by the last three methods were found to be in good agreement (see Table I). They indicate that the compositions of all these vapor-transported epitaxies contained less than 3 w/o of boron. For instance, a predetermined source of 75 mole % of boron monoarsenide (which is equivalent to 8 w/o of boron) yielded a sample containing only 2.8 w/o of boron. Evidently a one-to-one transport of boron and gallium from the source to the substrate does not follow in this III-V mixed crystal, but the relative rates of transport of Ga and B seemed to be fairly uniform since in each case the layer was found to be homogeneous. The variation of composition along the parallel and vertical plane of the epitaxy-substrate interface was measured to be less than ±0.1 w/o of boron (by E-B probe analysis).

Table I. Analytical results

Sample No.	E-B probe analysis, w/o		"Wet" chemical analysis, w/o			$B_{substituted}$ / $Ga_{replaced}$	Lattice constant, Å
	B & As	Ga	B	Ga	As		
122	Balance	46.50	0.78	46.6	52.65	2.0	5.648
129	—	—	1.51	46.8	51.70	7.5	—
126	Balance	46.60	2.80	45.2	52.30	5.2	5.638

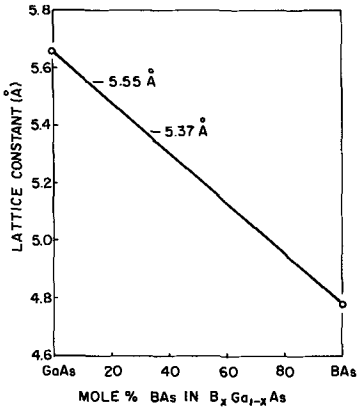

Fig. 3. Variation of lattice constant with composition in an idealized solid solution of $B_xGa_{1-x}As$ system.

The lattice constants of the mixed crystals were measured by the Laue back-reflection technique at room temperature. Both the chemical analyses and the lattice constants given in Table I indicate that the epitaxial layers do not consist of simple solid solutions of BAs and GaAs. The analytical data show that substitution occurs with more than one boron atom per gallium atom replaced. The ratio of boron atoms substituted to gallium atoms replaced is quite variable, ranging from about two for sample 122, to 5.2 for sample 126, and 7.5 for sample 129. These ratios are only approximate because of their sensitivity to small errors in the analytical results for gallium and arsenic. A similar conclusion is reached on consideration of the lattice-parameter values. Application of Vegards' law to BAs-GaAs solid solutions would predict a much larger contraction of the lattice with increasing boron concentration than that observed. Thus the 2.82 w/o boron of sample 126 corresponds to approximately 32 mole % BAs in a BAs-GaAs solid solution and would, by Vegards' law, be expected to have a lattice constant of 5.37Å (Fig. 3) instead of the measured value of 5.638Å. A similar discrepancy exists for sample 122. These discrepancies are too large to be accounted for by usually encountered deviations from Vegards' law and, together with the analytical results, indicate that the boron is present in a form other than that of a BAs-GaAs solid solution.

In order to determine whether the excess numbers of boron atoms existed in a second phase or whether the layers were mixed crystals of boron subarsenide-gallium arsenide, both x-ray powder pattern determinations and high-magnification microscopic examinations were made. The x-ray patterns showed neither broadening of the back-reflection peaks nor the presence of additional peaks, indicating a high degree of crystalline perfection in these layers and the absence of a second phase. High-magnification microscopic examination of the polished and etched layers also revealed no evidence of any second-phase precipitate. It appears therefore that the excess boron atoms were in solid solution, even in samples of the highest boron concentration. Although our experiments could not determine directly whether the excess boron atoms are present in the lattice substitutionally, interstitially, or both, the chemical and x-ray data suggest that the resulting epitaxies were homogeneous mixed crystals of boron subarsenide and gallium arsenide. Analytical evidence for this is afforded by the fact that the ratios of the boron substituted to the arsenic replaced in the layers of boron content greater than 1.5 w/o are compatible with the value 6.0 to be expected for GaAs-B_6As solid solutions. One discrepancy (in sample 122) may reflect experimental inaccuracy, as the determination of this ratio is less accurate at low boron concentrations, or it may represent a small content of BAs.

Table II. Electrical properties of boron arsenide-gallium arsenide mixed crystals

Sample No.	Boron composition, w/o	Free carrier conc., atoms/cm³	Hall mobility cm²/volt-sec	Resistivity, ohm-cm
122	0.78	$n = 1.6 \times 10^{18}$	515	7.3×10^{-3}
126	2.8	$n = 7.3 \times 10^{17}$	280	3.1×10^{-2}

In addition, it should be noted that the lattice parameter for the rhombohedral boron subarsenide equivalent to that of a cubic structure is 5.3177Å, which is a closer match to that of GaAs (5.6533Å) than the 4.7778Å of cubic boron monoarsenide. The rhombohedral structure may be considered a cubic form which has been elongated or compressed along a body diagonal axis and the angle θ of rhombohedral boron subarsenide is 70° 32′, which is identical to the angle between the two (111) faces of the cubic structure. It is structurally quite conceivable for solid solutions of boron subarsenide-gallium arsenide to form. The values of the lattice constant of our mixed crystal layers given in Table I are in close agreement with those resulting from application of Vegards' law to such solid solutions.

Electrical properties.—Specimens used for electrical measurements were cut from the center portion of the epitaxial layer to avoid any unnecessary variation of homogeneity from either the surface or the epitaxy-substrate interface. They were in the form of rectangular blocks of 16 x 11 x 19 mils. The Hall mobilities and free carrier concentrations of these epitaxies were calculated and are listed in Table II.

Although many factors may contribute to the electrical properties of these mixed crystals, it should be noted that a significantly lower Hall mobility is observed in these epitaxial mixed crystals than in gallium arsenide of comparable free carrier concentrations, *e.g.*, in sample No. 122 for a free carrier concentration of $1.6 \times 10^{18}/cm^3$ the Hall mobility is almost five times lower than that for GaAs having the same free carrier concentration. Furthermore, the Hall mobility of the higher boron composition sample (No. 126) decreased by a factor approaching two, where the free carrier concentration is approximately two times lower than the lower boron composition sample (No. 122). Similar behavior has also been observed in other mixed crystals such as GaAs-GaP (8), InSb-GaSb (9), InAs-InP (10), etc., where a pronounced decrease in mobility was found with increasing content of the lower mobility component. This is further indirect evidence that the epitaxial layers are crystals of mixed boron and gallium arsenide since a decrease of Hall mobility accompanies an increase in boron

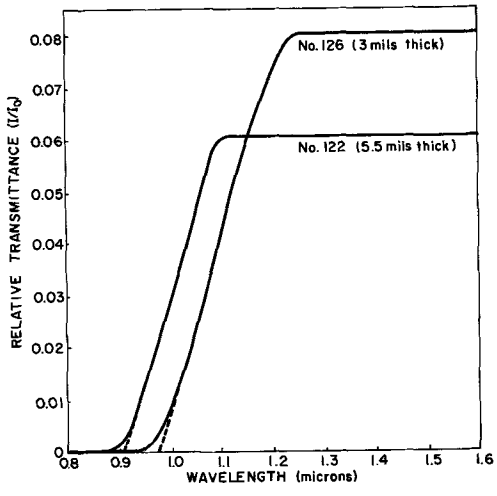

Fig. 4. Variation in optical transmission (300°K) of two different mixed crystal compositions.

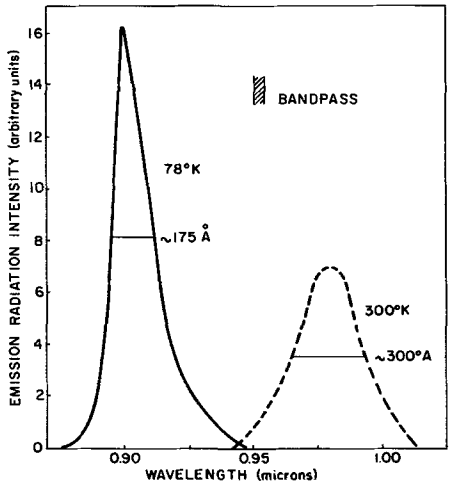

Fig. 5. Comparison of emission spectra at same current level for a mixed crystal diode at 300° and 78°K. Current level, 1.0-A peak current, 2-μsec pulse width, 1000 pulses/sec.

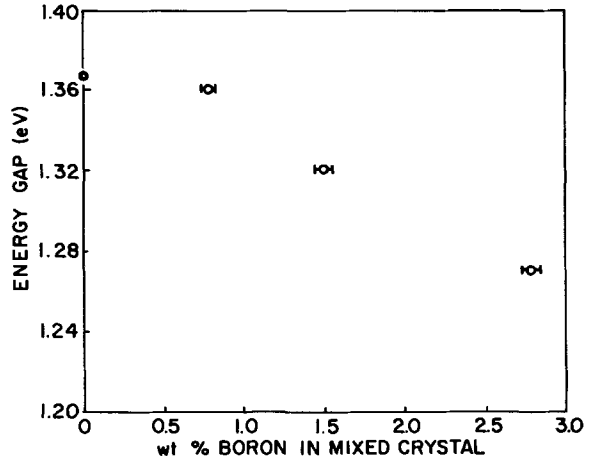

Fig. 6. Emission energy gap (300°K) vs. variation of boron concentration in mixed crystal system.

concentration. Of particular interest is the question of whether the mobility of the carriers is decreased in this mixed crystal by alloy scattering, *i.e.*, by virtue of a statistical distribution of the atoms of the components. At this stage of the investigation, however, the mobilities of boron arsenides and the parameters governing the mobility are not sufficiently known to permit discussion of the scattering mechanism.

Optical properties.—Absorption properties of these epitaxial mixed crystals were measured in the wavelength range of 0.6-1.6μ using a Perkin-Elmer Spectrophotometer Model No. 350. These specimens were first lapped and polished with diamond grit to a mirror-finish surface. Figure 4 shows curves of optical transmittance *vs.* wavelength of both the 0.8 and 2.8 w/o samples at room temperature. Their respective optical energy gaps, extrapolated from the slope of these curves to zero transmission, are 1.36 ev (0.91μ) and 1.27 ev (0.98μ).

Since all the epitaxial mixed crystals made in this investigation were n-type, p-n junctions were fabricated by the standard closed-tube zinc diffusion technique, using zinc arsenide as diffusant to give a surface concentration of $N_A \sim 10^{19}/cm^3$.

Diode emission was measured with a Perkin-Elmer Model No. 112 spectrometer and an RCA 7102 detector. Within the spectrometer scanning range of 0.65-1.52μ, only one radiation peak was observed from each diode at both 300° and 78°K. Since these radiative peaks vary with the square of the pulse current of the diode (*i.e.*, as i^2), and their intensity rises as the temperature decreases (Fig. 5), it is reasonable to assume that they are due to transitions across the energy gaps. These measured emission peaks agree fairly well with the values obtained from the transmission data, since by definition, the energy gaps obtained from the diode-emission data are always lower than those from the optical transmission measurements (11). The absence of impurity emission in these diodes made it impossible in this experiment to determine whether the material has a direct or indirect band gap.

Figure 6 shows that there is a systematic decrease of emission-energy gap with increasing boron composition in the mixed crystal diodes. Previous investigators have shown that GaAs diodes of n- and p-type impurity levels comparable to the present diodes show no decrease in band-edge emission energy. Thus the present decrease is evidently due to the increased concentration of the boron-containing constituent of the solid solutions. This is similar to the decrease of the energy gap with increase in composition of the second terminal compound found in other III-V mixed crystals of comparable terminal energy gap values, *e.g.*, InSb-GaSb (12).

Another feature of interest is the narrowing of the bandwidth of these diode emission peaks from about 300Å at room temperature to 175Å at 78°K (Fig. 5). This shows that the composition along the p-n junction is fairly homogeneous and that the broadening of the bandwidth at higher temperature is due mostly to thermal smearing.

Acknowledgment

The author would like to express her gratitude to R. Weberling, W. Sutkowski, J. Cosgrove, and their associates for providing, the "wet" chemical, E-B probe, x-ray and spectrophotometric analysis which were indispensable in interpreting the results. Technical assistance in the experimental work was skillfully supplied by A. Marx. The author is indebted to Dr. B. Smith whose interest and encouragement made possible this work, and to Dr. D. Baird for carefully reviewing the manuscript and giving valuable comments.

Manuscript received March 4, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Optical Study of $GeCl_4$ Ge, He, and H_2 Systems

K. E. Haq[1]

International Business Machines Corporation Watson Research Center, Yorktown Heights, New York

ABSTRACT

The optical absorption characteristics of $GeCl_4$, Ge, He, and H_2 systems have been studied at elevated temperatures under flow conditions for the wavelength region between 2300-5000Å. It is found that at all temperatures the behavior of $GeCl_4$, Ge, and He systems is very similar to that of the $GeCl_4$, Ge system in a sealed tube. However, in the case of $GeCl_4$-H_2 system, hydrogen reacts with $GeCl_4$ at temperatures of 500°C and above and gives rise to $GeCl_2$. In addition, when $GeCl_4$ carried by hydrogen is passed through a germanium bed, it is found that at 350°C $GeCl_4$ reacts with Ge to give rise to $GeCl_2$, and at 450°C hydrogen reacts with $GeCl_2$ with precipitation of free germanium.

In an earlier paper (1), the results of optical absorption studies of $GeCl_4$, with and without solid germanium present in the system, were reported. As the data were acquired in a sealed system, the results were indicative of the species formed at elevated temperatures in the absence of any carrier gas. Since most methods for deposition of epitaxial Ge films utilize carrier gases, it is of practical importance to know the vapor phase species in a $GeCl_4$ system at elevated temperatures under dynamic conditions, particularly in the presence of carrier gases, such as helium, hydrogen, etc. Hence, the measurements have been extended to flow systems. In the present paper the results of studies of the following systems are reported: (*i*) $GeCl_4$-He, (*ii*) $GeCl_4$-He-Ge, (*iii*) $GeCl_4$-H_2, and (*iv*) $GeCl_4$-H_2-Ge.

Experimental

Apparatus.—A detailed description of the optical arrangement used for measurements was given in the earlier report (1). The arrangement shown in Fig. 1 was used for introducing the $GeCl_4$ and carrier gas mixture into the sample cell. The carrier gas, high-purity helium, or hydrogen, as the case might be, first passed through a molecular sieve and then through a flow meter before entering the bubbler. To ensure proper saturation of the gas, the bubbler was provided with a glass frit for dispersing the gas. It was also provided with a by-pass line so that the whole system could be flushed out by passing pure helium through it whenever necessary. The temperature of the bubbler was held constant by means of a suitable temperature bath, in order to maintain a constant concentration of $GeCl_4$ in the gas stream. The exit end of the absorption cell was connected to a long glass tube with a tapered end to prevent back diffusion of air and moisture. On the entrance side of the cell, a section, approximately 9 in. in length, of the quartz tube which connected the cell with the rest of the apparatus was inside the furnace and was maintained at the same temperature as the cell itself. This section of the tube served two purposes: (*a*) it enabled the gas to come to temperature equilibrium before entering the cell; and (*b*) whenever necessary it could be filled with crushed germanium and used as a germanium bed.

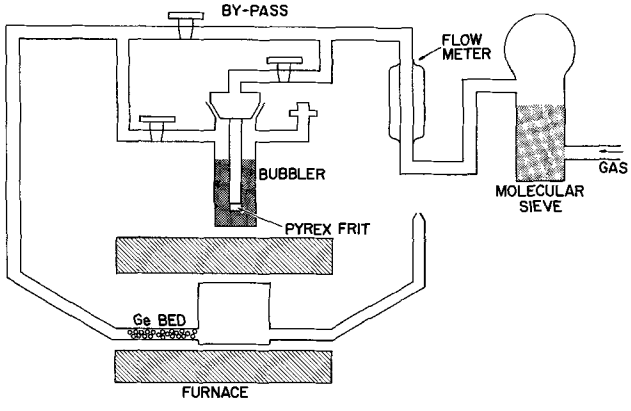

Fig. 1. Experimental arrangement for introducing the $GeCl_4$ and carrier gas mixture into the sample cell.

In the present case the furnace consisted of a single winding so that the cell and the germanium bed could be maintained at the same temperature. Further, to produce a uniform temperature over the entire length of the furnace a copper liner was inserted inside the furnace tube.

Procedure.—The system was first flushed with helium by using the by-pass line in the bubbler; then it was heated to the temperature at which the absorption measurement was to be made. The intensity of the light beam transmitted through the cell was then measured over the whole spectral range to get the I_o values at different wavelengths. If hydrogen was used as the carrier gas, the initial intensity I_o of the light beam was measured with hydrogen flowing through the system. This was a great improvement over the previous sealed tube system in that the initial intensity of the beam could be measured at all temperatures with only the carrier gas present in the cell; thus the effect of the instrumental distortion due to heating could be avoided. Further, the absorption measurements at different concentrations of $GeCl_4$ could be made merely by maintaining the $GeCl_4$ bubbler at different temperatures.

After the measurement of I_o the by-pass line was closed and the carrier gas was allowed to pass through the bubbler. When the cell was completely filled with the mixture of $GeCl_4$ and carrier gas emerging from the bubbler, the final intensity I of the light beam transmitted through the cell was measured. Whether or not the carrier gas in the cell was completely replaced by the mixture was determined by observing the absorption at a suitable wavelength in the region of the absorption continuum of $GeCl_4$. In cases where a germanium bed was used in the path of the gas stream, it was determined by observing the intensity of the transmitted beam at 3150Å, which is believed to be the peak of the $GeCl_2$ absorption band.

Results and Discussion

In order to facilitate discussion, the results of the sealed system are briefly reviewed: Pure $GeCl_4$ exhibited no absorption band within the wavelength range in which the investigation was made. However, it had an absorption edge which begins at 2300Å at 150°C. With increase in temperature the edge extended into longer wavelength regions. This absorption edge was shown to be part of a dissociation continuum of $GeCl_4$. When solid germanium in molar

[1] Present address: Electronics Research Center, NASA, Cambridge, Massachusetts.

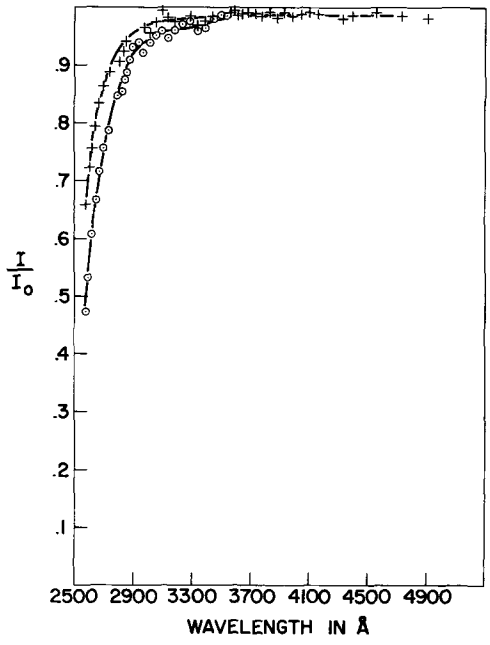

Fig. 2. Transmittance of $GeCl_4$ and He system, $GeCl_4$ at 22°C, flow rate < 10 cc/min; + 500°C; ⊙ 600°C.

quantity less than that of $GeCl_4$ was added to the system, an absorption band with a peak at 3150Å was observed. This was interpreted to be due to $GeCl_2$. If the molar quantity of solid germanium was more than that of the tetrahalide, an additional band with a peak at 4120Å was also observed. In both cases there was an enhancement of absorption in the region of the dissociation continuum of $GeCl_4$. The above results were observed for a wide range of $GeCl_4$ pressures, including those at which the measurements in the open tube systems reported below were made.

The $GeCl_4$-He *system.*—The transmission characteristics of the $GeCl_4$-He open tube system are shown in Fig. 2. The results are very similar to those obtained with pure $GeCl_4$ in a sealed tube. However, in the present case, the increase in absorption with temperature rise at a given wavelength within the absorption continuum was found to be much less than the corresponding increase observed for a closed tube. This difference between the two systems can be explained in the following way. In the case of the open tube system, the total pressure was constant at all temperatures, and hence the density of $GeCl_4$ decreased as the temperature was raised. Thus the increase in the $GeCl_4$ absorption due to temperature rise was largely compensated for by the corresponding decrease in density of the material. As a result, the enhancement in the total absorption was not as great as in the case of the closed tube system, where the density remained constant.

The $GeCl_4$-He-Ge *system.*—The transmittance of the $GeCl_4$-He-Ge system is shown in Fig. 3. The characteristic absorption band with a peak at 3150Å believed to be due to $GeCl_2$ is readily observed. In a manner analogous to the behavior observed in the sealed system, an additional increase in absorption within the continuum region of $GeCl_4$ absorption was observed with temperature increase on introduction of a source of Ge. Thus, in the case of the $GeCl_4$-He system with the partial pressure of $GeCl_4$ at 78 mm, the absorption at 2600Å at 500°C was found to be 27.5% whereas in the case of the $GeCl_4$-He-Ge system with the partial pressure of $GeCl_4$ at 6 mm the absorption was 55%. The above observation lends credence to the earlier conclusion that the species formed as a result of the reaction between $GeCl_4$ and Ge absorbs in the region of the dissociation continuum of $GeCl_4$.

It should be pointed out that, in addition to the 3150Å absorption band, there is a smaller band with the peak at 4120Å which was observed also in the case of the "germanium excess system" in a sealed tube. This result is not unexpected since the present situation represents a germanium excess system. Thus the behavior of the above two systems, namely, $GeCl_4$-He and $GeCl_4$-He-Ge was quite analogous to that of their respective analogs in a sealed tube, *i.e.*, the $GeCl_4$ and $GeCl_4$-Ge systems.

The $GeCl_4$-H_2 *system.*—The transmittance of the $GeCl_4$-H_2 system shown in Fig. 4 indicates that up to 500°C no reaction occurs between hydrogen and $GeCl_4$. At temperatures of 500°C and above, it appears that hydrogen does react with $GeCl_4$ as is evident from the appearance of the absorption band at 3150Å which is attributed to $GeCl_2$.

The $GeCl_4$-H_2-Ge *system.*—Figure 5 shows the transmittance of the $GeCl_4$-H_2-Ge system. In this case the reaction appears to proceed in two steps. At temperatures below 450°C the system behaves in the same way as the $GeCl_4$-He-Ge system. In this temperature

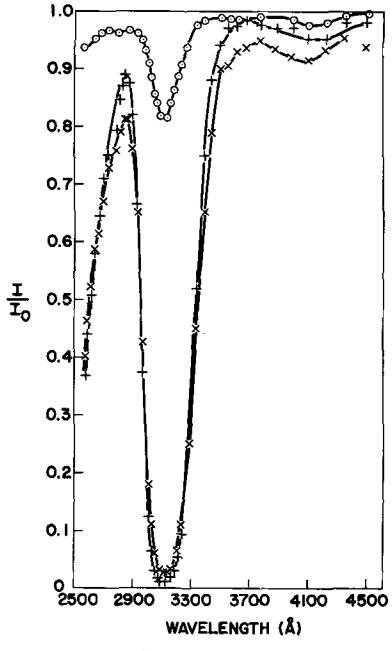

Fig. 3. Transmittance of $GeCl_4$, Ge, and He system. $GeCl_4$ at −20°C; flow < 10 cc/min; ⊙ 350°C; + 500°C; × 600°C.

range, hydrogen appears to act only as a carrier gas, without participating in the reaction. At temperatures of 450°C and above, the effect of hydrogen as a reactant becomes apparent in the form of absorption over a wide spectral range. When the cell was visually examined at the conclusion of a run, elemental germanium was found to be deposited on the walls and the windows of the cell. The absorption over the wide spectral range might be due either to the coating of the cell windows by germanium film alone or to some unknown species plus a germanium film. By the present technique alone no simple means could be devised to determine if any other species were formed.

It may be contended that the deposition of germanium took place by disproportionation rather than by a reaction between hydrogen and $GeCl_2$. However, the following arguments mitigate against this contention: (*A*) The absorption cell was located near the center of the furnace, whereas the germanium bed extended from the entrance end of the cell to the furnace opening. In this geometrical configuration, the temperature of the cell was equal to or higher than that of the germanium bed. Thus the deposition of germanium on the cell windows by disproportionation is unlikely in view of the fact that in the temperature range under consideration transport by this process takes place from hot to cold. (*B*) If the germanium were deposited by disproportionation, then the same result would have been observed in the case of the $GeCl_4$-He-Ge system.

The above results suggest that, in the deposition of germanium films by hydrogen reduction of $GeCl_4$ an intermediate process is involved in which the formation of $GeCl_2$ and HCl precedes the actual precipitation of germanium. If this is indeed the case, the epitaxial film growth occurs in the presence of $GeCl_2$ and HCl from the beginning. Therefore, this suggests further that in the epitaxial growth process significant etching of the seed wafer attends the phenomenon of an over-all net deposition of Ge. Such an occurrence provides an explanation for the impurity gradient observed across a grown junction.

Diffusion-Induced Stress and Lattice Disorders in Silicon

J. E. Lawrence

Fairchild Semiconductor, Division of Fairchild Camera & Instrument Corporation, Palo Alto, California

ABSTRACT

The planar diffusion of boron or phosphorus into silicon can create stresses sufficient to form dislocations within the diffused region and contribute to dislocation formation near the crystal surface outside the diffused region. The effects of two dislocation networks which form within a diffused region are investigated: one network consists of a planar array of concentric loops (Frank-Read source) while the other network consists of a grid of edge dislocations terminating at nodes. The dislocations comprising the concentric loop network can relieve essentially all of the stress created by the diffused impurities. The edge dislocations comprising the grid network do not relieve a large amount of the lattice stress, thus causing the nondiffused silicon lattice surrounding the diffused region to become strained. This strain often extends over 100μ from the diffused region within zones bound by the $\langle\bar{1}10\rangle$ tangents of the diffused region. Dislocations which form in these nondiffused zones as a result of the diffused impurity stress appear as either intersecting lines or periodically spaced parallel dislocations which terminate at the crystal surface. The impurity-induced lattice strain near the crystal surface outside the diffused region contributes to excessive recombination currents in p^+n junctions.

One of the initial steps in forming a planar p-n junction consists of depositing a controlled amount of a dopant impurity such as boron or phosphorus on a silicon surface through a window in a silicon dioxide film. This process creates a shallow diffused region, normally 2μ deep, with a dopant impurity concentration near the solubility limit of the solute in the silicon lattice. Since both boron and phosphorus atoms have smaller ionic radii than silicon (1) and since they occupy substitutional sites in the silicon matrix, a net

contraction of the silicon lattice occurs in the region of impurity diffusion (2). This contraction leads to the formation of dislocations within the diffused region. Prussin (3) and others (1, 4-6) have observed such dislocations to form during uniform sheet diffusion processes. This contraction in planar diffused structures often contributes to the formation of lattice imperfections outside the diffused region as well as dislocations within the diffused region as reported by Ino *et al.* (7).

The present work was undertaken to determine the significance of the dopant impurity concentration and residual strain (due to stresses other than diffused impurities) in the formation of crystal disorder during an impurity diffusion. The electrical behavior of crystal disorder generated during an impurity diffusion was investigated by determining the reverse bias characteristics of selected p^+n junctions. This analysis extends the scope of the work of Rindner and Braun (8) who reported a recombination current dependence on lattice strain.

Experimental

The investigation in general was conducted by systematically varying the concentration of diffused impurities while performing diffusion tests in crystals containing lattice strain from stresses other than that associated with the diffusion process. The amount of stress associated with the minimum concentration of diffused impurities required to noticeably influence the strain in the nondiffused lattice outside a diffused region was determined by comparing the effects of the diffused impurity stress and the effects of stress from an external force. The manner in which a silicon crystal adjusts to accommodate diffused impurities was investigated by determining the configuration and density of crystal disorder formed during an impurity diffusion.

Silicon wafers cut to the (111) surface, lapped to 400μ thick, and chemically polished to a final thickness of 200μ comprised the starting material for this investigation. The freshly polished wafers were oxidized at 1200°C in a steam ambient for periods up to 2 hr to grow a silicon dioxide film thick enough to restrict adequately the penetration of dopant impurities from the silicon lattice. Windows were then opened in the protective film by the photoresist process to allow the selective diffusion of dopant impurities.

The oxidized wafers were deformed by different means to introduce varying amounts and distributions of strain in the crystals prior to the dopant impurity diffusion. This was accomplished by bending, depressing, impulse stressing in the $<\bar{1}10>$ and $<\bar{2}11>$ directions, or combinations of the above. The deformed wafers were then cleaved into large chips to enable the effects of several different concentrations of diffused impurities to be analyzed on wafer sections which contain essentially the same amount and crystallographic distribution of strain prior to the diffusion process. (Care was continuously taken to minimize a variation in strain between different chips.)

The dopant impurities were planar diffused into the test wafer chips from a constant near-solubility limit surface concentration of dopant impurities. The concentration of dopant impurities that passed into the silicon lattice through oxide windows was controlled by varying the duration of the deposition process. Boron deposition was performed at 1200°C in a furnace containing a constant concentration boron tribromide source. The phosphorus deposition was performed at 1070°C in a furnace containing a constant phosphorus oxychloride source. The influence of the concentration of diffused impurities on the manner in which the lattice adjusts was investigated by systematically increasing the periods of deposition from 3 to 10 min for boron, providing $Q = 1.1 \times 10^{16}$ atoms/cm^2 to 4.8×10^{16} atoms/cm^2, and 5 to 30 min for phosphorus, providing $Q = 3.2 \times 10^{16}$ atoms/cm^2 to 4.7×10^{16} atoms/cm^2, assuming a complementary error function distribution. The time required for the silicon lattice to stabilize after the impurity deposition was investigated by diffusion-annealing tests at 1200°C in a dry oxygen ambient for periods of 5 min to 6 hr.

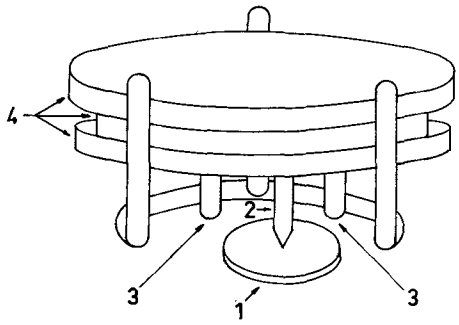

Fig. 1. High-temperature loading apparatus used to simulate surface component of lattice stress generated by diffused impurities: 1, silicon specimen; 2, silicon pin (contract area $A_S = 2 \times 10^3$ μ^2); 3, quartz weight stabilizers; and 4, silicon weights; size: 2 x 2 x 3 cm.

Several wafers prepared for impurity deposition tests were physically deformed by a weighted pin to approximate the stress created outside the diffused region by the diffusion of boron. These loading tests were conducted on wafer chips at 1200°C for a period identical to that in which matching wafer chips were boron diffused. The surface component of stress generated by the weighted pin was systematically varied from 10^7 dynes/cm^2 to 10^{10} dynes/cm^2 during a series of tests using the high-temperature stress apparatus shown in Fig. 1. The application of stress by this apparatus was found to create no plastic deformation at room temperature; however, when it was used to apply the same stress at 1200°C, essentially all of the lattice deformation occurred within the first minute of thermal treatment.

The manner in which the silicon lattice adjusts to accommodate diffused impurities and the adjustment during loading tests was determined by analyzing the type, density, and distribution of lattice disorders created during the respective tests. These structural disorders were delineated by a copper decoration and preferential chemical etching technique (9), by electron transmission microscopy, and by surface x-ray topography. Dislocations, faults, and voids which are copper decorated resist 30 sec of Sirtl (10) etching to create topographic irregularities on the silicon surface that can be analyzed on a conventional optical microscope. The electron transmission microscopy technique was applied to the analysis of copper-decorated and copper-free crystal disorders. Such analysis was aided by the development of a quick and reliable technique for preparing uniform films 1000Å thick and greater than 2 mm in diameter (11). Verification of the copper decoration-preferential etching and electron transmission observations was provided by an x-ray topograph of the diffused surface.

Results

The amount of lattice stress created during an impurity deposition process was found to depend on the total concentration of diffused impurities and not the surface concentration of diffused impurities. This stress is relieved by the generation of dislocations within the diffused region and often by the deformation of the nondiffused lattice surrounding the diffused region. The lowest concentration of diffused boron that is necessary to create a stress sufficient to alter the position of a pre-existing dislocation in the nondiffused lattice adjoining the diffused region is Q min. = 2.6×10^{16} boron/cm^2 with a junction depth of 1.5μ. Above this value of Q min. the stress associated with the diffused impurities is sufficient to deform the non-

diffused lattice surrounding the diffused region and thus alter the position of pre-existing dislocations in the nondiffused lattice. Below this value of Q min. the lattice within the diffused region appears to compensate, through dislocation generation, for all except a nondetectable amount of the stress created by the diffused boron. The total diffused impurity concentration, Q max, that is necessary to generate a stress sufficient to create a dislocation in the "strain-free" nondiffused lattice surrounding a diffused region is greater than $Q = 4.8 \times 10^{16}$ boron/cm^2 with $x_j = 2.2\mu$ or 4.7×10^{16} phosphorus/cm^2, the highest doping levels achieved in this study. The concentration of diffused impurities necessary to generate a stress sufficient to form a dislocation in the nondiffused lattice surrounding a diffused region decreases as the amount of nonimpurity strain in the surrounding lattice increases. Ino *et al.* (7) have reported the concentration of diffused impurities sufficient to cause plastic deformation in the surrounding nondiffused lattice as being less than the maximum values achieved in this study. It is possible that they did not perform their tests using samples with very low background lattice strain. The impurity content required to form a dislocation within a diffused region is less than the quantity required to form a dislocation outside the diffused region. Shockley (1) identifies $Q = 3 \times 10^{15}$ boron/cm^2 as the theoretical minimum dopant concentration necessary for generating dislocations within the diffused region of an ideal silicon lattice.

Lattice strain from nonimpurity stresses was essential in this investigation for our method of determining the manner in which the lattice adjusts during an impurity diffusion was based on analyzing the nature of the dislocations which form during the deposition process. As mentioned above, the Q max obtained in this investigation was not sufficient to cause plastic deformation in the "strain-free" nondiffused lattice surrounding a diffused region. The surrounding nondiffused lattice was made to deform plastically in the presence of an elastic strain induced by diffused impurities by maintaining the amount of nonimpurity lattice deformation slightly below the elastic limit of the silicon lattice. In so doing, the amount and distribution of any elastic strain caused by the diffused impurities would be recorded by an array of newly formed dislocations. No quantitative measure of the magnitude of lattice strain from bending, depressing, or impulse stressing was obtained. Comparative tests were performed which allowed the nonimpurity induced strain to be distinguished from the diffused impurity stress's contribution to defect formation during the impurity deposition process. Wafer bending did not induce sufficient strain prior to impurity deposition noticeably to influence the adjustment of the lattice during an impurity deposition.

The degree to which the lattice surrounding the diffused region must deform during an impurity deposition is very greatly influenced by the structure of the lattice disorder which forms in the diffused region to alleviate the stress generated by the diffused impurities. Two configurations of dislocation networks which commonly form within a diffused region are schematically illustrated in Fig. 2A. One network, "A" in Fig. 2A, generally lies in a subsurface (111) plane near the penetration front of the diffused region and thus does not intersect the crystal surface except when it climbs to the surface near the surface periphery of the diffused region. The stress vector associated with the diffused region is in the direction of impurity diffusion, *viz.*, the $\langle\bar{1}\bar{1}\bar{1}\rangle$ direction in the center of planar diffused regions of (111) wafers. The individual dislocations comprising this subsurface network terminate at nodes, thus forming a flat grid-like array. This network is very likely formed by a dislocation reaction between pairs of dislocations gliding in the same (111) plane. These dislocations are probably edge in character for they lie in a (111) slip plane perpendicular to the $[\bar{1}\bar{1}\bar{1}]$ applied stress. Dislocations which form within the diffused region during a uniform sheet diffusion process and possess similar characteristics have been identified as edge dislocations earlier (4). The other network, "B" in Fig. 2A, consists of an array of concentric loops lying in a plane inclined to the crystal surface. The inclined plane intersects the crystal surface at a $\langle\bar{1}10\rangle$ direction, very likely a $\{\bar{1}11\}$ plane. Figure 2B illustrates the distribution of individual dislocations comprising this dislocation network at a deflection $\vec{g} \cdot \vec{b} \neq 0$. A single reflection was found, but not identified, such that $\vec{g} \cdot \vec{b} = 0$ for all dislocations comprising this network. This observation identified all of the composite dislocations as having the same Burgers vector and that the concentric loop network was very likely formed by the Frank-Read mechanism (12). Formation conditions leading to the generation of this dislocation network within a diffused region are provided by a $\langle\bar{2}11\rangle$ directed impulse stress and a $[\bar{1}\bar{1}\bar{1}]$ directed impurity stress. The exact interaction between these two stress fields is complex and difficult to analyze experimentally.

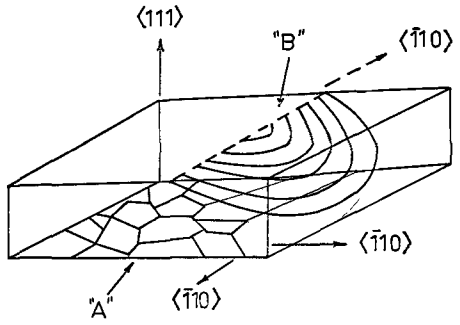

Fig. 2A. Two dislocation networks that form within a diffused region: network "A" is a (111) grid of edge dislocation lying near the subsurface diffusion front, network "B" consists of concentric loops of the Frank-Read formation type.

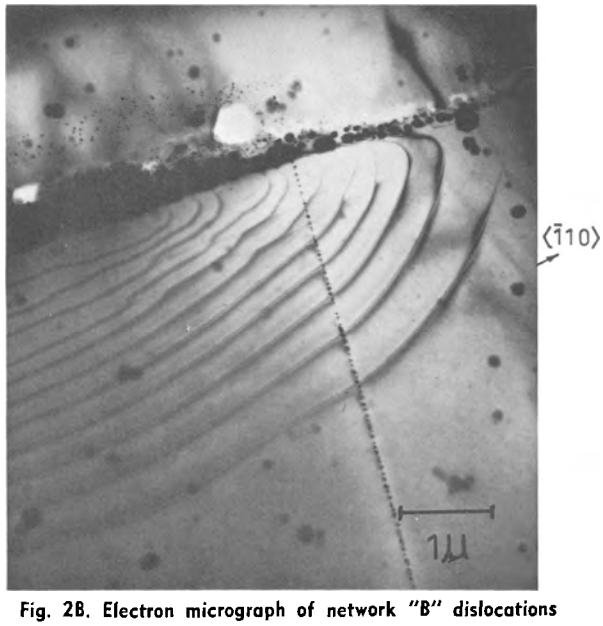

Fig. 2B. Electron micrograph of network "B" dislocations

These two dislocation networks were analyzed in this investigation, not to resolve their exact formation mechanism, but to understand their relationship to the manner in which the lattice adjusts during an impurity deposition process. The great amount of lattice stress generated during the deposition process is reduced by the formation of either network configuration. The (111) grid network, however, has been found

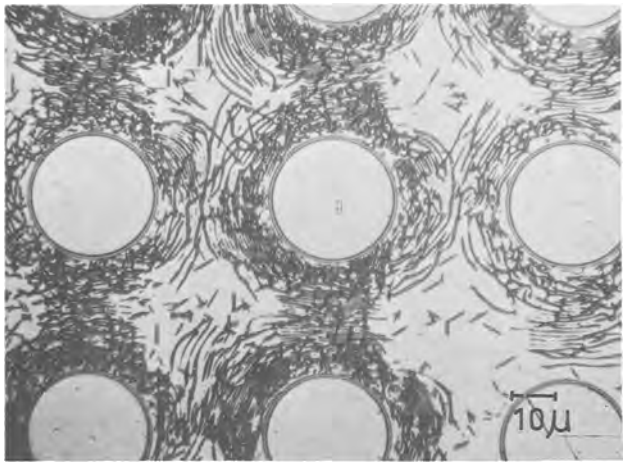

Fig. 3A. Dislocation (dark curved line) in the nondiffused lattice surrounding a planar diffused region delineated by copper decoration and preferential etching.

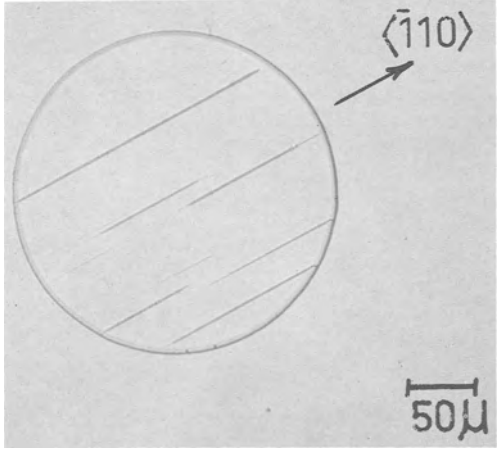

Fig. 3B. No dislocations (absence of dark lines)) in the nondiffused lattice surrounding a planar diffused region delineated by copper decoration and preferential etching. Parallel lines within diffused region are network "B" dislocations.

to relieve much less of the stress generated by the diffused impurities than concentric loop network. This was determined by analyzing the dislocation network configuration within a diffused region and the lines of plastic deformation in the nondiffused lattice surrounding the diffused region which formed during the deposition process. The dark lines surrounding the circular diffused regions in Fig. 3A are delineated dislocations which formed in the nondiffused lattice due to the inability of the (111) grid network dislocations within the diffused region to relieve the lattice stress created by the diffused impurities. In contrast, the absence of dark lines in the nondiffused lattice surrounding the diffused region in Fig. 3B identified the concentric loop network dislocations within the diffused region as relieving essentially all of the stress created by the diffused impurities.

The nondiffused lattice surrounding the diffused region prefers to deform within particular zones to relieve the impurity-induced stress remaining after the formation of the (111) grid network dislocations within the diffused region. These zones are bound by the $\langle\bar{1}10\rangle$ tangents of the diffused region as schematically represented in Fig. 4A and shows in the micrograph in Fig. 4B.

The lines of plastic deformation which form in the surrounding nondiffused lattice as a combination of the elastic strain fields associated with the diffused impurity and the nonimpurity induced deformation are dislocations as determined by $\vec{g} \cdot \vec{b} = 0$ contrast ex-

periments on the electron microscope. These dislocations appear in two general configurations: "random intersecting lines" and "periodic lines" generally perpendicular to the $\langle\bar{1}10\rangle$ projection of the diffused region. The intersecting line configuration of dislocations, shown in Fig. 3A and 5A and graphically at "A" in Fig. 4A, develops in a region near the diffused region where nonparallel stresses from several portions of a diffused region intersect. The dislocations comprising this network configuration are neither pure edge nor screw. They do, however, generally lie in a (111) plane below the crystal surface. Most of the dislocations comprising the intersecting line configuration terminate at nodes with other dislocations gliding in the same (111) plane. The "periodic line" configuration, shown in Fig. 3A and 5B and graphically at "B" in Fig. 4A, develops when a near-unidirectional strain field exists. Each dislocation in a "periodic line" network is a shallow loop aligned to a general $\langle\bar{2}11\rangle$ direction. They terminate on the crystal surface at a $\langle\bar{1}10\rangle$ tangent of the diffused region. The etch pits which define the $\langle\bar{1}10\rangle$ tangents of the diffused regions in Fig. 4B are at the surface intersections of $\langle\bar{2}11\rangle$ oriented dislocation loops comprising "parallel line" networks. These dislocations are primarily edge in character for they lie in the (111) slip plane perpendicular to the direction of the stress vector, *viz.*, $\langle\bar{1}10\rangle$. The portion of these dislocations near their ends are not edge in character for they leave the (111) slip plane and climb to the crystal surface. These dislocations are often several hundred microns long and lie less than 2μ below the crystal surface.

The dislocations which develop in the nondiffused lattice surrounding a diffused region during the deposition process were found to be initiated by a flow of the surface lattice by comparing the structure and distribution of these disorders with those created by

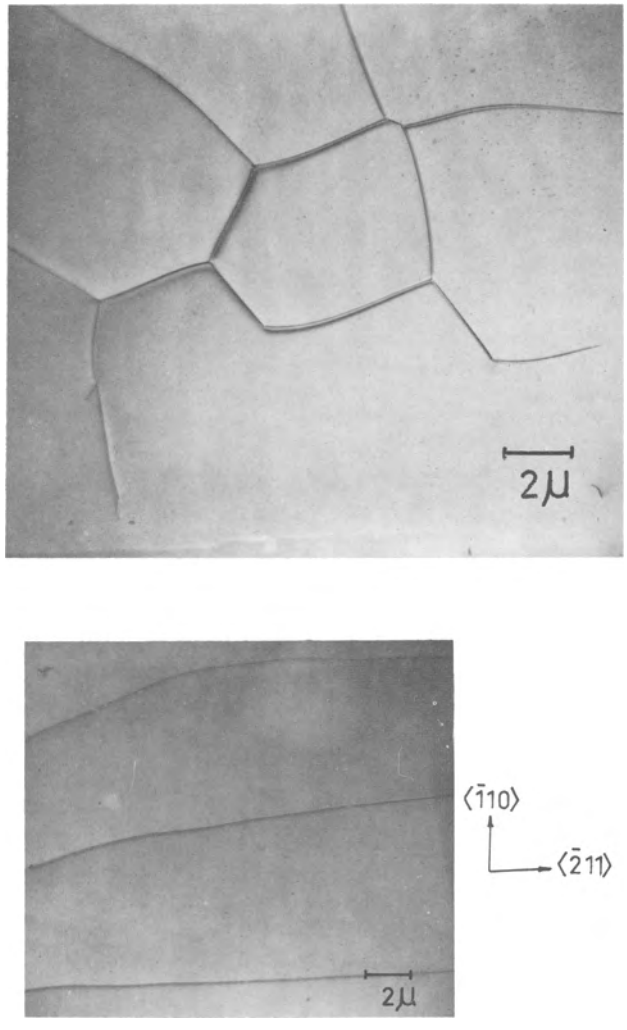

Fig. 5A (top). Dislocation networks created in the nondiffused lattice surrounding a diffused region to relieve the stress induced by diffused impurities; "Intersecting Line Network" Fig. 5B (bottom) "Periodic Line Network." Electron micrographs.

physically deforming the crystal surface. Weighted-pin tests conducted at 1200°C (the boron deposition temperature) produced a distribution of lines identical to those caused by the diffusion of dopant impurities illustrated in Fig. 5. An electron transmission analysis of the lines created by both sources confirmed their structural similarity. The magnitude of the impurity-induced stress at the surface periphery of a diffused region was identified by associating the lowest Q required to form dislocations in the surrounding lattice with the lowest surface component of loading stress required to form similar dislocations. Comparative tests were conducted on the same wafers to normalize the contribution of nonimpurity lattice strain. The loading tests identified $\sigma_1 = 2.5 \pm 2 \times 10^9$ dynes/cm^2 as being the magnitude of the peripheral surface stress created in the nondiffused lattice surrounding a region where boron of $Q_1 = 2.6 \times 10^{16}$ atoms/cm^2 had been planar diffused and (111) grid network dislocations had formed within the diffused region.

Calculated Stress

The magnitude of the stress generated within a diffused region by the diffused impurities can be calculated using an expression formulated by Prussin (3). He adjusted Timoshenko's expression (13) for mechanical stresses in a thin plate to comply with a complementary error-function distribution of diffused atoms as the deformation source, assuming the impurity stress-mechanical stress relationship identified in this work. The Prussin expression for the maximum impurity-induced stress along the crystal surface inside the diffused region is

$$(\sigma x)_{\max} = \frac{\beta C_S E}{(1-\nu)}$$

where β is the solute lattice contraction coefficient, C_S is the solute surface concentration, E is Young's modulus, and ν is Poisson's ratio. Using this expression Prussin calculated $(\sigma x) = 6.0 \times 10^9$ dynes/cm^2 for boron. Since the publication of Prussin's work, improved values of these factors have been reported. Wortman and Evans (14) identifies Young's modulus and Poisson's ratio as $E = 1.7 \times 10^{12}$ dynes/cm^2 and $\nu = 0.33$ for the [1̄10] direction of the (110) plane. The value of the solubility limit of boron in silicon has remained at $C_S = 5 \times 10^{22}$ (15). β can be calculated using the following general expression

$$\beta = \left[1 - \left(\frac{r_{sol}}{r_{Si}}\right)^3\right] N^{-1}$$

where r_{Si} is the covalent radius of silicon, $r_{Si} = 1.17$Å (16), $r_{sol} = 0.98$Å for boron (1), and N is the concentration of silicon atom sites, $N = 5 \times 10^{22}$/cm^3. These values in the above expression provide $\beta = 8.2 \times 10^{-24}$ cm^3/atom. This value lies between the values of β calculated from the contracted lattice parameters reported by Horn (17), 16×10^{-24} cm^3/atom, and Pearson *et al.* (2), 6.6×10^{-24} cm^3/atom. Applying these improved values to Prussin's expression provides (σx) max $= 1.0 \times 10^{10}$ dynes/cm^2 as the maximum internal stress created by the diffusion of boron into silicon. A further refinement of these values or the above expressions at this time would have little justification for the magnitude of the impurity-induced stress in the surrounding nondiffused lattice is greatly influenced by the noncontrolled formation of lattice disorder within the diffused region. The stress required to cause yield in highly boron doped silicon whiskers was obtained by extrapolating the data of Pearson *et al.* (18) to 1200°C, σ(yield limit) $= 1.0 \times 10^9$ dynes/cm^2. The first approximation values obtained from Prussin's expression identify the stress generated within the diffused region as exceeding the amount required to cause yield, as it should since lines of plastic deformation are created within the diffused region.

Results—Electrical

The strain in the nondiffused lattice surrounding a diffused region resulting from the diffused boron stress contributes directly to excessive currents in reverse biased p^+n junctions as Fig. 6 indicates. Curve A identifies the log I *vs.* log V trace of a diode with no associated dislocations in the nondiffused lattice surrounding the deposited region, similar to that shown in Fig. 3B. Curves B and C identify the electrical

characteristics of two diodes, one with a moderately large density of associated dislocations in the nondiffused lattice, curve B, and the other with an extremely large quantity of associated dislocations in the nondiffused lattice, curve C, similar to those shown in Fig. 3A. The density of associated dislocations in the nondiffused lattice corresponds to the strength of the impurity-induced strain observed in the nondiffused lattice surrounding a diffused region.

Summary

The manner in which the silicon lattice adjusts to accommodate a large quantity of small diffused impurities has been investigated. The results of this investigation can be incorporated into a model which describes the behavior of the silicon lattice during an impurity deposition process.

The planar diffusion of boron during a 1200°C deposition process creates a maximum calculated stress near 1.0×10^{10} dynes/cm^2 within the diffused region. The silicon lattice in deforming to relieve this stress forms either of two different dislocation networks within the diffused region. The two dislocation networks relieve different amounts of the impurity-induced stress as identified earlier and verified in the x-ray topograph in Fig. 7. One of the dislocation networks (Frank-Read source) consists of a family of concentric dislocation loops which lie in a plane inclined to the crystal surface. The dislocations in this network relieve essentially all of the lattice stress created by the planar deposition process as shown at (A) in Fig. 7. This is very likely due to the size of the individual dislocations and their possessing significant screw as well as edge dislocation components. A different dislocation network commonly develops within the diffused region near the diffusion front of shallow diffused structures. The dislocations comprising this network are generally edge in character, but acquire dominant screw character near the periphery of the diffused region where the network leaves the (111) slip plane. The formation of these dislocations tends to lower the stress within the diffused region by only one order of magnitude, thus causing the nondiffused lattice surrounding the diffused region to deform to relieve the impurity induced strain as shown at (B) in Fig. 7. The nondiffused lattice surrounding the diffused region deforms within highly restricted zones when the lattice within the diffused region is unable to relieve the diffused impurity stress. These zones are bound by the $<\bar{1}10>$ tangents of the diffused region and extend to the depth of the region created by the planar deposition process, normally two microns. Portions of the nondiffused lattice a distance greater than 100μ from a diffused region are often deformed due to an impurity deposition.

The electrical characteristics of the p^+n junction created during the planar deposition of boron are influenced by the deformation of the nondiffused lattice surrounding the diffused region. Reverse currents in the nanoampere range have been associated with the above lattice deformation source.

Acknowledgments

The author wishes to thank Dr. R. N. Tucker for his stimulating discussions throughout the development of the study summarized in this paper. The electron transmission specimen preparation and analysis was performed with the skillful assistance of H. Koehler and D. Mattern. The author is also grateful to Dr. E. Meieran for the x-ray surface topograph and interesting discussions. Part of this work was supported by R.A.D.C., Contract number AF 30(602)-3776.

Manuscript received Jan. 17, 1966; revised manuscript received May 3, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Epitaxial Growth of Silicon Carbide by the Thermal Reduction Technique

R. B. Campbell and T. L. Chu

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The epitaxial growth of silicon carbide on the basal plane of hexagonal silicon carbide substrates has been accomplished by the thermal reduction of carbon and silicon tetrachlorides, and experimental parameters of the growth process have been studied. Using good *in situ* etching techniques and inert susceptor materials, epitaxial silicon carbide layers with structural perfection similar to that of the substrate were grown at a substrate temperature of 1700°C and a deposition rate of 0.5 μ/min. Doped silicon carbide layers were prepared using nitrogen, arsine, or phosphine as n-type dopants and diborane as a p-type dopant, and the electrical properties of these layers were evaluated by Hall measurements in the temperature range 78°-900°K. Preliminary junction structures prepared by doping techniques were found to be capable of supporting up to 50v at 500°C.

Silicon carbide devices, such as rectifiers (1), charged particle detectors (2), and unipolar transistors (3) are capable of operation at high temperatures, 500°C or above. Because of its refractory nature, the fabrication of silicon carbide junctions is difficult and involved. The epitaxial growth technique appears to be a promising junction formation method since epitaxial silicon carbide layers of controlled dopant distribution can be deposited on silicon carbide substrates at relatively low temperatures compared to the sublimation process (4).

The feasibility of using the thermal reduction of mixtures of carbon and silicon tetrachlorides with hydrogen for the isoepitaxial growth of silicon carbide, in a manner similar to the epitaxial growth of silicon by the hydrogen reduction of silicon tetrachloride, has been reported (5). The epitaxial growth of silicon carbide, however, poses the complicating problem in that it exists in cubic and hexagonal phases with the latter possessing a variety of polytypes. It was found in the early work (5) that either phase could be deposited on the basal planes of hexagonal silicon carbide substrates, depending on experimental conditions. Furthermore, the cubic phase was grown at substrate temperatures (brightness) of 1660°-1775°C, and the hexagonal phase was grown on mechanically polished substrates at brightness temperatures higher than 1725°C.

In this work, the epitaxial growth of silicon carbide on the basal planes of hexagonal silicon carbide substrates by the thermal reduction technique has been further studied with the aim of preparing rectifying junctions. To achieve this, new experimental techniques were devised to prepare epitaxial silicon carbide layers with structural perfection similar to that of the substrate. Doping techniques were also developed to control the conductivity type and carrier concentration of the epitaxial layer. Using these techniques, preliminary work on the preparation of silicon carbide p-n junctions was carried out. Various aspects of the isoepitaxial growth of silicon carbide are discussed in this paper.

Structural Perfection of Epitaxial Silicon Carbide

The structural perfection of the epitaxial layer is an important factor determining its usefulness for device purposes. It has been well established in the epitaxial silicon technology that the structural perfection of the epitaxial layer prepared under proper conditions of substrate temperature and growth rate is determined predominately by the purity of the growth apparatus and reactants, and the surface conditions of the substrate. Contaminants from the growth apparatus and foreign impurities on the substrate surface are the principal causes of imperfections in the epitaxial layer. Because of the temperatures required for the epitaxial growth of hexagonal silicon carbide, the purity of the growth apparatus is more difficult to maintain than in the silicon process. For example, the rf susceptor for the support and heating of silicon carbide substrates must be stable and inert toward silicon carbide and the reactants under the conditions used in the growth process. The choice of susceptor material therefore is limited. Refractory metals react with silicon carbide at high temperatures, and graphite and refractory carbides, including silicon carbide, react with hydrogen to form hydrocarbons. Refractory silicides were found to be more stable under conditions used for the epitaxial growth of silicon carbide. Tantalum silicide-coated tantalum was used as the susceptor in this work with satisfactory results.

The substrate surface should be free from foreign impurities and mechanical damage. While the usual etching and cleaning operations remove residual abrasives, dust, etc., they do not provide clean substrate surfaces required for the epitaxial growth process. The *in situ* etching of substrates has been shown to be useful for producing epitaxial silicon layers of good perfection (6). Chlorine-oxygen mixtures (7) or hydrogen (8) can be used as etchants. The hydrogen etch provides a clean and microscopically smooth surface and is particularly convenient to use in this process.

Experimental.—Electronic grade silicon tetrachloride and carbon tetrachloride were used for the epitaxial growth of silicon carbide. They were introduced into the reaction tube by using a measured amount of hydrogen as a carrier gas. The hydrogen was purified by diffusion through a palladium-silver alloy. Since nitrogen is electrically active in silicon carbide, the silicon and carbon tetrachlorides were thoroughly outgassed to remove dissolved air and the growth system was made gas-tight to minimize any undesirable doping.

Hexagonal silicon carbide platelets with main faces of (0001) orientation grown by the sublimation technique (4) were used as substrates for the epitaxial growth process. They were selected on the basis of optical examination and were etched in a molten 1:3 sodium peroxide-sodium hydroxide mixture to determine the polarity of faces (10).[1] The face of the sub-

[1] The (0001) and (000$\bar{1}$) faces of hexagonal silicon carbide exhibit different etching behaviors toward molten sodium peroxide. One face remains smooth and the other becomes rough in appearance. The former has been shown in a recent work to be the silicon face (10).

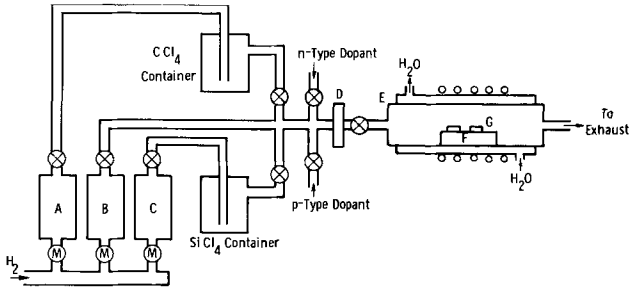

Fig. 1. Schematic diagram of the apparatus for the epitaxial growth of silicon carbide by the thermal reduction technique. Ⓜ metering valve; ⊗ shut-off valve; A, B, C flowmeters; D filter; E water-cooled reaction tube; F tantalum silicide coated susceptor; G SiC substrates.

strates with the desired polarity was then successively lapped with boron carbide and polished with diamond paste. The substrates were subsequently cleaned ultrasonically in hydrofluoric acid and water.

The growth experiments were carried out in a gas flow system, using a horizontal, water cooled quartz tube of 2.5 cm ID with gas inlet and exhaust tubes. The silicon carbide substrates were supported on a tantalum silicide-coated tantalum susceptor in the reaction tube, and the susceptor heated externally by an rf generator. Prior to the growth process, the substrates were etched with hydrogen at 1650°-1700°C[2] to remove about 10μ of silicon carbide from the substrate. A schematic of the apparatus is shown in Fig. 1.

During the growth process, the substrates were maintained at 1700°-1715°C. The flow rate of hydrogen was 2.5 l/min, and the concentration of silicon and carbon tetrachlorides in the reactant mixture was 0.04-0.1%. Under these conditions, the linear velocity of the reactant over the substrate surface in our apparatus at room temperature was about 12 cm/sec, and this high linear velocity was essential to provide a uniform flux of the reactant over the substrates.

The structural perfection of deposited silicon carbide layers was evaluated principally by chemical etching technique and optical microscopy. Imperfections in these layers were readily revealed by etching the specimen with a 3:1 $NaOH$-Na_2O_2 mixture at 700°C for 5-15 sec.

Results and discussion.—Under proper conditions of cleanness, the structural perfection of epitaxial silicon carbide layers is affected by the substrate temperature, growth rate, imperfections in substrates, etc. Using a given hydrogen flow rate at a given substrate temperature, the growth rate of silicon carbide depends on the concentrations of silicon and carbon tetrachlorides in the reactant mixture. In this work, equal concentrations of carbon and silicon tetrachlorides were used. Table I summarizes the growth rate of silicon carbide layers on the silicon face of the substrate as a function of the reactant composition; the substrate temperature was 1700°C and the hydrogen flow rate was 2.5 l/min. (The growth rate was found to be approximately 50% greater on the carbon face of the substrate.) The observed growth rate is the net result of the deposition of silicon carbide by thermal reduction and the etching of silicon carbide by hydrogen. Since the etch rate of silicon carbide by hydrogen is considerable at the temperature used for the deposition process, approximately 2 μ/min, the composition of the reactant mixture becomes very critical. Under a given set of growth conditions, there exists a definite reactant composition at which no net deposition of silicon carbide occurs, and any deviation from this composition results in the etching of the substrate or the deposition of silicon carbide. As indicated in Table I, the silicon carbide substrates were found to be etched when the concentration of carbon and silicon tetrachlorides was 0.055% or less. As the concentration of the tetrachlorides was gradually increased, the growth rate of silicon carbide increased rapidly. However, at tetrachloride concentrations of 0.08% or higher, the grown layer had large areas of apparently polycrystalline material.

Chemical etching and optical microscope examinations indicated that epitaxial layers grown at rates of about 0.5 μ/min were similar to the substrate in structural perfection and that defects in the grown layer were usually propagated from the substrate. An example is given in Fig. 2 where a noted defect in a grown layer is correlated, after the removal of this layer, with defects in the substrate. The apparent unevenness of the substrate surface was due to the higher etch rate in the defect areas.

The epitaxial growth of hexagonal silicon carbide layers of good structural perfection was achieved only over a limited temperature range. Using a reactant mixture containing 0.06-0.065% of carbon and silicon tetrachlorides, the grown layer was of cubic phase at temperatures below 1700°C. These layers were characterized by high concentrations of linear etch figures

[2] All temperatures reported here were brightness temperatures measured with a micro-optical pyrometer. These temperatures are about 100°C lower than the true temperature because of the emissivity correction of silicon carbide and the reflection loss at the wall of the reaction tube.

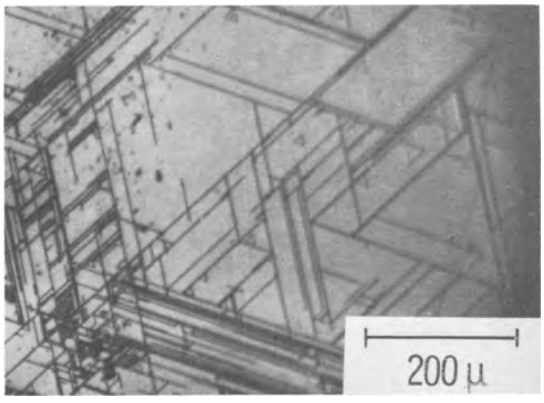

Fig. 3. Linear etch figures associated with stacking faults in a cubic silicon carbide layer deposited on a hexagonal substrate.

at 60° or 120° to each other (Fig. 3), and these etch figures are presumably stacking fault traces (11). Hexagonal silicon carbide layers were grown from 1700° to 1730°C, and no growth occurred at higher temperatures due to the increased etching rate of silicon carbide by hydrogen. Even when the concentrations of carbon and silicon tetrachlorides in the reactant mixture were increased by a factor of four, no growth was observed at substrate temperatures above 1750°C.

Epitaxial Growth of Doped Silicon Carbide Layers and Formation of Epitaxial Junctions

The electrical properties of epitaxial silicon carbide layers obtained by the thermal reduction technique without intentional doping are determined predominately by impurities in the reactant mixture and in the growth apparatus. When these impurity effects are known, controlled addition of dopants into the reactant can yield epitaxial layers of desired conductivity type and carrier concentrations. Junction structures can be prepared accordingly by programming the type and concentration of the dopant during the growth process.

Experimental.—The electrical properties of epitaxial silicon carbide layers deposited on substrates of opposite conductivity type were evaluated by resistivity and Hall in the temperature range 78°-900°K, using the van der Pauw technique (12). The specimen was ultrasonically cut into a disk form, 1.5-6.5 mm in diameter. Four contacts were then applied to the epitaxial layer. Using gold wires of 25μ diameter, the disk was attached to a ceramic plate having gold contacts, and these contacts served as voltage and current leads for the measurement. From the resistivity and Hall constant the carrier concentration and carrier mobility can be determined. The carrier mobility is independent of the thickness of the layer.

The control of carrier concentration in epitaxial silicon carbide layers was achieved by using diborane as a p-type dopant and nitrogen, arsine, or phosphine as n-type dopants. A series of growth experiments were carried out using varied amounts of each dopant to determine the relation between the electrical properties of the epitaxial layer and the composition of the reactant.

Subsequent to the control of the carrier concentration in the epitaxial layer, rectifying junctions were prepared by two principal approaches. In the first, an n- or p-type epitaxial layer was deposited on substrates of opposite conductivity type, and a p-n junction was formed near the growth interface. The second approach was aimed at the preparation of p^+ n^+-type structures by depositing an undoped silicon carbide layer onto a highly doped n-type substrate followed by the deposition of a highly doped p-type layer. The junctions were usually 25 mm^2 in area. To determine the electrical properties of epitaxial junctions, ohmic contacts were alloyed to the n-type and p-type regions, using Au-Ta and Au-Ta-Al alloys respectively, at 1225°C. The units were then etched in molten sodium peroxide and tested for electrical tests.

Table II. Electrical properties of doped silicon carbide Layers measured at room temperature

Flow rate of dopant, mole/min	Resistivity, ohm-cm	Mobility, cm^2/v-sec	Carrier conc, cm^{-3}
N_2 6×10^{-3}	0.053	48	2.8×10^{18}
N_2 2×10^{-4}	0.023	52	6.0×10^{18}
PH_3 0.5×10^{-6}	0.07	155	5.6×10^{17}
PH_3 2.2×10^{-6}	0.02	109	2.6×10^{18}
AsH_3 0.5×10^{-6}	0.32	37	5×10^{17}
B_2H_6 2.2×10^{-5}	90.4	2	4×10^{16}

Results and discussion.—Epitaxial silicon carbide layers grown by the thermal reduction technique without intentional doping were n-type, with representative room temperature resistivity of 0.07 ohm-cm, mobility of 290 cm^2/v-sec, and net carrier concentration of 3×10^{17} cm^{-3}. It is believed that these carriers were due to residual nitrogen in the reactants and in the apparatus.

When dopants were introduced into the reactant mixture under conditions yielding epitaxial silicon carbide layers of good perfection, the growth rate was found to increase more than 50%, with degradation in the quality of the layer. To obtain doped layers of good perfection, the concentrations of carbon and silicon tetrachlorides in the reactant were reduced to 0.04% to achieve a growth rate of 0.5 μ/min. The electrical properties of several representative doped layers, measured at room temperature, are summarized in Table II. The phosphorus doped layers showed a significantly higher mobility than similarly doped nitrogen or arsenic doped layers. Figure 4 shows the resistivity and carrier concentration of a phosphorus doped epitaxial silicon carbide layer in the temperature range 78°-900°K. The temperature dependence of the carrier concentration exhibits two distinct slopes corresponding to activation energies of 0.03 and 0.10 ev. It cannot be stated with certainty if both donor levels are associated with phosphorus or if an unknown impurity is present.

Many diodes were made by depositing n-type epitaxial layers on p-type substrates. The resistivity and mobility of representative substrate crystals were 0.01

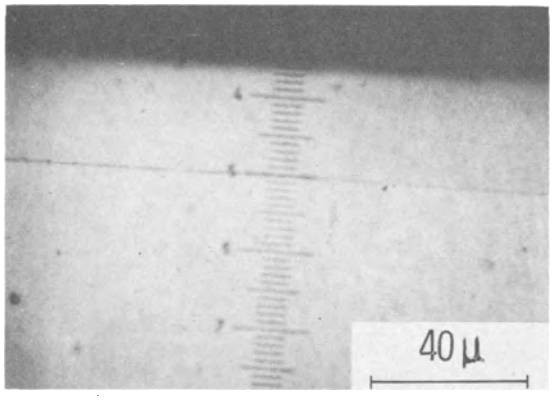

Fig. 5. An epitaxial p-n junction in silicon carbide delineated by electrolytic etching of a vertically cross-sectioned surface.

ohm-cm and 30 cm^2/v-sec, respectively. The epitaxial layers were usually 15 to 30μ in thickness, with properties as given in Table II. Figure 5 shows a p-n junction delineated by electrolytic etching of vertically cross-sectioned surface in a 75:1 methanol: HF mixture. These epitaxial junctions generally exhibited a low forward voltage (1.5-2.5v at 1-5A) with a reverse capability of 50v at 500°C. Several p^+ n^+-type structures were made and the reverse characteristics were similar.

Summary and Conclusions

Epitaxial silicon carbide layers of good structural perfection have been deposited on the basal plane of hexagonal silicon carbide substrates at temperatures considerably below its sublimation temperature by a thermal reduction technique. The substrate temperature, the concentrations of carbon and silicon tetrachlorides in the reactant mixture, the surface condition of the substrate, and the purity of the growth apparatus are important factors affecting the quality of the grown layer. The conductivity type of, and carrier concentration in, the grown layer have been controlled to a reasonable degree by using diborane as a p-type dopant and nitrogen, arsine, or phosphine as n-type dopants. Epitaxial junction structures have been prepared by varying the dopant concentration in the reactant mixture during the growth process. Although the preliminary structures could not support high voltages, the epitaxial growth technique is believed to be a practical method for preparing junction structures in silicon carbide and is worthy of further investigations.

The Growth of $FeSn_2$ Layers on Specifically Oriented Iron Single Crystals

H. E. Biber and W. T. Harter

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

$FeSn_2$ layers on tinplate exhibit three different types of structure, the primary forms of which occur on the {100}, {110}, and {111} faces of iron. The rate and manner of growth of the alloy layer on each of these three faces have been studied for a heating rate that simulated commercial flow brighening of tinplate. Results show that the alloy layer grows at a different rate on each face. The alloy growth on both the {100} and {110} faces exhibits arrests that are associated with completion of base-metal coverage by the alloy layer. Results provide a reasonably clear understanding of the manner in which alloy layers grow on tinplate during commercial flow brightening.

Electrolytic tinplate, as it emerges from a plating bath, has a dull surface quite different from the highly reflective surface traditionally associated with tinplate. To impart high reflectivity to the surface, the matte tinplate is briefly heated above 232°C, the melting point of tin, and then quenched. This heating operation, known as flow brightening, also promotes a reaction between the iron and the tin, which results in the formation of a thin layer of $FeSn_2$ at the interface between the steel base and the protective tin coating.

The structure of this alloy layer has been a subject of considerable interest in the tinplate industry. Stoll (1), Ebben and Lawson (2), and Gabe and Mort (3) have shown by electron microscopy that alloy layers on commercial tinplate consist of numerous small crystallites of $FeSn_2$. The arrangement of these crystallites and their coverage of the steel base were

shown to vary from one small area to the next. These variations were thought to be caused by the varying orientation of the grains in the surface of the steel base. To obtain a better understanding of the influence of substrate orientation on alloy-layer structure and of the manner in which alloy layers grow during commercial flow brightening, our laboratory undertook a detailed study with specifically oriented iron single crystals.

Experimental

The single crystals were prepared by the strain-anneal technique developed by Stein and Low (4). Vacuum-melted iron of 99.9% purity was used, and single-crystal strips 0.04 x 1 x about 4 in. were obtained in approximately half of the trials. Results of chemical analyses of the starting materials are given in Table I, and the orientations of those single crystals used in this study are plotted on the unit stereographic triangle shown in Fig. 1.

For convenience the single-crystal strips were divided into half-inch squares. One large face of each square was polished with 0.3μ alumina on a wheel covered with kittenear broadcloth. After a 10-sec etch in 2% nital, the polished surface was coated with a nominal 60 μin. layer of tin in a PSA-DDS electrolyte at 110°F at a current density of 25 amp/ft^2. The electrolyte contained, per liter, 55g of stannous sulfate, 57 ml of 65% phenolsulfonic acid, and 6g of dihydroxydiphenylsulfone.

The matte tinplate squares were heated from the unplated side by a 500-w projection lamp. The lamp voltage was adjusted for each square before heating so that the tin coating melted 7.0 ± 0.2 sec from the start of heating. The amount of alloy layer on a ¼-in. diameter circular area of the heated specimens was determined by the coulometric method of Kunze and Willey (5).

To prepare the specimens for electron microscopy, the free tin on the surface was removed by anodic dissolution in 5% sodium hydroxide solution. Specimens were carefully washed in flowing water, rinsed with methanol, and dried in a draft of warm air. Replicas of the alloy layer were prepared by a technique developed by Ebben and Lawson (2). The shadowing angle was about 45°. The replicas were examined in a Hitachi HU-10 electron microscope.

For comparison, alloy-layer growth rates on polycrystalline steel were determined for these same heating conditions with ½-in. squares of matte tinplate prepared in a circulation cell. In addition some tinplated single crystal squares were heated in a 240°C oil bath and the resulting alloy layer examined by electron microscopy.

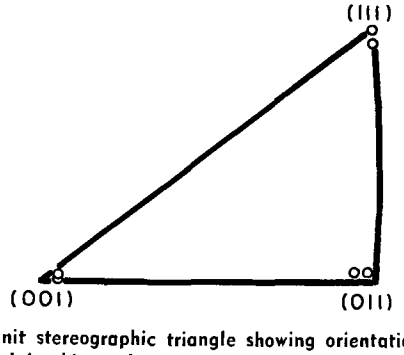

Fig. 1. Unit stereographic triangle showing orientations of single crystals used in this study.

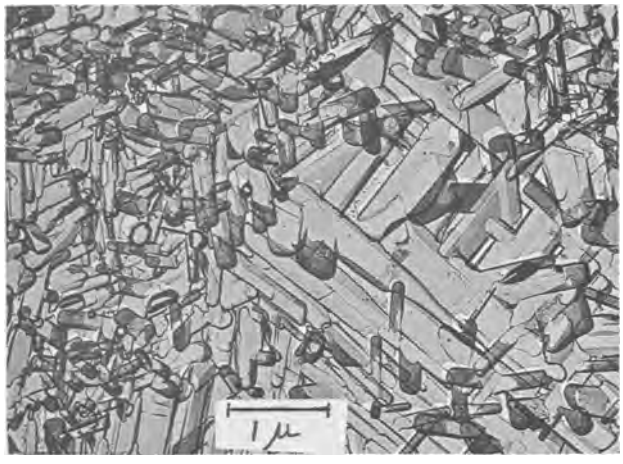

Fig. 2. Typical iron-tin alloy layer on steel

Results

On commercial flow-brightened tinplate the amount of alloyed tin is normally between 0.05 and 0.10 lb/bb (pounds per base box: 0.056 and 0.112 mg/cm^2, respectively). In electron micrographs of typical alloy layers on steel, Fig. 2, there appear to be many different alloy-layer structures. However, a study of the alloy layers formed on iron single crystals shows

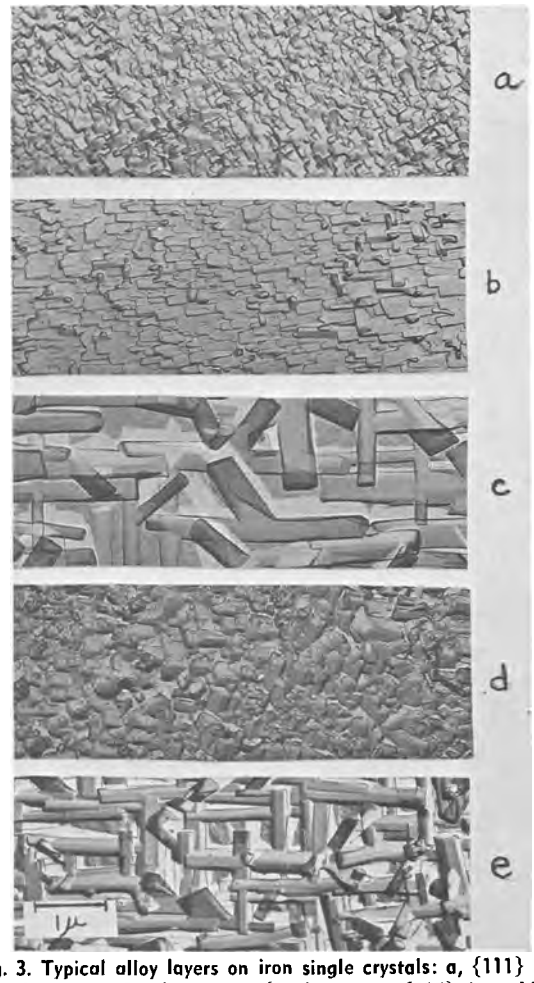

Fig. 3. Typical alloy layers on iron single crystals: a, {111} face; b, {110} face; c, {100} face; d, {112} face; e, {115} face. Identical magnification for each micrograph.

that there are actually only three basic alloy-layer structures. These occur on the {111}, {110}, and {100} faces of the iron crystal, Fig. 3a-c. On the {111} face the alloy layer consists of small columnar crystallites that project from the surface at various angles, Fig. 3a; on the {110} face the crystallites lie parallel to one another on the surface, Fig. 3b; and on the {100} face the crystallites are arranged in an approximately orthogonal array on the substrate surface, Fig. 3c. Alloy-layer structures on other faces of the iron crystal are simply variations of these three basic forms and resemble most closely the basic form on the primary face that is closest in orientation to the face in question. For example, the {112} face lies closest to the {111} face, forming angles of 19.5, 30.0, and 35.3° with the {111}, {110}, and {100} faces, respectively, and the alloy layer on this face has a {111}-like structure, Fig. 3d. The {115} face lies closest to the {100} face, forming angles of 38.9, 35.3, and 15.8° with the {111}, {110}, and {100} faces, respectively, and the alloy layer on this face has a {100}-like structure, Fig. 3e. Close inspection of Fig. 2 will show that each of the structures present can be placed in one of the three general classifications, "{111}", "{110}", or "{100}." It follows then that, with respect to alloy layer formation, the grains of steel in the surface of the substrate can also be grouped into these three general types, according to the structure of the alloy layer formed on them.

Thus, to obtain an understanding of the manner in which the alloy layer grows on commercial tinplate during flow brightening, it was sufficient to study alloy-layer growth on just the three principal faces of iron. The heating conditions were intended to simulate actual heating during flow brightening on an electrolytic tinning line. The melting time of 7 sec was within the range of commercial melting times, yet long enough to give a growth rate sufficiently slow that brief changes in the alloy-layer growth process might be observed. The heating curve obtained with the projection lamp, Fig. 4, did not differ greatly from estimates of the commercial heating curve.

Data for the growth of alloy layers on the {100}, {110}, and {111} faces of iron with these heating conditions are presented in Fig. 5. On the {100} face the alloy layer formed very slowly before the tin coating melted; less than 0.01 lb/bb of alloyed tin was formed in the first 7 sec of heating. After the tin coating melted, the alloy layer grew very rapidly for about 3.5 sec (to 10.5 sec), then the growth rate abruptly

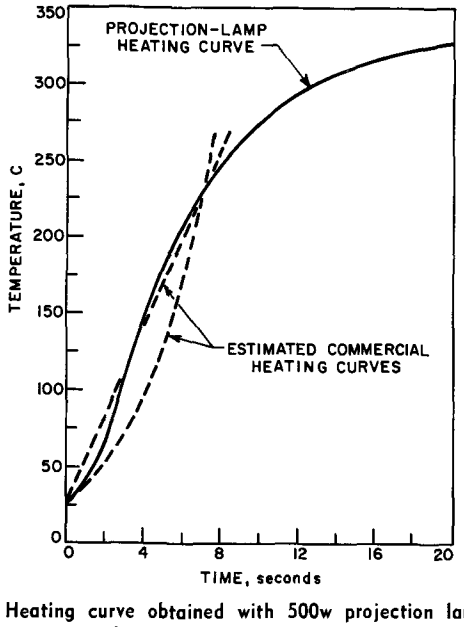

Fig. 4. Heating curve obtained with 500w projection lamp and estimated commercial heating curves.

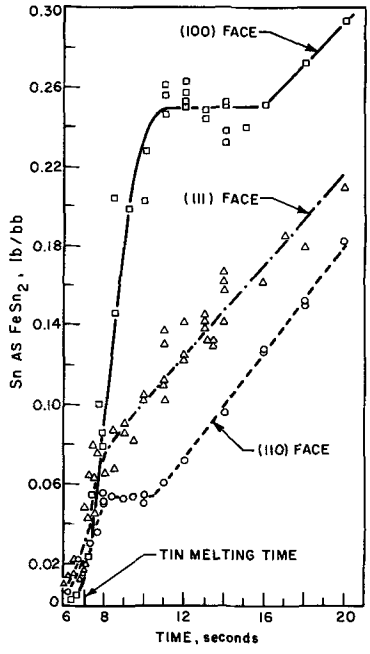

Fig. 5. Alloy-layer growth curves for each of the three principal faces of iron.

decreased, and from about 11 to 16 sec there was no additional alloy-layer growth. Following this arrest, the alloy layer resumed its growth, and from 16 to 20 sec (the extent of the measurements on the single crystals) grew at a uniform rate of about 0.011 lb/bb-sec.

On the {110} face the amount of alloy layer that formed before the tin coating melted was about twice that on the {100} face. However, after the tin coating melted, the {110} face exhibited the smallest over-all growth rate of the three faces. A growth arrest occurred for this face also, but lasted only from 8 to about 11 sec after start of heating. From 12 to 20 sec the alloy layer grew at a uniform rate of about 0.014 lb/bb-sec.

The amount of alloy layer formed on the {111} face before the coating melted was about the same as that on the {110} face. After the tin coating melted, the alloy layer on this face initially grew at a rate intermediate to the rates on the {110} and {100} faces for the same period. There was no growth arrest on this face, although after 8 sec the growth rate decreased. This decrease may have been at least partly due to the general decrease in heating rate after 8 sec. From 9 to 20 sec the alloy layer grew at a uniform rate of about 0.011 lb/bb-sec.

In order to relate changes in the growth rates to changes in the alloy-layer structures, electron micrographs were made of alloy layers at different stages of growth on the three crystal faces. Micrographs for the {100} face are shown in Fig. 6. Before the tin coating melted there were only a few small crystallites on the surface. Obviously the nucleation rate was low on this face. In addition, the nucleation must have occurred within a brief interval because all the crystallites were about the same size and shape. Most of them were arranged at approximately right angles to one another; however, a few were skewed at angles of about 45°. After the tin coating melted, the crystallites at right angles grew rapidly over the surface and produced the approximately orthogonal network that is characteristic of the alloy layer on the {100} face. Meanwhile, the skewed crystallites grew upward at various angles to the surface. Because they projected from the surface, the carbon replica film formed on their undersides as well as on their topsides. Thus, these secondary crystallites can be distinguished easily from the base crystallites in the micrographs because

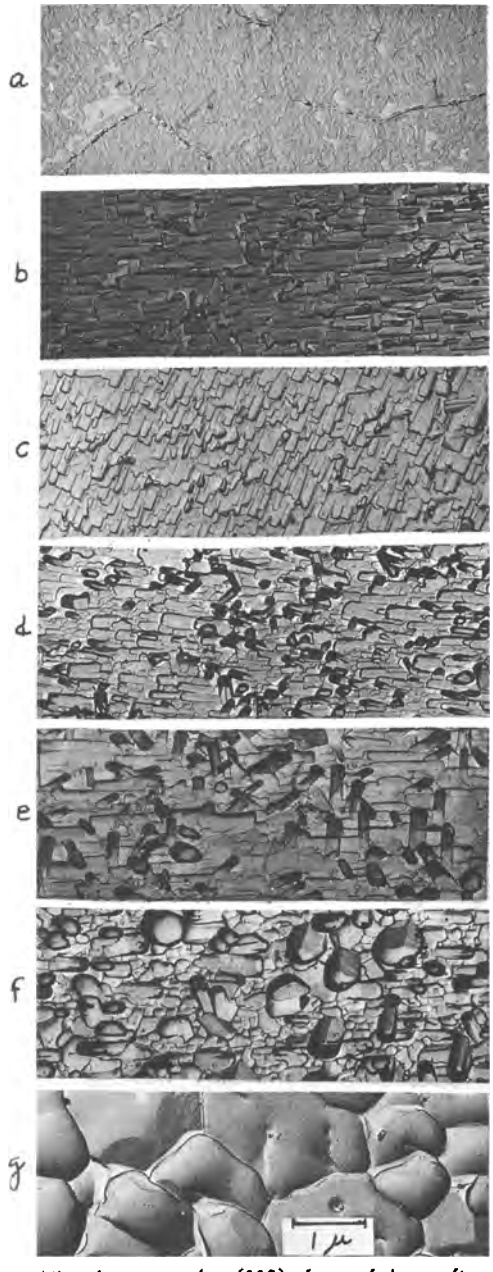

Fig. 7. Alloy layer on the {110} face of iron after various heating times: a, 6.75 sec; b, 7.75 sec; c, 9.5 sec; d, 11.5 sec; e, 13.5 sec; f, 15.0 sec; g, 18.0 sec. Identical magnification for each micrograph.

their ends are darker. The base crystallites gradually impinged upon one another, but even after 10 sec heating, considerable areas of substrate were still exposed. However, shortly afterward numerous small crystallites suddenly formed on these previously unalloyed areas and completed the coverage of the substrate by the alloy layer. This event coincided with the beginning of the growth arrest. During the growth arrest the ends and edges of the crystallites became rounded, but no new alloy was observed. Electron diffraction analysis revealed only $FeSn_2$ before, during, and after the growth arrest. When growth resumed the crystallites coalesced and formed massive particles, some faces of which were flat, while others were rounded. The secondary crystallites were no longer obvious, and the orthogonal relationship of the base crystallites was not as pronounced as it was in the early stages of growth.

The micrographs of the alloy layers on the {110} face are shown in Fig. 7. The nucleation rate on this face was much higher than that on the {100} face. Before the tin coating melted, there were many small crystallites of $FeSn_2$ on the surface; however, they did not cover the substrate completely. After the tin coating melted, the small crystallites formed larger columnar crystallites that were, in general, parallel to one another on the surface. In addition, secondary crystallites started to form on the base crystallites. Small areas of substrate remained exposed until the growth arrest began, but they were not observed thereafter. Thus, it appears that on the {110} face, as on the {100} face, the start of the growth arrest coincides with the disappearance of exposed substrate. During the growth arrest there was no appreciable change in the alloy-layer structure. Again electron-diffraction analysis showed only $FeSn_2$ before, during, and after the arrest. For a short while after the arrest, the secondary crystallites increased appreciably in size and thereby became the prominent feature of the

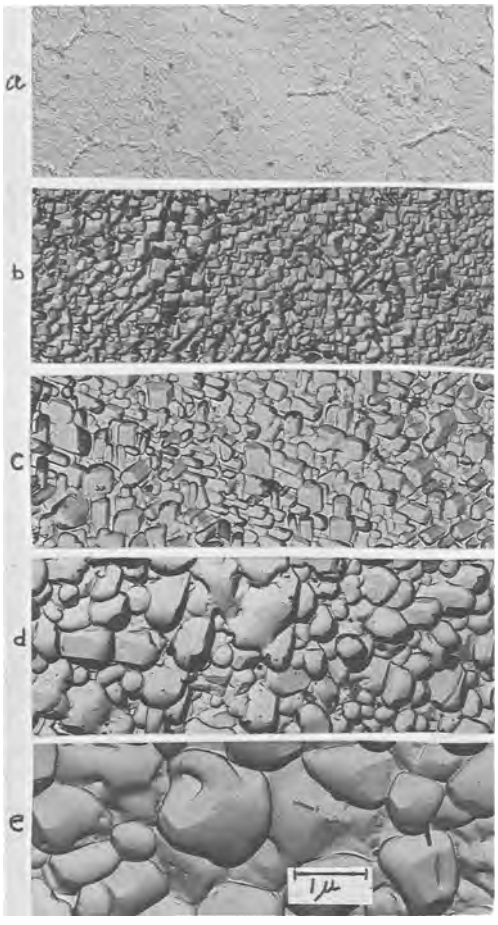

Fig. 8. Alloy layer on the {111} face of iron after various heating times: a, 6.75 sec; b, 8.0 sec; c, 11.0 sec; d, 14.0 sec; e, 18.0 sec. Identical magnification for each micrograph.

layer. However, with further heating the crystallites coalesced and formed massive rounded particles.

The electron micrographs of the alloy layers formed on the {111} face are shown in Fig. 8. Before the tin coating melted the base metal was completely covered with small crystallites of $FeSn_2$. After the coating melted, the small crystallites formed columnar crystallites that protruded from the surface at various angles. They grew together continuously and eventually formed massive rounded particles. In the later portion of the heating period the structure of the alloy layer on the {111} face was similar to that on the {110} face.

Discussion

The reader's attention is directed to the micrographs of the alloy layers on the {110} and {111} faces prior to melting of the tin coating, Fig. 7a and 8a. Certain of the crystallites in these micrographs are raised appreciably above the other crystallites on the surface. These crystallites, some of which are marked by arrows, delineate the grain boundaries of the matte tin deposit.[1] The grain boundaries of the matte tin deposit extended upward, away from the surface of the iron single crystal. The alloy crystallites grew upward along these grain boundaries. Because of the more favorable diffusion conditions at the grain boundaries, these crystallites were able to grow faster than those on other parts of the substrate surface. It is reasonable to expect that this upward growth of the alloy crystallites resulted from the combination of tin atoms at the upper extremities of the crystallites with iron atoms that had diffused upward from the substrate. Thus, the presence of these "grain boundaries" in the alloy layer is evidence that alloy-layer growth depends mainly on diffusion of the iron atoms.

In the early stages of growth, shortly after nucleation, both slow and rapid diffusion paths should be available for this iron-atom movement. The slow diffusion paths will be through the lattices of the crystallites, and the rapid diffusion paths will be along the surfaces of the substrate and the crystallites. When the crystallites impinge and completely cover the iron substrate, the paths of rapid diffusion between the substrate and the growing alloy surface(s) are closed off. This causes the growth rate to decrease to a value indicative of the lattice diffusion alone. But the results for the {100} and {110} faces show that when the coverage is completed the growth rate drops to zero. Thus it must be concluded that lattice diffusion did not contribute significantly to the alloy-layer growth. If lattice diffusion had contributed significantly, it would have continued to do so after surface diffusion ceased and the decreased growth rate would have been greater than zero. [A similar situation has been observed in the oxidation of magnesium where the initial layer of oxide apparently forms only by surface diffusion (6)].

A further indication of the insignificance of lattice diffusion is given by the fact that in the later portion of the heating period each crystal face exhibited the same alloy-layer growth rate even though the amount of alloy on each face was substantially different. If lattice diffusion were significant, the instantaneous growth rate on the {100} face would have been much smaller than that on the {110} face because the iron atoms would have had to diffuse through a much greater thickness of alloy to reach the growing surface.

The results of this study provide a reasonably clear understanding of the growth of the alloy layer during rapid heating as in commercial flow brightening. The alloy crystallites are nucleated at specific sites on the steel surface. The nature of these sites is unknown, but it is obvious that they differ in number for the different crystal faces of iron. When the nucleation rate is low, as on those faces that form a "{100}"-like alloy-layer structure, the individual crystallites are widely separated and must grow considerable distances over the surface before they can impinge. Because the crystallites thicken as they grow laterally, a relatively large amount of alloy has been formed when the crystallites finally impinge and completely cover the substrate. The elimination of the surface diffusion paths as a result of the impingement causes the growth to cease. In order for the alloy layer to resume its growth, the iron atoms must find new paths to the extremities of the crystallites. The growth arrest that follows completion of coverage of the substrate is believed to represent the time required to establish these new paths. Because lattice diffusion is apparently insignificant, these new paths are probably formed at "grain" boundaries in the alloy layer. The rounding of the edges of the crystallites during the arrest could be part of the process of establishing these new paths. The flow of atoms along these new diffusion paths should be slower than along the surface diffusion paths. Thus the growth rate after the arrest will be slower than that prior to the arrest.

When the nucleation rate is high, as on the {110} face, the crystallites have a shorter distance to grow laterally before they impinge. Thus the completion of coverage of the substrate, and therefore the growth arrest, occurs sooner than on the {100} face. Furthermore the total amount of alloy layer at the time of the growth arrest will be less than that on the {100} face.

When the nucleation rate is very high, as on the {111} face, the alloy crystallites completely cover the substrate shortly after nucleation, early in the heating period. Presumably a growth arrest occurs at this time, but is not observable because the amount of alloy

[1] The electrodeposited tin coatings were polycrystalline despite the single crystal substrates. No epitaxy was observed between the tin deposit and the substrate.

layer is below the limit of detection of the analytical method. This is in accord with the trend shown by the {100} and {110} faces where with increasing nucleation rate, the time of heating before the arrest and the amount of alloy formed at the time of the arrest decrease. After the tin coating melts, the alloy layer grows without interruption presumably by diffusion along paths established after the arrest.

Some investigators have been interested in studying the effects of processing variations on iron-tin alloy layer structure with the goal of increasing the coverage of the steel base and thereby possibly increasing the corrosion resistance of the tinplate. These studies are usually made with polycrystalline steel substrates. Thus all three types of alloy layer structure ({100}, {110}, and {111}) are likely to be encountered. Care must be taken in drawing conclusions from such studies so that changes in alloy layer structure due to differences in the underlying steel grain orientations are not incorrectly attributed to processing changes. It should also be noted that with normal processing, complete coverage of the {100}-type steel grains can be achieved if the heating during flow brightening is continued until the onset of the {100} growth arrest.

In a recent paper (7) it was shown that the growth rates of iron-tin alloy layers on polycrystalline substrates are greatly affected by the heating rate. With rapid heating rates (room temperature to 232°C in 10 sec or less) there is a marked growth arrest; with slow heating rates (room temperature to 232°C in about 50 sec) the arrest is not observed. These observations can now be explained in terms of the results of the present study. Alloy-layer growth curves were determined for two different lots of matte tinplate with the same heating conditions as those used for the single crystals, Fig. 9. For these particular steels two growth arrests were observed. The first arrest occurred after about 8 sec of heating and the second occurred after about 10 sec of heating. Comparison with the growth curves for single crystals shows that the first arrest was obviously due to the {110}-type grains on the steel surface and the second arrest was obviously due to the {100}-type steel grains. It will be noted that the amount of alloy layer at any given time of heating was somewhat different for the two tinplates. This is not surprising when one considers the markedly different growth rates on the {100}, {110}, and {111} faces and the fact that different steels will have somewhat different ratios of {100}, {110}, and {111}-type grains on their surfaces. The {110} arrest is not always observed. It will be absent from the growth curve if the time interval between measurements is too long or if the steel has a small number of {110}-type grains. Thus in the previously reported growth curves for rapid heating rates, only one arrest, that due to the {100}-type steel grains was observed.

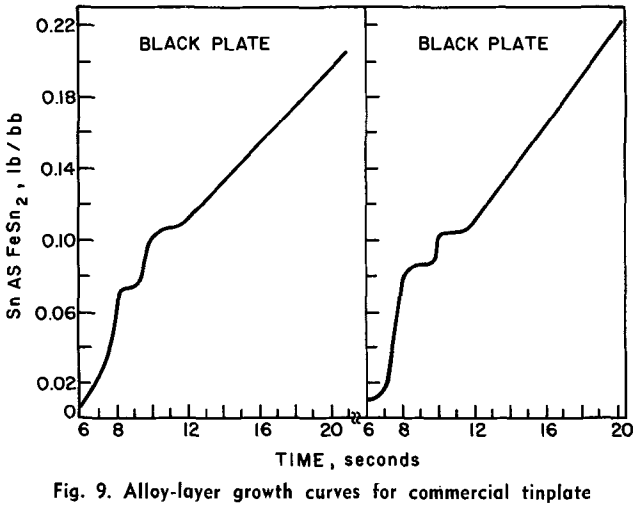

Fig. 9. Alloy-layer growth curves for commercial tinplate

The disappearance of this {100} growth arrest was due to a change in the growth behavior on the {100} grains as the heating rate was reduced. To understand how this change was effected, it is necessary to consider the alloy-layer growth on these grains in greater detail. Close examination of the sizes of the crystallites in Fig. 6a and b will show that before the tin coating melts lateral growth of the crystallites is favored over outward growth, but after the coating melts the reverse is true. With a rapid heating rate the coating melts before there is much lateral growth. Because there are relatively few crystallites on the {100} face they make considerable outward growth before their lateral growth causes them to impinge. Therefore the alloy layer on the {100}-type steel grains is relatively thick when it completes coverage of the base metal. The completion of base metal coverage marks the onset of the growth arrest. Because, as the single crystal data of Fig. 5 show, the amount of alloy on these grains is much greater than that on the {110}- and {111}-type steel grains, the alloy-layer growth curve for the tinplate for this period in the heating mainly reflects the growth on the {100}-type grains. Thus the {100} growth arrest is very pronounced in the alloy-layer growth curve for the tinplate.

As the heating rate is decreased there is an increase in the amount of lateral growth that occurs before the coating melts. When the heating rate is decreased sufficiently the {100}-type grains are completely covered by the alloy layer when the coating melts or shortly thereafter. However, the amount of alloy is relatively small because the outward growth of the crystallites was not favored and because, as the single crystal data show, the growth rate on the {100} face before the coating melts is less than that on the {110} and {111} faces. These considerations are illustrated by Fig. 10. This alloy layer was formed by slowly heating a {100} single crystal for 60 sec. The tin coating melted just at the end of the heating period. The substrate is almost completely covered, but the amount of alloy is only 0.025 lb/bb. (This alloy layer should be compared to that in Fig. 6c which was formed by rapid heating. The latter alloy layer provides much less substrate coverage even though the amount of alloy is about 0.23 lb/bb.) Thus with a slow heating rate the contribution of the {100}-type grains to the alloy layer growth data is much less than that when the tinplate is rapidly heated. Therefore, with a slow heating rate, the {100} growth arrest is not observed in the alloy-layer growth curve for tinplate.

An interesting observation concerning substrate surface preparation was made in the course of this study. We wanted to determine whether the same alloy-layer structures would result when a method of surface preparation other than mechanical polishing and etching was used. The single crystal sections were electropolished in a mixture of 15% perchloric acid and 85% acetic acid, rinsed with methanol, and electroplated with tin. Extensive rinsing with methanol prior to plating was necessary to obtain uniform matte deposits. The alloy layers that were subsequently formed had the same general morphologies as those observed

Fig. 10. Alloy layer on the {100} face of iron formed by slowly heating the single crystal for 60 sec.

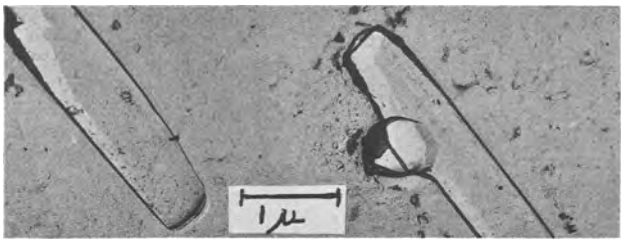

Fig. 11. Alloy layer on electropolished {100} face of iron

on the mechanically polished and etched surfaces; however, the alloy layer on the {100} face was always much less continuous. Even though the surface was rinsed sufficiently to give a uniform matte deposit, something remained on the surface and acted as a barrier to the nucleation of alloy crystallites. This effect was only observed for the {100} face. An example is shown in Fig. 11. (This micrograph was made with a different replication technique and for this reason is not of the same quality as the other micrographs.) A similar obstruction of $FeSn_2$ crystallite growth on the {100} face was observed by Luner and Murray for vacuum-deposited tin coatings (8).

Summary

It has been shown that the iron-tin alloy layers on commercial tinplate have three basic structures. These occur on the {100}, {110}, and {111} faces of iron. The rate and manner of growth of the alloy layer on each of these faces has been studied for a heating rate that simulated commercial flow brightening. The results of this study provide an understanding of the manner in which the alloy layer grows on tinplate. With this heating rate, before the tin coating melts, the alloy layer completely covers the {111} face, and almost completely covers the {110} face, but provides very little coverage on the {100} face. At the time of melting the amount of alloy on the {111} and {110} faces is about twice that on the {100} face. Immediately after melting the alloy layer on the {111} face grows at a rate which is faster than that on the {110} face, but slower than that on the {100} face. The {110} and {100} faces both exhibit growth arrests; that on the {100} face occurs later and lasts longer than that on the {110} face. The growth arrest on each face coincides with completion of base-metal coverage by the alloy layer on that face. It is believed that the duration of the growth arrest represents the time necessary to establish new diffusion paths for continued growth of the alloy layer.

Evidence is presented which shows that the alloy-layer growth depends on the diffusion of iron atoms from the substrate.

Oxidation of Silicon at High Temperatures and Low Pressure under Flow Conditions and the Vapor Pressure of Silicon

Earl A. Gulbransen, Kenneth F. Andrew, and Fred A. Brassart

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Wagner has predicted from thermochemical and diffusion theory analyses that silicon may react actively or passively with oxygen at high temperature depending on the oxygen pressure. To determine the characteristics of the oxidation reaction for these reaction conditions, a kinetic study was made at temperatures between 1100° and 1300°C and pressures of 9×10^{-3}, 4×10^{-2}, and 1×10^{-1} Torr using a dynamic reaction system. Very fast reactions were found where predicted. The results were also related to (*i*) kinetic theory reaction efficiencies and (*ii*) gas flow efficiencies. Vapor pressure studies were made using the Langmuir method.

The oxidation behavior of high-purity silicon has been studied extensively under conditions where protective oxides are formed (1-7). In low-pressure oxygen atmospheres, silicon can form a volatile oxide above 1000°C. For these conditions, silicon may oxidize at a rapid rate. Wagner (8) has discussed the transition from active to passive oxidation for oxidation of silicon in inert gas atmospheres containing low partial pressures of oxygen.

This paper reports a kinetic study on the oxidation of silicon in low-pressure pure oxygen atmospheres under flow conditions in the temperature range of 1100°-1300°C.

Thermochemical Analyses

Table I shows the four reactions which occur in the silicon-oxygen system and the values of the equilibrium constants for the reactions. Both SiO(g) and SiO_2(s) can form. SiO_2(s) does not appreciably dissociate to SiO(g) in oxygen atmospheres of 9×10^{-3} Torr at temperatures below the mp of silicon, 1420°C. The solid phase reaction of Si(s) with SiO_2(s) can proceed in atmospheres of low pressures of SiO(g). The reverse reaction can proceed in high-pressure atmospheres of SiO(g).

Silicon is especially sensitive to reactions with gases containing carbon under conditions where a SiO_2(s) film is absent.

Experimental

The apparatus and method have been described (10). A Cahn type of microbalance (11) was used to follow the rate of oxidation in a dynamic type of reaction system. The rate of oxidation was followed

Table I. Thermochemical analyses of reactions in silicon-oxygen system

Reactions	Equilibrium constants (log K_p) (9) 927°-1527°C			
	927°	1127°	1327°	1527°
[1] $Si(s) + \frac{1}{2}O_2(g) \rightleftarrows SiO(g)$	8.397	8.222	7.707	7.201
[2] $Si(s) + O_2(g) \rightleftarrows SiO_2(s)$	30.26	24.65	20.45	17.10
[3] $\frac{1}{2}Si(s) + \frac{1}{2}SiO_2(s) \rightleftarrows SiO(g)$	−6.333	−4.106	−2.520	−1.347
[4] $SiO_2(s) \rightleftarrows SiO(g) + \frac{1}{2}O_2(g)$	−21.37	−16.43	−12.75	−9.90

continuously at constant pressure and temperature under controlled gas flow conditions. Gas flow velocities up to 53.5 meters/sec were used.

The reaction system consisted of a high-density alumina furnace tube 2 cm in diameter attached to the system by a Viton O-ring. The furnace tube was pretreated by baking in oxygen at 1500°C to remove any residual carbon gases and carbonaceous material so as to prevent the formation of SiC films on the silicon surface.

P-type semiconductor grade of silicon having a resistivity of 425 ohm-cm and a boron content of 10^{16} atoms/cm^3 was used. The single crystal silicon strip was 0.025-0.030 cm thick and 1 cm wide and had the (111) crystal plane in the surface. Pieces 0.5 cm wide were prepared by scribing and cracking, and a 0.075 cm diameter hole was drilled by cavitation to support the specimen. A 0.06 cm quartz fiber was used to support the specimen from the balance.

Reagent grade oxygen was used. The incoming and exit gases were checked by a mass spectrometer to aid in detecting contaminants which could form SiC(s) films.

Results and Discussion

The experimental work was divided in three sections: (*a*) the weight losses of silicon in vacuum at temperatures of 1100°-1350°C; (*b*) the reaction of silicon with low-pressure high-purity oxygen under flow conditions; and (*c*) the effect of contaminating gases on the oxidation of silicon in flow environments.

Vapor pressure of silicon.—To test the cleanliness of our silicon surfaces we have made vapor pressure measurements. If the surfaces are free from $SiO_2(s)$ and SiC(s) films, reasonable vapor pressure data should be measured.

The specimens were cleaned and pretreated at 1300°C in vacuum before starting the vaporization experiments. Several series of weight loss curves were made at temperatures of 1100°-1350°C. Typical weight loss data are given in Table II in units of g/cm^2-sec. Assuming the weight loss curves are due to the volatilization of silicon, the vapor pressures can be evaluated from the Langmuir equation (12)

$$\frac{dw'}{dt} = \alpha P \left(\frac{M}{2\pi RT} \right)^{1/2} \qquad [5]$$

Here M is the molecular weight of the evaporating species, T is the absolute temperature, dw'/dt is the rate of evaporation in g/cm^2-sec, and α is the condensation coefficient.

Table II. Rate of vaporization, vapor pressure, and heats of sublimation

Temp, °C	Rate, g/cm^2-sec × 10^7	−log P, atm	$\Delta H°_{298.15}$, kcal/mole
1100	3.76 × 10^{-2}	−9.20	106.15
1150	9.86 × 10^{-2}	−8.80	107.39
1150	9.63 × 10^{-2}	−8.81	107.46
1200	4.34 × 10^{-1}	−8.15	106.73
1200	4.36 × 10^{-1}	−8.15	106.73
1250	1.10	−7.74	107.46
1250	1.15	−7.72	107.32
1300	2.76	−7.33	107.96
1300	3.36	−7.24	107.32
1350	14.1	−6.61	105.98

Mean $\Delta H°_{298.15} = 107.1 \pm 0.6$

Table II and Fig. 1 show the calculated vapor pressure values assuming monatomic silicon and $\alpha = 1$. Figure 1 also includes the values given by the JANAF tables (9). An evaluation is made in these tables of the earlier data.

Table II shows the calculated values for the heats of sublimation $\Delta H°_{298.15}$ using the equation.

$$\frac{\Delta H°_{298.15}}{T} = -R \ln p - \left(\frac{F° - H°_{298.15}}{T} \right)_{gas} + \left(\frac{F° - H°_{298.15}}{T} \right)_{solid} \qquad [6]$$

where $(F° - H°_{298.15}/T)_{gas}$ and $(F° - H°_{298.15}/T)_{solid}$ are the free energy functions of the gas and solid, respectively. The mean value of $\Delta H°_{298.15}$ is 107.1 ± 0.6 kcal/mole and may be compared with an averaged value of 106.0 kcal/mole given in the JANAF tables (9).

The vapor pressure data given in Fig. 1 suggests that silicon is volatilizing from clean surfaces.

Low-pressure oxidation studies.—Rates of oxidation were determined on cleaned samples of silicon. All samples were pretreated at 1300°C for 15 min at 5 x 10^{-6} Torr. Three pressures 9 x 10^{-3}, 4 x 10^{-2}, and 1 x 10^{-1} Torr and three temperatures 1100°, 1200°, and 1300°C were used. The oxygen flow rates varied due to experimental difficulties in controlling the reaction pressure manually.

Linear weight loss curves were obtained in all of the experiments except in the 1100°C and 0.1 Torr experiment. The experimental weight change *vs.* time curves for 1100°C are shown in Fig. 2. At 1 x 10^{-1} Torr pressure, a small weight gain was found indicating a protective oxide was formed. At 9 x 10^{-3} and 4 x 10^{-2} Torr, weight loss curves were found indicating SiO(g) was formed. The experimental weight

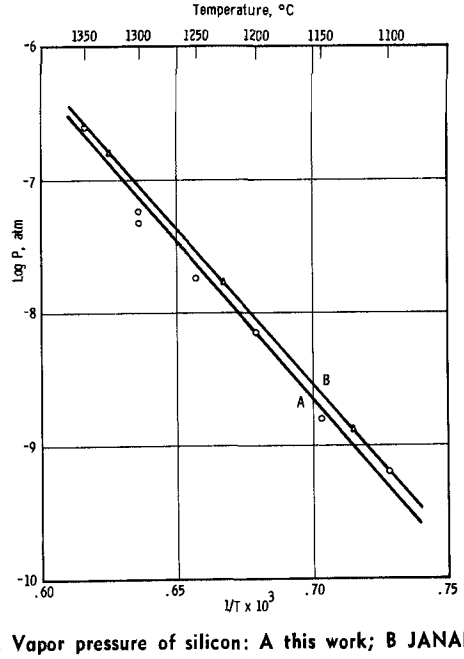

Fig. 1. Vapor pressure of silicon: A this work; B JANAF tables; December 31, 1962.

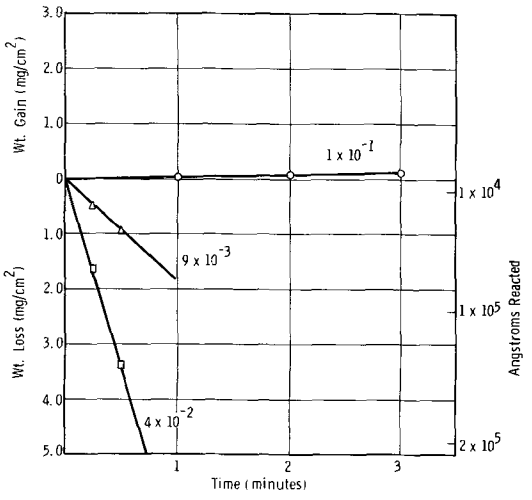

Fig. 2. Weight *vs.* time, oxidation of high-purity silicon, 1100°C, 9 x 10^{-3}, 4 x 10^{-2}, 1 x 10^{-1} Torr, flow conditions.

change *vs.* time curves at 1200° and 1300°C showed weight losses for the three pressures.

Table III shows the rates of oxidation in units of grams per second, atoms of Si reacted per second, and atoms of Si reacted per cm²-sec. Temperature was found to have no important effect on the observed rates of oxidation at a given pressure. Pressure and gas flow were the important factors in the determination of the rates of oxidation.

Figure 3 shows a log rate of oxidation *vs.* log flow rate plot of all of the data. The rate data at 9 x 10^{-3} Torr and 4 x 10^{-2} Torr show the rates of oxidation to be a nearly linear function of the flow rate and independent of temperature. Above 4 x 10^{-2} Torr pressure, the rate data fall from the linear dependence relation.

A plot of the log rate of oxidation *vs.* log of pressure also shows a nearly linear dependence. Since the flow rate is also a function of the pressure, it is difficult to separate the flow and pressure variables.

We conclude that the observed rates of oxidation, in our experiments, are a function mainly of the pressure and gas flow. This suggests that the access of oxygen to the surface is the rate-limiting factor in the reaction for these conditions.

We have evaluated the kinetic theory efficiencies using the collision rate of oxygen molecules, n, with a surface given by the equation

$$n = 3.5 \times 10^{22} \frac{P}{(MT)^{1/2}} \qquad [7]$$

Here P is the pressure in Torr and M is the molecular weight of oxygen molecules. Assuming 2 silicon atoms are reacted for each oxygen molecule, we calculate a kinetic theory efficiency of 8.7, 9.1, and 10.3% for the 9 x 10^{-3}, 4 x 10^{-2}, and 1 x 10^{-1} Torr experiments at 1300°C. These are very large numbers considering

the fact that the rate of oxidation is still limited by gas flow. This suggests a very low heat of activation for the chemical processes involved in the reaction mechanism. These processes include adsorption, chemical reaction and desorption.

Table IV shows the results of calculations on the flow efficiencies, the actual gas flow in cubic centimeters per second, and the gas velocity at temperature. The flow efficiency, E, was given by the equation

$$E = \frac{2(dn/dt)}{F} \times 100 \qquad [8]$$

Here we assume SiO(g) was formed at the silicon surface and that SiO(g) was further oxidized in the gas phase or on the furnace tube surfaces to SiO_2(s). Two atoms of oxygen were required per silicon atom. dn/dt was the actual rate of silicon reacting per second and F was the flow rate in atoms of O per sec.

Table IV shows the flow efficiency calculations for the several temperatures and pressures. Flow efficiencies up to 73.8% were calculated. The gas velocities were calculated before reaching the reaction zone in the furnace tube.

We now need to explain why silicon reacts with oxygen at 1100°C and 4 x 10^{-2} Torr to lose weight while above 1 x 10^{-1} Torr, the sample gains weight. This is due to the formation of a SiO_2(s) film at the higher pressure which protects the surface from the fast type of reaction. SiO(g) formed by reaction [1] can act to reverse reaction [3] to form a SiO_2(s) film.

We suggest that the oxidation conditions of 1100°C and 1 x 10^{-1} Torr are conditions where a stable silica film can form.

Effect of contaminants.—The rates of oxidation of silicon at low oxygen pressures and at temperatures of 1100°-1300°C are very sensitive to the formation of silicon carbide films. This phenomenon was noticed when tank oxygen was used as the reaction gas and when the alumina furnace tubes were not sufficiently treated at high temperature with oxygen to remove

Table IV. Flow efficiencies and gas velocities, low-pressure oxidation of silicon

P, Torr	Temp, °C	Flow, atom O/sec	dn/dt, atoms Si/sec	Flow eff., %	Flow, cc/sec	Gas velocity, cm/sec

* Weight gain.

gases containing carbon and contaminants. Transparent oxidation resistant films were formed on the silicon specimens.

Electron diffraction studies were made on films formed at 1100° and 1300°C, which were of the order of 1μ thick, using 250 kv electrons to penetrate the film. The electron diffraction patterns were compared to patterns from films formed on silicon when reacted with carbon dioxide, to patterns of crystals of synthetic α-SiC_{II}, and to x-ray diffraction data on α-SiC_{II}, 6 H Polytype. These studies showed that the film formed in tank oxygen using improperly pretreated furnace tubes at 1300°C was α-SiC_{II}.

We conclude that for certain low-pressure oxygen atmospheres at 1300°C, CO_2 and other contaminants form α-SiC_{II} on a silicon surface. The α-SiC_{II} reacts with oxygen but at a slower rate than the rate of formation of α-SiC_{II}. The net result is the formation of an α-SiC_{II} film.

Discussion.—Wagner (8) has treated the gas diffusion controlled oxidation process of silicon in an inert gas at low partial pressures of oxygen. Oxygen diffuses through the boundary layer to the silicon interface and SiO gas diffuses away from the surface through the same boundary layer. Wagner gives the following equation for the maximum oxygen pressure under which a bare silicon surface can exist.

$$p_{O_2(max)} = \frac{1}{2} (D_{SiO}/D_{O_2})^{1/2} p_{SiO(eq)} \qquad [9]$$

Here $p_{SiO(eq)}$ is the equilibrium pressure of SiO(g) from Eq. [3]. D_{SiO}/D_{O_2} is the ratio of diffusion constants for SiO(g) and O_2 in the boundary layer and depends on the characteristics of the boundary layer. Wagner estimates the ratio of D_{SiO}/D_{O_2} to be 0.64.

A similar analysis can be made for the reaction of silicon in low-pressure pure oxygen atmospheres under flow conditions. The thickness and the chemical composition of the boundary layer will be different. However, the ratio of diffusion coefficients can be assumed to be the same.

Assuming Wagner's equation can be applied to the transition conditions for active and passive oxidation, the following values of $p_{O_2(max)}$ were calculated from Eq. [9] and the equilibrium value of $p_{(SiO)}$. At 1100°C, $p_{O_2(max)} = 1.2 \times 10^{-2}$ Torr. At 1200°C, $p_{O_2(max)} = 8.8 \times 10^{-2}$ Torr and at 1300°C, $p_{O_2(max)} = 0.56$ Torr.

Experimentally we found that the maximum oxygen pressure at 1100°C for the formation of a silica film is between 4×10^{-2} and 1×10^{-1} Torr. This compares to a value of 1.2×10^{-2} Torr calculated from Eq. [9]. Gas flow may have an important effect in raising the maximum oxygen pressure to maintain fast oxidation reactions on bare silicon surfaces.

Summary and Conclusions

Kinetic studies show silicon loses weight when reacted with low-pressure oxygen environments of 9×10^{-3} and 4×10^{-2} Torr. For these conditions silicon reacted to form volatile silicon monoxide. Any silica which may form was reduced by silicon to form volatile silicon monoxide. Very fast oxidation rates were found. At 10^{-1} Torr and 1200°C, an oxidation rate of 3.7×10^{18} silicon atoms per cm^2-second was observed. This was 7100Å of silicon reacting per second. The rates of oxidation were nearly independent of temperature, but were a linear function of gas flow or pressure. Flow efficiencies of over 70% were found for the 9×10^{-3} Torr pressure runs.

Several conclusions were made from the kinetic studies. (*A*) Gas diffusion processes were rate controlling for the conditions of the reaction; (*B*) silicon reacted completely with oxygen under the conditions with only trace amounts of silica as residues; (*C*) Maximum oxygen pressure for maintaining oxide free surfaces were increased by the imposition of flow on the reaction; (*D*) Extreme care must be used to avoid contamination of the gas source or system with gases containing carbon; (*E*) the rate of oxidation was a direct function of flow or gas pressure.

Manuscript received July 2, 1965; revised manuscript received April 15, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965. The work described here was supported in part by the U. S. Army Research Office, Durham, North Carolina.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Studies of the Electrochemical Kinetics of Indium

III. Systems In + $InCl_3$ and In + Combined Sulfate-Chloride Electrolyte

V. Markovac[1] and B. Lovrecek

Institute of Electrochemistry and Electrochemical Technology,

Faculty of Technology, University of Zagreb, Zagreb, Yugoslavia

ABSTRACT

In previous papers the kinetics of the deposition and dissolution of indium in indium sulfate solutions at *p*H 2.5 had been studied by a galvanostatic method of single current pulses. Continuing this work and using a similar experimental technique, kinetics of the deposition and dissolution of indium in indium chloride and combined indium sulfate-chloride solutions at *p*H 2.5 have been studied. The analysis of experimental data obtained by polarization in indium chloride solutions indicates that in the wide range of c.d.'s up to 1.0×10^{-1} amp/cm^2 the cathodic and anodic processes occur near the equilibrium potential. When the c.d.'s are higher, it was found that the first cathodic reaction step is rate-determining, and that during anodic polarization disproportionation reactions probably take place.

The curves η_A-$\log_{10} i$ obtained by cathodic polarization in the combined sulfate-chloride solutions show steep increases in the overvoltage of ca 400 mv, at certain characteristic c.d.'s, depending on the concentration of chloride in the solutions. It is concluded that in the range of c.d.'s before the steep increases, deposition of indium occurs by analogous mechanism as in the pure chloride medium. In the range after the steep increases, deposition of indium occurs as in the pure sulfate medium. The mechanism of this rapid change in the deposition of indium is discussed. From the analysis of the results of the anodic polarization in the combined electrolytes, it follows, that the third reaction step is rate-determining in accordance with the observations for the pure sulfate and chloride solutions.

This paper is a continuation of the study of electrochemical kinetics of indium in indium + indium sulfate system over a wide range of c.d.'s published in previous papers (1, 2). Now we have studied the mechanism of electrochemical deposition and dissolution of indium in pure chloride electrolyte and in combined sulfate-chloride electrolyte. For the analysis of the experimental data, the expressions for kinetics of "many step" electrode reactions were used (3).

Experimental

Apparatus for cathodic and anodic polarization of indium (as 0.3% indium analgam) consisting of an electrolytical cell with air thermostat, nitrogen purification unit and electrical device, was essentially the same as described (1, 2). The exception was an electrical device for supplying galvanostatic single pulses, used mostly in this work. In this case a rectangular wave pulse generator was used. The generator was constructed on the resistance basis, with a built-in Western Electric D171584 relay for triggering both the pulse and the time sweep of a cathode-ray oscilloscope. A Hewlett-Packard H15-130B oscilloscope with the bandwidth d.c. to 300 kc, and the sensitivity 1 mv/cm to 125 v/cm in 15 ranges, was used. On the oscilloscope a built in front panel switch permitted single sweep operation.

Polarization was carried out in the following electrolytes: 0.116*N* $InCl_3$ + 0.5*N* KCl, *p*H 2.5; 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 + 0.05*N* KCl, *p*H 2.5; 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 + 0.075*N* KCl *p*H 2.5. Chemicals used were of analytical reagent grade, and water was redistilled.

Experimental procedure and obtaining both the $\eta_t - t$ curves and the activation overpotentials η_A were carried out in the same way as previously described (1).

Results

Activation overpotential-current density relationship for chloride electrolytes.—When the values of activation overpotential η_A (obtained by subtraction of the ohmic overpotential from the experimental steady-state potential) were plotted against the logarithms of c.d. $\log_{10} i$, the curves for cathodic and anodic polarization in pure chloride solutions were obtained (Fig. 1). Both curves show linear relations in the range of the higher c.d.'s for the cathodic polarization at $1.7 \times 10^{-1} - 3.5 \times 10^{-1}$ amp/cm^2, and at $2.2 \times 10^{-1} - 4.5 \times 10^{-1}$ amp/cm^2 for the anodic one.

Double-wave $\eta_t - t$ curves at cathodic polarization in combined sulfate-chloride electrolytes.—As was shown in a previous paper (1) experimentally obtained $\eta_t - t$ curves for cathodic and anodic polarization reach the steady-state potentials and are represented with a single wave. That was at all measuring points in all electrolytes except at cathodic polarization in combined sulfate-chloride electrolytes. At cathodic polarization in solutions containing both sulfate and chloride the curves $\eta_t - t$ with two waves

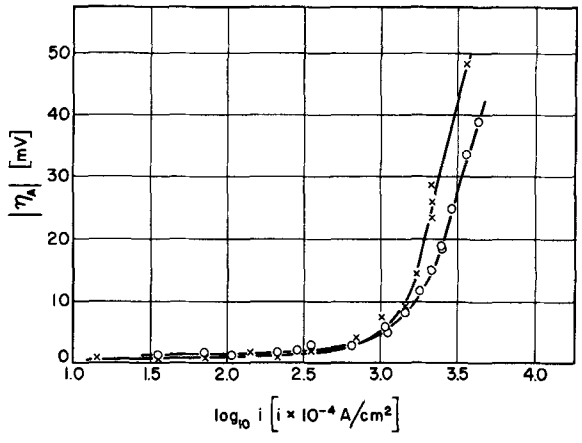

Fig. 1. η_A-$\log_{10} i$ curves for cathodic and anodic polarization. Electrolyte, 0.116*N* $InCl_3$ + 0.5*N* KCl; *p*H = 2:5; × cathodic; ○ anodic polarization.

[1] Present address: Scientific Research Staff, Ford Motor Company, Dearborn, Michigan.

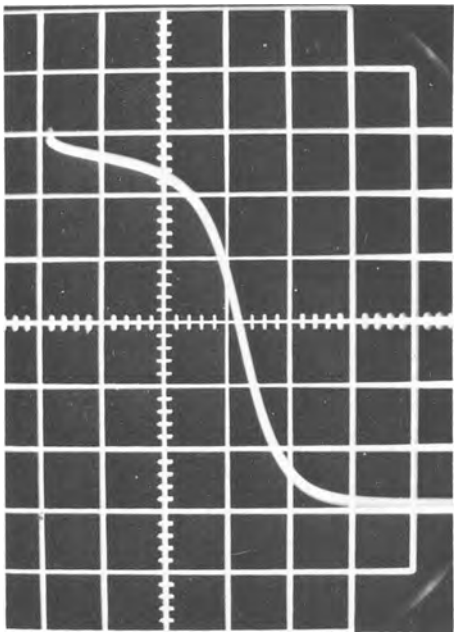

Fig. 2. Oscillogram of η_t-t double-wave curve for cathodic c.d. 5.97×10^{-3} amp/cm^2; sensitivity, 100 mv/cm; sweep time, 2 msec/cm; electrolyte, 0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4 + 0.075N KCl; pH = 2.5.

were observed on the screen of the oscilloscope (Fig. 2) in the very narrow regions of c.d.'s depending on the concentration of chloride in the solutions. With slightly lower c.d. only a single-wave $\eta_t - t$ curve was obtained, similar to those obtained in the pure chloride solutions. With slightly higher c.d. than that characteristic for the appearance of a double-wave curve, also a single-wave curve was observed, but similar to those from pure sulfate solutions. On changing the oscilloscope sweep rate it was possible to record the first and second wave just as the double-wave curve, only in the very narrow regions of c.d.'s.

Activation overpotential-current density relationship for combined sulfate-chloride electrolytes.—Experimentally obtained $\eta_A - \log_{10} i$ curves for cathodic polarization of indium in combined sulfate-chloride solutions show very rapid increases for about 400 mv (Fig. 3). For the electrolyte with 0.05N KCl, a rapid increase appears at c.d. of 3.0×10^{-3} amp/cm^2, but for the electrolyte with the higher concentration of chloride (0.075N KCl) the rapid increase is shifted to the region of higher c.d.'s and appears at 6.0×10^{-3} amp/cm^2. Before and after these rapid increases both curves show similar shapes forming the Tafel-linear relations.

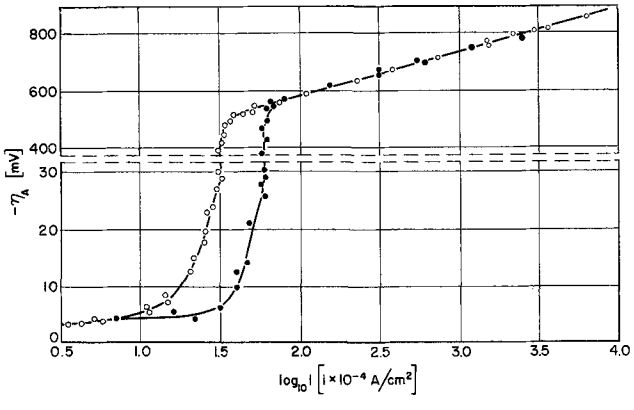

Fig. 3. η_A-$\log_{10} i$ curves for cathodic polarization. ○ electrolyte 0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4 + 0.05N KCl; pH = 2.5. ●, electrolyte: 0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4 + 0.075N KCl; pH = 2.5.

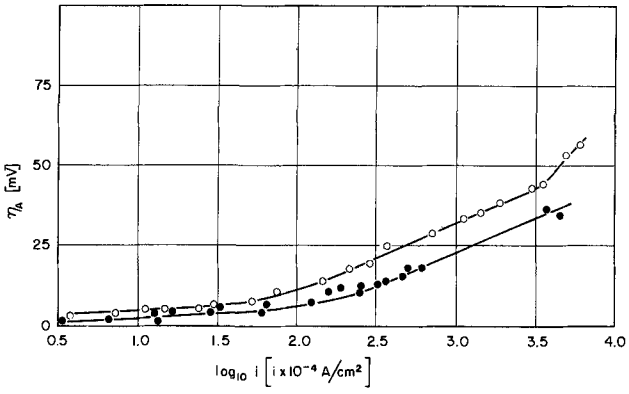

Fig. 4. η_A-$\log_{10} i$ curves for anodic polarization. ○ electrolyte: 0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4 + 0.05N KCl; pH = 2.5. ● electrolyte: 0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4 + 0.075N KCl; pH = 2.5.

Experimental curves $\eta_A - \log_{10} i$ for anodic polarization of indium in combined sulfate-chloride electrolytes also show linear relations (Fig. 4). For the electrolyte with 0.05N KCl, the linear part of the curve appears at $1.5 \times 10^{-2} - 3.0 \times 10^{-1}$ amp/cm^2, while for the electrolyte with the higher concentration of chloride (0.075N KCl) the linear part of the curve is shifted to a region of higher c.d.'s ($2.4 \times 10^{-2} - 3.3 \times 10^{-1}$ amp/cm^2).

The linear parts of the experimental $\eta_A - \log_{10} i$ curves, *i.e.*, Tafel lines, were treated with an earlier developed method (3) using expressions for the slowest reaction step, *i.e.*, the rate-determining step

$$\frac{\partial \log_{10} i_-}{\partial V} = -\frac{z\mathbf{F}}{2.303\,RT}(n_c^* - \alpha) \qquad [1]$$

$$\frac{\partial \log_{10} i_+}{\partial V} = \frac{z\mathbf{F}}{2.303\,RT}(n_a^* - 1 + \alpha) \qquad [2]$$

Since the left sides of Eq. [1] and [2] represent the slopes of the experimental Tafel lines, it was possible to calculate n_c^*, n_a^* and α from the experimental data. n_c^* and n_a^* are the ordinal numbers of the slowest reaction step for cathodic and anodic polarization (small integer), α the transfer coefficient ($0 < \alpha < 1$), and z the number of electrons involved in the slowest reaction step.

Results of the calculations are presented in Table I and Table II.

Table I. Kinetic parameters for cathodic polarization

Electrolyte	Range of c.d., amp/cm^2	$\frac{\partial \log_{10} i_- \#}{\partial V}$	$\alpha\#$	n_c^*	z
0.116N $InCl_3$ + 0.5N KCl, pH 2.5	1.7×10^{-1} to 3.5×10^{-1}	9.10	0.48	1	1
0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4	2.2×10^{-3} to 3.0×10^{-3}	10.18	0.41	1	1
+ 0.05N KCl, pH 2.5	5.0×10^{-3} to 6.5×10^{-1}	6.60	0.81	1	2
0.116N $In_2(SO_4)_3$ + 0.5N K_2SO_4	4.5×10^{-3} to 6.0×10^{-3}	8.91	0.48	1	1
+ 0.075N KCl, pH 2.5	7.0×10^{-3} to 2.5×10^{-1}	7.40	0.79	1	2

Mean values derived from 2-4 complete experimental curves.

Table II. Kinetic parameters for anodic polarization

Electrolyte	Range of c.d., amp/cm²	$\frac{\partial \log_{10} i_+ \#}{\partial V}$	$\alpha\#$	n_a*	z
0.116*N* $InCl_3$ + 0.5*N* KCl, pH 2.5	2.2×10^{-1} to 4.5×10^{-1}	11.95	0.69	1	1
0.116*N* $In_2(SO_4)_3$ + 0.05*N* K_2SO_4 + 0.05*N* KCl, pH 2.5	1.5×10^{-2} to 3.0×10^{-1}	48.5	0.81	3	1
0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 + 0.075*N* KCl, pH 2.5	2.4×10^{-2} to 3.3×10^{-1}	49.2	0.86	3	1

Mean values derived from 2-4 complete experimental curves.

Discussion

Activation overpotential-logarithms of c.d. curves for chloride electrolytes.—Experimentally obtained $\eta_A - \log_{10} i$ curves show very low activation overpotentials for both cathodic and anodic polarization over a wide range of c.d.'s (Fig. 1), which is in agreement with other authors (4-6). In comparison with the results obtained in sulfate media (1), the exchange current i_o is now shifted to the region of significantly higher c.d.'s (three orders of magnitude). Losev and Molodov (7) do not indicate such a difference between the exchange currents in the sulfate and chloride electrolytes. The difference between our data and those found by Losev and Molodov is probably due to the fact that our data were obtained in the pure sulfate and chloride electrolytes, but their electrolytes almost always contained a large amount of perchlorate ion (7-10).

The shift of the exchange current to the higher values indicates that the processes of deposition and dissolution of indium in chloride media take place near the equilibrium potentials over a wide c.d. range. At higher c.d.'s the experimental $\eta_A - \log_{10} i$ curve for cathodic polarization (Fig. 1) also shows linear dependence, and the slope indicates using Eq. [1] that the first step is the slowest one.[2] The same was found in the case of electrochemical deposition of indium in sulfate solutions for lower c.d.'s (1).

$$In^{3+} \xrightarrow[\text{slowest}]{+e_o^-} In^{2+} \xrightarrow{+e_o^-} In^{1+} \xrightarrow{+e_o^-} In^{o} \qquad [3]$$

In the case of anodic polarization of indium in chloride solutions in the region of higher c.d.'s, the slope of the experimentally obtained η_A-$\log_{10} i$ curve according to Eq. [2] indicates that the first step is the slowest one, although it would be expected to be the third reaction step, by analogy with cathodic polarization.

$$In^{o} \xrightarrow[\text{slowest}]{-e_o^-} In^{1+} \xrightarrow{-e_o^-} In^{2+} \xrightarrow{-e_o^-} In^{3+} \qquad [4]$$

In the same way as for anodic polarization of indium in sulfate solutions (2), it can be assumed that the less stable ions, In^{2+} and In^{1+}, are accumulated because of the slow third reaction step. These ions permit and accelerate disproportionation reactions:

$$2In^{2+} \longrightarrow In^{3+} + In^{1+} \qquad [5]$$

$$3In^{1+} \longrightarrow In^{3+} + 2In^{o} \qquad [6]$$

The disproportionation reactions for the anodic dissolution of indium amalgam in chloride solutions are also proposed by other authors (11), and their observations are consistent with our explanations. With such disproportionation reactions it is easy to imagine that the second and third reaction steps of anodic dissolution of indium are less and less significant for the rate of over-all process of dissolution, especially in the region of higher c.d.'s. So, it is quite acceptable that the first step is controlling the over-all reaction in the region of higher c.d.'s.

Activation overpotential-logarithms of c.d. curves for combined sulfate-chloride electrolytes.—With the galvanostatic method of fast single pulses applied in this work for cathodic and anodic polarization of indium in sulfate and chloride solutions, the observations of other authors (4-6) are confirmed about the inhibition of sulfate ions and the activation of chloride ions. For better understanding of these effects, the polarization of indium was carried on in combined sulfate-chloride solutions.

The curves η_A-$\log_{10} i$ for cathodic polarization of indium in combined sulfate-chloride electrolytes (Fig. 3) show rapid increases[3] for about 400 mv at characteristic c.d.'s, depending on the concentration of chloride in the solutions.

Since with minimal increase or decrease of c.d. one can record only one wave, the second or first, respectively, it could be concluded that on increasing the c.d. the mechanism of deposition of indium rapidly changes. With lower c.d.'s (less than 3.0×10^{-3} amp/cm² for solution with 0.05*N* KCl and less than 6.0×10^{-3} amp/cm² for solution with 0.075N KCl) the deposition of indium is carried on under conditions characteristic for chloride media. By increasing the c.d.'s it is no longer possible to record the process characteristic for chloride media, but the process continues with remarkably higher overpotentials which suggests the existing conditions characteristic for sulfate media. This rapid change in the mechanism of deposition of indium in combined sulfate-chloride electrolytes can be explained by conceptions about the mechanism of the activating effect of chloride on the deposition of metals (4, 6), and the desorption of chloride by increasing the negative potential (13, 14).

We can presume that absorbed chloride ions or indium chloro-complexes enable easy discharge of indium (low overpotentials), probably because of their deformation ability. Increasing the c.d. over a characteristic value, which is dependent on the concentration of chloride in solution, increases the cathodic overpotential, so that we presume that desorption of chloride or chlorocomplexes takes place. So, the activating effect of chloride is lost, and the first process stipulated by indium chloride disappears. Furthermore, with galvanostatic conditions of the experiments, cathodic overpotential (*i.e.*, negative potential of electrode) simultaneously with desorption of chloride, necessarily increases until it attains the value adequate for the deposition of indium in sulfate media. Consequently at higher c.d., indium can only be deposited with the characteristics of sulfate media. In support of such a conception about the effect of chloride on the mechanism of deposition of indium, is also the fact that by increasing the concentration of chloride in combined sulfate-chloride solutions, the rapid change in mechanism of deposition of indium appears at a higher c.d., characteristic for a higher concentration of chloride.

The analysis of experimental curves η_A-$\log_{10} i$ (Fig. 3) shows in c.d. region, before the rapid increase, the analogy with the curve obtained in pure chloride media, and it is also calculated by Eq. [1], that the first cathodic reaction step is the rate-determining step. In the c.d. region after this change, the curves perfectly coincide with the curve obtained in pure sulfate media at the corresponding c.d. (2), so we may presume, following the explanations from previous paper (2) and Eq. [1] that here too, the reaction of In^{3+} with two electrons controls the over-all process of deposition of indium (Table I).

[2] In all equations comprising indium ions, we do not indicate the probable aqueous and/or chloro complexes, for the sake of simplicity.

[3] A similar "discontinuous jump in potential" was observed recently by polarographic studies, and was published as a short communication by R. E. Visco (12). The author described this phenomenon as "negative resistance" affected by anion adsorption.

The experimental curve η_A-$\log_{10} i$ for anodic polarization of indium in combined sulfate-chloride electrolytes (Fig. 4) indicates in a certain c.d. region that the third anodic reaction step is the rate-determining step (Table II). The same phenomenon has already been recorded in pure sulfate solutions, but in a lower c.d. region (1, 15). By increasing the concentration of chloride in combined sulfate-chloride electrolytes, a linear part of η_A-$\log_{10} i$ curve shifts to the higher c.d. region. These facts are also in accordance with the conception of the activating effect of chlorides and inhibiting effect of sulfates. Supporting this are observations in pure chloride solutions, where the process is carried on close to the equilibrium potential.

In the extremely high c.d. region, the slopes of the curves start to change, so here we can presume that disproportionation reactions take place.

Manuscript received Sept. 30, 1965; revised manuscript received May 9, 1966. Part of this work was presented at the 14th CITCE Meeting, Moscow, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Interaction of Carbon Dioxide with Hydrogen Chemisorbed on a Platinum Electrode

Bernard J. Piersma,[1] Theodore B. Warner, and Sigmund Schuldiner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The effect of CO_2 on the oxidation of hydrogen atoms chemisorbed on a Pt electrode has been examined with potentiostatic and transient galvanostatic techniques. The results indicate that CO_2 is not reduced, but that H_{ad} oxidation is inhibited by CO_2, or possibly HCO_3^-. Under these conditions the inhibited or blocked H_{ad} is stable at potentials negative to 0.3v (*vs.* NHE). Dissociation of formic acid to H_{ad} and CO_2 may inhibit the further oxidation of HCOOH by a similar H_{ad}-CO_2 blocking mechanism.

The interaction of CO_2 with electrolytically generated hydrogen at platinum electrodes in acid solution has been reported by Giner (1), who demonstrated a difference between the anodic polarization behaviors of hydrogen-covered electrodes in CO_2 and in He saturated solutions. Giner concluded that CO_2 is reduced by reaction with electrochemically formed chemisorbed hydrogen, H_{ad}, between 0.0 and 0.25v (all potentials reported here are *vs* the NHE). The chemisorbed product, which he called "reduced CO_2," was oxidized at about 0.7v, at 25°C, during anodic galvanostatic polarization and oxidized in the potential region of 0.5-0.9v, during linear potential sweeps.

This study was initiated with the objectives: (*a*) to demonstrate that the experimental results observed by Giner were indeed due to his assumed interaction (or reaction) and not to an oxidizable impurity, (*b*) to investigate the nature of the adsorbed oxidizable species, and (c) to examine the implications of such an interaction on the interpretation of anodic organic reactions.

Experimental

Apparatus.—The electrolytic cell, purification of He and H_2, and general procedures were as previously described (2, 3). High current galvanostatic pulses (2.33 a/cm^2) were obtained with an Electro-Pulse Model 3450D generator. Low constant currents were applied either from an Electronic Measurements Company C-612 constant current supply (0.2 ma/cm^2-0.6 μa/cm^2) or a Keithley Model 600A electrometer (down to 0.05 μa/cm^2), both being switched manually. Cell polarization was either observed and photographed on a recalibrated Tektronix Type 547 oscilloscope or recorded on a Varian Associates Model G-11A strip chart recorder from the output of a Keithley Model 603 electrometer amplifier. Constant potentials were maintained with a Wenking Model 61-R fast rise potentiostat.

The Pd tube and miniature glass reference electrodes, large Pt gauze counter electrode, and 0.19 cm^2 true area Pt bead working electrode have been discussed previously (2, 3). All current densities are expressed in terms of true area as determined from the charge required to deposit one monolayer of oxygen atoms.[2] Baker Analyzed Reagent Grade CO_2 (purity 99.9992%; O_2 1.5 ppm; N_2 + CO, 6 ppm) was purified by passage through a trap containing, at different times, either palladium catalyst supported on alumina at −50°C, palladium oxide supported on alumina at 400°C, or Hopcalite followed by copper turnings (to remove possible traces of oxygen generated by the Hopcalite) both held at 350°C.

Galvanostatic technique.—Anodic charging curves were obtained in solutions saturated with purified He, CO_2, or a mixture of 22% H_2-78% CO_2. Prior to each charging curve, the electrode was either left at open circuit until the potential became stable or potentiostated at a given potential (the dependence of the charging curves on potential and time was examined). The open circuit potentials were 0.3v, or less, indicat-

[1] National Academy of Sciences Postdoctoral Resident Research Associate.

[2] The electrode area remained unchanged after 45 days of continuous use which included extended periods of anodization during pre-electrolysis. The constancy of areas of bright Pt beads is a general observation in this Laboratory. Barring failure in the mounting, an electrode area change has never been observed during normal use over periods as long as six months.

ing a low concentration of oxygen in the electrolyte as a result of gas purification, tightness of the closed system and the oxygen gettering of the Pd tube reference electrode (which contained enough dissolved hydrogen to maintain a stable α Pd-H potential of +0.055v). The working electrode was always anodized in a way such that dermasorbed oxygen, *i.e.*, oxygen dissolved into the skin of the Pt (2, 4), would not be formed. A convenient gas flow was established (experiments showed that the results were independent of flow rate) and the chosen sequence of currents and/or potentials were applied.

In all the low current experiments, the fixed current was switched from anodic to cathodic before a significant amount of oxygen could be generated. In high current experiments the electrode was cleaned with a 2.33 amp/cm^2 anodic pulse lasting less than 500 μsec (to avoid the formation of dermasorbed oxygen). Immediately after the cleaning pulse, the electrode potential was fixed with the potentiostat for a given time (to allow for interaction of CO_2 with H_{ad}) followed by another 2.33 amp/cm^2 anodic pulse, applied to determine the amounts of sorbed H, H_{ad}-CO_2 interaction (H_{ad}-CO_2 merely signifies the presence of both species on the surface), and O_{ad}. Switching between galvanostatic and potentiostatic control was manual with a switching time of less than 0.5 sec. The time of switching was not important since it was established that the amount of H_{ad}-CO_2 formed at a given potential for a set interaction time was unchanged at open circuit for at least 72 hr. The first pulse (or cleaning pulse) rapidly anodized the electrode to O_2 evolution, removed previously sorbed H_{ad}-CO_2 and provided a reproducible state. Thus, just prior to potentiostatic control, the electrode was free from dermasorbed oxygen and H_{ad}-CO_2. Each successive pulse not only gave the required charging curve, but stripped the surface of H_{ad}-CO_2, presenting a clean surface for the start of another experiment. The current pulses for a given current density were of the same duration.

Results

Low current galvanostatic charging curves.—After the cleanliness of the electrolyte and electrode surface had been established,[3] charging curves were obtained with He (flow rate of 88 std cc/min) (Fig. 1a) and then with CO_2 (flow rate of 4 std cc/min[4]) (Fig. 1b). In trace 1, Fig. 1a, the electrode was anodized from open circuit to 0.8v, and then cathodized to 0.0v. In trace 2, this procedure was preceded by cathodization for 10 sec to deposit chemisorbed hydrogen. In each case, the current was reversed at 0.8v, avoiding the deposition of oxygen as verified by the forms of the charging curves.

Analysis of these charging curves in He saturated solution showed that Q_a (the number of coulombs/square centimeter of anodic charge) required to polarize the electrode to 0.8v increased (*a*) as stirring rate decreased, (*b*) as the potential from which charging was started decreased, and (*c*) as the time of precathodization increased. These observations are attributed to the oxidation of hydrogen generated during precathodization which would contribute to Q_a. In solutions stirred with He flowed at 88 ml/min, Q_a varied from 600 μcoul/cm^2 when anodization was begun from the open circuit potential of 0.065v, to about 900 μcoul/cm^2 for 10 sec precathodization and about 1000 μcoul/cm^2 for 40 sec precathodization. Q_c (the number of coulombs/square centimeter of cathodic charge), required to polarize the electrode from 0.8 to 0.0v remained roughly constant at 520 ± 40 μcoul/cm^2. The variation between Q_a and Q_c noted here differs from Giner's results, where he found the anodic and cathodic branches roughly equal.

[3] The linearity of the voltage *vs.* time relation in the oxygen atom adsorption region has been found to be a reliable test of electrode cleanliness (5). Typical linear regions are seen, *e.g.*, in Fig. 3.

[4] A variation of the flow rates of CO_2 from 4 std cc/min to 250 std cc/min had no effect on the charging curves.

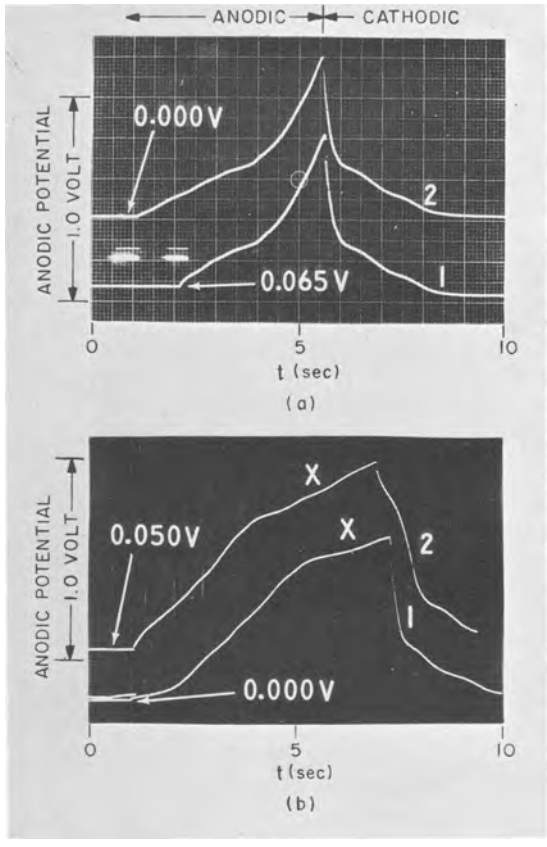

Fig. 1. Charging curves in 1M H_2SO_4 at 25°C. i = 0.2 ma/cm^2: (a) He flow 88 ml/min., trace 1 from open circuit potential of 0.065v, trace 2 immediately following cathodization to 0.00v. (b) CO_2 flow rate 4 ml/min, trace 1 immediately following cathodization to 0.00v, trace 2 following trace 1 after stable open circuit potential attained.

Figure 1b is typical of the charging curves obtained when CO_2 was substituted for He, where trace 1 was taken after 10 sec of precathodization and trace 2 taken from open circuit. The new plateau (designated region X by Giner) which appears at 0.69v was well below the potential of oxygen atom formation. Region X developed slowly, requiring about 15 min at open circuit to reach a maximum. Q_a was independent of the stirring rate with CO_2, indicating that the electrode surface had become passive to the oxidation of hydrogen formed in precathodization.

Purification of CO_2.—Slow adsorption of traces of an oxidizable impurity could affect both the appearance of the charging curves and the time required for the X region to develop. Carbon monoxide is one trace impurity possibly present in the CO_2 used and previous work (5, 6) has shown that extremely small amounts of CO will affect charging curves. Accordingly, the several purification techniques used were designed either to remove trace amounts of CO and organic compounds, or to oxidize them completely to CO_2. Since it is difficult to prove the absence of impurity, the criterion for acceptably pure CO_2 was that the X region develop identically after the CO_2 was purified in the several ways in separate experiments: *i.e.*, through Pd at −50°C, through PdO at 400°C, and through Hopcalite and copper at 350°C. The strong chemisorption of CO on Pd is well known (7); thus a Pd cold trap should be highly specific for CO and also very efficient for most organic impurities. PdO and Hopcalite were used to oxidize any organic impurity present completely to CO_2. In every experiment carried out, the X region developed identically.

CO_2 was replaced with He between each set of experiments and the electrode was tested for cleanliness. Figure 2 presents typical results, in this case obtained 65 min after starting the flow of He. The first trace

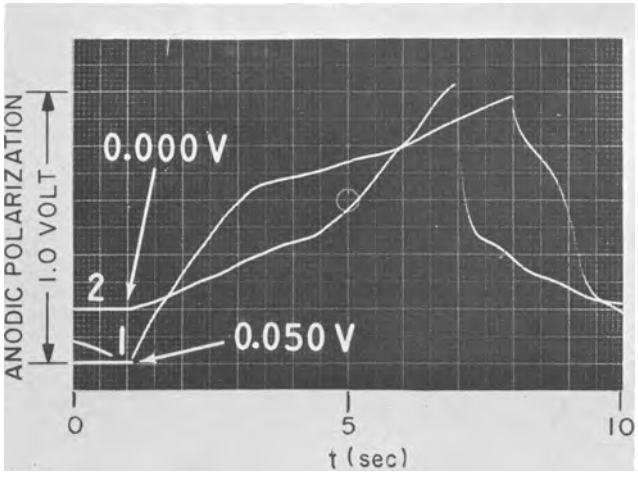

Fig. 2. Charging curves in 1M H_2SO_4 at 25°C. He flow 56 ml/min, i = 0.2 ma/cm^2. Effect of replacing CO_2 with He. Trace 1 first charging curve from open circuit; trace 2 second charging curve, precathodized 10 sec.

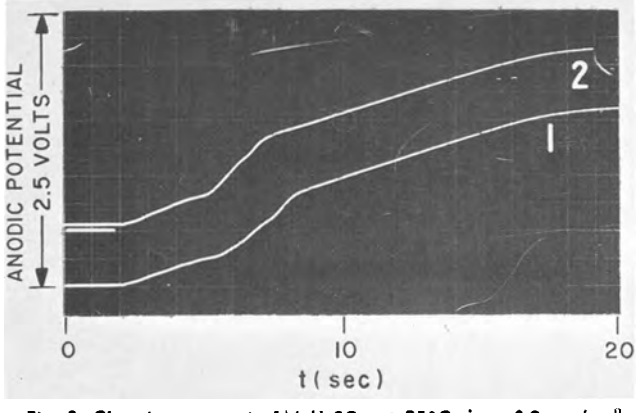

Fig. 3. Charging curves in 1M H_2SO_4 at 25°C. i = 0.2 ma/cm^2, He flow 56 ml/min. Electrode cleanliness tests. Trace 1 time since last polarization 2 min, precathodized 60 sec; trace 2 time since trace 1, 13 min, precathodized 10 sec.

shows that H_{ad}-CO_2 is adsorbed strongly enough to give the equivalent of a full monolayer, assuming a one electron discharge. Further experiments showed that even after 75 hr of He flow, a full monolayer is still present on the electrode. After the electrode surface was cleaned by the first pulse, the second trace (Fig. 2) shows that no oxidizable material is adsorbed from solution. Finally, to eliminate the possibility of slow adsorption of solution impurities, charging curves were taken after a waiting period at open circuit; *e.g.*, trace 2 of Fig. 3, which had a period of 13 min between pulses, shows no evidence of adsorption of oxidizable impurity.

High current charging curves.—The rate of formation of H_{ad}-CO_2 was examined both as a function of potential and of interaction time (c.f. Fig. 5). Figure 4 presents typical results of the influence of interaction time on the amount of H_{ad}-CO_2 formed at a

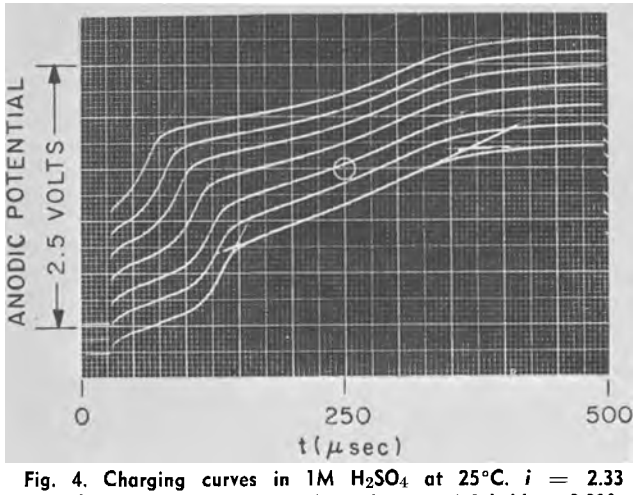

Fig. 4. Charging curves in 1M H_2SO_4 at 25°C. i = 2.33 amp/cm^2, CO_2 flow 2 ml/min, electrode potential held at 0.000v between pulses. Effect of time on X region: lowest pulse 1 sec after initial pulse, succeeding pulses reading upward were respectively 5, 10, 20, 40, 80, and 300 sec after preceding pulse.

given potential, in this case 0.00v. From this figure we see that as the interaction time increases, a dip, characteristic of the oxidation of many organic compounds, develops in the oxygen region at approximately 0.9v in the case of high-current pulses. Paralleling this oxidation plateau is the decrease in length of the usual hydrogen region.

The following quantities were determined from the oscillograms, in terms of microcoulombs/square centimeter: (*a*) Q_t, the total charge required to polarize the electrode to the potential at which O_2 evolution occurs, (*b*) (Q_H + Q_{Hdl}), the quantity of charge required to polarize the electrode to the potential at the start of the X region (H atom oxidation and double layer charging), and (c) (Q_O + Q_{Odl}), the quantity of charge required to polarize the electrode from the start of the X region to the potential of oxygen evolution (oxidation of adsorbed species, formation of a monolayer of O atoms and double layer charging). Thus

$$Q_t = Q_H + Q_{Hdl} + Q_O + Q_{Odl} \quad [1]$$

For a clean Pt electrode (3) in the absence of CO_2

$$Q_O^{CO_2\text{-free}} + Q_{Odl}^{CO_2\text{-free}} = 426\ \mu\text{coul/cm}^2 + 36\ \mu\text{coul/cm}^2 = 460 \pm 20\ \mu\text{coul/cm}^2 \quad [2]$$

Assuming that the charge required to form one monolayer of O atoms and to charge the double layer is identical for CO_2 and He saturated solutions, then

$$Q_X = Q_O + Q_{Odl} - 460\ \mu\text{coul/cm}^2 \quad [3]$$

where Q_X is the charge required to oxidize H_{ad}-CO_2.

When the electrode was potentiostated at 0.00v, Q_t reached a limiting value in less than 1 sec and remained constant as the interaction time increased, *i.e.*, as Q_H decreased, Q_O increased by an equivalent amount. As the electrode was held at successively more positive potentials, longer interaction times which, how-

ever, were always less than 2400 sec, were required to reach a limiting value of Q_t. These data are collected in columns 3 and 4 of Table I. For comparison, the values of $Q_t^{CO_2\text{-free}}$ (Q_t in CO_2-free solution) are given in column 2. $Q_t^{CO_2\text{-free}}$ values were determined by addition of $Q_O^{CO_2\text{-free}} + Q_{Odl}^{CO_2\text{-free}}$, given above, with $Q_H^{CO_2\text{-free}} + Q_{Hdl}^{CO_2\text{-free}}$, derived from data obtained previously for hydrogen coverage of Pt electrodes as a function of open circuit potential and for double layer capacity as a function of potential [Fig. 10 and 5, ref. (3)]. The comparison of $Q_t^{CO_2\text{-free}}$, obtained in this way, with Q_t (cf. column 6, Table I) implicitly assumes that the coverage of a Pt electrode by hydrogen is the same when the electrode is at a given potential at open circuit and when it is maintained at this potential with a potentiostat. Limiting Q_X values, as determined using Eq. [3], are given in column 5. Q_H values, obtained from the anodic charging curves and corrected for double layer charging, are given in column 7.

The potential, V_p, at which oxidation of H_{ad}-CO_2 first occurs is a function of current density. Measurements of V_p (*i.e.*, the potential at the beginning of the X region) were made on charging curves obtained at different charging currents. The relationship is shown in Fig. 6.

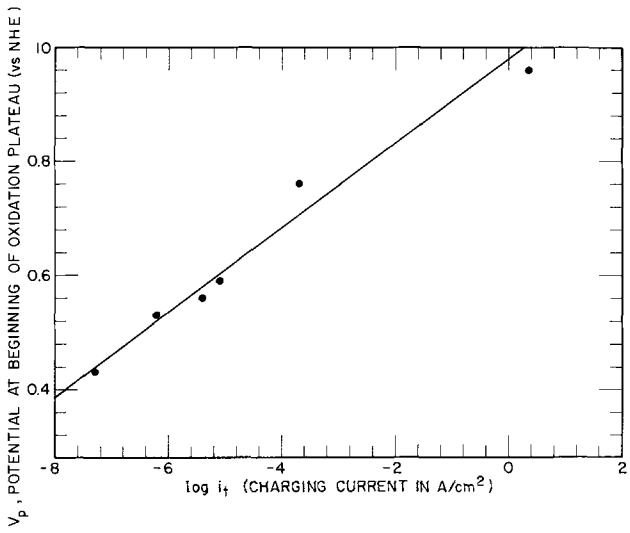

Fig. 6. Dependence of potential, V_p, at beginning of oxidation plateau on applied anodic charging current density, i_t.

Discussion

This work gives qualitative confirmation of the experimental observations of Giner (1) and gives additional information about the chemisorbed species. There is now concrete evidence that CO_2 is not reduced to CO. Under transient conditions (6, 8), the potential at which CO oxidation begins is in the range 0.9-1.3v, depending on the CO partial pressure. CO also does not appear to react when potentiostated below 0.9v (9). The initial potential of oxidation of the species resulting from the interaction of CO_2 with H_{ad} is dependent on the charging current (cf. Fig. 6), independent of the initial surface coverage, and in every case is below 1.0v. This chemisorbed species is completely oxidized at 0.3v under potentiostatic conditions. Furthermore, the shapes of the anodic charging curves for the "X region" resulting from the H_{ad}-CO_2 interaction are markedly different from those for the oxidation of CO, both in the presence and absence of hydrogen (6, 10).

In addition to establishing that CO_2 is not reduced by H_{ad} to CO, the results strongly indicate that CO_2 is not reduced at all. Limiting Q_x values found at interaction potentials below 0.250v (see Table I) show

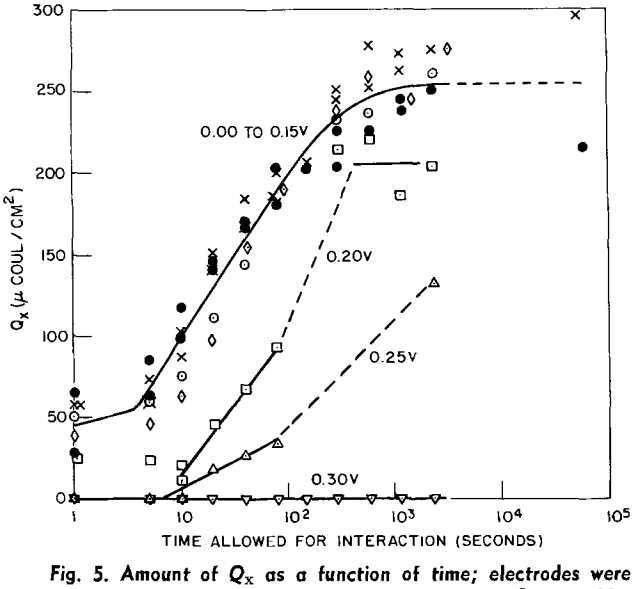

Fig. 5. Amount of Q_x as a function of time; electrodes were held at different potentials during interaction time: ○ = 0.00v, ● = 0.065v, X = 0.10v, ◇ = 0.15v, □ = 0.20v, △ = 0.25v, ▽ = 0.30v.

that the "X-region" is virtually saturated with an oxidizable species. On the other hand, V_p was found to depend only on charging current (Fig. 6). If a reduced CO_2 surface compound were formed, then V_p should depend on current density only if the oxidation rate depended on a slow charge transfer or chemical reaction step following change transfer. However, if the oxidation were dependent on a change transfer or chemical rate, then the degree of surface coverage of the reduced CO_2 should affect the initial oxidation potential. The results, as shown, *e.g.*, in Fig. 4, indicate that V_p is independent of the degree of coverage, strongly suggesting that no reduced CO_2 specie is oxidized, *i.e.*, that CO_2 is not reduced. Further evidence against the possibility of CO_2 reduction is seen in Fig. 5 which shows that Q_x is independent of the interaction potential and hence H_{ad} concentration from 0.00 to 0.15v.

The experimental results can be explained if there exists on the electrode surface only a small number of active sites at which oxidation can occur (*e.g.*, most of the sites could be blocked for oxidation by another species) and the process involves diffusion of the oxidizable species to these sites. It is well known that there are several types of sorbed atomic H. If the concentration of active H_{ad} were low, the rate of oxidation could be affected by the rate of diffusion of irreversibly held H atoms. At low current densities diffusion of H atoms to reactive sites would be fast enough to maintain a relatively constant coverage of these sites. At high current densities a diffusion overvoltage of H atoms would increase V_p. This mechanism is supported by the fact that V_p is independent of Q_x whereas in the "X region," the potential increases as the H coverage decreases.

Information concerning the nature of the sorbed H atoms in the presence of CO_2 is obtained from analysis of the data in Table I and Fig. 5 which show:

(*a*) At a given potential, hydrogen in excess of the amount formed in CO_2-free solution ($Q_t - Q_t^{CO_2\text{-free}}$) is generated on the electrode (column 6, Table I).

(*b*) At sufficiently long interaction times, the hydrogen ionization region normally associated with a Pt electrode in CO_2-free solution essentially disappears (column 7, Table I). The small values of Q_H at 0.00 and 0.065v are an indication that some active hydrogen is present at these potentials.

(*c*) Q_x remains essentially constant (260 ± 35 μcoul/cm^2) up to 0.15v (column 5, Table I), an amount of charge approximately equal to that required to oxidize the hydrogen normally adsorbed on

a clean Pt electrode at 0.00v (230 μcoul/cm^2). The rapid decrease in Q_x above 0.15v suggests that above this potential, there is insufficient hydrogen produced to form a monolayer. We infer from this that the excess hydrogen required to give the observed $Q_t - Q_t^{CO_2\text{-free}}$ is all strongly bonded to Pt since reversibly held H atoms cannot exist above about 0.15v and only strongly bound H atoms will be formed.[5] Since the sites available for the strongly bound H atoms will be limited, the equivalent of a full monolayer of H_{ad} cannot build up.

The fact that CO_2 can inhibit H_{ad} reactions on a Pt electrode is confirmed in Fig. 7, which compares the cathodic polarization behaviors in both 1M H_2SO_4 saturated with a CO_2 + He mixture and saturated with pure He. Behavior in pure CO_2 was found to be essentially the same as in CO_2 + He. Helium was added to increase gas stirring rates to establish a limit beyond which increased stirring did not increase current density. The decrease in current density at a given overpotential is indicative of a poisoned surface. It is difficult to see how CO_2 itself could act as an electrode poison. One possibility is that the HCO_3^- or $CO_3^=$ ions present in solution are the poisons. The formation of complexes having bicarbonate or carbonate structures in the gas phase adsorption of CO_2 has recently been suggested (11). The poisoning effect of these anions could then be similar to the effects of iodide ion on the rate of hydrogen ionization in H_2SO_4, reported by Shanina (12), who found the poisoning effect to occur slowly. Slygin and Frumkin (13) showed that the shapes of anodic charging curves for hydrogen ionization depend on the anion in solution. For example, several plateaus which were present for oxidation in H_2SO_4, could not be detected in HCl or HBr solutions. From arrests in the charging curves on platinized Pt in H_2SO_4 at about 0.7v, Slygin and Frumkin (13) suggested that some hydrogen could be so firmly bound as to require this higher potential for oxidation. The fact that they obtained a lengthening of this plateau with more intensive platinization, which presumably generated more sites at which H atoms could be strongly adsorbed, argues against a solution poison. Their results do suggest that under certain conditions, a much higher potential than expected is required to oxidize hydrogen.

The most probable effect of CO_2 on H_{ad} is one which shifts the equilibrium of the reaction

$$H_{ad} = H^+ + e^- \quad [4]$$

[5] Recent work (18) in this Laboratory has shown that the Nernst potential relation for a H^+/H_2 electrode on Pt (in a system for which the O_2 leakage is so low that the equivalent O_2 partial pressure above the solution is less than 10^{-9} atm) holds only to 0.18v (1×10^{-6} atm H_2). This 0.18v potential is independent of H_2 partial pressure below 1×10^{-6} atm. Hence at potentials of 0.18v and higher, the H^+/H_2 exchange is not potential-determining and the intermediate H_{ad} activity must be negligibly small. The conclusion that reversibly held H atoms cannot exist above about 0.18v thus appears valid.

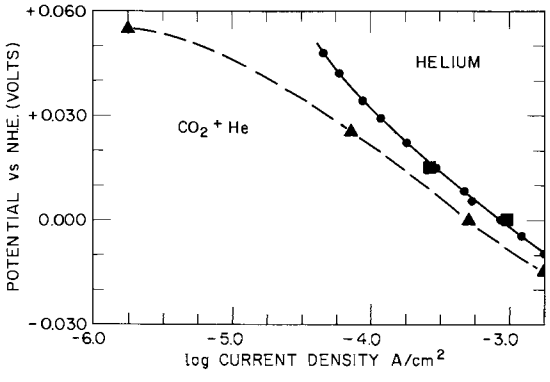

Fig. 7. Cathodic steady-state current density vs. potential in vigorously stirred solution (current density independent of higher gas flow rates). ○ Schuldiner (17); □ this work in solution stirred with helium at 690 std ml/min; △ this work in solution stirred with CO_2 + He at rates > 690 std ml/min.

such that at a given interaction potential the formation of additional H_{ad} is favored. Giner has previously inferred a similar shift in equilibrium. To examine further the question of reduced CO_2 compound formation, an intensive search was made (using charging curves after long periods at open circuit, cf. Fig. 2) to detect traces of a species in solution. None was ever found. In addition, Johnson and Kuhn (14) were unable by chemical analysis to detect a reduced CO_2 compound in solution after 24 hr of reaction.

Giner (15) came to the conclusion that upon anodic oxidation on Pt, and to some extent at open circuit, methanol and formic acid gave a product which was the same as that formed by reaction of CO_2 with atomic H. He considered that the CO_2 was reduced by atomic H. Vielstich and Vogel (19) concluded from their experiments on the anodic oxidation of formic acid that neither carbon monoxide nor oxalic acid are reaction products. We believe that in formic acid solution dissociation to H_{ad} and CO_2 takes place and that inhibition of H_{ad} or formic acid oxidation results. This interaction of the products of dissociative adsorption has several implications for the anodic oxidation of organic compounds and particularly for formic acid. The dissociative mechanism for formic acid oxidation;

$$HCOOH = HCOOH_{ad} \quad [5]$$

$$HCOOH_{ad} = H_{ad} + HCOO_{ad} \quad [6]$$

$$H_{ad} = H^+ + e^- \quad [4]$$

$$HCOO_{ad} = CO_2 + H^+ + e^- \quad [7]$$

has been generally accepted in the literature [cf. ref. (16)]. The present results indicate that such a mechanism cannot continue at potentials negative to 0.3v in H_2SO_4 at Pt electrodes at 25°C. After sufficient interaction of H_{ad} and CO_2 the formic acid dissociation could not proceed on a major fraction of the electrode surface, because of the blocking effect of CO_2.

A decrease in current with time is generally found for the potentiostated oxidation of organic compounds. Recently it has been suggested that this might be due to "reduced CO_2." However, this work shows that under steady state conditions CO_2 cannot block H_{ad} oxidation at/or above 0.3v. Hence a poisoning effect due to this at potentials above 0.3v is impossible. The present results also imply that the complete oxidation of organic compounds on Pt at potentials below 0.3v, *e.g.* to obtain higher cell voltages in electrochemical energy converters using organic fuels, may not be feasible.

Conclusions

1. CO_2 in solution, or possibly HCO_3^-, interacts strongly on Pt to affect subsequent oxidation of adsorbed hydrogen. The rate of this interaction is relatively slow; about 15 min are required to attain limiting conditions.

2. The interaction is apparently not simple physical adsorption of CO_2 on the metal substrate, nor is a reduced CO_2 surface compound nor a soluble species that is stable in solution formed. The H_{ad} blocked by CO_2 interaction is stable on the surface and irreversibly sorbed.

3. The oxidizable species is not CO.

4. Limiting coverage of H_{ad} blocked by CO_2 or HCO_3^- is ~260 μcoul/cm^2. This H_{ad} is stable at potentials negative to 0.3v. When potentiostated at 0.3v it is completely oxidized.

5. CO_2 or HCO_3^- inhibits the hydrogen evolution reaction on Pt.

6. Coulometric measurements strongly indicate that active (or weakly bound) hydrogen is present on the electrode below about 0.15v, but not above.

7. It is tentatively suggested that formic acid dissociates to H_{ad} and CO_2 and that CO_2 or HCO_3^- interacts on Pt to retard oxidation of HCOOH.

Oxygen Overvoltage Measurements on Bright Platinum in Acid Solutions

IV. Methanol-Containing Solutions

James P. Hoare

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Oxygen overvoltage measurements were made both galvanostatically and potentiostatically on bright Pt cathodes in O_2-saturated $2N$ H_2SO_4 solutions containing methanol. These curves were compared with those obtained in MeOH-free solutions. The rest potential was lowered by nearly 200 mv in an acid solution of 0.5M MeOH caused by a local cell set up between the $O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O$ and the $(CH_3OH)_{ads} \rightarrow (CO)_{ads} + 4H^+ + 4e$ reactions. The presence of $(CO)_{ads}$ does not interfere with the over-all kinetics of the reduction of oxygen but, by a blocking action, reduces the number of active sites on the electrode surface available for the reduction of oxygen. This causes an increase in the overvoltage of about 40 to 60 mv. Although MeOH is oxidized at high current densities at the cathode, this current is not available to the external circuit since it is produced by a local cell mechanism. The equal number of coulombs of O_2 consumed in the local cell process also involves an additional loss of energy to the external circuit.

At first sight, methanol appears to be an ideal fuel for fuel cells (1, 2) since it is electrochemically active at low temperatures; it is inexpensive, and being a liquid it may be handled in the same way as gasoline. Because of the high solubility of MeOH in water solutions, MeOH may interact with the fuel cell cathode (3), producing intolerable polarization losses.

Studies of the anodic oxidation of MeOH at noble metal electrodes in acid and alkaline solutions (4-8) and of the adsorption of MeOH on the electrode surface as a function of potential (9-11) have been carried out. It appears that competition for surface sites from both H_2 adsorption at less noble potentials and oxygen adsorption at more noble potentials produces a maximum in the θ-potential curves at about 0.7v (9-11) on platinum in acid solutions. It is found that MeOH is oxidized all the way to CO_2 in acid solutions but stops at HCOOH in alkaline solutions.

To our knowledge, however, polarization curves for the reduction of oxygen in the presence of methanol-containing electrolytes cannot be found in the reviewed literature. In this report there is presented an account of the oxygen overvoltage measurements obtained on bright Pt electrodes galvanostatically and potentiostatically in oxygen saturated sulfuric acid solutions containing methanol. So that the effects of mass transfer may be more clearly separated from the effects of activation overvoltage on the polarization curves, these studies were carried out on the bright Pt electrodes instead of the porous diffusion electrodes required for fuel cell investigations.

Experimental

Test electrodes in the shape of small beads (0.02-0.03 cm^2 in area) melted at the end of pure (99.99%) Pt wires were mounted with Teflon spaghetti in a Teflon cell (12). The purification techniques and the cell and electrode preparation have been described before (12). Attention was paid to the rigorous control of impurities. The procedures for determining the galvanostatic (13) and the potentiostatic (14) data are the same as those recorded previously. Since the recorded data are steady state measurements, each potential (galvanostatic) and each current (potentiostatic) point was noted after the tested parameter had not changed sensibly in value for at least 60 sec. Under some circumstances, it required an hour or more to reach this steady value. Reagent grade absolute methanol was added to the electrolyte in the cell by means of a micropipette inserted through the gas exit tube in the cell top after the system had come to a steady rest potential in O_2-saturated, H_2O_2-free, $2N$

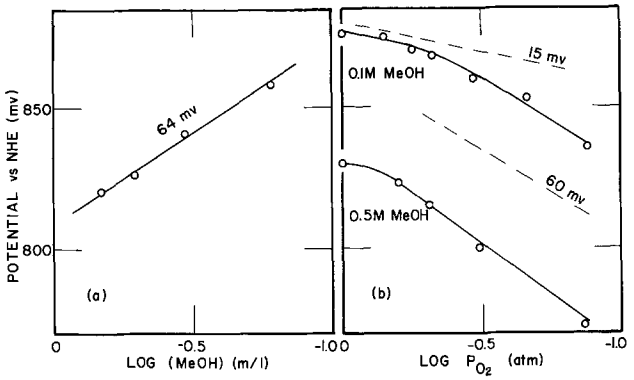

Fig. 1. Dependence of the rest potential on the bulk concentration of MeOH (a) and on the partial pressure of oxygen (b).

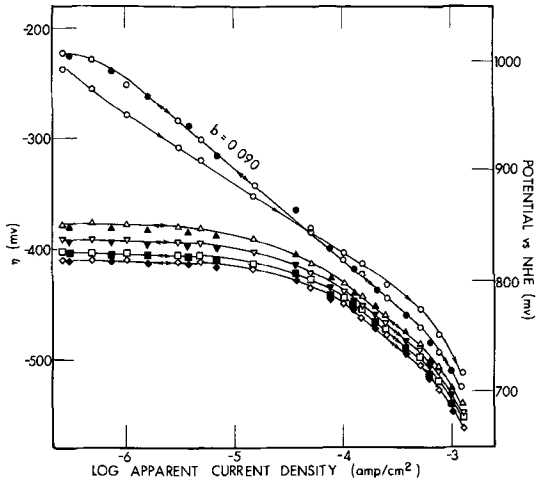

Fig. 2. O_2-η measurements on bright Pt obtained galvanostatically in MeOH containing acid solutions. Open symbols represent increasing current; filled, decreasing. MeOH concentrations are: ○, zero; △, 0.17; ▽, 0.34; □, 0.51; ◇, 0.68M.

H_2SO_4 solution. The studies were carried out over a range of concentrations of MeOH from 0.05 to 0.8 mole/liter. Unless otherwise stated, all potentials are recorded with respect to the normal hydrogen electrode (NHE), and the temperature at which this work was carried out was 25° ± 1°C. Partial pressure of oxygen measurements were obtained by diluting the O_2 stream with N_2 and monitoring the per cent of O_2 in the gas with a Beckman Oxygen Analyzer. To minimize mass transfer effects, the solutions were stirred with gas flows above 300 cc/min.

Results

The steady rest potential of a bright Pt bead in O_2-saturated 2*N* H_2SO_4 solution was 1048 mv, and when 0.1 cc of MeOH was added to the electrolyte (MeOH = 0.17M), the potential fell directly to 865 mv. After about 300 sec the potential was steady at 858 mv. Additional amounts of MeOH added to the solution produced further shifts of the potential toward less noble values. A plot of the rest potential as a function of the log of the MeOH concentration is given in Fig. 1a which gives a straight line with a slope of 64 mv. The rest potential also depended on the partial pressure of oxygen, P_{O_2}, and a plot of potential *vs.* log P_{O_2} is presented in Fig. 1b at two methanol concentrations. Lines with the indicated slopes were drawn as an aid in the analysis of the curves. In order to determine the effect of possible metal-metal oxide reactions on the rest potential, four noble-metal electrodes, Pt, Pd, Rh, Au, were placed in oxygen saturated 2*N* H_2SO_4 solution, and the open-circuit potential after 6 hr is recorded in the first line of Table I. In the next three lines of Table I, the rest potential is recorded just after, 1000 sec after, and 18 hr after adding MeOH to the system.

Table I. Rest potential of noble metal oxygen electrodes in oxygen saturated 2*N* H_2SO_4 solution containing 0.05M MeOH

	Pd (mv)	Pt (mv)	Rh (mv)	Au (mv)
In MeOH-free solution	925	1008	935	892
Made solution 0.005M in MeOH	922	920	931	888
After 1000 sec	928	928	929	885
After 18 hr	912	900	910	886

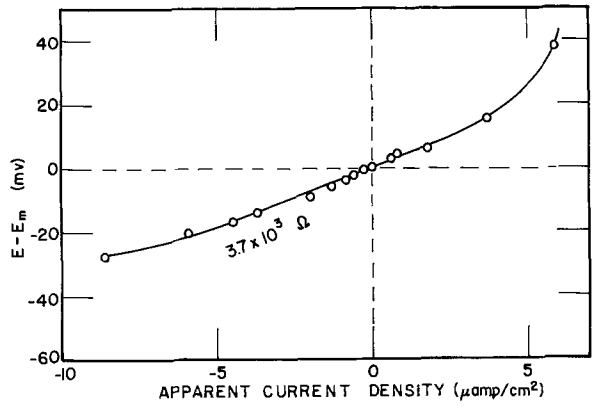

Fig. 3. Polarization of Pt electrode in O_2-saturated 2*N* H_2SO_4 solution 0.05 molar in MeOH at very low current densities.

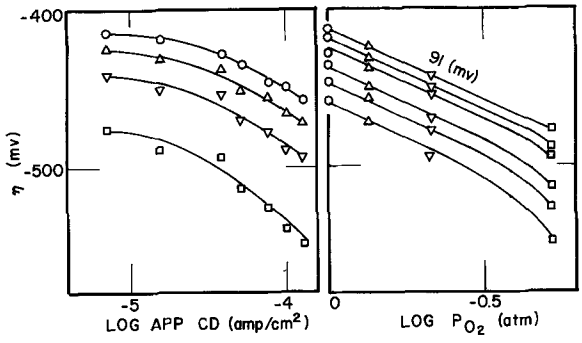

Fig. 4. Variation of overvoltage with partial pressure of oxygen. A plot of the overvoltage as a function of the log of the current density obtained galvanostatically is given on the left side for various values of P_{O_2}. P_{O_2} = 1, ○; 0.74, △; 0.46, ▽; 0.19 atm, □. These data were used to construct the plot of overvoltage as a function of log P_{O_2} on the right side. Curves for six different values of current density are shown. As the current density increases, the deviation from a 91-mv slope increases.

The top curve of Fig. 2 is the steady-state galvanostatic overvoltage curve for the reduction of oxygen in the absence of MeOH. The first cycle of increasing and decreasing current is shown, after which a reproducible curve with a slope of 0.09 is obtained from the average of three additional complete cycles of cathodic polarization (deviation from the mean within ±6 mv). Four additional polarization curves are given for increasing concentrations of MeOH, 0.17M, 0.34M, 0.51M, and 0.68M. These curves were very reproducible since the deviation from the mean value, averaged over three complete cycles of polarization, was within ±2 mv. The polarization of a Pt/O_2 electrode in O_2-saturated 2*N* H_2SO_4 solution containing 0.05M MeOH at low current densities is plotted in Fig. 3. In Fig. 4a, the influence of P_{O_2} on the η is shown for an acid solution 0.68M in MeOH, and in Fig. 4b the η-log P_{O_2} curves are plotted from the data in Fig. 4a.

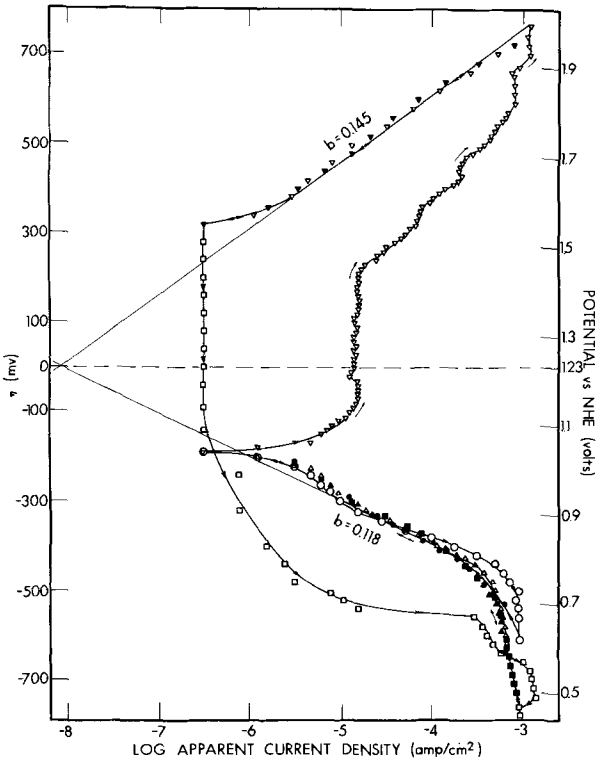

Fig. 5. Oxygen overvoltage curves obtained potentiostatically on Pt anodes and cathodes in O_2-saturated 2*N* H_2SO_4 free of MeOH. Open symbols represent increasing and filled decreasing polarization. ○, First cathodic curve; △, reproducible cathodic curve; ▽, anodic curves; □, cathodic curve of preanodized Pt. Tafel lines cross at zero η (1229 mv); i_o is 8.5 x 10^{-9} amp/cm².

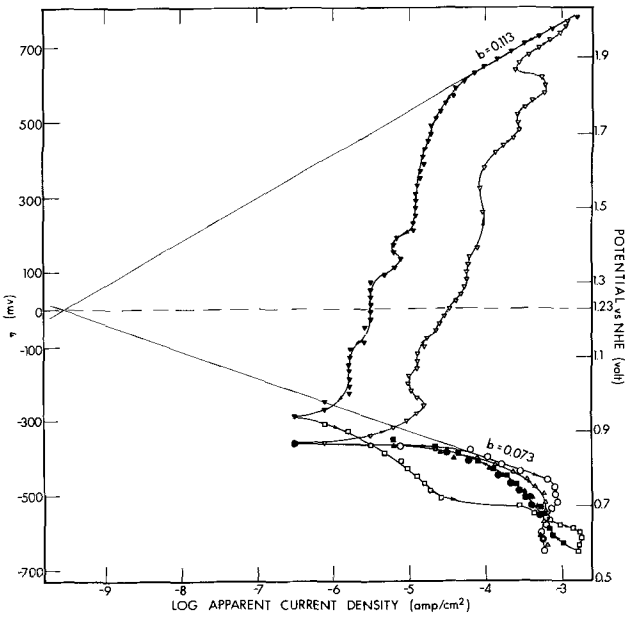

Fig. 6. Oxygen overvoltage curves obtained potentiostatically on Pt electrodes in O_2-saturated 2*N* H_2SO_4 solution containing 0.1M MeOH. Open symbols represent increasing and filled decreasing polarization. ○, First cathodic curve; △, second cathodic curve; ▽, first anodic curve; □, cathodic curve of preanodized Pt. Tafel lines of first polarization curves cross at zero η (1229 mv); i_o is 2.6 x 10^{-10} amp/cm².

Steady-state overvoltage curves for the anodic evolution and cathodic reduction of O_2 on bright Pt obtained potentiostatically in MeOH-free 2*N* H_2SO_4 solution are presented in Fig. 5. The points on the extreme left of the figure represent virtually zero current density. The same data for an acid solution which is 0.1M in MeOH is shown in Fig. 6.

Discussion

The rest potential.—As pointed out by Shlygin and Bogdanovskii (6), the shift of the rest potential of a Pt/O_2 electrode toward less noble values with the addition of MeOH cannot be caused by a purely double layer or specific adsorption effect because the magnitude of the shift is too great. Besides, the shift is in the wrong direction, and therefore, it is more likely produced by an electron transfer process. Since the standard potential, $E°$, of the O_2/H_2O reaction

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O \qquad [1]$$

is 1229 mv (15), and of the $MeOH/CO_2$ reaction

$$CH_3OH + H_2O \rightleftharpoons CO_2 + 6H^+ + 6e \qquad [2]$$

is 20 mv (8), the rest potential does not obey a Nernst relationship (see Fig. 1) and must be determined by a mixed potential mechanism. Giner (8) has also come to this conclusion.

Since the rest potential depends on P_{O_2} as seen in Fig. 1b and since the slope of the *E*-log P_{O_2} curve is low at high values of P_{O_2}, it is reasonable to assume that the O_2/H_2O reaction is one of the partial reactions making up the local cell. As shown in Fig. 1b, the rest potential also depends on the MeOH concentration in the bulk of the solution as has been recorded in the literature (4-11). Although Breiter (9, 10) concludes that MeOH is not adsorbed on Pt above 800 mv, Giner (8) and Bagotskii and co-workers (11) give evidence of MeOH adsorption above a volt. It therefore appears that the oxidation of MeOH could be the other half reaction of the local cell.

From studies of the oxidation of MeOH (8) and the reduction of CO_2 (16) at Pt electrodes, Giner has proposed that a stable intermediate, such as adsorbed CO or COOH, which inhibits the electrode reactions, is formed in these systems. It is possible (4-6) that the first step in the oxidation of MeOH is the oxidation of the hydroxyl hydrogen as

$$(CH_3OH)_{ads} \rightarrow (CH_3O)_{ads} + H^+ + e \qquad [3]$$

One may visualize further, with the discharge of three more electrons in acid solutions, the oxidation of the remaining three hydrogens of the methyl group giving successively $(H_2CO)_{ads}$, $(HCO)_{ads}$, and finally $(CO)_{ads}$. The over-all reaction would be

$$(CH_3OH)_{ads} \rightarrow (CO)_{ads} + 4H^+ + 4e \qquad [4]$$

Warner and Schuldiner (17) have shown that CO is strongly adsorbed on Pt. To remove the CO involves the discharge of a molecule of H_2O, and probably, as suggested by Warner and Schuldiner, the CO reacts rapidly with the adsorbed oxygen atoms produced by the discharge of H_2O.

Because the rest potential depends both on the MeOH concentration and on the P_{O_2} (Fig. 1), it is likely to be controlled by both half-reactions. A possible explanation for the observed behavior may be described in terms of a mixed potential composed of the O_2/H_2O, Eq. [1], and the MeOH/Pt-CO, Eq. [4], reactions. Sketches of the local cell polarization diagrams are given in Fig. 7 which show the influence of the concentration of O_2 and MeOH on the shape of the polarization curves. In these diagrams, the A-curves refer to the O_2/H_2O reaction and the B-curves to the MeOH/Pt-CO reaction. E_a is the standard potential, 1229 mv, and E_b is the $E°$ for the MeOH/Pt-O reaction which is unknown but which must be less noble than 800 mv according to mixed potential considerations (18).

The change in slope of the rest potential-log P_{O_2} curve (Fig. 1b) from 15 mv to 60 mv with decreasing

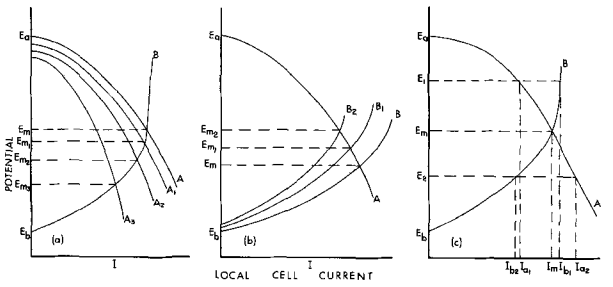

Fig. 7. Mixed potential diagrams. A-curves represent polarization of the O_2/H_2O reaction and B-curves the MeOH/Pt-CO reaction. The abscissa represents the absolute value of the local cell current, I. E_a and E_b are the $E°$ values for the respective partial reactions. (a) Curves A to A_3 represent the polarization curves for decreasing values of P_{O_2}, and the corresponding values of the mixed potential are shown as E_m to E_{m3}. (b) Curves B to B_2 represent the polarization curves for increasing concentrations of MeOH, and the corresponding mixed potential values are shown as E_m to E_{m2}. (c) When the potential is shifted anodically to E_1, the current in the external circuit is I_{b1}-I_{a1} and is positive; when shifted cathodically to E_2, external current is I_{b2}-I_{a2} and is negative.

values of P_{O_2} in MeOH-containing solutions may be interpreted in terms of the effect of adsorbed MeOH on the local cell polarization curve of the O_2/H_2O partial reaction (A-curves in Fig. 7a). At high values of P_{O_2}, the A-curve crosses the MeOH/Pt-CO polarization curve at a point, E_m, where the B-curve is at a limiting current. Consequently, the rest potential is determined by the O_2/H_2O reaction, and a value of 15 mv is expected for the slope of the E-log P_{O_2} curve. As the value of P_{O_2} decreases, the overvoltage for the reduction of O_2 increases as seen in Fig. 4, and hence, it is reasonable to suppose that the local cell polarization curves (A-curves of Fig. 7a) become more steep with decreasing P_{O_2}. Therefore, at lower P_{O_2} values, the A-curves cut the B-curve at points where the MeOH/Pt-CO polarization curve is no longer at a limiting current. Under these conditions, the rest potential is no longer controlled solely by the O_2/H_2O partial reaction but is also strongly influenced by the MeOH/Pt-CO reaction. This effect produces a larger change in rest potential, $E_{m3} - E_{m2}$, for a given change in P_{O_2} at low P_{O_2} than $E_{m1} - E_m$ for the same change in P_{O_2} at high P_{O_2}. This effect is reflected in the change to a higher slope (60 mv) in Fig. 1b.

As the methanol concentration is increased from 0.1 to 0.5M, the O_2/H_2O reaction becomes more inhibited, and the local cell polarization curves become steeper. From this viewpoint, the rest potential would be determined by the O_2/H_2O reaction over a shorter range of P_{O_2} values. As seen in Fig. 1b, the deviation from the 15-mv slope would occur at higher values of P_{O_2}.

According to the Nernst equation, the reversible methanol potential becomes more noble with decreasing MeOH concentrations. In Fig. 7b, the local cell polarization curves for the MeOH/Pt-CO reaction (B-curves) reach a limiting current at lower values of the current with decreasing MeOH concentrations. As a result, for a given change in MeOH concentration the change in E_m is much larger than the corresponding change in E_b, thus accounting for the apparent 1-electron dependency in Fig. 1a instead of the expected 4-electron dependency of Eq. [4].

Apparently, only the reduction of oxygen and the oxidation of methanol are involved in the mixed potential mechanism. Metal-metal oxide reactions do not seem to be important, because as shown in Table I, the rest potential is independent of the electrode material. The gold electrode may be somewhat out of line, but this may be caused by the observation (19) that gold slightly adsorbs MeOH. Current is not contributed to the external circuit by these local cell processes.

The mixed potential region.—If, however, the system is polarized from an external source, the observed current is the difference between the partial currents

$$I = I_a - I_b \qquad [5]$$

as pictured in Fig. 7c. It was shown (13) that an overvoltage, η_p, may be defined as $E - E_m$. A plot of $E - E_m$ as a function of the apparent current density obtained galvanostatically is presented in Fig. 3. In the vicinity of $E = E_m$, a linear curve passing through the mixed potential without a change in slope is obtained. The linear anodic branch is shorter than the cathodic which agrees with the mixed potential diagram in Fig. 7c. For relatively large values of η_p ($E_1 - E_m$ and $E_2 - E_m$ in Fig. 7c), the cathodic is larger than the anodic current for the same values of the anodic and cathodic overvoltage.

From the slope of the curve in Fig. 3, a value of 2.7 x 10^{-4} mho is obtained for $di/d\eta_p$; and it may be shown (13) that the local cell current at $E = E_m$ is given by

$$i_m = (di/d\eta_p)\frac{RT}{F} \qquad [6]$$

A value of 7.1 x 10^{-7} amp/cm^2 is obtained for i_m, the rate of oxidation of MeOH at a Pt surface in the presence of oxygen.

Galvanostatic reduction of oxygen.—For comparison, the galvanostatic cathodic overvoltage curve for the reduction of oxygen on a Pt electrode in MeOH-free, O_2-saturated 2N H_2SO_4 is plotted in Fig. 2. With MeOH present, the overvoltage is greatly increased at low current densities, but the curve is flat in this region due to the polarization of the mixed potential process. When the system is cathodized to higher currents, the mixed potential mechanism no longer controls the kinetics, and the reduction of oxygen contributes virtually all of the current to the external circuit. In this case the system is no longer a polyelectrode but a simple electrode, and a Tafel region with a slope equal to that on pure Pt in 2N H_2SO_4 solution is obtained. At current densities of about 10^{-3} amp/cm^2, the system reaches a limiting current leading to the reduction of H^+ ions.

Because the overvoltage is dependent on P_{O_2} (Fig. 4) and the presence of H_2O_2 may be detected with $TiSO_4$ reagent, it is concluded that O_2 is being reduced at the Pt cathode. Since the shape and slope of the overvoltage curves at high current densities are the same for H_2SO_4 solutions in the presence and in the absence of MeOH, the mechanism of O_2 reduction is likely to be the same in both cases. The observed effect, of course, is an increase in the overvoltage with increased MeOH concentration without a change in slope. It seems then that the presence of MeOH in the electrolyte only blocks some of the active sites for the reduction of oxygen with adsorbed CO. As a result, the electrode area available for O_2 reduction is reduced, and the system must go to a higher overvoltage to supply the same current that was obtained in the absence of MeOH. Methanol is oxidized at the high current densities by the mixed potential mechanism, but none of this current reaches the external circuit, since it appears entirely in the local cell circuit. Consequently the presence of MeOH does not interfere with the kinetics of the reduction of oxygen but only effectively increases the activation energy for the reduction-of-oxygen process by poisoning some of the surface reaction sites.

Potentiostatic data in the absence of MeOH.—To obtain additional evidence for these conclusions, potentiostatic polarization studies were made on Pt anodes and cathodes in O_2-saturated acid solutions both in the absence and in the presence of MeOH. Four complete cycles of polarization are shown in Fig. 5 for the reduction of oxygen on a Pt cathode in the absence of MeOH. The first cycle is shown by the circles (open for increasing and filled for decreasing polarization),

and the average of the next three cycles is shown by the triangles.

It is to be noted that the overvoltage for increasing polarization during the first cycle is greater than the average steady-state value (triangles) at low current densities but less at the high current densities. This effect was observed on the galvanostatic curves in Fig. 2 and Fig. 2 of ref. (13). Using triangular potential sweep techniques, Breiter (20) concluded that the presence of adsorbed oxygen on a Pt electrode inhibited the reduction of O_2 to H_2O_2. Bianchi and coworkers (21) found that the presence of adsorbed oxygen on a Pt electrode accelerated the reduction of H_2O_2 to H_2O. From a series of studies of the reduction of O_2 at a rotating ring electrode, Myuller and Nekrasov (22) observed that the reduction of oxygen to H_2O occurred in two stages: reduction of O_2 to H_2O_2 and reduction of H_2O_2 to H_2O. It is interesting to note that the specific rate, k_2, of the second stage was an order of magnitude larger than the specific rate k_1, of the first stage on oxidized Pt, but on reduced Pt, $k_1 > k_2$.

When a Pt electrode which is at a steady-state rest potential is first cathodized, the surface initially is partially covered with adsorbed oxygen. At low current densities where H_2O_2 concentrations are not built up in solution because the peroxide-decomposing capabilities of the electrode surface are adequate for the demanded current, the overvoltage is increased by the Pt-O layer since the rate of reduction of O_2 to H_2O_2 is inhibited. At high current densities, on the other hand, the rate of decomposition of H_2O_2 becomes important as the H_2O_2 concentration in solution builds up. In this case, the presence of the Pt-O layer enhances the rate of catalytic decomposition of H_2O_2, because, in agreement with Bianchi *et al.*, H_2O_2 is decomposed by reacting chemically with the Pt-O layer

$$H_2O_2 + Pt-O \rightarrow H_2O + O_2 + Pt \qquad [7]$$

Here the η is lowered by the Pt-O layer. Finally, at the high current densities where the limiting current for O_2 reduction is reached, the Pt-O layer is completely reduced, and now, the H_2O_2 is catalytically decomposed by an electrochemical process as suggested by Gerischer and Gerischer (23) and described by Fig. 5 of ref. (24). After the Pt-O layer is removed, the polarization curve follows the reproducible steady-state polarization curve (triangles) in Fig. 5. These data support the contention that O_2 is reduced at Pt cathodes in acid solutions in two 2-electron stages with H_2O_2 being formed as a stable intermediate. This is contrary to the conclusion arrived at by Liang and Juliard (25).

When a Pt/O_2 electrode is anodized from the steady-state rest potential, the initial part of the curve (open inverted triangles in Fig. 5) is the mixed potential region (13) in which a local cell mechanism composed of the O_2/H_2O and the Pt/Pt-O reactions (12) is kinetically controlling. As the potential is made more noble, a point is reached where the current no longer increases. Although a few wiggles are observed in this part of the curve, it is essentially a limiting current region. In this potential range, 1140 (η = —90 mv) to 1460 mv (η = 230 mv), it is believed that the surface becomes more covered with an electronically conducting monolayer of Pt-O. Since the surface coverage, θ, is potential-dependent (26, 27) and the layer is electronically conducting, the only change produced by an increase in potential is an increase in θ. At potentials above 1460 mv (η = 230 mv), oxygen is evolved on the conducting Pt-O layer. In the potential range between 1820 (η = 590 mv) and 1900 mv (η = 670), some Pt-O sites are converted to PtO_2 sites in a second limiting current region. Finally O_2 is evolved on a surface composed of Pt-O and PtO_2 sites. Once this surface is formed, a reproducible Tafel region with a slope of 0.145 is obtained over the current density range indicated in Fig. 5. The points in the Tafel region at the top of Fig. 5 are the average of three complete cycles of polarization with a deviation of ± 0.05 units of log i.

Apparently PtO_2 is unstable in the presence of Pt at potentials lower than about 1700 mv (η = 470 mv) because an oxide reduction curve such as that obtained in the Pd/O_2 case (14) was not observed when the anodized Pt electrode was cathodized. Instead, virtually zero current was obtained below 1500 mv (η = 270 mv) until a potential below 1100 mv (η = —130 mv) was reached. This behavior indicates that an oxide as such does not exist on a Pt surface in acid solutions below 1500 mv (η = 270 mv). In this region, it is believed that the surface is covered by a Pt-O layer (12, 13) with oxygen dissolved in surface layers of the Pt metal as suggested by Schuldiner and Warner (28).

Because the surface is strongly covered with adsorbed atomic oxygen, Pt-O, it would be expected from Myuller and Nekrasov's work that the reduction of O_2 to H_2O_2 would be greatly inhibited on such a surface. Indeed, as seen in Fig. 5 (open squares), the η is very large at low current densities as predicted. In addition, just as would be expected, the η is lower for the Pt-O surface than for the reduced surface in the high current density region where the catalytic decomposition of H_2O_2 is important. Once the Pt-O layer is removed in the high cathodic current density region, the overvoltage curve becomes identical with the original steady-state curve as shown by the filled squares in Fig. 5.

As a point of interest, the cathodic Tafel slope is about 0.09 for galvanostatic measurements but is very close (0.118) to 0.12, the value associated with an electron transfer controlled mechanism, for potentiostatic measurements. An explanation may be similar to that suggested in the Pd/O_2 case (14). In the galvanostatic case, the current or rate of reaction is fixed, and because of the activation energies involved, the concentration of a stable intermediate such as H_2O_2 may build up in solution. Such concentration changes may cause variations in potential [lower the potential (24) in the case of H_2O_2] which produce a flattening of the Tafel curve. The experimental conditions are fixed in the potentiostatic case, and the current or rate must adjust to this environment. Here, the effect of the intermediate, H_2O_2, is included in the kinetics, and a flattening of the curve does not occur. It has been suggested (13) that the rate-determining step is the discharge of the first electron

$$(O_2)_{ads} + e \rightarrow (O_2^-)_{ads}$$

so that a slope of 0.12 is expected.

Since the extrapolated anodic and cathodic Tafel lines cross at zero η, it is concluded that the over-all electrode reaction is the O_2/H_2O reaction, Eq. [1]. A value of 8.5×10^{-9} amp/cm^2 is obtained for i_o which is in good agreement with that, 1.3×10^{-9} amp/cm^2, found galvanostatically (13).

Potentiostatic data in the presence of MeOH.—In Fig. 6 the overvoltage curves obtained for an oxygen saturated acid solution containing MeOH on a Pt cathode are nearly the same as the galvanostatic curves in Fig. 2; the flat mixed potential region is followed by a Tafel region. Even in the high current density region there is lowering of the overvoltage caused by the Pt-O layer on the first half-cycle of polarization as discussed for Fig. 5. When this layer is removed, the η increases in the high current density region. The effect of the Pt-O layer is not observed at low current densities because the current is controlled by the MeOH mixed potential mechanism and not by the pure reduction of O_2 as shown in Fig. 5. These data show that virtually all of the external current goes into the reduction of oxygen.

When this system is anodized, a mixed potential region is observed initially, followed by a negative

resistance region at about 1000 mv (η = −230 mv). Another such negative resistance region is observed above 1800 mv (η = 570) where it is believed that PtO_2 is formed. Above 1860 mv (η = 630 mv), most of the current goes into the evolution of oxygen, because the overvoltage curves are the same whether the solution does (Fig. 6) or does not (Fig. 5) contain MeOH. Between the mixed potential and the oxygen evolution regions, a limiting region such as that observed in Fig. 5 is not observed because as the potential increases more MeOH is oxidized and hence the current increases. Both the evolution of oxygen and the oxidation of MeOH occur simultaneously between 1000 mv (η = −230 mv) and 1860 mv (η = 630 mv).

A Tafel region is observed above 1860 mv (η = 630 mv). It seems that in this region the presence of PtO_2 strongly inhibits the oxidation of MeOH, and nearly all of the current is used in evolving O_2 on the oxide covered Pt surface. With cathodic polarization below 1860 mv (filled, inverted triangles in Fig. 6) where the PtO_2 layer decomposes, the evolution of oxygen is overshadowed by the MeOH oxidation, and the η decreases rapidly compared with the corresponding curve in Fig. 5. Below 1500 mv (η = 270 mv) virtually all of the external current is contributed by the oxidation of MeOH. Finally, an open-circuit value of 940 mv is obtained which is more noble than the original value of 870 mv. This is to be expected because some of the MeOH has been oxidized, and as seen in Fig. 1a, the rest potential becomes more noble as the bulk concentration of MeOH decreases.

When this preanodized electrode is cathodized (open squares in Fig. 6), the polarization curve at low current densities falls to large values of the cathodic η just as in the case where MeOH is absent (Fig. 5). Similarly, the η is lower for the anodized surface than for the reduced surface at high current densities. As before, once the Pt-O layer is removed, the overvoltage curve becomes identical with the curve obtained for a reduced Pt surface (filled squares in Fig. 6).

Interestingly, the extrapolated Tafel lines from the first cycle of anodic and cathodic polarization cross at zero η. This is taken to be an indication that the overall electrode process at high anodic and high cathodic current densities is the O_2/H_2O reaction as in the MeOH-free case (Fig. 5). The i_o, 2.6 x 10^{-10}, is over a magnitude lower than the i_o value in the absence of MeOH. This behavior reflects the blocking action of the electrode reaction by the adsorbed CO, resulting in a poisoning of the catalytic Pt surface.

These data support the conclusion that the presence of MeOH at a Pt/O_2 cathode does not alter the kinetics of the O_2 reduction process but effectively reduces the available number of sites on which the electrode process can occur at high current densities. The visible effect is an increase in η for a given current density. A more drastic increase in η is observed at low current densities produced by the action of the MeOH mixed potential mechanism.

Kinetics of Electrode Reactions with Adsorbed Films

T. Biegler[1] and H. A. Laitinen

Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois

ABSTRACT

The kinetics of reduction of cadmium ion on a mercury electrode partly covered by n-butanol, thymol, and leucoriboflavin and of plumbite ion in the presence of n-butanol was examined by the method of faradaic impedance with polarographic generation of reactants. Exchange currents and rate constants were lower than expected on the basis of a linear dependence on coverage. A small increase in the transfer coefficient for the reduction of cadmium was observed with partial coverage by leucoriboflavin. Slopes of the impedance plots were independent of coverage. Changes in polarographic log plots and $E_{1/2}$ values with decreasing rate constant were in line with the accepted criterion for polarographic reversibility.

Several authors have examined the kinetics of electrode reactions on surfaces partly covered by adsorbed films of uncharged electroinactive species (1-5). In most cases a linear relationship between exchange current or rate constant and fractional coverage has been demonstrated, a finding which tends to support a simple model for the influence of such adsorption on a reaction. Rek (4), working with the ferro-/ferri-oxalate system, reported a nonlinear dependence of exchange current on coverage by thymol, as well as by ionic surface-active species. Recently, Aramata and Delahay (5) showed that the effect of n-amyl alcohol on the zinc/zinc amalgam system was not simply a blocking of the reaction at covered portions of the surface, but that changes in double layer structure played a large part in the over-all effect. That this is true even at potentials near the electrocapillary maximum will be shown in the following communication in which results of a study undertaken to obtain kinetic data for several systems with clean and partly covered surfaces are presented.

Experimental

Electrode kinetic parameters were determined by measurement of faradaic impedance with polarographic generation of reactants; full experimental details have been described elsewhere (6). Briefly, the impedance of a dropping mercury electrode connected in a manual polarographic circuit was measured with a bridge technique at several frequencies in the range 100-2000 cps. The rate constant was obtained from the impedance at the half-wave potential of a reversible polarographic wave and the transfer coefficient from impedance data at several points on such a wave.

Surface coverages were obtained from the differential capacity of the electrode/solution interface, assuming linear dependence of capacity on coverage. This assumption is probably justified here since in all cases the potential was in the vicinity of the electrocapillary maximum and double layer capacities were independent of frequency (7). For leucoriboflavin, linearity between capacity and coverage in the potential range of interest has been fairly well established (8). Leucoriboflavin was generated at the electrode surface by diffusion-controlled reduction of riboflavin present in the solution in very small concentrations (0.4-2 x 10^{-5}M). Coverage was therefore a function of time and care was taken to obtain impedance measurements at approximately the same time during drop life for all the frequencies used. The same precaution was necessary with small concentrations of thymol where time dependent double layer capacities, indicating diffusion control of adsorption, were noted.

[1] Present address: Department of Physical Chemistry, University of Bristol, England.

Since a dropping mercury electrode was used no special purification procedures were deemed necessary. This attitude was justified by the good agreement with other workers on kinetic parameters for reactions at a clean mercury surface (6). Reagents used were of analytical grade. Solutions were prepared with water distilled from alkaline permanganate in an all-glass apparatus. General experimental procedure was as outlined previously (6). When a volatile surface active component was used the nitrogen for deaeration was first passed through a wash bottle containing a solution of the same composition as in the cell. All experiments were carried out in a water bath at 25°C.

Results and Discussion

Behavior of the Faradaic impedance.—In all cases examined the faradaic impedance behaved normally by the usual criteria (9); plots of the faradaic resistance AR_f (A is the electrode area) and reactance $A/\omega C_f$ against $\omega^{-1/2}$, where ω is the angular frequency of the alternating voltage, were parallel and the reactance plots passed through the origin. In a series of runs with increasing concentration of surface active material the reactance plots coincided, within experimental error, with that for discharge on a clean surface. The only effect of the adsorbed film was to move the resistance and reactance lines further apart as the process became slower (Fig. 1). This contrasts with the results of Laitinen *et al.* (3) in which the plots became steeper with increasing coverage.

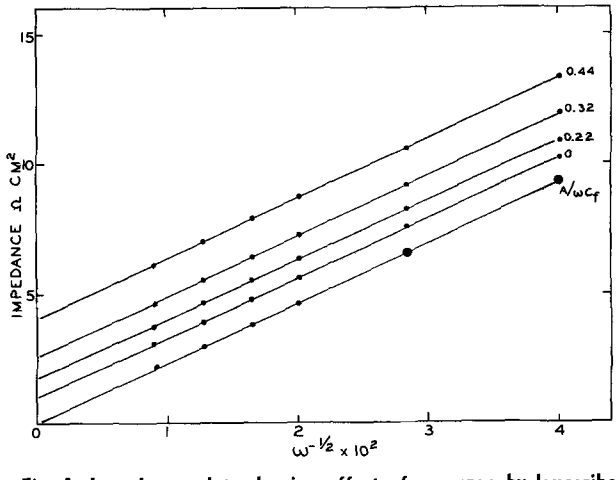

Fig. 1. Impedance plots showing effect of coverage by leucoriboflavin on discharge of 0.286 mM Cd^{++} in 0.1M $HClO_4$, 0.9M $NaClO_4$. Reactance plot (lower line) shows range of values at each frequency for the four runs. Numbers on resistance plots indicate coverage.

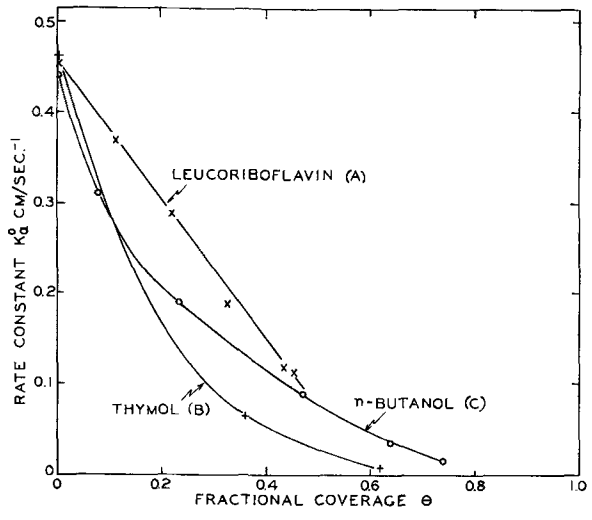

Fig. 2. Effect of surface coverage on apparent rate constant for discharge of cadmium ion. Adsorbed species indicated on diagram. Supporting electrolyte was 0.1M $HClO_4$, 0.9M $NaClO_4$. Cadmium concentrations were: A, 0.286 mM; B, 0.372 mM; C, 0.363 mM.

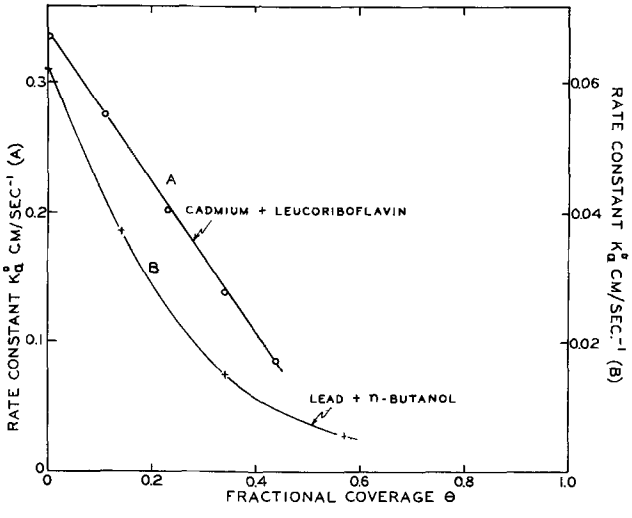

Fig. 3. Effect of coverage on apparent rate constant for: A, 0.280 mM Cd^{++} in 1.0M $HClO_4$; adsorbed species leucoriboflavin; B, 0.406 mM $HPbO_2^-$ in 0.1M NaOH, 0.9M $NaClO_4$; adsorbed species n-butanol.

Constancy of slope suggests at first that the adsorbed layer influences the reaction uniformly over the whole electrode surface rather than blocking it only at covered portions. However, at the frequencies used here (100-2000 cps) the diffusion layer for the a-c process ranges in thickness from about 2 x 10^{-4} to 2 x 10^{-3} cm which is very large compared with the dimensions of an adsorbed molecule or even of a relatively large island of such molecules. Under these circumstances the diffusion part of the faradaic impedance is unaffected by nonuniformity of reaction kinetics at the surface (10), and the electrode behaves with its total area.

Effect of coverage on rate constants.—Relationships between rate constants and fractional surface coverages (θ) for several systems are shown in Fig. 2 and 3. Coverage by leucoriboflavin appeared to affect the rate constant in a linear manner while for the other systems the plots were curved. In no case did the results show a linear dependence of rate on coverage of the type found previously (1-4) where k_a^0 approaches zero as θ approaches unity; all rate constants were smaller than predicted by such a dependence. Values of α needed to calculate k_a^0 (6) were assumed to be the same as for a clean surface although only minor changes would result if this assumption were not correct (see also below).

In a recent paper (5) it has been suggested that the over-all effect of a surface film can be accounted for by considering two factors, first a change in potential at the reaction site, assumed to be the outer Helmholtz plane, and second a linear decrease of current density with coverage. According to this view, correction of exchange current values for the potential drop across the diffuse double layer (Ψ) or, alternatively, normalization of exchange currents to a given potential of the outer Helmholtz plane, conveniently the value for the clean surface at the standard potential (Ψ_0), should give exchange currents and rate constants which depend linearly on coverage. We lack the necessary data to make such corrections, but nevertheless it is of interest to calculate the theoretical changes in Ψ which would cause the observed departures from linearity.

Thus, if I_θ is the measured exchange current density at coverage θ when the potential of the outer Helmholtz plane is Ψ_θ, then the exchange current I_θ^0 which would have been observed in the absence of any change in Ψ with adsorption, *i.e.* with $\Psi = \Psi_0$, is given by

$$\frac{I_\theta^0}{I_\theta} = \exp\left[\frac{(z - \alpha n)\mathbf{F}}{RT}(\Psi_\theta - \Psi_0)\right] \qquad [1]$$

where z is the charge on the reacting ion and n is the number of electrons involved in the reaction. I_θ^0 is estimated from the coverage by assuming that I_θ^0 changes linearly with θ and is zero when $\theta = 1$. Equation [1] is then used to calculate $\Psi_\theta - \Psi_0$, the change in potential of the outer Helmholtz plane needed to account for the observed difference between I_θ^0 and I_θ. Plots of $\Psi_\theta - \Psi_0$ (denoted in the following as $\Delta\Psi$) against θ are shown in Fig. 4.

As noted above, lack of knowledge of the double layer properties for these systems prevents a full analysis of the results, but it is possible to speculate on the likelihood of some of the $\Delta\Psi$ values of Fig. 4. The electrocapillary maximum (ecm) in 1M $NaClO_4$ is —0.493v *vs.* SCE (11) and is certainly close to this value in the supporting electrolyte used for A, B, and C of Fig. 4. Addition of 0.1M NaOH as in Fig. 4D also probably causes little change in the ecm in view of the minor specific adsorption of OH^- (12). The cadmium half-wave potential (—0.57v *vs.* SCE) is therefore some 75 mv cathodic to the ecm and, by analogy with data for perchloric acid (13), Ψ_0 is esti-

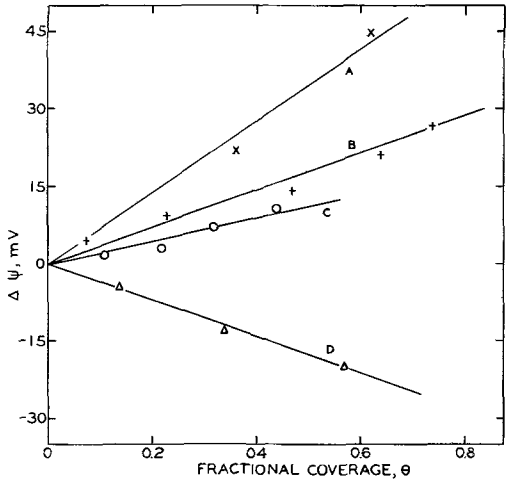

Fig. 4. Plots of $\Delta\psi$ (see text) as a function of fractional coverage θ for the following systems: A, 0.372 mM Cd^{++} in 0.1M $HClO_4$, 0.9M $NaClO_4$ plus thymol; B, 0.363 mM Cd^{++} in 0.1M $HClO_4$, 0.9M $NaClO_4$ plus n-butanol; C, 0.286 mM Cd^{++} in 0.1M $HClO_4$, 0.9M $NaClO_4$ plus leucoriboflavin; D, 0.406 mM $HPbO_2^-$ in 0.1M. NaOH, 0.9M $NaClO_4$ plus n-butanol.

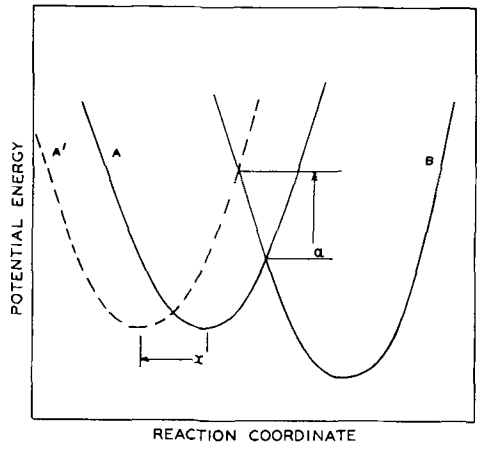

Fig. 5. Schematic energy diagram for electrode reaction. A and B are curves for reactants and products, respectively. A is shifted by a distance x along the reaction coordinate to A' and a is the increase in activation energy.

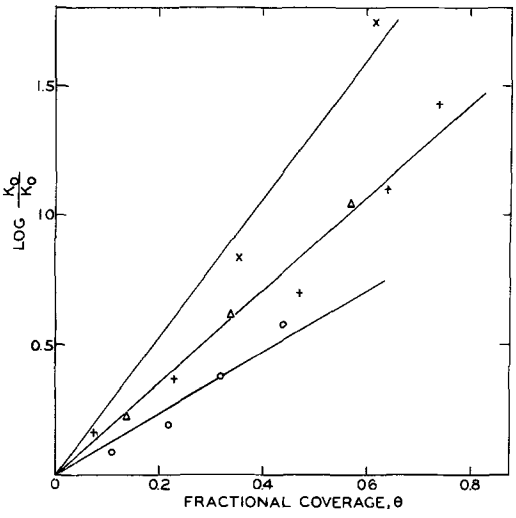

Fig. 6. Plots of log k_0/k_θ vs. θ for the systems of Fig. 4. X—A, +—B, O—C, Δ—D.

mated to be −23 mv. This relatively large value is due to the appreciable specific adsorption of perchlorate ion. Nothing is known of the effects of n-butanol on perchlorate adsorption, but even if such adsorption were markedly decreased $\Delta\Psi$ values of greater than about +20 mv seem unlikely in view of the fact that butanol shifts the ecm anodically. Thymol causes a cathodic shift of the ecm (15), but the large values of $\Delta\Psi$ required by Fig. 4A seem improbable. It is even harder to accept the negative values of $\Delta\Psi$ in Fig. 4D [Ψ_0 for this case is estimated from (13) to be −25 mv] and, if the model were correct the present behavior would provide evidence against the discharging species having a negative charge as was assumed in the calculation. It may be concluded that two of the systems studied here do not support the model proposed by Aramata and Delahay (5) while in the other systems the required changes in Ψ are feasible although not confirmed.

Another relatively simple model which has not been considered previously can be used to give a reasonable explanation of the present results. The assumptions made are: (a) The reaction is slowed down in the presence of adsorbed neutral molecules by virtue of the increased separation between the outer Helmholtz plane and the electrode surface; (b) this separation is a linear function of coverage; and (c) the effect of such increased separation may be represented by an increase in distance, along the reaction coordinate, between potential energy curves of the type conventionally used to represent the course of electrode reactions (Fig. 5). If the intersection of these curves occurs well above the energy minima, the increase in activation energy may be approximated to a linear function of the increased separation. By equating this energy to the heat of activation we can write

$$\Delta H_\theta^\ddagger = \Delta H_0^\ddagger + (\Delta H_1^\ddagger - \Delta H_0^\ddagger)\,\theta \qquad [2]$$

where the subscripts refer to the coverage. The rate constant is given by

$$k_\theta = A \exp\left(\frac{-\Delta H_\theta^\ddagger}{RT}\right) \qquad [3]$$

where A is a pre-exponential factor, assumed here to remain constant, *i.e.*, the entropy of activation is unchanged. It follows that

$$\log\frac{k_0}{k_\theta} = \theta\left(\frac{\Delta H_1^\ddagger - \Delta H_0^\ddagger}{2.3\,RT}\right) \qquad [4]$$

k_0 being the rate for the clean surface.

Plots of log k_0/k_θ *vs.* θ are shown in Fig. 6. Agreement with Eq. [4] is not entirely convincing, and it should be noted that extrapolation to $\theta = 1$ gives rate constants only about two orders of magnitude smaller than k_0 whereas it is well known that the rates of such reactions at high coverages are very much less than this. Another point is that "Frumkin" corrections of the type given by Eq. [1] have been neglected here and should be included in a complete treatment. However, as a first approximation the above model appears to account for the present results with reasonable success. Further development of this model would need to include a more thorough consideration of the shapes of the potential energy curves and the possibility that the slopes at the point of intersection vary with separation. Clearly, increased slopes on the upper branches of these curves would result in a faster change of a with x (Fig. 5) and could account for more rapid changes of k_θ with θ at higher coverages.

Effect of coverage on transfer coefficient.—Table I contains the results of α determinations for discharge of cadmium in presence and absence of surface films. In the case of butanol, coverage calculated from double layer capacities changed with potential, and the value given for α, which does not differ significantly from that for a clean surface, may be misleading. We have attempted to make approximate corrections to measured exchange currents by noting the rate of change of k_a° with θ for a similar system (cf. Fig. 2C) and calculating exchange currents for an arbitrarily selected coverage, in this case 0.35, which was the measured value of θ at $E_{1/2}$. This procedure gave $\alpha = 0.20$ so we must admit the possibility that α did in fact increase slightly.

Leucoriboflavin was chosen as an adsorbate for α determinations because coverage is essentially independent of potential (8). Experimentally, constant coverage is ensured by making all impedance measurements with a given bulk concentration of riboflavin at a fixed time, or within a small time range, during

Table I. Effect of surface films on α for discharge of Cd^{++}

the life of a mercury drop. For example, the present impedance data were obtained at times varying from 9.36 to 9.78 sec from initiation of a drop, giving a variation in coverage (which depends on $t^{1/2}$) of $\pm 1.3\%$ about a mean value. This was quite satisfactory for the present purposes and the small increase in α shown in Table II is probably significant.

Low values of α connected with reduction of cadmium ion in several electrolytes have been attributed to a slow "chemical" step, possibly dehydration of the hydrated ion, preceding the electrochemical reaction (16, 17). In the systems studied here the exchange current was lowered by a factor of four or five with little effect on α. It is of course possible that both the chemical and charge transfer steps were equally affected and there is not enough information to decide whether these results provide evidence for or against the dehydration step hypothesis. It would seem important to examine these reactions at high coverages where the relative rates of chemical and electrochemical steps may be greatly altered with a concomitant change in the apparent value of α.

Relation between rate constant and polarographic reversibility.—Polarographic data for reduction of plumbite ion ($HPbO_2^-$) in presence of n-butanol are shown in Table II together with the measured exchange currents and rate constants. These results give direct evidence for the validity of the usually accepted criterion of polarographic reversibility, $k_a^o \geq 2 \times 10^{-2}$ cm sec^{-1} (18); a small but significant increase in $E_{1/2}$ and the slope of the conventional polarographic log plot (E *vs.* log $(i_d - i)/i$) occurred when the rate constant fell below this value. It should be noted that, because the method used here to measure k_a^o is strictly valid only for a reversible wave, values at the higher coverages must be taken as approximate.

Technical Notes

Orthovanadate Phosphors with Zircon Structure

Frank J. Avella

General Telephone & Electronics Laboratories, Bayside, New York

The development by Levine and Palilla (1, 2) of europium-activated yttrium orthovanadate (YVO_4:Eu) as a highly efficient red-emitting cathodoluminescent phosphor and its recent adoption as a new primary for color television has aroused interest in other orthovanadates as potential hosts for lanthanide activators. Earlier, Van Uitert *et al.* (3) reported that YVO_4:Eu exhibits red fluorescence under ultraviolet excitation. Recently Brixner *et al.* (4) investigated $Ca_3(VO_4)_2$ and found it to be moderately efficient as a host for Eu; it is, however, substantially inferior to YVO_4. More efficient than $Ca_3(VO_4)_2$ are systems based on $M^{III}VO_4$, where M^{III} = Gd, Lu, and La. These have been described by Palilla, Levine, and Rinkevics (5) and Brixner and Abramson (6).

Several investigators have described the crystal structures of $M^{III}VO_4$ (7-11). When M^{III} has an ionic radius ranging approximately from 0.81 to 1.11Å (12), the material crystallizes with the tetragonal zircon-xenotime structure. This range includes the trivalent ions of Sc, Y and all the rare earth luminogens. Because trivalent La is a larger ion (1.15Å), its orthovanadate crystallizes in the monoclinic system with the monazite structure. However, $LaVO_4$ can accommodate small amounts of rare earths without serious lattice distortion. With Eu^{III} as the activator, the tetragonal vanadates have proved to be the better hosts (5). The crystal field of the monazite lattice favors the $^5D_0 \rightarrow {}^7F_1$ transition in Eu^{3+}, producing emission dominated by spectral lines between 558 and 595 nm.

In the zircon lattice with its D_{2d} site symmetry, the $^5D_0 \rightarrow {}^7F_2$ transition predominates and gives rise to the principal emission lines between 609 and 620 nm. Because of the greater intensity and more favorable color of the latter emission, YVO_4:Eu was recently adopted for use as the red-emitting primary in trichromatic cathode-ray tubes for television. This has led to further investigation of orthovanadate phosphors of the zircon type.

This paper presents data on a new series of Eu-activated phosphors derived from zircon-structured $M^{III}VO_4$ by substituting a divalent-tetravalent cation pair for two trivalent cations to form $M_{0.5}{}^{II}M_{0.5}{}^{IV}VO_4$. Activation with Eu^{III} is effected without need for charge compensation by partial replacement of both cations as represented by the formula $M_{0.5(1-x)}{}^{II}Eu_xM_{0.5(1-x)}{}^{IV}VO_4$. The choice of divalent and tetravalent cations is governed by their size, which should approximate that of the rare earth ions if the orthovanadates are to crystallize with the zircon structure. Some deviation from this size range may be possible on the part of one cation of the pair if the other stabilizes the zircon lattice.

Experimental

The following tetravalent ions were chosen for this investigation; their ionic crystal radii (12) are given in parentheses: Zr(0.80Å), Hf(0.81Å), Pb(0.84Å), Ce(1.01Å), Th(0.95Å) and U(0.89Å). The divalent ions were Mg(0.65Å), Ca(0.99Å), Sr(1.13Å), Ba(1.35Å), Zn(0.74Å), and Cd(0.97Å).

Preparation of powdered samples involved dry-blending appropriate reagent grade oxides, nitrates or carbonates in stoichiometric amounts, firing in open platinum crucibles at 500°-550°C for 5 hr, mortaring, and refiring between 600° and 900°C for upwards of 16 hr.

Synthesis results.—In the initial experiments Ca, which had been found capable of isostructural substitution for small amounts of Y in YVO_4, was paired with the tetravalent ions. Monophase products resulted when M^{IV} = Zr, Ce, and Th. X-ray diffraction data in Table I show by analogy that these compounds are isomorphs of the rare earth orthovanadates and, therefore, have the zircon structure. Hf, Pb, and U yielded multiphase products with indications of possible zircon-like phases. Of the three monophase materials, $Ca_{0.5}Ce_{0.5}VO_4$ had a body color too dark for consideration as a phosphor host, leaving Zr and Th for further evaluation.

When paired with the divalent ions, Zr formed the zircon structure only with Ca. Th was successfully paired with Sr and Cd in addition to Ca, while with Mg and Zn, zircon-like phases were major constituents of multiphase products. All of these materials were light tan or white in body color. Similar results have been reported by Schwartz for the zircon forms of $M_{0.5}{}^{II}Th_{0.5}VO_4$, where M^{II} = Ca, Sr, Cd, and Pb (13), and of $M_{0.5}{}^{II}Ce_{0.5}VO_4$, where M^{II} = Ca, Sr, and Cd (14).

The unactivated II-IV orthovanadates exhibit only feeble luminescence under ultraviolet excitation at room temperature, but the introduction of Eu^{3+} results in strong red photoluminescence. Maximum emission intensity is attained with an Eu concentration of approximately 15g a/o (atom per cent). Unlike $M^{III}VO_4$:Eu, the Eu-activated II-IV compounds respond only weakly to cathode-ray excitation. Activation with rare earths other than Eu produces very weak photoluminescence except for Sm which gives moderate emission. X-ray diffraction data verified that the introduction of rare earths into the II-IV lattices is actually isostructural. Furthermore, Eu stabilizes the Zn-Th compound and eliminates the nonzircon phase.

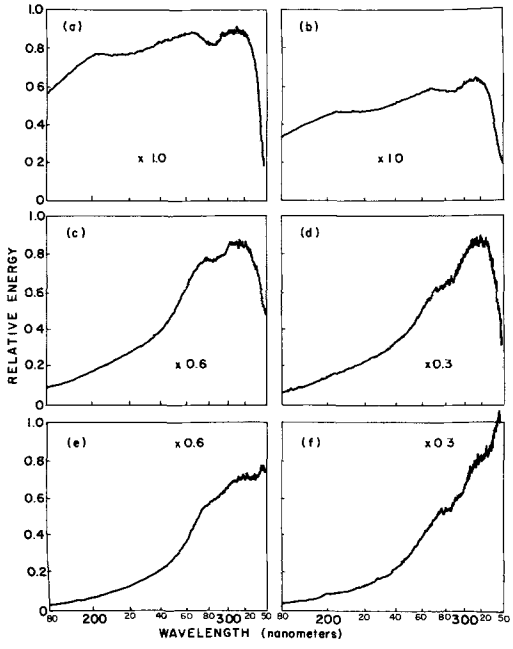

Fig. 1. Excitation spectra of Eu-activated orthovanadates: a, $Y_{0.95}Eu_{0.05}VO_4$; b, $Ca_{0.425}Eu_{0.150}Zr_{0.425}VO_4$; c, $Ca_{0.425}Eu_{0.150}Th_{0.425}VO_4$; d, $Sr_{0.425}Eu_{0.150}Th_{0.425}VO_4$; e, $Cd_{0.425}Eu_{0.150}Th_{0.425}VO_4$; f, $Zn_{0.425}Eu_{0.150}Th_{0.425}VO_4$.

Spectral measurements.—Excitation spectra presented in Fig. 1 were obtained by the method of Eby (15) where instrumental corrections are applied to produce spectra in terms of relative energy. Comparison of intensities is possible between phosphors when the ordinates are multiplied by the indicated factors. The emission spectra of Fig. 2 were determined by the method of Wiggins (16). A General Electric S-4 100w medium-pressure mercury vapor lamp was employed for excitation. The spectra were resolved with a ¾-meter Czerny-Turner Spectrometer (1200 line/mm grating and 50μ slit width) and detected with an ITT F4013 photomultiplier (S-20 response). In the Wiggins technique a correction function derived from the output of an NBS 1000w quartz-

iodine standard lamp serves as an internal reference so that spectra appear directly in terms of relative energy. In this series of spectral determinations no provision was made for comparing the emission intensities of the several phosphors.

Discussion

Palilla *et al.* (5) have found that $M^{III}VO_4$:Eu compounds with either a zircon or monazite structure possess similar excitation spectra. They hypothesized that excitation occurs mainly through the orthovanadate ligand and is largely independent of the cation. The spectra of Fig. 1 show, however, that variations in the cationic species do alter the excitation characteristics of the II-IV orthovanadates. When compared with YVO_4:Eu, the CaZr compound is the most similar. Its excitation band is broad and has essentially the same character. The other II-IV phosphors exhibit relatively much less absorption at the shorter wavelengths. Absorption maxima between 260 and 280 nm and between 310 and 320 nm are common to each of these phosphors, including YVO_4:Eu. However, the Cd and Zn ions have introduced new primary excitations at longer wavelengths. These are near the instrumental limit of 350 nm and are not well defined in the figure.

Luminescence of the II-IV phosphors is dominated by emission from $^5D_0 \rightarrow {}^7F_2$ transitions, as expected from Eu^{3+} in the D_{2d} site of a zircon-type orthovanadate lattice. However, variations in spectral detail relative to YVO_4:Eu occur to different degrees in the emission resulting from transitions to the principal multiplets $^7F_{1,2,3}$. Most pronounced is line broadening, observed up to fivefold (width at half peak height) for the strong emission line lying near 619 nm. There also are small differences in the wavelengths and relative intensities of some emission lines. These effects indicate that substitution of $M^{II}M^{IV}$ for M^{III} has altered the crystal field influence on the Eu^{3+} ion, but that the lattice symmetry still governs the general character of the emission.

Another difference between the $M^{II}M^{IV}$ and M^{III} phosphors is seen in the reaction of their luminosity to increases in temperature up to 400°C. While little change is seen in the luminosity of YVO_4:Eu, the room temperature value for the CdTh and ZnTh compounds is reduced to about 75% at 200°C, 50% at 300°C, and 20% at 400°C.

Table II. Relative luminosity data

Formulation	Excitation at primary maxima	Excitation with S-4 mercury lamp
$Y_{0.95}Eu_{0.05}VO_4$	100	100
$Ca_{0.425}Eu_{0.150}Zr_{0.425}VO_4$	50	56
$Ca_{0.425}Eu_{0.150}Th_{0.425}VO_4$	57	54
$Sr_{0.425}Eu_{0.150}Th_{0.425}VO_4$	39	40
$Cd_{0.425}Eu_{0.150}Th_{0.425}VO_4$	39	80
$Zn_{0.425}Eu_{0.150}Th_{0.425}VO_4$	47	84

Because the emission spectra of these orthovanadates are similar, it is possible to approximate phosphor efficiency by comparing luminosity values obtained when the exciting radiation corresponds in wavelength to the primary excitation maximum for each sample. In the experimental arrangement the exciting wavelengths were selected from radiation of a Hanovia 901C-1 xenon lamp with the excitation monochromator of the Aminco-Bowman Spectrophotofluorometer. Visible harmonics were eliminated with a Corning 7-54 filter. Luminosity values measured with an RCA 1P21 photomultiplier fitted with a Kodak Wratten 106 filter were corrected for variations with wavelength of lamp output and 7-54 filter transmission characteristics by using sodium salicylate powder as a quantum counter (17). These data are presented in the first column of Table II. $Ca_{0.425}Eu_{0.150}Th_{0.425}VO_4$ was found to be the most luminous and, therefore, the most efficient of the II-IV phosphors. The luminosity value, however, is only 57% that of YVO_4:Eu.

A different situation exists when a medium-pressure mercury lamp is the excitation source. The data in the second column of Table II were obtained using General Electric S-4 lamp radiation filtered with the Corning 7-54 to eliminate the visible component which would be reflected by the sample. Again, detection was performed with the 1P21 photomultiplier and Wratten 106 combination. Under these conditions, the ZnTh and CdTh phosphors, having their principal excitation maxima closer to the dominant 3650-3654Å band of the mercury discharge, yield 84 and 80, respectively, on a luminosity scale where YVO_4:Eu is rated 100. Thus, two of the II-IV vanadates may possibly substitute for YVO_4:Eu in applications where excitation by medium- or high-pressure mercury discharge is required.

Summary

$M_{0.5}^{II}M_{0.5}^{IV}VO_4$:Eu analogues of zircon-structured $M^{III}VO_4$:Eu were synthesized. Luminescence spectra show the preferred electronic transitions in the Eu^{3+} activator to be characteristic of zircon symmetry in an orthovanadate lattice. The $M^{II}M^{IV}$ cation pair introduce variations in luminescence fine structure and in excitation characteristics. Luminosity approaches that of YVO_4:Eu under certain conditions of excitation.

Current-Induced Oscillations in Liquid Ge

R. L. Anderson

Department of Electrical Engineering, Syracuse University, Syracuse, New York

During experiments on the Peltier effect at germanium solid-liquid interfaces, we have observed mechanical oscillations in the liquid Ge. It is the purpose of this note to describe some of the characteristics of these oscillations.

Bars of Ge were cut 10 cm long and from 0.2 to 1.0 cm^2 in cross-sectional area. The Ge was placed on a quartz boat in a quartz tube. Tungsten leads were attached to either end of the bar and were fed through stoppers at both ends of the tube. A molten zone 1-2 cm long was formed near the center of the bar by heating this region with two focused 1000w projector lamps (1). After the molten zone was formed, a direct current source was applied to the tungsten leads. Ambients of hydrogen, nitrogen, and argon were used at atmospheric pressure.

Germanium bars ranging in doping level from degenerate p-type to degenerate n-type (at room temperature) were used. Ga, In, and Sb were used as dopants. In all cases, with the application of current, the molten zone is displaced in the direction of current flow (2). The displacement is dependent on current density, being about ½ cm at the highest densities used.

In high-purity Ge an unexpected additional effect was observed. Tiny wavelets were seen to build up in the melt at the positive interface and gradually to propagate toward the negative interface. Concurrently, the liquid zone was observed to constrict near the positive interface and "bulge" near the negative interface. This is shown schematically in Fig. 1. The constriction and bulge become more pronounced with time until suddenly the liquid relaxes to its original (displaced) position and the process is repeated. The relaxation time is typically of the order of 40 sec.

The relaxation oscillation was clearly observable through the quartz tube; however, detail in the tiny wavelets was not. For closer observation, the wavelets were "frozen in" by shutting off the projection lamps while current continued to flow through the bar. We believe that the wavelets frozen into the bar are indicative of those in the melt before freezing, because wavelets are observed in the refreeze only in the area in which they were seen in the melt immediately before freezing. Further, wavelets are not seen, either in the melt or in the refreeze, in the absence of current.

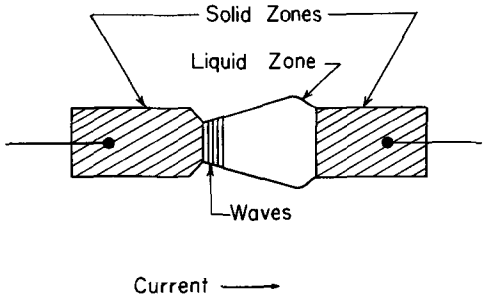

Fig. 1. Schematic representation showing constriction, bulge, and wavelets in liquid Ge.

In Fig. 2 and 3 are shown three representative patterns which were frozen into the melt. Figure 2 shows the region which before freezing was the positive solid-liquid interface. This sample was frozen at the beginning of a cycle, *i.e.*, little constriction had taken place. The portion on the right was liquid. The wavelets frozen into this portion appear as lines and the distance between crests, near the interface, is approximately 8μ. Figure 3a shows a region in the constricted area of another bar. Wavelets of approximately 20μ between crests are superimposed on a structured base. The direction of current is as shown. In Fig. 3b is shown a region taken at the bulge (but entirely in the melt) of another bar. Here the distance between crests is 60μ. A series of mounds is also visible; these mounds appear nearly regularly spaced in both directions. A crack which appeared on freezing is seen near the center of the picture.

The wavelet amplitude and the constriction are greatest for high-purity material and decrease rapidly

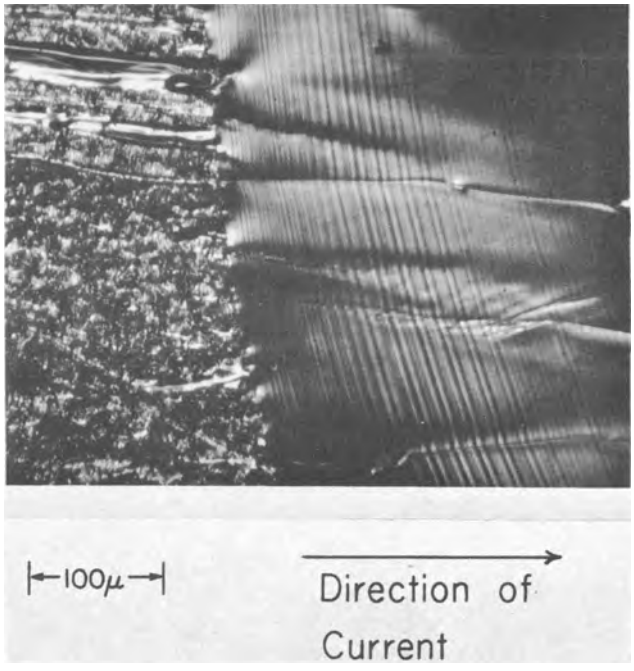

Fig. 2. Boundary between solid and refreeze. The waves are visible in the refrozen portion.

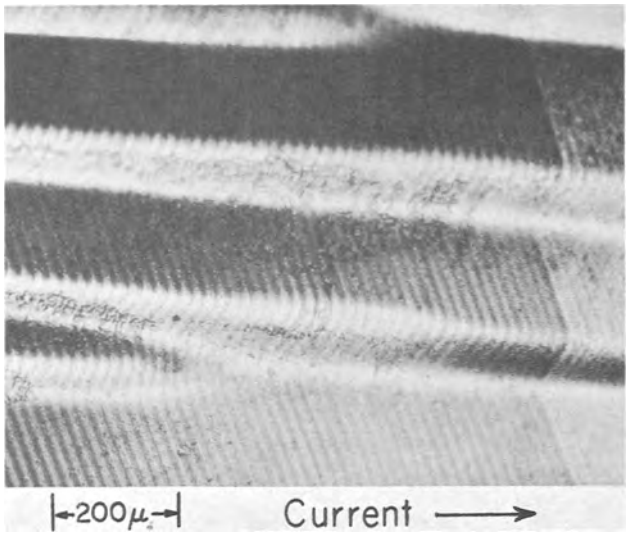

Fig. 3a. Wavelets on a structured base

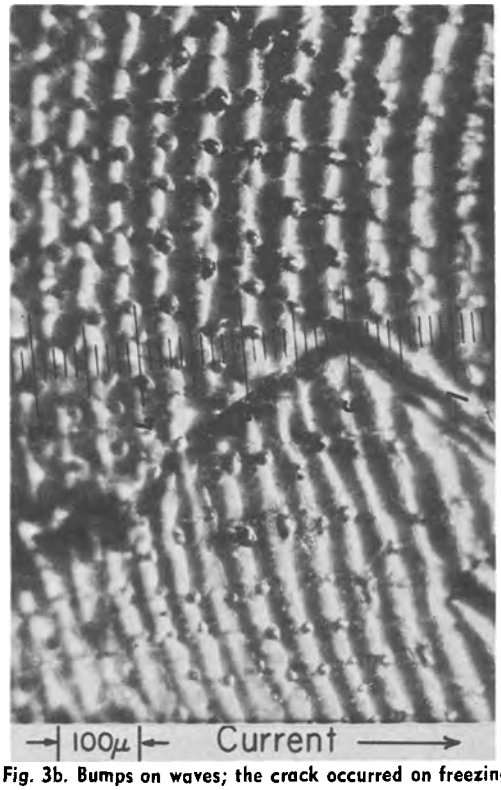

Fig. 3b. Bumps on waves; the crack occurred on freezing

as the impurity concentration is increased. Over a period of an hour the amplitude decreases substantially as the germanium becomes contaminated from the ambient. The impurity concentration above which oscillations are not observed is about 10^{15}-10^{16} cm^{-3}. No oscillations were observed in similar experiments involving tin.

It is found that increasing the current increases the amplitude of the wavelets but appears to have little influence on wavelengh. Although we were unable to observe wavelets at current densities below about 2 amp/cm^2, we believe that no current threshold for their formation exists, but merely that the amplitude was too small to see. The period of the relaxation oscillation seems little affected by current although maximum deformation of the melt increases with increasing current. At sufficiently high current (approximately 200 amp/cm^2 in the highest purity samples) the constriction is so great that it actually pinches the bar into two pieces.

There appears to be a relationship between the wavelets and the relaxation oscillation described here since both effects are always present simultaneously. Further, the degree of deformation (constriction and bulge) appears to depend on the area covered by wavelets. Immediately after a relaxation there is no deformation and no wavelets. As the wavelets begin to spread from the positive interface, the deformation also increases. It appears as though increased surface tension is associated with the wavelets resulting in constriction in this region and a corresponding bulge in the molten zone not covered with wavelets. We have never observed the molten zone to be totally covered with wavelets.

The displacement of the liquid zone on the application of current is thought to be primarily a result of Peltier heating at the positive interface and Peltier cooling at the negative interface (2), although the Thomson effect, electrolysis, and momentum transfer from current carriers to impurity ions (3-6) may affect the magnitude of the displacement.

Although oscillations at liquid-solid interfaces resulting from electric current flow have not been reported, Komarov and Regel (7) have observed oscillations in bismuth and in lead when the temperature gradient at an interface exceeds a threshold of 40°-60°C/cm. The impurity content is presumably not important in this effect since the addition of up to 2 a/o (atom per cent) of tin had no appreciable affect in the results. The oscillations are explained by the excitation of the surface by turbulent convection currents produced in the ambient by the high-temperature gradient. Cole and Winegard (8) have measured the temperature fluctuation in the melt near a solid-liquid interface for tin. The magnitude of the fluctuation increases with temperature gradient and is attributed to convection in the liquid. Mechanical oscillations were not reported.

It is believed that the current-induced oscillations reported here are not connected directly with the oscillations attributed to a large temperature gradient because our results are very sensitive to impurity content and because of the apparent absence of a threshold current. Although the temperature gradient at the interface would be expected to be altered by the Peltier effect on the application of current, if the effect depended on exceeding a temperature gradient threshold, this would be manifested by an apparent current threshold.

It is doubtful that the oscillations result from an electronic effect since the conduction in liquid Ge is thought to be metallic in nature (9), and it seems improbable that a small impurity content would affect the conduction appreciably. Likewise a plasma effect would appear to be ruled out because of the high concentration of electrons present in the liquid. It may be that these waves are associated with surface tension. It is known that a minute quantity of impurities changes surface tension in many materials. The current flow may move the impurities toward one end of the molten zone by electrolysis or by ion entrainment and thus create a gradient in surface tension in the liquid zone which might explain the pinch and bulge effects. It is not clear, however, how this would explain the wavelets or the relaxation. It is conceivable, however, that they might be associated with the change in surface tension at the positive interface due to charge accumulation, which in turn results from current flow across the discontinuity in electrical conductivity (10).

Evaporated Ohmic Contacts on GaAs

W. A. Schmidt

United States Naval Research Laboratory, Washington, D. C.

Various schemes have been proposed for making ohmic contacts to GaAs (1-4). One of the common ones involves evaporation of a metal on the semiconductor surface, followed by alloying using conventional solders.

We have had considerable difficulties in making such evaporated contacts, and we therefore felt that a description of our technique may not be without general interest.

Contacts to both p and n material were made in the same manner. The GaAs material was first prepared by abrasive processes using either 25μ garnet or 600 grit silicon carbide; the surface to be metalized was etched in dilute nitric acid (4 pt. HNO_3:1 pt. H_2O) for 30 sec, then rinsed in water, acetone, and methanol. The sample was immediately mounted on a holder and placed in a vacuum evaporator. With the bell jar pumped down to 2 x 10^{-6}, the GaAs sample was heated to about 550°C to heat-clean the surface. After cleaning for a few minutes at the elevated temperature the power was turned off and the sample allowed to cool. When the sample cooled to about 200°C a 1μ thick film of silver was evaporated onto the surface. The temperature was again raised to 550°C and held there for a few minutes to heat treat the silver contact. After this the power was turned off and the wafer allowed to cool to room temperature, at which temperature a 0.3μ nickel film was deposited. The nickel film was not followed by a heat-treatment.

These contacts were tested for mechanical strength by pulling off small copper wires that had been soldered to the contact. (Fig. 1) It can be seen that some of the GaAs was pulled off along with the solder bead. The electrical nature of the contact was investigated using small area contacts that had been formed by masking small regions and abrading away the surrounding area.

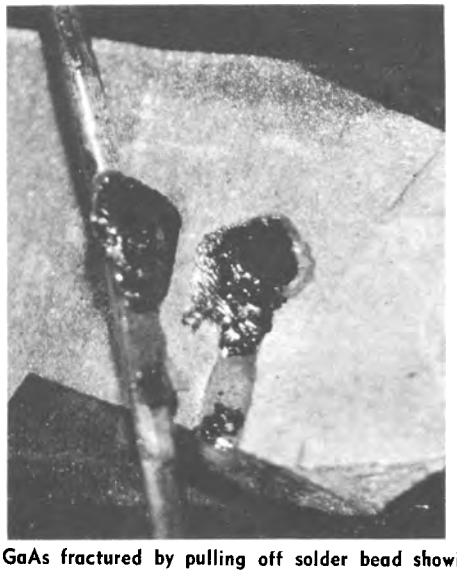

Fig. 1. GaAs fractured by pulling off solder bead showing both the piece removed and the crater in the GaAs.

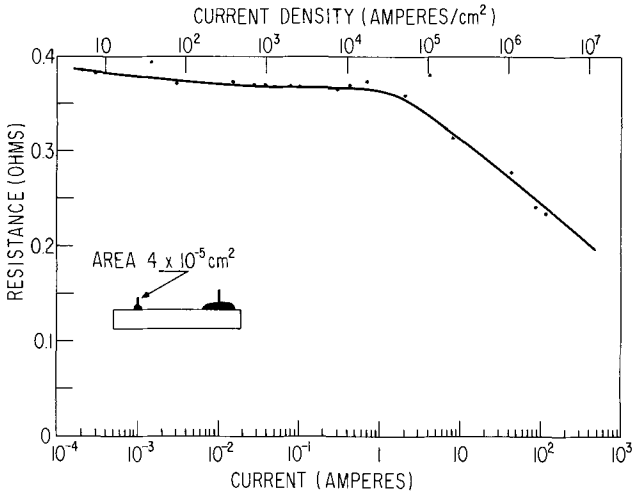

Fig. 2. Resistance between two contacts (see inset) as a function of current.

The I-V characteristic for a pair of contacts on 0.0033 ohm-cm material was measured with d.c. and with 1μ second pulses for currents above 100 ma. No significant deviations of this characteristic were noted when the current polarity was reversed. Figure 2 is a plot of the measured resistance up to a current density of 3 x 10^6 amp/cm^2. Taking the worst case, that all of the resistance is due to the contact, we find that the specific contact resistance is less than 2 x 10^{-5} ohm cm^2. (The total contact resistance $R_T = R_s/A$ where R_s is the specific contact resistance and A is the contact area.)

The same technique has been applied to polycrystalline n- and p-type GaAs with 10^{17} carriers/cm^3.

The Arsenic-Rich Region of the Ga-As-Zn Ternary Phase System —Modification of the Ternary Diagram

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

In several recent papers (1, 2), the ternary phase diagrams of gallium and arsenic with Zn, Sn, and Ge have been presented. A striking feature of these phase diagrams is the extensive primary phase field of GaAs. In the case of the gallium-arsenide-zinc system (1) experimental data on the arsenic-rich side of the diagram were not obtained by this author. Instead, isotherms in the GaAs primary phase field were estimated by the use of a regular solution approximation. In order to more accurately present the Ga-As-Zn ternary phase diagram, phase transition data on the GaAs-Zn_3As_2 cut of the ternary system have been obtained by the differential thermal analysis procedure previously described (1). The only modification to the procedure was that the starting materials were GaAs and Zn_3As_2 rather than GaAs plus zinc and arsenic. This was necessary in order to prevent explosions which occur as a result of the reaction of zinc with arsenic in the restricted volume of the D.T.A. cell.

In Fig. 1 are presented the thermal effect data obtained when mixtures with over-all compositions along the GaAs-Zn_3As_2 cut were cooled. Also presented are the thermal effect data of Köster and Ulrich (3) for the same cut, and the melting point of GaAs obtained in this work. The latter value (1237° ± 2°C) is in excellent agreement with the value of 1238°C obtained by Köster and Thoma (4). T_1 represents the temperature at which the surface of primary crystallization is reached, T_2 represents the temperature of appearance of a second solid phase, and T_3 is the temperature at which a ternary eutectic between GaAs, Zn_3As_2, and $ZnAs_2$ precipitates.

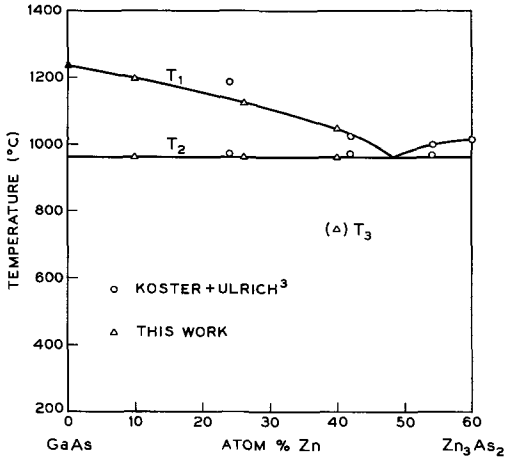

Fig. 1. Thermal effects in the GaAs-Zn_3As_2 pseudobinary system; ○ Köster and Ulrich (3); △ this work.

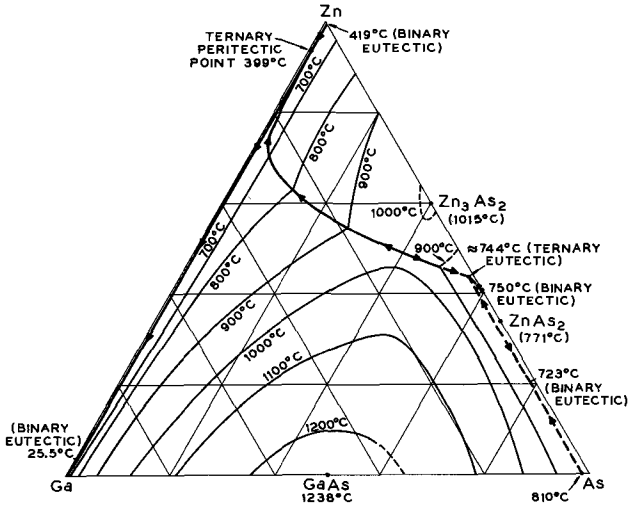

Fig. 2. The Ga-As-Zn ternary phase diagram

Some of the thermal effect data reported by Köster and Ulrich (3) on the GaAs-Zn_3As_2 cut and the GaAs-$ZnAs_2$ cut are consistent with the data reported earlier by this author (1) and that reported here. Their T_1 thermal effects in the vicinity of 1200°C are, however, in disagreement with the measurements reported here and with a reasonable extrapolation of our earlier data. A possible reason for this disagreement has already been presented (1).

The ternary Ga-As-Zn phase diagram based on our previous D.T.A. studies (1) and the data presented here is shown in Fig. 2. The method used for the construction of the diagram is similar to that employed for the Ga-As-Sn and Ga-As-Ge phase diagrams (2). This diagram is similar to that reported before except that the isotherms are all somewhat more distorted in the direction of the As-Zn binary axis.

Acknowledgment

The Reversible Oxygen Potential in Phosphoric Acid Solutions

Raymond Thacker and James P. Hoare

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

It has been found that the potential of a bright platinum electrode which had been treated in concentrated nitric acid for 72 hr (1, 2) became steady at the normal oxygen potential, 1230 mv (3), for periods of time greater than 24 hr in O_2-saturated, H_2O_2-free $2N$ H_2SO_4 solutions. From rest potential studies (1), steady-state polarization measurements (2), and double layer capacity data (4), it was concluded that such a treatment produced a complete, electronically conducting film of adsorbed oxygen on the Pt surface which rendered the electrode surface inert to oxygen. Consequently, the mixed potential which was ordinarily observed (5) was suppressed, and the reversible oxygen potential was reached. Other investigators who have obtained this complete passivating film by anodization and exposure of the platinum to pure oxygen for long periods of time (6, 7) have also observed the reversible oxygen potential. This complete film is unstable in sulfuric acid solutions and eventually becomes incomplete, whereupon a mixed potential mechanism (5) sets in and the rest potential falls to less noble values.

In addition to forming the passivating film of adsorbed oxygen, it was concluded (2, 4) that the HNO_3 treatment also enabled a certain amount of oxygen to be dissolved in the surface layers of the Pt metal to form a Pt-O alloy. Recently, Warner and Schuldiner (8) referred to this absorbed oxygen as "dermasorbed oxygen" and found (9) that it was difficult to remove. X-ray analysis of the treated Pt (10) showed a shifting of the diffraction lines from those obtained on untreated Pt, and vacuum fusion analysis (10) showed that the treated samples contained more oxygen than the untreated samples. Nitric acid-treated Pt electrodes are called Pt-O-alloy electrodes (2, 4).

Since phosphoric acid is another good CO_2-rejecting electrolyte, it was considered important to look into the behavior of the rest potential of the Pt-O-alloy electrode in phosphoric acid solutions.

Test electrodes were made in the form of small beads melted at the end of bright Pt wires or in the form of squares of bright Pt gauze spot-welded to Pt wire leads. These electrodes were sealed into glass holders and mounted in a glass cell (11). The cell and electrode cleaning procedures were similar to those described before (4, 5, 11). The clean electrodes were soaked in concentrated HNO_3 for at least 72 hr, after which they were leached in triply distilled water for 2 hr with frequent changes of the water before being placed in the cell. Phosphoric acid solutions of 5, 3, 1, and 0.5M were made from reagent grade concentrated H_3PO_4 and were anodically preelectrolyzed in a separate vessel for 3 days followed by cathodic preelectrolysis for an additional 3 days. Any peroxide generated in the preelectrolysis procedure was removed by bubbling H_2 over Pt gauze in the solution until a negative test with $TiSO_4$ (12) was obtained. This purified solution was placed in the cell, and the rest potential was determined against a saturated calomel electrode (SCE). All potentials are reported with reference to a hydrogen electrode in the same solution, since in each solution the potential of a hydrogen electrode was determined against the SCE. The temperature was 25° ± 1°C. Duplicate runs on different electrodes were made in all solutions, and the spread of values of the steady potential (±0.5 mv) obtained from one electrode to another (±5 mv) is given in Tables I and II. All solutions were saturated with O_2. Similar measurements were made in 5, 1, 0.5, and 0.1M H_2SO_4 solutions.

Table I. Rest potentials of Pt-O-alloy electrodes in H_3PO_4 solution

Solution, M	Rest potential, mv	Activity of H_2O	Activity of H_3PO_4	1230—E, mv	0.03 log $a_{H_3PO_4}$, mv
5	1195 ± 5	0.87	9.72	35	30
3	1212 ± 5	0.93	4.05	18	18
1	1226 ± 5	0.98	0.96	4	−0.5
0.5	1230 ± 5	0.99	0.99	—	—

Table II. Rest potentials of Pt-O-alloy electrodes in H_2SO_4 solution

Solution, M	Rest potential, mv	Activity of H_2O
5	1226 ± 5	0.70
1	1227 ± 5	0.96
0.5	1225 ± 5	0.98
0.1	1225 ± 5	0.99

As pointed out by Bockris *et al.* (6, 13), rigorous control of impurities was required for reproducible results. In Table I are presented the steady-state rest potentials in various phosphoric acid solutions and in Table II those for sulfuric acid solutions. The rest potentials in H_3PO_4 solutions were steady for longer periods of time (about 72 hr) than those in H_2SO_4 solutions (about 24 hr). Such behavior may be interpreted to mean that the complete adsorbed oxygen film is more stable in H_3PO_4 solutions. Such behavior is not surprising because it is known (14) that Na_3PO_4 solutions are good inhibitors for the corrosion of iron. The presence of Na_3PO_4 assists in the formation of the protective film of cubic oxide on the iron surface. Possibly, the presence of phosphate ion stabilized the adsorbed oxygen film on the Pt-O-alloy electrodes.

An interesting point is the fact that the rest potential deviates from the normal oxygen potential, 1230 mv, at the higher H_3PO_4 concentrations, whereas this is not true in H_2SO_4 solutions. In both cases, the change in activity of water as seen in column 3 and taken from the literature (15, 16) cannot account for these observations since the water correction would be too small and, in any event, is in the wrong direction. The activity of phosphoric acid (15), recorded in column 4 of Table I, decreases with decreasing H_3PO_4 concentration in correlation with the decrease in the shift of the rest potential from the reversible potential recorded in column 5.

If the Nernst equation is written for the cell, one obtains

$$E = E^\circ_{O_2} - E^\circ_{H_2} - \frac{RT}{4\mathbf{F}} \ln \frac{a^2_{H_2O}}{P_{O_2} a^4_{H^+}} + \frac{RT}{\mathbf{F}} \ln \frac{P^{1/2}_{H_2}}{a_{H^+}} \quad [1]$$

or

$$E = 1230 - 0 - \left[\frac{0.06}{4} (2 \log a_{H_2O} - \log P_{O_2}) \right] + 0.03 \log P_{H_2} \quad [2]$$

Since the partial pressures of oxygen, P_{O_2}, and of hydrogen, P_{H_2}, are unity and the activity of water, a_{H_2O}, is approximately unity, the potential of the cell, E, is $E^\circ_{O_2} = 1230$ mv as found in the case of the sulfuric acid solutions in Table II. However, in solutions 1M or greater in phosphoric acid, the rest potential may be accounted for empirically by adding a term involving the activity of phosphoric acid, $a_{H_3PO_4}$,

$$-\frac{RT}{2\mathbf{F}} \ln a_{H_3PO_4} \quad [3]$$

to Eq. [1]. The value of this correction term is given in column 6 of Table I. This behavior indicates that anion adsorption of $H_2PO_4^-$ ions is important in solutions with concentrations greater than 1M H_3PO_4 and shifts the rest potential to less noble values. The effects of the adsorption of ions on electrode processes has been summarized by Frumkin (17) and Delahay (18). With acid solutions below 1M in H_3PO_4 and up to 5M in H_2SO_4, anion adsorption does not affect the rest potential significantly. From anion adsorption studies (17-19), one would expect a smaller effect with HSO_4^- than with $H_2PO_4^-$ ions.

As a check on the effect of the $H_2PO_4^-$ ion on the rest potential, the following experiment was performed. A Pt-O-alloy electrode was permitted to come to a steady open-circuit potential in 5M, H_2O_2-free, O_2-saturated H_3PO_4 solution. The potential came to the steady value of 1199 mv in agreement with the data in Table I. This electrode was removed from the 5M H_3PO_4 and washed with triply distilled water. After plunging the electrode in 1M H_2SO_4 solution, the rest potential rose to a steady value of 1227 mv. These results are offered in support of the conclusions reached concerning the effect of the adsorption of $H_2PO_4^-$ ions on the rest potential.

An important observation was the fact that several electrodes came to a steady rest potential in molar acid solutions at values between 1000 and 1100 mv. In each case it was found that the metal-to-glass seal was defective, and solution contact was made with the Pt wire lead which had not been exposed to HNO_3. The preferred explanation is the suggestion that a mixed potential is set up between sites on the electrode completely covered by the adsorbed oxygen film and uncovered Pt sites on the partially covered Pt lead wire. In this case a potential less noble than 1230 mv is to be expected as found on untreated Pt electrodes (5).

The Performance of Flooded Porous Fuel Cell Electrodes

Ralph Brown and John A. Rockett

Pratt & Whitney Division, United Aircraft Corporation, East Hartford, Connecticut

ABSTRACT

The thin-meniscus model that is often applied to porous gas diffusion fuel cell electrodes has been found unsatisfactory for hydrogen reacting at nickel sinters in highly concentrated KOH electrolyte. The relative insensitivity of the performance to the gas-electrolyte pressure difference, which should have a strong influence on the active thin-meniscus area, requires the assumption that the flooded volume of the electrode is active. A model for a flooded pore is treated and the results of an approximate analytical solution compared with data.

The usual model for a biporous sintered electrode considers a thin liquid meniscus that covers the metal surface in that portion of the electrode from which liquid has been expelled (1-3). The typically low solubility-diffusivity products of gases in electrolytes causes those metal surfaces surrounded by any more liquid than a thin meniscus to be inactive, the transport rate of the reactant gas through the liquid being too small. We have applied this model to an oxygen electrode in alkaline electrolyte with a good deal of success. There are experimental indications, however, that suggest this model does not always apply when hydrogen reacts at a nickel sinter in alkaline electrolyte.

Part of a biporous electrode is the fine-pore region on the electrolyte side which acts as a gas barrier to prevent bubbling of the gas through the electrode. The pores are small enough that capillary forces are sufficient to maintain a specified gas-electrolyte pressure difference. The remaining portion of the electrode is the coarse pore region from which electrolyte has been expelled at operating gas-electrolyte pressure differences. Since the coarse pore contains a distribution of pore sizes, the gas-filled volume in which thin liquid meniscus covers the metal will increase with increasing pressure differences. The performance should then improve as pressure difference rises and more active meniscus area becomes available. This is the case for oxygen electrodes as illustrated in Fig. 1. The results were obtained from an experiment in which two 5-in. diameter electrodes were spaced about ¼ in. apart by a ring that was electrically insulated from the electrodes. The electrolyte contained between the electrodes and ring was connected by a nickel tube to a ¼ in. diameter Teflon tube which served as an electrolyte level indicator. As the electrode gas pressure was varied, the displacement of electrolyte in the electrode was determined by the electrolyte level in the calibrated Teflon tube. Hydrogen was bled through a silver palladium tube which was immersed in the electrolyte in the Teflon tube. This served as a reference electrode. The arrangement measured both the electrolyte displacement and potential as a function of gas to electrolyte pressure difference. Figure 1 shows that good performance on an oxygen electrode was obtained only after a considerable fraction of electrolyte was displaced. Below a gas to electrolyte pressure difference of 6 psi, where very little electrolyte was displaced by gas, the current at 0.2v polarization was very small. This behavior is not shown in Fig. 2, where a similar experiment was done on a hydrogen electrode. At 2 psi gas to electrolyte pressure difference, where the electrolyte displacement indicated the electrode was essentially flooded, the polarization was only slightly greater than pressure differences at which 30% of the void volume was displaced. This insensitivity of the hydrogen electrode to the gas-electrolyte pressure difference was observed for hydrogen electrodes at temperatures of 150°-250°C and KOH concentrations of 70-85%. Since gas displacement of electrolyte is unnecessary for good performance, the need for a large area of thin meniscus is not established. The only possible conclusion is that the flooded portion of the electrode is active. A means of transport for the hydrogen into the flooded region other than that limited by the low bulk solubility-diffusivity product must be assumed. Surface diffusion could account for the high effective hydrogen diffusivity if we assume enough thin meniscus is available to allow the hydrogen to get to the metal surface without causing a significant gas diffusion polarization.

The purpose of this paper is to describe the solution of the flooded electrode problem and determine if the results are consistent with hydrogen half cell data. The more complex problem of considering both gas-filled regions and flooded regions in one electrode

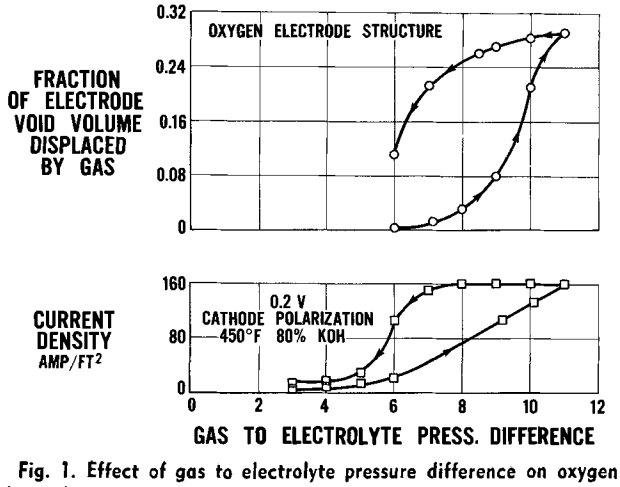

Fig. 1. Effect of gas to electrolyte pressure difference on oxygen electrode.

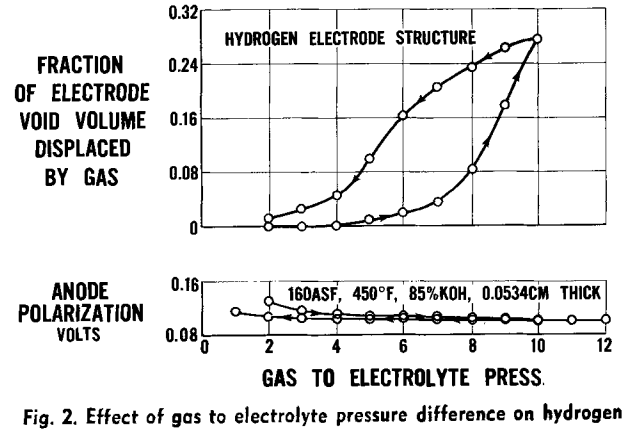

Fig. 2. Effect of gas to electrolyte pressure difference on hydrogen electrode.

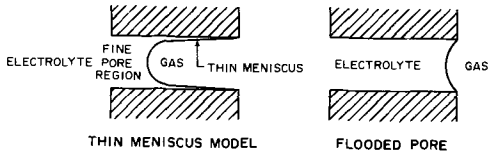

Fig. 3. Electrode models

is not discussed. This would involve a more sophisticated description of the electrode structure than the cylindrical pore model assumed here.

Theoretical Model

For purposes of comparison, both geometric models for the flooded electrode and the gas-filled electrode are shown in Fig. 3. The electrode is considered as an array of cylindrical pores whose diameter is that of the mean pore size of the structure. In the gas-filled model, the flooded portion represents the fine pore layer and the gas-filled coarse pore is coated with a thin liquid meniscus. The transport rate of gas through this thin liquid film is relatively high compared to what it would be in the flooded portion. In the flooded model, the entire cylinder is full of liquid, but gas can diffuse either along the surface or through the bulk metal. This effectively increases the diffusivity over what it would be in just the bulk liquid.

The next major assumption deals with the half-cell reaction. The over-all reaction for the oxidation of hydrogen in alkaline electrolyte is as follows

$$H_2 + 2\,OH^- \rightleftharpoons 2H_2O + 2e^- \qquad [1]$$

In order to write a precise kinetic expression for the net half-cell reaction, the sequence and relative rate constant for each reaction step must be known. For the case where the activity ratios of the electrolyte species are approximately unity, the following expression has been shown to be valid (4).

$$i = i_1 \left[\frac{\alpha_{H_2}}{\alpha_{H_2}^{\circ}} e^{\frac{F}{RT}\eta} - e^{-\frac{F}{RT}\eta} \right] \qquad [2]$$

In order to include the activity of the electrolyte species, the kinetic expression is written as follows

$$i = i_1 \left[\left(\frac{\alpha_{H_2}}{\alpha_{H_2}^{\circ}} \right) \left(\frac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^2 e^{\frac{F}{RT}\eta} - \left(\frac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{-\frac{F}{RT}\eta} \right] \qquad [3]$$

The placement of these electrolyte species activity ratios with respect to the forward and reverse terms is arbitrary, but their exponents are consistent with the thermodynamics of the over-all reversible reaction. One of the most important assumptions regarding the choice of the kinetic expression is that the controlling step takes place either before or is the step during which the H-H bond is broken. This means that the hydrogen exchange current is directly proportional to hydrogen partial pressure.

Mathematical Formulation

The analysis considers a differential slice cut from the cylinder as shown in Fig. 4. The local current density on the metal surface is given by the kinetic expression. The potential, E, of the electrode is measured relative to a reference probe located in the bulk liquid to the left of the electrode fine pore. The ohmic potential in the electrolyte, ϕ, is chosen as zero at the left edge of the fine pore and chosen to have increasingly positive values in the positive x direction. The local metal-solution potential difference at any point in the pore is given by the difference between the electrode potential and the solution potential. The kinetic expression of Eq. [3] can then be

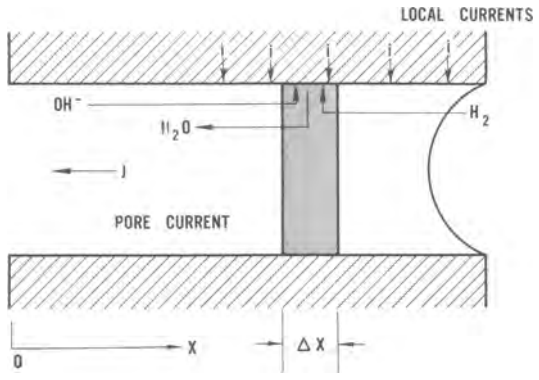

Fig. 4. Single pore

written with the driving potentials in terms of the solution potential.

$$i = i_1 \left[\left(\frac{\alpha_{H_2}}{\alpha_{H_2}^{\circ}} \right) \left(\frac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^2 e^{\frac{F}{RT}(E-\phi)} - \left(\frac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{-\frac{F}{RT}(E-\phi)} \right] \qquad [4]$$

The local current density is related to the current in the axial direction of the pore by making a current balance on the differential wafer. Radial variations are neglected making the problem one-dimensional and the pore current goes in the negative x direction.

$$i = \frac{1}{2\pi R} \frac{dJ}{dx} \qquad [5]$$

The current in the axial direction of the pore is related to the ohmic potential in the electrolyte by Ohm's law.

$$J = -\pi R^2 \sigma \frac{d\phi}{dx} \qquad [6]$$

Substitution of Eq. [6] into Eq. [5] relates the ohmic potential in the electrolyte to the local current density.

$$i = -\frac{R\sigma}{2} \frac{d^2\phi}{dx^2} \qquad [7]$$

The current associated with the hydrogen flux in the axial direction of the pore can be related to the hydrogen activity by Fick's diffusion law.

$$J_{H_2} = -\pi R^2 n F D_{H_2} \alpha_{H_2}^{\circ} \frac{d(\alpha_{H_2}/\alpha_{H_2}^{\circ})}{dx} \qquad [8]$$

Substitution of Eq. [8] into Eq. [5] relates the hydrogen activity ratio to the local current density. The sign changes in this substitution to account for the fact that hydrogen moves to the surface in a direction opposite to that chosen for the local currents.

$$i = \frac{R}{2} n F D_{H_2} \alpha_{H_2}^{\circ} \frac{d^2(\alpha_{H_2}/\alpha_{H_2}^{\circ})}{dx^2} \qquad [9]$$

The water and KOH activity ratios can be related to the ohmic potential in the electrolyte as will be shown in a following section. This being the case, the local current density at any given electrode polarization is a function of only the ohmic potential in the electrolyte and the hydrogen activity ratio. Equations [7] and [9] are then the two equations in ϕ and $\alpha_{H_2}/\alpha_{H_2}^{\circ}$ that must be solved simultaneously in order to obtain $\alpha_{H_2}/\alpha_{H_2}^{\circ}$ as a function of x. The total pore current is then found by evaluating the first derivative of $\alpha_{H_2}/\alpha_{H_2}^{\circ}$ with respect to x at the point where all the hydrogen passes. The total current is

$$J = -\pi R^2 nF D_{H_2\alpha_{H_2}^o} \left.\frac{d(\alpha_{H_2}/\alpha_{H_2}^o)}{dx}\right|_{x=L} \quad [10]$$

Boundary conditions for Eq. [7] and [9] are defined at both ends of the pore. At the electrolyte side, the electrolyte potential is chosen at zero and no more hydrogen diffuses in the axial direction as none is consumed to the left of this point.

$$\text{at } x = 0: \quad \phi = 0 \quad [11a]$$

$$\frac{d(\alpha_{H_2}/\alpha_{H_2}^o)}{dx} = 0 \quad [11b]$$

At the gas side, the hydrogen activity is at its reference value and there is no ohmic gradient as no current is generated to the right of this point.

$$\text{at } x = L: \quad \alpha_{H_2}/\alpha_{H_2}^o = 1 \quad [12a]$$

$$\frac{d\phi}{dx} = 0 \quad [12b]$$

We have two simultaneous second-order equations to solve. The one in $\alpha_{H_2}/\alpha_{H_2}^o$ is linear, but the one in ϕ is nonlinear. If we neglect both the ohmic and the electrolyte concentration polarizations, both equations become linear and an analytical solution is readily obtained. The approximations are

$$E - \phi \cong E \quad [13]$$

$$\frac{\alpha_{H_2O}}{\alpha_{H_2O}^o} = \frac{\alpha_{KOH}}{\alpha_{KOH}^o} \cong 1 \quad [14]$$

The approximate differential equations become

$$-\frac{R\sigma}{2}\frac{d^2\phi}{dx^2} = i_1\left[\frac{\alpha_{H_2}}{\alpha_{H_2}^o}e^{FE/RT} - e^{-FE/RT}\right] \quad [15]$$

$$\frac{nFD_{H_2\alpha_{H_2}^o}}{2}\frac{d^2(\alpha_{H_2}/\alpha_{H_2}^o)}{dx^2} = i_1\left[\frac{\alpha_{H_2}}{\alpha_{H_2}^o}e^{FE/RT} - e^{-FE/RT}\right] \quad [16]$$

Equation [16] can be solved for the hydrogen activity ratio as a function of x by applying the boundary conditions of Eq. [11b] and [12a]

$$\frac{\alpha_{H_2}}{\alpha_{H_2}^o} = (1 - e^{-2FE/RT}) \frac{\cosh\left[\left(\frac{i_1}{RFD_{H_2\alpha_{H_2}^o}}\right)^{1/2} e^{FE/2RT}x\right]}{\cosh\left[\left(\frac{i_1}{RFD_{H_2\alpha_{H_2}^o}}\right)^{1/2} e^{FE/2RT}L\right]} + e^{-2FE/RT} \quad [17]$$

This is now differentiated with respect to x, evaluated at $X=L$, and substituted into Eq. [10] to obtain the total pore current.

$$J = 2\pi R\sqrt{RFD_{H_2\alpha_{H_2}^o}i_1}\,(e^{FE/2RT} - e^{-3FE/2RT}) \tanh\left[\sqrt{\frac{i_1}{RFD_{H_2\alpha_{H_2}^o}}}\,e^{FE/2RT}L\right] \quad [18]$$

The numerical solution of Eq. [7] and [9] was obtained by employing the method of quasilinearization. The solution of this system via quasilinearization entails expanding the expression for local current density into a truncated Taylor series. This reduces the nonlinear, two-point boundary value problem to the problem of solving a sequence of linear two-point problems. The sequence of linear two-point problems can then be solved in terms of initial value techniques through a numerical construction of Green's functions.

Transport of Electrolyte Species

The hydroxyl ion that is consumed in the reaction must diffuse axially through the pore from the bulk electrolyte to the reaction surface. If ideal solutions are assumed and bulk transport is neglected, the transport equations for both potassium and hydroxyl ions show a term proportional to KOH concentration gradient and a term proportional to ohmic potential.

$$J = \pi R^2\left[-FD_{OH}\frac{dC_{OH}}{dx} - \lambda_{OH}C_{KOH}\frac{d\phi}{dx}\right] \quad [19]$$

$$o = \pi R^2\left[-FD_K\frac{dC_K}{dx} + \lambda_K C_{KOH}\frac{d\phi}{dx}\right] \quad [20]$$

Equation [20] can be integrated using a reference concentration, C_{KOH}^o, as that in the bulk electrolyte where the reference electrolyte potential is zero. The variation of the diffusivity and ion equivalent conductance with concentration are neglected.

$$\frac{C_{KOH}}{C_{KOH}^o} = e^{-\frac{\lambda_K}{FD_K}\phi} \quad [21]$$

In extremely dilute solutions, the Nernst-Einstein relation could be applied to the coefficient of ϕ in Eq. [21] and the concentration variation as a function of ϕ would be known. In a nonideal electrolyte, however, the correct driving force for the diffusive transport is not the concentration gradient, but the gradient of chemical potential. Equation [21] can be corrected to the proper diffusive driving force by a simple adjustment to the diffusivity.

$$D_K = D_K^o\frac{\partial(\ln \alpha_{KOH})}{\partial(\ln C_{KOH})} \quad [22]$$

Application of the correction in Eq. [21] assumes the correction factor does not vary strongly with concentration. There are other correction factors for the diffusivity which are functions of the electrolyte fluid properties such as viscosity and density. These same corrections apply to the equivalent ion conductance so that the conductance to diffusivity ratio is assumed constant. With these assumptions, the Nernst-Einstein relation can be applied.

$$\frac{\lambda_K}{FD_K^o} = \frac{F}{RT} \quad [23]$$

The KOH concentration variation as a function of potential can now be written by substituting Eq. [22] and [23] into [21].

$$\frac{C_{KOH}}{C_{KOH}^o} = e^{-\frac{F\phi}{RT\frac{\partial(\ln \alpha_{KOH})}{\partial(\ln C_{KOH})}}} \quad [24]$$

It is necessary to relate the concentration changes to activity changes as are required in the kinetic equation. Activity coefficients for KOH have been measured but only to 50 w/o (weight per cent) (6). Water vapor pressures have been measured over highly concentrated KOH over a wide range of temperature (7). The solvent activity is defined as the ratio of electrolyte vapor pressure to pure solvent vapor pressure. The water vapor pressure data give us the water activity as a function of the solvent concentration. Specifically, the water vapor pressure data were related to the water concentration by the following empirical expression

$$p_{H_2O} = e^{(AF_{H_2O}^2 + BF_{H_2O} + C)} \quad [25]$$

where F_{H_2O} is the weight fraction water, $A = 34.135$; $B = 45.110\text{-}0.024055T$; $C = 0.021597\text{-}14.01648T$; and T is temperature, °F.

In order to calculate the water activity, the above expression is divided by the pure water vapor pressure which can be related to temperature by the Clausius-Clapyron equation. The water activity is

then known as a function of the water molar density or the KOH molar density from the following expressions

$$F_{H_2O} = C_{H_2O}M_{H_2O}/\rho \quad [26]$$

$$1 - F_{H_2O} = C_{KOH}M_{KOH}/\rho \quad [27]$$

The water activity ratio corresponding to the KOH molar density ratio of Eq. [24] is then given by substitution of Eq. [27] into Eq. [25] and taking water vapor pressure ratios

$$\ln \frac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} = A\left[\left(1 - \frac{C_{KOH}M_{KOH}}{\rho}\right)^2 - \left(1 - \frac{C_{KOH}^{\circ}M_{KOH}}{\rho}\right)^2\right] + B\frac{M_{KOH}}{\rho}(C_{KOH}^{\circ} - C_{KOH}) \quad [28]$$

The KOH activity ratio is related to the water activities by application of the Gibbs-Duhem expression

$$\ln \frac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} = -\int_{\ln \alpha_{H_2O}^{\circ}}^{\ln \alpha_{H_2O}} \frac{C_{H_2O}}{C_{KOH}} d(\ln \alpha_{H_2O}) \quad [29]$$

Application of the Gibbs-Duhem relation can also be employed to obtain the Onsager-Fuoss correction employed in Eq. [24]. Equation [29] is simply differentiated with respect to $\ln C_{KOH}$

$$\frac{\partial(\ln \alpha_{KOH})}{\partial(\ln C_{KOH})} = -C_{H_2O}\frac{\partial(\ln \alpha_{H_2O})}{\partial(\ln C_{KOH})} \quad [30]$$

The above relation is computed at the reference KOH concentration since, as previously indicated, it varies slightly with concentration.

It was assumed initially that bulk transport properties would be neglected. This is only precisely correct in a pore where the axial water diffusion molar flux is equal and opposite to the hydroxyl ion flux. Unless the product water of the total cell is allowed to evaporate into the hydrogen gas, the axial water diffusion flux does not balance the hydroxyl ion flux. It was found experimentally, however, that anode polarization was unaffected by wide variations in the flow rates of pure hydrogen over the electrode. These flow variations affect the water vapor pressure in the gas and so control the amounts of water transported through the working electrode. This experimental result indicates that the assumption of no bulk flow is a good one.

Comparison with Experiment

Hydrogen electrode half-cell data were measured for KOH concentrations ranging from 70 to 85 w/o and temperatures ranging from 300° to 500°F. The current-polarization measurements had been made on electrodes having essentially the same properties. These electrodes were 0.079 cm thick, had 70% porosity, and a 6μ mean pore diameter. The thickness of these electrodes was low enough that they exhibited little variation in performance over a range of gas-electrolyte pressure differences. The reason for this requirement will be amplified in the discussion.

The numerical solution of the equations proved quite time-consuming, requiring at least a minute on the IBM 7040 to make the computations required to define adequately one polarization curve. Considering the expense of the computation and the fact that electrolyte concentration and ohmic polarizations are a small portion of the total polarization at usual operating currents, the approximate solution given in Eq. [18] was employed to fit the data. This assumes that the polarization is controlled by gas diffusion and activation. The expression, written in terms of the current density in the electrode, is

$$I = 2P_{cp}\sqrt{\frac{FD_{H_2}\alpha_{H_2}^{\circ}i_1}{R}}\left(e^{FE/2RT} - e^{-3FE/2RT}\right)$$

$$\tanh\left[\frac{L}{R}e^{FE/2RT}\sqrt{\frac{i_1R}{FD_{H_2}\alpha_{H_2}^{\circ}}}\right] \quad [31]$$

There are two parameters that cannot be estimated and are employed as empirical factors in the theory-data fits. One is the exchange current, i_1, and the other is a characteristic hydrogen diffusion current, $FD_{H_2}\alpha_{H_2}^{\circ}/R$. No information on exchange currents in porous sinters is available. The diffusivity, being an "effective diffusivity" including metal surface and metal bulk diffusion, bears no relation to diffusivities in the electrolyte. All other terms in Eq. [31] are either sinter properties or physical constants. A typical theory-data fit is shown for data in 80% KOH in Fig. 5. Similar comparisons could be shown for data at other concentrations, but this comparison is sufficient to illustrate the point. The exchange currents employed for the fits in Fig. 5 and for fits with data from 75% and 83.5% KOH are plotted in Fig. 6 on a scale of logarithm current versus reciprocal temperature. The straight line is indicative of an Arrhenius law dependence on temperature as should be expected of a kinetic rate constant.

The fitted values of the solubility-diffusivity product were compared with hydrogen solubility measurements made in our laboratories which showed that $D_{H_2}\alpha_{H_2}^{\circ} = 10^{12}$ moles/cm-sec in 80% KOH at 450°F. The fitted values were about 10^4-10^5 greater than the measured values indicating that a means of diffusive transport other than diffusion through the liquid is a necessary assumption.

Discussion

The approximate solution given in Eq. [31] shows that the electrode current density at a given polarization is directly proportional to the geometric mean of the exchange current and the characteristic hydro-

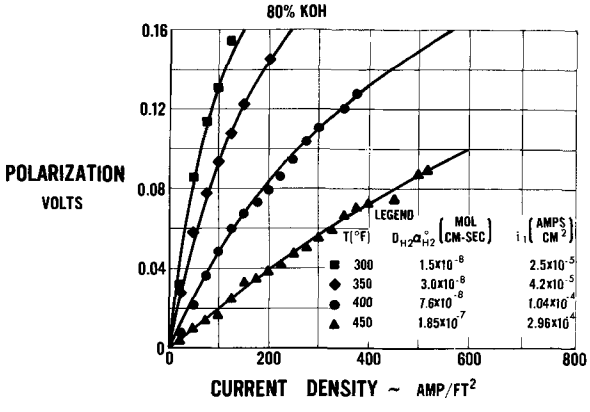

Fig. 5. Comparison of data and theory

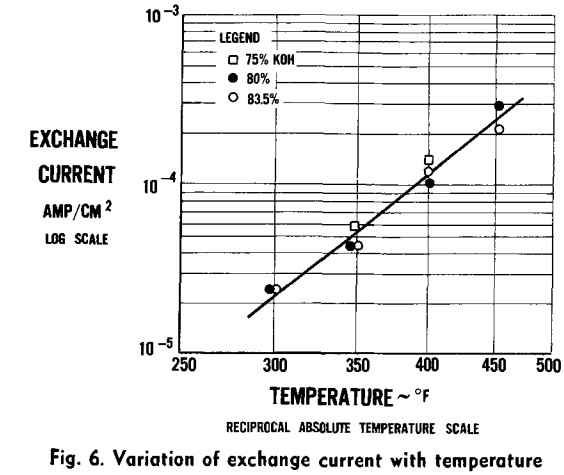

Fig. 6. Variation of exchange current with temperature

gen diffusion current. The fact that the pore current is a geometric mean of a diffusion property and a catalytic property illustrates a general feature of gas diffusion electrodes; their performance is not limited by one effect but by an interplay of several. Although electrolyte concentration and ohmic polarizations can be neglected, no useful approximation in which gas diffusion or activation polarization is eliminated can be made. The exchange current and diffusion current are both proportional to hydrogen partial pressure. The electrode current is then directly proportional to hydrogen partial pressure. Without going into too much detail, it is appropriate to point out a difference in this result and the result for the thin-meniscus model. The current in the thin-meniscus model is also proportional to the geometric mean of two properties, but only one of them is proportional to the gas partial pressure. The thin-meniscus model then predicts current is proportional to the square root of gas partial pressure.

The local current densities have their largest values at the gas side of the electrode where the gas concentration is at its highest. The current density decreases toward the electrolyte side of the electrode as consumption of gas lowers its concentration. The entire electrode produces current, but as the thickness is increased, the added electrode surface makes diminishingly small contributions to the current. This is illustrated in Fig. 7 where the fitted parameters for 75% KOH and 400°F were employed and the effect of varying electrode thickness is shown. Increasing the electrode thickness beyond 0.3 cm no longer produces any more improvement in the current.

Several comparisons were made between the approximate and rigorous solutions to determine the

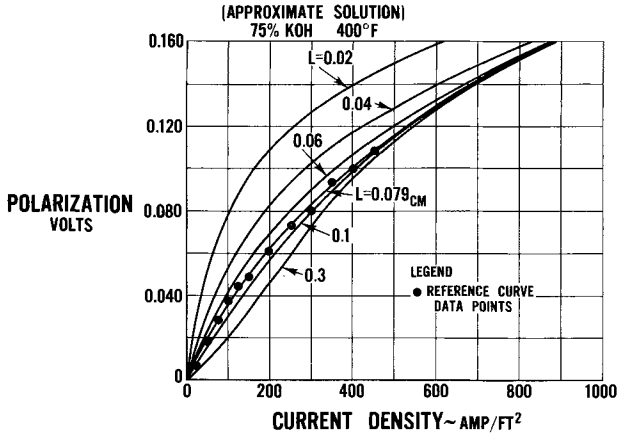

Fig. 7. Effect of electrode thickness on performance (approximate solution).

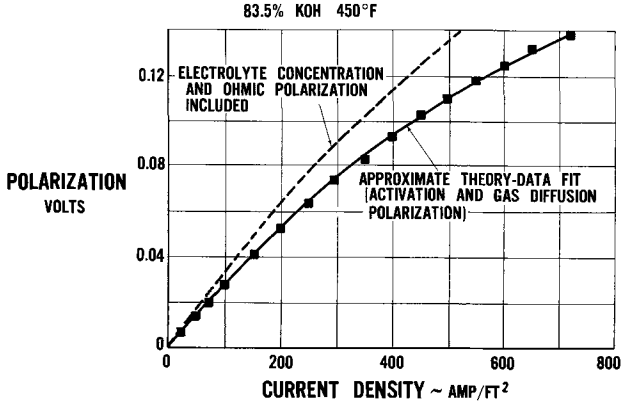

Fig. 8. Comparison of exact and approximate solutions

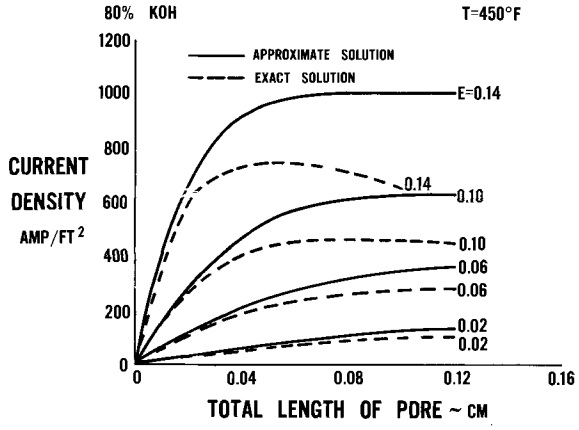

Fig. 9. Variation of cell performance with total pore length

validity of the assumption that there are negligible electrolyte concentration and ohmic polarizations. An example is shown in Fig. 8 where the constants from the approximate solution fit are employed in the nonlinear equations to calculate the polarization as a function of current. The rigorous solution shows a higher polarization as the ohmic and concentration polarizations are added. If the rigorous solution were fit to the data, an adjustment in the empirical constants would have to be made so that the total theoretical polarization would equal the experimental values. The purpose of Fig. 8, however, is to show that ohmic and electrolyte concentration polarizations account for about 15 to 20% of the total. This is not a negligible portion, but is small enough that its effect on the shape of the curve is small. This added portion is very close to linear with current density. The approximate solution, although not precisely correct, is still useful to fit data.

It was pointed out that increasing the electrode thickness increases the reactive surface and can help performance, but it also increases the electrolyte concentration and ohmic polarizations. This suggests that a flooded anode should have an optimum thickness for maximum performance. This is illustrated in Fig. 9 where the rigorous solution was made for several electrode thicknesses. The optimum thickness is lower at higher polarizations because the electrolyte concentration and ohmic polarizations are a higher portion of the total than at lower polarizations. Thicker anodes are found experimentally to be more sensitive to gas-electrolyte pressure difference than thin ones. This is because at the lower pressure differences the average position of the gas-electrolyte interface is close to the gas side. The effective flooded thickness is then too large. With increasing pressure differences, however, the flooded thickness is smaller. This line of argument suggests that there could be an optimum gas-electrolyte pressure difference for thick anodes, and this has been experimentally observed.

Having a theory that fits performance data taken over a wide range of electrolyte concentrations and temperatures leads us to a better understanding of the behavior of porous gas diffusion electrodes. The fact that a theory for a flooded electrode can be employed to fit hydrogen anode data helps explain their relative insensitivity to gas-electrolyte pressure difference. There are, however, certain limitations. Since certain empirical values of inestimable physical quantities are required in the fitting, the proof of the theory is, in part, circumstantial. Furthermore, the assumption of cylindrical pores of one size eliminates the possibility of estimating accurately the effects of both pore size distribution and the relative gas-filled to liquid-filled volumes in the electrode. The gas-filled volume should be considered, as there must be enough thin meniscus so that gas can diffuse to the metal surface if it is to take this route to the flooded part of

the sinter. Finally, perhaps the most difficult empirical result to accept is the fact that surface diffusion must explain a factor of 10^4-10^5 greater diffusion than that of hydrogen in the bulk electrolyte. The only reported determination of surface diffusion of hydrogen on nickel describes the results of field emission experiments (8). Extrapolating these measurements from 250° to 280°K to our experimental region of 500°K, the surface diffusivity is around 10^{-6} cm²/sec. Although this is about the same order of magnitude as the diffusivity in bulk electrolyte, another factor of 10^{+5} is required. We can argue, however, that the field emission results can be several orders of magnitude off when applied to these conditions. At the low pressures employed in field emission experiments, only the most tightly held molecules are held on the surface and are observed. At higher pressures, it would be expected that the less tightly held molecules would have considerably more mobility. Furthermore, the effect of the electrolyte could be very important. Measurements of hydrogen diffusion through porous nickel sinters at 500°K are being planned and the results may clear up the difficulty. In spite of these limitations, we have a model that seems to approximate the gross mechanisms in anodes and we can go on from this point to treat more sophisticated descriptions of the electrodes.

The Manganese Dioxide Electrode in Alkaline Electrolyte; The Electron-Proton Mechanism for the Discharge Process from MnO_2 to $MnO_{1.5}$

A. Kozawa and R. A. Powers

Research Laboratory, Consumer Products Division, Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

In the study of cathodic reduction of electrolytic manganese dioxide at constant-current discharge in alkaline electrolytes, effects of D_2O, Zn(II) ion added to the electrolyte, and of temperature on the discharge curves of the electrodeposited MnO_2 on a graphite rod were investigated. Results are discussed in view of the electron-proton mechanism. The potential *vs.* x value in MnO_x curve agrees in general with that calculated from

$$E = E^\circ - \frac{RT}{F} \ln \frac{[Mn^{3+}]_{solid}}{[Mn^{4+}]_{solid}}$$

corresponding to a reaction

$$MnO_2 + H_2O + e^- \rightarrow MnOOH + OH^-$$

which is assumed to take place in one phase of the oxide electrode system ($Mn^{3+} - Mn^{4+} - O^= - OH^-$). In 9M KOH prepared with KOH + D_2O, the polarization of the MnO_2 electrode was greater than that in electrolyte prepared with KOH + H_2O. Addition of zinc ion had no effect on the discharge curve from MnO_2 to $MnO_{1.5}$. A new definition of E° for a homogeneous redox solid system is proposed and the value for the $Mn^{4+} - Mn^{3+} - O^= - OH^-$ system compared to the conventional thermodynamic E° value. A few potential-controlling factors of the MnO_2 electrode are discussed.

The cathodic reduction of electrolytic manganese dioxide (γ-MnO_2) in alkaline electrolyte has been investigated by Cahoon and Korver (1), Bell and Huber (2), and Kozawa and Yeager (3). Those results have been compared and discussed in a previous publication (3). In the first two investigations (1,2) the manganese dioxide electrodes were constructed in a manner similar to that used in a battery (powdered electrolytic

MnO_2 and graphite mixed with KOH solution and pressed together), but in the third investigation (3) a much simpler electrode (MnO_2 electrodeposited on spectroscopic graphite rods) was used. Based on the discharge curves (potential *vs.* x in MnO_x) of the simpler electrode at constant current, Kozawa and Yeager found two steps in the electrochemical reduction of MnO_2 (refer to curve B in Fig. 4); the first step from MnO_2 to $MnO_{1.5}$ and the second step from $MnO_{1.5}$ to $MnO_{1.0}$, where there is a dip on the recorded potential-time curve at the end of the first step. In the first step the potential decreased continuously and therefore, during this period, the solid phase must be homogeneous according to the thermodynamic considerations presented by Vetter (4). In the second step a considerable portion of the discharge curve was flat; that is, it maintained a constant potential. This must mean that two solid phases are involved in the second step according to the thermodynamic consideration (4). Kozawa and Yeager proposed a new discharge mechanism (3) for the second step which has been further investigated. The results will be presented in a separate paper.

In the previous publication (3) the homogeneous phase discharge of the first step was discussed in accordance with the electron-proton mechanism, which has been proposed and investigated by Coleman (5), Vosburgh and co-workers (6, 7), Scott (8), Kornfeil (9), and Era, Takehara, and Yoshizawa (10). It was assumed in the electron-proton mechanism that MnO_2 was electrochemically reduced to MnOOH by receiving electrons and protons into the MnO_2 lattice without changing much of the original structure.

In this paper, attention will be focused on the first step of the discharge process. It was found that the two-step reduction which was observed in previous study (3) is also observed with a conventional cathode construction currently used in the alkaline MnO_2 cell. Effects of D_2O, zinc ion added to the electrolyte, and of temperature on the discharge curve of the electrodeposited MnO_2 on graphite rods will be presented and discussed from the point of view of the electron-proton mechanism.

Electron-Proton Mechanism

Since the purpose of this investigation is to test further the electron-proton mechanism in alkaline electrolyte, some details of the mechanism will be discussed here with the aid of Fig. 1. As we can see by Eq. [1] and in Fig. 1, in the cathodic reduction of MnO_2 (ionic crystal)

$$MnO_2 + H_2O + e^- \rightarrow MnOOH + OH^- \qquad [1]$$

electrons are introduced into the lattice and Mn^{4+} is reduced to Mn^{3+}. As a result of electron exchange between Mn^{4+} and Mn^{3+} in the lattice, the position of Mn^{3+} (not the manganese ion itself) moves around in the entire lattice. At the same time, H_2O molecules (an abundant source of protons under this condition) may be decomposed at the solid-solution interface, and protons are introduced into the lattice forming OH^-. Since the OH^- in the lattice is rotating and vibrating, the O-H bond is broken, and H^+ is transferred to the adjacent $O^=$ to form OH^- again. Thus, OH^- also moves around in the entire lattice by means of the proton jumping from one $O^=$ site to another.

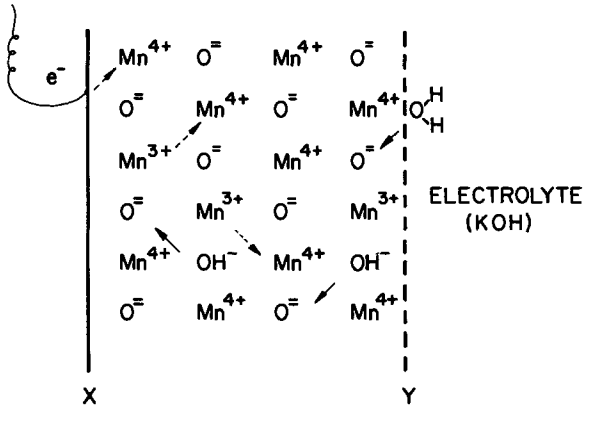

Fig. 1. Schematic presentation of the solid phase (Mn^{4+} — Mn^{3+} — $O^=$ — OH^-) during the discharge of MnO_2. The arrows show the directions of movement of the electrons and protons: ——— proton movement; - - - - electron movement; X, MnO_2-electronic conductor interface; Y, MnO_2-solution interface.

As the discharge proceeds, the concentrations of Mn^{3+} and OH^- in the lattice increase, and in an open-circuit condition, both of these species become distributed homogeneously throughout the oxide lattice. At equilibrium the electrode potential of the oxide having a homogeneous phase may be determined by the activity of the electron in the lattice, or by the ratio of $[Mn^{3+}]/[Mn^{4+}]$ in the solid, because of the relatively free electron exchange between Mn^{3+} and Mn^{4+}. As long as the lattice parameters (distance between two adjacent $O^=$ and that between two adjacent Mn^{4+}) permit fairly free movement of protons (through $O^=$ sites) and electrons (through Mn^{4+} sites) in the manner described above, the electrochemical reduction can take place in a homogeneous phase. However, as the discharge proceeds the original MnO_2 lattice expands, because the ionic radius of OH^- (1.53Å) (36) is greater than that of $O^=$ (1.40Å) (36), and Mn^{3+} (0.62Å) (37) is greater than Mn^{4+} (0.52 (38). Therefore, at a certain point, the crystal structure may be transformed to a new form in which such a free movement of the electron and proton may not be possible.

The potential-generating mechanism of the homogeneous $Mn^{3+} — Mn^{4+} — O^= — OH^-$ phase in contact with an electrolyte is somewhat analogous to an aqueous redox system; for example, an aqueous solution containing Fe^{2+} and Fe^{3+} ions which consists of a homogeneous phase and the potential can be expressed by Eq. [2].

$$E = E^\circ - \frac{RT}{F} \ln \frac{[Fe^{2+}]}{[Fe^{3+}]} \qquad [2]$$

In the $Mn^{3+} — Mn^{4+} — O^= — OH^-$ system, electrons and protons move around and the system is in an electrochemical equilibrium with species (OH^-, H_2O) in the electrolyte. The two systems may be considered similar in the relation of the electrode potentials to the variable activities of the oxidized and reduced forms present in a homogeneous phase. Therefore, the electrode potential of the oxide electrode system ($Mn^{4+} — Mn^{3+} — O^= — OH^-$) of a homogeneous phase may be expressed by Eq. [3], as a first approximation, with $[OH^-]$ and $[H_2O]$ assumed constant.

$$E = E^\circ - \frac{RT}{F} \ln \frac{[Mn^{3+}]_{\text{solid}}}{[Mn^{4+}]_{\text{solid}}} \qquad [3]$$

This can be tested experimentally by comparing the open-circuit potential of the MnO_2 electrode at various stages of the discharge to the calculated curve (Fig. 2, curve a) from Eq. [3]. If the discharge does not proceed through a homogeneous phase, but involves a conversion of one solid phase (MnO_2) to another separate solid phase (MnOOH or Mn_2O_3), the open-circuit potential must be constant in thermodynamic principle at any stage of the discharge, because in Eq. [4] the activities of those solid phases do not vary with the quantities present and must be constant in the entire range of the discharge as indicated by curve b in Fig. 2.

$$E = E' - \frac{RT}{F} \ln \frac{a_{MnOOH}}{a_{MnO_2}} \qquad [4]$$

An example of this kind of mechanism in which two solid phases are involved is the second step of the

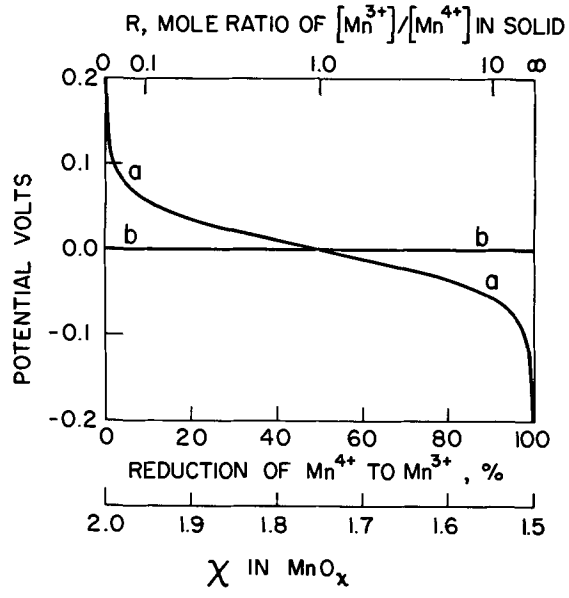

Fig. 2. Equilibrium potential curves for one-phase and two-phase reductions. Curve a, calculated from Eq. [3] for a one-phase (or homogeneous phase) reduction. Line b, for two-phase reduction (Eq. [4]). R and x in MnO_x are related by x = (2 + 1.5R)/(1 + R).

discharge, from MnOOH to $Mn(OH)_2$ in alkaline electrolyte, in which the open-circuit potential was constant (see Fig. 5). As a matter of fact, many of the electrode reactions in batteries currently in use seem to be heterogeneous phase (two-phase) reactions; $PbO_2 \rightarrow PbSO_4$, $NiOOH \rightarrow Ni(OH)_2$, $Zn \rightarrow ZnO \cdot x\,aq$, $Cd \rightarrow Cd(OH)_2$, etc., because the open-circuit potentials of these electrodes are almost unchanged at any stage of the discharge as has been well recognized. However, V_2O_5 (11) seems to be discharged in a homogeneous phase, although a homogeneous-phase reduction does not necessarily mean that the electron-proton mechanism is the only possibility. Cathodic reduction of PbO_2, TiO_2, Tl_2O_3 were studied and compared to that of MnO_2 by Mark and Vosburgh (46).

In this paper, the $E - x$ (in MnO_x) relation was obtained in 1M and 9M KOH and compared to the curve calculated from Eq. [3] (curve a in Fig. 2). Discharge curves at constant current were taken in KOH electrolyte prepared with both H_2O and D_2O, because if the discharge mechanism involves the proton migration in the oxide lattice, the deuterium ion, which is twice as heavy as a proton, should show more polarization. The effect of zinc ion added to 9M KOH was examined at constant current discharge, because this probably gives some indication whether or not a new solid phase is forming in the discharge process.

The electron-proton mechanism for the discharge process of manganese dioxide was proposed and investigated mainly in the Leclanché electrolyte (NH_4Cl-$ZnCl_2$-H_2O) (1, 2, 5-9). In this research alkaline electrolytes (1M NaOH and 9M KOH) were used in order to test some of the details of the electron-proton mechanism, because the concentration polarization (due to pH change) is practically negligible in these electrolytes, and most of the observed polarization during the discharge in alkaline electrolyte is attributed to the activation polarization which includes the slow diffusion process in the solid phase as well as the charge transfer process at the oxide-electrolyte interface.

Experimental

Preparation of MnO_2 electrodes.—Manganese dioxide was electrodeposited on spectroscopic graphite rods (AGKSP), 7.7 cm or 2.5 cm long and 4.5 mm in diameter, from 0.5M $MnSO_4$ + 0.5M H_2SO_4 or 1M $MnSO_4$ + 0.5M H_2SO_4 at 90° ± 1°C at a constant current of 20 ma for 5.0 min, or 5 ma for 20 min for the 2.5 cm rod. The electrode construction and the electrodeposition bath were described in the previous paper (3). After the electrodeposition the electrode with manganese dioxide was taken out of the Teflon holder, kept in a large amount of 0.1*N* H_2SO_4 with slow stirring for at least 24 hr, and then transferred into a large amount of distilled water. The electrode was washed for another 48 hr in distilled water, which was changed approximately every 12 hr, with slow stirring, and kept in distilled water until used.

In this study, the electrodes had much less MnO_2 [approximately 3.0 mg each instead of 10.6 mg as in previous experiments (3)], because the thinner the MnO_2 layer the faster the diffusion equilibrium in the solid should be, and the easier to replace H_2O by D_2O in the pores of the MnO_2 layer. Current efficiency of the electrodeposition was approximately 60-90% in the present experiments. The lower current efficiency than 100% was attributed to a side reaction (oxygen evolution) and varied depending on the current density and particularly on the kind of graphite rod. It was found by chemical analysis (7) the x value in MnO_x was 1.98-1.99 regardless of the current efficiency in the electrodeposition and that the amount of MnO_2 was almost constant (within 5%) among the electrodes prepared at the same time under the same conditions. It was also found that the discharge time to the dip (see Fig. 4) at the end of the first step of the discharge (around —0.40 to —0.45v *vs.* Hg/HgO [9M KOH] for the discharge in 9M KOH) is a good measure of the amount of MnO_2.

Discharge experiments.—All the discharges were carried out at constant current, continuously or intermittently, at room temperature (23° ± 0.5°C) or at higher temperature (65° and 95°C) in a polarographic H-cell (Fig. 3). Both arms of the H-cell were filled with electrolyte (1M NaOH or 9M KOH) and the solution levels were kept almost equal. The assembled electrode was placed in one arm and nitrogen gas bubbled through for 10 to 15 min to expel dissolved oxygen. The electrode was wrapped with a filter paper to avoid loss of dissolved Mn^{3+} ion, having a form $[Mn(OH)_4]^-$ and reddish color, from the electrode, particularly from 9M KOH at high temperature. During the discharge the solution was not stirred. The potential was measured against the Hg/HgO (1M NaOH or 9M KOH) reference electrode in

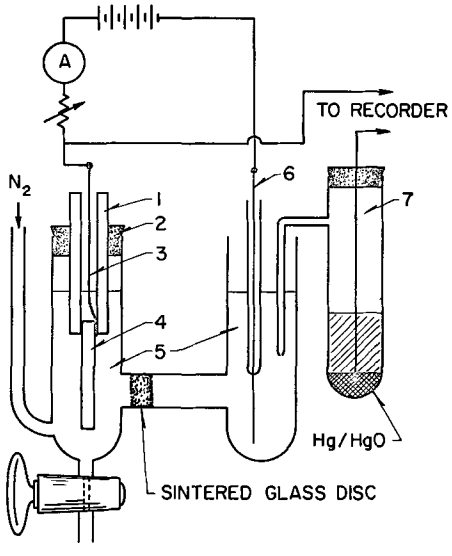

Fig. 3. Discharge cell and electrode construction: 1, Teflon tubing electrode holder; 2, Teflon stopper; 3, platinum lead wire, epoxy-coated except at the end contact; 4, graphite electrode with MnO_2 electrodeposited on it; 5, electrolyte; 6, counter electrode; 7, reference electrode.

the same solution. For the discharges at 65° and 95°C, the H-cell was placed in a thermostat, but the reference electrode was kept at room temperature.

Before the discharge the electrode was kept at room temperature for at least 48 hr in the electrolyte, which had the same concentration as that which was to be used in the discharge, but without the platinum lead (see Fig. 3) and the Teflon holder. It was checked and found that further immersion prior to the discharge, up to 10 days, did not show any change in the discharge behavior, including the experiments in D_2O solutions.

Discharge of the conventional MnO_2 *cathode.*—Powdered electrolytic manganese dioxide (32g), graphite, acetylene black, 9M KOH, and a small amount of binding material were mixed thoroughly. The mixture was molded in a D-size steel can by applying high pressure to form a cathode layer approximately 3.0 mm thick along the inside of the can. Then a paper separator, electrolyte (9M KOH), and a zinc anode (CMC-gelled zinc powder) were added in a manner which made it similar to a conventional cell. The cell was discharged at a constant current of 10 ma at room temperature, and the cathode potential was measured against a Hg/HgO (9M KOH) reference electrode. Provision was made to prevent loss of moisture from the cell and absorption of carbon dioxide into the electrolyte. After the zinc anode was exhausted an external constant current source was used to discharge the cathode completely. The net MnO_2 in the cathode was found to be 30.0g by chemical analysis of the electrolytic manganese dioxide.

Results and Discussion

Discharge curve of the molded cathode.—Bell and Huber (2) obtained a three step discharge curve (curve C in Fig. 4) in the discharge of a manganese dioxide cathode constructed with powdered electrolytic MnO_2 and graphite. Kozawa and Yeager (3) obtained a two-step discharge curve (curve B in Fig. 4) in the discharge of electrodeposited manganese dioxide on a porous graphite rod. It is suspected that this difference in the discharge behavior may be due to a difference in a physical factor, such as the contact between MnO_2 particles and graphite particles. In order to check this point, the present cathode was molded under high pressure and discharged at extremely low current density (10 ma per D-size cell or 0.33 ma/g of MnO_2) over a two-month period. Under such a low current density, conductivity of the oxide particles and the contact resistance between the oxide and graphite particles probably does not influence the discharge process. The present results are plotted on the basis of calculated x values (in MnO_x) from the electricity drawn. The curve is shown in Fig. 4 (curve A) where two steps are clearly seen corresponding to the two steps of curve B which was obtained with electrodeposited MnO_2 on a porous graphite rod. During the discharge of the cathode at 10 ma, practically no polarization (no potential difference between the closed circuit and the open circuit potentials) was observed in the first step and also in the beginning of the second step. The remaining part of the second step shows considerable polarization (dotted line ab shows open-circuit potential).

The present result (curve A in Fig. 4) proves that even with a powder electrode construction the two-step reduction of MnO_2 takes place in alkaline electrolyte under proper discharge conditions.

E-log $[Mn^{3+}]/[Mn^{4+}]$ *relation.*—Several electrodeposited electrodes were discharged at 250 μa, continuously and intermittently in 1M NaOH and 9M KOH. Typical results are shown in Fig. 5. Curve a shows the closed-circuit potential of the two discharges: one was discharged continuously and the other intermittently over a period of four days while the open-circuit potentials were taken at various stages of the discharge. The closed-circuit potentials of the two discharges are essentially the same. The recovery curves were taken at various stages of the discharge. Only three curves (curves c, d, and e) are shown here, which indicates that most of the polarization recovered within 60 min. The open-circuit potentials after a few hours were almost equal to those after an overnight period (about 15 hr).

At the end of the first step a dip was observed at 110 min as noted in Fig. 5. Therefore, 110 minutes was taken as a measure of the MnO_2 present in this electrode. The equilibrium potential observed experimentally (curve b in Fig. 5) was compared to the calculated curve from Eq. [3]. In this comparison, the middle point of the first step (that is, 110/2 = 55 min discharge) where $[Mn^{3+}]_{solid}/[Mn^{4+}]_{solid} = R = 1.0$ was chosen as a reference point. In other words, a curve obtained from $E = E^o - 0.059 \log R$ was superimposed on the curve b in Fig. 5 based on the reference point. This choice of the reference point seems to be reasonable since the initial open-circuit potential cannot be chosen for the reference point because a calculated potential for 100% MnO_2 is $+\infty$. Also, at the middle point, where $R = 1.0$, the potential is rather insensitive to the composition (R);

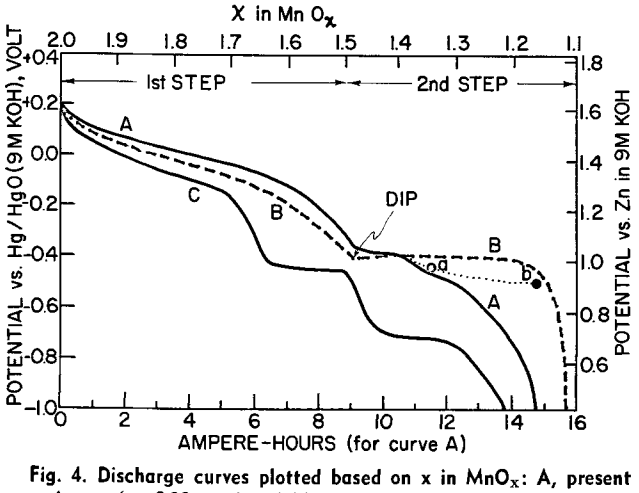

Fig. 4. Discharge curves plotted based on x in MnO_x: A, present experiment (at 0.33 ma/g of MnO_2); B, Kozawa and Yeager (3), electrodeposited MnO_2 on a graphite rod (at 11 ma/g of MnO_2); C, Bell and Huber (2), (at 0.5 ma/g of MnO_2).

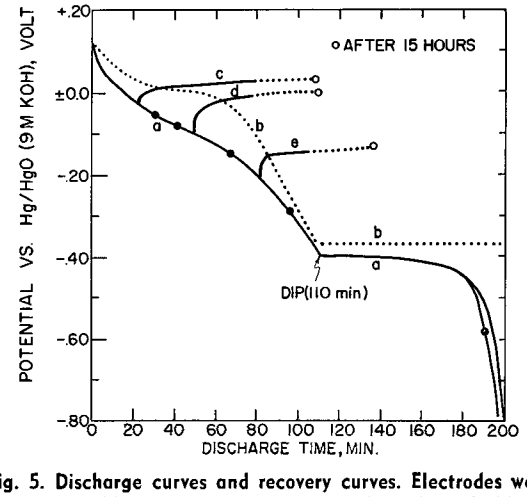

Fig. 5. Discharge curves and recovery curves. Electrodes were 7.7 cm long with MnO_2 electrodeposited on them from 0.5M $MnSO_4$ + 0.5M H_2SO_4 at 90°C at 20 ma for 5 min. They were discharged at 250 μa in 9M KOH at 23°C. Curve a, ——— closed circuit potential on intermittent discharge; —•— closed circuit potential on continuous discharge; curve b, open-circuit equilibrium potential; curves c, d, and e, recovery curves.

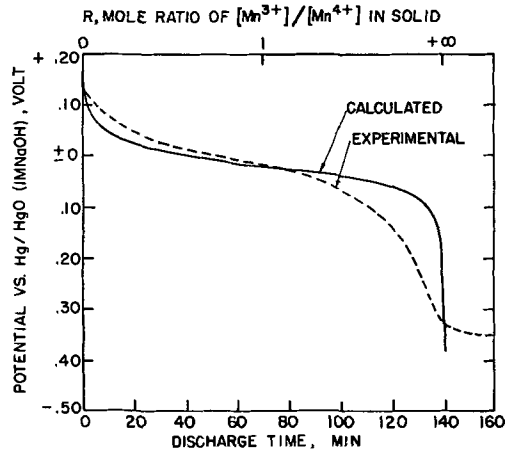

Fig. 7. Comparison of the potential vs. log $[Mn^{3+}]/[Mn^{4+}]$ relation for the equilibrium open circuit potential obtained in 1M NaOH at 23°C. The preparation of the electrode and the discharge conditions are the same as described in Fig. 5, excepting the electrolyte for discharge.

therefore, some experimental error in obtaining the middle point would not seriously influence the comparison. The comparisons are shown in Fig. 6 and 7 for the results obtained in 9M KOH and 1M NaOH, respectively. We can see that the agreement between the experimentally obtained and the calculated curves is not perfect in the entire range, but the general shape of the curve seems to agree with the original assumptions, a homogeneous phase discharge from MnO_2 to $MnO_{1.5}$.

The main disagreement between the observed and the calculated curves occurs at the later stage of the discharge. This can be well explained by assuming that at the later stage of the discharge a new lower oxide phase (Mn_2O_3) is formed on the surface of the original oxide ($Mn^{4+} - Mn^{3+} - O^{=} - OH^{-}$ system) and the potential is determined or largely controlled by the Mn_2O_3 phase on the surface. These assumptions are substantiated by the following facts and discussion. The x-ray study (2) in the course of discharge of electrolytic MnO_2 in alkaline electrolyte showed that at the beginning stage of the discharge ($MnO_2 \rightarrow MnO_{1.7}$) a lattice dilation of the original structure took place, rather than the formation of a new phase, indicating a homogeneous phase discharge, and in the subsequent stage of the discharge formation of lower oxide phases such as α-MnOOH and γ-Mn_2O_3 took place. It was previously demonstrated (12) that the formation of one or two layers of lower oxide on the surface of electrolytic MnO_2 brings the electrode potential of the MnO_2 to as low as that of Mn_2O_3 (in the experiment the lower-oxide film on the MnO_2 surface is formed by addition of Mn^{++} to a solution containing suspended MnO_2). We shall note here the important fact that when MnO_2 is reduced electrochemically even to a large extent (for example, 50% of the MnO_2 converted to lower oxide) the potential decrease is only 170 mv or so from its beginning value (see Fig. 4, 6, and 7), but when the MnO_2 is reduced chemically by adding Mn^{++} ($MnO_2 + Mn^{++} \rightarrow Mn_2O_3$ on the surface) only 15% reduction (150 mg of Mn^{++} added to 1.5g of MnO_2) (12) brought the potential decrease of 250 mv to roughly the potential of Mn_2O_3. This is evidence that the lower oxide phase formed chemically on the MnO_2 surface does not diffuse into the MnO_2 lattice, or at least cannot function as a homogeneous phase. Consequently the electrode potential under this condition is determined essentially by the surface oxide. Although the formation of the lower oxide depends on the discharge conditions, particularly on current density or surface area of the MnO_2, for the electrochemical reduction of MnO_2 at moderate or low-current discharge such a lower-oxide phase is not likely to be formed on the surface during the stage of the discharge from $MnO_{2.0}$ to $MnO_{1.75}$, and the potential is determined by the activity of the whole solid phase (a homogeneous $Mn^{4+} - Mn^{3+} - O^{=} - OH^{-}$ phase) as described earlier in this paper.

This viewpoint is also supported by the following experiment. In order to compare the potentials of MnO_2 which is partially reduced, the MnO_2 electrode was reduced by two different chemical methods: (*i*) addition of a calculated amount of Mn^{++} to reduce half of the MnO_2 to $MnO_{1.5}$ and (*ii*) addition of a calculated amount of Sb^{+++} to reduce half of the MnO_2 to $MnO_{1.5}$. The experiments were carried out in 9M KOH with the MnO_2 electrodeposited on a graphite rod. In these experiments Sb^{+++} or Mn^{++} ion was added to a N_2-saturated 9M KOH solution in which the MnO_2 electrode had been dipped in the same manner as in the discharge experiment in the H-cell. While stirring by means of bubbling N_2 gas, the potential was measured with time. It was assumed that the reaction of Mn^{++} or Sb^{+++} with MnO_2 was completed when the equilibrium potential was attained. In the case of Sb^{+++} addition, Sb^{+++} must be oxidized to Sb^{5+} in the potential range of the MnO_2-$MnO_{1.5}$ as seen from the polarographic behavior (see Fig. 8 and its legend), and the reaction product (Sb^{5+}) is a soluble form which does not form a new

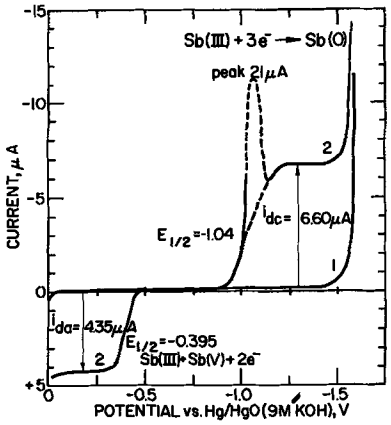

Fig. 8. Polarographic behavior of Sb^{+++} in 9M KOH at 23°C. The Sb^{+++} solution was prepared by dissolving Sb_2O_3 in 9M KOH. Curve 1, in 9M KOH; curve 2, in 9M KOH + 1 x 10^{-3}M Sb^{+++}. The ratio of the anodic limiting current (i_{da}) to the cathodic limiting current (i_{dc}) is 2:3 and the anodic and cathodic processes and their half-wave potentials are shown in the figure. The characteristics of the glass capillary were m = 1.42 mg/sec, t = 5.82 sec at open circuit in 9M KOH.

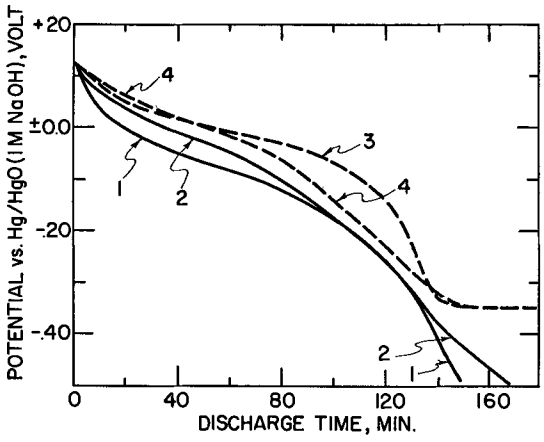

Fig. 9. Effect of temperature on the discharge of MnO_2 electrodes in 1M NaOH. The preparation conditions of the electrodes were the same as described in the caption of Fig. 5. They were discharged at 250 μa in 1M NaOH continuously and intermittently. Curve 1, closed-circuit potential at 23°C; curve 2, closed-circuit potential at 65°C; curve 3, open-circuit equilibrium potential at 23°C; curve 4, open-circuit equilibrium potential at 65°C.

lower oxide on the MnO_2 surface. In the case of Mn^{++} addition, Mn^{++} reacts with MnO_2 to form $MnO_{1.5}$ on the surface, although some of the Mn^{3+} can dissolve in the 9M KOH probably as $[Mn(OH)_4]^-$ (13).

The equilibrium potential attained in 10 hr in the Sb^{+++} addition was —0.01v *vs.* Hg/HgO (9M KOH) which is very close to the potential obtained at the discharge $R = 1.0$, but the equilibrium potential observed in the addition of Mn^{++} ion was much lower than that. The conclusion may be made here that the potential of partially reduced MnO_2 does not depend on the reduction method, chemical or electrochemical, as long as a new lower-oxide phase is not formed on the MnO_2 surface. Once a lower oxide is formed on the MnO_2 surface the potential is controlled largely by this lower oxide. The large disagreement between the observed and calculated curves at the later stage of the discharge, as shown in Fig. 6 and 7, can be understood on the basis of the lower oxide formation on the MnO_2 surface.

Effect of temperature.—The effect of temperature on the discharge curves is shown in Fig. 9. The discharges were carried out in 1M NaOH at 23°, 65°, and 95°C, but only the curves at 23° and 65°C are shown because those at 65°C or higher had very little difference. The temperature effect was examined only in 1M NaOH because Mn^{3+} and Mn^{2+} ions have fairly large solubilities in concentrated alkaline electrolyte, particularly at higher temperatures (13). The initial open-circuit potential of the MnO_2 electrode was practically constant in the temperature range (23°-95°C) when measured against the Hg/HgO (1M KOH) kept at 23°C. The main difference between the closed-circuit potentials at 23° and at 65°C occurs in the initial half of the discharge (compare curves 1 and 2 in Fig. 9). On the other hand the difference in the open-circuit potential occurs during the later half (compare curves 3 and 4).

Under the discharge conditions, ohmic drop and concentration polarization (due to the species in the solution) are negligible. Therefore, the polarization is mainly attributed to the slow diffusion of the proton and electron in the lattice and of the proton generation process at the solid solution interface ($H_2O \rightarrow H^+ + OH^-$). During the initial half of the discharge the original MnO_2 lattice may be well maintained, and polarization of this kind is expected to be much less at higher temperatures; therefore, the closed circuit potential should be kept higher at higher temperatures. However, during the later half of the discharge the potential is largely controlled by the formation of the lower oxide on the surface as mentioned above. The lower oxide formation is probably a chemical step following the primary electrochemical step and is probably taking place more rapidly at higher temperatures. On this basis the lower open-circuit potential at higher temperatures may be well interpreted.

Effect of D_2O.—A 9M KOH electrolyte was prepared by dissolving KOH pellets into 99.9 mole % D_2O. From the NMR study of the KOH-H_2O system (14), the proton exchange between H_2O (or D_2O) and OH^- is fast. Therefore, the average D_2O content in the KOH-D_2O electrolyte is approximately 85%. The discharge in the KOH-D_2O electrolyte was carried out at two current densities (250 μa or 1 ma per electrode) and the results were shown in Fig. 10 and 11, in which closed-circuit potentials on the continuous discharges are shown. At each condition (in electrolyte and current density) 3 to 5 electrodes were discharged to see the reproducibility of the experiment, and the highest and the lowest curves in each con-

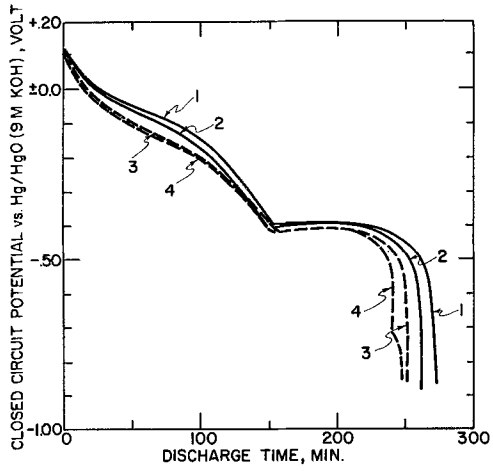

Fig. 10. Effect of D_2O at 250 μa discharges. Electrodes were 7.7 cm long with MnO_2 electrodeposited on them from 0.5M $MnSO_4$ + 0.5M H_2SO_4 at 90°C at 20 ma for 5 min. They were discharged at a constant current (250 μa) at 23°C. Curves 1 and 2, in 9M KOH in H_2O; curves 3 and 4, in 9M KOH in D_2O.

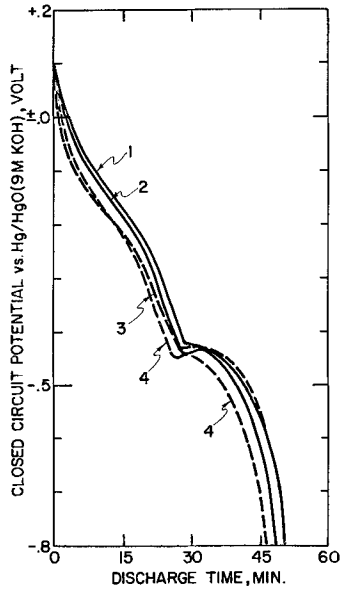

Fig. 11. Effect of D_2O at 1.0 ma discharge. Electrodes were prepared under the same conditions as described in the caption of Fig. 10. They were discharged at a constant current (1.0 ma) at 23°C. Curves 1 and 2, in 9M KOH in H_2O; curves 3 and 4, in 9M KOH in D_2O.

dition are shown in the figures to give the limit of the reproducibility. For the comparison and evaluation, the amount of MnO_2 present in the electrode must be taken into account, and the discharge time to the dip at the end of the first step should be considered as a measure of the MnO_2 present as mentioned previously. We can see in Fig. 10 and 11 that under these discharge conditions the polarization during the discharge of the first step is greater by approximately 60 mv in the KOH-D_2O electrolyte than in the KOH-H_2O electrolyte.

Effect of Zn(II) *ion.*—In previous publications concerned with the discharge reaction of manganese dioxide in the Leclanché cell, the formation of a lower oxide of manganese (hetaerolite) containing zinc, such as $ZnO \cdot Mn_2O_3$ or $ZnMn_2O_4$ has been shown (15-17). It was also shown that the formation of hetaerolite should give more energy output because of the difference in the ΔF from a thermodynamic calculation (18).

$$Zn + 2MnO_2 = ZnO + Mn_2O_3 \quad F = -66.5 \text{ kcal} \ (1.44\text{v})$$

$$Zn + 2MnO_2 = ZnMn_2O_4 \quad F = -72.8 \text{ kcal} \ (1.58\text{v})$$

If the discharge mechanism of the first step in alkaline electrolyte is not the electron-proton mechanism, but rather one involving a phase change from MnO_2 to a lower oxide phase containing zinc ion, then the zinc ion present in the electrolyte may be incorporated in the lower oxide phase as in the case of Leclanché electrolyte (NH_4Cl-$ZnCl_2$-H_2O), because the zinc-containing oxide is more favorable from the free energy value shown above.

This was tested by discharging the electrodes in 9M KOH and in 9M KOH saturated with ZnO, approximately 1M solution in ZnO (19). A typical result is shown in Fig. 12, in which we can see that the first step is not influenced by the presence of Zn(II) ion (the complex form is $[Zn(OH)_4]^=$ in the solution (20)). This result is in agreement with the proton-electron mechanism for the first step of the discharge.

Discussion

Reasons and results which substantiate the electron-proton mechanism for the first step of the discharge of MnO_2 are summarized below.

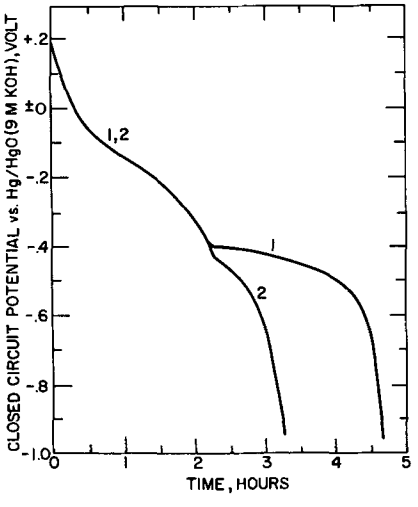

Fig. 12. Effect of zinc oxide on the discharge of MnO_2 in 9M KOH. Electrodes were 2.5 cm long with MnO_2 electrodeposited on them from 1M $MnSO_4$ + 0.5M H_2SO_4 at 5 ma for 20 min at 90°C. They were discharged at 250 μa (constant current) at 23°C. Curve 1, in 9M KOH; curve 2, in 9M KOH saturated with ZnO (approximately 1M).

1. During the electrochemical reduction of MnO_2, the potential (open-and closed-circuit potentials) decreases continuously and the $E - x$ (in MnO_x) curve agrees in general with the calculated curve by assuming a homogeneous phase reduction. The electron and proton movement in the solid phase can be fast compared to ions ($O^=$, OH^-, metal ions) and it seems reasonable to expect a homogeneous phase during the reduction.
2. The x-ray study by Bell and Huber (2) indicates that no new phase appeared at the beginning stage of the discharge of MnO_2, at least until $MnO_{1.7}$, substantiating a homogeneous phase discharge, although an amorphous phase cannot be detected by the x-ray method.
3. D_2O in place of H_2O in the KOH electrolyte increases the polarization.
4. Addition of a complexing agent (triethanolamine) has very little effect on the first-step discharge (3). This indicates that a phase change through dissolved species of manganese (II) is not likely to be involved in the discharge process, although Cahoon *et al.* (40, 41) described such a discharge mechanism in Leclanché electrolyte.
5. Addition of Zn^{++} ion in the electrolyte (KOH) has no effect.
6. The KOH concentration in a range of 0.1-9M KOH has very little influence on the discharge curve of the first step (3).

Based on the potential-generating mechanism in accordance with electron-proton movement in the Mn^{4+} — Mn^{3+} — $O^=$ — OH^- system, the following discussion is given in order to account for the potential of manganese dioxide.

$E - x$ in MnO_x relation.—Recently Vosburgh and DeLap (42), Bode *et al.* (43, 44) and Feitknecht *et al.* (45) examined the $E - x$ in MnO_x relation by reducing γ-MnO_2 chemically with hydrazine (43, 45) or electrochemically (42, 44). All of them found that the potential decreased almost linearly with decreasing x value for γ-MnO_2 between $MnO_{2.0}$ and $MnO_{1.5}$. We, however, plotted the potential against log R $\left(R = [Mn^{3+}]/[Mn^{4+}] \text{ in the solid, and } R \text{ and } x \text{ in } MnO_x \text{ are related by } x = \frac{2 + 1.5R}{1 + R} \right)$, since this plot gives a sharp increase and a sharp decrease in approaching to $x = 2.0$ and $x = 1.5$, respectively, and seems to give a better fitting to the data obtained in the present work. It should be noted, however, that the E — log R plot gives an almost straight line between $x = 1.9$ and 1.6 as shown in Fig. 2.

E^o of the MnO_x system.—In the past a number of attempts have been made to measure the correct potential of MnO_2 (21-29) and to understand the potential of the MnO_2-Zn cell on the basis of chemical thermodynamics (18). It seems that two factors disturbed the potential measurement. It has been recognized in recent years that ion-exchange properties (27-31) on the surface of MnO_2 play an important role in the potential measurement because the proton released to the solution by cation adsorption on the MnO_2 surface (30) acidifies the solution and the pH of the solution in the fine pores of the MnO_2 is considerably lower than that in the bulk solution. Now we know that a stable and reproducible potential can be obtained by using an electrolyte solution having a large pH buffer capacity or by digesting the manganese dioxide thoroughly in the solution.

Another factor which disturbed the previous investigators in obtaining a reproducible potential in neutral or alkaline solutions still seems to be unsettled. The potential value for the Pt/MnO_2, Mn^{++}, H^+ electrode in acid solution is in a range of 1.233 to 1.241v (28), and the values obtained by various workers agree with the value estimated from thermo-

dynamic data by Wadsley and Walkley (32). The potential of the so-called MnO_2-MnOOH system in neutral and alkaline solutions varied considerably. Various factors such as purity (MnO_2 content), crystal structure, (α-, β-, γ-MnO_2, etc.) heat-treatment (29), and the surface condition (12) of the oxide have been considered so far, but no satisfactory explanation has been given. According to the potential-generating mechanism of MnO_2 presented in this paper, the potential of pure MnO_2 has practically no meaning because the ratio $[Mn^{3+}]_{solid}/[Mn^{4+}]_{solid}$ is zero or a very low value; therefore, the potential is $+\infty$ (or a very high value from Eq. [3]). The ratio is also, in most cases, uncertain for a given sample. The practical potential value of pure MnO_2 in aqueous solutions may be limited to the redox potential of the O_2-H_2O system (O_2 evolution by H_2O decomposition). This is probably one important reason, in addition to the effect of the presence of the lower oxide on the surface which was discussed previously in this paper, why the potentials of MnO_2 so far obtained have been in poor agreement.

The E^o of the homogeneous solid having a redox couple like the Mn^{4+} — Mn^{3+} — $O^=$ — OH^- system has not been defined, but it seems reasonable to define the E^o as a potential at $[Mn^{3+}]_{solid}/[Mn^{4+}]_{solid} = 1.0$. The approximate standard potential thus defined of the Mn^{4+} — Mn^{3+} — $O^=$ — OH^- system is -0.01 ± 0.01v *vs.* Hg/HgO (1M NaOH) (or $+0.103$ *vs.* NHE).

In the construction of the *p*H-potential diagram which is based on chemical thermodynamics, the line for

$$2MnO_2 + 2H^+ + 2e^- = Mn_2O_3 + H_2O \qquad [5]$$

was found to be $E = 1.014 - 0.0591$ *p*H (33). This value was obtained from the ΔF when the β-MnO_2 phase is converted to the Mn_2O_3 phase; that is, the calculation is based on the hypothetical electrochemical reaction involving two solid phases. The activity of the solid does not depend on the quantity of the solid phase; and therefore, the potential should be constant while the ratio of the amount of β-MnO_2 and Mn_2O_3 changes during the hypothetical electrode reduction. The *p*H-potential diagram, therefore, has a single straight line for Eq. [5]. However, the true electrochemical reduction of MnO_2 seems to be a homogeneous phase reduction, regardless of the crystal structure (α-, β-, γ-MnO_2), although this has been examined only with γ-MnO_2 in this paper. Therefore, the *p*H-potential diagram for the homogeneous phase system (MnO_2-Mn_2O_3) is not a single straight line, but should be a zone for a range of the R value ($=[Mn^{3+}]/[Mn^{4+}]$). The E^o value for the hypothetical heterogeneous phase reaction in alkaline solution (Eq. [6]) is found to be $E = 1.014 - 0.059 \times 14 = +0.188$.

$$2MnO_2 + H_2O + 2e^- = Mn_2O_3 + 2OH^- \qquad [6]$$

This E^o value ($+0.188$ *vs.* NHE) for the hypothetical heterogeneous reaction, however, is not too far from the E^o value ($+0.103$ *vs.* NHE), which has been defined and found in this study for the homogeneous phase.

It is obvious in the discussion above that the previous effort (18) in understanding the open-circuit voltage of the MnO_2-Zn cell from the thermodynamic E^o value is not correct in principle because of the potential generating mechanism of the MnO_2 electrode.

Effect of lower oxide.—It was shown previously in this paper that a few layers of the lower oxide ($MnO_{1.5}$) present on the MnO_2 surface have a great influence on the potential of the MnO_2. This means that the lower oxide of manganese is a separate phase from the MnO_2 and the lower oxide phase does not diffuse into the MnO_2. In order to interpret or evaluate the potential of MnO_2, this fact must be taken into account in addition to the nature of the Mn^{4+} — Mn^{3+} — $O^=$ — OH^- system (curve a in Fig. 2 or Eq. [4]).

Deviation during the initial half.—In Fig. 6 and 7, the experimentally observed open-circuit potential deviates somewhat to higher potentials from the calculated curves, particularly in Fig. 7. This may be explained in one of the following factors or in both. The first is the activity of the Mn^{3+} and Mn^{4+} ions in the solid. In the calculation of the curve, no consideration was made on the activity coefficient of Mn^{3+} and Mn^{4+} ions in the solid, but simply the ratio of the concentrations $[Mn^{3+}]/[Mn^{4+}]$ was used. The deviation may be due to this. The second is the reference point in the comparison of the observed and the calculated curves. The reference point was taken as that at $[Mn^{3+}]/[Mn^{4+}] = 1.0$ by assuming that no lower oxide structure has begun to form on the surface of the original Mn^{4+} — Mn^{3+} — $O^=$ — OH^- structure. But the lower oxide may have started slightly at the point where $[Mn^{3+}]/[Mn^{4+}] = 1.0$. When such is found to be true, the reference point should be taken at a point where the ratio $[Mn^{3+}]/[Mn^{4+}]$ is less than 1.0 and the curve should be recompared.

Estimation of the D_2O *effect.*—In the electron-proton mechanism discussed earlier in this paper, the possible effect of D_2O in the electrolyte may be expected in two processes. One is in the dissociation of water molecules at the solid-solution interface and the other is in the proton diffusion process by jumping from one $O^=$ site to another within the MnO_2 lattice. However, the two processes may be considered the same for the purpose of estimation of the D_2O effect because the essential thing in those processes is a breakage of O-H bonds. Therefore, the difference which is expected in the polarization will be roughly estimated here on the basis of the difference in the bond energy between O-H and O-D.

The deuterium isotope effect in chemical kinetics has been widely studied and summarized in reviews (34, 35). Among the various factors (34) which contribute to the general lower reactivity of O-D bonds as compared to O-H bonds, only one, a difference in the activation energy in breaking the bond by $\frac{1}{2}h(\nu_D - \nu_H)$ which is derived from the lower zero point energy in O-D, was considered here. The difference in the energy is found to be 1400 cal (34) per mole from the stretching vibration. If the cathodic reduction current of MnO_2 is controlled by the rate of proton diffusion in the lattice, then the ratio of the current i_D/i_H at a given potential may be estimated as follows.

$$\frac{i_D}{i_H} = \frac{C_{D^+}}{C_{H^+}} \frac{K_D}{K_H} \exp \frac{\Delta G^*}{RT}$$

where ΔG^* is 1400 cal. By assuming that the concentrations (C's) at the interface and the K's are approximately equal, the ratio is found to be approximately 1/10 at room temperature. In this calculation, a possibility for penetration of the potential-energy barrier or tunneling was neglected. If the tunneling contributes to the process, the deuterium effect may be somewhat more pronounced. Therefore, we can expect at least 10 times higher current in H_2O electrolyte than in D_2O at a given potential.

Although the present results on the preliminary experiments (Fig. 10 and 11) demonstrate the D_2O effect qualitatively, they cannot be compared immediately to the estimated value, because the discharge was carried out at constant current in an 85% D_2O solution. However, the estimation indicates that the effect should be in a measurable range and a more refined experiment should be done to evaluate the D_2O effect in KOD + D_2O electrolyte by discharging at constant voltage.

Acknowledgment

The authors wish to thank Professor E. B. Yeager of Western Reserve University, Professor H. A. Laitinen of the University of Illinois and Professor W. C. Vosburgh of Duke University for their discussion and suggestions on this paper and also Mr. William Adams for his assistance in the preparation of this paper.

Manuscript received April 6, 1966; revised manuscript received June 3, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

The Pitting Potential of Stainless Steels in Chloride Media

V. Hospadaruk and J. V. Petrocelli

Applied Research Laboratory, Ford Motor Company, Dearborn, Michigan

ABSTRACT

Anodic and cathodic potentiostatic polarization curves were obtained for various stainless steel alloys in sodium chloride and calcium chloride solutions. In the pH range 2 to 8 pitting occurs in the passive region. For a given chloride ion concentration pit initiation does not occur until a certain electrode potential, the pitting potential, is reached. The pitting potential is dependent on alloy composition and may be used as a relative measure of pitting tendency for various alloys. Calcium ion enobles the pitting potential when the chloride ion concentration is about 1*N* or less. The implications of a pitting potential on passivity theories is briefly discussed.

Stainless steel alloys are generally used in environments where they are in the passive state. Corrosion of the alloys in the passive state is usually localized and of the pitting type. Stainless steels are particularly susceptible to this type of corrosion when halide ions are present.

While several factors affecting pit growth have been described in the literature, the actual mechanism of pitting, especially pit initiation, is not known (1, 2). The first use of electrochemical methods in pitting corrosion studies of these alloys were aimed at accelerating the pitting by anodic polarization and measuring either the "break-through" potential or the density of pits formed in a given time.

The need for a satisfactory pit initiation test and the various attempts to devise one have been thoroughly reviewed by Streicher (2).

Streicher developed an electrolytic pitting test for stainless steels, the results of which showed some correlation with the known effect of alloy composition on service behavior (2). The specimen was anodically polarized and the current increased from zero to 3

ma/cm² and held at this value for 5 min. The number of pits formed per unit area was used as a measure of the relative resistance to pitting corrosion.

Rozenfeld *et al.* obtained galvanostatic anodic polarization curves for various alloys which showed that the curves may depend on alloy composition in dilute sodium chloride solutions (3).

These studies did not elucidate the mechanisms involved nor consider the role of the cathodic reactions in the actual corrosion process.

More recent papers, some of which appeared during the course of this work, began to shed more light on pit initiation. Kolotyrkin (4) and Schwenk (5) by using potentiostatic techniques have given strong evidence that the pitting of a given alloy at a given aggressive anion concentration can occur only within a definite potential range. Riggs (6) obtained potentiostatic anodic curves for AISI type 316 stainless steel in strong sulfuric acid solutions containing halide ions. The data also indicate the potential dependency of pitting for this alloy.

Since most of the electrochemical behavior of stainless steels described in the literature is for acid solutions, one objective of this study was to obtain information in weakly acid to alkaline media containing chloride ion. In particular the effects of calcium chloride versus sodium chloride were of interest. As a part of a broad program to obtain a better understanding of passivity and pitting attack by the aggressive anions it was desirable to explore the potentiostatic technique as a means of studying pit initiation and perhaps for the evaluation of the relative pitting tendency of various alloys.

Further experimental evidence that nucleation of pits on an otherwise passive surface is a function of the potential is important in the consideration of passivity theories. If this relationship is true, it must be accounted for in any acceptable theory of passivity.

The data presented describe the electrochemistry of several commercial alloys in solutions of sodium chloride and calcium chloride.

Experimental Procedure

The stainless steel alloys AISI 201, 301, 316, and 434 and a chromized steel were used. Compositions of the steel alloys are given in Table I. The chromized steel surface was prepared by a diffusion process, the coating was about 1.5 mils thick with a chromium content of about 35% at the surface.

Commercial steels were obtained in sheet form; they had been produced by conventional hot and cold rolling, annealed at 1700°-1800°F, slow cooled with a final 33% cold reduction. The surfaces were buffed to a bright finish. Specimens were thoroughly degreased and given a 30-sec treatment in 3.5*N* H_2SO_4.

Solutions were prepared with double-distilled water and reagent grade chemicals. The *p*H was adjusted with sodium hydroxide or sulfuric acid. Deaeration of solutions was accomplished by the use of pure nitrogen which was passed over hot copper turnings.

Electrode area was about 1 cm², and the potentiostatic polarization curves were obtained in the conventional manner. Prior to obtaining the anodic curves the specimens were cathodically polarized to about —1.00v, into the active state, in order to remove any film present on the surface.[1] The polarization curve

[1] Experiments conducted without precathodization showed that the general behavior and results would not be altered significantly.

Table I. Stainless steel composition, values in weight per cent

was then obtained by step-wise increase in the potential by about 25 mv; waiting for a fairly steady current value at each potential, this usually required about 20-30 min. For some special experiments here designated as "rapid polarizations" the rate was fixed at 10 mv/min. All potential values are given *vs.* the saturated calomel electrode.

Experimental Results

All of the steels exhibited stable passive behavior in neutral solutions which did not contain chloride ions. Curve A in Fig. 1 shows a typical anodic curve in sodium sulfate. The active and transition portions of the curve, shown dashed, is schematic. The very low value of the passivating current density in neutral solutions makes these portions difficult to obtain experimentally. It is significant to note that the cathodic curve for hydrogen ion reduction lies above the passive "peak" so that the steels are in the stable passive state in oxygen-free neutral solutions.

The other curves in Fig. 1 show typical results obtained in the presence of chloride ion. Any one steel assumes passive behavior until a certain potential is reached where the current begins to rise sharply and pits begin to form on the otherwise passive surface. The value ot this potential, designated here as the pitting potential, *Ep*, is dependent on the alloy composition and chloride ion concentration. For any given alloy and solution the *Ep* is fairly reproducible within about ±0.05v. The deviations may be due to variations in surface composition from one specimen to another, *i.e.*, chromium and/or nickel depleted areas would yield lower values.

The results are about the same in sodium chloride and calcium chloride at a given concentration of chloride ion and *p*H, except in solutions about 1.5*N* and less in chloride ion. At these lower concentrations there is a tendency for the calcium ion to increase the *Ep*.

Specimens held below the pitting potential for several days did not pit. On the other hand, if the potential of a pitting specimen was decreased below the pitting potential, the pitting would stop. The curves in Fig. 2 show a typical result. Curve 1 depicts the increase in current due to pitting, while curve 2 shows the decrease in current and final cessation of pitting. The amount of hysteresis depends on the time allowed for pitting. The greater the pit depth the

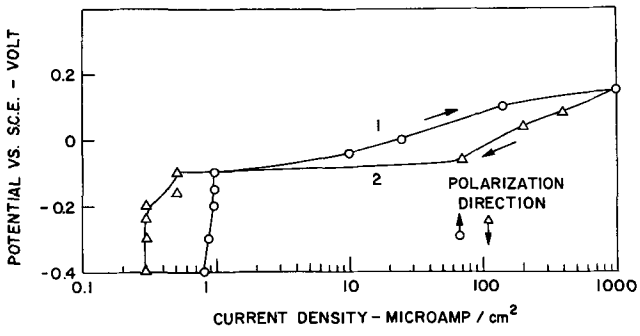

Fig. 2. Initiation and subsequent healing of pits on 434 in 0.5 NaCl pH 6. The specimen was potentiostatically polarized beyond the pitting potential and then back to potentials below Ep.

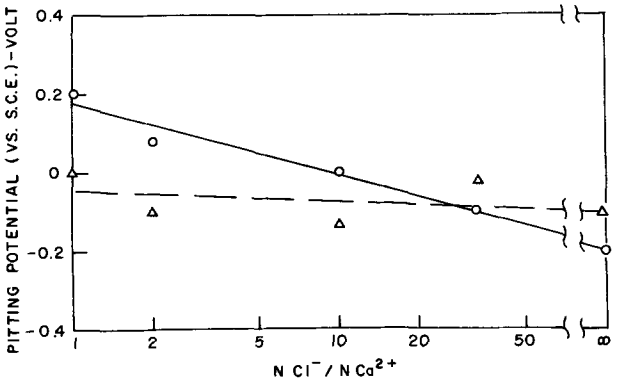

Fig. 5. Effect of the concentration ratio, N Cl^-/N Ca^{2+}, on the pitting potential of steels 434 and 201 for a constant 1N chloride ion concentration, pH 6: ○ 434; △ 201.

greater the hysteresis. This time effect may be due to the increase in metal ion concentration, hence lower pH, and chloride concentration at the bottom of deep pits.

Returning to Fig. 1, the potential required for the nucleation of pits on the various alloys increases in the order of 434 < 201 < 301 < 316 < chromized steel. This indicates that the inherent proneness to pitting corrosion should be in the reverse order.

The effect of chromium content on pitting tendency is shown by the anodic curve for the chromized steel given in Fig. 1. This steel showed no pitting and the behavior is almost identical to that of pure chromium. There is no rise in current prior to the transpassive region.

The effect of chloride concentration on the pitting potential in sodium chloride at pH 6 is shown in Fig. 3. The pitting potential of the austenitic steels is practically independent of concentration in the range 0.1-5.0*N* NaCl. In contrast, the pitting potential of the 434 steel decreased linearly with the decrease in log [Cl^-].

The pitting potential of these alloys was found to be practically independent of pH in the range pH 3-8 in sodium chloride.

As previously indicated, below about 1.5*N* chloride ion the *Ep* are somewhat greater in calcium chloride than in sodium chloride. The effect is quite pronounced with the 434 type steel, where there is an actual reversal in the relative order of *Ep*. In calcium chloride, below about 1.5*N* the *Ep* is greater than that of the austenitic steels. The pitting potential of 434 shows a sharp decrease between 1 and 3*N* calcium chloride and seems to reach a limiting value of about —0.3v with further increase in salt concentration, as shown in Fig. 4.

The specific effect of the calcium ion was also determined by obtaining the variations of *Ep* with the ratio of chloride ion concentration to calcium ion concentration at a constant (1.0*N*) chloride ion concentration at pH 6.0. The solutions were made by using the appropriate mixtures of calcium and sodium chloride. Results are shown in Fig. 5. The values for 301 are not shown since they are the same as those for 201. The pitting potential of 301 and 201 are practically independent of the chloride ion to calcium ion ratio, while that of 434 decreases almost linearly as the logarithm of the ratio increases.

The effect of pH on the pitting potential in 0.1 and 3.0*N* calcium chloride is shown in Fig. 6. In contrast to sodium chloride solutions the pH has a significant effect on the pitting potential, particularly in the more dilute calcium chloride solution. The pitting po-

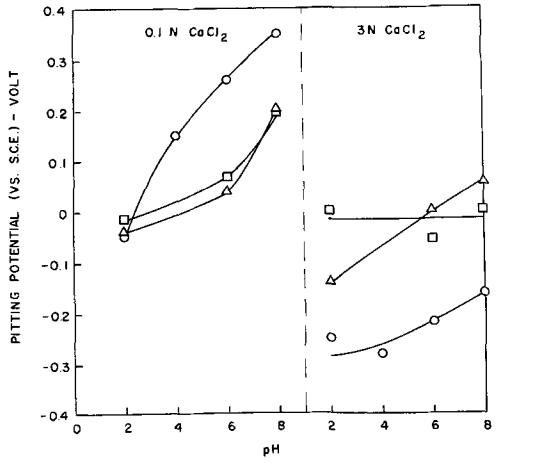

Fig. 6. Effect of pH on the pitting potential of 434, 201, and 301 steels on 0.1 and 3N calcium chloride: ○ 434; □ 301; △ 201.

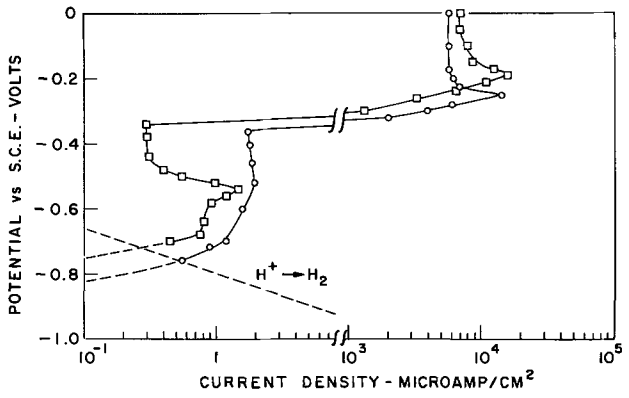

Fig. 7. Anodic polarization of 434, ○, and 301, □, in air-free 11.2N calcium chloride, pH 6. The hydrogen ion reduction curve is included.

tential increases as the *p*H increases, and the change is greater with 434 than the other steels.

As was the case in sodium chloride, the chromized steel was immune to pitting in the *p*H range 3-8 in calcium chloride, even in a 11.2*N* (saturated) solution.

Some rapid polarization curves[2] for the steels in viscous 11.2*N* calcium chloride, saturated solution at room temperature, are shown in Fig. 7. In this chloride concentration the behavior of the austenitic and ferritic steels are very similar. It is very interesting to note that the passivating current density is somewhat greater than in the more dilute solutions so that the active and transition portions of the curve may be obtained at *p*H 6.0.

At lower *p*H values the usual displacement of the passivating potential, hence transition portion, toward more noble potentials causes the *Ep* value to occur near the maximum of the passivity curve.

In these very concentrated solutions, 8.0-11.0*N* calcium chloride, the pit density is very high with probably rapid lateral pit growth so that the surface actually dissolves more or less uniformly as in active dissolution. The current density increases to very high values within a very small potential range until a limiting current density of about 10 ma/cm² is reached. The dissolution rate then remains practically constant with further increase in potential.

Immersion tests in the various solutions for periods of about three weeks confirmed the relative corrosion behavior predicted by the anodic and cathodic polarization curves.

In contrast to the pure metals, iron and nickel, the stainless steel alloys used in this work have a limiting potential below which they do not pit, even when chloride ion is 11*N*. This limiting value is about —0.3 to —0.35v on the saturated calomel scale. This, together with the observation that an occasional 434 specimen exhibited an abnormally high pitting potential and the oscillatory current behavior in some instances, strongly indicates that a healing process may occur at the lower end of the pitting potential zone.

In an attempt to detect a transient type of pitting, nucleation followed by healing, some rapid anodic polarizations were run. A rate of 10 mv/min was chosen. Some results obtained with 301 and 434 steels are given in Fig. 8. Curves A and C show the rapid steady increase in current at the same pitting potential as obtained in steady-state polarizations. The rapid curve B is representative of those occasionally obtained with some 434 specimens which have abnormally high steady-state pitting potentials. The curves B and C do show a "hump" which indicates that some pitting was initiated at about —0.20v, but that healing soon occurred; further pit initiation did not occur until about 0.0v.

Although, as previously indicated, the pitting potential for 434 steel increases as the chloride ion concentration decreases; the hump is apparently independent of chloride concentration and begins at about —0.25v.

Since, in all of the experiments reported above, the passive film was formed in the chloride medium, it was desirable to determine if this was a necessary criterion for pitting. Specimens of 434 steel were polarized in a chloride-free solution to +0.50v and held at this potential until "steady state" conditions were achieved. Chloride ion was then added to the solution to a final concentration of 0.2*N*. In about 5 min the current began to increase, indicating pitting. After a few more minutes the potential was reduced to —0.20v and the pitting stopped. A typical behavior is shown by curves A and B in Fig. 9. The potential was then increased again until pitting resumed, curve C. This time the specimen did not pit until +0.70v.

The results show that a passive film formed in a chloride-free medium is susceptible to chloride attack, and that pitting is potential dependent.

Some galvanostatic anodic charging experiments were performed in order to obtain the relationship between this type of data and the potentiostatic results. Specimens were polarized by imposing a constant current density of 7 μa/cm² until the pitting was well established. Results are shown in Fig. 10.

The potential rises rapidly until the onset of oscillations, when pitting begins. The potential then drops sharply, followed by a slow decay to a quasisteady state. The potential regions where oscillations of potential occur, the so-called break-through potentials, are about 400 to 500 mv more noble than the pitting potential obtained by the potentiostatic method. Values also vary with the magnitude of the current used.

The potential value obtained at the intersection of the extrapolated potential decay curves, marked E_c in Fig. 10, approximates closely the potentiostatic pitting potentials.

It will be noted that the specimens were in the active state (potential at about —1.00v) at the start of

[2] Steady-state polarizations did not shift the value of *Ep*.

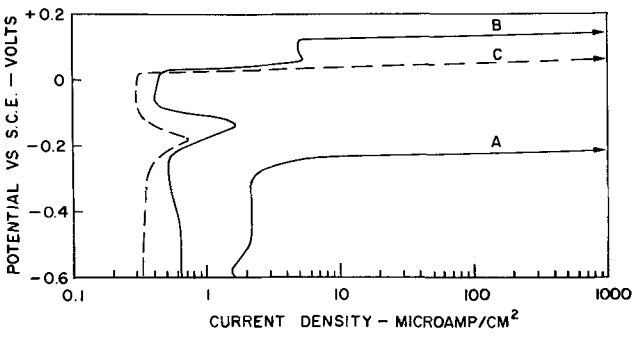

Fig. 8. Anodic polarization of 434 and 301 steels in air-free 6N NaCl, pH 6, at the rate of 10 mv/min in 20 mv steps. A and B, 434; C 301.

the charging. The results show that the passive film is formed and then begins to pit. It is interesting to note that 434, which seems to have the greatest pitting tendency, has the shortest period of oscillations.

Discussion

The results show that the nucleation of pits on an otherwise passive surface is a function of the electrode potential. For a given chloride ion concentration and alloy composition, pitting does not occur until a certain potential is reached or exceeded. This pitting potential is characteristic of the alloy and may be used as a measure of the relative pitting tendency of various alloys. The potentiostatic technique is very promising as a pit initiation test.

The experimental data seem to indicate that all sites are not equally susceptible to pitting and that the nucleation of pits occurs over some broad potential range. Apparently, pit initiation at the measured *Ep* takes place at only the more susceptible sites. A special situation exists with highly concentrated chloride solutions such as 11.2*N* calcium chloride. Pit nucleation occurs so readily that the entire electrode surface is rapidly pitted at a potential not more than 50 mv above *Ep*.

In the use of *Ep* as a measure of pitting tendency it should be noted that service performance will also depend on the cathodic polarization curve. In order for pitting corrosion to occur in service the cathodic curve for the reduction of oxygen (or any other oxidant) must intersect the anodic curve at the pitting potential or more noble values. Thus, two alloys with significantly different *Ep* may both undergo pitting corrosion if the cathodic curve intersects the anodic curve at the *Ep* value on both alloys.

The oxygen reduction curve on the alloys used in this work does not vary appreciably with the alloy composition and as the curves in Fig. 1 indicate, all but AISI 316 of the stainless steels may be expected to undergo some pitting corrosion since the steady-state passive current, *i* pass., is slightly lower than the experimental value shown. The severity should decrease in the order 434 > 201 > 301 > 316.

It is interesting to note that the *Ep* of these alloys does not vary significantly with *p*H in the *p*H range 3-8. The decrease in pitting with increase in *p*H usually encountered in service is apparently due mostly to the shift of the cathodic curve to lower potentials as the *p*H increases. This exemplifies the important role of the cathodic curve.

The importance of the cathodic reaction is again demonstrated by the behavior of the stainless steel at open-circuit immersion in 11.2*N* calcium chloride solution. Although the pitting potential in this medium is at the minimum value of —0.30 to —0.35v the pitting attack after long-term immersion was not severe due to the low oxygen solubility and rate of diffusion in the viscous solution.

The role of chromium in increasing the pitting potential is especially noteworthy.

The specific effect of calcium ion and its dependency on *p*H is no doubt due to the adsorption of the ion or a basic calcium compound on the surface. It is not clear, however, why the effect is so pronounced on the 434 type steel.

The relationship between pit nucleation on the passive surface and electrode potential requires an explanation which is consistent with any acceptable theory of passivity. This aspect of the problem is under consideration, and we expect to offer suggestions at a future date.

Meanwhile, the following comments should be made. The important question is not why the chloride ion should cause a break-down of passivity, but rather why does it occur at potentials which may be significantly greater than the passivation potential. It is logical to assume that, if the chloride ion is adsorbed onto the surface at sufficient concentrations, it would prevent further film formation and/or create anion vacancies in the film so that it might collapse. The ability of chloride to become incorporated into a film lattice has been shown by Beck *et al.* in the case of aluminum (7).

An increase in the adsorption of chloride ion onto the passive surface with an increase in the measured electrode potential is not an obvious deduction. The potentiostatic anodic curve of the metals in question show a well defined constant current region. The "oxide" film theory is the most consistent theory with this experimental fact.

Accordingly the film thickens with an increase in the measured electrode potential along this current plateau. In the steady state the rate of film formation is equal to the rate of film dissolution. The potential distribution across the film has been discussed by Vetter (8) and Weil (9) and is shown schematically in Fig. 11. The increase in the measured electrode potential is predominantly if not entirely due to the increase in, V_{ox}, the potential difference across the film. The potential $e_{o/s}$, of the oxide-solution interface remains constant, in fact very close to the equilibrium potential for the reaction

$$[H_2O]_{ad} \rightleftarrows O_{ox} = +2H^+$$

Since the rate of chloride ion adsorption should be dependent on $e_{o/s}$, it is not clear how this rate or equilibrium concentration of adsorbed chloride ion increases with the measured potential.

One might possibly deduce that the chloride effect is a function of the film thickness and/or composition changes, which are dependent on the potential.

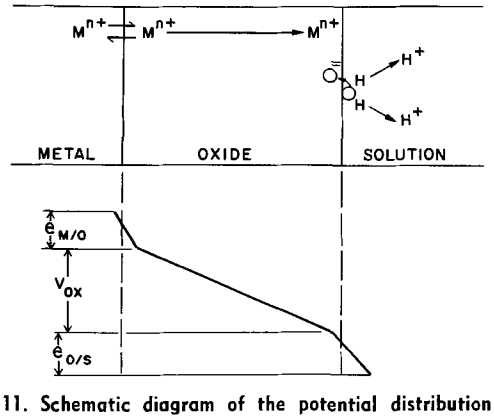

Fig. 11. Schematic diagram of the potential distribution across the oxide film.

One possible explanation which we suggest at this time is that during the dynamic situation where film growth and film dissolution are occurring at the same rate on the average there will be fluctuations so that certain areas become entirely free of film for brief periods of time. When the measured electrode potential is increased the potential difference at the "bare" metal-solution interface will become very high, with the promotion of very rapid adsorption of chloride ions.

The presence of a high concentration of adsorbed chloride ions at these sites will of course prevent further growth of the passive film and result in the establishment of active pits.

Such fluctuations in filmed-bare areas are likely because the emergence of metallic ions from the metal into the passive film, required for film growth, should occur at much greater rates at ledges, kinks, etc., than at the planar sites at the metal-oxide interface. At some critical "interledge" distance the film dissolution may momentarily exceed formation on a small planar site.

As previously indicated, we expect to treat this aspect of the aggressive anion effect in more detail at a future date.

Oxidation of Copper Single Crystals in Aqueous Solutions of Inorganic Salts

IV. Effect of *p*H on Oxide Topography in $CuSO_4$ and $Cu(OAc)_2$ Solutions

D. B. Scott[1] and G. Tyler Miller, Jr.[2]

Department of Chemistry, Hampden-Sydney College, Hampden-Sydney, Virginia

ABSTRACT

Electron microscopic techniques were used to determine the effect of *p*H on the topography of Cu_2O formed on the (100), (110), and (111) faces of copper single crystals oxidized in aqueous solutions of $CuSO_4$ and $Cu(OAc)_2$. During reaction, changes in *p*H near the reacting metal surface were followed using a microprobe electrode. The *p*H near the metal surface dropped during reaction in $CuSO_4$ solutions, but remained constant in $Cu(OAc)_2$ solutions. Previous studies at constant initial bulk *p*H showed oxide polyhedra formation in $CuSO_4$ solutions and the formation of relatively smooth continuous films in $Cu(OAc)_2$ solutions. Comparison of oxide topography at the same surface *p*H rather than initial bulk *p*H revealed polyhedra formation in both systems, although polyhedra were more run together in the $Cu(OAc)_2$ system. Several other effects of anion were observed. Thus, *p*H appeared to be the major variable affecting oxide topography with the anion present acting as a second variable controlling the amount of surface covered by oxide. These results were shown to be consistent with a reaction mechanism proposed in an earlier paper in this series.

This is the fourth in a series of papers describing the oxidation of copper single crystals in solutions of copper(II) salts. The first two papers (1, 2) were concerned with the topography of the copper(I) oxide formed by oxidation in solutions of $CuSO_4$, $Cu(ClO_4)_2$, $Cu(OAc)_2$, and $Cu(CHO_2)_2$. The third paper (3) presented the relative rates of oxidation of the (100), (111), and (110) faces of Cu in 0.05*N* $Cu(OAc)_2$, described the kinetics involved, and proposed a reaction mechanism for copper(I) oxide formation.

These previous studies showed that at a constant initial bulk *p*H a relatively smooth film of oxide was formed in the $Cu(OAc)_2$ and $Cu(CHO_2)_2$ solutions, while well-defined oxide polyhedra formed in both the $CuSO_4$ and $Cu(ClO_4)_2$ solutions. The relative rates of oxide growth for the $Cu(OAc)_2$ system was shown to be: (100) > (111) > (110), but the shape of the rate curves differed considerably (3).

Although those previous studies demonstrated the important effect of the anion on oxide topography at a given initial *p*H, it did not provide any information on the effect of *p*H on oxide topography. It seemed probable that another major variable or perhaps the variable controlling polyhedra or smooth film formation could result from changes either in the bulk *p*H of the solution or local changes in *p*H near the reacting surface. The present paper reports results obtained in an attempt to check this hypothesis and to gain additional evidence as to the validity of the reaction mechanism previously proposed (3).

Experimental Procedure

Known crystallographic (111), (100), and (110) faces of carefully prepared copper single crystals were exposed for 10 min to 0.05*N* solutions of $Cu(OAc)_2$ and $CuSO_4$ maintained at 30° ± 0.05°C and with *p*H values ranging from 4.8 to 3.0 in increments of 0.1 *p*H unit. The *p*H of a given solution was adjusted to the desired value by the addition of small

Table I. Values of initial and final bulk pH for the $CuSO_4$ system after immersion for 10 min

Initial bulk pH	Final bulk pH (111)	(100)	(110)
4.50	4.04	4.10	4.00
4.30	3.96	3.97	3.97
3.80	3.74	3.72	3.70
3.20	3.23	3.21	3.21
3.10	3.13	3.16	3.14

amounts of 0.05*N* $Cu(OAc)_2$ or 0.05*N* $CuSO_4$ solutions which had been adjusted to a *p*H of 2.0 by addition of reagent grade HOAc or H_2SO_4, respectively. After immersion, the crystal surfaces were washed and replicated, and the replicas were examined with an electron microscope. The detailed procedures used were the same as those described in the previous papers (1, 2).

A second series of experiments was run in order to determine whether small changes in *p*H were occurring near the surface of the crystal face during reaction. A small microprobe glass electrode was fixed at a distance of approximately 1 mm from the flat face of the metal. The *p*H changes in the solution were measured and recorded by following voltage change *vs.* a mercury-mercurous sulfate reference electrode. In order to minimize any effect of anions, the reference electrode was connected to the solution through a Luggin capillary.

Experimental Results

Experiments on the determination of *p*H changes approximately 1 mm from the surface of the crystal face yielded the very significant fact that for the $CuSO_4$ (initial *p*H 4.30) solution the *p*H dropped almost immediately on introduction of the crystal into the solution to a value of 4.00. This value remained relatively constant during the 10-min immersion period.

A similar series of experiments by Barker and Miller (4) in $Cu(OAc)_2$ showed that there was very little change in *p*H at a distance of approximately 1 mm from the surface. This was to be expected, since the $Cu(OAc)_2$-HOAc mixture served as a buffer system.

The final bulk *p*H values of the $Cu(OAc)_2$ solutions after 10 min of oxidation were essentially the same as the initial bulk values, while there was a considerable drop between the initial and final *p*H in the unbuffered $CuSO_4$ solutions. Results in $CuSO_4$ indicated that this final bulk *p*H was approximately equal to the value to which the surface *p*H fell when the crystal was first immersed in the solution.

A summary of the final bulk *p*H values for the $CuSO_4$ system is given in Table I.

The effect of *p*H on oxide topography on the (110) face oxidized in $CuSO_4$ solutions is shown in Fig. 1. It can be seen that as the bulk *p*H is lowered from 4.30 (Fig. 1b) to 3.10 (Fig. 1e) the amount of exposed metal surface area increased and the polyhedra became well defined with little running together. An analysis of shadow heights indicated that the polyhedra decreased in height as the *p*H was decreased. At *p*H values below 3.10 no oxide was formed on any of the three faces tested. It should be noted that the oxide formed on the (100) face seems to be more unstable than that formed on the (110) and (111) faces, since very little oxide remained even at a *p*H of 3.10. By comparing Fig. 1a to Fig. 1b it can be seen that the trend is reversed as the *p*H was raised from *p*H 4.30 to 4.50. This phenomenon was present on all three faces.

Figure 2 shows that this same general trend was observed on all three faces. Figure 1b, 2a, and 2b show, respectively, the oxide topography of the (110), (100), and (111) faces after 10 min in $CuSO_4$ solutions at constant *p*H. These photographs reveal that the

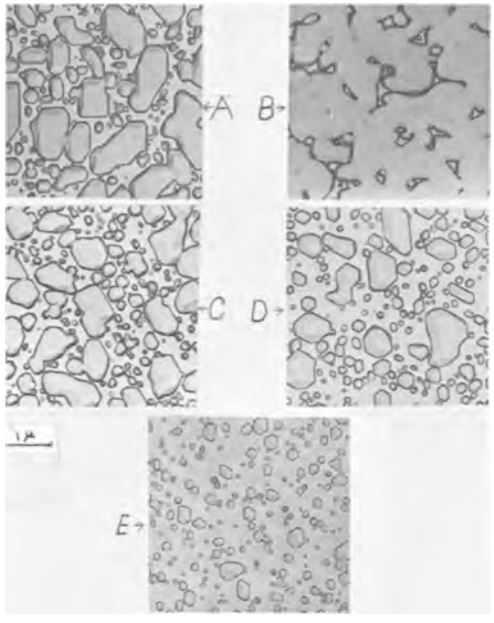

Fig. 1. Effect of pH on oxide growth on the (110) face of Cu after immersion in 0.05N $CuSO_4$ at 30.0°C for 10 min: a, pH = 4.50(4.00); b, pH = 4.30(3.97); c, pH = 3.80(3.70); d, pH = 3.20(3.20); e, pH = 3.10(3.14). pH values listed first are initial bulk values and values in parentheses are final bulk values. Magnification 15,000X before reduction for publication.

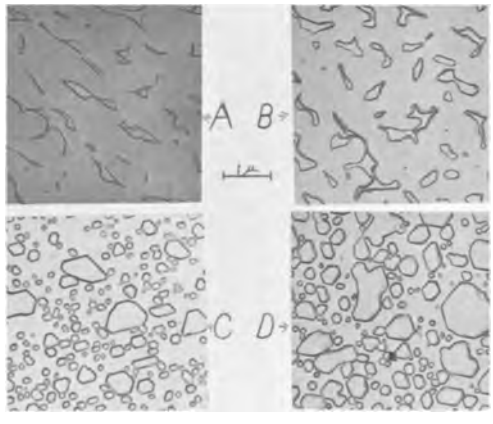

Fig. 2. Effect of pH on oxide growth on the (100) and (111) faces of Cu after immersion in 0.05N $CuSO_4$ at 30.0°C for 10 min: a, (100), pH = 4.30(3.97); b, (111), pH = 4.30(3.96); c, (100), pH = 3.20(3.20); d, (111), pH = 3.20(3.23). Values in parentheses are final bulk pH values. Magnification 15,000X before reduction for publication.

amount of bare metal surface present was approximately the same on all faces at the same *p*H. The same effect can be seen when the bulk *p*H is lowered to 3.20 by comparing Fig. 1d, 2c, and 2d. Thus, it appears that in the $CuSO_4$ system the area of exposed metal surface depends primarily on *p*H and does not vary significantly with face. As noted before, the (100) face at a *p*H of 3.10 represents an exception to this generalization, since very little oxide remains at this *p*H.

The effect of *p*H on oxide topography on the (110) face in $Cu(OAc)_2$ solutions is summarized in Fig. 3. Similar results were observed for the (100) and (111) faces. As the *p*H was lowered, the amount of bare metal surface area again increased. However, by comparing Fig. 3 with Fig. 1, it can be seen that the polyhedra were more run together in the $Cu(OAc)_2$ system than in the $CuSO_4$ system. Thus, although the primary variable affecting polyhedra formation and

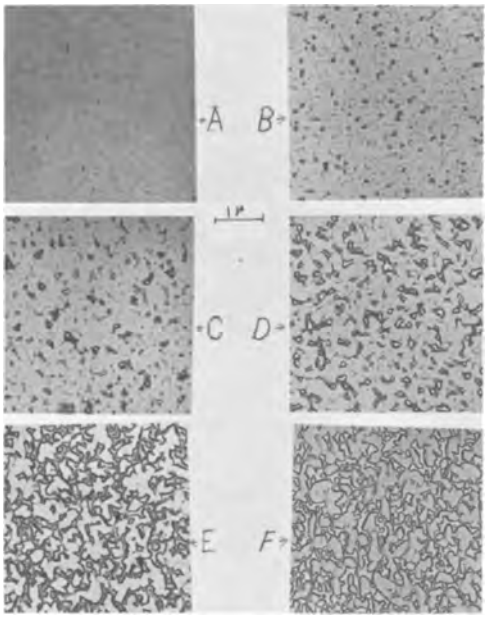

Fig. 3. Effect of pH on oxide growth on the (110) face of Cu after immersion in 0.05N $Cu(OAc)_2$ at 30.0°C for 10 min: a, pH = 4.30; b, pH = 4.20; c, pH= 4.10; d, pH = 4.00; e, pH = 3.90; f, pH = 3.80.

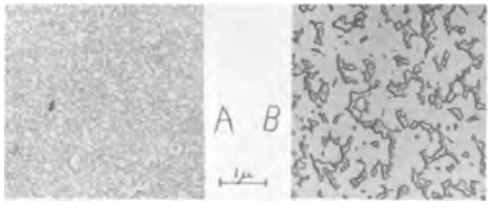

Fig. 4. Effect of pH on oxide growth on the (100) and (111) faces of Cu after immersion in 0.05N $Cu(OAc)_2$ at 30.0°C for 10 min: a, (100), pH = 4.10; b, (111), pH = 4.10.

surface coverage appears to be pH, the anion present is an additional variable that affects the degree of surface coverage.

The results shown in Fig. 1 and 2 revealed that at the same pH in the $CuSO_4$ system the amount of oxide coverage for the (100), (111), and the (110) faces was approximately the same. Figure 4, when compared with Fig. 3c, shows a similar comparison at the same pH in the $Cu(OAc)_2$ system. An examination of these photographs reveals that the amount of exposed metal surface area did vary with crystal face in this system in the order (100) > (111) > (110). The bulk pH at which no oxide remained on the surface was found to be in the same relative order (100) (pH 3.8) > (111) (pH 3.6) > (110) (pH ~ 3.5). Thus, the degree of surface coverage at the same bulk pH varied with face in the $Cu(OAc)_2$ system, but remained essentially constant with face in the $CuSO_4$ system.

Discussion

In the previous study (1), oxide formation in $CuSO_4$ (initial pH 4.30) was compared to that formed in $Cu(OAc)_2$ at the same initial bulk pH (4.30). It was found that, in general, oxide polyhedra formed in $CuSO_4$ solutions while relatively smooth continuous films formed in $Cu(OAc)_2$ solutions.

The present study revealed that in order to determine the effect of anion on oxide topography, the two systems should not be compared at the same initial value for the bulk pH. It was shown that a $CuSO_4$ solution with an initial bulk pH of 4.30 had a pH of approximately 4.0 near the surface during the immersion period, while there was no drop in pH near the surface in $Cu(OAc)_2$-HOAc solutions which act as a buffer system. Thus, in order to determine the effect of anion on topography, it is more meaningful to compare the oxidation in $CuSO_4$, having an initial bulk pH of 4.30, with oxidation in $Cu(OAc)_2$ with an initial bulk pH of 4.00. By comparing Fig. 1b with Fig. 3d, it can be seen that polyhedra tend to form in both systems when the pH near the surface is constant, although the polyhedra are more run together in the $Cu(OAc)_2$ system.

It is recognized that even this comparison might not be strictly valid, since the pH was measured at a distance of 1 mm from the surface and the pH nearer the surface would probably be lower than 4.00. The value of 4.00 is assumed to be reasonable, however, since at 1 mm from the surface the pH remained essentially constant during the reaction and since movement of the microprobe electrode closer to the surface gave no appreciable change in pH. In any case, since the pH near the surface in all of the $CuSO_4$ solutions tested was 4.00 or lower, the $CuSO_4$ system should be compared with a $Cu(OAc)_2$ solution in which the pH is 4.00 or lower. All such comparisons indicate polyhedra formation in both systems with the formation of more run together polyhedra in the $Cu(OAc)_2$ system.

Although polyhedra formation, and thus the degree of surface coverage, appear to depend primarily on pH, the degree of surface coverage was definitely affected by the anion present. At least three important effects of the anion were observed. First, as mentioned above, polyhedra formed in $Cu(OAc)_2$ solutions were more run together than those formed in $CuSO_4$ solutions. Second, the amount of surface covered at a given pH apparently did not vary significantly with crystal face in the $CuSO_4$ system, while the degree of surface coverage did vary with face in the $Cu(OAc)_2$ system. Finally, the pH value below which oxide did not form varied in the two systems [below 3.5-3.7 in $Cu(OAc)_2$ and below 3.1 in $CuSO_4$]. A more detailed interpretation of the effect of anion on oxidation was given in previous papers (2, 3).

It is felt that the results reported in this paper are consistent with the mechanism for oxidation of copper single crystals in solutions of $Cu(OAc)_2$ proposed in an earlier paper by Porterfield and Miller (3). The rate-determining step was postulated as the migration of "$\oplus$" (positive holes) through the oxide to specific reaction sites occurring at crevices or holes in the oxide. Continued or enhanced oxide growth of individual polyhedra was directly proportional to the amount of bare metal surface. The over-all net reaction was postulated as

$$Cu^{2+} + Cu + H_2O \rightleftarrows Cu_2O + 2H^+$$

Under a given set of reaction conditions, a balance between oxide formation and the reverse reaction of film dissolution would be achieved. The rate of the reverse dissolution reaction would also be directly proportional to the amount of bare metal surface present.

According to this mechanism, the pH near the surface should decrease during oxide formation, as was observed in the present study for the unbuffered $CuSO_4$ system. Furthermore, an examination of Fig. 3c 4a, and 4b shows that the amount of bare metal surface exposed in the $Cu(OAc)_2$ system follows the order (100) > (111) >(110), which is the same order as the oxidation rates determined in the previous study (3). The present study also demonstrated that, as pH decreased, the relative amount of metal surface exposed increased. This is also consistent with the proposed mechanism since an increase in H^+ would shift the equilibrium to the left due to the common ion effect and less Cu_2O would form on the surface. Further evidence was found in that the pH

below which no oxide formed in $Cu(OAc)_2$ is in the same order (100) (pH 3.8) > (111) (pH 3.6) > (110) (pH ~ 3.5). This mechanism would also account for the slight rise in pH found in the $CuSO_4$ system at low pH values (<3.2) as shown in Table I. The presence of a relatively high initial concentration of H^+ would tend to dissolve some or all of the thin film of Cu_2O formed during polishing and washing and thus yield a slight increase in pH.

Ives and Dawson (5) have given an excellent discussion of the electrochemical theory of oxidation of copper in aqueous solutions. Much of their discussion is consistent with the data obtained in the present work, although their duplex film model is not applicable to the present system, since it was proposed for systems containing very low concentrations of Cu(II) ion.

One additional result that needs to be discussed is the fact that although the amount of metal surface area exposed in the $CuSO_4$ system increased as the pH was lowered from 4.30 (Fig. 1b) to 3.10 (Fig. 1e), this trend was reversed when the pH was raised to 4.50 (Fig. 1a). One possible interpretation of this unexpected result can be offered in terms of the Pourbaix diagram for copper (6). According to the Pourbaix plot of potential *vs.* pH, Cu_2O is thermodynamically stable over a band of pH-potential values with Cu_2O dissolving to form Cu and Cu^{+2} at low pH values and with conversion to CuO at high pH values. Thus, either raising or lowering the pH eventually results in the thermodynamic instability of Cu_2O. It is recognized, however, that this line of reasoning may not be valid, since it consists of using a thermodynamic argument to account for a kinetic phenomenon in a system not at equilibrium. Additional experimentation will have to be carried out in order to obtain more information on this phenomenon.

ABSTRACT

The H^+ activity of diluted strong acids, such as $HClO_4$ or HCl, rises by the addition of such neutral salts as $NaClO_4$, $Ba(ClO_4)_2$ from 10^{-1} to 10 at constant concentration of the acid. The effect of this increase of activity on the anodic dissolution of Fe, Co, and Ni has been investigated. Fe and Co show the order $z^+_{H+} = -2$ with respect to the H^+ activity, which was found by many other authors with respect to the H^+ concentration when stationary measurements were accomplished. In accordance with the Heusler mechanism the order changed to $z^+_{H+} = -1$ at unstationary measurements. The cathodic process has the order $z^-_{H+} = 0.5$ to 0.7 with respect to the H^+ concentration and 0.5 with regard to H^+ activity changed by addition of neutral salts. The anodic dissolution is influenced by the nature of the cations ($Na^+ < Ba^{++} < Li^+$).

On the contrary the order of anodic dissolution of Ni is $z^+_{H+} = -0.5$ with regard to H^+ concentration as well as to activity both at stationary and unstationary measurements. The cathodic process at Ni has the order $z^-_{H+} = +1$ with regard to H^+ concentration and 0.5 with regard to H^+ activity changed by addition of neutral salts. At the hydrogen ion discharge on the mercury electrode the order of reaction z^-_{H+} with regard to H^+ concentration rises from 0.5 to 1 with increasing ionic strength according to the theory of Frumkin. The dependence upon a_{H+} at constant H^+ concentration is complicated. The current density at constant potential passes through a maximum with increasing H^+ activity and content of neutral salt. Height and position of this maximum with regard to the neutral salt concentration depend on the potential. A qualitative interpretation of the experimental results is proposed.

When neutral salts such as $NaClO_4$ or $LiClO_4$ are added to dilute aqueous solutions of strong acids, a linear decrease of the pH value ($pH = -\log a_{H+}$) with salt concentration, m_{salt}, is observed, starting from about 1 mole/kg (1). The concentration of H^+ remains constant; therefore, the activity coefficient, f_{H+}, must grow exponentially with m_{salt}. The gradient $\Delta pH/\Delta m_{salt}$ depends on the ionic radius; the electrostatic interpretation of the pH shift is in sufficient agreement with the experimental results (2). The activity coefficients of the anions (f_{Cl-}, f_{Br-}, etc.) remain relatively constant (± 0.1) (2) over a concentration range of the salt which leads to an increase of f_{H+} by two orders of magnitude and more. Equi-

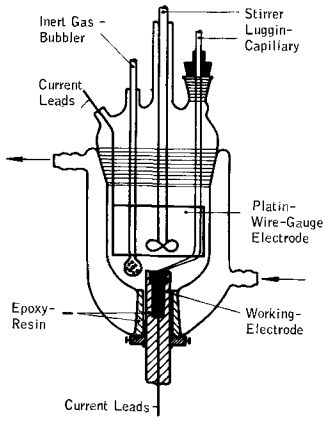

Fig. 1. Experimental procedure, the cell

libria in which H^+ take part are shifted by neutral salts according to the increase in their activity (2). The present work deals with the influence of the *p*H shift by neutral salts on the kinetics of electrode processes, in particular with the effect of neutral salts on the rate of anodic dissolution of Fe, Co, and Ni in the active region (at constant acid concentration) and on the kinetics of hydrogen ion discharge on these metals. Hydrogen ion discharge was also studied on the dropping mercury electrode, at constant H^+ concentration under variation of the H^+ activity by addition of salt as well as at high ionic strength under variation of the H^+ concentration.

Experimental Procedure

The electrodes were rods of metals such as Fe, Co, and Ni which had been molded into a special resin (EPOXID). On their front side, anodic and cathodic current-potential curves were measured galvanostatically in the cell shown in Fig. 1, according to a quasistationary method as used, for instance, by Heusler (3). The potentials were determined by a compensation method against a calomel electrode inside a Luggin capillary tube (Fig. 1). Before each measurement, the working electrode was resurfaced, polished, and degreased in the same manner. The salts were purified by repeated recrystallizations. Traces of impurities which would have disturbed especially the H^+ deposition were eliminated from the acid-salt solution by a preelectrolysis using an auxiliary electrode (4). From the various current-potential curves, the values of the current density, $(j)_\epsilon$, belonging to a certain constant potential ϵ, were read off, and from these the reaction order, z_{H+}, with respect to a_{H+} was found by plotting log j against *p*H.

Experiments on the dropping mercury electrode were made in an ordinary polarographic cell. The electrolyte solution was purified in an analogous way. Part of the values of the current density were measured at constant potential at a stationary mercury electrode (5) as a function of m_{H+} and of a_{H+}, respectively. So far, stationary measurements have been made predominantly on all electrodes; at the present time, we are working with a pulse method, and we shall report these results later.

Results

Armco iron.—According to the work of Heusler (6) and other authors, the current density of anodic dissolution of iron in the active region decreases with the square of the concentration of hydroxyl ions; the Tafel gradient $d\eta/d \log j$ is 30 mv. Other authors (7) have sometimes reported different (smaller) exponents, but they are in any case negative with respect to a_{H+}; that means the H^+ inhibit the anodic dissolution at higher concentration. When the *p*H value of sulfuric acid is varied by adding Na_2SO_4 at constant ionic strength j^+_{Fe} decreases with $a_{H+}{}^{-1.63}$. In Fig. 2,

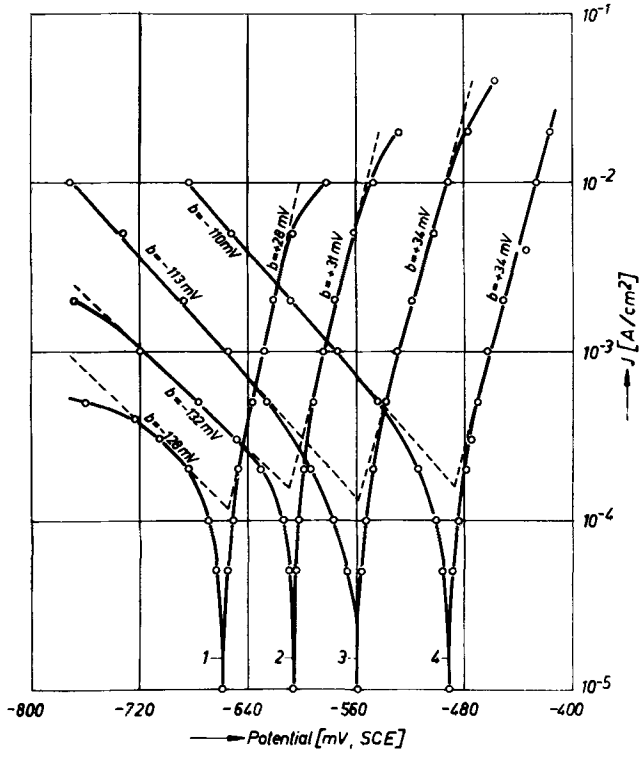

Fig. 2. Anodic and cathodic current-potential curves of the system Fe/H_2SO_4 + Na_2SO_4 (with stirring, t = 25°C, bubbling of H_2 galvanostatic, quasistationary). $c_{H_2SO_4}$ + $c_{Na_2SO_4}$ = 0.5N, except for curve 4. Curve 1, 0.001N H_2SO_4 + 0.499N Na_2SO_4, pH 3.66; curve 2, 0.01N H_2SO_4 + 0.49N Na_2SO_4, pH 2.62; curve 3, 0.1N H_2SO_4 + 0.4N Na_2SO_4, pH 1.51; curve 4, 1N H_2SO_4.

the current-potential curves are plotted semilogarithmically, and the anodic and cathodic gradients are listed.

In Fig. 3, (log J^+_{Fe}) and (log $j^-_{H+})^{Fe}$ are plotted against *p*H at constant potential, ϵ. Thus, the reaction order of active iron dissolution with respect to H^+ is, as mentioned above, $z^+_{H+} = -1.63$, and $b^{Fe} = 30$ mv; for the hydrogen reaction, we obtain $z^-_{H+} = +0.5$ and $b^{H_2} = 120$ mv (the Tafel slope of H^+ discharge). This value holds on iron up to high ionic strengths. We must point out that the addition of Na_2SO_4 to H_2SO_4 not only causes a change in the activity coefficient of H^+ but also a reduction in their number, according to the shift of the equilibrium: $H^+ + SO^{=}_4 \rightleftharpoons HSO^-_4$; it is for this reason that an increase in $pH = -\log m_{H+}f_{H+}$ can take place. But, when perchlorates are added to $HClO_4$, only the activity coefficient grows while m_{H+} remains constant.

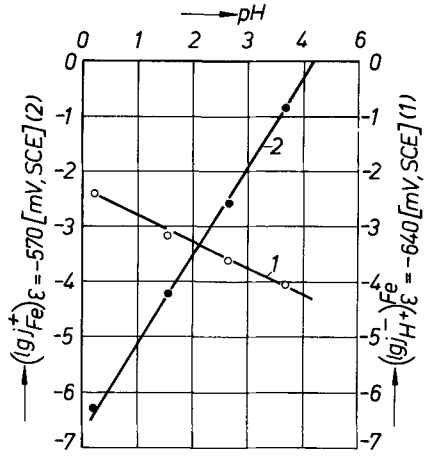

Fig. 3. Cathodic and anodic transfer current densities as a function of the *p*H value, at ϵ = const (taken from Fig. 2).

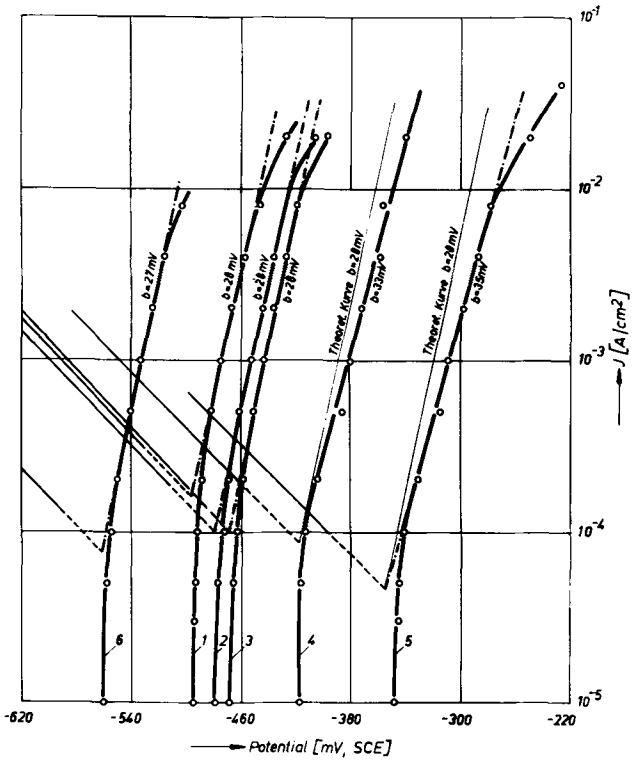

Fig. 4. Cathodic and anodic current-potential curves of the system Fe/0.1M $HClO_4$ + various amounts of $NaClO_4$, and also with addition of Na_2SO_4 (galvanostatic, quasistationary, bubbling of H_2, with stirring, t = 25°C). Curve 1, 0.1M $HClO_4$; curve 2, 0.1M $HClO_4$ + 1.06 mole/kg $NaClO_4$; curve 3, 0.1M $HClO_4$ + 2.85 mole/kg $NaClO_4$; curve 4, 0.1M $HClO_4$ + 6.72 mole/kg $NaClO_4$; curve 5, 0.1M $HClO_4$ + 1.85 mole/kg $NaClO_4$; curve 6, 0.1M $HClO_4$ + 1.5 mole/l Na_2SO_4.

In Fig. 4, the anodic and cathodic current-potential curves in 0.1M $HClO_4$ with additions of $NaClO_4$ are shown. It is seen that the Tafel slopes $d\eta/d \log j$ remain nearly constant, whereas the curves are shifted toward more positive values with increasing concentration of $NaClO_4$. If now for $\epsilon = -420$ mv (SCE) the logarithm of the anodic current density is plotted against the salt concentration, a straight line is found (Fig. 5) which has a slope of — 0.338 $(mole/kg)^{-1}$.

According to a pH shift of — 0.19 pH/mole $NaClO_4$, we may calculate from

$$j^+_{Fe} = K^+ \left[a^o \cdot 10^{K \cdot m_{salt}}\right] Z^+_{H^+} \cdot \exp\left[\frac{(\alpha \cdot n + \nu)F}{RT}\epsilon\right]$$

$$\log j^+_{Fe} = \log [K^+ \cdot a^o Z^+_{H^+}] + K \cdot m_{salt} \cdot Z^+_{H^+} + \frac{(\alpha \cdot n + \nu)F}{2.303RT} \cdot \epsilon$$

that

$$\left[\frac{d \log j^+_{Fe}}{d m_{salt}}\right]_\epsilon = K \cdot z^+_{H^+} = -0.338$$

and, using the value $K = 0.19$, we obtain $z^+_{H^+} \cong -1.8$. Therefore, the anodic current density of active dissolution of iron decreases at constant number of H^+ ions with their activity and at constant ionic strength with their concentration.

The cathodic curves (Fig. 6) are not so definite because the Tafel slope changes as shown. They give an order of H^+ discharge with respect to a_{H^+} of $z^-_{H^+} = +0.46$. At constant H^+ concentration, the current

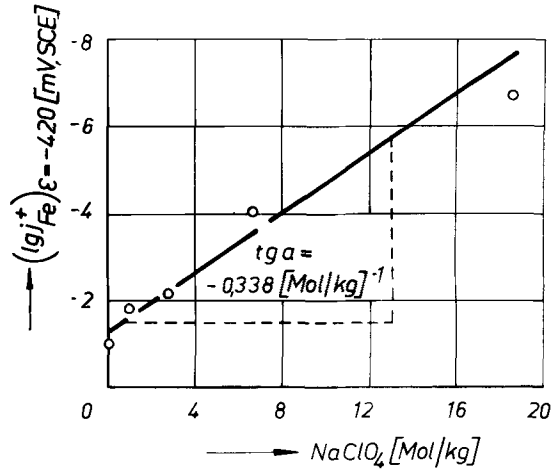

Fig. 5. (log $j^+_{Fe})_\epsilon$ as a function of the $NaClO_4$ concentration (from Fig. 4), at ϵ = const.

density also grows with the square root of the H^+ activity.

Analogous experiments were carried out with additions of $LiClO_4$ and $Ba(ClO_4)_2$ where the $\Delta pH/\Delta m_{salt}$ were, respectively, 0.26 and 0.42 $(mole/kg)^{-1}$. The order of active dissolution of iron was $(z^+_{H^+})^{Fe} = -2.7$ for $LiClO_4$ and $(z^+_{H^+})^{Fe} = -2.2$ for $Ba(ClO_4)_2$. In Fig. 7, log j^+_{Fe} at $\epsilon = -420$ mv (SCE) is plotted against the pH value as lowered by addition of neutral salts in 0.1M $HClO_4$. It shows that $LiClO_4$ gives the highest decrease, $NaClO_4$ the smallest. Evidently the

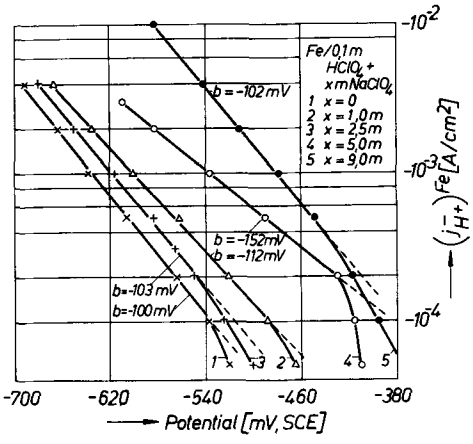

Fig. 6. Cathodic current-potential curves of the system Fe/0.1M $HClO_4$ + various amounts of $NaClO_4$ (mole/l) (galvanostatic, quasistationary, bubbling of H_2, with stirring, t = 25°C).

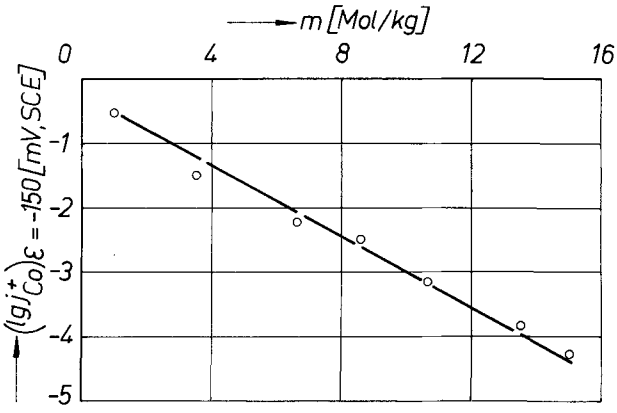

Fig. 10. (log $j^+_{Co})_\epsilon$ as a function of the $NaClO_4$ concentration (taken from Fig. 9).

cation is here of importance, too. The exponent z^+_{H+} increases nearly in the same way with decreasing ionic radius as the gradient $\Delta pH/\Delta m_{salt}$, if it is referred to equivalents. The b^{Fe} values, however, are independent of the cationic species, within the measuring accuracy.

In the case of hydrogen ion discharge, however, all these salts have about the same order as $NaClO_4$, that is 0.5. In Fig. 8, $(\log j^-_{H+})_\epsilon^{Fe}$ at $\epsilon = -560$ mv (SCE) is plotted against the pH value for increasing additions of perchlorates. For H^+ discharge, the effect of variation of the H^+ concentration at constant salt concentration has also been examined; in this case, too, the value of z^-_{H+} of about 0.5 was found. We may conclude from these results that both the anodic and the cathodic electrode reaction on iron are functions of a_{H+} and thus of $m_{H+}f_{H+}$, with $|z^+_{H+}| > 1$ and $z^-_{H+} = 0.5$.

Cobalt (99.9%).—The experiments (8) carried out so far on cobalt have shown the same reaction orders with respect to a_{H+} for the active anodic dissolution as well as H^+ discharge as those found on iron, when the H^+ activity was raised at constant H^+ concentration by addition of neutral salts. Here, too, the Tafel slope b^{Co} does not change when $NaClO_4$ is added to 0.1M $HClO_4$, as shown in Fig. 9, but its value (≅ 38 mv) is somewhat higher than on Fe. There is a linear decrease of log j^+_{Co} with salt concentration (Fig. 10); the result is: $j^+_{Co} \propto a^{-1.7}_{H+}$. Heusler (9) has found $b^{Co} = 29 \pm 5$ mv and $z_{H+} = -2 \pm 0.3$, similar results have been reported by Iofa and Vei Bao-min (10) and Kravtsov and Lokshtanova (11).

On cobalt, too, the Tafel slopes of H^+ discharge are not very constant when neutral salts are added. If, disregarding this, the reaction order with respect to a_{H+} is calculated, one finds also $z_{H+} = +0.5$, independent of the ionic strength.

Nickel (99.9%).—For the active anodic dissolution of nickel, we find no straight Tafel lines but S-shaped curves when making stationary measurements. This is in agreement with the findings of other authors (12). When we try, in spite of this, to calculate a reaction order with respect to a_{H+}, we find that it is smaller (in its absolute value) than −1 ($z^+_{H+} \cong -0.5$ to −0.6), both for an increase in a_{H+} at constant ionic strength when raising the acid concentration and for an increase in the activity coefficient at constant acid concentration by addition of neutral salt. Okamoto (12) reported $z^+_{H+} = -1$ with $b^{Ni} = 98$ −120 mv, but the uncertainty is rather great, not only on account of the insufficient linearity of log j but also on account of the pH dependence of the Tafel slopes.

For H^+ discharge on nickel, we find values for z^-_{H+} at constant ionic strength, J, which grow from +0.5 at $J = 1$ to +0.9 at $J = 10$ when the acid concentration is changed; the Tafel slope is about 110 mv. However, if $NaClO_4$ is added (up to 15 mole/kg) at constant acid concentration (0.1M $HClO_4$), the order remains almost constant; it changes with the addition of salt from 0.4 to 0.6 (Fig. 11). The Tafel lines are well defined and show a constant slope of 110 mv.

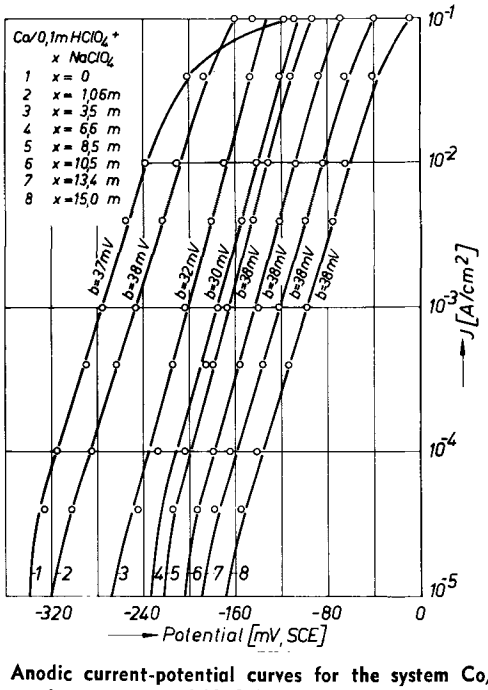

Fig. 9. Anodic current-potential curves for the system Co/0.1M $HClO_4$ + various amounts of $NaClO_4$ (galvanostatic, quasistationary, bubbling of N_2, with stirring, $t = 25°C$).

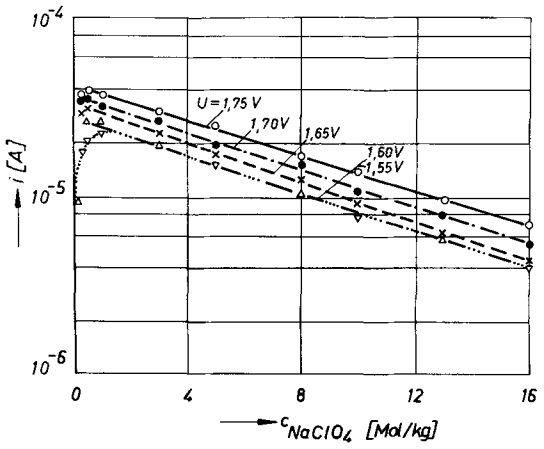

Fig. 12. Cathodic transfer current on a stationary mercury drop as a function of $NaClO_4$ concentration in 0.001M $HClO_4$ solution at ϵ = const (potentiostatic, bubbling of H_2, t = 25°C).

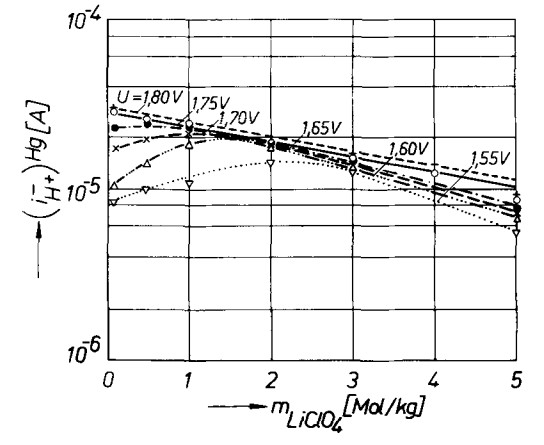

Fig. 13. Cathodic transfer current on a stationary mercury drop as a function of $LiClO_4$ concentration in 0.001M $HClO_4$ solution at ϵ = const (potentiostatic, bubbling of H_2, t = 25°C.

Nickel also differs from the two other metals with respect to the cathodic process.

Mercury (dropping electrode).—We have measured the effect of $NaClO_4$ and $LiClO_4$ on the transfer current (i^-_{H+}) on mercury in order to examine the conditions at a metal where the transfer reaction of hydrogen ion discharge is very strongly inhibited and has been studied extensively. We used a dropping electrode because eventually existing traces of impurities which may cause a drop in overvoltage cannot concentrate on the cathode. Part of the potentiostatic (cathodic) stationary current density-potential curves (Fig. 12, 13) have been obtained with a stationary mercury drop which had no effect on the results (5). For an increase in concentration of $HClO_4$ from $1 \cdot 10^{-3}$ to $50 \cdot 10^{-3}$ mole/kg, at constant concentration of $NaClO_4$ (0.1 mole/kg), the result was $(i^-_{H+})_\epsilon = k \cdot m^{1/2}{}_{H+}$. When the concentration of $HClO_4$ was varied over the same range for larger (constant) concentrations of $NaClO_4$, the exponent increased to a value of 1 (see Table I). If, at a concentration of $1 \cdot 10^{-3}$ mole/kg $HClO_4$, the $NaClO_4$ concentration is brought up to saturation, the dependence of i^-_{H+} on m_{NaClO_4} is also a function of the potential. At first, the transfer current increases, however, at higher concentrations it drops monotonously, see Fig. 12. The maximum becomes flatter as the potential increases and shifts to lower salt concentrations, as evidenced by measurements with $LiClO_4$ (Fig. 13). In the region of linear decrease, one has for i^-_{H+},

Table I. Electrochemical reaction order of the transfer reaction of H^+ discharge on Hg with respect to $[H^+]$ as a function of the ionic strength obtained by variation of $[H^+]$

c_{NaClO_4}, m/kg	$\frac{\partial \log i}{\partial \log m_{H^+}}$
0.1	0.45
0.5	0.46
1	0.61
5	0.73
10	0.97
16	1.04

$$\log (i^-_{H+})_\epsilon = \log k \cdot m^{z}{}_{H+} + K_H \cdot m$$

The value of z_{H+} increases with salt concentration from 0.5 to 1, as seen above, and K_H has a value of —0.048 for $NaClO_4$ and of —0.095 for $LiClO_4$. Here, too, the smaller cation has the greater influence.

Discussion

The influence of H^+ concentration on active iron dissolution has been known for a long time. It is usually referred, according to a suggestion by Frumkin (14), to the effect of OH^-; different reaction mechanisms are discussed, and Heusler maintains that the OH^- ions have a catalytic effect. Our experiments have shown that the current density $(j^+_{Me})_\epsilon$ at constant m_{H+} is proportional to $a_{H+}{}^{-p}$;[1] of course, a proportionality to the activity of OH^- ions, introduced by means of the ionic product of water, may also be considered. In this case, the shift in the activity of water caused by the high ionic strengths must be taken into account. We have been able to show (2) that a_{OH-} may increase as well as decrease by the addition of neutral salts. When $NaClO_4$ is added to alkaline solution, the *p*H value first decreases, and with it a_{OH-}, but later on, it increases (Fig. 14), and with it a_{OH-} increases, too. In $LiClO_4$ solutions, the *p*H value of alkaline solutions decreases monotonously as m_{LiClO_4} increases, but the behavior of $j_{Me}{}^+$ is almost the same in the two solutions. Further, the ionic product $m_{H+} \cdot m_{OH-}$ changes with growing additions of salt. It passes, for instance, through a maximum at 1 mole/kg $NaClO_4$ and reaches about 10^{-16} (mole/kg)[2] at 16 mole/kg $NaClO_4$ (13). This is the reason why the hydroxyl ion concentration decreases by about 2 powers of ten in acid solutions at these high salt concentrations. Consequently, we might write $(j^+_{Me})_\epsilon \propto m_{OH}{}^q$ or $(j^+_{Me})_\epsilon \propto a_{OH}{}^q$, respectively.[2] Since, however, the surface concentration of OH^- is extremely small (less than 1 ion/cm² in a film of 50Å), and a_{OH-} or m_{OH-} are, on the other hand, not linear functions of the salt concentration, we would prefer to assume that the equilibrium

[1] *p* represents the order of reaction with respect to H^+.

$$Me + OH_2 \rightleftharpoons MeOH_{ad} + e^- + H^+ \quad [1]$$

which precedes the transfer reaction brings about a dependence on $a_{H^+}{}^{-1}$. We have seen that, indeed, higher negative exponents are found on Fe and Co, although recently values of —1 have been reported (7). The assumption that a further proton equilibrium takes part in the electrode process is not very plausible. We can ascertain, on the other hand, that the exponents of a_{H^+} which are greater than unity are different from 2.0 at constant Tafel slope. Perhaps we may assume that the H^+ produce some kind of electrostatic inhibition. We know that these ions interchange very quickly with the H atoms of the water, and thus a mean positive charge density will be produced at the metal surface owing to the H_2O molecules present in the double layer, and this charge will increase with the number of H^+ and their excess power, $RT \ln f_{H^+}$. The metal ions going into solution have to pass through this positive potential barrier, and hence the anodic dissolution reaction is further inhibited. In this way, it is also possible to explain qualitatively the influence of the cations. The smaller their radius, the stronger their hydration and the more will they contribute to the structure of such a positive charge barrier with their own high charge density (when ion pairs are formed on the metal surface) and with that of the H^+ ions which alternate with the H atoms of their hydration water. At nickel, a different over-all mechanism of anodic dissolution must probably be assumed if the reaction [1] does not participate; however, at least the electrostatic inhibition by H^+ should be active, and this would agree with the exponents of 0.5-0.6.

Of course, this "electrostatic" inhibition effect of H^+ should, first of all, raise the anodic dissolution potential, and indeed the overvoltage increases remarkably with increasing a_{H^+} at constant current density.

In hydrogen ion discharge, the transfer current should increase with the square root of the H^+ concentration, according to the theory of Frumkin (14) which gives due regard to the ζ potential. If at high ionic strengths the influence of the ζ potential ceases, the value of the exponent should increase to 1, as verified by Frumkin on mercury. According to our results, even at high salt concentrations, a significant increase of the exponent with increasing H^+ concentration cannot be detected on Fe (and Co), but it is observed on Ni. The theory of Frumkin is confirmed in a particularly remarkable way on Hg where the exponent $z^-{}_{H^+}$ increases with growing ionic strength to 1 as m_{H^+} rises.

If, at $m_{H^+} = 0.1$ mole/kg, a_{H^+} is raised by addition of salt, the value of $z^-{}_{H^+}$ on Ni is found to be 0.4. According to Frumkin, $z^-{}_{H^+}$ is itself a function of the ionic strength; it should, therefore, increase to 1 with growing addition of salt. An inhibition is evidently in operation here which is especially significant on Hg. On this metal, $j^-{}_{H^+}$ decreases with increasing ionic strength and activity of H^+, even at m_{H^+} = constant. This dependence is, moreover, a function of the potential. Qualitatively, this may be explained as follows. At m_{H^+} = const and growing salt concentration in the double layer, the protons are displaced more the higher the concentration and the charge density of the cations and the more negative the potential. At very negative potentials, this may lead to a monotonous decrease of $j^-{}_{H^+}$ with a_{H^+} or with salt concentration, respectively. At high ionic strength, on the other hand, a growing quantity of H^+ will produce an increase of $j^-{}_{H^+}$. Of course, the question remains open as yet why we find a value of 0.5 for $z^-{}_{H^+}$ on Fe and Co, independent of the ionic strength when we vary m_{H^+} and a_{H^+}. We do not like to propose an explanation for it at this time because the measurements are not especially reproducible, the Tafel lines are not well defined, and the slopes are not constant so that the results do not seem to be certain enough.

Summary

The current densities of anodic dissolution of Fe, Co, and Ni are measured at constant hydrogen ion concentration with increasing additions of neutral salts which lead to a rapid increase of the activity of H^+. The anodic current density decreases with the activity of H^+, too, where $j^+{}_{Me} = K \cdot a_{H^+}{}^{-z^+}$, z_+ depends on the cation of the salt and is less than unity in the case of nickel. The current density of H^+ discharge is studied on the same metals as well as on Hg as a function of the addition of neutral salts. For the ferrous metals, an increase with $a_{H^+}{}^{+0.5}$ is found; on nickel, the exponent increases at high ionic strength to 0.9. On mercury, $j^-{}_{H^+} \propto m_{H^+}{}^{0.5}$ at small ionic strength; the dependence becomes $j^-{}_{H^+} \propto m_{H^+}{}^{1.0}$ at high ionic strength. The dependence on a_{H^+} at constant H^+ concentration is complicated. A qualitative interpretation of the experimental results is proposed.

Manuscript received Dec. 20, 1965; revised manuscript received May 20, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

SYMBOLS

$z^+{}_{H^+}$	Order of reaction with respect to H^+
α	Transfer coefficient
n	Transfer valence
ν	Number of equilibriums, preceding and potential dependent
K^+, K	Factors of proportionality
a^o	Activity of H^+ without salt addition
m_{salt}	Molality of added neutral salt

Deformation of Anodic Oxide Films

S. F. Bubar and D. A. Vermilyea

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Tantalum oxide films on smooth, pure substrates can be deformed as much as 50% before fracture. On surfaces containing impurity particles the films contain many flaws which nucleate cracks after relatively little deformation. Zirconium oxide films showed some evidence of deformation, but much less than tantalum oxide. Aluminum oxide films showed no evidence of deformation.

Protection against corrosion is usually afforded by a thin film of reaction product. The behavior of such a film during deformation of the underlying metal would be of great importance in determining corrosion under such conditions and may play a decisive role in stress corrosion cracking and corrosion fatigue. It is usually assumed that reaction films are brittle, and one currently popular theory of stress corrosion cracking asserts that repeated cracking of the passive film allows continued corrosion. Bradhurst and Leach (1) have shown that barrier-type anodic oxide films on aluminum are brittle, while Edeleanu and Law (2) have demonstrated that both porous anodic aluminum oxide films and the natural corrosion film on aluminum are brittle. Young (3), on the other hand, reported that anodic films on tantalum changed color during deformation of the metal indicating some deformation of the oxide, and Dunn (4) has told us that anodic films on tantalum deform along with the substrate when tantalum sheet is rolled. In this paper we report the use of a new technique to obtain quantitative information about the deformation of anodic films on aluminum, zirconium, and tantalum.

Experimental

Our technique relies on the fact that electrons can flow (presumably by tunneling) through very thin insulating oxide films to reduce ions in solution, while thicker films block such electronic currents. Figures 1 and 2 show typical results obtained with the materials and solutions used in this study. The data for tantalum show that the results are nearly independent of the nature of the test solution, but are strongly influenced by the purity of the tantalum. We found that the borate plus ferri-ferro cyanide solution was sufficiently stable for our purposes and that the attack on the aluminum oxide films during a test was negligible.

In order to detect film fracture anodized wire specimens were stretched in solutions with a potential applied such that the new film formed in any bare areas generated by fracture was 15-20Å thick. From the current flowing after straining and the data in Fig. 1 and 2 the amount of bare surface was calculated. Corrections were made for changes in specimen area as a result of the decrease in wire diameter and the fact that grease covered wire is drawn into the cell near the stationary grip; the latter correction was very small. The currents were time-dependent, since initially on any bare surface both anodization and reduction of ferric ions was occurring. Five minutes were allowed for the current to reach a reasonably steady value after each increment of strain. The apparatus used is shown in Fig. 3. The technique is capable of detecting a change in the bare surface of $3 \times 10^{-4}\%$.

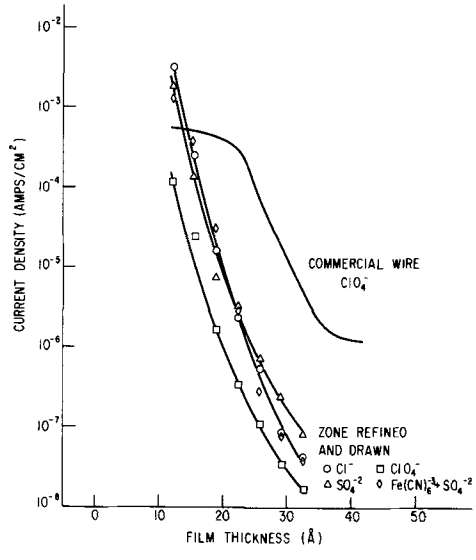

Fig. 1. Thickness dependence of electronic current through tantalum oxide films. All solutions were 1M in the acid of the anion shown and contained 0.1M each of aquo Fe^{+3} and Fe^{+2} ions except for one sulfate solution in which cyanide complexes were used. The test potential was about —0.1v on the hydrogen scale.

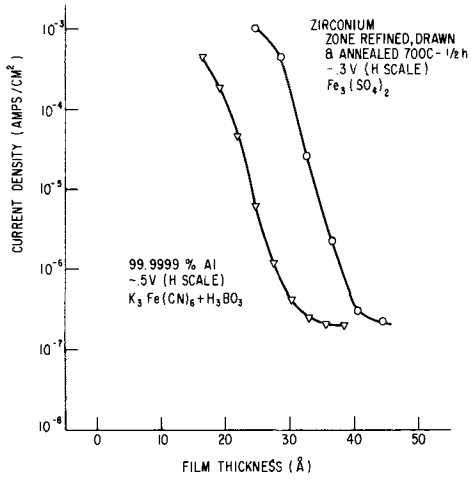

Fig. 2. Thickness dependence of electronic current through aluminum oxide and zirconium oxide films. For zirconium the solution contained 1M H_2SO_4 plus 0.1M each of Fe^{+3} and Fe^{+2}, while for aluminum the solution contained 1M H_3BO_3 plus 0.1M Fe^{+3} and Fe^{+2} as cyanide complexes.

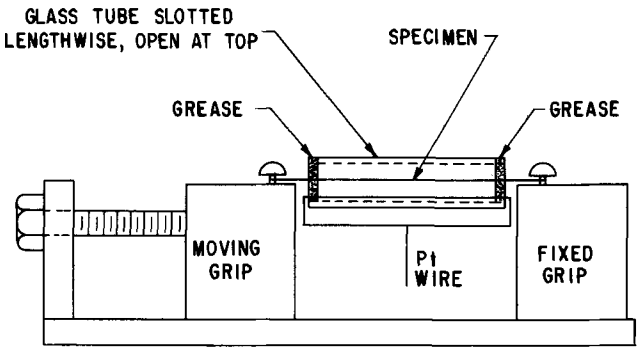

Fig. 3. Sketch of apparatus

Specimens were anodized at room temperature in 1 w/o (weight per cent) ammonium borate solution, and the film thicknesses were calculated from the applied potential using 17 Å/v for Ta_2O_5, 20 Å/v for ZrO_2, and 14 Å/v for Al_2O_3. The wires were chemically or electrochemically polished before anodizing. For tantalum, chemical polishing in (parts by volume) $5H_2SO_4$, $2HNO_3$, 2HF was followed by a 5-sec dip in concentrated HF. Aluminum was either electropolished in $5HClO_4$, 100 glacial acetic or chemically polished in a HNO_3-H_3PO_4 mixture, both treatments being followed by immersion in either HF or NaOH to remove the polishing residue. The results were the same after all treatments. Zirconium was chemically polished in a solution of 5 lactic acid, $5HNO_3$, $2H_2O$, 1HF, and the residue was not removed. This zirconium polishing solution is unstable (5, 6) and should not be stored.

Results and Discussion

Figure 4-8 give curves of per cent bare surface *vs.* per cent elongation of the wire for the metals studied. In the figures the "theoretical" curve was calculated from the relationship

$$\% \text{ Bare surface} = 100\left[1-\left(\frac{l_o}{l}\right)^{1/2}\right] \qquad [1]$$

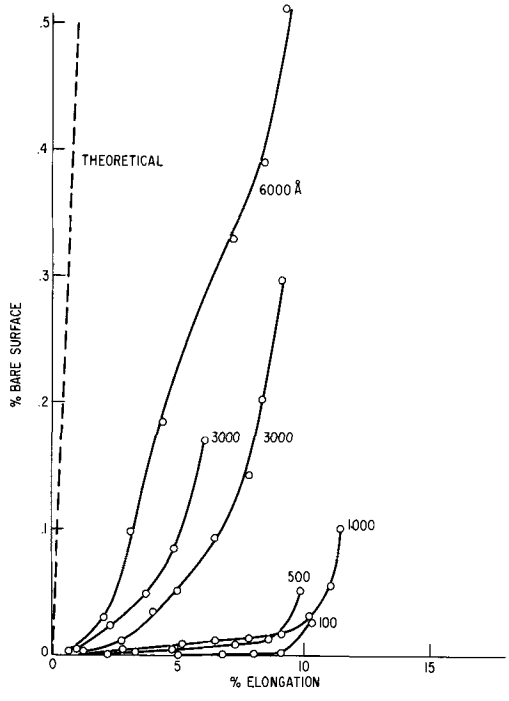

Fig. 4. Bare surface produced during straining of vacuum annealed tantalum wires covered with anodic films of the thicknesses shown. Perchlorate solution.

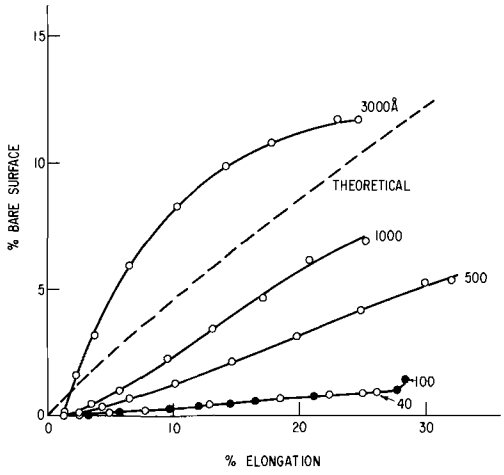

Fig. 5. Bare surface produced during straining of as received tantalum wire covered with anodic films of the thicknesses shown. Perchlorate solution.

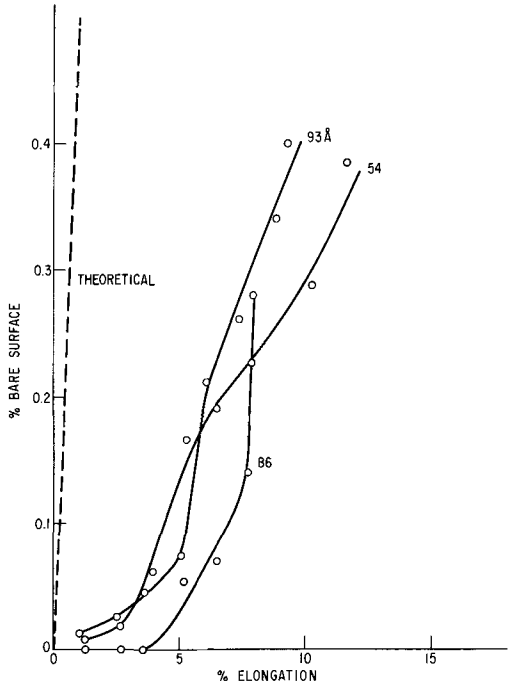

Fig. 6. Bare surface produced during straining of vacuum annealed tantalum wire covered with films formed in air at 300°C to the thicknesses shown. Perchlorate solution.

in which l_o is the initial specimen length and l is the length at any time. Equation [1] was derived on the assumptions that the volumes of metal and film are constant, that the film cracks at $l = l_o$, and that the film maintains contact with the metal while the diameter is reduced due to elongation. It should be noted that this last assumption requires some deformation of the film.

Figure 1 shows that Ta_2O_5 films formed on a very pure substrate can undergo extensive deformation before fracture. Films up to 1000Å showed essentially no evidence of fracture before the wire broke, and even then the crack area was small despite the very great deformation of the metal, which necked down to a chisel-shaped point. No evidence of loss of adhesion was observed. Thicker films also adhere perfectly, but show less capacity for deformation. On all of these specimens deformation was very nonuniform, some grains deforming much more than others with extensive local deformation markings visible. By

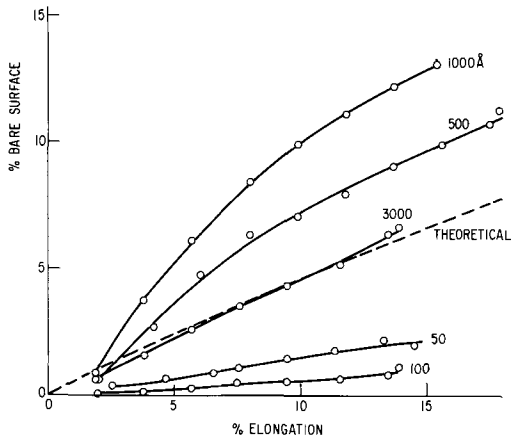

Fig. 7. Bare surface produced during straining of zirconium wire covered with anodic films of the thicknesses shown. Sulfate solution.

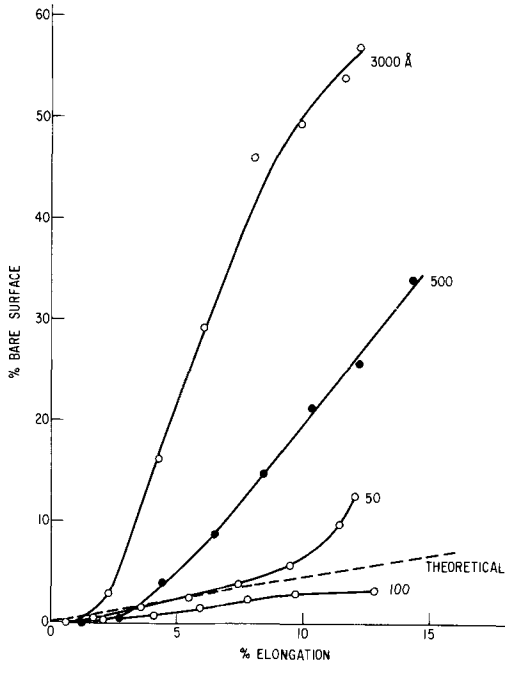

Fig. 8. Bare surface produced during straining of aluminum wire covered with anodic films of the thicknesses shown. Borate plus cyanide complex solution.

comparing colors after deformation it could be seen that reductions in film thickness as great as 20-30% occurred on some grains. From the relationship

$$t = \left(\frac{l_o}{l}\right)^{1/2} t_o \qquad [2]$$

where t and t_o are the final initial film thicknesses, it is deduced that the film must have elongated on some grains as much as about 50%. While these large deformations are probably plastic, this has not been proven. For one 1150Å film essentially identical results were obtained when the film was stretched in air instead of in the electrolytic solution.

When films less than 500Å thick fractured many small jagged cracks were seen in local regions of high strain while thicker films (1000-6000Å) cracked circumferentially. Examination of films during elongation showed that virtually all cracks which started prior to necking of the specimen nucleated at flaws in the film. It was also observed that cracks passed very close to other flaws with no obvious interaction.

When this same material was stretched without having been vacuum annealed the curves shown in Fig. 5 were obtained. For comparable elongations there is a many-fold increase in the amount of bare surface (or a many-fold decrease in film ductility). It is believed that the many flaws present in the films on the less pure material nucleated cracks at much smaller strains.

Films formed in air at 300°C gave the results shown in Fig. 6. It is evident that there is less ductility than for specimens having comparably thick anodic films. Thermal tantalum oxide films grown at <350°C are amorphous, as are the anodic films, but it is possible that there are crystal nuclei present and that these initiate cracks. This hypothesis is supported by the fact that a specimen which was anodized to form a 100Å film prior to heat treatment at 300°C for 2 hr gave no indication of film failure until the wire broke at ~9.5% elongation. Crystallization of anodic film does not occur at 300°C in such short times. A 100Å anodic film heat treated at 450°C for 2 hr was completely crystallized in a basket weave pattern similar to a Widmanstatten pattern and had grown to a thickness of perhaps 700Å. Such crystalline films cracked primarily at metal substrate grain boundaries, and the behavior in the test cell indicated that there was no appreciable ductility.

A few specimens were prepared from tantalum which was zone refined, drawn to 0.030 in. diameter, and vacuum annealed at 1400°C for 1 hr in this laboratory. The results of tests using such wire were essentially the same as those using vacuum annealed wire.

Figure 7 shows data obtained with films formed on a zone refined zirconium rod which was drawn to 0.030 in. diameter using three anneals at 700°C for ½ hr. The curves as a group show ~80 times as much bare surface for a given strain as the vacuum annealed tantalum, or slightly less ductility than the as-received tantalum. The decrease in ductility with film thickness is not as well ordered for zirconium as it is for tantalum. Some deformation of the zirconium oxide films is suggested by the fact that they did generally maintain contact with the substrate. It is possible

Fig. 9. Electron micrograph (indirect replica) of an aluminum wire surface after straining 14.7%. The wire was originally covered with a 500Å film.

that these zirconium wires contained particles of oxide which produced flaws in the oxide films, and that better films would deform more before fracture.

The cracks in the anodized zirconium films ran in all directions, each grain (~1/5 wire diameter) having a distinct set of cracks. Only on the 3000Å film was there some degree of crack continuity across grain boundaries. The multiple cracks broke the film into many tiny pieces which occasionally flaked off. There was no evidence of film color change due to elongation as was the case with tantalum.

Data obtained for films formed on aluminum specimens of 99.9999% purity are shown in Fig. 8. Examination after elongation revealed extensive loss of contact with the substrate as shown in Fig. 9. Evidently the anodic aluminum oxide film is not even sufficiently ductile to maintain contact with the wire as the diameter decreases. The greater than theoretical amount of bare surface is further evidence for this loss of contact.

Conclusions

Anodic tantalum oxide films exhibit great ductility, as much as 50%. Zirconium oxide films show some ductility, and possibly better specimens might show much more. Aluminum oxide films appear to be completely brittle. The technique is limited to the study of oxide films which are insulating, and thus we were not able to use it on stainless steel or nickel. We hope to use other techniques to measure the ductility of oxides on such metals.

Dielectric Properties of Semiconducting Iron Phosphate Glasses

Kent W. Hansen and Mary T. Splann

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

The dielectric constant and loss factor of glasses containing 55 mole % FeO_x-45 mole % P_2O_5 with varying Fe^{+3}/Fe_{total} ratios were measured as a function of temperature and frequency. An a-c dispersion was observed between 10^{-2} and 10^5 cps with a temperature dependence equivalent to the d-c conductivity temperature dependence. The dielectric constant was independent of frequency and temperature below the dispersion region. There was a distribution of relaxation times associated with the dispersion process.

In a previous paper it was suggested that electrical conduction in iron-phosphate glasses containing over 20 mole % FeO_x is an electronic process (1). The charge transfer results from holes (or electrons) migrating between Fe^{+3} and Fe^{+2} ions. In the proposed mechanism, the carrier concentration is essentially independent of temperature, whereas the carrier mobility is a thermally activated process. This conduction mechanism is similar to that proposed for $Li_xNi_{1-x}O$ and other transition metal oxides (2,3) and is often referred to as a "hopping" process. Munakata proposed a "hopping" model for electrical conduction in the vanadate glasses (4).

The dielectric loss and mechanical loss have been measured in $Li_xNi_{1-x}O$ (5) and $Li_xMn_{1-x}O$ (6). In each case the loss data were correlated with the hole movement around the lithium ion. Snowden and Saltsburg (7) measured the a-c conductivity of NiO at room temperature as a function of frequency. They observed a dispersion which they attribute to the hopping of the hole.

Dielectric loss measurements have been made on vanadium-phosphate and tungsten-phosphate glasses (8). The authors observed that the slope of the plot of the logarithm of d-c conductivity *vs.* reciprocal temperature was nearly equivalent to the slope of the logarithm of frequency *vs.* reciprocal of T_{max}, where T_{max} is the temperature at which tan δ was a maximum. Ioffe *et al.* suggested that conduction involves charge transfer between ions of different valencies.

The dielectric properties of glasses in the As-Te system have also been measured (9). The activation energies for conduction and dielectric relaxation were found to be nearly the same.

This paper contains work on the dielectric properties of glasses containing 55 mole % FeO_x-45 mole % P_2O_5 with different Fe^{+3}/Fe^{+2} ratios. The dielectric loss and constant were measured as a function of frequency and temperature. A correlation is made between the dielectric loss factor and d-c electrical conduction.

Experimental Procedure

The glasses included in this paper were studied previously (1). The preparation and characterization of these glasses are given there. Table I gives the composition, $Fe^{+3}/Fe^{+2} + Fe^{+3}$ ratio, and sign of the carrier determined from the thermoelectric power.

The samples were in the form of polished plates, 2 in. x 2 in. x 2 mm. Three-terminal electrodes were applied to the samples following ASTM specifications (10). Several electrode materials were used for comparison: Hanovia Liquid Gold Bright, vacuum evaporated gold, du Pont air-drying silver paint, and vacuum evaporated silver.

D-C conductivity, a-c conductivity and capacitance were measured as a function of temperature (from room temperature to ~100°C) and the latter two as a function of frequency (from 10^{-2} to 10^5 cps) in an air atmosphere. The accuracy of the electrical measurements was ± 10%. The d-c conductivity was measured with a Beckman Ultrohmeter at a potential of

Table I. Fe^{+3}/Fe_T ratio and sign of carrier for glasses containing 55 mole % FeO_x-45 mole % P_2O_5

Glass	$\frac{Fe^{+3}}{Fe^{+3} + Fe^{+2}}$	Conduction carrier
1	0.793	n
2	0.465	n
3	0.147	p

20v. The samples were ohmic up to at least 300 v/cm.

Between 10^{-2} and 10^{3} cps the a-c conductivity and capacitance were measured with a bridge designed by Weingarten (11). With this bridge the conductivity was determined from the following equation

$$\gamma_T = \frac{1}{R} \times \frac{t}{A} \text{ (ohm cm)}^{-1} \quad [1]$$

where R is resistance, t is sample thickness, and A is electrode area. The General Radio 1610A capacitance measuring assembly was used for the frequency range 10^2 to 10^5 cps. The conductivity was calculated from the measured values of loss tangent (tan δ) and relative dielectric constant (K') from the following relationship

$$\gamma_T = \frac{K' \times f \times \tan \delta}{1.8 \times 10^{12}} \text{ (ohm cm)}^{-1} \quad [2]$$

where f is frequency.

The measured conductivity (given in Eq. [1] and [2]) is the total conductivity (γ_T) which is a sum of the d-c conductivity ($\gamma_{d\text{-}c}$) and the a-c conductivity ($\gamma_{a\text{-}c}$). As the temperature increases and/or the frequency decreases, ($\gamma_{d\text{-}c}$) becomes a larger part of the total conductivity. In order to study the relaxation peaks, ($\gamma_{d\text{-}c}$) was subtracted from the measured conductivity, such that

$$\gamma_{a\text{-}c} = \gamma_T - \gamma_{d\text{-}c} \quad [3]$$

Using the adjusted conductivity ($\gamma_{a\text{-}c}$), the relative loss factor (K'') was calculated (12).

$$K'' = \frac{1.8 \times 10^{12} \times \gamma_{a\text{-}c}}{f} \quad [4]$$

This technique was used by Taylor (13) and Heroux (14) to investigate ionic conducting glasses.

The relative dielectric constant (K') was calculated from the following equation (12)

$$K' = C \times \frac{t}{0.0885 \times A} \quad [5]$$

where C is the measured capacitance in pica-farads, t is the sample thickness in cm, and A is the electrode area in cm^2.

Results and Discussion

Figures 1a and 1b contain plots of relative dielectric constant (K') and loss factor (K'') *vs.* the logarithm of the frequency for glasses 1 and 2, using gold electrodes. Only data for representative temperatures are shown. The upper temperature at which meaningful a-c loss data could be taken was limited by the d-c conduction loss. As can be seen in Fig. 1, the loss factor (K'') goes through a maximum as the frequency goes from 10^0 to 10^4 cps. This maximum shifts to higher frequencies as the temperature increases.

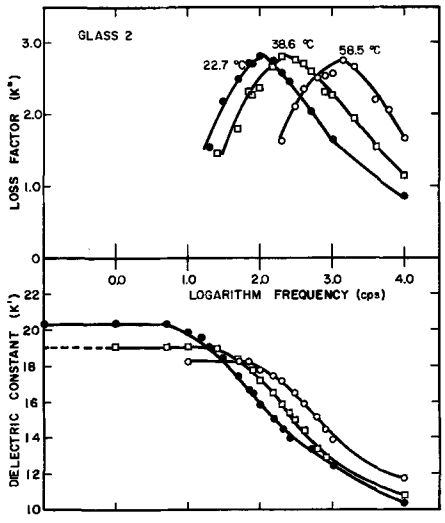

Fig. 1b. Dielectric constant and loss factor *vs.* logarithm of frequency for glass 2.

The dielectric constant (K') was found to be independent of frequency and temperature below the dispersion range. The leveling-off of the dielectric constant at low frequencies indicates the relaxation mechanism is one which does not lead to polarization, such as ionic migration. The dielectric constant of ionic conducting glasses increases rapidly as the frequency decreases in this region (14). The data in Fig. 1 are consistent with the electronic conduction mechanism proposed earlier (1).

Figure 2 contains a plot of K'' and K' *vs.* the logarithm of the frequency at representative temperatures for glasses 1 and 3 with silver electrodes. As in the case where gold electrodes were used, a loss peak was observed that shifted to higher frequencies as the temperature increased. The magnitude and temperature dependence (see Fig. 3) of the loss factor

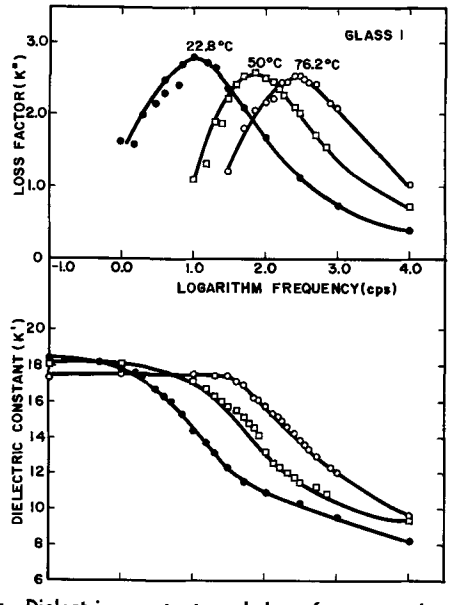

Fig. 1a. Dielectric constant and loss factor *vs.* logarithm of frequency for glass 1.

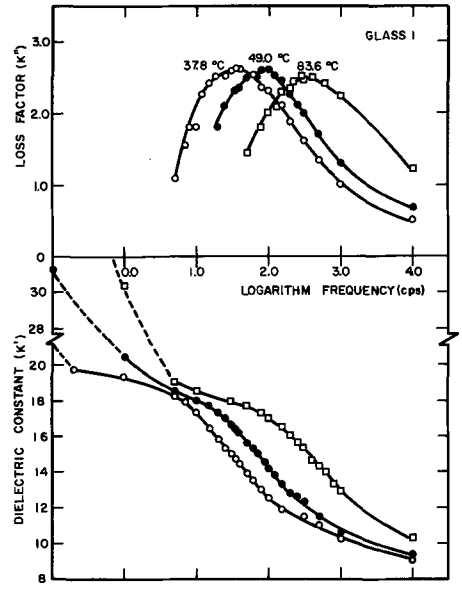

Fig. 2a. Dielectric constant and loss factor *vs.* logarithm of frequency for glass 1 with silver electrodes.

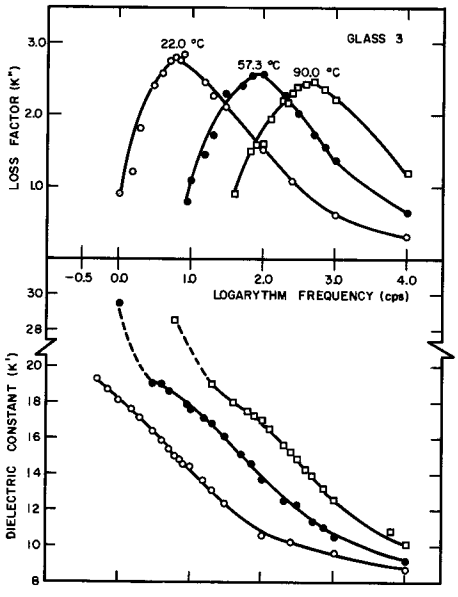

Fig. 2b. Dielectric constant and loss factor vs. logarithm of frequency for glass 3 with silver electrodes.

were the same for gold and silver electrodes. However, the dielectric constant increased rapidly with decreasing frequency at low frequencies. It is believed that this can be attributed to silver migration into the surface of the glass. After the silver electrodes were removed from glass 1 and gold electrodes reapplied, the dielectric constant did not completely level off as shown in Fig. 1. This is further evidence that silver had migrated into the glass surface.

The logarithm of the frequency (f_{max}) at which the loss factor is a maximum is plotted *vs.* $1/T$ in Fig. 3. Assuming the relaxation time (τ) is given by

$$\tau = \tau_0 e^{E/kT} \qquad [6]$$

where τ is $1/2\pi f_{max}$, τ_0 is a constant, and E is an activation energy; the activation energies given in Fig. 3 were calculated using the method of least squares.

If the conduction mobility (μ) is temperature dependent, such that $\mu T \alpha e^{-E/kT}$, the d-c conductivity can best be expressed by $\gamma_{d\text{-}c}T = \gamma_0 e^{-E/kT}$ rather than $\gamma_{d\text{-}c} = \gamma_0 e^{-E/kT}$. The logarithm of conductivity x temperature *vs.* $1/T$ is plotted in Fig. 4. The activation energies in the low-temperature region agree very well with the activation energies determined from a-c loss data in Fig. 3.

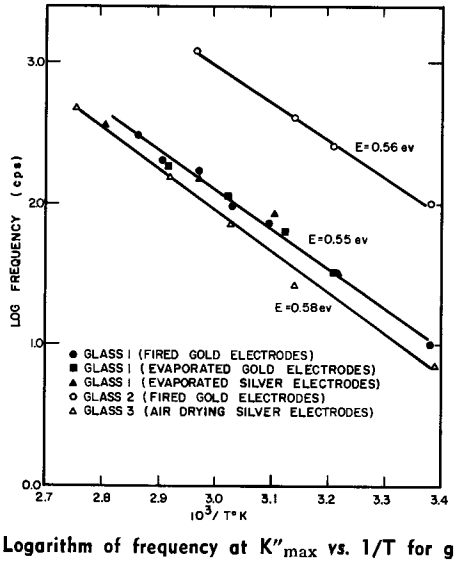

Fig. 3. Logarithm of frequency at K''_{max} vs. 1/T for glasses 1, 2, and 3.

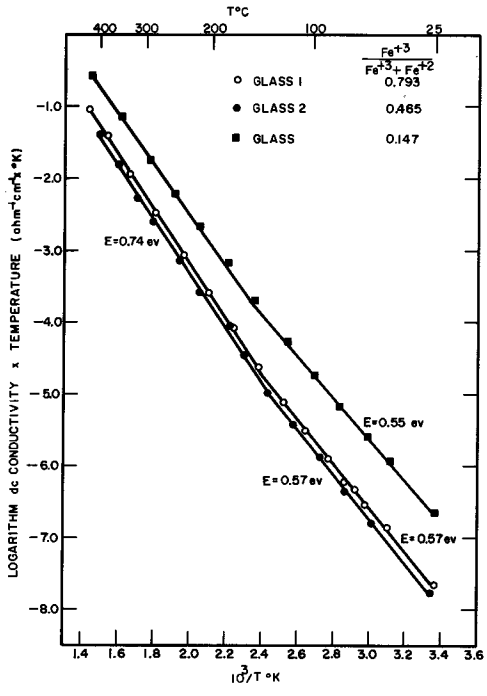

Fig. 4. Logarithm of d-c conductivity x temperature vs. 1/T

Killias (15) has suggested that the conduction activation energy is temperature dependent and is given by

$$E = \epsilon_0\left(1 - \frac{\theta_R}{T}\right) \qquad [7]$$

where ϵ_0 and θ_R are constants, and T is temperature. He suggests the temperature dependence is due to a distribution of jump distances. Figure 5 contains a plot of the logarithm of the d-c conductivity and frequency at which K'' is a maximum *vs.* $\left(\frac{1}{T} - \frac{\theta_R}{T^2}\right)$ for glass 1. θ_R was determined using the method of least squares. The conductivity data do give a straight line as predicted by Killias. It can be seen that the temperature dependence is the same for both the d-c conductivity and the loss factor data whether E is assumed to be temperature dependent or not. This suggests the relaxation time (τ) is associated with the

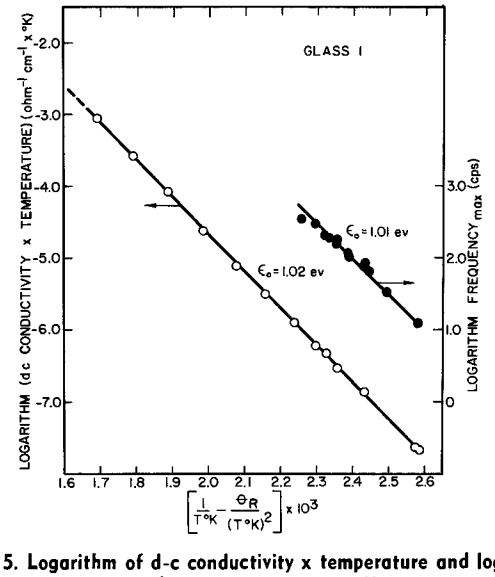

Fig. 5. Logarithm of d-c conductivity x temperature and logarithm f_{max} vs. $(1/T - \theta_R/T^2)$ where θ_R = 69.4°K.

conduction mechanism. It is believed the dielectric loss is due to electrons (or holes) hopping between Fe^{3+} and Fe^{+2} ions.

For a thermally activated diffusion process, the Nernst-Einstein equation relates the conductivity and relaxation time as follows

$$\gamma_{d\text{-}c} = \frac{ne^2d^2}{kT}\left(\frac{1}{\tau}\right) \quad [8]$$

where n is the carrier concentration, e is electronic charge, and d is the jump distance. For glass 3, n calculated from Eq. [8] was found to be 1.5 x 10^{20} cm^{-3} and 1.2 x 10^{20} cm^{-3} at 45.3° and 69.7°C, respectively. This compares with $n \approx 7 \times 10^{20}$ cm^{-3} at 200°C determined from

$$n = N_0 e \frac{-|Q|T}{kT} \quad [9]$$

where N_0 is total available sites, and Q is the thermoelectric power (1). Considering the accuracy of the measurements and the fact that two independent techniques were used, this is good agreement and indicates the carrier concentration is nearly independent of temperature. The d-c conductivity changed nearly three orders of magnitude over this temperature range. The agreement between n calculated from Eq. [8] and [9] is further evidence that the relaxation process and the conduction mechanism result from charge transfer between Fe^{+3} and Fe^{+2} ions.

Following the procedure of Yager (16) and Heroux (14), it was determined that there is a distribution of relaxation times rather than a single time. This is not surprising since the glass structure is amorphous. When a single relaxation process is in effect, the dielectric constant (K'_s) and loss factor (K''_s) are given by the following equations (12, 16)

$$K'_s = K_\infty + \frac{K_\infty k}{1+\omega^2\tau^2} \quad [10]$$

and

$$K''_s = \frac{K_\infty k\omega\tau}{1+\omega^2\tau^2} \quad [11]$$

where K_∞ is the dielectric constant at infinite frequency, k is a constant, and ω is 2π x frequency.

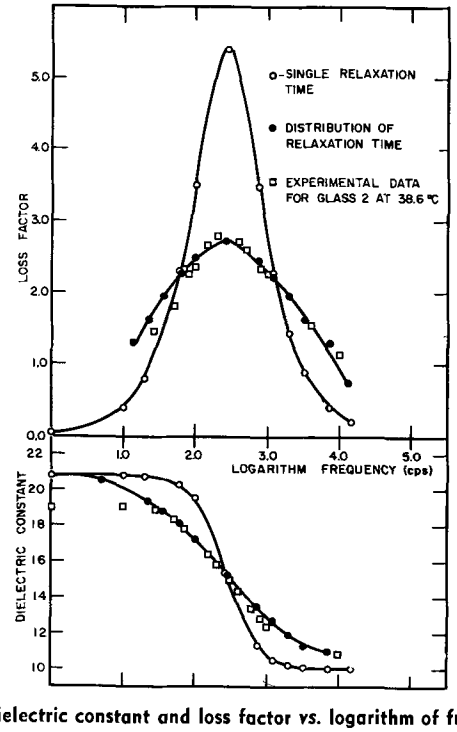

Fig. 6. Dielectric constant and loss factor vs. logarithm of frequency

Wagner (16, 17) proposed a Gaussian distribution of relaxation times which are spread logarithmically about a most probable relaxation time ($\bar{\tau}$). From expressions given by Yager for dielectric constant and loss, we have

$$K'_w = K_\infty + \frac{K_\infty bk \exp(-b^2Z_0^2)}{\sqrt{\pi}} \int_0^\infty \exp(-b^2u^2) \times \frac{\cosh u(2b^2Z_0-1)}{\cosh u} du \quad [12]$$

and

$$K''_w = \frac{K_\infty bk \exp(-b^2Z_0^2)}{\sqrt{\pi}} \int_0^\infty \exp(-b^2u^2) \times \frac{\cosh 2b^2Z_0u}{\cosh u} du \quad [13]$$

where $Z_0 = \ln \omega\bar{\tau}$, $Z = \ln \tau/\bar{\tau}$, and $u = Z + Z_0 = \ln \omega\tau$. Using a technique developed by Yager (16), Eq. [12] and [13] were evaluated. In Fig. 6 these results are compared with the experimental values of K'' and K' for glass 2 and K'_s and K''_s determined from Eq. [10] and [11]. The experimental data fit the Wagner curve reasonably well indicating there is a distribution of relaxation times rather than a single process. It can be seen that the experimental loss data fall below the theoretical curve at the low frequencies. This can be attributed to the fact that there is a greater error in determining K'' in this region than at higher frequencies because γ_T approaches $\gamma_{d\text{-}c}$ rapidly as the frequency decreases in this range.

Conclusions

1. The d-c conduction activation energy is equal to the activation energy of the dielectric relaxation process in the frequency range 10^{-2} to 10^5 cps.
2. The dielectric constant is independent of frequency and temperature below the dispersion region when gold electrodes are used.
3. There is a distribution of relaxation times rather than a single relaxation time associated with the dispersion process.
4. The a-c dispersion between 10^{-2} and 10^5 cps and the d-c conductivity are probably a result of charge carriers jumping between Fe^{+3} and Fe^{+2} ions.

Some Cross-Substitutional Alloys of CdTe

J. C. Woolley and E. W. Williams[1]

Physics Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

The alloys of CdTe with the cross-substitutionally derived ternary compounds $AgInTe_2$ and $CuGaTe_2$ are considered. It is found, in the case of the ternaries themselves, that neither is completely stable and that both tend to decompose under certain conditions of annealing. The alloys have been prepared by melt and anneal method, with due regard to the stability of the ternary concerned. By x-ray powder photograph techniques, the composition ranges for single phase zinc blende or chalcopyrite structure or for two-phase behavior have been determined and the lattice parameter data are given. For the single phase alloys, values of optical energy gap have been determined by the usual I. R. absorption method.

The development of ternary compounds from binaries by cross-substitution is well known (1-3). In the case of A^{II} C^{VI} compounds, it has been shown that many of the derived ternary A^{I} B^{III} C_2^{VI} compounds are stable and the crystallographic and semiconducting properties of these ternaries have been investigated (1, 4-6). The ternaries derived from zinc blende type A^{II} C^{VI} compounds show ordering of the A^{I} and B^{III} atoms and hence have a chalcopyrite structure rather than zinc blende. In the case of tellurides, the derived ternaries, *e.g.*, $AgInTe_2$, $CuInTe_2$, $CuGaTe_2$, etc., have received some attention (4, 8, 9).

A further step in the development of new materials is the consideration of solid solution between an A^{II} C^{VI} compound and a derived A^{I} B^{III} C_2^{VI} compound, where the particular C^{VI} element is common to both. The resulting alloys can be looked on as the results of partial cross-substitution in the binary compound. Such solid solutions which have already received attention are ZnS-$CuGaS_2$ and ZnS-$AgGaS_2$ [Apple (10)], $CdTe$-$CuInTe_2$ [Chernyavsky (11)], and $CdTe$-$AgInTe_2$ and $HgTe$-$AgInTe_2$ [Rodot (12)]. In these cases, complete solid solution was found for the ZnS-$CuGaS_2$ and $CdTe$-$CuInTe_2$ alloys, while the range of solid solution of $AgGaS_2$ in ZnS was found to be limited to 5 mole %. In the case of $CdTe$-$AgInTe_2$ and $HgTe$-$AgInTe_2$, Rodot (12) investigated thermoelectric properties, and the range of solid solution, etc., was not determined.

Here we consider certain alloys of CdTe, *viz.*, $CdTe$-$AgInTe_2$ and $CdTe$-$CuGaTe_2$. The ranges of solid solution have been found and the values of lattice parameters determined by x-ray powder photograph techniques. The room temperature optical energy gap has been obtained for the single phase samples by normal I.R. absorption measurements. The methods used are the same as those used in the investigation of the corresponding cross-substitutional alloys of InSb, etc., and which have been described in some detail previously (13).

Preparation and Problems of Stability of Compounds

The separate compounds were prepared by melting together the appropriate component elements. In the case of CdTe, the ingot was melted in a vertical furnace and then slowly cooled by lowering out of the furnace hot zone. The part of the ingot which solidified first was used to provide the CdTe required, this material being p-type with approximately 10^{15} carriers/cc.

The ternary compounds were produced by melting components and then quenching in water. With these quenched samples, $CuGaTe_2$ was found to have lattice parameter values of $a_0 = 6.025$Å and $c/a = 1.983$, while the optical energy gap E_g was 1.17 ev. The corresponding values for the quenched $AgInTe_2$ were $a_0 = 6.446$Å $c/a = 1.960$, and $E_g = 0.97$ ev. Previously reported values for these compounds are (1, 5): $CuGaTe_2$ $a = 6.006$Å, $c/a = 1.987$; $AgInTe_2$ $a = 6.419$Å; $c/a = 1.962$, $E_g = 0.96$ ev.

To check the behavior of these ternary compounds, they were annealed at various temperatures similar to those to be used when the alloys were annealed. It was found that when $CuGaTe_2$ (mp 870°C) was annealed at 750°C a second phase began to appear. Although it was difficult to detect the presence of this phase with the x-ray powder photographs, the results of both photomicrographic analysis and optical absorption measurements showed its presence. Even in the quenched state, a number of small needle-like inclusions were observed; on annealing at 750°C these inclusions grew, and then the second phase was observed to segregate out at the grain boundaries and to cause large cracks. Correspondingly, the quenched sample gave a normal absorption curve with an absorption edge at an energy of 1.17 ev, but after the sample was annealed at 750°C, a broad absorption peak appeared on the low energy side of the absorption edge at photon energies of about 0.7-0.9 ev, and the magnitude of this peak increased with continued annealing. When the $CuGaTe_2$ was annealed at lower temperatures (*e.g.*, 400°C), no growth of a second phase was observed in the photomicrographs beyond the small inclusions of the quenched state, and the optical absorption curve did not change with annealing from that for the quenched material.

The behavior of $CuGaTe_2$ appears similar to that observed for $AgSbTe_2$ which shows a precipitation of Sb_2Te_3 (14) on zone melting. However the precipitated phase in $CuGaTe_2$ would not appear to be Ga_2Te_3 as this has too high an energy gap to produce the observed I.R. absorption peak.

When $AgInTe_2$ (mp 680°C) was annealed at 600°C, no changes in behavior could be detected from that for the quenched material. However when samples were annealed at 400°C for 10 days, photomicrographs showed the appearance of a second phase (possibly tellurium) at the grain boundaries. In an x-ray photograph of this material the value of the lattice parameter a_0 (6.455Å) was found to be a little higher than that for the samples quenched and annealed at 600°C.

Thus neither of the ternary compounds were found to be stable over the whole temperature range from room temperature to melting point, $CuGaTe_2$ being

[1] Present address: Texas Instruments Inc., Dallas, Texas.

definitely unstable at 750°C and $AgInTe_2$ apparently showing a precipitated phase when annealed at 400°C. As the main interest of the work was in the semiconducting properties of the materials and not in phase diagram data, the ternary compounds were not investigated further. However, as is indicated in the next section, it was found that over a considerable range of composition, the solid solutions in CdTe could be retained in a homogeneous single phase condition. The properties of these alloys were therefore investigated further.

Properties of the Alloys

In all cases the alloys were prepared by melting together the appropriate amounts of CdTe and the ternary compound concerned, and then quenching in water. Such samples showed blurred x-ray lines, were generally in nonequilibrium condition and needed annealing to give equilibrium.

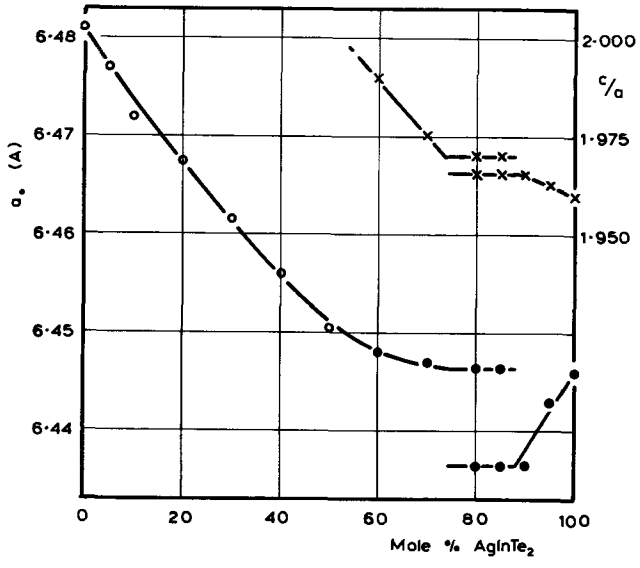

Fig. 1. Variation of lattice parameters with composition for CdTe-$AgInTe_2$ alloys: ○ zinc blende a_0; ● chalcopyrite a_0; X chalcopyrite c/a.

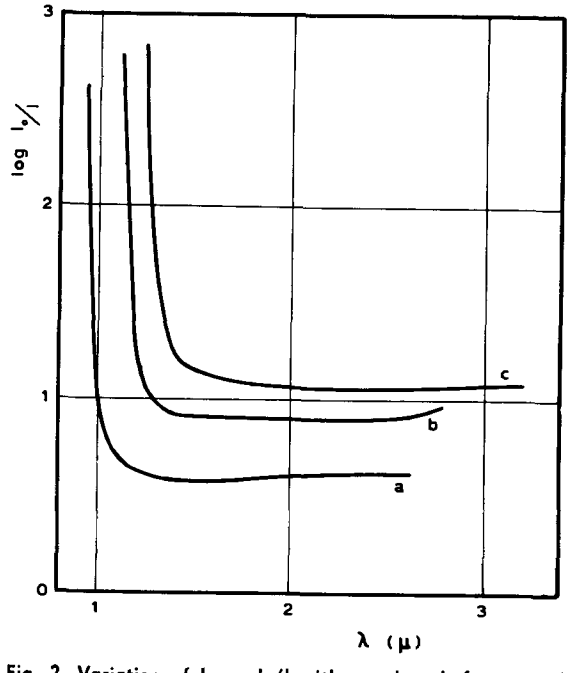

Fig. 2. Variation of $\log_{10} I_0/I$ with wavelength for transmission measurements on typical CdTe-$AgInTe_2$ alloys. Curve a, 90 mole % CdTe 10 mole % $AgInTe_2$; curve b, 60 mole % CdTe 40 mole % $AgInTe_2$; curve c, $AgInTe_2$.

CdTe-$AgInTe_2$.—Alloys were made up at 10 mole % intervals across the composition range plus extra specimens at 5, 85, and 95 mole % $AgInTe_2$.[2] All alloys were annealed initially at 600°C. Samples in the range 0-50 mole % $AgInTe_2$ were in good equilibrium condition after annealing for 30 days, but those in the range 60-95 mole % $AgInTe_2$ needed 60-90 days of annealing to obtain equilibrium. The values of lattice parameter for the alloys are shown in Fig. 1. From 0 to 50 mole % $AgInTe_2$, the alloys were single phase with zinc blende structure, while from 60 mole % onward the structures were chalcopyrite. The 60, 70, 90, and 95 mole % alloys were single phase, but the 80 and 85 mole % alloys were two phase, both phases having chalcopyrite structure. The 70 and 80 mole % alloys were then annealed for 30 days at 400°C. Both then showed the same two phase behavior. Thus the miscibility gap is wider at lower temperatures.

Optical absorption measurements were made on samples of all single phase alloys, samples of thickness in the range 100-200μ being used. Typical absorption curves are shown in Fig. 2, and the resulting values of the optical energy gap E_g are shown in Fig. 3. It is seen that the value of E_g varies smoothly with com-

[2] In calculating mole %, CdTe has been treated as Cd_2Te_2.

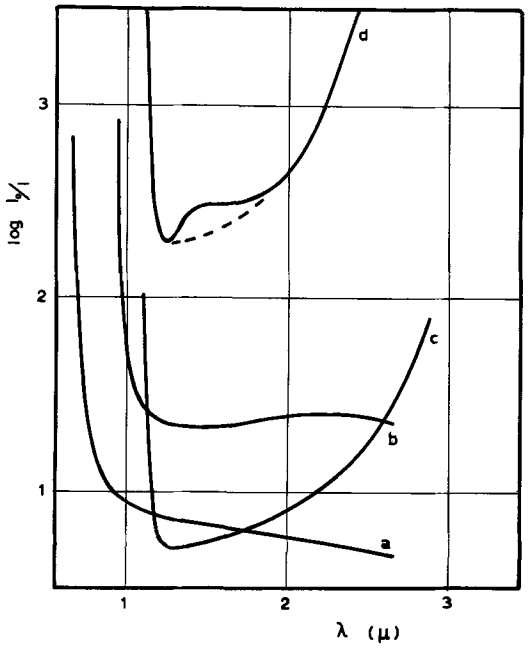

Fig. 5. Variation of $\log_{10} I_0/I$ with wavelength for transmission measurements on typical CdTe-$CuGaTe_2$ alloys. Curve a, CdTe; curve b, 90 mole % CdTe 10 mole % $CuGaTe_2$; curve c, 70 mole % CdTe 30 mole % $CuGaTe_2$; curve d, 50 mole % CdTe 50 mole % $CuGaTe_2$.

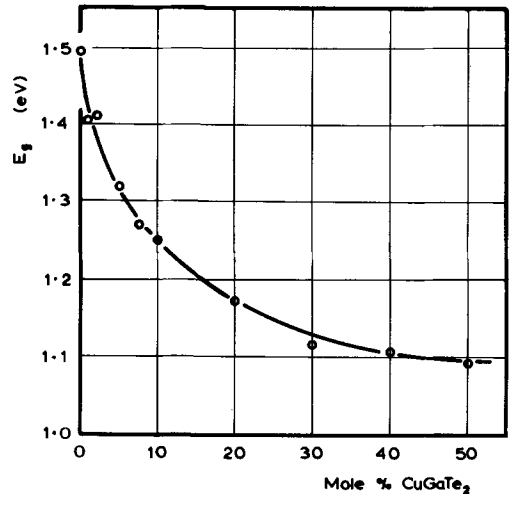

Fig. 6. Variation of optical energy gap E_g with composition for CdTe-$CuGaTe_2$ alloys.

position and that the onset of ordering in the chalcopyrite structure has little effect on the value of E_g.

CdTe-$CuGaTe_2$.—Again alloys were made up at 10 mole % intervals across the composition range plus alloys at 5 and 95 mole % $CuGaTe_2$. Samples of all alloys were annealed at 750°, 650°, and 350°C. The x-ray results obtained were the same for all three temperatures, and again annealing times of 30-60 days were needed at the higher temperatures to produce good equilibrium conditions. Values of lattice parameter are shown in Fig. 4. It is seen that single phase solid solution in the zinc blende phase occurs out to the 60 mole % $CuGaTe_2$ alloy, but that the 70, 80, 90, and 95 mole % alloys were two phase. The optical absorption curve of the 50 mole % alloy (Fig. 5) showed a small absorption peak on the low energy side of the absorption edge, indicating the presence of a small amount of second phase. Thus, despite the x-ray data shown in Fig. 4, this sample would not have been completely single phase, probably because of incomplete approach to equilibrium.

Because of the problems of stability in $CuGaTe_2$ described above, no attempt was made to investigate further the alloys containing more than 50 mole %. $CuGaTe_2$ or to determine any small range of solubility in the chalcopyrite structure, which would clearly be less than 5 mole %.

Optical absorption measurements were made on samples in the composition range 0-50 mole % $CuGaTe_2$, the samples again being of thickness in the range 100-200μ. Typical absorption curves are shown in Fig. 5, and the resulting variation of E_g is shown in Fig. 6.

Summary

1. As with other ternary chalcogenides (14, 15), complications are caused by the instability of the compounds. Thus, while $AgInTe_2$ is more stable than $CuGaTe_2$, even in the former there appears to be some segregation to grain boundaries with annealing at 400°C. Zalar (15) observed similar behavior in $CuInTe_2$.

2. In each case, a wide range of solid solution occurs in the relatively stable zinc blende type structure. The form of Fig. 1 and 4 indicates that pseudobinary conditions probably apply in the two sections investigated.

3. In the optical energy gap results, for both systems the value of E_g drops rapidly as ternary compound is added to CdTe, and then the E_g *vs.* composition curve levels out. Over the range 0-30 mole % ternary for the two cases, the curves of E_g *vs.* composition coincide within the limits of experimental error. This variation in E_g is very similar to that for the ZnS-$CuGaS_2$ system (10). The rapid fall in E_g is probably due to the weaker bonding in the ternary chalcogenides.

Acknowledgments

The authors wish to thank Dr. J. Warner for some preliminary x-ray investigations.

Growth of Vanadium on Silicon Substrates

K. J. Miller, M. J. Grieco, and S. M. Sze

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Vanadium has been grown on (111) oriented silicon substrates using the hydrogen reduction of VCl_4. The reaction kinetics related to the growth of the deposits has been investigated. V-Si diodes fabricated from the deposited vanadium on silicon samples were found to have a barrier height of 0.70 ± 0.04v in agreement with that theoretically predicted in other studies.

Recent interest in the chemical deposition of metals on semiconductor substrates has been stimulated by potential applications in the fabrication of diodes and metal-base transistors. Deposition of molybdenum on silicon has been reported by Casey *et al.* (1) and Lindmayer (2); the latter author reported that 100Å thick molybdenum layers on silicon were not single crystal. Crowell *et al.* (3) have reported deposition of polycrystalline tungsten films on silicon, germanium, and gallium arsenide substrates. The purpose of this paper is to present data on the growth of vanadium on silicon substrates and to study the feasibility of V-Si diode fabrication from these structures.

A schematic diagram of the deposition apparatus used is shown in Fig. 1. The deposition apparatus was the vertical reactor, RF-heated type, conventionally used for the hydrogen reduction of silicon tetrahalides (4). The VCl_4 was prepared by the reaction between vanadium and chlorine. The chlorine was passed over vanadium at 800°-1000°C. The chlorine was purified by passing it through graphite heated to 650°C. The VCl_4 was condensed at 0°C in a cold finger for subsequent controlled vaporization in a purified hydrogen flow. During deposition, hydrogen was passed over the VCl_4 at the rate of 0.5 l/min and another 4 l/min flow of hydrogen bypassed the cold finger and flowed into the reactor. The VCl_4 partial pressure was controlled by thermostating at temperatures from −15° to 25°C. The VCl_4 vapor pressure values used for calculating partial pressures of VCl_4 were obtained by extrapolating the data of Simons and Powell (5) below 39.5°C. It was assumed that the only significant compound formed from the V-Cl_2 reaction was VCl_4. The vanadium was obtained from Gallard-Schlesinger Chemical Corporation and was 99.9%. Silicon substrate samples were 1.5 ohm-cm, n-type single crystal wafers oriented in the (111) plane and were electrochemically polished. Over-all deposited thickness was determined by masking a portion of the substrate with a silicon chip and measuring the resulting step in the vanadium deposit with a Zeiss interference microscope. Vanadium was deposited with an over-all average thickness up to 10μ.

Variables affecting the deposition rate of vanadium which have been studied are the silicon substrate temperature and the partial pressure of VCl_4. The effect of temperature was studied between 1140° and 1300°C at a VCl_4 partial pressure of 0.2 Torr. For study of the variation of deposition rate with partial pressure variation, the VCl_4 was varied between 0.08 and 0.9 Torr, and silicon substrate samples were held at 1300°C. Figure 2 shows the variation of the vanadium deposition rate with temperature. The kinetic data for the deposition rate between 1140° and 1300°C could be fitted to an Arrhenius type equation

$$r = Ae^{-\Delta H_a/RT}$$

where ΔH_a, the apparent activation energy for the over-all reaction, was 72 ± 2 kcal/mole.

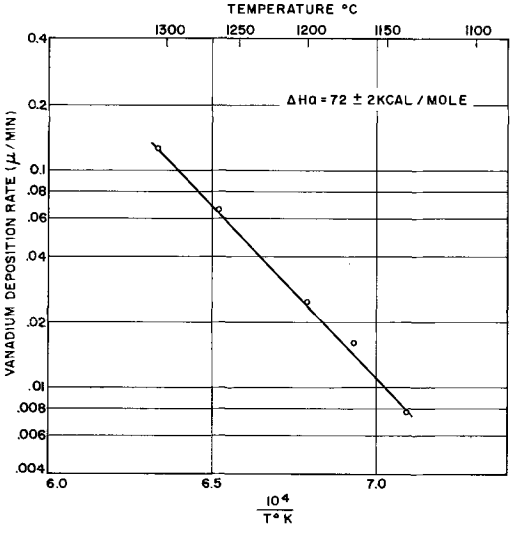

Fig. 2. Temperature dependence of vanadium deposition at 0.2 Torr VCl_4 pressure.

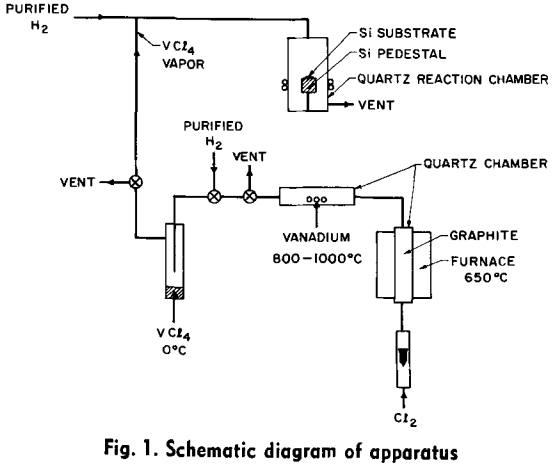

Fig. 1. Schematic diagram of apparatus

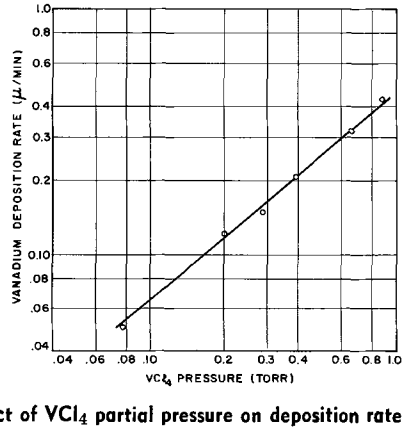

Fig. 3. Effect of VCl_4 partial pressure on deposition rate at 1300°C

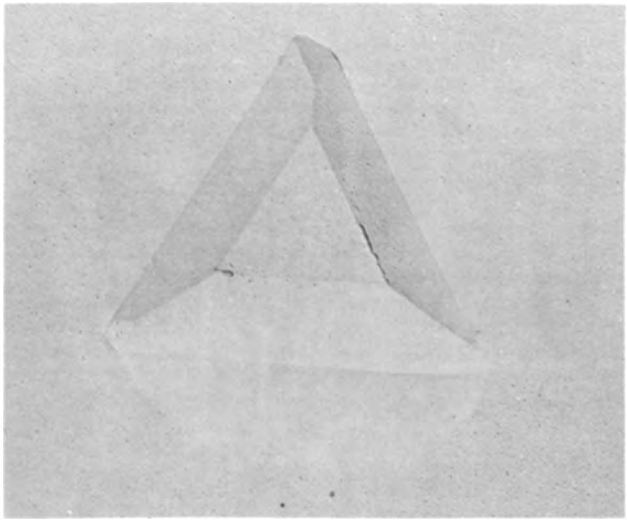

Fig. 4. Electron micrograph of deposited vanadium crystallite. Magnification 8000X.

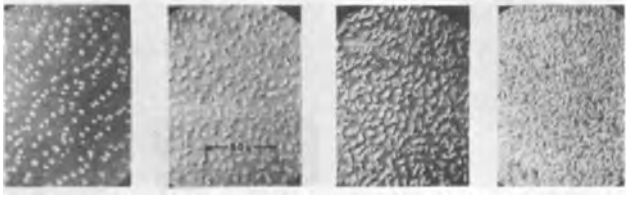

Fig. 5. Micrographs showing increasing density of deposited vanadium crystallites for average deposit thickness from 1 to 5μ (left to right).

Figure 3 shows the effect of the partial pressure of VCl_4 on the deposition rate of vanadium. Over the pressure range studied the deposition rate obeyed a relation of the type

$$r = kp^n_{VCl_4}$$

The slope of the deposition rate-pressure line in Fig. 3 gives a value of $n = 0.9$, indicating that the deposition reaction is close to first order. It can be assumed that the low partial pressures of VCl_4 used favor a heterogeneous reaction. Tyzack and England (7) have concluded that the following reduction reaction of VCl_2 to form vanadium is rate-controlling

$$VCl_2 + H_2 \rightarrow V + 2HCl$$

Their conclusion is apparently based on the increasing positive value of $\Delta G°$ with decreasing temperature below about 1250°C.

Vanadium crystal growth was observed to take place by island formation similar to that observed by Manasevit *et al.* (6) for epitaxial silicon growth on sapphire. The surface deposits were analyzed for vanadium by an electron probe microanalyzer. The electron probe used for these studies was a Microscan, manufactured by the Cambridge Instrument Company. This scanning type electron probe permitted two-dimension displays of the sample surface and showed the deposits to be vanadium particles or clusters. Transmission electron diffraction patterns obtained from vanadium deposited surfaces indicate that the vanadium crystallites are of the same (111) orientation as that of the silicon substrate and are single crystalline. No evidence of silicides was observed. Figure 4 shows a typical vanadium crystallite as viewed by electron microscopy. Optical microscopic examination of vanadium deposited surfaces showed that the deposits consisted of an array of discrete vanadium crystallites. Vanadium crystallite density varied with the over-all average depth of deposited vanadium. Figure 5 shows this density variation, for average depth of deposit from 1μ increasing to 5μ.

Vanadium-silicon diodes were made from vanadium which was deposited approximately 10μ thick and which covered approximately 80% of the silicon surfaces. The diodes were made using the procedure previously described for tungsten-silicon diodes (3): Au-Sb ohmic contacts were alloyed to the back surface of the silicon substrates at 370°C, 10 mil diameter gold dots were evaporated on the deposited vanadium surface, and samples were etched in 10:1 HNO_3:HF to remove vanadium from the unmasked areas. Because the substrate temperature during vanadium deposition is 100°C lower than the V-Si eutectic temperature, and diffraction studies did not show silicide formation, the junction is believed to be of the nonalloyed type. Current-voltage and capacitance-voltage measurements were used to investigate the V-Si diode characteristics. Typical forward current density-voltage plots are shown in Fig. 6. These curves can be fitted by the diode equation (8)

$$J = J_s[e^{(qV_a/nkT)} - 1]$$

where V_a is the voltage applied across the junction, n is an empirical constant, and J_s is the saturation current density. The value of n obtained from Fig. 6 is about 1.1 for current densities ranging from 10^{-4} to

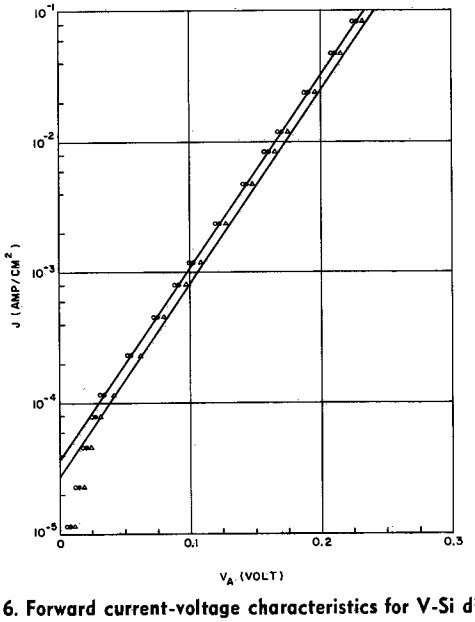

Fig. 6. Forward current-voltage characteristics for V-Si diodes

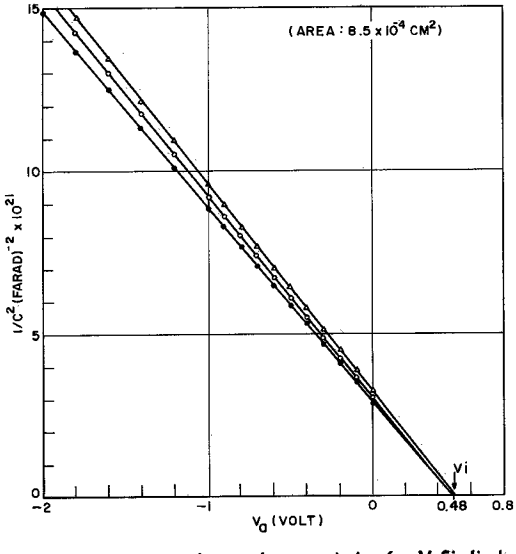

Fig. 7. Capacitance-voltage characteristics for V-Si diodes

10^{-1} amp/cm^2. The value of J_s is $(3.0\text{-}3.6)\times10^{-5}$ amp/cm^2. The barrier height, Φ_B, was found to be 0.70 ± 0.04v based on the assumption that the Richardson equation

$$J_s = A^*T^2e^{(-q\Phi_B/kT)}$$

can be used to relate the barrier height, Φ_B, and J_s (3). A theoretical value of A^*, 258 amp/cm^2/K^2, has been used (9). The J_s is the sum of the currents for V-Si and Au-Si diodes, because, as discussed above, approximately 80% of the areas are covered by vanadium and 20% covered by gold. However, the barrier height of Au-Si diode is about 0.80v (10) which is 0.1v higher than the presently measured barrier height. The correction in Φ_B of V-Si diode is less than 0.025v. The reverse characteristics of the diodes were qualitatively consistent with the diode equation with a reverse current density of the order of 10 ma/cm^2 at 10v.

Capacitance-voltage measurements on V-Si diodes are shown in Fig. 7. The doping level, N_D, determined from resistivity measurement, was 3.8×10^{15} cm^{-3}, and from the slope of the $1/C^2$ *vs.* V_a plot 4.3×10^{15} cm^{-3}. The barrier height can also be determined from the data in Fig. 7 by use of the equation (3, 11)

$$\Phi_B = V_i + V_f + kT/q - \Delta\Phi$$

where V_i is the voltage intercept, 0.48 ± 0.04v, V_f, the depth of the Fermi level below the conduction band, is 0.288v for 1.5 ohm-cm, n-type silicon, and $\Delta\Phi$ is the image force barrier lowering (12), approximately 15 mv for V-Si diodes. Thus Φ_B was found to be 0.71 ± 0.04v. Since the measured capacitance over the voltage range will only be affected by the combined diode system to less than 2%, the correction for Φ_B of V-Si diode is again of the order of 0.025v.

The consistency of the value of the barrier height obtained from the above measurements and the fact that n is close to unity and $1/C^2$ is linearly dependent on V_a indicate the existence of a Schottky junction. The barrier height obtained in this study has been found to be in reasonable agreement with that predicted theoretically by Cowley and Sze (13) based on the assumptions that the contact between the metal and the semiconductor has an interfacial layer of the order of atomic dimension and the surface state density at the interface is a property only of the semiconductor surface.

Selective Epitaxial Deposition of Gallium Arsenide in Holes

Don W. Shaw

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Epitaxial deposition of gallium arsenide in holes etched into gallium arsenide substrates was investigated. Single crystal deposits with excellent surfaces were obtained. The effect of substrate orientation on the degree of lateral overgrowth above the substrate surface was studied. Depositions in {100} oriented substrates produce faceted deposits, whose upper surfaces are several microns above the substrate surface. Epitaxial hole deposits with surfaces level with or nearly level with the substrate surface are obtained with accurately oriented {111}-B substrates.

The importance of selective epitaxial deposition has long been realized in integrated circuit technology. Generally the technique involves epitaxial deposition onto the substrate only in certain areas which are exposed by windows in a protective film (*e.g.*, SiO_2). This technique has been investigated both for silicon (1) and gallium arsenide (2) substrates.

Extension of the technique to include selective depositions in substrate holes has not been widely reported. The investigations which have been reported, such as the recent studies by Jackson (3), have been directed toward the epitaxial deposition of silicon in holes etched into a silicon substrate. However, the selective deposition of gallium arsenide in substrate holes has been generally neglected.

Due to the availability of semi-insulating gallium arsenide, the three-dimensional integrated circuit or functional electronic block has become increasingly promising (4). In view of this as well as the accelerating importance of integrated circuits in general, an investigation of the nature of epitaxial deposition of GaAs in substrate holes was undertaken.

Experimental

Both semi-insulating (Cr doped) and n-type (Te doped) gallium arsenide substrates were employed. The crystals were x-ray oriented and cut into 25 mil thick slices, which were then polished with a sodium hypochlorite solution according to the method of Reisman and Rohr (5). Either {100} or {111}-B surfaces

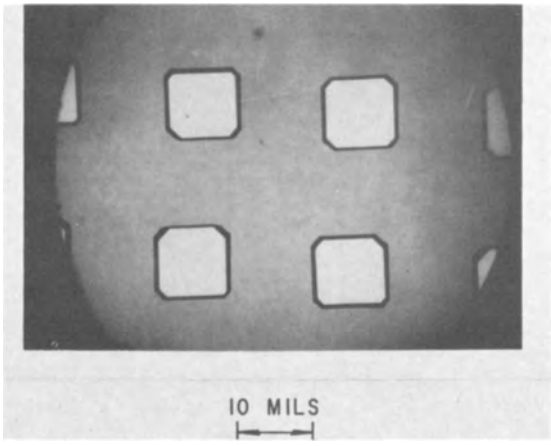

Fig. 1. Epitaxial deposits of GaAs in 8 x 10 mil holes etched ~ 15μ deep into a {100} GaAs substrate.

were utilized for all depositions. The slices were coated with protective SiO_2 layers by pyrolysis of tetraethyl orthosilicate in an evacuated system. Generally the SiO_2 thicknesses varied between 2500 and 4000Å.

Windows were formed in the SiO_2 films by masking with photoresist (Kodak Metal-Etch Resist) and etching away the unmasked areas. Then holes were formed in the substrate at the areas exposed by the windows. Three techniques were used to form the substrate holes: (*i*) etching with a Br_2:CH_3OH (1:1000) solution at room temperature; (*ii*) etching with a H_2SO_4:H_2O_2:H_2O (5:1:1) solution at 65°C; and (*iii*) vapor etching with HCl at 850°C in the epitaxial deposition reactor. The method of hole formation did not have a significant effect on the appearance of the final deposit.

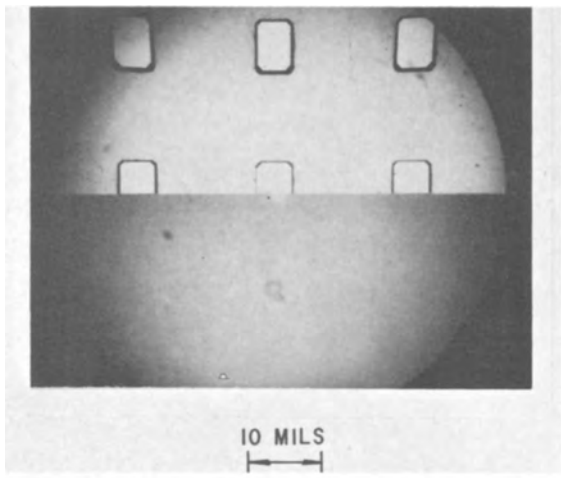
The deposition process utilizes a vapor phase reaction of Ga and GaAs with $AsCl_3$ in an open flow system similar to that previously described (6, 7). The source temperature was maintained at 825°C, while the temperature of the substrate zone was varied between 750°-780°C. The substrate temperature was adjusted experimentally to the point that the deposition was so selective that no extraneous GaAs deposits were obtained on the reactor walls or the protective SiO_2 mask. The $AsCl_3$ flux was 1.0 x 10^{-4} mole/min, while the total gas flow ($AsCl_3$ + H_2) amounted to 380 ml/min. Under these conditions the {111}-B was found to be the slowest growing orientation.

Results and Discussion

Figure 1 illustrates typical deposits of epitaxial GaAs in holes etched into a {100} substrate. The upper {100} surfaces are very smooth, and the single crystal character of the deposits is indicated by the presence of facets. The deposits shown in Fig. 1 have an average height above the substrate surface of 27μ while the original hole depths averaged 15μ.

In order to investigate the crystallography of the {100} deposits, slices were cleaved along the {110} cleavage planes so that cross sections of the deposits were revealed (Fig. 2). Measurements of the interfacial angles between the {100} upper surface and the two side facets such as revealed in Fig. 2b yield values of 55° for each side. Although occasionally side facets which were perpendicular to the upper {100} surface were observed in the cleavage cross sections, by far the greatest majority of the side facets were inclined at an angle of 55° with the upper surface. Since the (111)-(100) interplanar angle is 54°44′, it indicates that four of the slow growing side facets (*i.e.*, the ones revealed by {110} cleavage cross sections) in {100} oriented deposits are {111} faces.

There are only two cleavage planes perpendicular to the surface of {100} oriented slices. Thus it is impossible to determine the angles between the remaining four side facets (the "corner" facets in Fig. 1 and 2) and the upper {100} surface by measurement of a cleavage cross section through them. The direction of the axes of intersections of the corner facets and the {100} upper surface is 45° from the axis of intersection of the {111} side facets and the upper surface.



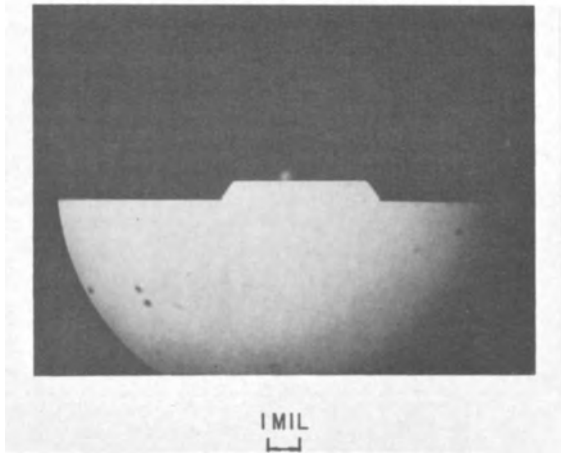


Fig. 2a (top). Epitaxial GaAs deposits in {100} GaAs substrate showing relative position of {110} cleavage plane.

Fig. 2b (bottom). Cross-sectional view along cleavage plane of center deposit shown in upper micrograph.

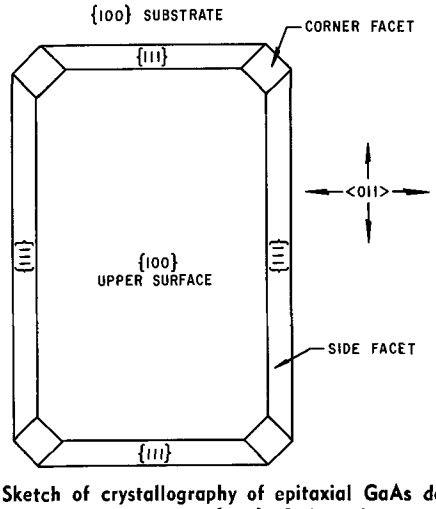

Fig. 3. Sketch of crystallography of epitaxial GaAs deposits obtained from holes etched into {100} GaAs substrates.

This indicates that {110} would be a likely orientation for the remaining four facets. Due to the inclined nature of the side and corner facets, prolonged deposition in holes etched in a {100} substrate should produce deposits with a pyramidal morphology. The crystallography of these deposits in {100} substrates is summarized by Fig. 3.

The tendency of {100} substrates to form deposits bounded on the sides by these well-defined facets results in a novel phenomenon if the hole walls are not oriented parallel to the {110} cleavage planes. This is illustrated by Fig. 4, where each of the deposits appears to have been rotated about an axis perpendicular to the {100} surface when compared with the shape of the original holes. However if the hole walls are oriented parallel with the {110} cleavage planes, no apparent rotation occurs (Fig. 3). The apparent rotation is due to the fact that the {100}-{111} zone axes (<110>) are in the same directions as the directions of the {110} cleavage planes. Thus if the hole walls are oriented at an angle with respect to the direction of the {110} cleavage planes, then the axes of intersection of the surface facet and the {111} side facets in {100} oriented substrates will be tilted at the same angle with respect to the hole walls and the deposit will appear to have "rotated" when compared with the original holes. In addition, misalignment of the hole walls from <110> directions will result in enhanced sizes of the corner facets relative to the sizes of the {111} side facets and an increased lateral overgrowth over the mask. Such a variation in the size ratios of the corner and side facets is evident from a comparison of Fig. 2 and 4.

Deposition in {111}-B substrates was investigated in an attempt to obtain deposits with upper surfaces level with or nearly level with the substrate surface by taking advantage of the slow growth characteristics of {111}-B faces. Initial deposits had excellent surfaces which were tilted from 3° to 6° with respect to the substrate surfaces (Fig. 5). Careful x-ray orientation studies revealed that the substrates themselves were slightly misoriented from the <111> direction by an amount equal to the surface tilt of the epitaxial deposit, indicating that the upper surface was indeed a {111}-B facet. In each deposit the lowest portion of the surface facet was flush with the substrate surface. This indicated that deposits with surfaces level with the substrate surface could be expected with accurately oriented {111}-B substrates.

Additional substrates were very precisely x-ray oriented in the <111> direction, and each slice was checked after polishing. The resulting substrates were oriented to <0.5° from the <111> direction. Deposits in holes etched into these substrates produced very flat deposits (Fig. 6) with heights above the substrate surface of $<2\mu$.

Comparison of the {111} deposits with the original holes revealed that some lateral overgrowth occurred. Since the upper {111}-B facet is a very slow growing surface in GaAs, prolonged deposition should result in overgrowth in a lateral direction over the SiO_2 film. Indeed considerable lateral overgrowth has been ob-

served (2) on <111> oriented GaAs exposed in windows formed in a protective SiO_2 film.

The upper surfaces of the epitaxial hole deposits are highly reflective and are considerably smoother than the usual large area epitaxial deposits. Although the latter may appear smooth under ordinary microscopy conditions, they usually exhibit growth steps when examined with an interference contrast microscope. However, these steps are only rarely observed on the upper surfaces of the hole deposits. This surface quality difference may be explained in terms of the relative upper surface areas available for growth. As shown in Fig. 7b and 7c, as epitaxial growth proceeds over a large area, growth steps are formed whose propagation effectively results in growth perpendicular to the substrate surface. However the step at the extreme left edge in Fig. 7b increases in area as growth progresses (Fig. 7c), since no "macroscopic" steps are growing over it. This results in a small surface facet at one edge of the large area epitaxial deposit. Such facets are observed experimentally on large area deposits.

During deposition in holes, the upper surface areas are restricted by the sizes of the holes. Thus when the hole is filled a relatively small upper surface area (<100 sq mils) is available for growth. In this case the growth steps propagate across the entire upper surface of the hole deposit (Fig. 7d and 7e). This results in very smooth upper surfaces or facets. Since these growth facets correspond to low-index planes, the upper surfaces will be tilted with respect to the substrate surface by an amount equal to the degree of substrate misorientation (Fig. 5). In view of this it is not surprising that smooth and highly reflective upper surfaces are obtained independently of the roughness or irregularity of the hole bottoms or walls. The substrate holes formed by vapor etching quite often had very rough sides and bottoms, but the epitaxial deposits in these holes inevitably possessed excellent faceted surfaces. This is significantly different from the usual epitaxial deposition where the surface quality of the substrate is of extreme importance to the quality of the deposit. Of course such an independence between the appearance of the deposit surfaces and the original hole surfaces would be realized only when the growth conditions tended to produce faceted deposits.

Although accurate growth rate comparisons between growth in holes and ordinary surface growth were not made, in general, less time is required to fill a hole of a given depth than to grow an ordinary surface layer of the same thickness. This may be related to the fact that growth in holes proceeds from the walls inward as well as from the bottom upward. Due to this growth mechanism, "incomplete" depositions result in deposits with cavities or depressions in the upper surfaces such as shown in Fig. 8. As illustrated by Fig. 8, the shape of the depressions depends on the substrate orientation. For example, holes etched into {111}-B substrates (Fig. 8c) tend to fill primarily from the walls inward with relatively little growth from the bottom upward. A similar phenomenon was observed by Gabor (8) with deposition of GaAs in channels etched into Ge crystals. Although the interiors of the cavities in Fig. 8a and 8b are rough and irregular, the partially formed upper surface facets are very smooth. This illustrates the phenomenon of obtaining smooth upper surfaces regardless of the irregularity of the original hole surfaces.

The selection of the slowest growing orientation as the substrate orientation allows close control of the amount of deposition. Holes etched to a given depth in accurately oriented {111}-B GaAs substrates fill rapidly until the slow-growing {111}-B surface facet is formed, whereupon the deposition rate drops considerably. Such a phenomenon allows one to fill holes of different depths during the same deposition and obtain surfaces which are nearly even with the substrate surface for each of the deposits.

Summary

It has been shown that excellent epitaxial deposits can be obtained in holes etched into GaAs substrates. The growth proceeds from the walls inward and from the bottom upward so as to form a cavity in incompletely filled holes. Depositions in holes etched into {100} substrates produced deposits whose upper surfaces were somewhat above the substrate surface. However these deposits were bounded on the sides by well-defined facets which tended to prevent extensive lateral overgrowth. Epitaxial deposition in accurately oriented {111}-B substrates yielded deposits with very flat {111}-B upper surfaces which were nearly level with the substrate surface. Prolonged depositions in {111}-B holes did not produce deposits with significant heights above the substrate surface; although some lateral overgrowth was observed.

Acknowledgments

The author wishes to express grateful appreciation to Mr. E. W. Mehal of this laboratory for his helpful discussions and encouragement, and to Mr. I. A. Sessions for his assistance in the experimental work.

This work was supported by the Air Force Avionics Laboratory, Research and Technology Division, Air

Force Systems Command, Wright-Patterson Air Force Base, Ohio, under Contract AF 33(615)-1275.

Manuscript received Feb. 21, 1966; revised manuscript received May 23, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

High-Temperature Oxidation

III. Zirconium and Hafnium Diborides

Joan B. Berkowitz-Mattuck

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

The oxidation of zone melted specimens of ZrB_2 and HfB_2 was studied at temperatures of 1200°-2000°K and at oxygen partial pressures of 1-700 Torr in helium. Parabolic rate behavior was observed. For ZrB_2 above 1400°K an activation energy of 77 ± 5 kcal/mole was determined. Below 1400°K the activation energy is much lower, and the mechanism of oxidation is different, probably because of the presence of boron oxide in the condensed phase. Below 1300°K, the parabolic rate constant appears to be directly proportional to oxygen partial pressure; at 1830°K, the rate constant is independent of oxygen pressure. For HfB_2 in the range 1480°-1870°K an activation energy of 47 ± 4 kcal/mole was observed. Around 1970°K, the transition temperature for the monoclinic to tetragonal phase change in HfO_2, there is a sharp increase in the rate of oxidation. The parabolic rate constant for total oxygen consumption increases as the 0.4 ± 0.1 power of the oxygen partial pressure at 1630° and 1760°K.

The oxidation of ZrB_2 was studied by Brown in the temperature range 649°-1315°C in pure oxygen and moist dry air (1). Since Brown worked with porous compacts of the diboride, his initial surface areas are unknown, and undoubtedly changed due to sintering during the course of exposure at high temperatures. He was able to conclude qualitatively that ZrB_2 is oxidized more rapidly in oxygen than in dry air in the range 650°-1100°C, and much more rapidly in moist air than in dry at 650°C.

Samsonov (2) oxidized ZrB_2 in air at 1000°C and measured a depth of corrosion of 0.45 mm after 150 hr. For material of theoretical density, this would correspond to stoichiometric oxidation of 0.274 g/cm² of the alloy, or to a total oxygen consumption of 0.0873 g/cm². The net weight change cannot be computed since an unknown portion of the $B_2O_3(l)$ must certainly have evaporated during the experiment. From metallographic examination of the oxide scale, Samsonov postulated the existence of ZrO(s) immediately adjacent to the alloy and a molten layer of B_2O_3 at the surface of the oxidized specimen. He assumed that, with increasing time of exposure, oxygen would diffuse through the $B_2O_3(l)$ to the alloy and react with ZrO(s) to form $ZrO_2(s)$, while at the same time B_2O_3 would vaporize gradually.

More recently, the oxidation of ZrB_2 was studied by Kuriakose and Margrave (3), who measured net weight change of fully dense samples with time, at temperatures of 1218°-1529°K and oxygen pressures between 100 and 760 Torr. They were able to fit their data to a parabolic rate law, with an activation energy for net weight gain of 19.8 ± 1.0 kcal/mole. The oxidation rate was independent of carrier gas flow rate and directly proportional to the oxygen partial pressure in helium.

No quantitative data have been reported in the literature for the oxidation of HfB_2. Samsonov exposed HfB_2 in air in a series of screening experiments and reported intensive oxidation above 600°-700°C and disintegrative oxidation at 1000°-1200°C (4).

The present work was undertaken to obtain data on the oxidation of ZrB_2 over a wider temperature and pressure range than that covered in previous studies, and to compare the oxidation of ZrB_2 and HfB_2 experimentally. In addition, in order to evaluate the effect of B_2O_3 volatility on the oxidation of ZrB_2, several measurements of total oxygen consumption were made under conditions for which Kuriakose and Margrave (3) had obtained net weight change data.

Experimental Method and Data Analysis

Samples of ZrB_2 were synthesized by the zone melting technique described by Westrum and Feick (5). Hafnium diboride was prepared by the same technique with a high-purity powdered starting material supplied by Wah Chang Corporation. The resultant zone refined bars contained less than 0.1% of zirconium.

The procedure for the oxidation experiments has been described in detail in earlier publications (6, 7). The only essential change necessitated in the work with borides was the substitution of platinum or rhodium support rods for the Al_2O_3 or ThO_2 fingers used previously. The B_2O_3 formed in the oxidation of diborides reacts with refractory oxides. Platinum was suitable for sample temperatures up to 1600°C; rhodium was required for higher temperature runs.

Specimens in the form of pellets, 0.3 cm long and 0.7 cm in diameter, were polished through diamond dust, cleaned, and degassed in helium prior to oxidation. A thermal conductivity apparatus was used both to monitor degassing and to measure the net oxygen consumed during the oxidation of inductively heated samples in a stream of helium and oxygen at a total pressure of one atmosphere.

A degassing temperature of about 1870°K was employed, and heating was continued until the signal from the monitoring thermal conductivity bridge in-

dicated a cessation of permanent gas evolution (approximately 30 min). Net weight changes during the degassing period were always less than 2 x 10^{-4} g. Temperatures were read with a Micro-Optical pyrometer, and were corrected for sample emissivity (assumed equal to 0.6) and the measured transmission characteristics of the optical system. A spectral emissivity of 0.6 ± 0.1 was measured early in the program both in inert and oxidizing atmospheres by comparing observed temperatures of diboride surfaces with observed temperatures of a black body cavity drilled ultrasonically in the samples. Within experimental error the measured emissivity did not vary enough during oxidation to affect the necessary correction factor appreciably. The variation in measured temperature during an experiment is about ±5°C. A carrier gas flow rate of 95 cc/min was used in most experiments, corresponding to a linear flow velocity in the neighborhood of the sample pellet of about 3.1 cm/sec.

In the oxidation experiments, a helium-oxygen stream is passed through the reference cell of a thermal conductivity bridge and over an inductively heated sample pellet which removes some of the oxygen by reaction. The gas stream, depleted in oxygen, is passed through the sampling cell of the thermal conductivity bridge. The reference and sampling cells form two arms of a Wheatstone bridge, whose output is continuously recorded. The signal obtained is proportional to the difference in oxygen partial pressure or gas density in the two cells. Since the measurements are carried out in an open flow system, the total pressure is everywhere close to 1 atm. Thus, when an experiment is run in pure oxygen, a zero signal is obtained, in spite of the fact that oxygen is consumed.

The output from the bridge, S, in millivolts is proportional to the difference in oxygen density in g/cc ($\rho_1 - \rho_2$) in the reference and sampling cells, respectively.

$$S = k\,(\rho_1 - \rho_2) \qquad [1]$$

where k is a proportionality constant. Since oxygen is consumed, the flow rates in the two cells must be different. If v_1 (cc/min) is the flow rate through the reference cell and v_2 is the flow rate through the sampling cell, then the desired rate of oxygen consumption by the sample under investigation, dm/dt (g/cm²-min) is given by

$$dm/dt = (\rho_1 v_1 - \rho_2 v_2) \qquad [2]$$

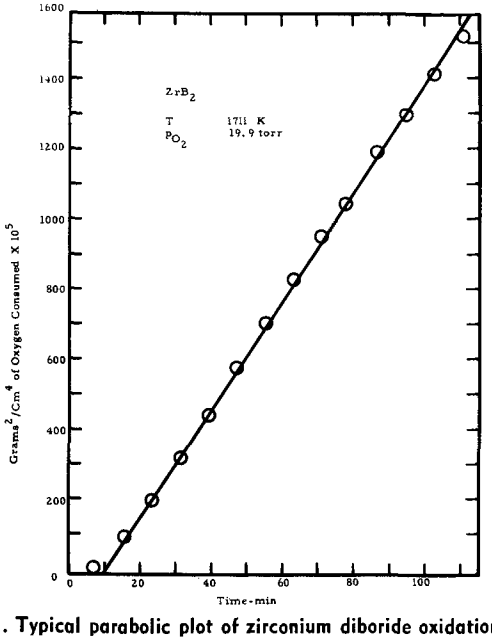

Fig. 1. Typical parabolic plot of zirconium diboride oxidation data

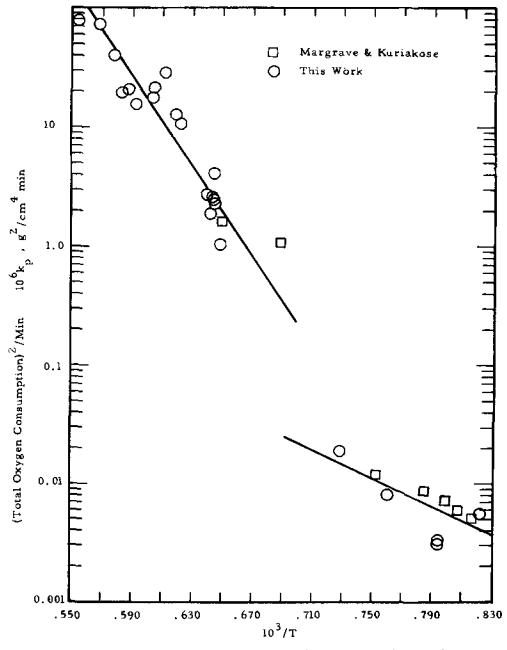

Fig. 2. Temperature dependence of the rate of total oxygen consumption for zirconium diboride-Arrhenius plot of parabolic rate constants, p_{O_2} = 37.5 Torr.

where m is total oxygen consumption in grams and t is time in minutes. The flow of helium must be constant throughout the system. Hence

$$\rho_{1,\mathrm{He}} v_1 = \rho_{2,\mathrm{He}} v_2 \qquad [3]$$

where $\rho_{1,\mathrm{He}}$ and $\rho_{2,\mathrm{He}}$ are the densities of helium in the reference and sampling cells, respectively. Solving [3] for v_2, and substituting in [2], one derives with the aid of [1] and the perfect gas laws an expression for the rate of oxygen consumption, dm/dt, in terms of measured quantities

$$dm/dt = v_1(S/k)/\{1 - p_1 + RT(S/k)/M\} \qquad [4]$$

where M is the molecular weight of oxygen, T is the temperature at which the flow rate v_1 is measured (298°K), R is the gas constant, and p_1 is the oxygen partial pressure in the initial gas stream in atmospheres. Since $\rho_2 \geq 0$, it follows that in [4] $RT(S/k)/M \leq p_1$. Therefore, if p_1 is a small fraction of an atmosphere, the rate of oxygen consumption, dm/dt, is directly proportional to the observed signal, apart from the previously discussed (6) effects introduced by the separation of reaction and detection sites. At high oxygen partial pressures, Eq. [4] must be used to interpret the results. In practice, the denominator in [4] is very nearly constant throughout any given experiment.

Results

Zirconium diboride.—The oxidation of zirconium diboride was studied in the temperature range 1200°-1820°K at oxygen partial pressures of 8-700 Torr. Parabolic rate behavior for total oxygen consumption was observed after an initial period of 10-30 min. The total oxygen consumed, m, represents the amount of oxygen in all of the product oxides, volatile or nonvolatile, formed during the oxidation experiment. A typical parabolic plot of m^2 *vs.* t, constructed from the corrected area under the experimental thermal conductivity curve according to Eq. [4] is shown in Fig. 1. The temperature dependence of the parabolic rate constants for total oxygen consumption is shown on a log k_p *vs.* $1/T$ plot in Fig. 2. Results were independent of carrier gas flow rate in the range 59-119 cc/min. Above 1400°K an activation energy of 77 ± 5 kcal/mole was calculated for the over-all oxidation process by the method of least squares. Below 1400°K, the activation

energy is clearly much less and will be discussed below in conjunction with the work of Kuriakose and Margrave (3).

The wide scatter of points about the least squares straight line in the high-temperature range is due to the high absolute value of the activation energy and to the presence of cracks in the as-prepared samples. Since the activation energy is high small errors in temperature measurement or small fluctuations in temperature during a run will result in large uncertainties in measured oxidation rates. For example, at 1500°K, an error or fluctuation of 10° in experimental temperature will be reflected in more than a 15% error in k_p. The presence of cracks, introduced in the zone-refining process, results in a difference between real and geometric surface areas. It will be shown below that the surface of a crack that extends into the bulk specimen is oxidized just as if it were external surface. Since the number of cracks is certainly not constant from one sample to another, the area used in computing k_p should really be the sum of gross geometric surface area and surface areas of cracks. The use of the former alone can introduce the observed scatter in the data.

The pressure dependence of oxidation rate was investigated briefly. The data suggest that rates increase linearly with pressure in the low-temperature range investigated, but become independent of pressure at higher temperatures. Kuriakose and Margrave (3) established that the rate of oxidation is linear at 1329°K over the oxygen pressure range 100-760 Torr. In reasonable agreement, we found an increase in parabolic rate constant of a factor of 13 (from 5.8 x 10^{-9} to 75.7 x 10^{-9} g^2/cm^4-min) with a pressure increase of a factor of 18 (from 37.5 to 694 Torr). On the other hand, we detected no change in oxidation rate with pressure at 1560°K over the range 8-40 Torr and at 1830°K over the range 20-700 Torr.

The data on both temperature and pressure dependence indicate that there is a fundamental difference in the mechanism of oxidation of ZrB_2 at low and high temperatures. Below 1330°K, oxidation proceeds with an activation energy of about 20 kcal/mole and seems to depend strongly on oxygen pressure. Above 1550°K, the activation energy is greater than 70 kcal/mole, and the rates become much less dependent on oxygen pressure.

Several samples were mounted and polished for metallographic examination of the oxide films. A typical specimen, oxidized for 114 min at a temperature of 1805°K and an oxygen partial pressure of 19.9 Torr, is shown in Fig. 3. The oxide in every photomicrograph shows considerable porosity, but we do not know whether it developed during oxidation at the high temperature, during cooling, or during polishing. Since ZrO_2 undergoes a phase transition with a change in density on cooling from 1805°K to room temperature, the physical properties of the oxide layer may be quite different during oxidation and after quenching. Hence, the microstructural observations must be interpreted with some caution. Figure 3a taken at a magnification of about 90X, shows clearly both the grain structure of the bulk material and the dense columnar oxide which forms on the surface during oxidation. Figure 3b is similar, but shows a region with an extensive crack running parallel to the ZrB_2 surface. Figure 3c at a magnification of about 450X focusses on the oxide within such a crack. The product is very similar to that on the surface of the refractory and appears to grow into the bulk material at certain preferred growth sites. Figures 3d, e, f, and g show the surface oxide once more at higher magnifications than Fig. 3a. The oxide is seen to be crystalline in nature, with the grains running for the most part perpendicular to the ZrB_2 surface. The oxide-metal interface is clearly not smooth, but the points of maximum growth rate do not seem to be related in an obvious way to the structure of the substrate. The interesting

photomicrograph in Fig. 3h at a magnification of 30X (and the same area at 90X magnification in Fig. 3i) shows the oxidation behavior of ZrB_2 in the neighborhood of a crack that intersects the surface. The surface of the crack as seen in these pictures is almost certainly the surface of the original alloy. Therefore, the oxide must grow by inward diffusion of oxygen. The columns of oxide are seen to run perpendicular to the outer surface of ZrB_2, and in like manner, are seen to run perpendicular to the surface of the crack (parallel to the sample surface). A crack then effec-

tively increases the surface area of the alloy above that of the outer or geometric surface area.

X-ray analysis of the oxidized surfaces of all of the ZrB_2 samples showed lines for monoclinic ZrO_2, and no extraneous lines. Analysis was of course performed at room temperature on quenched samples and therefore does not necessarily reflect accurately the structure of the high-temperature oxide. Evidence was not found in either the photomicrographs or in x-ray for the existence of a lower oxide adjacent to the alloy substrate.

Gross oxidation behavior is typically monitored by net weight change or total oxygen consumption. In order to compare results obtained by the two methods, it is necessary to take into account any volatile oxides that may be formed. The oxidation of ZrB_2 is expected to yield the oxides ZrO_2 and B_2O_3. The latter has an appreciable vapor pressure, ranging from 2.3×10^{-6} atm at 1400°K to 5.4×10^{-2} atm at 2000°K (8). Thus the total oxygen consumption measurements reported above represent the sum of the amounts of oxygen in each of the product oxides. The net weight change measurements of Kuriakose and Margrave (3) represent the sum of a weight gain due to formation of condensed oxides and a weight loss due to vaporization of boron as $B_2O_3(g)$. The importance of oxide volatility in the over-all oxidation process must therefore be evaluated.

If it is assumed that the composition of the boride is not changed during oxidation, then the oxidation reaction may be considered in terms of two nonelementary steps as follows

$$ZrB_2(c) + (5/2)\ O_2(g) \rightarrow ZrO_2(c) + B_2O_3(l) \quad [5]$$

$$B_2O_3(l) \rightarrow B_2O_3(g) \quad [6]$$

The measured oxygen consumption, m, up to some time t, may be written as

$$m = \frac{2[O]}{[ZrO_2]} \cdot w_{ZrO_2(c)} + \frac{3[O]}{[B_2O_3]} \cdot w_{B_2O_3(l)} \quad [7]$$

where w_X is the number of grams of product X formed per unit boride surface area up to time t, and the symbols in brackets are molecular weights. Since the oxidation is supposed to be nonpreferential, the number of moles of $ZrO_2(c)$ formed must be equal to the number of moles of $B_2O_3(l)$ formed in the same time period. The measured oxygen consumption m and the net weight change w_{net} differ by the amount of B_2O_3 vaporized

$$w_{net} = m - w_{B_2O_3(g)} \quad [8]$$

If the amount of B_2O_3 that vaporizes is negligible, then

$$w_{net} = m \quad [9]$$

If B_2O_3 vaporizes as rapidly as it forms, then $w_{B_2O_3(g)} = w_{B_2O_3(l)}$, and

$$w_{net} = \left\{\frac{2}{5} - \frac{2[B]}{5[O]}\right\} m \quad [10]$$

The equilibrium rate of vaporization of B_2O_3 in vacuum is known. At a total pressure of 1 atm, the rate of vaporization is expected to be a factor of 10 to 1000 times less than the equilibrium rate (9). For the purposes of this discussion, it will be assumed that during the oxidation of ZrB_2, B_2O_3 vaporizes linearly at one one-hundredth of the equilibrium rate G as long as liquid B_2O_3 is present. If the rate of formation of $B_2O_3(l)$ is smaller than $0.01G$, the liquid will vaporize as rapidly as it forms.

Since the measured oxygen consumption was found to follow a parabolic rate law, it follows from [7] and from the assumption of stoichiometric oxidation that the condensed oxides $ZrO_2(c)$ and $B_2O_3(l)$ must also grow parabolically. Hence, at any temperature, there will be some time t_o after which the rate of vaporization of $B_2O_3(g)$ will exactly balance the rate of formation of $B_2O_3(l)$. At t_o

$$\frac{dw_{B_2O_3(g)}}{dt} = \frac{dw_{B_2O_3(l)}}{dt} \quad [11]$$

On the basis of the preceding discussion

$$\frac{dw_{B_2O_3(g)}}{dt} = 0.01G \quad [12]$$

$$\frac{dm}{dt} = \frac{k_p}{2m} \quad [13]$$

and hence

$$\frac{dw_{B_2O_3(l)}}{dt} = \frac{(k_p)^{1/2}[B_2O_3]}{(2)t^{1/2}(5)[O]} \quad [14]$$

where k_p is the parabolic rate constant for measured oxygen consumption. Equating [12] and [13], one can solve for the time t_o

$$t_o = \frac{0.19 \times 10^4 k_p}{G^2} \quad [15]$$

where k_p values can be taken from Fig. 2 and G values from the literature.

At 1330°K, t_o = 570 min, and the loss of $B_2O_3(g)$ over the 2-hr period of the present oxidation experiments is negligible. Therefore, to an excellent approximation, at all temperatures below 1330°K, weight gain and total oxygen consumption should be identical. At 1440°K and above, $t_o \leq 5$ min. Hence above 1440°K B_2O_3 should vaporize as rapidly as it forms, and the relationship between weight gain and total oxygen consumption should be given by Eq. [10]. Although we did not do chemical analysis on the oxides formed on the diboride surfaces, it may be noted that a dark gray glazed surface appeared below 1400°K, while a white crystalline oxide was formed at higher temperatures.

For purposes of comparison in Fig. 2, the weight change data of Margrave and Kuriakose (3) obtained at an oxygen pressure of 1 atm were converted to total oxygen consumption values at an oxygen pressure of 37.5 Torr by means of Eq. [9] below 1330°K and Eq. [10] above 1440°K, with the assumption of linear pressure dependence. On this basis, agreement between the two laboratories is good.

From thermodynamic considerations, one might also expect $BO_2(g)$ to be a significant volatile species formed on high-temperature oxidation. However, the relative amounts of $B_2O_3(g)$ and $BO_2(g)$ produced in the oxidation experiment would depend on kinetic factors and would have to be determined by independent measurement. Nonetheless, under our experimental conditions, any $BO_2(g)$ formed at the oxidizing surface would condense on the cool walls of the reaction chamber to $B_2O_3(c)$ with release of oxygen. Therefore, our measured oxygen consumption values would correspond to the stoichiometry of reactions [5] and [6].

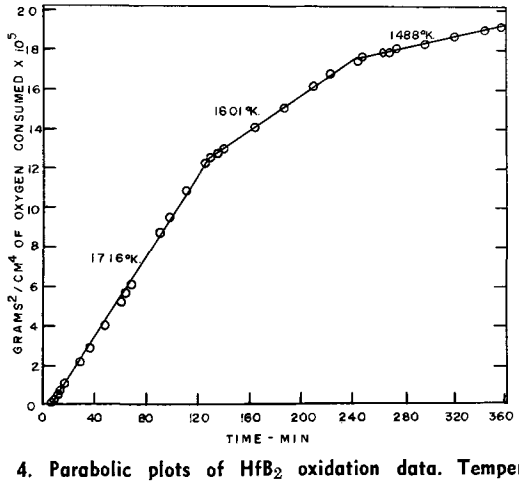

Fig. 4. Parabolic plots of HfB_2 oxidation data. Temperature 1720°, 1600°, and 1490°K, p_{O_2} = 19.9 Torr.

Hafnium diboride.—The oxidation of HfB_2 was studied at temperatures of 1480°-2000°K and oxygen partial pressures of 1-700 Torr. For all of the conditions investigated, the data could be fitted to a parabolic rate equation. Results of several experiments in which the temperature was varied during the run, are plotted parabolically in Fig. 4, 5, and 6, respectively.

The parabolic rate constants for total oxygen consumption are plotted in the form log k_p *vs.* $1/T$ in Fig. 7 at an oxygen pressure of 37.5 Torr. The activation energy for total oxygen consumption is 47 ± 4 kcal/mole in the range 1480°-1870°K. Around 1970°K, the transition temperature for the monoclinic to tetragonal phase change in HfO_2, there is a remarkably abrupt increase in the rate of oxidation. Following the analysis presented earlier for ZrB_2 it is found that at temperatures above 1488°K, the lowest temperature investigated, the rate of vaporization of B_2O_3 should be equal to its rate of formation, and HfO_2(c) should be the only condensed oxide on the surface of HfB_2. Therefore, the change in slope of the Arrhenius curve is not due to a change in the relative rates of formation of B_2O_3(l) and B_2O_3(g) as it might be in the ZrB_2 case, and it can be correlated directly with a phase change in the metal oxide. Measurements above the oxide transition temperature cover too small a range for a reliable numerical estimate of activation energy.

The data taken at 1630° and 1760°K for oxygen partial pressures between 1.4 and 694 Torr are plotted as a function of oxygen partial pressure on a log-log plot in Fig. 8. A least squares analysis of the data yields a pressure coefficient for total oxygen consumption of 0.4 ± 0.1, *i.e.*

$$k_p \propto p^{0.4\pm0.1}$$

Several samples were mounted and polished for metallographic examination after oxidation. Oxide was polished off one circular face revealing the alloy beneath and leaving the oxide at the outer rim. A photomicrograph of a pellet that had been oxidized for 2 hr at 1760°K and 26.8 Torr is shown in Fig. 9. The structure of the oxide is quite different from that shown in Fig. 3 on zirconium diboride. Two layers are clearly visible, a thin outer region and a thicker inner one. The patches of oxide at the left, apparently unconnected with the oxide at the outer rim, are probably areas of the surface which were oxidized more rapidly than the bulk alloy, and hence were not polished away during preparation of the sample. The oxidation rate may be a function of the crystalline orientation of the diboride. The crack in the right-hand quarter of the figure may be filled with oxide, suggesting that the oxide grows in part by outward diffusion of hafnium.

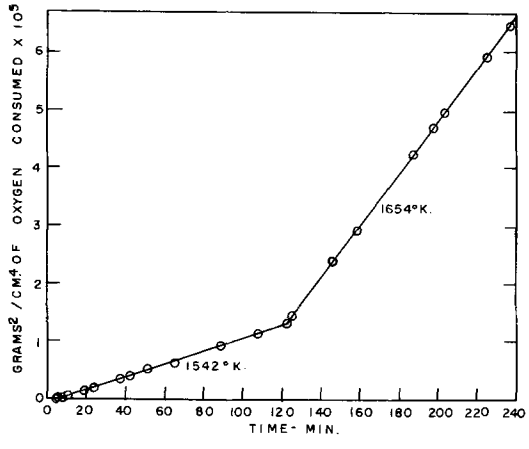

Fig. 5. Parabolic plots of HfB_2 oxidation data. Temperature 1650° and 1542°K, p_{O_2} = 19.9 Torr.

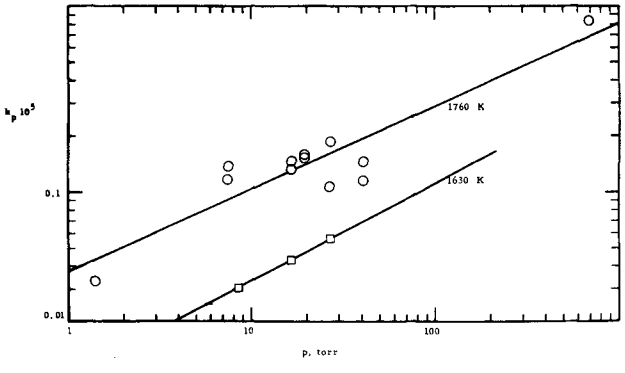

Fig. 8. Pressure dependence of the oxidation of hafnium diboride at 1760° and 1630°K.

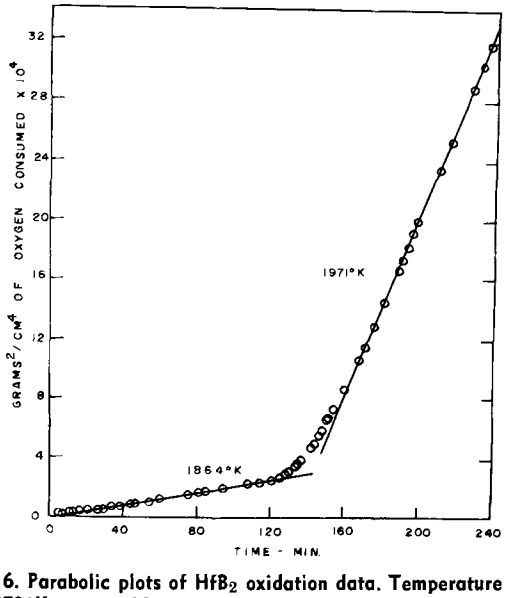

Fig. 6. Parabolic plots of HfB_2 oxidation data. Temperature 1860° and 1970°K, p_{O_2} = 18.5 Torr.

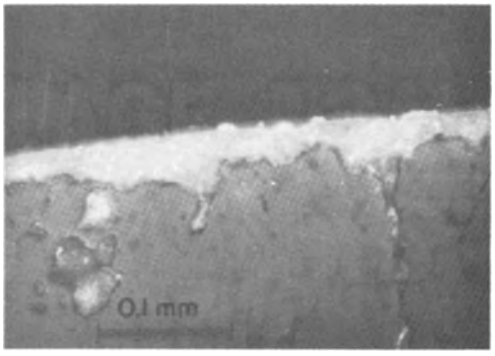

Fig. 9. Photomicrograph of oxidized hafnium diboride. Temperature 1760°K, p_{O_2} = 26.8 Torr.

Photomicrographs of the surface of a pellet that had been oxidized for 2 hr at 1864°K and for 2 hr at 1971°K at an oxygen partial pressure of 18.5 Torr are shown in Fig. 10. The thicker outer layer of oxide was probably formed at the higher temperature, the narrower inner layer at the lower, again suggesting motion of hafnium. In Fig. 11 a photomicrograph of a pellet that had been oxidized for 2 hr at 1654°K and for two hr at 1542°K at an oxygen pressure of 19.9 Torr is shown. The oxide is very similar to that shown in Fig. 9. A layered structure due to the change in temperature in the middle of the run could not be positively identified.

Discussion

In order to compare the zirconium diboride and hafnium diboride results in the 1400°-1900°K range, the parabolic rate constants for oxygen consumption were converted to an alloy consumption basis on the assumption of nonpreferential oxidation of the alloys to $B_2O_3(g)$ and metal dioxide. Results are compared in an Arrhenius plot in Fig. 12. In this temperature range, the parabolic rate constants for oxidation of HfB_2 are almost an order of magnitude less than the corresponding constants for ZrB_2. In Fig. 2 and 7 it is seen that the rate of oxidation of zirconium diboride increases sharply near 1400°K, while the rate of oxidation of hafnium diboride shows a similar increase around 1970°K. In the case of hafnium diboride, the jump in oxidation rate is clearly due to the monoclinic to tetragonal transition in the oxide. In the case of zirconium diboride, the phase transition in ZrO_2 does occur around 1400°K, but the increase in oxidation rate might also be due to the fact that $B_2O_3(l)$ is present on the surface of the alloy in the low-temperature range, but vaporized as rapidly as it is

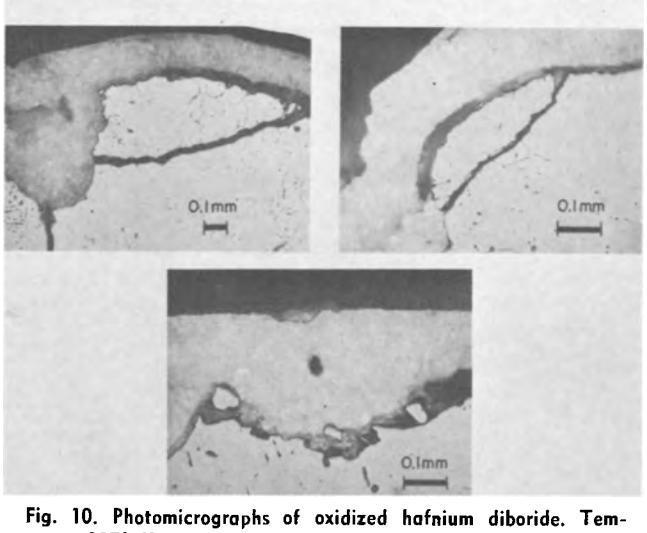

Fig. 10. Photomicrographs of oxidized hafnium diboride. Temperature 1970°K, p_{O_2} = 18.5 Torr. Top left, 65X; top right, 130X; center, 130X all before reduction for publication.

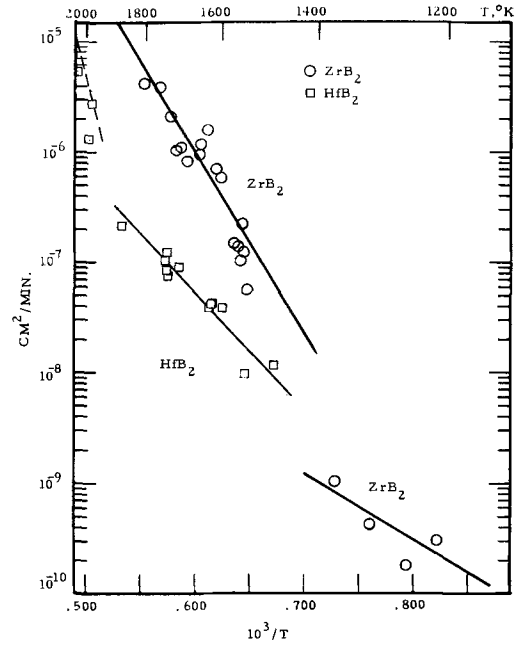

Fig. 12. Comparison of parabolic rate constants for oxidation of hafnium diboride and zirconium diboride as a function of temperature.

formed at higher temperatures. In any case, for both ZrB_2 and HfB_2 the monoclinic oxide appears to impart greater oxidation resistance than the tetragonal modification.

It has been suggested that the vaporization of $B_2O_3(g)$ during the oxidation of ZrB_2 and HfB_2 might influence the microstructure of the $ZrO_2(c)$ or $HfO_2(c)$, presumably formed simultaneously. If $B_2O_3(g)$ were produced at the boride/dioxide interface, it would be expected to cause rupture and/or porosity in the dioxide film and hence result in an enhanced net rate of oxidation. If on the other hand, the rate of diffusion of boron through the dioxide film were much more rapid than the rate of oxidation, gaseous $B_2O_3(g)$ would be formed at the dioxide/ambient interface, and the structure of the dioxide would be little affected. In the latter case, boron would have to be present in the dioxide film and should be detectable by appropriate techniques.

Although the experimental data for both zirconium diboride and hafnium were fitted to a parabolic rate equation, the mechanism of oxidation is not clear. ZrO_2 and HfO_2 are normally considered to be anion deficit semiconductors, and one might expect the oxidation of HfB_2 and ZrB_2 to be controlled by diffusion of oxygen ions via vacancies in the respective metal oxides. If this mechanism were valid, however, the activation energy for diffusion should be equal to the activation energy for oxidation, and the rate of oxi-

dation should be independent of oxygen partial pressure (10). The linear pressure dependence for oxidation of ZrB_2 found by Margrave and Kuriakose at 1329°K over the range 100-760 Torr and confirmed by us at 1200°K precludes a simple diffusion mechanism via anion vacancies in this temperature range. Above the phase transition temperature for ZrO_2, diffusion data is not available. However, the activation energy of 77 ± 5 kcal/mole found for oxidation is not an unreasonable energy for diffusion if one estimates the activation energy as the sum of the energy for formation of a vacancy plus that for motion of a vacancy (11). Furthermore, at 1830°K the parabolic rate constant for total oxygen consumption was found to be independent of oxygen pressure. Alternatively, one of the referees, in reviewing the manuscript, pointed out that the activation energy for oxidation corresponds very closely to the energy of formation of $BO_2(g)$ from $B_2O_3(l)$ and $O_2(g)$. The significance of gaseous $BO_2(g)$ in the oxidation of the borides obviously warrants additional experimental study.

The oxidation of HfB_2 to monoclinic $HfO_2(c)$ and gaseous $B_2O_3(g)$ was found to depend on the 0.4 ± 0.1 power of the oxygen pressure, which again is too high to be consistent with a diffusion mechanism via oxygen anion vacancies. In fact, the oxidation behavior in the neighborhood of a crack and the layered structure observed when the temperature was raised or lowered in the middle of a run suggested that hafnium is the major diffusing species during the oxidation of HfB_2.

Acknowledgment

The hot pressed samples of HfB_2 identified in Fig. 7 were supplied by ManLabs and were investigated under subcontract to AF 33(657)-8635. Able laboratory assistance in obtaining the oxidation measurements was given by Richard F. Quigley.

This research was supported by the United States Air Force under Contract No. AF 33(616)-6154, monitored by the Air Force Materials Laboratory, Research and Technology Division, Wright-Patterson Air Force Base, Ohio.

Manuscript received July 8, 1965; revised manuscript received May 16, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Deposition of Silica Films by the Glow Discharge Technique

D. R. Secrist[1] and J. D. Mackenzie

Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

Noncrystalline SiO_2 films were deposited on various substrates at low temperatures and pressures by decomposing tetraethoxysilane by oxygen species from an R. F. induced oxygen plasma. The rate of deposition was controlled by physical adsorption; the apparent heats of adsorption of silica on NaCl, Pt, fused SiO_2, Al, and Al_2O_3 were determined. A mechanism for formation is presented. The decomposition of the tetraethoxysilane obeyed a first order rate law. The specific rate constant was calculated at 310°C and 250μ pressure.

Studies and utilization of thin films, both metallic and nonmetallic, have experienced considerable growth in the last decade. Silica films, in particular, have enjoyed a multitude of applications. For instance, masks for semiconductor devices or dielectric capacitors for miniaturized solid-state circuits are conveniently formed with glassy silica. Silica films can be formed by many techniques (1), most of which necessitate relatively high temperatures. The "glow discharge" method to be described facilitates the deposition of glassy silica films from the vapor phase at low temperatures and pressures by the decomposition of tetraethoxysilane with energized oxygen species from the discharge. Alt *et al.* (2) and Ing and Davern (3), for example, have prepared amorphous silicon oxide films of unknown stoichiometry in one form of the glow discharge technique. We have modified this technique by the use of a microwave glow-discharge. The effects of temperature, pressure, metal-organic flow (evaporation) rate, and nature of the substrate on the rate of film growth are reported in this paper.

[1] Present address: International Business Machines Corporation, Poughkeepsie, New York.

Experimental

Materials.—Tetraethoxysilane $(C_2H_5O)_4Si$, and tetraethysilane, $(C_2H_5)_4Si$, were obtained from Metallomer Laboratories, Maynard, Massachusetts, and were of >98% purity.

Apparatus.—The glow discharge apparatus consisted basically of a modified bell jar which could be maintained at low pressures under sustained gas flow. A schematic drawing of the flow system is illustrated in Fig. 1. Molecular oxygen was admitted to the system through a 0.003-in. precision bore capillary which was positioned between the legs of a mercury manometer. With a pressure differential of 770 mm, the in-

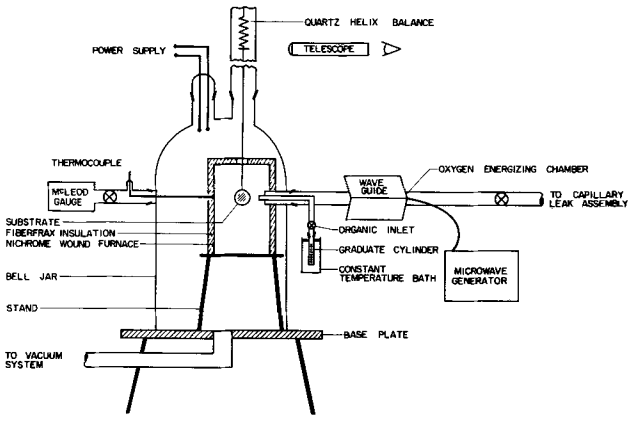

Fig. 1. Schematic drawing of glow discharge apparatus

coming gas flow rate was experimentally determined to be 1.76 ± 0.05 cm³/min at 25°C. A Pyrex tube, 2.54 cm in diameter, served as the glow discharge chamber. The electrodeless discharge was produced with a Raytheon PGM-10 Microwave Generator. This unit could supply 100w of microwave energy at a fixed frequency of 2,450 Mcps. The R.F. energy, as generated by a magnetron, was transferred by a coaxial cable to the antenna (labelled wave guide in Fig. 1) for dissipation.

The predominant excited product from a low-energy and low-pressure oxygen discharge has been identified as atomic oxygen in the ground state (4, 5). The atomic oxygen and other energized species thus formed were allowed to flow into the bell jar through a 0.5-in. diameter Pyrex tube. By the use of a nitrogen dioxide-titration technique (4), it was estimated that about 10% of the flowing molecular oxygen entered the bell jar as atomic oxygen. Tetraethoxysilane (as contained in a graduate cylinder immersed in a constant temperature bath) was introduced into the bell jar through a 5 mm diameter Pyrex tube under its own vapor pressure. The metal-organic evaporation rate (flow rate) at any particular bath temperature could be altered by adjusting a 1 mm bore Teflon stopcock, which served as the inlet valve into the bell jar. A constant temperature bath could be maintained inside an insulated two liter Dewar flask for long periods.

Initial experiments indicated that when the substrate was maintained at temperatures below 180°C, water was present in the films (6). Two nichrome-wound furnaces were therefore designed to "contain" the gas reaction. The majority of the studies were performed inside an aluminum furnace 2¼ in. in diameter and 4 in. long. A fused silica cylinder 1⅜ in. in diameter and 2½ in. long was used as the second furnace core. In each case, the top of the furnace was covered with a transite lid. The constant temperature zone for these furnaces extended 1 cm above and below the gas inlet port with a maximum radial temperature variation of ±5°C for points 1 cm from the cylinder axes. The substrate temperature was measured under deposition conditions with a calibrated chromel-alumel thermocouple. The corresponding furnace wall temperature was noted and used in subsequent experiments for temperature control.

The ultimate vacuum achieved in the glow discharge system was 240μ with an oxygen flow rate of 1.76 cm³/min. Periodic pressure measurements were made with a Stokes McLeod gauge and did not include the partial pressures of condensable gases such as water. Two liquid nitrogen cold traps were placed in the line leading to the vacuum pump to remove objectionable materials from the system. A thermocouple vacuum gauge was employed to monitor the exhaust pressure on a continuous basis.

Film deposition.—Depending on the nature of a particular experiment, the substrate on which a film was to be deposited was suspended from either a quartz helix balance or the furnace roof. Preliminary infrared transmission studies were conducted for the purpose of identifying the film deposited; wafers of NaCl and KBr were used as substrates. The substrates employed in the kinetic studies were hung from the fused silica balance and were limited in weight by the load capacity of the balance, which was 20 mg. For this work, the desirable weight of a specimen was arbitrarily set at 10 ± 1 mg. The fused silica substrates were of irregular shape and approximately 0.75 cm in diameter. Aluminum and platinum foils were available in the form of 1 cm diameter pans. To examine the effects of Al_2O_3 on the deposition rate, an alumina (Lucalox) substrate was prepared by grinding a wafer of the material to a thickness of 0.002 in. A sodium chloride disk 1 cm in diameter was formed by the compaction of NaCl powder in a die at 12,000 psi pressure.

With the exception of the sodium chloride substrate, the general cleaning procedure adopted consisted of the rapid dipping of the specimens into a 48% solution of hydrofluoric acid, followed by rinsing with distilled water. All substrates were positioned in the reaction vessel in the same manner, with their wide dimension perpendicular to the gas inlet tube. (The thin dimension is perpendicular to the inlet tube in Fig. 1.) Approximately 1 hr was required for the furnace to attain thermal equilibrium. During the period when the furnace temperature was increasing, the system was purged with tank purity oxygen gas supplied by the Linde Company (assay 99.7% oxygen). The average dew point of the gas was determined to be −56°F (0.071 mg water/liter) and was relatively constant from cylinder to cylinder. When the furnace had reached thermal equilibrium, the glow discharge was initiated with a Tesla coil and the substrate was bombarded with atomic and other excited oxygen species for 10-15 min as an additional cleaning procedure. In this work, the microwave generator was operated at 90% of its rated power output. On opening the metal-organic inlet valve, approximately 5 min were required for the system to return to thermal equilibrium. The temperature variation thereafter was limited to ±2°C. The total pressure of the glow discharge system (excluding condensable gases) increased by about 10% and was reproducible for specific organic evaporation rates.

The fused silica balance used in this study had a sensitivity of 1 cm/mg (Microchemical Specialties Company, Berkeley, California). A weight of 1 mg caused an extension of 10.1 mm from zero, and 98.6 mm after an appropriate load of 10 mg (approximate substrate weight). A typical weight gain experiment would extend the helix by 1-2 mm. Over this limited working range, the helix extension per unit weight gain was linear. A Bausch and Lomb optical reader was employed to determine the cumulative weight of the film deposited. The telescope combined a 5 mm diameter objective field with a filar micrometer eyepiece containing a cross-line divisible to 5000 parts. The minimum extension detectable with this arrangement was 0.005 mm, which corresponded to a weight gain of approximately 0.5 μg (or a 15Å layer of SiO_2 on a 1 cm diameter pan). Measurements were made every 5 or 10 min for the duration of the deposition period, which generally lasted from 1½ to 2 hr. The incoming gas flow rate was slow enough so that the substrate was stable in the position perpendicular to the flow inlet tube. The damping period of the helix was practically instantaneous; no oscillation was observed under equilibrium conditions. At the end of an experiment, the volume of the metal-organic evaporated was measured to ±0.025 cm³.

Table I. Gas analyses

Per cent	Gas Outlet Sample	Furnace Sample
O_2	12	7
CO_2	30	23
CO	38	52
H_2	20	18
H_2O	80μ/250μ*	Trace
$(C_2H_5O)_4Si$	Trace	Trace
CH_4	Trace	—
Alcohols	—	—

* Total gas sample pressure = 250μ; partial pressure of water = 80μ; partial pressure of noncondensable gases = 170μ.
$(C_2H_5O)_4Si$, density = 0.9356 g/cm^3 at 20°C; evaporation rate = 0.12 cm^3/hr at 25°C; oxygen flow rate = 1.76 cm^3/min at 25°C and 770 mm Hg; furnace temperature = 310°C.

Results and Discussion

Gas analysis.—A quantitative analysis of the gaseous reaction products was made by mass spectrometry. Results are shown in Table I. The decomposition is seen to produce extensive amounts of water. With a metal-organic evaporation rate of 0.12 cm^3/hr, the partial pressure of water for a gas sample collected from the outlet system was about 30% of the total pressure. The water produced in this manner could be chemically incorporated into the oxide films when the substrates were held below a certain temperature, which depended on the metal-organic flow rate (6). For example, with a $(C_2H_5O)_4Si$ evaporation rate of 0.015 cm^3/hr, silicic acid was observed to form below 180°C, as determined by infrared transmission studies. The acid exhibited a characteristic absorption band at approximately 11μ. In addition, the major Si-O absorption mode was modified by a "shoulder" at approximately 8.5μ. When the evaporation rate was increased to 0.15 cm^3/hr, the presence of acid was observed at temperatures as high as 290°C.

Film evaluation.—The refractive indices of the silica films were measured as 1.458 ± 0.002, by the "Becke Line" method. Specimens were obtained from the substrate and/or gas inlet tube. The index of refraction for high-purity silica glass (supplied by the General Electric Company) was measured as 1.458 ± 0.002, in good agreement with the film values. The films were isotropic when observed with polarized light and were amorphous by x-ray diffraction. A comparison of the infrared absorption spectrum of a silica film deposited on a NaCl substrate with that of fused silica glass is shown in Fig. 2. The infrared band at 1080 cm^{-1} has been identified as a definite Si-O-Si bond stretching vibration. The band at 800 cm^{-1} is not well understood, but has often been associated with the occurrence of ring groups in the glassy structure. The major Si-O stretching mode for the film has shifted to a somewhat lower frequency. A similar shift of the same absorption band has been reported for samples of silica glass which were highly stressed and densified by either the application of very high pressures or by neutron irradiation (7, 8). Pliskin and Lehman (9) have shown that porosity in the films and bond strain can affect the spectrum in the same manner. It is also possible that a variation of the Si-O-Si angle or a change in the orientation of silica tetrahedra could occur during the build-up of a silica network by vapor deposition and cause a shift.

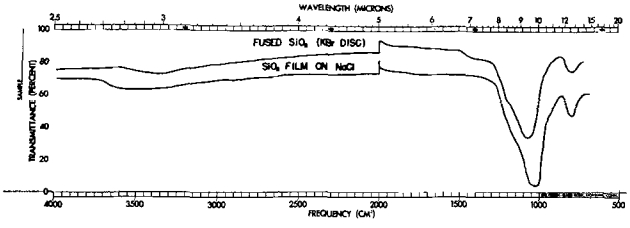

Fig. 2. Comparison of the infrared absorption spectra of a noncrystalline silica film prepared by vapor deposition, and fused silica glass.

The relative thickness of the films deposited on the front and back faces of a 1-in. diameter NaCl wafer was determined by measuring the area under the main infrared absorption band. The spectrum for both films was recorded and then re-examined after one film had been removed from the wafer. The area under the Si-O band for both films was approximately twice the area recorded for the single film. In this way, the films were determined to be of approximately the same thickness, which showed that the "silicon-oxygen specie" concentration in the gas phase immediately surrounding the substrate was relatively uniform. The thin silica films (5000Å) adhered well to all of the substrates. Films 3μ in thickness were readily deposited on the aluminum, fused silica, or alumina substrates, but spalled off from platinum foil when the thickness exceeded about 5000Å. This behavior could not be attributed to the differences in the thermal expansion coefficients of the substrates. Some of the films were re-examined after three weeks' exposure to the atmosphere. The refractive indices and infrared absorption spectra were unchanged.

Kinetics of deposition.—The decomposition of the $(C_2H_5O)_4Si$ was studied in a flowing system maintained at 250 ± 10μ pressure. By this method, the reaction products were removed from the system, and the secondary reactions were substantially reduced. The effect of temperature on the deposition rate of the glassy silica films was studied with a constant metal-organic evaporation rate of 0.15 ± 0.01 cm^3/hr. The effect of minor pressure variations was found to be negligible. For example when the total gas pressure was increased to 500μ (by the use of a valve leading to the vacuum pump), no change was detected in the rate of deposition. However, any further increase of the total pressure rapidly decreased the rate of deposition due to (*i*) poisoning effects from the reaction products and (*ii*) an increased recombination rate of the oxygen atoms in the gas phase. Under equilibrium conditions, the rate of deposition was constant, as shown in Fig. 3. The variation of the deposition rate with temperature could be described by the Arrhenius equation above 290°C.

$$r = A \exp(-H/RT) \quad [1]$$

where r is the deposition rate (mg/cm^2/min), A a constant, H the apparent heat of adsorption —(kcal/

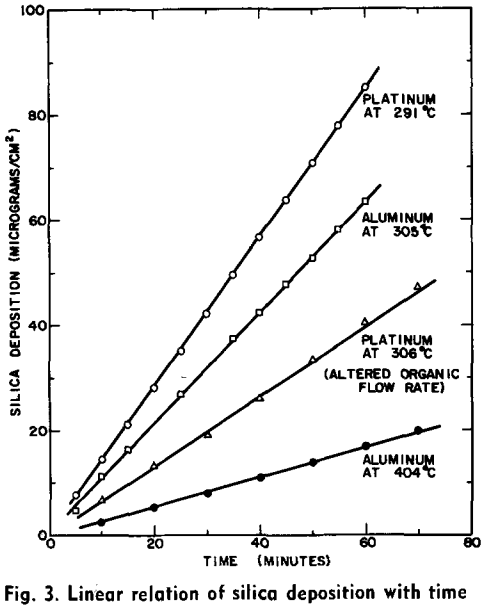

Fig. 3. Linear relation of silica deposition with time

mole), R gas constant (1.99 cal/degree/mole), and T substrate temperature (°K).

The relationship between logarithm r and reciprocal temperature is shown in Fig. 4. The data have been spread to show the temperature dependence of the deposition rate on each substrate. From Fig. 4, it is apparent that the deposition rate is relatively insensitive to temperature at least for platinum below about 290°C. Above this temperature, the rate decreases with increasing temperature. In addition, the rate of deposition on sodium chloride, fused silica, and platinum is equivalent, but different from the deposition rate on aluminum and alumina (for all practical purposes, the aluminum substrate, can be considered as alumina, since a surface layer of the oxide is always present). As previously mentioned, silicic acid was identified as a major constituent in the films formed below 290°C when the metal-organic evaporation rate was 0.15 cm³/hr. The relatively constant deposition rate noted in Fig. 4 below approximately 290°C can be associated with this acid formation. However, this does not imply that the acid is formed on the substrate surface. Brady (10) has stated that both $Si(OH)_4$ and $Si_2O(OH)_6$ probably exist in the vapor phase when steam is equilibrated with a siliceous molecule at relatively high pressures, and Straub (11) has suggested that silicic acid can be formed in the vapor phase. In addition, Brewer and Elliott (12) have proposed that $Si(OH)_2 \cdot 3H_2O$ can exist as a volatile specie. It is conceivable, therefore, that the silicic acid observed in the present study could be formed in the vapor phase. Since about 30% of the total gas pressure of the system was due to the water formed in the decomposition process, it was apparent that the mixture of "silicon-oxygen species" and water molecules or "hydrated silicon-oxygen species" bombarding the substrate surface was well in excess of the number which could be deposited. It is proposed that a maximum adsorption of the mixture occurs until a temperature is reached when the incorporation of water into the film is thermodynamically unfavorable, in this case, 290°C. Above this temperature, silica is deposited. Supporting evidence for this mechanism is offered by the work of Hockey and Pethica (13), who reported that the hydration of silica made by burning $SiCl_4$ in a hydrogen-oxygen mixture occurred as chemisorbed hydroxyl groups bonded to surface silicon atoms. In their studies, the surface hydroxyl groups could be removed from the silica surface by heating in the range 200°-400°C.

The decrease in the deposition rate above 290°C is characteristic of an adsorption-controlled process. In order for the free energy of the system to decrease, heat must be evolved, and the rate of an exothermic process will generally decrease with increasing temperature. From an atomistic viewpoint, in this study, the "silicon-oxygen specie" could be imagined to possess a mean lifetime in which to select a site on the substrate surface. As the temperature is raised, more kinetic energy would be imparted to the specie, and the mean lifetime for adsorption would be decreased. Klerer (14) has proposed a similar mechanism for the deposition of organic polymer films on silicon below 250°C.

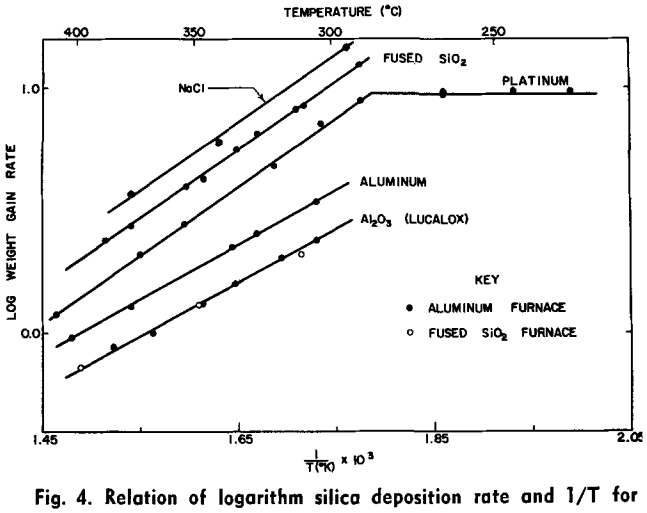

Fig. 4. Relation of logarithm silica deposition rate and 1/T for deposition on various substrates.

The apparent heats of adsorption of silica glass on the various substrates were calculated from the slopes of the lines in Fig. 4. A regression analysis of the data was made to determine the most probable slopes and the standard deviations. The apparent heat of adsorption of silica on the fused silica, NaCl, and platinum substrates was calculated to be 12.7 kcal/mole, with a standard deviation of 0.2 kcal/mole. For the aluminum or alumina substrates, the apparent heat of adsorption was calculated to be 9.5 kcal/mole, with a standard deviation of 0.3 kcal/mole. The magnitudes of the heats of adsorption are typical of those reported for physical adsorption processes, *e.g.*, the heat of adsorption of CO_2 on silica gel is approximately 7.1 kcal/mole; that of water on charcoal is about 10.0 kcal/mole (15).

In general, it may be stated that the heat of adsorption of the same adsorbate on different substrates is approximately the same (16). For multimolecular adsorption, the initial substrate surface is masked after several monolayers of adsorbate have been deposited. For example, in this study all subsequent condensate will fall on a SiO_2 layer rather than the original substrate surface. For this reason, the rate of deposition on all substrates should be similar. The difference in the apparent heat of adsorption of silica on the platinum, silica, or NaCl substrates and the alumina or aluminum substrates is real and much larger than the limit of error imposed by the standard deviations. It was concluded that the nature of the aluminum oxide surface was responsible for the difference in the apparent heats of adsorption observed. The reaction of alumina with silica to form a compound was not considered, since the rate of deposition of silica became constant soon after the metal-organic vapor was admitted to the reaction furnace. In addition, the rate of such a reaction would probably be quite slow at 300°-400°C.

The chemical nature of a substrate surface has been reported to influence a number of processes, even though the surface is covered with many molecular layers of adsorbate. For example, a mica substrate will affect the crystallization behavior of ammonium iodide through a film of cellulose acetate or rubber 1000Å in thickness (17). A similar observation was made in the present study when a potassium bromide substrate was used in place of a NaCl disk for the identification of silicic acid below 290°C. Silicic acid inclusions were not detected by infrared analysis when the films were formed on NaCl substrates held at 290°C (for metal-organic evaporation rates up to 1 cm³/hr). However, under similar conditions of temperature and pressure, but with an altered organic evaporation rate of 0.15 cm³/hr, silicic acid was observed to form in the film deposited on a KBr substrate. (The NaCl and KBr substrates were single crystals and showed no evidence of water by infrared analysis prior to these experiments.) From this experiment, it was concluded that the hydrophilic nature of the KBr surface could account for the selective absorption of water into the silica structure.

The adsorptive properties of an oxide surface are usually dependent on the degree of hydration and the chemical state of the hydrated surface (when the adsorbates can form hydrogen bonds). Peri and Hannon have reported that both hydroxyl groups and water molecules are held on the surfaces of γ-alumina (18). In their work, the water molecules were desorbed on

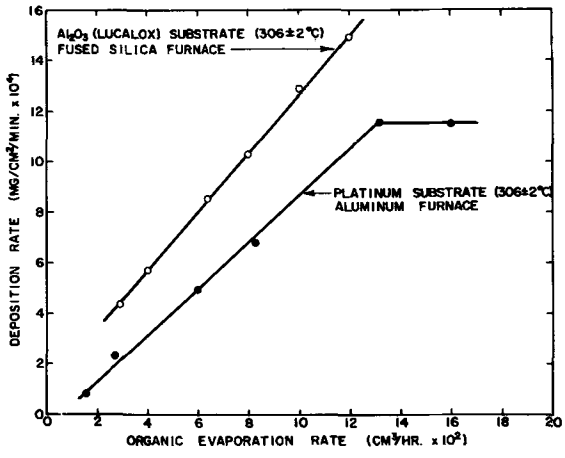

Fig. 5. Relation of silica deposition rate and tetraethoxysilane evaporation rate.

heating in a vacuum to 400°C, but about 40% of the surface area remained covered with hydroxyl groups. A similar state of hydration probably existed on the surface of the alumina disk used in this study. In the same way that the KBr substrate adsorbed water, it is proposed that a hydrated alumina surface would tend to incorporate further hydroxyl groups into the silica film. The adsorption of hydroxyl groups would account for the difference in the apparent heat of adsorption observed with the alumina surfaces.

Reaction order and specific rate constant.—The deposition rate of silica was directly proportional to the concentration (evaporation rate) of tetraethoxysilane for evaporation rates below 0.13 cm³/hr. This relationship is illustrated in Fig. 5 for silica glass deposited onto platinum and aluminum foil. For evaporation rates below 0.13 cm³/hr, it is evident that the decomposition of the metal-organic obeyed a first order rate law of the form

$$k = \frac{2.303}{t} \log \frac{a}{(a-x)} \qquad [2]$$

where k is the specific rate constant, sec^{-1}, t the reaction time, sec, a the metal-organic evaporation rate, cm³/hr, and x the metal-organic decomposition rate, cm³/hr. For evaporation rates in excess of 0.13 cm³/hr, the substrate area was rate limiting.

The maximum amount of tetraethoxysilane which could be decomposed in the oxygen plasma was not determined in this investigation, However, an indication of the amount of tetraethoxysilane decomposed could be obtained from the total pressure of the system. A slight, but progressive increase in pressure was noticed when the metal-organic evaporation rate was increased from 0.13 to 0.16 cm³/hr. Hence, the amount of silane decomposed was not rate limiting. The deposition rate on the alumina substrate was greater than that on the platinum substrate because of a variation in the "silicon-oxygen specie" concentration (the volume of the fused silica furnace was about one-third of that for the aluminum furnace with the same organic flow rate). The incorporation of hydroxyl groups into the silica film deposited on the alumina substrate would account for the difference in the slopes of the two lines in Fig. 5, as previously discussed.

In order to apply Eq. [2] to a flow system, Frost and Pearson (19) redefined the time variable as $t = V/u$, where V is the volume of the reaction chamber and u is the gas flow rate. The time variable V/u was a measure of the time that a gas reactant would spend in passing through the reaction vessel. In deriving this equation, it was assumed that the rate of the gas flow through the reaction furnace was constant and that the gases did not mix. An approximate value of the specific rate constant for the decomposition of tetraethoxysilane can be calculated from this latter equation. The following assumptions were made: (*a*) the rate of gas flow through the furnace was constant; (*b*) gas mixing did not occur; (*c*) the total reaction took place in the furnace; (*d*) the inlet gas temperature was similar to the furnace temperature; (*e*) the ideal gas law was applicable to both oxygen and tetraethoxysilane.

These assumptions are not unreasonable. The constant silica deposition rate would indicate that the flow rates were fairly constant. The reactant gases were fed into the furnace through individual inlet tubes and did not premix. The rate of deposition of silica decreased rapidly as the substrate was lowered in the reaction furnace, which showed that the reaction took place predominantly in the furnace vessel. The inlet gas temperature was similar to the furnace temperature because the radial temperature variation in the furnace was not appreciable under flow conditions. For the temperature and pressure conditions of the experiment, oxygen does not deviate appreciably from the ideal gas law. The oxygen flow rate was much larger than that of the metal-organic vapor, so that even if the ideal gas law were not obeyed by the latter, the effect on the calculations involved would be minor.

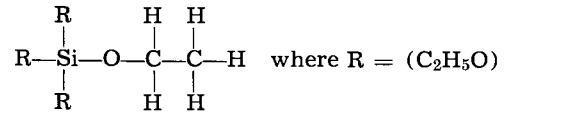
A calculation of the rate constant was made for the fused silica furnace (volume = 62.5 cm³) for a metal-organic evaporation rate of 0.12 cm³/hr. The amount of tetraethoxysilane decomposed was estimated from a knowledge of the reactant products and their respective concentrations. In view of the reaction products, it was evident that the oxidation of the tetraethoxysilane was quite complete. From Table I, the total number of moles of oxygen combined as either carbon monoxide or carbon dioxide is seen to be similar for the two gas samples; the amount of oxygen present in each case would be equivalent if the condensable water vapor pressure was taken into account (O_2 = 12% based on noncondensable gas pressure, O_2 = 8% including water pressure). By comparing the total number of moles of oxygen consumed (including oxygen available from the tetraethoxysilane) with the amount of oxygen required for the complete combustion of the tetraethoxysilane according to the analysis in Table I, it was estimated that 85% of the tetraethoxysilane was decomposed under equilibrium conditions. A 10% error in this estimate would cause a 37% error in the specific rate constant.

The total gas flow rate was calculated by assuming that the ideal gas law held for both the oxygen and tetraethoxysilane. The gas flow rate determined in this way was 1.96 cm³/min at 25°C and 1 atm pressure. This flow rate was corrected for a temperature of 310°C (furnace temperature) and 250μ pressure by the application of the ideal gas law. The values were then substituted into Eq. [2], and the specific rate constant was calculated to be 5.85 sec^{-1}. In view of the assumptions required for this calculation, the limits of error were estimated to be ±50%, or $k = 6 \pm 3$ sec^{-1} at 310°C and 250μ pressure.

Mechanism of film formation.—In this study, the energy necessary for the decomposition was supplied in the form of an oxygen plasma produced in a glow discharge. The predominant specie obtained from an oxygen discharge has been identified as atomic oxygen in the ground state (4, 5). The homogeneous recombination of atomic oxygen in the gas phase is accompanied by the release of 59.1 kcal/mole of atomic oxygen (20); it was presumed that the amount of energy liberated when the oxygen atoms interacted with the metal-organic molecules was of a similar order of magnitude.

A mechanism for the decomposition can be postulated from a consideration of the bond energies within

the molecule and the reaction products. The tetraethoxysilane molecule can be represented as



The bond energies involved are taken from Cottrell (20) and are as follows:

Si—O (108 kcal/mole)
C —O (86 kcal/mole)
C —H (96 kcal/mole)
C —C (83 kcal/mole)

From these data, it was apparent that the Si-O bond would be the least likely to rupture. The C-O bond is comparatively weaker, and rupture of this bond would free a C_2H_5 group. At the same time, hydrogen could be detached from the molecule. Although the subsequent reactions are too numerous to list, it is probable that the following preliminary reactions are among those which occurred

$$C_2H_5 \rightarrow C_xH_y \quad [3]$$

$$H + H \rightarrow H_2 \quad [4]$$

$$C_xH_y + O + O_2 \rightarrow CO_2 + H_2O \quad [5]$$

To determine whether the decomposition was influenced by the chemical nature of the furnace vessel, experiments were conducted in both a fused silica furnace (volume = 62.5 cm^3, surface = 81 cm^2) and an aluminum furnace (volume = 202 cm^3, surface = 181 cm^2). The apparent heats of adsorption of silica on an alumina substrate were found to be similar (see Fig. 4). This indicated that the mechanism of the decomposition was independent of the reaction chamber. In order to establish whether thermal energy contributed to the decomposition rate, two weight gain experiments were conducted at 400°C without a glow discharge and under both static and dynamic conditions. No decomposition or adsorption of the organic vapor occurred on a platinum substrate during an 8-hr period, which demonstrated that silica was not being deposited under these conditions.

Ing and Davern (3) have deposited silicon oxide films of unknown stoichiometry by decomposing tetraethoxysilane by a glow discharge operated at 0.5 megacycle. A mechanism for film growth was proposed, based on the high-energy particle bombardment decomposition of tetraethoxysilane in the gas phase to yield silicon oxide clusters. It was thought that the clusters were subsequently deposited on a substrate surface and that any attached organic groups were then further dissociated.

Glassy silica films were prepared in our studies by decomposing tetraethoxysilane in an argon plasma. The index of refraction of the films was measured as 1.458 ± 0.002, in agreement with the value for silica glass. The infrared adsorption spectra of these two monocrystalline solids were also similar, and exhibited absorption bands at 9.2 and 12.5μ. This experiment showed that the "silicon-oxygen specie" was available from the metal-organic molecule. Evidently the metal-organic molecule can absorb sufficient energy to cause bond rupture and a silicon-oxygen specie is formed. The rate of film growth in the argon plasma was exceedingly slow; a film of approximately 2000Å in thickness was deposited after 6 hr. This suggested that the rate of the decomposition was dependent on the simultaneous oxidation of the molecule. However, the amount of energy transferred in an argon plasma may be rate controlling and was not determined.

In order to ascertain whether the silicon oxygen specie could be formed entirely in the vapor phase, tetraethylsilane, $(C_2H_5)_4Si$, was decomposed in an oxygen plasma. It was found that the silica films deposited in this manner were indistinguishable from the silica films formed from $(C_2H_5O)_4Si$. The refractive indices and infrared adsorption spectra were similar; the apparent heats of adsorption on platinum were also the same, as determined from the temperature dependence of the deposition rate, which is shown in Fig. 6. With a $(C_2H_5)_4Si$ evaporation rate of 0.08 cm^3/hr, the deposition rate of silica on a platinum foil kept at 306°C was 4.15 x 10^{-4} mg/cm^2 min. Under similar conditions, the deposition rate with $(C_2H_5O)_4Si$ was 6.9 x 10^{-4} mg/cm^2 min. These deposition rates are not too different. It was concluded, therefore, that the silicon-oxygen specie which formed the Si-O-Si network could be synthesized directly in the vapor phase. Since the deposition of silica was possible in an argon plasma, it is reasonable to suspect that the main role of an oxidizing atmosphere was to remove the hydrocarbon portions of the metal-organic molecule.

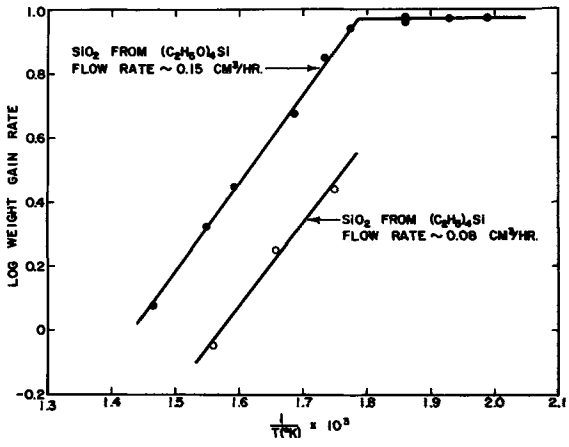


Fig. 6. Relation of logarithm silica deposition rate and 1/T for noncrystalline silica films prepared by the vapor phase decomposition of tetraethoxysilane and tetraethylsilane. (Deposition on platinum foil).

Based on the foregoing experiments, the following mechanism is proposed for the growth of a silicon dioxide film: The metal-organic molecules and energized oxygen species, predominantly atomic oxygen, enter the reaction furnace and collide. As a result, some of the metal-organic molecules absorb sufficient energy to cause bond rupture. A simultaneous oxidation of the hydrocarbon portions of the molecule assists the decomposition process and silicon-oxygen species are rapidly formed in the gas phase. Each specie is then imagined to possess a mean lifetime in which to select a site on the substrate and become physically adsorbed. The Si-O-Si network is formed when additional silicon-oxygen species are adsorbed. These species are not necessarily SiO_2 molecules, but may correspond to "free radicals" of the type SiO, SiO_3, or SiO_4, which are available from the metal-organic molecule. The adsorbed "radicals" may then crosslink to form a network of SiO_4 tetrahedra, and the over-all composition of the film deposited would correspond to SiO_2. As previously mentioned, the refractive indices and infrared adsorption spectra of all silica films deposited in this study were similar to the same properties of silica glass formed by fusion and subsequent cooling. Silicon dioxide always forms a network, whether it is crystalline quartz, cristobalite, tridymite, or a glass. It appears that the network is structurally the most stable form of the solid.

Conclusions

1. Noncrystalline SiO_2 films can be deposited at low temperatures by the decomposition of tetraethoxysilane by a gaseous plasma produced with a glow discharge. These films are structurally similar to silica

glass prepared by conventional fusion techniques, as evidenced by their infrared absorption spectra and refractive indices.

2. The decomposition of tetraethoxysilane by an oxygen plasma produces extensive water. This water can be chemically incorporated into the oxide films when the substrates are held below a certain temperature, which depends on the organic flow rate.

3. The decomposition of tetraethoxysilane by an oxygen plasma obeys a first order rate law at 250μ pressures and temperatures near 300°C.

4. The deposition rate of silica is directly proportional to the $(C_2H_5O)_4Si$ evaporation rate below a limiting value, which is dependent on the available surface area of the substrate and its temperature.

5. The silicon-oxygen species which form the silica network are physically adsorbed by the substrate below 410°C. The apparent heat of adsorption of silica on NaCl, Pt, or fused SiO_2 is 12.7 ± 0.2 kcal/mole. The apparent heat of adsorption on Al_2O_3 or Al is 9.5 ± 0.3 kcal/mole. The difference in the apparent heats of adsorption of silica is most likely due to the incorporation of hydroxyl groups into the silica film deposited on the alumina or aluminum substrates.

Electrical Conductance Study of Na^+ Ion Mobility in Silicogermanate, Aluminogermanate, and Aluminosilicate Melts

E. F. Riebling

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

Correlations between Na^+ ion mobility, as determined by electrical conductance measurements, and structure changes were examined for ternary oxide melts between 1100° and 1700°C. Positive Λ and negative $\Delta H_K^{\neq}$ deviations for 25 mole % Na_2O silicogermanate melts, as well as negative Λ and positive $\Delta H_A^{\neq}$ deviations for high silica or germania content melts with Al/Na < 1.0, can be related to (*a*) the oxygen packing around the Na^+ ion, and (*b*) the local electroneutrality requirements (Na^+ remains near AlO_4^- portion of anions). Specific differences between the latter melts appear to be related to structural dissimilarities. The cation mobility increase that accompanies the gradual substitution of equimolar amounts of Al_2O_3 and Na_2O for either GeO_2 or SiO_2 suggests the formation of more open, cristobalite-like liquids as the 1/1/2 composition is approached in each system. Similarities between glass and melt conductance phenomena are also discussed.

Recent experimental studies have examined the temperature and compositional dependence of viscosity and density for ternary melts in the $Na_2O \cdot SiO_2 \cdot GeO_2$ (1), $Na_2O \cdot Al_2O_3 \cdot GeO_2$ (2, 3) and $Na_2O \cdot Al_2O_3 \cdot SiO_2$ (4) systems. Various partial molar volume models were developed to explain the observed molar volumes and other properties. Thus, GeO_6 octahedra were found to disappear by the time 50% of the GeO_2 is replaced in 25 mole % Na_2O melts in the first system. The GeO_6 octahedra stability limits in the second system apparently lie within the ternary compositions bounded by a 10 mole % semicircular sweep of the 23 mole % Na_2O point on the binary sodium germanate system. The aluminosilicate study revealed AlO_4 tetrahedra at all melt compositions with Al/Na $\leq$ 1.0.

A previous electrical conductance study of binary alkali germanate melts (5) showed that it was possible, to a limited degree, to correlate equivalent conductance (Λ) trends with both the cation field strength and the structure changes that were known to occur with the addition of alkali oxide to molten GeO_2. These findings prompted the attempt of a similar survey for selected series of related, but relatively more complicated ternary oxide melts that contained two network forming species.

This paper presents electrical conductance results for the following series of melts: (*a*) 25 mole % Na_2O silicogermanates, (*b*) Al/Na = 1.0 germanates, (*c*) 25 mole % Na_2O aluminogermanates, (*d*) 75 mole % GeO_2 sodium aluminogermanates, (*e*) Al/Na = 1.0 silicates, (*f*) 20 mole % Na_2O aluminosilicates, and (*g*) 75 mole % SiO_2 sodium aluminosilicates. The main objective was to search for possible correlations between sodium ion mobility and the previously postulated melt structure changes. The influence of anion variations on cation mobility was of specific interest.

Experimental

The individual glasses were prepared in Pt·20% Rh crucibles from Baker Reagent Grade analyzed Na_2CO_3 and Al_2O_3, Eagle Picher Electronic Grade GeO_2, and 200 mesh Pennsylvania Glass Sand Company ceramic Grade SiO_2. Preparative techniques and chemical analysis procedures, including spectrographic analysis of the GeO_2 and SiO_2 powders, have been described in detail elsewhere (1, 2, 4).

A dipping electrode arrangement (parallel Pt·40% Rh wires) was used to measure the melt resistances. Details of the instrument and its calibration procedures are described in greater detail elsewhere (6). Resistances were measured at 10 kc for an electrode immersion depth of 8 mm. Any contributions to the total impedance by capacitive reactances in the melt were negligible at that frequency. Capacitive effects were rather small between 1 kc ($\sim$ 0.02 μf) and 10 kc ($\sim$ 0.001 μf). While the normal resistance decrease amounted to 1-5% over the 1 to 10 kc range, less than a 1% decrease was generally observed between 5 and 10 kc. The capacitance level and frequency dependence of the sodium aluminosilicate melts were slightly larger than the above values.

Previous density and viscosity experiments (4) with sodium aluminosilicate melts had shown the need to use an argon atmosphere in order to eliminate reboil bubbles.[1] Consequently, the electrode arrangements were adapted to allow placement of an alumina argon inlet tube just above the radiation shield. The argon rate was approximately 1-1/3 l/hr. Argon was used only for the sodium alumino-silicate melts.[2]

The experimentally determined resistances, including a known temperature dependent contribution from the leads ($\sim$2.5 ohm), ranged from 3.5 to 5 ohms for the $Na_2O·SiO_2·GeO_2$ melts, from 3.5 to 30 ohms for the $Na_2O·Al_2O_3·GeO_2$ melts, and from 3.5 to 7 ohms for the $Na_2O·Al_2O_3·SiO_2$ melts.

Results

All of the specific conductance (κ) data observed the Arrhenius relationship with respect to temperature. Temperature cycling during each run produced no hysteresis effects. This allowed the use of a least squares treatment for the κ values. Table I gives the least squares constants of the log κ equations for each composition studied in the three systems to be discussed.

As before (5), the following equation was used to calculate equivalent conductances (Λ)

$$\Lambda = 100\,\kappa M/\rho m Z x \qquad [1]$$

where M is the molecular weight of M_xO_y, ρ is the melt density (g/cc), m the weight % M_xO_y, Z the charge on M, and x the number of M atoms per molecule of M_xO_y. The equivalent conductance so calculated is that due to one gram equivalent per cubic centimeter and is free of concentration effects. A composition dependent change of Λ can therefore be associated with a change of cation mobility.

The Λ isotherms are depicted as a function of composition for all of the melts studied in Fig. 1 through 7. Figure 1 shows Λ isotherms for 1100° and 1300°C

[1] Oxygen reboil, which can occur at a platinum-oxide melt interface, results from the discharge of a concentration or thermal cell. For more details see J. H. Cowan, W. M. Buehl, and J. R. Hutchins, III, to be published in *J. Am. Ceram. Soc.*

[2] Experiments showed that an air or oxygen atmosphere causes about a 10% reduction of the specific conductance (κ) for these melts. Re-imposition of an argon atmosphere does not cause a complete return to the original κ level. Reboil bubble formation and only partial removal in these viscous silicate melts could explain this effect.

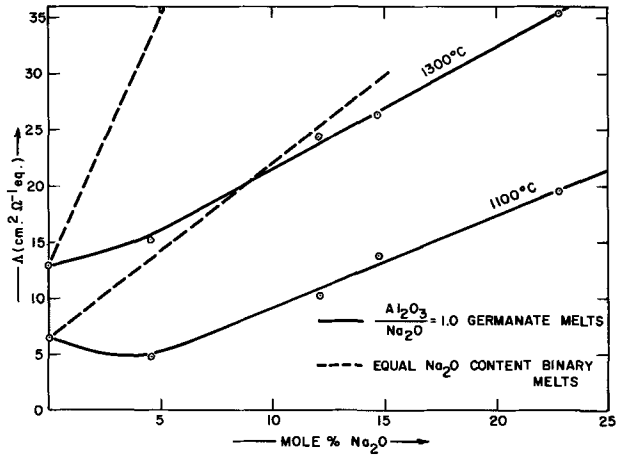

Fig. 2. Equivalent conductance isotherms vs. mole % Na_2O for equimolar sodium aluminate substituted germanate melts.

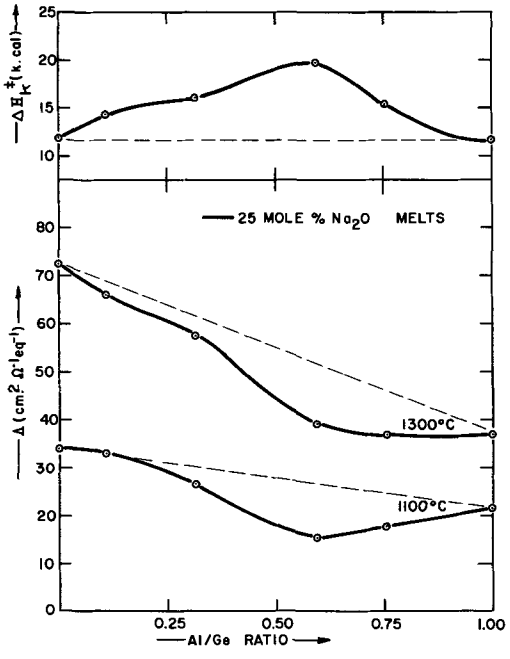

Fig. 3. Equivalent conductance isotherms and activation energy vs. Al/Ge ratio for 25 mole % Na_2O aluminogermanate melts.

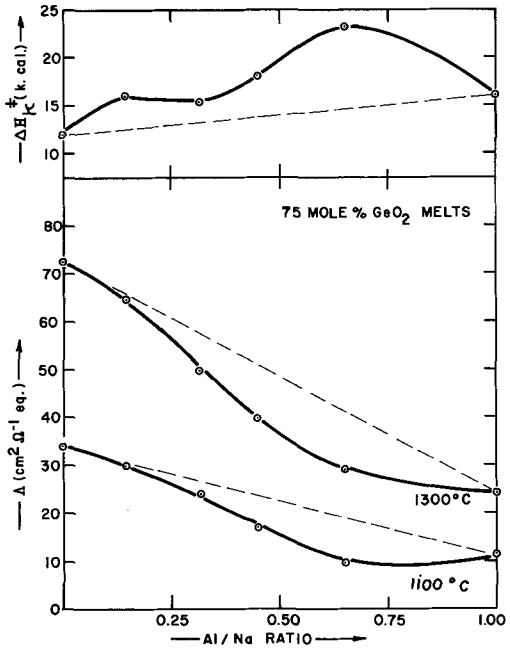

Fig. 4. Equivalent conductance isotherms and activation energy vs. Al/Na ratio for 75 mole % GeO_2 melts.

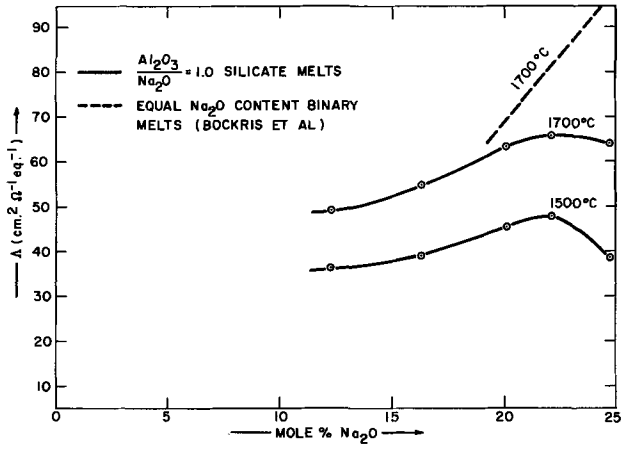

Fig. 5. Equivalent conductance isotherms vs. mole % Na_2O for equimolar sodium aluminate substituted silicate melts.

as a function of per cent GeO_2 replaced by SiO_2. Three of the four reruns produced differences at 1300°C that all but disappeared at 1100°C. These differences (15-20%) were larger than the usual level of reproducibility (< 5%). The reason for the better agreement at 1100°C is that the log κ *vs.* $1/T$(°K) plots for these six runs and reruns tend to intersect near the lower temperature. All four reruns were completed with the same electrode arrangement, which did not change calibration with use.

The 1100° and 1300°C equivalent conductance isotherms for the Al/Na = 1.0 germanate melts, the 25 mole % Na_2O aluminogermanate melts, and the 75 mole % GeO_2 sodium aluminogermanate melts are shown as functions of the mole % Na_2O in Fig. 2, of the Al/Ge ratio in Fig. 3, and of the Al/Na ratio in Fig. 4, respectively. A reproducibility check of one melt (composition No. 20) gave κ results that agreed to within 5%.

The 1500° and 1700°C equivalent conductance isotherms for the Al/Na = 1.0 silicate melts, the 20 mole % aluminosilicate melts, and the 75 mole % SiO_2 sodium aluminosilicate melts are shown as functions of the mole % Na_2O in Fig. 5, of the Al/Si ratio in Fig. 6, and of the Al/Na ratio in Fig. 7, respectively. A small amount of reaction was noted at the mullite tip for samples No. 27 and 28, primarily because of their higher Na_2O contents and the high temperatures. A fresh sample of No. 28 was rerun (No. 28R) at lower temperatures for shorter times. No mullite corrosion was observed and the κ points all agreed with the first few κ points from No. 28. Sample No. 24 was rerun as a check and showed a good level of reproducibility (Table I).

Discussion

The $Na_2O \cdot SiO_2 \cdot GeO_2$ *System*

The $\Lambda_{1300°C}$ fluctuations observed in the 0-50% GeO_2 replaced region (Fig. 1) could be associated with the previously suggested (1) structure change (disappearance of GeO_6 octahedra) for these melts. However, because of the lower net resistances at the higher temperatures and because of the lack of complete reproducibility, the above association is difficult to justify. Instead, the $\Lambda_{1100°C}$ isotherm (~ mp of GeO_2) will be assumed to more closely resemble reality for interpretive purposes.

The calculation of the Λ values was performed in such a fashion as to eliminate concentration or relative number of charge carriers as a factor. Thus, the fact that $\Lambda_{1100°C}$ exhibits positive deviations from ideality (or additivity) of up to 25% with the sub-

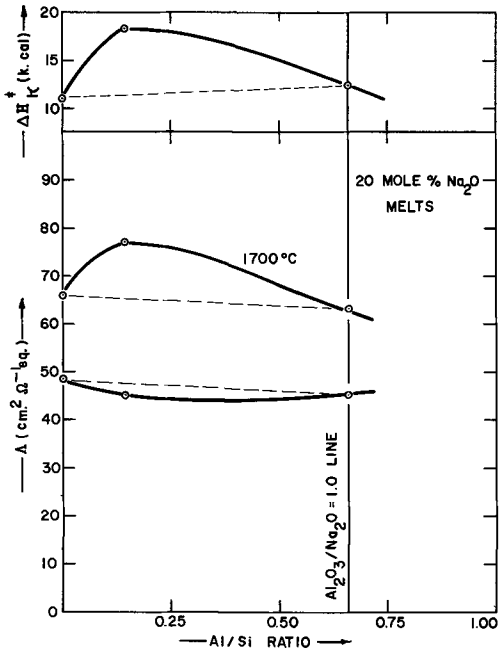

Fig. 6. Equivalent conductance isotherms and activation energy vs. Al/Si ratio for 20 mole % Na_2O aluminosilicate melts.

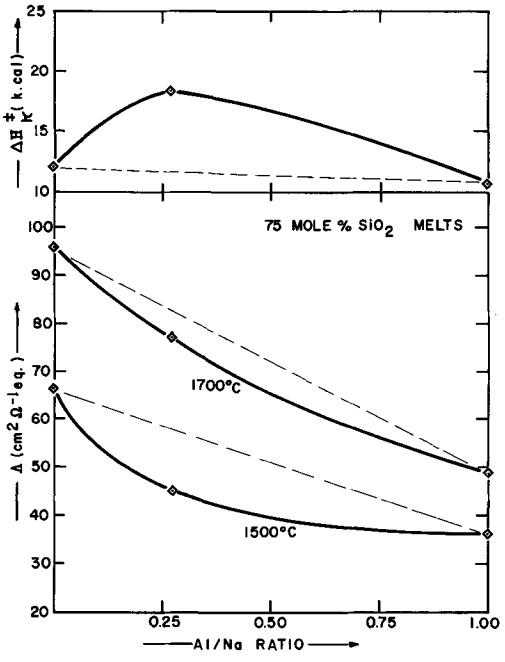

Fig. 7. Equivalent conductance isotherms and activation energy vs. Al/Na ratio for 75 mole % SiO_2 melts.

stitution of SiO_2 for GeO_2 is suggestive of an enhanced Na^+ ion mobility. The deviations from additivity are certainly greater than the normal experimental uncertainty associated with these measurements.

Of significance is the fact that cation mobility is enhanced for melts with greater than 50% GeO_2 replacement as well as for those melts with lesser GeO_2 replacements. The density and viscosity results indicated an absence of GeO_6 octahedra, with just GeO_4 and SiO_4 tetrahedra present, for the higher SiO_2 content melts. Thus, enhanced cation mobility does not appear to be directly related to the coordination number of germanium (IV).

One factor that can influence cation mobility is cation size or field strength. Thus, $\Lambda_{Li^+} > \Lambda_{Na^+} > \Lambda_{K^+}$ for the binary alkali germanates (5). Each Na^+ ion in these oxide melts can be thought of as possessing

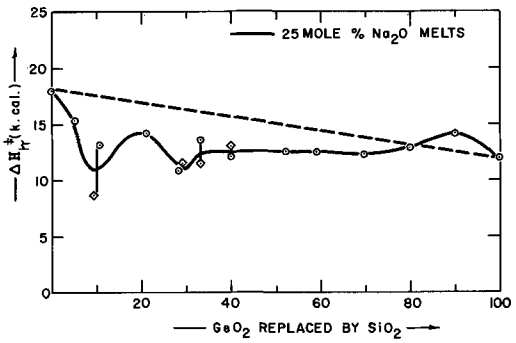

Fig. 8. Activation energy vs. composition for $Na_2O \cdot SiO_2 \cdot GeO_2$ melts

an oxygen polyhedron. The most plausible partial molar volume model for these 25 mole % Na_2O melts (1) involves smaller than ideal (~ 13%) partial molar volumes for Na_2O ($\bar{v}_{Na_2O}$). It is entirely possible that cation mobility could become enhanced if the oxygen packing of an NaO_4 or NaO_6 grouping were more efficient. This assumes that the entire cation-oxygen polyhedron is in some way involved in the activated process of ionic migration in a weak applied a-c electric field.

The above reasoning does not imply that the same oxygen environment moves with the cation (in this case, the Na^+ ion) during the process (mechanism) of activated complex formation. A simple cooperative positional adjustment of the surrounding oxygens could afford the Na^+ ion the opportunity to move a short distance. This cooperative rearrangement could be easier to accomplish, thereby increasing cation mobility (as observed), if the oxygen packing around the Na^+ ion were to become less voluminous (as seems to be the case). The negative $\Delta H^{\neq}_K$ departures from ideality (Fig. 8), which suggest a more favorable energy barrier, tend to support the above explanation of the enhanced cation mobility.

Bockris *et al.* (7) used Eyrings' theory of absolute reaction rates to develop an equation for the entropy of activation ($\Delta S^{\neq}_\Lambda$) for molten binary alkali silicate melts. That equation (5) was used to calculate $\Delta S^{\neq}_\Lambda$ values which are of the order of 0 to —3.0 e.u. for the present ternary oxide melts. This produces $\Delta H^{\neq}_\Lambda / T\Delta S^{\neq}_\Lambda$ ratios that lie between 3 and 20. Thus, as with the binary alkali germanates (5), $\Delta H^{\neq}_\Lambda$ appears to be the predominant and hence the significant term in the expression for $\Delta F^{\neq}_\Lambda$. This reinforces the relative role played by $\Delta H^{\neq}_\Lambda$ in the above analysis.

Another possibility is that the hole size and number distributions in the mixed anion melts are such that they enhance cation mobility to the extent of about 25%. Molar volume deviations can be associated in an approximate fashion with a change in the degree of openness in a liquid [melting point volume changes have been related to a change in the number of holes (8)]. However, the molar volume deviations from additivity, with respect to the experimentally determined end members of this system, amount to only about + 0.2% at the most (1).

The $Na_2O \cdot Al_2O_3 \cdot GeO_2$ *System*

Equimolar sodium aluminate melts.—The general trend of cation mobility is to increase with increase of alkali oxide content as the $Na_2O \cdot Al_2O_3 \cdot 2GeO_2$ (1/1/2) melt composition is approached (Fig. 2). This is an indication that the melt structure is being altered to the extent that the Na^+ ion mobility increases by a factor of four times. However, the cation mobility at 1100°C in the 1/1/2 ternary melt is still only 40% of the value obtained for a binary 25 mole % Na_2O germanate melt (dashed lines in Fig. 2). The same relationship holds for binary and ternary melts containing only 10 mole % Na_2O.

The above results suggest that the ternary melt structures are somewhat different from the previously postulated rather extensive network breakup associated with the formation of GeO_6 octahedra in binary alkali germanate melts (9). Thus, the lower cation mobilities support the density model of these ternary melts. That is, these equimolar sodium aluminate ternary melts tend to retain a three-dimensional type of liquid that gradually loosens as the 1/1/2 composition is approached.

Of significance is the fact that while the cation mobility increase is linearly related to the per cent Na_2O in the 5-25 mole % Na_2O region, mobility changes are small for the 0 to 5 mole % Na_2O region (Fig. 2). The $\Lambda_{1100°C}$ isotherm actually appears to go through a minimum when it is compared with the binary results. This phenomenon could be associated with the previously reported retention of a "random damaged network" to lower GeO_2 or SiO_2 contents in the presence of Al_2O_3 (2, 4, 10).

The activation energy dependence on composition for these Al/Na = 1.0 germanate melts (Fig. 9) is not as conclusive as the conductance trends. Although the $\Delta H^{\neq}_{\kappa}$ decrease is less pronounced for the 0 to 5 mole % ternary melts when it is compared to the binary melt trends, and hence agrees with the analysis of that conductance data, the slight $\Delta H^{\neq}_{\kappa}$ trend observed for larger Na_2O content ternary melts is unusual. It is possible that the slight change of mechanism suggested by the entropy of activation data for the 5 to 25 mole % Na_2O ternary melts does not show up in the $\Delta H^{\neq}_{\kappa}$ comparison ($\Delta H^{\neq}_{\Lambda} > T\Delta S^{\neq}_{\Lambda}$). The $\Delta S^{\neq}_{\Lambda}$ values are more negative (by about 2 to 3 e.u.) for these ternary melts. This suggests a slightly more restricted configuration for the activated complex in the ternary melts, which is in general agreement with their tighter three dimensional nature.

75 Mole % GeO_2 melts.—Two trends of the Λ *vs.* Al/Na ratio plots presented in Fig. 4 suggest melt structure changes, first, the Λ decrease that accompanies the substitution of Al_2O_3 for Na_2O. This agrees with the postulated extensive GeO_6 octahedra concentration that exists at the binary point and the three-dimensional nature of melts on the Al/Na = 1.0 line. Second, the negative departures from ideality (additivity) which can amount to as much as 25-50%. These deviations suggest that cation mobility is somehow retarded more than expected as AlO_4 tetrahedra substitute for the GeO_4 tetrahedra that link clusters of GeO_6 octahedra.

If one assumes that the $\bar{v}_{Na_2O}$ alone governs the Na^+ ion mobility, the results must be interpretable in terms of a relatively constant $\bar{v}_{Na_2O}$ of about 35 cc (3). Examination of Fig. 4 shows that this is not completely possible because the largest Λ deviations occur for Al/Na ratios > 0.5 and coincide with a pronounced $\Delta H^{\neq}_{\kappa}$ maximum at about Al/Na = 0.7. Clearly, cation mobility and the conductance mechanism in this case are influenced to a greater extent by the structure changes than by the packing of oxygens around the Na^+ ion. Cation location (near a charged AlO_4^- grouping)[3] could be more restricting for the intermediate compositions because of the limited positional possibilities for the AlO_4 tetrahedra, which appear to replace GeO_4 tetrahedra, not GeO_6 octahedra, at intermediate compositions.

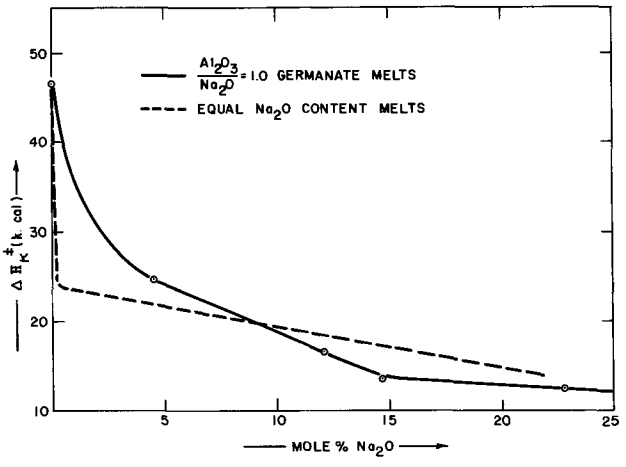

Fig. 9. Activation energy *vs.* mole % Na_2O for equimolar sodium aluminate substituted germanate melts.

25 Mole % Na_2O melts.—The Λ minima and the $\Delta H^{\neq}_{\kappa}$ maximum in Fig. 3 occur close to Al/Ge = 0.6, which corresponds to an Al/Na ratio of 0.7. This Al/Na ratio is close to the value at which similar phenomena occur for the 75 mole % GeO_2 melts (Fig. 4). It appears that a $\Delta H^{\neq}_{\kappa}$ ridge and a Λ valley occur along the Al/Na = 0.7 ternary line.

It was uncertain (3) as to whether the elimination of GeO_6 octahedra at the 25 mole % Na_2O level was (*a*) sudden or (*b*) gradual. The viscosity (2) and expansion coefficient results (3) favored the first possibility, which involved a sharp $\bar{v}_{Na_2O}$ minimum below Al/Ge $\cong$ 0.3 (as opposed to a gradual $\bar{v}_{Na_2O}$ change for the second model). Although the $\Delta H^{\neq}_{\kappa}$ increases slightly, the Λ deviations are minimal for these low alumina melts (Fig. 3).

Most of the conductance irregularities thus occur for alumina substitutions that are higher than anticipated from the molar volume models. It is difficult to say whether these Λ and $\Delta H^{\neq}_{\kappa}$ deviations are directly connected with the disappearance of GeO_6 octahedra or whether they simply reflect the gross structure change from a relatively fluid binary liquid to a ternary liquid that is three-dimensionally oriented. Either of these effects seems to outweigh the v_{Na_2O} factor for the series under discussion.

Certainly, the absolute value of cation mobility drops more sharply (with most of the concurrent $\Delta H^{\neq}_{\kappa}$ increase) below Al/Ge = 0.5 (Fig. 3). One could infer that most of the gross structure change does occur before the Al/Ge ratio exceeds 0.5. This conclusion would agree with the most likely molar volume model (3).

The $Na_2O \cdot Al_2O_3 \cdot SiO_2$ System

Equimolar sodium aluminate melts.—There is some degree of similarity between these conductance results (Fig. 5) and those just discussed for the analogous germanates (Fig. 2). Cation mobility appears to increase in the 10-20 mole % Na_2O region for both systems. This strengthens the conclusion that more open carnegieite-like network liquids are obtained as the 1/1/2 composition is approached.

However, there are specific cation mobility differences between the silicate and the germanates that outweigh the above similarity. First, the Na^+ ion mobility in the silicate melts can be about four times the value in the germanate melts. For example, $\Lambda_{1700°C} \sim 52.5$ in the silicate *vs.* $\Lambda_{1100°C} \sim 13.2$ in the germanate (both for the 15 mole % Na_2O composition).[4] Second, the Na^+ ion mobilities can be similar for the binary (7) and ternary silicate melts (Fig. 5). This is not the case for the germanates where the mobilities were considerably less in the ternary melts (Fig. 2). Third, the Na^+ ion mobility increases by a factor of 89% for the 10 and 20 mole % Na_2O ternary germanates compared to only a 31% increase for similar silicate melts. It appears that the relative structure change that accompanies substitution of Al_2O_3 and Na_2O is greater for the Al/Na = 1.0 germanate melts. This

[3] This factor does not exist for the substitution of SiO_4 tetrahedra for GeO_4 tetrahedra and GeO_6 octahedra.

[4] These reference temperatures are close to the melting points of the respective network forming oxides. A similar comparison between the binary alkali disilicate and digermanate melts revealed quite similar sodium ion mobilities (5).

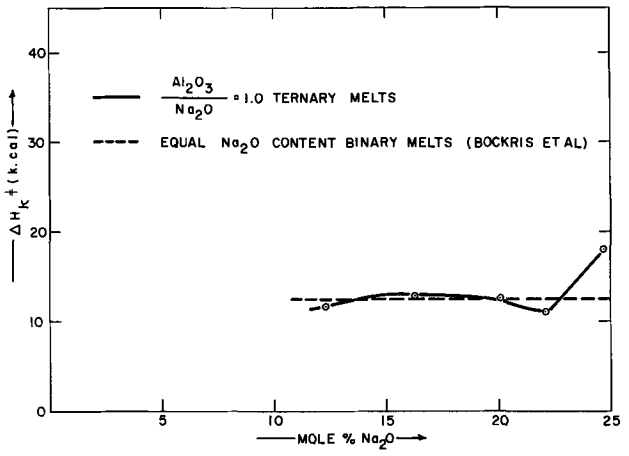

Fig. 10. Activation energy vs. mole % Na_2O for equimolar sodium aluminate substituted silicate melts.

conductance based conclusion agrees with the previous density and viscosity based conclusions.

The Na^+ ion mobility differences between these ternary silicate and germanate melts with an Al/Na ratio of 1.0 do not appear to be related to $\bar{v}_{Na_2O}$. That parameter takes a value of about 35 cc in the best partial molar volume models for the 1/1/2 melt composition in both series.

The $\Delta H^{\neq}_K$ plot shown for these melts in Fig. 10 is in agreement with most of the above discussion. Thus, the $\Delta H^{\neq}_K$ values in the 10 to 20 mole % Na_2O ternary region are similar to those reported by Bockris *et al.* (7) for the corresponding binary melts.[5] However, $\Delta H^{\neq}_K$ for molten carnegieite is about 50% greater than the value obtained for its germanate analogue (Fig. 9). This contrasts with much higher cation mobility (by a factor of three times) in the 1/1/2 silicate melt compared to the 1/1/2 germanate melt at the melting temperatures of the respective network forming oxides. A possible explanation of this paradox may be found in the fact that $\Delta H^{\neq}_K$ is strongly proportional to cation volume for low alkali content melts (< 10 mole % M_2O) that contain a high concentration of network forming tetrahedra (as per the melts under discussion). It was implied that hole size could thus play a significant role in the conductance mechanism (5). The present $\Delta H^{\neq}_K$ observations may be a manifestation of just such a parameter.

75 Mole % SiO_2 melts.—The Λ decrease that accompanies the substitution of Al_2O_3 for Na_2O (Fig. 7) is partially expected because the Na_2O content is reduced from 25 to 12.5 mole % in the process. A similar Λ decrease was observed by Bockris *et al.* for binary alkali silicates in the 25-19 mole % Na_2O region (7). Of more significance is the structure change later postulated for these particular binary melts by Bockris *et al.* (11). The decrease of alkali content was visualized as being accompanied by an increase of the size of silica-like "icebergs," with the alkali cations located between "icebergs." A random damaged silica network was supposed to be formed at about 12 mole % Na_2O. This phenomenon has recently been proposed for molar volume models of the ternary melt compositions under discussion (4). The now observed cation mobility trend agrees with this over-all picture.[6]

The Λ deviations from additivity are negative (Fig. 7), but do not exhibit the type of trend observed for similar 75 mole % GeO_2 melts (Fig. 4). The maximum Λ deviations appear to occur at lower Al/Na ratios in the silicates. The same might be said of the $\Delta H^{\neq}_K$ maximum (Fig. 7). Indeed, the fact that these maximum deviations occur at different Al/Na ratios in the two systems only serves to emphasize the structural differences. The fact that the trends are similar, in spite of the vastly different structures involved, could be due to coincidence or to an interplay of the parameters that influence cation mobility and the associated mechanism. As with the ternary aluminogermanates, one of the parameters influencing these Λ deviations could be the restriction that the Na^+ ion be near a charged AlO_4^- grouping.

20 Mole % Na_2O melts.—The electrical conductance results for the 20 mole % Na_2O series, although there is just one intermediate point close to the binary in composition, do suggest the presence of Λ_{1700} and $\Delta H^{\neq}_K$ maxima (Fig. 6). These observations differ from the previously discussed Λ minima (and $\Delta H^{\neq}_K$ maximum) that were found for the 25 mole % Na_2O aluminogermanate melts at a Al/Ge ratio of about 0.6 (Fig. 3).

The Λ_{1700} maximum is slight while the Λ_{1500} isotherm changes very little with composition (Fig. 6). Lower temperatures would probably produce a Λ minimum, thereby creating a Λ and $\Delta H^{\neq}_K$ situation below the melting point of SiO_2 that would be analogous to the germanate case for temperatures above the melting point of GeO_2. The lower temperature Λ minima, as well as the $\Delta H^{\neq}_K$ increase, can be rationalized in terms of the $\bar{v}_{Na_2O}$ increase that has been postulated for these particular silicate melts (4). The influence of this parameter could be more temperature dependent for this series than with the other melts studied. This might be associated with the postulated gradual change from a silica-like iceberg binary liquid to an open, cristobalite-like ternary liquid containing 60 mole % SiO_2 (4).

Comparison of Melts and Glasses

A recent electrical conductance and transport number study of several Al/Na < 1.0 sodium aluminosilicate glasses (12, 13) has confirmed the glasses to be essentially ionic conductors, with the Na^+ ion carrying most of the current. Similar results have been reported for binary alkali silicate melts (8). This suggests the possibility of a similarity between conductive processes in the glass and liquid states for a given sodium aluminosilicate composition. This correlation is known to exist for binary alkali germanate compositions (5) where for example, the ratio of $\Delta H^{\neq}_K$ melt/$\Delta H^{\neq}_K$ glass for a 25 mole % Na_2O germanate is about 0.67 in spite of a much greater cation mobility in the melt.

A comparison of the activation energies obtained by Isard (14) for Al/Na = 1.0 sodium aluminosilicate glasses with the present values for the corresponding high-temperature melts (Fig. 10) reveals a close similarity, again in spite of higher melt mobilities. Isard's $\Delta H^{\neq}_K$ values show a progressive decrease from about 17 to 13 kcal for ~ 20 mole % Na_2O glasses between the binary and the Al/Na = 1.0 line. These energies are similar in magnitude but different in trend to those reported for the corresponding melts in Fig. 6. It is interesting that Isard explained his glass state results in terms of an expansion of the coordination shell around sodium ions, but only for glasses with Al/Na < 1.0, that was caused by elimination of nonbridging oxygens with the addition of Al_2O_3.

The above electrical conductance similarities between the glass and liquid states for a given ternary oxide composition series are understandable in light of the recently discovered molar volume similarity for some of these sodium aluminosilicate glasses and liquids (4). The volume models for these liquids involved $\bar{v}_{Na_2O}$ values that increased with increase of Al_2O_3 content, regardless of the Al/Na ratio.

[5] The reason for the $\Delta H^{\neq}_K$ increase at the 1/1/2 composition is unclear. The K and $\Delta H^{\neq}_K$ data reproduced to within several per cent for runs with completely different carnegieite samples.

[6] The general Λ decrease observed for these 75 mole % SiO_2 melts could also be explained in terms of the $\bar{v}_{Na_2O}$ increase that occurs as the Al/Na = 1.0 line is approached (4).

Conclusions

In general, the equivalent conductance information obtained for these ternary oxide melts agrees with previously proposed molar volume structural models and data. In contrast to simple molten salt mixtures such as KI·KBr, where cation mobility deviations can be correlated with anion differences, no one particular factor seems to govern cation mobility in all of these ternary oxide melt systems. The gross melt structure changes are much more pronounced and are much more specific to each system for most of the molten oxide mixtures thus far studied. This situation serves to produce a somewhat incomplete unified interpretation of cation mobility for these ternary oxide melts.

The Permeation of Electrolytic Hydrogen through Platinum

E. Gileadi,[1] M. A. Fullenwider, and J. O'M. Bockris

The Electrochemistry Laboratory, John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The absorption and permeation of electrolytically generated hydrogen through thin platinum foils have been observed directly by an electrochemical method. The diffusion coefficient and the associated apparent energy of activation were determined. The concentration of absorbed hydrogen was obtained, and it was shown that atomic hydrogen tends to concentrate in areas of high strain in the metal where it can be in a lower energy state. Hydrogen embrittlement phenomena similar to those found in iron and steel were observed. The variation of cathodic overpotential with time was explained in terms of the change in hydrogen concentration in the bulk of the metal near the cathodic surface.

The diffusion of hydrogen through platinum from the gas phase at high temperatures of 700°-1000°C was reported by Richardson *et al.* (1) in 1904. The diffusion coefficient was not obtained, but the apparent energy of activation for the over-all permeation process was calculated. It was also stated in this work that "it is a well-known fact that platinum through which hydrogen diffuses becomes brittle and will break under small stress." In 1956, Hoare and Schuldiner (2) used a membrane electrode (bi-electrode) to observe the variation of overpotential on one side of the membrane as a function of the applied cathodic current density on the other side. In the experimental setup used by these authors the cathodic and anodic sides were not connected to one another electrolytically, and the change in overpotential on the anodic side could only arise due to diffusion of atomic hydrogen from the cathodic side through the membrane. Hoare and Schuldiner used this method to study the kinetics of hydrogen evolution on Pd. They also observed a very small change (1 mv) in the potential of a platinum membrane only when the cathodic side was poisoned with a small amount of As_2O_3 added to the solution. Kheifetz and Krasikov (3) observed a change in the potential of zero charge of the anodic surface of a Pt membrane with time during constant current hydrogen evolution on the cathodic side. This was interpreted as due to the change in the concentration of absorbed hydrogen in the metal.

[1] Present address: Department of Chemistry Tel-Aviv University, Tel-Aviv, Israel.

Analysis of galvanostatic transients on Pt has recently (4) led to the conclusion that both hydrogen and oxygen are absorbed to an appreciable extent in Pt.

While the above evidence strongly implies that hydrogen can diffuse into platinum, there is no direct evidence so far for the permeation of electrolytic-hydrogen through platinum, and the diffusion coefficient for this process has not yet been reported.

In this paper the permeation of electrolytically produced hydrogen through Pt at relatively low temperatures (50°-80°C) has been observed directly. Further, the diffusion coefficient and its variation with temperature have been determined. The concentration of absorbed hydrogen is obtained and a model for the state of absorbed hydrogen in the metal is proposed.

Experimental

Method of measurement.—A simple, yet accurate and sensitive method for measuring the rate of hydrogen permeation through thin metal foils has been devised by Devanathan and Stachurski and described in detail elsewhere (5). In essence it consists of a bi-electrode (2) in the form of a thin foil which separates two identical electrochemical cells. On the cathodic side of the foil, hydrogen is evolved at a fixed rate, while the diffusion side is kept at an anodic potential such that the concentration of adsorbed atomic hydrogen on this surface is essentially zero. Thus, hydrogen which diffuses through the membrane and emerges on the anodic side is immediately ionized, and the current passed to maintain constant potential

on this surface is directly proportional to the hydrogen permeation rate.

Calculation of D and C_o.—Analysis of the diffusion problem with the boundary conditions imposed on the system, *i.e.*, $C(o,t) = C_o$; $C(L,t) = 0$ and $C(x,o) = 0$ allows one to calculate the diffusion coefficient from the form of the permeation transient as shown elsewhere (5, 6). Thus, the permeation rate J_t during the transient is given by

$$J_t/J_\infty = \frac{2}{\pi^{1/2}} \frac{1}{\tau^{1/2}} \exp(-1/4\tau) \quad [1]$$

where τ is a dimensionless parameter

$$\tau = Dt/L^2 \quad [2]$$

For $J_t/J_\infty = 0.50$, one finds $\tau = 0.138$, and thus by measuring the time required to reach this fractional permeation rate, the diffusion coefficient may be calculated. In general one can write Eq. [2] in the form

$$t_\gamma = \tau_\gamma L^2/D \quad [3]$$

where t_γ is the time required for the permeation rate J_t to reach a fraction γ of its steady-state value J_∞, L is the thickness of the membrane, and D is the diffusion coefficient. Under steady-state diffusion conditions Fick's first law applies giving

$$J_\infty = FD(C_o - C_L)/L = FDC_o/L \quad [4]$$

where J_∞ is the permeation rate in units of current density, $C_o \equiv C(o,t)$ = constant, and $C_L \equiv C(L,t) = 0$. From Eq. [3] and [4] both the diffusion coefficient and the concentration of hydrogen in the metal just under the cathodic surface can be calculated on the basis of a single permeation experiment.

Electrodes.—Platinum foils of thickness ranging from 2 to 5 x 10^{-3} cm were used in these experiments. The foils were first degreased by refluxing overnight in 1:1 methanol-benzene and then heated for 3 hr at 600°C in an atmosphere of argon to ensure zero hydrogen concentration in the metal. Calculated values of D and C_o are all based on the first transient. Only transients which have the theoretically expected shape were accepted for the calculation of D. This can be tested in a simple manner in that D should not vary systematically with γ. Cracks in the metal foil allowing contact between the electrolyte on the two sides of the membrane are easily detected. For such a membrane, turning on the cathodic current immediately affects the current recorded on the anodic side, while for an uncracked electrode a certain time elapses before the effect of a change on the cathodic surface is propagated through the membrane and can be observed on the anodic side.

Solution preparation.—A 0.1*N* sulfuric acid solution prepared from reagent grade H_2SO_4 and conductivity water was used on the cathodic side. The solution was preelectrolyzed externally in an auxiliary compartment and transferred to the cell with nitrogen pressure. Arsenic oxide was added in a concentration of 5 mg As_2O_3 per liter. No permeation current could be observed when hydrogen evolution occurred in unpoisoned solution (2).

On the anodic side a 0.2*N* NaOH solution was used. Analytical grade NaOH and conductivity water were used to make up this solution. The purity of the solution on the anodic side is important in that it determines largely the background current and hence limits the sensitivity of the measurement. Stable background currents of the order of 1 μa/cm^2 were observed and permeation rates as low as a few tenths of a microampere could be measured.

Results and Discussion

Shape of the permeation transient.—The shape of a typical set of permeation transients obtained at 70°C for a foil thickness of 3.8 x 10^{-3} cm is shown in Fig. 1. The diffusion coefficient was calculated from the shape of the first transient, obtained with a polarization current density of 0.5 ma/cm^2.

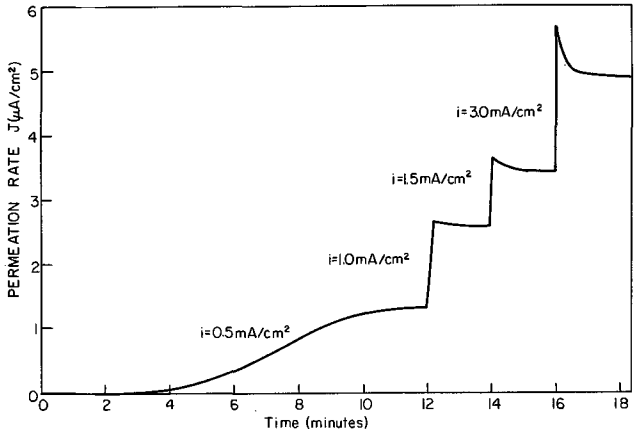

Fig. 1. Shape of successive permeation transients with increasing cathodic current density. L = 3.8 x 10^{-3} cm, 70°C.

At higher current densities the initial rise of the permeation rate is followed by a slower decrease towards a steady state. A similar behavior was observed by Bockris, McBreen, and Nanis (7, 8) for the permeation of hydrogen through iron and steel membranes and was associated there with the onset of hydrogen embrittlement. Thus, when the concentration of hydrogen in the metal exceeds its saturation value, corresponding to a critical cathodic current density i_{crit}, the hydrogen atoms diffuse to the surface of small crevices and voids in the metal and recombine there to form gaseous H_2, which can generate a high internal pressure, expand the crevices and voids, and cause further cracking. In view of the similarity in the form of the permeation transients at higher current density for Pt and Fe, and the early observation (1) that hydrogen embrittlement of Pt does indeed occur at high temperature, it may be concluded that the "overshoots" in the permeation transients for Pt are indicative of a similar embrittlement phenomenon.

At 70° the value of the critical current density according to Fig. 1 is just below 1.0 ma/cm^2. Qualitative evidence indicates that, unlike in the case of iron, $i_{crit.}$ decreases with increasing temperature.

Evidence for diffusion controlled permeation.—In Fig. 2 the steady-state permeation rate J_∞ is plotted as a function of $1/L$ for three thickness of Pt foil at 70°C. A linear plot is obtained going through the origin, as expected according to Eq. [4]. The slope of the straight line equals FDC_o. With D calculated independently from the shape of the transient (Eq. [3]), the concentration of hydrogen at $x = o$, namely, just below the cathodic surface, can be obtained.

A second test of the assumption of diffusion controlled permeation rate is based on Eq. [3]. Thus, a plot of t_γ *vs.* L^2 should be a straight line going through the origin. This is shown to be the case in Fig. 3 for $\gamma = 0.5$ at 70°C. Figures 2 and 3 show that the permeation of hydrogen through Pt is diffusion controlled both during the transient and at steady state. From the slopes of Fig. 2 and 3, one obtains

$$D_{70°C} = 3.4 \times 10^{-9} \text{ cm}^2/\text{sec}$$

$$C_{o_{70°C}} = 2.7 \times 10^{-5} \text{ gram atom/cm}^3$$

It should be noted that while both these quantities depend on the bulk properties of the metal, the concentration C_o is also a sensitive function of the state of the surface. It will depend on the applied cathodic current density and on the composition of the solu-

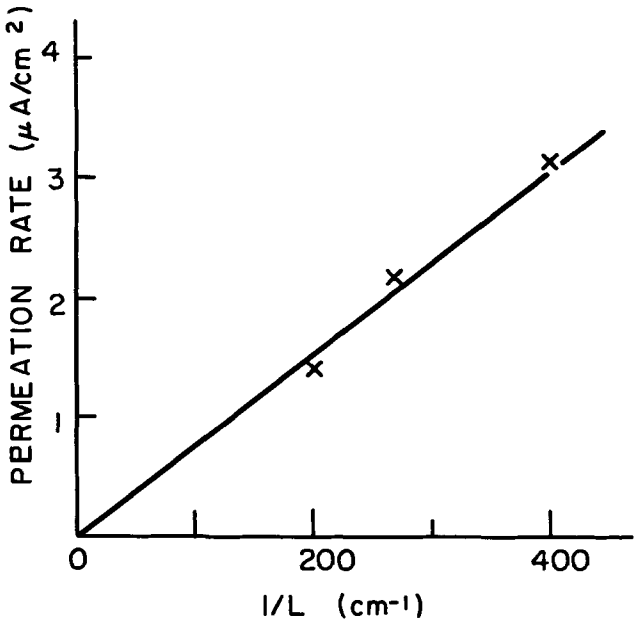

Fig. 2. Permeation rate as a function of 1/L. Cathodic current density 0.5 ma cm^{-2}, 70°C.

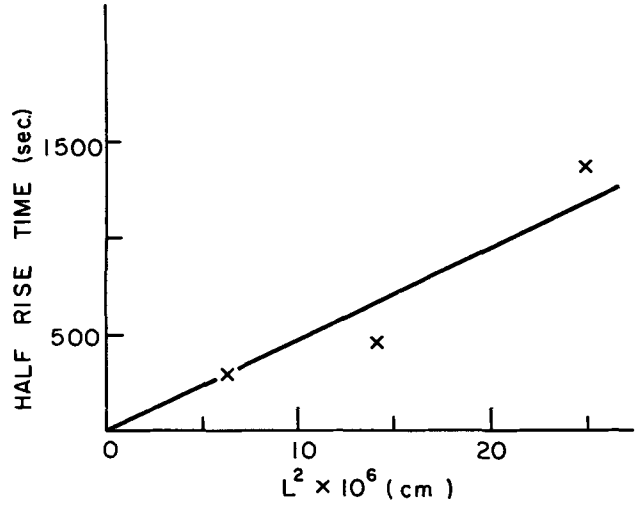

Fig. 3. Half rise time (t_γ for $\gamma = 0.5$) as a function of L^2. Cathodic current density 0.5 ma cm^{-2}, 70°C.

tion, in particular the amount and nature of surface poison added, while D is independent of these quantities.

Heat of activation for diffusion.—The diffusion coefficient was studied as a function of temperature over the range of 50°-80°C, using a polarization current density of 0.5 ma/cm^2. A straight semilogarithmic plot was obtained up to 70°C, giving an apparent energy of activation of 9.6 kcal/mole for the diffusion process (Fig. 4).

Above 70°C the value of D dropped sharply, as shown by the three lower points in Fig. 4, taken at 72.5°, 75°, and 80°C. However, when the polarizing current density was reduced to 0.2 ma/cm^2, higher diffusion coefficients were measured, which fall on a straight line with values obtained at lower temperatures, as shown in Fig. 4.

The interpretation of this phenomenon lies in the decrease of critical current density $i_{crit.}$ at which embrittlement occurs with increasing temperature. Thus, at 70°C or below, the cathodic current applied was less than $i_{crit.}$, and a regular transient resulted. Above 70°C $i_{crit.} < 0.5$ ma/cm^2 and the form of the transient is distorted, giving rise to an apparent low value of

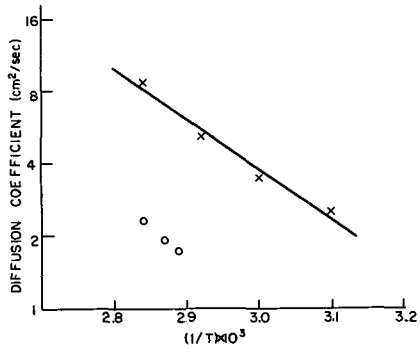

Fig. 4. Semilogarithmic plot of D vs. 1/T. L = 3.8 x 10^{-3} cm

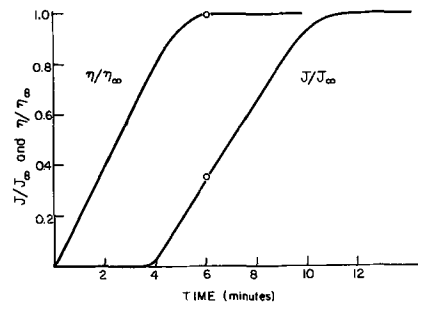

Fig. 5. Plots of (normalized) cathodic overpotential and permeation rate as a function of time. L = 3.8 x 10^{-3}, 70°C.

D. When the polarizing current is reduced to 0.2 ma/cm^{-2} (which is less than $i_{crit.}$ at 80°C) a value of D is obtained which is consistent with those at lower temperatures. It may be concluded, hence, that the diffusion coefficient is independent of the applied cathodic current density, as long as this is kept below a critical value. This may be regarded as further evidence that the permeation process is diffusion controlled in these systems, and that a critical change in the internal structure of the metal takes place at $i_{crit.}$.

Variation of overpotential with time.—Figure 5 shows the variation of cathodic overpotential with time during a permeation transient at 70°C. Both the overpotential η and the permeation rate J are plotted on a normalized scale as η/η_∞ and J/J_∞ in the same experiment. It may be seen that the overpotential reaches its steady-state value when $J/J_\infty = 0.35$, *i.e.*, at a time t_γ corresponding to $\gamma = 0.35$. Repeated experiments under a variety of conditions show that η/η_∞ approaches unity at times t_γ corresponding to $\gamma = 0.25$-0.50. The steady value of the overpotential reached after a relatively short time in these experiments is in contrast to the long time variation of η observed in hydrogen evolution studies on platinum (9).

The variation of η with time during the transient may be interpreted in terms of a change in the properties of the electrode due to hydrogen absorption. Thus, when steady-state permeation is attained the concentration of hydrogen at any point in the metal reaches a constant, time-independent value and no further change in overpotential will occur. The question still remains why the overpotential reaches a steady-state value when J_t/J_∞ is substantially smaller than unity. Figure 6 shows the calculated concentration profile of hydrogen in the metal at times t_γ corresponding to $\gamma = 1.0$; 0.5; 0.35; 0.25. At low values of x/L (*i.e.*, close to the cathodic surface) the concentration approaches its steady-state value when $\gamma > 0.25$. Figure 7 shows the variation of C with time at a distance x from the cathodic surface such that $x/L = 1/16$. The concentration of hydrogen inside the metal

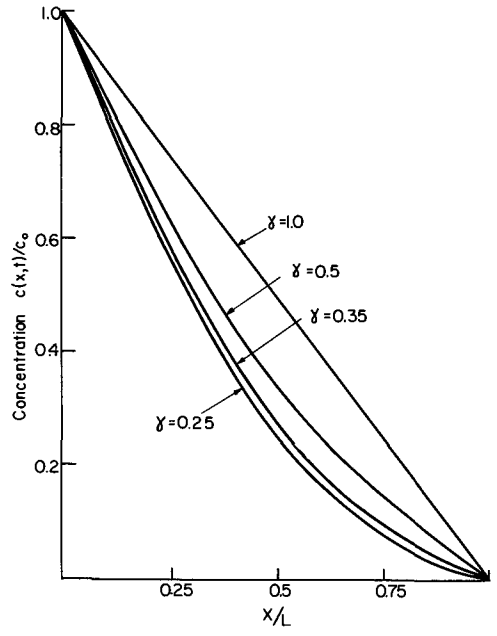

Fig. 6. Calculated concentration profiles of absorbed hydrogen in the metal foil at various times during the transient.

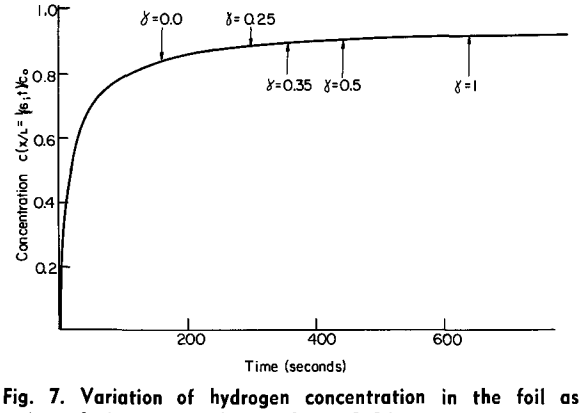

Fig. 7. Variation of hydrogen concentration in the foil as a function of time at a plane x/L = 1/16.

rises initially very rapidly and reaches 91% of its steady-state value at the break-through time.[2] At $\gamma = 0.25$ the concentration has reached 96% of its steady-state value and thereafter it changes very slowly with time. Since the cathodic overpotential depends on the state of the surface and perhaps a region in the bulk of the metal close to the surface ($x/L << 1$) it will not be expected to change much with time when γ has reached a value of 0.25-0.5, in agreement with experiment.

At room temperature D is about one order of magnitude smaller than at 70°. The time required for a wire electrode of 0.5 mm diameter to become saturated with hydrogen under these conditions is of the order of 50 hr, and the overpotential may hence be expected to change with time at constant current density for at least 10-20 hr.

Support for the view that hydrogen absorption in Pt can affect the kinetic parameters on the surface is found in recent studies of the potential of zero charge of Pt (10) which was found to depend critically on the presence of absorbed hydrogen. Also, time variation of the overpotential for hydrogen evolution on Pd cathodes was observed by Frumkin and Aladgalova (11) and interpreted similarly in terms of the changes in the metal structure caused by absorption of hydrogen.

[2] The break-through time has been defined (6) as the time elapsed between turning on the cathodic current and the emergence of the first measured amount of hydrogen on the anodic side.

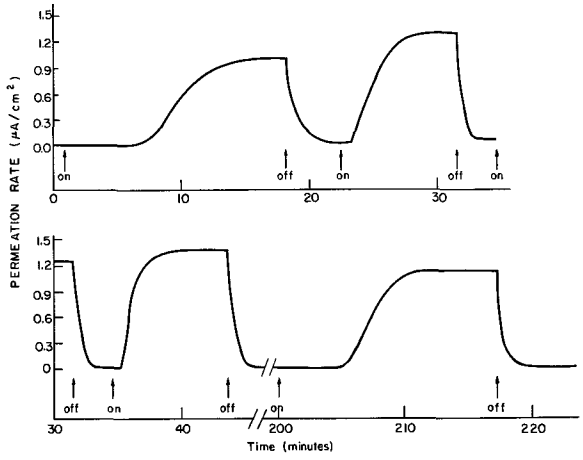

Fig. 8. Successive permeation transients through a foil. L = 2.5 x 10^{-3} cm, 70°C, cathodic current density = 0.1 ma cm^{-2}.

Stability of absorbed hydrogen in platinum.—Results of an experiment in which the cathodic polarization current density was switched on and off several times are shown in Fig. 8. The observations in this experiment may be summarized as follows: (*A*) The first transient differs substantially from following transients. The difference between the second and third transient, on the other hand, is small. (*B*) When the cathodic current is switched off the transient decays rapidly (the permeation current goes to zero within 3-4 min). (*C*) With the cathodic current switched off and the anodic potential maintained (*i.e.*, a condition where the hydrogen already in the metal is being "pulled out" while no new hydrogen is introduced) the membrane recovers very slowly to its original state. In the experiment shown in Fig. 8, 150 min were not quite enough to restore the original state of the membrane, even though the transient taken after this time resembles much closer the first transient than the second and third transients, which were taken a few minutes after the current was switched off (cf. Fig. 8).

In the case of hydrogen permeation through iron it has been shown (7, 8) that hydrogen diffuses through the lattice and not along grain boundaries. If this applies also to Pt, then hydrogen will move from one interstitial site to another, and in its interstitial position will cause a certain strain in the lattice structure. It can easily be shown (12) that under these conditions an uneven distribution of hydrogen in the metal will result, and points of local strain will constitute "islands" where the concentration of hydrogen will be larger than in the bulk.

A simple equilibrium of the type

$$H_b \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_i \qquad [5]$$

may now be considered, where H_b is a hydrogen atom in a lattice site in the bulk of the metal and H_i is an atom of hydrogen in an island. If H_i represents a substantially more stable state than H_b, then the equilibrium constant $K = k_1/k_{-1}$ will be much larger than unity. Thus most atoms will reside on islands rather than in the bulk, and the rate of reaching an island will be much larger than the rate of escape from it.

Consider now the experimental evidence shown in Fig. 8 in the light of this model. During the first transient, hydrogen diffuses slowly through the metal because most of it is used to saturate the islands of high strain. When the cathodic current is switched off, hydrogen atoms from the bulk lattice diffuse out relatively quickly, but their escape from the islands of high strain is slow and does not occur to an appreciable extent within a few minutes. When the cathodic current is switched on again, diffusion occurs

through a hydrogen-loaded membrane, *i.e.*, one in which the islands of strain have already been saturated with hydrogen. Diffusion through such a membrane occurs much faster, as evidenced by the shorter transient (cf. the second and third transients in Fig. 8). When the cathodic current is switched off for several hours the hydrogen atoms absorbed in islands of high strain slowly diffuse out, and the initial state of the membrane can be restored.

An order of magnitude type calculation of the ratio of rate constants in Eq. [5] may be made on the basis of the data presented in Fig. 8.

From the shape of the second and third transients it may be inferred that saturation of the islands has almost, but not quite reached equilibrium during the first transient which lasted 18 min. On the other hand, the original state of the membrane was almost restored in 150 min between the third and the fourth transient. The amount of hydrogen taken out from the membrane after the current is switched off may be obtained from the area under the permeation decay transients in Fig. 8. The charge measured is $Q = (2\text{-}4) \times 10^{-4}$ coulombs. Thus

$$C_o = 2\overline{C} = 2Q/FV \qquad [6]$$

where $\overline{C}$ is the average concentration of free hydrogen in the metal, Q is the measured charge during decay, and V is the volume of the membrane. For a 1 cm^2 membrane having a thickness of 2.5×10^{-3} cm, this gives $C_o = (1.6\text{-}3.2) \times 10^{-6}$ gram atom/cm^3, as compared to a total concentration of 2.7×10^{-5} gram atom/cm^3 obtained above. Thus about 85-95% of all the hydrogen absorbed in Pt is concentrated in areas of high strain, and $K = 8\text{-}17$.

The diffusion coefficient calculated from the third transient is about 7 times that obtained from the first transient. It is this diffusion coefficient which should be used in Eq. [4] to obtain the concentration (C_o) of free hydrogen absorbed in the bulk of the metal. This gives rise to $C_o = 3.8 \times 10^{-6}$ gram atom/cm^3 and $K = 6$. It may thus be concluded that 85-95% of the hydrogen absorbed in Pt is concentrated in islands of local strain which are in slow equilibrium with hydrogen absorbed in the bulk. The equilibrium constant for the transfer of hydrogen atoms from the bulk to an island (Eq. [5]) is in the range of 6-17, and the time required to saturate an island is about ten times shorter than the time required to eliminate all the hydrogen from the metal under a given set of conditions.

Conclusions

The permeation of electrolytically generated hydrogen through Pt membranes has been observed directly in the temperature range of 50°-80°C. The process is shown to be diffusion controlled at steady state and during the transient. The diffusion coefficient at 70°C is 3.4×10^{-9} cm^2/sec, and the apparent energy of activation for the diffusion process is $\Delta H^{\neq}_D = 9.6$ kcal/gram atom. The total concentration of absorbed hydrogen just below the cathodic surface is $C_o = 2.7 \times 10^{-5}$ gram atom/cm^3. Most of the absorbed hydrogen is concentrated in regions of local strain in the crystal and only some 5-15% is free to move through the lattice. Hydrogen atoms absorbed in regions of local strain are relatively stable and take much longer to diffuse out than in.

Hydrogen permeation becomes detectable only when the cathodic surface of the membrane is poisoned, as others have found (2). Hydrogen embrittlement was found to occur, as in the case of iron and steel (7, 8). The overpotential for hydrogen evolution was shown to depend on the concentration of absorbed hydrogen just under the cathodic surface. Calculation using an experimental value of the diffusion coefficient shows that in a typical experiment at room temperature a variation of cathodic overpotential due to this effect could be observed for up to 10-20 hr.

Electrochemistry of the Lithium Hydride Cell

James A. Plambeck,[1] John P. Elder,[2] and H. A. Laitinen[3]

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

The hydrogen/lithium hydride electrode, which is of interest in thermally regenerative fuel cells, has been studied in fused LiCl-KCl eutectic at 375°C by voltammetric and chronopotentiometric techniques. The diffusion coefficient of LiH under these conditions is $1.67 \pm 0.04 \times 10^{-5}$ cm²/sec. Differences between anodic chronopotentiograms obtained using tungsten and iron flag electrodes are discussed.

Considerable attention has been directed toward thermally regenerative ionic hydride cells as direct energy conversion devices (1). As a consequence, a study of the electrochemistry involved in the operation of such cells is of potential interest. Such an investigation is described in this paper.

Lewis (2) initiated the electrochemical studies of saline hydrides when he showed that molten lithium hydride will conduct electricity. Moers (3), Peters (4), and Potter and Bockris (5) have studied the electrolysis of solid lithium hydride. In all cases, simultaneous cathodic deposition of lithium and anodic evolution of hydrogen were observed. Bardwell (6) dissolved calcium hydride in molten purified LiCl-KCl eutectic at about 365°C; electrolysis of these solutions evolved hydrogen at the iron anode in amounts calculated from Faraday's law for the discharge of hydride ion. This work has been questioned by Potter and Bockris (5) who were unable to detect any anodically evolved hydrogen from a solution of calcium hydride in this eutectic.

Johnson *et al.* (7) concluded from LiH-LiCl solid-liquid equilibrium studies that polymerization of lithium hydride in lithium chloride does not occur. Similar studies (8) of the LiH-NaCl reciprocal system yield evidence for the existence of unionized monomeric lithium hydride in dilute solutions in molten chlorides. Johnson and Heinrich (9) have made equilibrium potential measurements on cells of the type $H_2(g)/LiH(x)$, $LiCl(1-x)/Li^0(liq.)$ using iron as the inert electrode material. The concentration dependence of the potential corresponded to one electron/LiH and the pressure dependence to two electrons/hydrogen molecule. The electrochemical equilibrium was apparently established at the three-phase solid iron-fused salt electrolyte-hydrogen gas interface.

Qualitative data on thermally regenerative fuel cells using lithium hydride have been reported (10-13). Indig and Snyder (14) have studied the lithium hydride-hydrogen electrode in LiCl-KCl eutectic and have shown apparent one-electron Nernstian behavior in concentration cells. These authors interpreted their coulombic efficiency data on the basis of two competing reactions, $LiH \rightarrow Li^+ + \frac{1}{2}H_2 + e^-$ and $LiH \rightarrow Li^+ + H^+ + 2e^-$. Additional evidence cited for the occurrence of the latter was the evolution of hydrogen at the cathode, presumably from discharge of H^+. Inasmuch as the reaction $H^+ + LiH \rightarrow H_2 + Li^+$ can be expected to occur in any melt containing lithium hydride, the two-electron oxidation appears unlikely and the cathodic hydrogen evolution is probably due to some reaction involving impurities; such reactions have been studied in this solvent (15, 16).

Experimental

Apparatus.—Any investigation of a system involving molten alkali metals and their salts requires the maintenance of an inert atmosphere of high purity. These conditions have been achieved by the development (17) of a helium-atmosphere purification unit. In normal operation, the impurity levels in the inert-atmosphere box are less than 0.5 ppm water and less than 10 ppm total for oxygen and nitrogen.

The cell was operated in a furnace well attached to the base of such a box. The reactivity of molten lithium and molten salt solutions of this metal severely limits the cell design. Molten lithium has a finite solubility in LiCl-KCl eutectic. Up to the present time, no suitable electrical insulator has been found capable of withstanding prolonged attack by molten lithium or molten-salt solutions of this metal. Accordingly, all electrodes must be suspended from an insulator above the solution.

A diagram of the cell is shown in Fig. 1. All materials except the pin vise, which was nickel-plated steel, and where otherwise stated, was type 316 stainless steel. The two lithium cup electrodes and the two stainless steel-sheathed chromel-alumel thermocouples (Pyro Electric, Inc., Walkerton, Indiana) were symmetrically located with respect to the central indicating electrode, which was supported by the pin vise.

The inner crucible fitted into the furnace well. To reduce thermal gradients, the outer surface of the well was covered with ⅛ in. nickel-plated copper over a length 5 in. from the base. With an electrolyte depth of 1½ in., the electrolyte surface temperature was 371°-372°C when the bulk temperature was maintained at 375°C. The liquid lithium electrodes were held below the electrolyte surface on cylindrical metal sponges fitted into the stainless steel cups. The stainless steel sponge (Huyck Metals, Milford, Connecticut) was wetted by liquid lithium at 600°C and held it with great tenacity; the lithium did not detach from its support on immersion in the molten electrolyte. By placing a cap with a small central orifice on top of the cup, the rate of solution of lithium in the electrolyte was rendered negligible. The thermocouple sheaths and electrode leads passed through nylon-lined brass tubes which extended from the bottom of the cell head base into the box. At the head of each brass tube was a modified, nylon-lined brass vacuum coupling (Type C, Vacuum Electronics Corporation, Chicago, Illinois). The electrode leads were connected to micrometer depth gauges (No. 605, Brown and Sharpe Manufacturing Company, Providence, Rhode Island). A stepless temperature controller (JYSCR set point unit, PSCR-27-120 power unit; West Instrument Corporation, Schiller Park, Illinois) operated the furnace (Marshall Products Company, Columbus, Ohio). Tem-

peratures in the furnace were monitored with a recording potentiometer (Honeywell, Minneapolis, Minnesota). The bulk electrolyte temperature was controlled to ±0.5°C. The disparity in the areas of the microelectrode and the lithium cup electrode was such that, for the minute currents which passed through the cell, the latter electrode remained unpolarized.

A Model XV polarograph (E. H. Sargent and Company, Chicago, Illinois) was used to obtain the voltammetric data. Chronopotentiometric measurements were made using conventional solid-state circuits specifically designed for a low-impedance system; the current-time traces were displayed on a Model 7664 oscilloscope equipped with a Model 453-A1 Polaroid camera (Fairchild Dumont Laboratories, Clifton, New Jersey).

Materials.—Lithium hydride was prepared and analyzed as described by Johnson, Wood, and Crouthamel (7). Lithium metal (Foote Mineral Company, Philadelphia, Pennsylvania), supplied sealed under an argon atmosphere, had an impurity level less than 0.003% with respect to sodium, potassium, chlorine, and nitrogen. Prior to use in the cell, the requisite amount of lithium was taken and trimmed to a bright surface. The LiCl-KCl eutectic (59 mole % LiCl, mp 352°C (18); Anderson Physics Laboratories, Inc., Champaign, Illinois) had been purified with HCl (19) followed by displacement of heavy metal impurities with magnesium. Commercial hydrogen gas was purified by a silver-palladium alloy diffusion apparatus (Milton Roy Company, Park Ridge, Illinois). The voltammetric microelectrode was a 0.009 in. iron wire (B and A Reagent, Allied Chemical Company, New York). The chronopotentiometry flags were cut from 0.01 in. Armco ingot iron sheet or fabricated from 0.04 in. sheet tungsten flags welded to tungsten wires under helium.

The crucible, electrodes, and thermocouples which came in contact with the molten electrolyte were cleaned mechanically, rinsed in water and acetone, evacuated, and stored in the helium atmosphere box. These components were assembled to the cell head, heated in hydrogen at 900°C for 16 hr, and evacuated to remove any remaining oxide films prior to loading of the cell. All cell materials were weighed, trimmed, and loaded into the cell inside the high-purity helium atmosphere box. The time expended in these operations was kept to a minimum, and the furnace well containing the cell was sealed from box atmosphere with the gastight head. The well atmosphere was evacuated and the well refilled with hydrogen or helium before the cell was heated to 375°C.

Procedures.—The LiCl-KCl eutectic held at 375°C was saturated with lithium prior to studies of the lithium hydride system by immersing a fiber metal sponge soaked with lithium metal in the melt for several days. Displacement of potassium by lithium did not become noticeable as long as the temperature was kept below 450°C.

To obtain reproducible voltammetric data it was necessary to record the cell current at each potential until a steady-state condition (±0.1 μa) was attained; the time required varied from 3 to 30 min. Although the geometric area of the microelectrode could not be determined accurately since it was not defined by an insulating material, it was estimated to average 5×10^{-3} cm^2 by microscopic examination at the conclusion of several experiments. The geometric area of each flag electrode used in the chronopotentiometric studies was measured with a micrometer.

The currents applied to the chronopotentiometry cell were such that the transition times were one second or less. Five minutes were allowed to elapse between successive current pulses; delays of 5, 10, and 30 min between pulses produced identical chronopotentiograms, but delays of less than 5 min produced shorter transition times. Mechanical stirring of the cell between pulses was not feasible, and it was therefore necessary to rely on convective mixing in the cell.

Analyses of solutions of lithium and lithium hydride in the melt were carried out by acidimetric titration of hydrolyzed samples.

Results and Discussion

Curves A and B in Fig. 2 show the current-potential relationships for the electrolyte and lithium-saturated electrolyte respectively, both in a helium atmosphere. In the fused salt electrolyte alone the iron dissolution potential was +1.48v (all potentials are given with respect to the $Li^o(l)/Li^+$ reference electrode). In the lithium-saturated electrolyte, the iron dissolution potential is +2.13v. The discrepancy of +0.65v can be explained by assuming that on introduction of the lithium electrode into the unsaturated electrolyte a displacement reaction $2Li^o + Mg^{++} \rightarrow Mg^o + 2Li^+$ proceeds and magnesium is deposited on the surface of the electrode. This creates a Mg^o/Mg^{++} electrode system, whose standard potential (20) is +0.72v. The

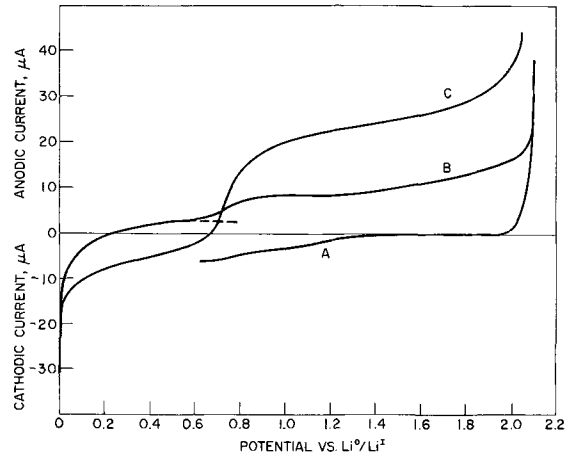

Fig. 2. Voltammetric data for the lithium hydride cell, LiCl-KCl eutectic, 375°C, iron microelectrode. (A) Electrolyte alone, helium atmosphere, 760 mm Hg; (B) lithium-saturated electrolyte, helium atmosphere, 760 mm Hg; (C) lithium-saturated electrolyte, hydrogen atmosphere, 760 mm Hg.

potential of this magnesium quasireference electrode is less positive than the standard potential due to the low concentration of magnesium ion in solution.

The section of curve B, Fig. 2, from 0 to +0.6v is characteristic of the oxidation of soluble lithium. The succeeding step can be analyzed using the Heyrovsky-Ilkovic equation (21) which gives $E_{1/2} = +0.74$v and $n = 1.1$. This step appears to be characteristic of lithium hydride oxidation. Although neither lithium hydride nor hydrogen was added to the cell, residual hydrogen from the preheating of the metallic parts in hydrogen could form lithium hydride by reaction with lithium metal dissolved in the fused salt. Since the stainless steel apparatus weighed several kilograms, it can be calculated (22) that more than enough hydrogen to produce the observed amount of LiH could have come from the stainless steel components. This amount of hydrogen would not, however, be sufficient to remove all lithium from solution, and thus the lithium oxidation wave should also be present.

Curve C, Fig. 2, was obtained for the same sample of lithium-saturated electrolyte, containing no added LiH, which had been held under 1 atm of hydrogen for two days. The shape and position of this curve, whose $E_{1/2}$ is the same as that of B, is characteristic of the lithium hydride-hydrogen system (compare with curve B, Fig. 3, which was obtained for the same electrolyte sample with solid LiH added). Between 0 and +0.66v activation effects appear to contribute toward the cathodic polarization inasmuch as the current is nowhere independent of the potential applied. A mass transfer-limited oxidation rate is attained at potentials more positive than +0.70v; this conclusion is supported by Fig. 4. The data of curve C, Fig. 2, are in accordance with the linear relationship shown in Fig. 4 on the assumption that all of the dissolved lithium was converted to lithium hydride by reaction with the hydrogen atmosphere over the two-day waiting period. Further evidence for this assumption is the fact that the blue color and anodic lithium wave characteristic of the lithium-saturated solvent disappeared during this time.

Curve B, Fig. 3, was observed for a dilute lithium hydride solution. As the microelectrode is made increasingly positive (forward polarization), at +0.40v the cathodic current approaches zero rapidly and becomes anodic (broken line). Between +0.48 and +0.52v, the anodic current becomes unstable, falls to zero, and finally attains a cathodic value commensurate with the extrapolation of the prepeak curve. Beyond this region steady currents are observed until the limiting anodic region is reached. In the limiting anodic region (+0.7 to +2.1v) the random current fluctuations observed are probably due to bubble formation during hydrogen gas evolution. The anodic limiting currents are directly proportional to the LiH concentration (Fig. 4). On reverse polarization, similar peaking behavior, but in a cathodic direction, is observed. If a steady-state condition is attained at each potential setting, this cathodic dip can be greatly minimized; such is not the case for the forward polarization anodic peak. Curve A, Fig. 3, is the current-voltage relationship for a saturated lithium hydride solution (*ca.* 5.0 mole % LiH). Stable currents are observed throughout except for random fluctuations in the anodic hydrogen evolution region. Curve B approaches A as the concentration of LiH increases. The peaking effect is observed until saturation is attained. For both forward and reverse polarization, the potential of maximum current increase in the unstable region is +0.42v. Similar peaking was observed when the iron microelectrode was replaced by a tungsten microelectrode of comparable size.

For a reversible electrochemical system containing soluble oxidized and reduced species and yielding composite anodic-cathodic polarization data, a form of the Heyrovsky-Ilkovic equation is valid (23). In Fig. 5, curve B of Fig. 3 is reproduced together with its analysis according to this equation. The value of the anodic limiting current $I_{L,A}$ was 73.0 μa. There is no well-defined cathodic plateau region, but the slope of the curve is minimal at +0.32v; the current at this potential was arbitrarily taken as the cathodic limiting current $I_{L,C}$. From eleven such plots obtained at different hydrogen pressures and hydride concentrations the mean n in the anodic region (line A) was 1.079, standard deviation, σ, 0.040, electrons/LiH. The

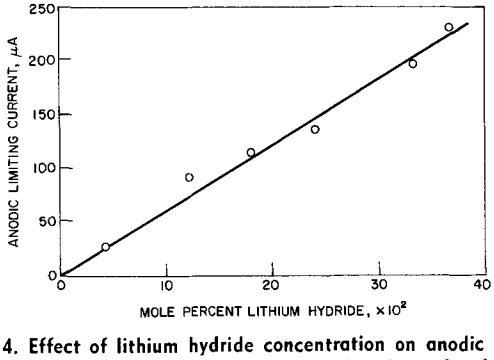

Fig. 4. Effect of lithium hydride concentration on anodic limiting current, LiCl-KCl eutectic, 375°C, iron microelectrode; hydrogen atmosphere, 760 mm Hg.

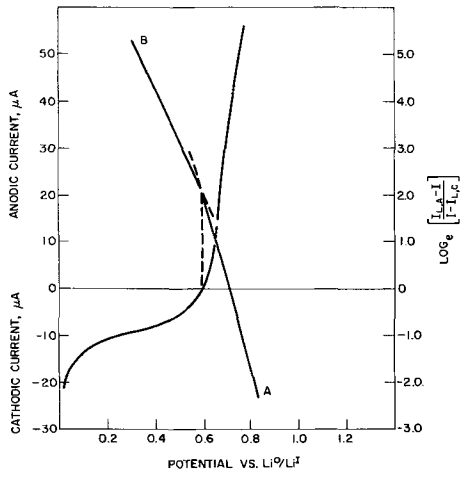

Fig. 5. Heyrovsky-Ilkovic analysis of voltammetric curve, LiCl-KCl eutectic, 375°C, iron microelectrode, 8 x 10^{-2} mole % LiH, hydrogen atmosphere, 760 mm Hg.

slope of the log plot line B varies in a random manner with the hydrogen pressure and amount of added hydride; in all cases, however, it is significantly less than that of A, as would be expected if the reduction occurring in this potential region involves at least one slow stage. The change of slope occurs at the zero current potential. Analysis of all the polarization data indicates that the cathodic reduction of hydrogen, but not the anodic oxidation of hydride, is characterized by an appreciable activation polarization under different experimental conditions.

If charge transfer processes are rate-determining, this rate can be expressed in terms of the equation below (24-26)

$$|\eta| = \frac{RT}{\beta\lambda F}\left[\ln I_C - \ln\left\{1 - \exp\left(\frac{-|\eta|\lambda F}{RT}\right)\right\}\right] - \frac{RT}{\beta\lambda F}\ln I_C^{\circ}$$

where I_C° is the exchange current, β the symmetry factor, η the cathodic overpotential, and λ the electron number. The electron number is n/ν where ν is the stoichiometric number (24).

Curve A, Fig. 6, is a graph of $|\eta|$ as a function of the cathodic current. It is difficult to be certain of the currents when the cathodic overpotential is much greater than 0.1v due to the proximity of the unstable peaking region. When $|\eta|$ is between 0 and 0.1v there is no linear (Tafel) region, which indicates that the data should be analyzed in terms of the equation given above.

A plot of $|\eta|$ *vs.* the logarithmic term in square brackets will be linear if and only if the correct value of λ is chosen. Examples of such plots are shown by curves B and C, Fig. 6. For $2 > \lambda > 1$, a family of curves intermediate between B and C is obtained; for $1 > \lambda > 0$ similar behavior is observed with curvature in the opposite sense. As can be seen, the correct choice is $\lambda = 1.0$. Similar analyses of data obtained at lower hydrogen pressures yield the same result. It is therefore concluded that the over-all kinetics of the electrochemical reduction reaction are governed by either a slow one-electron transfer step or a one-electron transfer step coupled with a slow chemical step. Although the uncertainty in the electrode area does not permit accurate determination of the exchange current density, it appears to be about 1 ma/cm². This is considerably lower than the exchange currents for metal-metal ion couples in LiCl-KCl eutectic at 450°C (27).

The time-current relationship at constant current for an electrode process under linear diffusion control (28) is $I\tau^{1/2} = 1/2\ nFAD^{1/2}\pi^{1/2}C$ where I is the current (amp), τ is the transition time (sec), C is the bulk concentration of the diffusing ion (moles cm^{-3}), D is the diffusion coefficient (cm^2sec^{-1}), A is the electrode area (cm^2), and the remaining terms have their usual significance. If the reaction is diffusion-controlled, $I\tau^{1/2}$ is independent of I for a given concentration of electroactive species. The amount of LiH present used in the calculation of the bulk concentration was the sum of the amount of LiH added and the amount formed from the lithium-saturated LiCl-KCl.

Chronopotentiometric measurements were made using tungsten flag electrodes. These anodic chronopotentiograms (Fig. 7) consistently contained four separate plateaus, A-D. Plateau D, due to chlorine evolution, occurs at +3.1v. A transition time could not be measured for plateau B, which appeared only as a change of slope in the potential-time curve and is probably due to the presence in the melt of an oxidizable impurity whose concentration is 10^{-4}M or less.

Plateau A is ascribed to the oxidation of lithium hydride since the transition time increased on the addition of lithium hydride to the cell. The potential of this plateau ranged from +0.5 to +0.7v, in agreement with the potential at which the voltammetric hydride wave was observed. The length and potential of this plateau appeared to be independent of hydrogen pressure. The value of $I\tau^{1/2}$ remained constant as the current density was varied from 0.1 to 4 amp/

cm^2. Data from a representative run are given in Table I. It is assumed that the over-all reaction on tungsten must be the two-electron process $2LiH \rightarrow H_2 + 2Li^+ + 2e^-$, as indicated by potentiometric studies (9). The over-all reaction cannot be $LiH + M{\cdot}H \rightarrow H_2 + Li^+ + e^-$ because the solubility of hydrogen in tungsten is negligible (29) and the values of $I\tau$ are such that an adsorbed monolayer could not supply enough hydrogen. On this basis the mean value of D was 1.67 x 10^{-5} cm^2/sec, σ, 0.04 x 10^{-5} (2.2%), from 39 determinations at hydrogen pressures from 0.5 to 1.0 atm and lithium hydride concentrations from 0.1 to 0.3M, over the range of current densities given above. This is in good agreement with the range of 0.6 to 3.5 x 10^{-5} cm^2/sec and precision of 2.6% reported for the diffusion coefficients of several metal ions in this eutectic at 450°C (30).

Plateau C was less well-defined than A and the changeover from C to D was often indistinct. The length and potential of C were independent of the amount of lithium hydride added to the cell and the hydrogen pressure above it; plateaus B, C, and D, but not A, were observed even with no added lithium hydride. Under all conditions $I\tau^{1/2}$ remained approximately constant as the current was varied. The potential (at $\tau/4$) of this plateau was +2.6 to +2.8v. The mean value of $nCD^{1/2}$ calculated for this plateau on the basis of linear diffusion control is 8 ± 1 x 10^{-7} cm^{-2} equiv $sec^{-1/2}$ using data taken over the ranges of conditions given above.

This plateau is ascribed to the oxidation of hydrogen to hydrogen ion, the standard potential, $E_M°$, of which is +2.61v (31). Quantitative analysis of this plateau does not appear to be possible even though $I\tau^{1/2}$ is approximately constant with I, indicating a diffusion-controlled process. It has been shown (32) that for stepwise reduction of diffusing species $\tau_2 = 3\tau_1$ when $n_1 = n_2$; the calculation is equally applicable to stepwise oxidation. In every LiH cell experiment, τ_2 and τ_1 were nearly equal with τ_2 being, in most cases, less than τ_1. This behavior can be explained on the basis that much of the hydrogen produced electrochemically leaves the electrode other than by diffusion; since the melt is saturated with hydrogen, such an explanation does not appear unlikely. The concentration of H_2 in the melt calculated from the value of $nCD^{1/2}$ given above would be about 0.1M. This is about one order of magnitude greater than the solubility of HF in molten fluorides (33) and three orders of magnitude greater than that of the rare gases in the same solvent (34, 35); it cannot be considered a true measure of the solubility of hydrogen in the melt.

Armco iron has been studied as an anode material in lithium hydride cells (36). For this reason chronopotentiometric studies were made using Armco iron as the flag electrode. These chronopotentiograms (Fig. 8) consistently contained only two plateaus. The second plateau corresponds in potential (20) to the oxidation of iron to Fe(II), which would occur without transition at an iron electrode. The first plateau is ascribed to the oxidation of lithium hydride since the transition time increased on addition of lithium hydride to the cell. Both τ and $I\tau^{1/2}$ decreased with decreasing hydrogen pressure at all lithium hydride concentrations studied. The value of neither $I\tau$ nor $I\tau^{1/2}$ was constant when the current density was varied under otherwise constant conditions. At low concentrations of lithium hydride, $I\tau^{1/2}$ increased with increasing I; as the concentration of lithium hydride was increased, the relative increase in $I\tau^{1/2}$ with I became less. The values of D calculated using the equation for linear diffusion control ranged from 3 times to 4000 times those determined with the tungsten electrode; the lowest values were obtained at high lithium hydride concentrations. Data from a representative run are given in Table II.

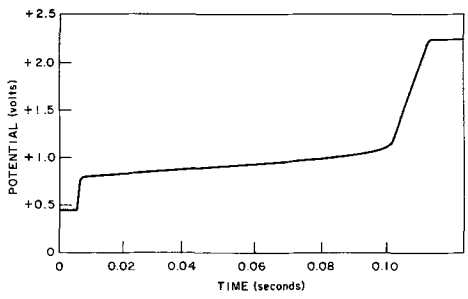

Fig. 8. Chronopotentiogram with iron electrode, LiCl-KCl eutectic, 375°C, electrode area 0.823 cm^2, current 860.2 ma, LiH 0.2662M.

Aqueous studies (37, 38) have shown that adsorption of the electroactive species causes the value of $I\tau^{1/2}$, and hence the calculated value of D, to increase with increasing current. Graphical attempts were made to fit all of the data taken using iron to each of the models discussed in these papers. Although no model could be successfully applied to all the data, the model in which an adsorbed layer is electrolyzed first followed by the diffusing species gave the best fit. These calculations are shown in Table III. The values of surface excess were calculated using the equation

$$I_0\tau = 1/2\, nFC\, \pi^{1/2}D^{1/2}\tau^{1/2} + nF\Gamma$$

for this model and the value of D calculated from the tungsten electrode studies. The slopes of the $I_0\tau - \tau^{1/2}$ plots were independent of hydrogen pressure while the surface excess calculated from the intercepts increased with hydrogen pressure. The surface excesses correspond to about 100 LiH monolayers, which is too thick a layer to be ascribed to an adsorption process. For this reason the adsorption models do not appear to explain these observations adequately.

These large surface excesses would be more reasonable if there were evidence for an increase in the

true surface area of iron electrodes. Such evidence exists; in all experiments, only that part of the iron electrode in contact with the electrolyte appeared to be roughened, as indicated by a marked blackening of the surface. The remainder of the iron electrodes, and the entire surface of the tungsten electrodes, remained bright. The blackening did not appear to increase with successive runs, which is not unexpected as the surface was renewed for each pulse by going to iron dissolution.

When transition times were monitored repetitively at iron with decreasing time intervals between application of successive pulses and other conditions constant, the transition times decreased steadily for intervals of less than 5 min. They were constant when the intervals were longer than 5 min, suggesting some interaction that is slow but complete in about 5 min.

Both τ and $I\tau^{1/2}$ decreased with decreasing cell hydrogen pressure when iron electrodes were used (Fig. 9). The transition times observed for the first transition on tungsten were not affected by the hydrogen pressure. This observation, coupled with the longer transition times observed on iron and the dependence of surface excess on hydrogen pressure, cannot be explained except by the existence of some interaction, on iron, with the hydrogen gas above the melt. In this connection it should be noted that the solubility of hydrogen in iron, 0.34 cm^3 (STP)/100g at 375°C (39), is much greater than that in tungsten (29). There appears to be no significant difference in the potential at which the oxidation occurs on iron ($E_{\tau/4}$ = 0.7 — 0.8) and tungsten ($E_{\tau/4}$ = 0.6 — 0.7), implying that this interaction occurs before the current is applied and does not affect the oxidation potential.

The activation overpotential observed in the cathodic reduction of hydrogen may be involved with this slow interaction, and the interaction could give rise to the voltammetric anodic and cathodic peaks. An alternative explanation for the peaking consistent with the above discussion is given in the thesis of the first author.

In conclusion, the chronopotentiometric indication of a large value of surface excess on iron could be explained in part by a larger true surface area of the electrode and in part by the existence of some interaction between iron, lithium hydride in the melt, and hydrogen. A more quantitative understanding of these processes does not appear to be possible at this time. Quantitative analysis of the voltammetric work is difficult, since the meniscus region at which the microelectrode touches the melt can be quite complex as shown by aqueous work (40, 41). In the absence of suitable insulating materials this problem cannot be avoided. Quantitative analysis of the chronopotentiometric data for iron is difficult due

to the complexity of the system, as well as a lack of general physical data related to hydride-melt systems.

Thermopotential Measurements of Alkali Halides

Jacob Greenberg

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio

ABSTRACT

Thermopotential measurements of NaCl, KCl, NaI, KI, and CsCl were made using inert (tungsten) electrodes. For NaCl and KCl, the maxima for the Seebeck coefficients were observed, one corresponding to a negative polarity at the hot junction and another corresponding to a positive polarity at the hot junction.

Experimental Procedure

Anhydrous salts were prepared by washing with liquid ammonia. The more conventional methods of purifying metal halides involve heating the salt and treating the melt to remove hydrolysis products. The heating of the salts in the presence of water produces hydrolysis products, which are then responsible in part for the corrosive action of the melts. By treating the solid with liquid ammonia at low temperatures, the introduction of hydrolysis products is limited. The water present in the halides becomes associated with the ammonia and is carried out in the diffusion stream (1).

The salts were purified in 300-ml round-bottom flasks. After the system was sealed off from the vacuum line, these halides were then transferred from the flasks to a quartz cell fitted with two tungsten electrodes by tilting the apparatus. The tungsten electrodes were initially beaded with a grading glass of slightly lower melting point than quartz. This was done in such a manner that the tungsten surface in contact with the graded glass was free of oxides. The seal was formed essentially by the compression of the metal in the glass. The tungsten electrodes that were beaded in this manner were then fused into the quartz container. A diagram of the cell used is shown in Fig. 1. In the cases of NaCl or KCl measurements were also made by filling the quartz cell directly and attaching the cell to a vacuum line. In such instances slowly raising the temperature of the solid while maintaining a pressure of less than 10^{-4} mm Hg gave satisfactory results.

The quartz cells were fitted with chromel-alumel thermocouples and covered with asbestos after having been suitably wrapped with high-temperature resistance wire. The heating wire was carefully wrapped to reduce the presence of temperature gradients, and the desired temperature differentials were imposed by use of a 10-ohm coil of resistance wire placed about one electrode. These heating units were supplied by two variable stepdown transformers and steady-state temperatures could be controlled to within 1%. Voltage measurements were made by means of a voltmeter with a high internal impedance and current-voltage plots were made with an X-Y recorder.

It was found that if a salt hydrate was submitted to the ammonia treatment (*e.g.*, $LiI \cdot 3H_2O$), a solution formed that persisted at room temperature. Pretreatment of the hydrate, which involved heating it in vacuum, was necessary in these cases. A volume expansion of the salt was observed in each system as a result of the ammonia treatment. In order that no residual ammonia would be present while measurements were being made, the cell was heated with a yellow flame until no pressure rise above 10^{-4} mm Hg

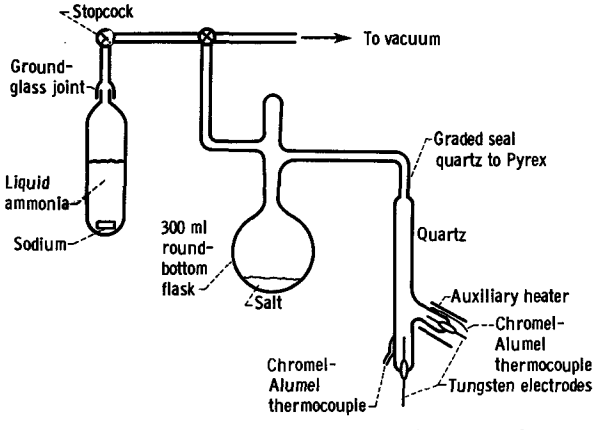

Fig. 1. Diagram of apparatus used to purify salts and measure thermopotentials.

was observed. The cell was then removed from the vacuum line.

Results

The use of inert electrodes implies that the electrode does not have an ion in common with the electrolyte as is the case with conventional thermocells. In measuring the potential some minimal current must flow with the consequent electrolysis of the electrolyte. In the case of NaCl this would result in the formation of decomposition products of sodium and chlorine at the electrodes interfaces. These elemental components with their corresponding ions in the electrolyte then constitute half-cell reactions that insure electrical contact to the electrolyte by providing a means for charge transfer. The presence of such half-cells constitutes a back-emf since the electrolysis of the salt will occur in such a manner as to negate the presence of the thermopotential. This would indicate that the observed voltage readings were somewhat lower than what would be expected if such half-cells did not exist. The observed voltage of the cell can then be considered to be analogous to a decomposition cell which was influenced by the preferential migration of ions in the thermal gradient.

The values of the Seebeck coefficient S observed are plotted in Fig. 2, and values for the discharge currents in CsCl are shown in Fig. 3. Temperature gradients of 10° to 50°C were maintained between the electrodes. All measurements were made when the voltage readings became reproducible after being at least 1 hr at the temperature of the measurement.

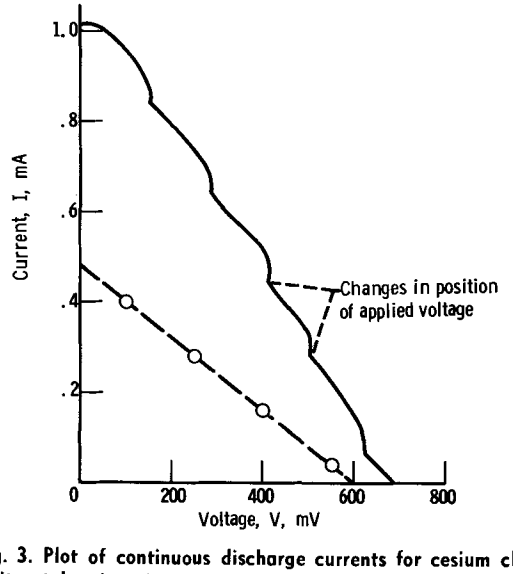

Fig. 3. Plot of continuous discharge currents for cesium chloride. Polarity at hot junction; temperature range, 720°-1002°C; average temperature, 852°C; Seebeck coefficients, 2.39 mv/°C. ——, Momentary fast-scan discharge; - - ○ - -, continuous discharge.

In order to obtain a possible indication of the number of mobile species present, the cells were allowed to discharge under their own thermopotential. The short-circuit currents observed were of the order of milliamperes; however, because of polarization by decomposition products these currents were short-lived. However, CsCl did maintain steady-state currents, possibly because of the increased solubility of decomposition products.

One of the principal sources of error in the measurements was introduced by too rapid a heating or cooling rate. In all cases, the salt was initially melted to ensure thermal equilibrium. To determine thermopotential values below the melting point, it was necessary to obtain as nearly a single crystal as possible. Too rapid a cooling rate would result in a polycrystalline material. Both of these conditions led to nonreproducible measurements of temperature and voltage. In addition, too rapid a cooling rate affected the quartz-tungsten seals. Since these seals are essentially of a compression type, they work well at high temperatures. When these seals were cooled to lower temperatures quickly, a crack would sometimes develop.

Although the lithium halide salts were run repeatedly no reproducible results were available. This may have been due to the failure to remove all impurities (H_2O, NH_3) as well as the accumulation of insoluble decomposition products at the electrodes.

Discussion

The thermopotential of the cell $\Delta\psi$ is a function of several terms (2).

$$\Delta\psi = \Delta\psi_{hom} + \Delta\psi_{het} + \Delta\psi_{el}$$

where $\Delta\psi_{hom}$ is the thermopotential evolved in salt as result of thermal gradient, $\Delta\psi_{het}$ is the potential due to reaction at electrodes, and $\Delta\psi_{el}$ is the potential due to having metal electrodes at two different temperatures.

Since $\Delta\psi_{el}$ is of the same order of magnitude as observed for metallic thermocouples and is of the order of microvolts, its effect can be considered as being negligible for these systems. Since there is a negligible current flowing through the cell and therefore there are minimal elemental components with which to constitute a half-cell at the electrodes, $\Delta\psi_{het}$ may be considered as being negligible (3). The observed thermopotentials are therefore a function of $\Delta\psi_{hom}$

$$\Delta\psi_{hom} \propto -\sum_R \left(\frac{t_R}{Z_R}\right)\frac{Q_R{}^{xx}}{T_{av}} \qquad [1]$$

where t_R = transference number of species R, Z_R = algebraic valence of species R, $Q_R{}^{xx}$ = reduced heat of transport, $T(S_R{}^x - S_R)$, $S_R{}^x$ = entropy of transport of species R, S_R = partial entropy of species R, and T_{av} = average temperature. The observed thermopotential, being a function of $\Delta\psi_{hom}$, can be written

$$\Delta\psi \propto -\sum_R \left(\frac{t_R}{Z_R}\right)\frac{Q_R{}^{xx}}{T_{av}} \qquad [2]$$

For NaCl this is

$$\Delta\psi \propto -t_{Na^+}\left(\frac{Q_{Na^+}{}^{xx}}{T_{av}}\right) + t_{Cl^-}\left(\frac{Q_{Cl^-}{}^{xx}}{T_{av}}\right) \qquad [3]$$

If the effects of temperature on the values of Eq. [3] are examined, a qualitative description of the ion processes involved when the NaCl system, for example, is heated from about 700° to 900°C can be evolved. It is known that the electrical conduction of solid alkali halides is a function of cation migration (4). The lower temperature values of the thermopotential are therefore due to cation migration from the hot to the cold zone. This results in a negative polarity at the hot junction. Since the values for the

reduced heats of transport Q_R^{xx} increase with temperature, the value of the thermopotential in the solid, where it is primarily a function of cation movement, can only go through a maximum if the transport number of the cation decreases. This would be due to the onset of anion conduction. A decrease in cation transport number with increasing temperature has also been observed in other systems (5). When the anion begins to contribute to the conduction of the system, it does so not only because of the influence of heat, but also because of the electrical potential established by the prior migration of cations. The rate of change of the entropy of transport for the anion as the temperature increases must therefore be large. The result of this is that, although the transport number of the anion is low, the product of the transport number and the reduced heat of transport of the anion is large and the value of the Seebeck coefficient goes to zero and then to a maximum of opposite polarity at the hot junction to the one initially observed at lower temperatures. As the temperature is raised further, the values of the transport numbers and associated ion entropies become nearly equal and the value of the Seebeck coefficient becomes minimal. In effect, therefore, in NaCl the transport number of Na^+ goes from 1.0 to ~0.5 and the transport number of Cl^- goes from 0 to ~0.5.

Since the value of the thermopotential in Eq. [3] is the result of the difference between two terms, it is possible to show this by graphically representing the terms themselves. This is shown in Fig. 4.

From the magnitude of the potentials measured it can be assumed that only a fraction of the ions present are actually mobile. An estimate of the number of mobile species can be made from the short-circuit currents observed when the cells were allowed to discharge under their own thermopotential. For a discharge time of 1 sec, the number of equivalents of salt which are dissociated to form mobile species are

$$\frac{10^{-3}\text{A} \times 1 \text{ sec}}{96\,500 \text{ C}} \cong 10^{-8} \text{ equivalents}$$

The discussion of transport phenomena concerns a relatively small fraction of dissociated species moving with respect to a much larger mass of undissociated species. The observed discharge currents were much higher (ma) than those observed for $ZnCl_2$ and $PbCl_2$ (μa) (6). This would indicate a larger degree of dissociation and consequently higher electrical conductivities observed in alkali halide melts.

It is interesting to note that the inflection points for the plot of Seebeck coefficients of NaCl and KCl as a function of temperature occur relatively close to the melting point. This is not the case for NaI. In the latter case it appears that the anion contribution to the thermopotential does not appear until about 50°C above the melting point. Thermopotential measurements of this kind can be used to make some inferences concerning the migration of the ion species as a function of temperature.

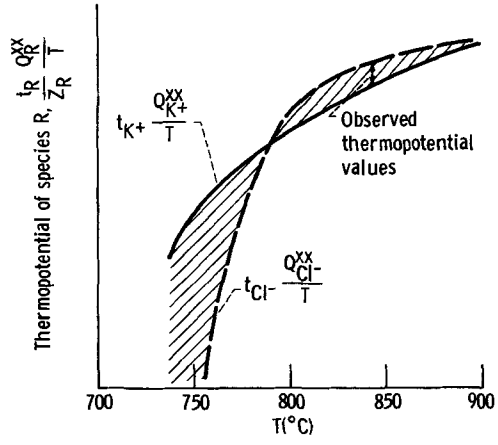

Fig. 4. Thermopotentials of potassium chloride plotted by difference of ion functions.

It should also be noted that, when the Seebeck coefficients from a thermocell with inert electrodes are subtracted from the Seebeck coefficients of thermocells with reversible electrodes, values of the single-ion entropies can be obtained. The thermopotential of a cell with inert electrodes is assumed to be a function primarily of the transference numbers and heats of transport of the ions constituting the electrolyte (Eq. [1]). However, in a classical thermocell with electrodes that are reversible to one of the ions of the electrolyte, the thermopotential is in addition a function of the change in entropy that occurs at the electrode with the passage of one Faraday.

$$F\frac{\Delta\phi}{\Delta T} \alpha -\sum_R \frac{t_R}{Z_R}\frac{Q_R^{xx}}{T_{av}} \quad \text{Inert electrodes}$$

$$F\frac{\Delta\phi}{\Delta T} \alpha -\sum_R \frac{t_R}{Z_R}\frac{Q_R^{xx}}{T_{av}} - \Delta S \quad \text{Reversible electrodes}$$

It is, therefore, possible to evaluate ΔS by subtraction when thermopotentials are available for both systems. Data are available on NaCl and KCl thermocells with chlorine electrodes (7). In this case ΔS may be defined as follows:

For the reaction $Cl^- \rightarrow \frac{1}{2}Cl_2 + e$

$$\Delta S = \tfrac{1}{2}S^\circ_{Cl_2} + S_e - S_{Cl^-}$$

where $S^\circ_{Cl_2}$ = molar entropy of chlorine gas at temperature; S_e = entropy of electron in electrode; and S_{Cl^-} = partial molar entropy of chloride ion in the electrolyte at temperature.

Since S_e will be of the order of 1% of $\frac{1}{2}S^\circ_{Cl_2}$ it can be neglected for a first approximation. The values of $S^\circ_{Cl_2}$ are listed; and we, therefore, can calculate the single-ion entropy of the chloride ion.

The lowest temperature for which reproducible results are reported for the Cl_2 — NaCl, Cl_2 — KCl thermocells is 927°C. At this temperature the Seebeck coefficient for the cell with inert electrodes is zero. This was explained as due to the fact that the transference numbers and reduced heats of transport for the cation and anion are equal. It was assumed that there are an equal number of dissociated, equally mobile ions of opposite charge so that a charge separation cannot be maintained. The Seebeck coefficient reported for the chlorine thermocell at this temperature is, therefore, directly proportional to the ΔS at the electrodes.

Chlorine thermocell at 927°C

$$F\left(\frac{\Delta\phi}{\Delta T}\right) = -\Delta S \alpha S_{Cl^-} - \frac{1}{2}S^\circ_{Cl_2}$$

$$\frac{\Delta\phi}{\Delta T} = -0.480 \times 10^{-3} \text{ v/°C [NaCl} - Cl_2 \text{ at 927°C]}$$

$$\frac{\Delta\phi}{\Delta T} = -0.475 \times 10^{-3} \text{ v/°C [KCl} - Cl_2 \text{ at 927°C]}$$

$F = 9.65 \times 10^4$ coulombs; 0.239 conv. to calories;

$$\frac{1}{2}S^\circ_{Cl_2} = 32.3 \text{ e.u.}$$

$S_{Cl^-} = 21.2$ e.u. (NaCl — Cl_2 at 927°C);

$S_{Cl^-} = 21.9$ e.u. (KCl — Cl_2 at 927°C)

These results, considering that we have neglected S_e, are in agreement with the approximation that the entropy of a system such as NaCl or KCl is equally

divided between cation and anion (8). Using this approximation with a small correction factor for the mass effect on diffusional entropy

$S_{Cl^-} = 21.9$ e.u. ($NaCl - Cl_2$ at 927°C);

$S_{Cl^-} = 22.12$ e.u. ($KCl - Cl_2$ at 927°C)

A deviation from this assumption is expected below 927°C since the maxima and minima observed are essentially due to the asymmetry in the number of allowable states (entropy) of the cation and anion.

Kinetics of Electrode Reactions

Mark Salomon

Wright Laboratory, Rutgers, The State University, New Brunswick, New Jersey

ABSTRACT

The use of absolute rate theory to predict rates of electrode reactions is discussed. It is shown that the rate of reaction at an electrode can be calculated from first principles if the absolute single electrode potential and its temperature coefficient are known. The single electrode potential can indeed be calculated and therefore used to predict the exchange current density for any electrode reaction. Exchange current densities calculated from first principles for various mechanisms in the oxygen and hydrogen evolution reactions are in good agreement with the presently accepted mechanisms.

The electrochemist has always maintained that the advantage of studying kinetics at electrodes is that the activation energy can be controlled simply by controlling the electrode potential. Despite this "advantage" the electrochemist cannot use absolute rate theory (1) to calculate reaction rates for single electrodes. Instead he is always left with at least one undefinable constant such as the "electrochemical" rate constant. If the rates at single electrodes could be calculated from first principles the electrochemist would have an additional method by which he could verify reaction mechanisms. It is the purpose of this paper to discuss and extend a new treatment of electrode kinetics in which absolute rate theory is used to predict the exchange current density. Calculations are based on the concept of single electrode potentials and the absolute entropies for half-cell reactions. Due to the importance of the single electrode potential and its temperature coefficient in the present calculations, a brief review is given on its evaluation, followed by exchange current density calculations for various mechanisms in the oxygen and hydrogen evolution reactions.

Kinetic principles.—For a rate-determining step involving a single electron transfer, the rate in amperes cm^{-2} is

$$i = kF\frac{\Pi c_i\gamma_i}{\gamma^{\neq}}$$

where k is the electrochemical rate constant, c_i is the concentration of the i-th species, and γ is the activity coefficient. For the activated complex, $\gamma^{\neq}$ will be assumed to be unity. The electrochemical rate constant differs from the familiar nonelectrochemical one in that in the former, the activation energy is a function of electrode potential according to ((2, 3)

$$k = A\ \exp -[E_o + \beta(\phi - \psi_1)zF]/RT \qquad [1]$$

Here E_o is the activation energy (including zero-point energies) which is modified by some fraction, β, of the electrode potential ϕ. The potential ψ_1 is that at the outer Helmholtz plane and can be calculated from Sterns theory of the double-layer (4). For unit charge transfer z is unity and denotes "direction" of the reaction, *i.e.*, whether an anion or a cation is the species being discharged. Hence for an anodic process involving such species as OH^-, Cl^-, CH_3COO^-, $z\mathbf{F}$ is negative, whereas for cathodic discharge of species such as H^+, Ag^+, Na^+, zF will be positive. Combining the above two equations and replacing the frequency factor A by its usual terms involving partition functions (1, 3) we have for the rate of discharge at the reversible potential, ϕ_r,

$$i_o = \tau F\frac{kT}{h}c_i\gamma_i \cdot \frac{Q^{\neq}/\sigma^{\neq}}{\Pi Q_i/\sigma_i} \cdot \exp -[E_o + \beta(\phi_r - \psi_1)zF]/RT \qquad [2]$$

where τ is the transmission coefficient which is unity (1), Q is the partition function per unit volume (q/v) or per unit area (q/A), and σ is a statistical factor denoting the number of reaction paths which is used instead of the symmetry number since use of the latter can lead to error (5, 6). For the case of proton discharge, Eq. [2] becomes

$$i_o = \frac{\sigma_{H_3O^+}}{\sigma^{\neq}}F\frac{kT}{h}C_M\,(1-\theta)\,a_{H_3O^+}\frac{q^{\neq}}{q_M\,Q_{H_3O^+}}$$

$$\exp -(1-\beta)\psi_1F/RT \cdot \exp -[E_o + \beta\phi_rF]/RT \qquad [3]$$

where the additional term in $-\psi_1F/RT$ arises from the use of bulk H_3O^+ activity instead of the surface activity (7). The reversible potential ϕ_r is that corresponding to the half-cell reaction

$$H_3O^+ + e_M \rightleftharpoons \frac{1}{2}H_2 + H_2O \qquad [4]$$

where the subscript in e_M indicates that ϕ_r is dependent on the metal which supplies the electrons. There are essentially two unknowns in Eq. [3], namely ϕ_r and E_o ($q^{\neq}$ is known if E_o is known). Hence if any one of these quantities is known, say E_o, we can use the experimental values of $Q_{H_3O^+}$, i_o, β, and ψ_1 to calculate ϕ_r. The problem involved in the calculation of ϕ_r therefore requires the evaluation of E_o. Placing all the constant terms in Eq. [3] in a constant A and from $-\phi F = \Delta H - T\Delta S$, we now have

$$i_o = F A C_M(1-\theta)\, a_{H_3O^+} \exp -(1-\beta)\psi_1 F/RT \cdot \exp -\beta\Delta S/R \cdot \exp -[E_o - \beta\Delta H]/RT \quad [5]$$

where ΔS and ΔH are, respectively, the entropy and enthalpy for the half-cell reaction [4]. The relation between the experimental energy of activation and frequency factor with the theoretical relations are (1, 3).

$$E_{exptl} = E_o + RT - \beta\Delta H \quad [6]$$

and

$$A_{exptl} = A \exp -\beta\Delta S/R \quad [7]$$

The absolute single electrode potential was calculated (3) by using a potential energy surface to fit E_o and A. We found ϕ_r for the h.e.r. at mercury to equal —0.225v at 25°C and —0.185v at 85°C (3). Having obtained ϕ_r for reaction [4] at a mercury electrode, it follows that the difference in ϕ_r for Hg and any other metal is simply equal to the difference in work functions of the two metals, *i.e.*

$$\phi_{r,M} - \phi_{r,Hg} = \Phi_M - \Phi_{Hg} \quad [8]$$

This result must be true if the measured p.d. between two reversible hydrogen electrodes at different metals is to be zero and can be confirmed by a simple consideration of the potentials of the various phases present [*e.g.* see (4), (10)]. From [8] it follows that ΔS is independent of the nature of the metal and that ΔH will vary accordingly. Applying this method now to predict i_o and E_{exptl} values for proton discharge at Ga and Cu cathodes, we found our calculated values of i_o and E_{exptl} to agree within 5% of the observed ones (3). The treatment can now be extended to other mechanisms in the oxygen and hydrogen evolution reactions.

Recombination rate of Pt *cathodes.*—It is generally believed (11-14) that the rate-determining step at Pt cathodes is the recombination of adsorbed H-atoms, *i.e.*

$$2MH \rightarrow 2M + H_2 \quad [9]$$

As further proof of this mechanism, the rate of recombination will now be calculated from first principles. Making the assumption that all pre-rate-determining steps are in quasi-equilibrium, the rate of recombination at the reversible potential is given by

$$i_o = \frac{2\sigma^2_{H_3O^+}}{\sigma^2_{H_2O}\sigma^{\neq}} \cdot \frac{FkT}{h} \left(\frac{a_{H_3O^+}}{a_{H_2O}}\right)^2 (1-\theta)^2 \frac{q^2_{H_2O} Q^{\neq}}{q^2_{H_3O^+}} \exp -E_o/RT \cdot \exp -2\phi_r F/RT \quad [10a]$$

In Eq. [10] we have treated the adsorbed H atoms as being mobile entities so that the concentration of metal sites does not enter into the rate equation (15, 16). We can simplify this equation slightly by taking the product of reaction paths and partition functions as being equal to unity (see appendix) and $a_{H_2O} = 1$ so that

$$i_o = 2F \frac{kT}{h} (a_{H_3O^+})^2 (1-\theta)^2 \exp \cdot -E_o/RT \cdot \exp -2\phi_r F/RT \quad [10b]$$

Using ϕ_r as calculated from Eq. [8], we could calculate i_o by varying the input parameters to a semi-empirical potential energy surface to fit E_{exptl} which is ~6 kcal mole^{-1} for the h.e.r. at platinum (17). However, this method gives rise to several problems. First, for the four-center activated complex, the semi-empirical method for evaluating E_o must be used and the author prefers, following the criticisms of Johnston (8, 9), not to commit himself to such a questionable method. The second difficulty involves the use of the tabulated value (18) of the metallic work function Φ_{Pt}. The work functions for randomly orientated metals do not exceed 5 ev with the exception of that for Pt (18). The value of $\Phi = 5.3$ ev for Pt appears to be much too high in comparison to the other metals, and this arises from the use of values varying from 6.3-6.4 ev in the averaging process. In fact if we omit all values of Φ in excess of 6 ev, then the average value is 4.94 ev which seems to be more reasonable.

In view of these difficulties, we could then proceed to calculate i_o in an alternative, but more valid, manner. By substituting Eq. [6] into [10b] noting that $-\phi_r F = \Delta H - T\Delta S$ we have

$$i_o = 2F \frac{ekT}{h} (a_{H_3O^+})^2 (1-\theta)^2 \exp -2\Delta S/R \cdot \exp -E_{exptl}/RT \quad [11]$$

and for 0.1N acid solution

$$i_o = 4.65 \cdot 10^{11} (1-\theta)^2 \cdot \exp -2\Delta S/R \cdot \exp -E_{exptl}/RT$$

Since $\Delta S = 15.48$ e.u. (3) and $E_{exptl} \doteq 6$ kcal mole^{-1} (17)

$$i_o = 0.12 (1-\theta)^2 \text{ amp cm}^{-2}$$

To arrive at a value for i_o, the coverage by adsorbed hydrogen, θ, must be known at the reversible potential. It is fairly well established that θ is large (19, 20), and from our own H/D-isotope work (14) we found that we could predict the experimental rate constant ratio, k_H/k_D, by fitting the coverage of H-atoms to 0.8-0.9. Hence taking $\phi_H \doteq 0.85$ we find that $i_o \doteq 2.7 \cdot 10^{-3}$ amp cm^{-2} which is in good agreement with the observed values (11, 12, 17, 21) which range from 10^{-4} to 5.10^{-3} amp cm^{-2}.

Rate of discharge in oxygen evolution.—One can now extend the above method to calculate the rate of discharge in the oxygen evolution reaction. The half-cell reaction in acid solution is written as

$$2H_3O^+ + \frac{1}{2}O_2 + 2e_M \rightleftharpoons 3H_2O \quad [12]$$

According to MacDonald and Conway (22), the discharge occurs from a water molecule in either acid or basic solution, and we can write the following discharge mechanism

$$M + H_2O \rightarrow M-OH^- + H^+ \quad \text{slow}$$
$$M-OH^- \rightarrow MOH + e_M \quad \text{fast}$$

so that, in effect, the OH^- species is involved in the rate-determining charge transfer step. The rate of discharge of OH^- at the reversible potential is then

$$i_o = \frac{\sigma_{H_2O}}{\sigma^{\neq}} F \frac{kT}{h} C_M (1-\theta)\, a_{H_2O} \frac{q^{\neq}}{q_M Q_{H_2O}} \exp -[E_o + \beta(\phi_r - \psi_1)zF]/RT \quad [13]$$

In Eq. [13] the concentration of metal sites must be considered because adsorbed oxide species are not mobile (15, 16). Also the ψ_1 potential can be calculated from Sterns theory [cf. (4)] taking the potential of zero charge for an oxide covered electrode to be about 0.5v *vs.* the normal hydrogen electrode (23). To evaluate i_o for the discharge of OH^- at a Pt anode in 0.1N acid solution, we shall proceed in a manner similar to that used above. We shall not attempt to calculate ϕ_r for reaction [12] but instead let us now simplify [13] as follows: taking $q^{\neq}/q_M = 1$ and

$Q_{H_2O} = 32.6$ (see appendix) and noting that $\sigma_{H_2O} = 2$ and $a_{H_2O} = 1$, we have

$$i_o = 2F \frac{ekT}{h} \frac{C_M (1-\theta)}{Q_{H_2O}} \exp -\beta\psi_1 F/RT \cdot \exp \beta\Delta S/R \cdot \exp -E_{exptl}/RT \quad [14]$$

The entropy change for the half-cell reaction [12] can be easily calculated as follows: combining the half-cell reactions in [4] and [12], the over-all entropy change is

$$\Delta S_{cell} = \Delta S_{O_2} + 2\Delta S_{H_2} \quad [15a]$$

where $\Delta S_{H_2} = -15.38$ e.u. as calculated previously (3) and described above. ΔS_{cell} can be calculated from standard entropy values such as those given by Latimer (24) from

$$\Delta S_{cell} = S_{H_2O} - \tfrac{1}{2} S_{O_2} - S_{H_2} \quad [15b]$$

From Latimer's tables $\Delta S_{cell} = -38.96$ e.u. and from [15a], $\Delta S_{O_2} = -8.21$ e.u. Taking $E_{exptl} = 22.1$ kcal mole^{-1} (25), $\beta = \tfrac{1}{2}$, $\psi_1 = 0.0950$v, and $C_{Pt} = 1.66 \cdot 10^{-9}$ mole cm^{-2}, Eq. 14 becomes

$$i_o = 2.11 \cdot 10^{-10} (1-\theta) \text{ amp cm}^{-2}$$

Since coverage by oxides is usually quite high (26) it follows that i_o is of the order of 10^{-11} amp cm^{-2} which is in satisfactory agreement with the experimental values which have been found to vary from 10^{-8} to 10^{-12} amp cm^{-2} (22, 25, 28).

Discussion

The method used here to predict i_o values is dependent on the knowledge of ϕ_r and E_{exptl}. The use of E_{exptl} rather than E_o to calculate i_o does not alter the reliability of the method because if E_o were used, one would have to vary the input parameters to the semi-empirical method and fit E_o to E_{exptl} by Eq. [6]. One major source of error is of course the experimental quantities since they have been found to vary considerably from one laboratory to another. For example, in the o.e.r., i_o values from 10^{-8} to 10^{-12} amp cm^{-2} have been reported, E_{exptl} values range from 18-25 kcal mole^{-1}, and values for β range from 0.4 to 0.65 (22, 25-29). Despite these variations, the i_o value calculated here agrees satisfactorily with the present assignment of a rate-determining OH^- discharge at platinum. Similar conclusions are reached concerning the calculated i_o values for atom recombination in the h.e.r. There is essentially no limit as to the type of electrode reaction for which we could calculate i_o values. The requirements are that we know the experimental E, i, and β values and that the reaction proceeds in a classical manner, *i.e.*, quantum mechanical tunneling contributions to the over-all rate of reaction are negligible. The calculation of ϕ_r for reaction [4] on Hg cathodes is based on a purely classical mechanism, and significant proton tunneling would therefore detract from the accuracy of this calculation. We have presented both theoretical and experimental evidence to show that tunneling of protons at Hg is negligible (2, 3, 30) and we feel our results are sufficient to counter the opinion that tunneling is significant (31, 32), in this reaction. There are several other metals which do appear to involve substantial tunneling of protons; *e.g.*, recent work on Ni indicates that tunneling effects are quite large (33). In fact, one can offer support of the tunneling mechanism indirectly by using the method present above. According to Bell (34) if we could calculate A and E from absolute rate theory (*i.e.*, corresponding to a classical mechanism), then both of these values should be larger than the experimental values if significant proton tunneling is involved. Preliminary calculations for the h.e.r. at Ni cathodes do in fact indicate that the calculated A and E values are too large (35) thereby indicating a tunneling mechanism according to Bell's criteria.

APPENDIX

In simplifying Eq. [10a] and [13], it was assumed that the ratio of partition functions is unity. The validity of this assumption can be demonstrated by evaluating the partition functions for translation, rotation, and vibration as follows:

The vibrational partition can be written as

$$q_{vib} = \prod^{3n-6} (1 - \exp - hc\nu/kT)^{-1} \qquad [16]$$

Providing ν(in cm^{-1}) is large, which is the usual case for real vibrations, q_{vib} is essentially unity.

For the rotational partition function, an equation similar to [16] was used because species in solution are subject to strong interactions by neighboring molecules or ions (*e.g.*, as in hydrogen bonding) and the molecule will not be free to rotate but will exhibit librational motion. Using the harmonic oscillator approximation [c.f. ref. (36)] q_{rot} can be calculated from [16] replacing $3n - 6$ by the degrees of rotational freedom. Since such librational frequencies have been observed to be around 650 cm^{-1} the assumption that $q_{rot} \to 1$ is a fairly good one. Ratios of q_{rot} approaching unity is even a better approximation.

The translational partition function for three degrees of freedom is

$$q_{tr} = 1.877 \cdot 10^{20} (MT)^{3/2} v_f \qquad [17]$$

where v_f is the free volume and M is the molecular weight in a.m.u. Taking $v_f = 4.4 \cdot 10^{-25}$ cm^3 for H_2O (38) and H_3O^+ (3), $q_{tr} = 32.6$ and 35.35, respectively. For two degrees of translational freedom

$$q_{tr} = 3.279 \cdot 10^{13} MT A_f \qquad [18]$$

where A_f is the free area. Since oxides are immobile, only the H_2 complex is considered to be mobile so that at 25°C

$$q_{tr} = 1.915 \times 10^{16} A_f$$

The activated complex possesses two degrees of translational freedom within the area A_f occupied by the site and this corresponds to $A_f \doteq 10^{-16} - 10^{-17}$ cm^2 so that $q_{tr} \doteq 1$ (16).

The rotational p.f. for two degrees of rotational freedom is given by

$$q_r = \frac{8\pi^2 IkT}{h^2} \qquad [19]$$

and taking $I = 4.6 \cdot 10^{-41}$ g cm^2 as an approximate value, $q_r \doteq 3$ at 25°C. Since the coverage by both adsorbed H and water dipoles is high, one would expect some type of restricted rotation and perhaps even a libration as in the case of water molecules. It is therefore reasonable to assume that q_{total} for H-atom recombination is unity so that from Eq. [10a], the ratio

$$\frac{\sigma^2_{H3O^+}}{\sigma^2_{H2O}\sigma^{\neq}} \cdot \frac{q^2_{H2O} Q^{\neq}}{q^2_{H3O}} \doteq 1$$

is a valid assumption for $\sigma_{H3O^+} = 3$, $\sigma_{H2O} = 2$, $\sigma^{\neq} = 2$.

However the ratio $q^{\neq}/q_M Q_{H2O}$ in Eq. [13], does not equal unity. For an immobile activated complex $q^{\neq}$ and $q_M \doteq 1$ (15, 16), but $Q_{H2O} = 32.6$, and this value was used in simplifying [13].

Optical Studies of Electrolyte Films on Gas Electrodes

Rolf H. Muller

Inorganic Materials Research Division, Lawrence Radiation Laboratory, University of California, Berkeley, California

ABSTRACT

The geometry of stable electrolyte films has been established on nickel and silver surfaces partially immersed in aqueous caustic solutions. Such films, which are very sensitive to factors affecting interfacial energies and may be useful for their determination, appear to be important for the mass transfer in certain gas diffusion electrodes.

The charge transfer at gas-consuming electrodes has long been assumed to occur at the top of the liquid meniscus where the gas, solid, and liquid phases, are in contact with each other. Although the concept of such a "line of reaction" leads one to postulate very large local current densities, and early observations by Grove (1) had indicated contributions of a finite electrode area, it was only recently that Wagner and Will called attention to the fact that neither gas diffusion through the bulk liquid near the meniscus nor surface diffusion of adsorbed gaseous species to the liquid phase, where reaction would take place as suggested by Schmid (3) and Justi (4), could account for many experimental results. Will (2) demonstrated that a relatively large electrode area participated in the electrode reaction. Similar conclusions can be drawn from computations by Iczkowski (5). The current distributions determined by Bennion and Tobias (6) and later by Maget and Roethlein (7) directly showed the spacial distribution of the electrochemical charge transfer reaction. Theoretical analysis of porous gas diffusion electrodes by Rockett (8) and Grens (9) and experiments by Katan *et al.* (10) have supported the concept of electrolyte films inside pores of some gas electrodes which are of practical interest.

Purpose of this study.—The finite current densities observed away from the apparent electrolyte meniscus suggested the existence of an electrolyte covering on the apparently dry metal surface, and it has been the purpose of this work to determine the extent of this electrolyte film on vertically oriented electrodes of simple geometry. In particular, the film thickness, which is an important parameter for the quantitative description of mass transfer on film-bearing gas electrodes, and the factors which affect it were to be studied. The rectangular and cylindrical electrodes employed may be regarded as highly idealized models of the capillaries in a porous body. The study was limited to mechanically polished nickel and silver electrode surfaces for reasons of optical reflection. Only cathodic polarization was employed in order to maintain the properties of the metal surface as much as possible.

Film interference.—Several techniques have been considered for the measurement of electrolyte film thickness as a function of position and time: Mechanical techniques, although independent of electrolyte and electrode materials, result in discontinuous, point-to-point measurements which may not be sensitive enough and also disturb the film. Electrical measurements could be made continuously; however, they depend on the electrolyte conductivity which is not well known and is a function of position. Electrical conductivity measurements also presuppose a uniform film over the test-distance and suffer from disturbance of the object by the probes. Of different optical techniques, light interference was finally chosen because

of the possibility of making continuous observations with a minimum of disturbance to the object, little requirement for uniform film geometry, and good sensitivity for the dimensions involved. A disadvantage of this technique is that it requires a knowledge of the refractive index of the film. The uncertainty of this quantity due to concentration variations, not *a priori* known, amounts, however, only to a few per cent. Light interference for the study of supported liquid films has recently been used by Bascom *et al.* (11) and Deryagin *et al.* (12).

Film interference, well known from the appearance of soap bubbles or oil spots on water, is due to partial reflection of an incident light wave on front and back sides of the film. The interference causes a tapered film to show, under monochromatic illumination, alternating bright and dark fringes which indicate contour lines spaced at distances corresponding to one wavelength optical path increment. The optical path difference ΔS in the film between interfering reflections depends on refractive index n, film thickness d and angle of refraction ϕ' as shown in Eq. [1]. It can also be expressed as a delay in phase, δ_{film}, given in Eq. [2] in radians where λ is the light wavelength in vacuum.

$$\Delta S = 2nd\cos\phi' \quad [1]$$

$$\delta_{film} = \Delta S\, 2\pi/\lambda \quad [2]$$

The use of white light results in interference colors which are often more sensitive to small film thickness variations than the corresponding monochromatic intensity variations, and which admit an easy distinction between the first few orders of interference. The colors can be calibrated by comparison with monochromatic patterns in a continuously tapered film; thus, the characteristics of the photographic color material do not affect the results. The observations on cylindrical electrodes are more difficult, but not basically different. A discussion of curved films has been given by Barakat (13).

As had been noted by Blodgett and Langmuir (14, 15), it is advantageous to use linearly polarized light to simplify the analysis of film interference. These authors also describe the improved contrast of an interference pattern when observed at a grazing angle of incidence. Similar observations are reported by Gaudin (16). A detailed analysis of interference in a transparent film on an absorbing substrate, which takes multiple reflections into account (17), shows that with light polarized parallel and normal to the plane of incidence (p and s polarization) "optimum angles of incidence" can be found for which the amplitudes of the interfering waves are equal, thus resulting in optimum interference contrast. The optimum angle of incidence is larger for p than for s polarization, it increases with increasing reflectivity of the metal substrate and decreases with increasing refractive index of the film. For many metal-film combinations 75° angle of incidence has been found to be a good intermediate value for observation with both s and p polarization.

For the quantitative interpretation of interference patterns in terms of film thickness, the phase change suffered by the light on reflection at the two film boundaries has to be taken into account as pointed out, *e.g.*, by Mayer (18), and discussed in a different context by Lindberg (19). The total phase difference δ between the interfering reflections is composed of a part δ_{film} due to the optical path in the film (taken negative as a relative delay in time) and the combined effect $\delta_{refl.}$ of the reflections as expressed in Eq. [3]. The latter quantity in turn represents the difference between the phase changes in dielectric and metallic reflections at the two film boundaries with respect to the incident wave (Eq. [4]).

$$\delta = \delta_{film} + \delta_{refl.} \quad [3]$$

$$\delta_{refl.} = \delta_{diel.} - \delta_{metal} \quad [4]$$

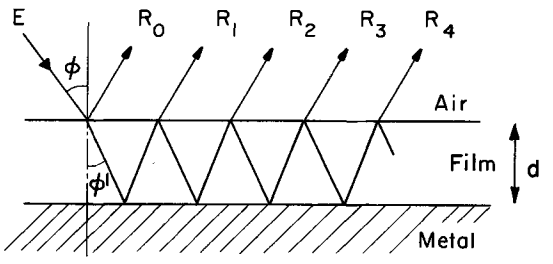

Fig. 1. Multiple beam interference from a transparent film on a metal substrate: E, incident wave; R, reflected waves; ϕ, angle of incidence on the film; ϕ', angle of refraction in the film.

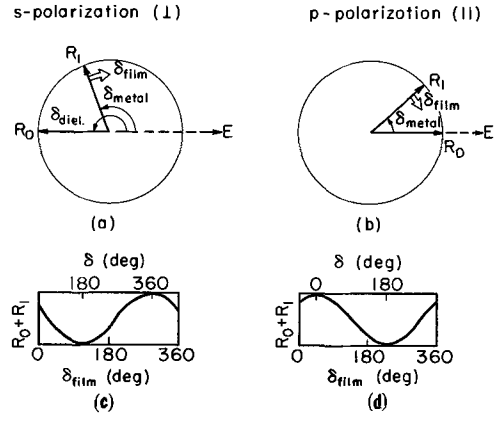

Fig. 2. Effect of phase changes in dielectric and metallic reflection on double beam film interference. (a), (b) vector representation of phase relationships between interfering waves R_0 and R_1 shown in Fig. 1; (c), (d) predicted interference intensity distribution in a wedge shaped film.

The phase changes in reflection affect the position of the origin of the film thickness scale deduced from the interference fringes and become particularly significant for film thicknesses of a wavelength of light or less. If only the first two of the multiple reflections in the film are considered for a moment (R_0 and R_1 in Fig. 1), the phase relationships can be visualized in a vector diagram illustrated in Fig. 2. This representation shows phase and amplitude as angular and radial coordinates, respectively, and takes the time-independent phase of the incident wave E at the gas-film interface as a reference. For an aqueous 3.4N KOH film (n = 1.365) on a nickel substrate and 75° angle of incidence ϕ on the film, for instance, (angle of incidence on the metal ϕ' = 45°) phase shifts δ_{metal} for the metallic reflection of 112° and 48° in the sense of a phase advance have been computed for s and p polarization, respectively, from the optical constants of the interface measured by ellipsometry (20). These values are indicated by the positions of the vectors R_1 in Fig. 2a and b. The vectors R_0 show a 180° or 0° phase change, with s and p polarization, respectively, characteristic of the dielectric reflection at the gas-film interface under angles of incidence larger than Brewster's angle. Since a film of increasing thickness increasingly delays reflection R_1 indicated by the double arrows in Fig. 2a and b, the sum of the two complex amplitudes R_0 and R_1, a measure of the observed interference intensity, as a function of film thickness goes first through a minimum for s polarization (Fig. 2c) but a maximum for p polarization (Fig. 2d). Thus, the interference patterns with the two polarizations are approximately complementary to each other. Because the characteristic interference fringes which can be used for a quantitative interpretation correspond to different film thicknesses in the two polarizations, the simultaneous use of both yields twice the number of measured contour lines.

Experimental

The electrolytic cells employed contained optically polished[1] metal electrodes of rectangular (1.5×3 cm high) or cylindrical (2×13 cm high) geometry made of nickel or silver and inert counter electrodes of large surface area located in separate cell compartments (to avoid possible contamination of the electrode surface by corrosion products from the anode). Openings were provided to control the electrolyte level and to maintain atmospheres of known composition in the cell volume not occupied by the liquid. The nitrogen or oxygen gas was kept water-saturated with solution of the bulk concentration. After careful mechanical degreasing, the electrodes were electrolytically cleaned by hydrogen evolution. It is important that every trace of grease be excluded from the cell, particularly in working with dilute solutions, where even deposits from the laboratory atmosphere have been found to spread from the outside of the cell through open ports onto the electrode surface. Most experiments were initiated by rapidly lowering the liquid level in the cell to 5 mm above the lower electrode edge and observing the subsequent drainage of the film as a function of time. The optical arrangement used for this observation is given in Fig. 3 as a plan view diagram. Two collimated light beams A-F polarized parallel and normal to the plane of incidence are directed toward the film-covered surface G under an angle of incidence ϕ. The respective reflections are collected by two objectives L and placed by a set of first surface minors M side by side on the frame N of a 16 mm movie camera geared for single frame exposure. The image of a clock K was also placed on each frame by the objective I and the two mirrors H in order to record elapsed time. An automatic interval timer activated the camera shutter and turned the illumination off between exposures in order to avoid heating by light absorption.

Results

The evaluation of interference pictures from typical experiments along the vertical center line of the electrode results in film profiles given in Fig. 4a and b. After the initial drainage, a stationary film geometry is reached after a period in the order of 10 hr. This period is shorter and the resulting stationary film is thicker for an oxygen-consuming electrode as compared to the same metal-solution system not electrochemically polarized. The stationary film geometry has been asserted not to change in selected experiments over periods of several weeks.

If viscous and gravitational forces only are considered for the thinning of the electrolyte film, Eq. [5] can be derived (21) for the dependence of film thickness d on vertical coordinate z (measured from the upper electrode edge down) and time t

$$d = (\mu/\rho g)^{1/2} z^{1/2} t^{-1/2} \qquad [5]$$

where μ is the viscosity, ρ the density, and g the gravitational acceleration. Under these assumptions, a plot of film thickness *vs.* inverse square root of time would result in a straight line through the origin for a given electrolyte composition and electrode position. Such an analysis of the previously shown film profiles (Fig. 4) 1 cm above the liquid level results in the curves of Fig. 5. It can be seen that the expected relationship holds down to about 1μ film thickness. With no electrochemical polarization of the electrode (Fig. 5a), the rate of film thinning gradually deviates from that of a free-flowing liquid due to the effect of interfacial forces until a steady state value of 0.31μ is reached after 20 hr. The film thinning with concurrent cathodic oxygen consumption under constant current (Fig. 5b) exhibits an abnormally rapid thinning rate before reaching a steady state value of 0.39μ after 6 hr. The rapid film thinning may be due to electroosmotic ef-

fects, the establishment of a concentration profile, and the nonuniformity of electrochemical polarization. Two steady-state film profiles measured on the same electrodes under different load are shown in Fig. 6a. The response of film thickness to changes in cathodic polarization occurs with a transition time in the order of 10 hr. The same steady-state profiles are attained from previously higher or lower polarization. Such changes can be expected to take place in fuel cell electrodes under variable load.

Stationary film profiles of KOH solution on nickel and silver, two electrode materials of practical interest, are compared in Fig. 6b. They reflect the different surface properties and electrochemical polarization characteristics of the two metals.

The dependence of the steady-state film thickness on the liquid composition has been investigated with different potassium hydroxide concentrations; the film thickness has been found to increase with increasing concentration. For this reason, a 3.5*N* KOH film could be grown upward on a vertical nickel surface previously in equilibrium with distilled water, which forms a coverage just barely observable by the interference method. Such a film growth, measured 1 cm above the liquid level, is illustrated in Fig. 7. It can be seen that the transition, again, takes in the order of 10 hr.

Discussion

The experiments conducted have established the geometry of stable electrolyte films on polished nickel and silver surfaces partially immersed in aqueous caustic solutions. The film geometry reflects a balance of interfacial forces and therefore depends on the properties of the liquid, those of the solid and the electrical potential applied between the two phases. A satisfactory theory of film behavior will have to take into consideration that stable configurations are reached both with and without reaction occurring in the film. Gradients of concentration and other properties in the film can be expected to affect its geometry, but these do not seem to be the principal cause of film stability. The nature of the interfacial forces at play cannot be defined at present; however, it can be speculated on thermodynamic grounds for an equilibrium situation that with a typical heat of immersion of 100 erg/cm² for metals in water, considerable energy is available for film formation, practically all of which is used for establishing the film-gas interface that typically requires 75 erg/cm².

While the electrolyte films studied are of a much simpler nature than those presumably existing inside certain porous gas diffusion electrodes, where the presence of capillary and pressure forces may lead to different film geometries, the results obtained suggest further studies in this area. These include the practical significance of the unexpectedly long transition times to steady state, the effects of electrode surface pretreatments, and the complex interrelation of film geometry with the spatial distribution of current, potential, concentration and temperature in the film. Resulting changes in contact angle of the liquid meniscus inside capillary electrodes have been reported by Bonnemay *et al.* (22), and oscillating phenomena suggested for this area (23) have recently been reported by Bockris *et al.* (24).

The accuracy of the technique employed greatly depends on the optical properties of the substrate which determine the phase change in metallic reflection. These properties were computed from the complex refractive index of the solution-metal interface measured before and after each experiment. Various possibilities explored to check the phase relationships used in the evaluation of the interference fringes indicate a maximum error in film thickness of 0.1μ. The first such check is based on the dependence of the optical path ΔS in the film on the angle of refraction ϕ' expressed in Eq. [1]. This dependence should extrapolate to zero for a given film viewed under different angles, and thus ascertain the origin of the film thickness scale. According to Snell's law, there is only a limited range of values which the angle of refraction can assume for the maximum variation in angle of incidence. Therefore, this test requires a long extrapolation and can detect only gross errors in phase (Fig. 8). It is, however, sensitive enough to reveal an error of a full interference order possible by a misinterpretation of fringes in the data evaluation. Another test can be based on the wavelength dependence of the film interference seen in Eq. [2] and requires observation of the same film under a given angle of incidence with monochromatic light of different wavelengths. This presupposes a knowledge of the dispersion of the optical constants of metal and film. A third possibility consists in observing the sequence of interference colors as a film of a low solute content is rapidly evaporated to dryness by the introduction of a water-free gas phase. The variable refractive index of the film which represents another, although minor, source of error could possibly be determined by measuring Brewster's angle of incidence at which the

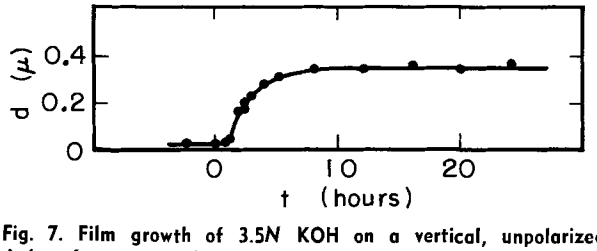

Fig. 7. Film growth of 3.5*N* KOH on a vertical, unpolarized nickel surface previously covered with a stationary distilled water film, observed 1 cm above the liquid level.

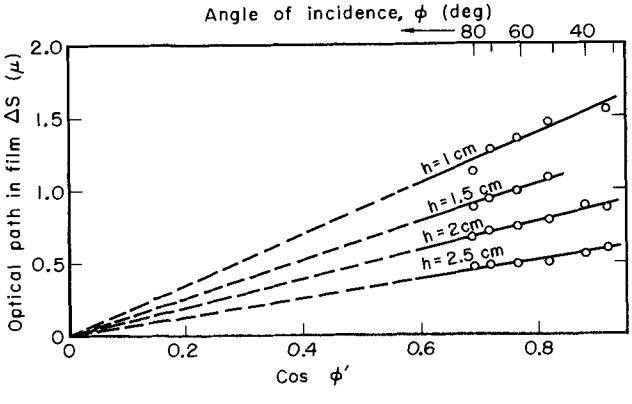

Fig. 8. Interference in the same film under different angles of incidence. Extrapolation of optical path length at different film levels h to check phase changes used in evaluation.

interference pattern completely disappears in p polarization (17). Finally, ellipsometry offers the possibility of simultaneously determining refractive index and thickness of the film provided that the optical constants of the film-metal interface and the approximate value of the film thickness are known. This check will have to be performed at a later time.

Experiments are in progress with larger flat electrodes in order to approach the behavior of an infinitely extended surface suitable for the analysis of surface forces and the derivation of interfacial thermodynamic data. A detailed understanding of electrolyte films on polarized electrodes may permit one to derive the electrocapillarity of solid electrodes.

Polarization Phenomena in Commercial Ion-Exchange Membranes

M. Block[1] and J. A. Kitchener

Department of Mining & Mineral Technology, Imperial College, London, England

ABSTRACT

Polarization phenomena occurring at ion-exchange membranes have been investigated with a number of commercial membranes of the type used in electrodialysis cells for desalting. Polarization is most marked with very dilute electrolyte solutions and with conditions favoring stagnation of the liquid films near the membrane; in particular, a horizontal membrane with upward direction of migration of counterions minimizes convection. Chronopotentiometric studies with this system have shown that the early stages of concentration polarization conform approximately to Sand's theory. Later, however, complicated phenomena are observed. At high current densities all of the cation-exchange membranes tested and certain of the anion-exchange membranes showed rapidly rising resistance, but certain other anion-exchangers were found capable of carrying high currents continuously, mainly in the form of hydroxyl ions. Experiments with radiotracers indicated that these differences did not arise from co-ion leakage or electroosmotic streaming. A possible explanation is that ease of passage of H^+ or OH^- ions through these membranes is dependent on the degree of microheterogeneity, which affects the possibility of transport by the Grotthus mechanism.

The permselectivity of most commercial ion-exchange membranes in dilute salt solutions is of the order of 90-100%, more or less, depending on the internal concentration of functional groups and the concentration of external electrolyte solution. In other words, when a direct current is passed through the system, about 90-100% of it is carried by migration of the counterions and the remainder by the movement of the co-ions of internal ("Donnan") electrolyte in the opposite direction. There is also some net transference of internal electrolyte solution by electroosmosis in the direction of migration of the counter ions. It is important to note, however, for the present problem, that these membranes are free from electronic conductivity, as shown by the fact that no evolution of oxygen or hydrogen gas is observed even when the membranes are subjected to very large potential gradients, *i.e.*, they do not behave as bipolar electrodes, but are purely electrolytic conductors.

Passage of current therefore leads to a reduction of concentration of electrolyte on the side which donates the counterions and an increase on the receiving side. Consequently, diffusion gradients are built up in the

[1] Present address: Vokes Ltd., Guildford, Surrey, England.

vicinity of the faces of the membrane and these constitute a type of concentration polarization, corresponding to the back emf that is detectable by means of Luggin capillary electrodes. Cooke (1) has made careful investigations of this type of membrane polarization. If the two solutions are stirred or otherwise renewed by flow, the extent of the diffusion regions is limited and a steady state is quickly reached in which diffusional transport up to and away from the membrane balances electrolytic transport through the membrane.

On the other hand, if convective transport is absent, or is inadequate in relation to the current passing, a more complicated sequence of events occurs. As extensive diffusion regions develop, the concentration of ions near the entry side of the membrane falls, and consequently an increasing potential gradient must be applied to maintain a given current density. The changes of density of the layers of solution and the differential heating may produce convection. Eventually, the local concentration of ions may become infinitesimal (*e.g.*, $<10^{-7}N$), and then an alternative process can take a significant part in carrying current, namely, the transport of one of the ionic species of water. With a cation-exchange membrane H^+ ions may be carried through, resulting in a rise of *p*H on the donating side and fall on the receiving side; with an anion-exchange membrane, transport of OH^- would produce the opposite *p*H changes. Such *p*H changes in electrodialysis have been known for many years and have been investigated by Bethe (2), Bethe and Toporoff (3), and more recently by Kressman and Tye (4), Frilette (5), Peers (6), Rosenberg and Tirrell (7), Uchino *et al.* (8), Cowan and Brown (9), Cooke (1), and Koblianski and Ulitin (10).

The conditions described in the preceding paragraph occur only at relatively high current densities and will be referred to as "high polarization" for brevity and to distinguish it from the simple steady-state concentration polarization. It is generally assumed that a certain critical current density is required to achieve high polarization, but the value necessary naturally depends on the set-up, the concentration and degree of agitation of the electrolyte, etc. The present work has shown that there is also considerable variation in polarization properties of different types of membrane.

It is generally accepted also that *p*H changes are more prominent with anion-exchange than with cation-exchange membranes, even above the supposed critical current density. For example, Cooke (1) found only 0.1% of the current to be carried by H^+ (from $0.05N$ solutions) whereas up to 60% transport by OH^- was found with anion-exchange membranes. (For this reason, in electrodialysis cells the diluate compartments generally become acidic and the concentrates alkaline.) These findings appear anomalous in relation to the theory of concentration polarization (see below).

In order to study the peculiarites of the high polarization regime, the conditions used in the present work were chosen to favor the onset of the condition, namely, high current densities, low electrolyte concentrations, absence of forced convection, and minimal natural convection. Under these conditions, not only is the permselectivity of the membranes practically unity, but also the diffusion zones approximate to the ideal plane-parallel layers required for Sand's well-known theory of concentration changes near an electrode to be applicable.

According to Sand's theory, which describes electrolysis at constant current under the influence of diffusion and electromigration and in absence of convection, the time required for the concentration of electrolyte to fall to zero at the plane of the electrode (membrane), the so-called "transition time," τ, is given by

$$\tau = \frac{\pi z^2 F^2 D C^2}{4I^2(1-T)^2}$$

where z is the valency of the current-carrying ion (*i.e.*, the counterion for a membrane), F is Faraday's constant, D and C the diffusion coefficient and bulk concentration of the electrolyte, I the current density, and T the transport number of the counterion in the solution. After the transition time has been passed, the current of counterions would fail to maintain I; if some other process takes over, a higher voltage will be required to maintain the current constant.

It follows that all membranes of a given ionic sign and with closely similar permselectivities should show the same transition time, irrespective of their chemical or physical structure. Similarly, if high polarization starts with depletion in the solution layers, the transition times for anion- and cation-exchange membranes should be in the inverse ratio of the squares of the transport numbers. The subsequent processes should depend on the mobilities of OH^- or H^+ in the membranes. As earlier published work had suggested that these ions would be especially mobile in the water-filled pores of strong-acid and strong-base ion-exchangers, a certain symmetry in the breakthrough of acid or alkali was to be expected, in contradiction to reported observations.

The experimental work described below was directed toward elucidation of these anomalies. Some unexpected results were obtained.

Experimental

Membranes.—The following membranes, kindly given by their manufacturers, were employed in the experiments (see Table I). Sometimes there were appreciable variations between replicate samples cut from different parts of the same sheet; furthermore certain membranes appeared to have asymmetric properties. However, only well-marked effects are reported here.

Methods.—The main technique employed was chronopotentiometry with horizontal membranes at a series of selected current densities, in absence of stirring. (Various auxiliary experiments are mentioned later.) The electrolyte was generally degassed $0.01N$ NaCl on both sides of the membrane, and the direction of applied potential was usually such that the counterions passed upward, thus causing dilution of the layer of solution below the membrane and concentration above it, the "stable" arrangement for minimizing convection.

Apparatus.—The cell shown in Fig. 1 is self-explanatory. The large silver-silver chloride electrodes could

Table I. List of commercial ion-exchange membranes investigated

Name of manufacturer	Trade name of membranes	Membrane designation: Cation-exchangers	Membrane designation: Anion-exchangers
Asahi Chemical Ind. Ltd. (Japan)	ACI	C; CK-1	A; CA-1
Asahi Glass Co. (Japan)	Selemion	—	AMG: AMT: AMP: ASG: AST: DMT*
American Machine and Foundry Co. (U.S.A.)	AMFion	C-60;	A-60
Ionac Chemical Co. (U.S.A.)	—	MC 3142	MA3148: MA3236
Ionics Inc. (U.S.A.)	Nepton	61 AZL	111 BZL
The Permutit Co. Ltd. (Gt. Britain)	Permaplex	C-20	A-20
Rohm and Haas Co. (U.S.A.)	Amberplex	C-1	A-1
Toyo Soda Mfg. Co. (Japan)	Toso	C	A

* In addition, the manufacturers kindly supplied specially prepared membranes, Selemion AM, AS, and CS, made without the usual reinforcing fibers.

carry 50 ma for 30 min, or 200 ma for short periods, without gassing. For small currents a stabilized constant current supply built according to the design of Reilley (11) was used: when higher voltages were needed, a 0-750v stabilized voltage supply was dropped across a bank of 10 kohm, 25w resistors, and the current through the cell was kept steady by manual adjustment of rotary switches. The voltage, V, across the whole cell was recorded as a function of time at selected currents, both with and without the membrane. The voltage differences between the curves indicated the extra potential drop across the membrane and its adjacent liquid films produced by polarization (since the processes occurring around the electrodes and in the bulk solution were the same, at a given current, whether a membrane was present or not.)

Results of Chronopotentiometry

Low currents.—Figure 2 shows typical results for V as a function of t, for a series of low current densities through the membrane. The rise of voltage corresponding to complete depletion (of Cl^- ions) at the membrane is obvious, but under ordinary laboratory conditions the transition time was not sharply defined.

Conversely, when the counterions were made to pass downward, the current either remained constant (0.4-0.6 ma) or oscillated (0.8 ma). These effects are clearly due to convection arising from density changes.

In order to prove that beyond $t = \tau$ current was being carried by OH^- ions from water, some membranes impregnated with phenolphthalein were used in chronopotentiometric tests and the point at which alkalinity appeared, as indicated by a red color on the upper face of the membrane, was noted. These points are indicated by triangles in Fig. 2. The change in pH could not have been due to counter-current leakage of H^+ co-ions, as the change in color was seen first at the diluate side of the membrane and it then spread through it. Breakthrough of alkali is seen to occur shortly after the voltage has begun to rise, the delay presumably corresponding to penetration through, and saturation of, the anion-exchange membrane.

It was observed that the chronopotentiometric curves, such as those shown in Fig. 2, were sensitive to vibrations and thermal fluctuations. When the apparatus was transferred to a laboratory where vibrations and draughts were minimal, the rise of voltage was sharper, as indicated by the continuous lines in Fig. 2. The apparent transition times interpolated on the curves for 0.3, 0.4, 0.5, 0.6, and 0.8 ma are 11.2, 5.8, 3.1_3, 2.3_0, and 1.1_3 min, respectively, and the inset to Fig. 2 shows that these results are in rough agreement with Sand's equation, though the points correspond to somewhat larger values of τ than predicted theoretically. This is almost certainly due to some residual disturbance of the liquid layers, the discrepancy being relatively smaller at the higher current densities. As τ is inversely proportional to I^2, it was not practicable to obtain the necessary readings with the present apparatus at current densities much above 1 ma/cm^2; however, there is no reason to doubt that the theory is valid.

Chronopotentiometric curves obtained with cation-exchange membranes at low current densities were similar in form to those with anion-exchange membranes (Fig. 3). Again the rise in voltage was progressively closer to the theoretical value predicted by Sand's equation the higher the current density (see arrows). Apparently the diffusion layers did not remain undisturbed for more than about 1 min with either type of membrane; but, as τ was theoretically 63.2 sec for an anion-exchange membrane at 1 ma/cm^2 and 28.1 sec for a cation-exchange membrane, the rise of voltage appears sharper at a given current density with the latter membranes.

Although different manufacturers' membranes gave somewhat different values, and even specimens from the same sheet were not identical, it was generally observed (cf. Fig. 2 and 3) that the voltage rose to higher values with the cation-exchange than with the anion-exchange membranes, suggesting that an easier current-carrying mechanism was present in the latter rather than the former (after exhaustion of the diffusion of sodium chloride). The obvious possibility is that, after the transition has been reached, further current is carried by the ions of water.

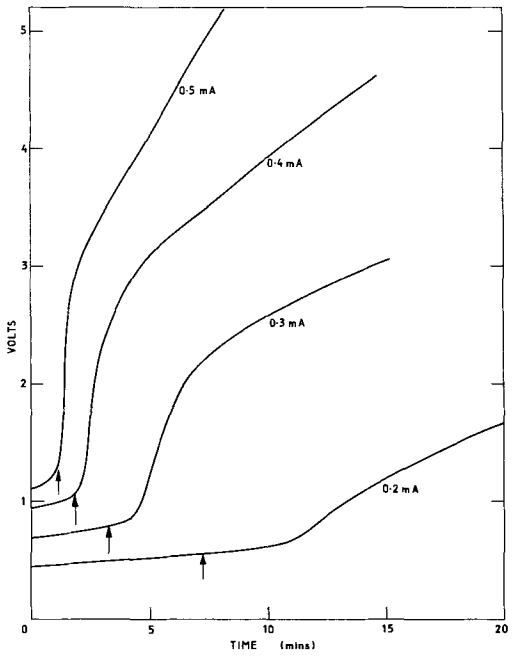

Fig. 3. Chronopotentiometric curves for cation-exchange membrane (ACI:C) at low current densities. (Arrows indicate theoretical transition points. Electrolyte: 0.01*N* NaCl.)

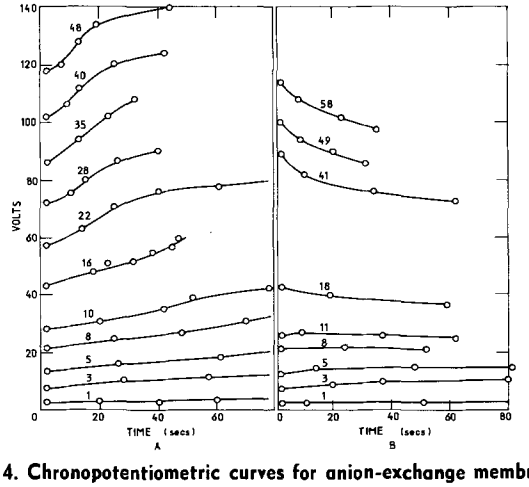

Fig. 4. Chronopotentiometric curves for anion-exchange membrane (Amberplex A1) at high current densities. (A, counter ions passing upward; B, counterions passing downward; numbers on curves are ma passing through disk of 1 cm diam. Electrolyte: 0.01*N* NaCl.)

At first sight this theory is contradicted by the apparently greater transport of OH^- by anion-exchangers than of H^+ by cation-exchangers. To check this important point, experiments were needed to determine the amounts of alkali and of acid transported respectively, and also the quantities of co-ion leaking through the membranes. However, to obtain measureable quantities for analytical determination, it was necessary to employ higher currents than those used in Fig. 2 and 3, and as certain other phenomena were then encountered, the chronopotentiometric data for higher currents will be considered next (Fig. 4 and 5).

High current densities.—With 5 ma/cm² or more, the theoretical transition time is 3 sec or less, and therefore too quick to be conveniently followed with the present apparatus. The first point recorded was arbitrarily taken immediately after the initial sharp movement of the voltmeter needle was complete. The phenomena responsible for the forms of Fig. 4 and 5 are, therefore, subsequent to the exhaustion of supply of diffusing counter ions from the solution, *i.e.*, they refer to events after the transition time.

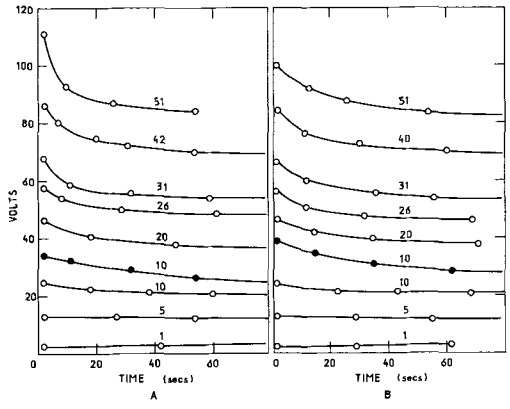

Fig. 5. Chronopotentiometric curves for anion-exchange membrane Toso A at high current densities. (A, counter ions passing upward; B, counter ions passing downward. ——●—— Measurements with agar gel disk below the membrane.) Electrolyte: 0.01*N* NaCl.

The voltage indicated in Fig. 4A and B refer to the total emf across the cell and therefore include the voltage drop across the electrolyte and polarization back emf's at the electrodes. It was not, however, necessary to determine these separately and subtract them from the total, as tests showed that, if just the membrane was omitted from the cell, the voltage required to pass a given current through the electrolyte plus reversible electrodes remained constant. Therefore, the significant feature is the change of voltage with time, corresponding to changes in effective resistance of the membrane and its adjacent layers of solution.

These experiments, unlike those at low c.d., revealed striking differences between different commercial membranes. All cation-exchange membranes, whether nominally "homogeneous" or "heterogeneous" in type, and certain anion-exchange membranes gave a set of curves similar to those of Fig. 4A, namely, with voltage rising with time, more and more steeply the higher the current passed. With the higher currents, the dissipation of power in the region of the membrane was so great (under static conditions) that eventually degassing and boiling brought the run to an end. (Temperature changes were checked by means of a small thermistor inserted below the membrane.) Application of the same power input in the form of a-c current produced no comparable local heating effects. Anion-exchange membranes falling in this class included ACI.A; ACI CA-1; Selemion AMT, AMP and DMT; AMFion A-60; Ionac MA 3236; Permaplex A-20; Amberplex A-1.

In contrast to the first type of membrane, certain other anion-exchange membranes yielded sets of curves of the kind shown in Fig. 5, the voltage decreasing with time and eventually levelling out to a constant value which could be maintained for long periods with only minor fluctuations. This class included TOSO A, Selemion AM, AS, AMG, ASG, AST and Nepton 111 BZL. The insertion of agar gel disks below the membrane increased the steepness of the curves similar to Fig. 4A but did not affect those similar to Fig. 5A.

For simplicity, the first type of membrane is referred to as "polarizing" and the second as "non-polarizing." The latter evidently possesses an adequate conduction mechanism to carry, for example, 50 ma/cm² continuously and even four times this value for short periods, whereas the former lacks such a mechanism.

It must be emphasized that these phenomena were observed only with arrangements conducive to stagnation of the solutions adjacent to the membrane (cf. Fig. 1). If the current was passed in the opposite direction (*i.e.*, counterions downward), curves of the

second type were obtained with all membranes; this is due, of course, to convection. The same applied to operation with the membrane vertical, or simply with reduction in thickness of the limiting orifice (1 cm thick) below the membrane. On the other hand, stirring of the solution above the membrane had no such effect. Therefore, the rising resistance of the polarizing membranes is associated with the membrane-diluate region.

Observations of the solution layers near the membrane were made during passage of current by means of the schlieren cell shown schematically in Fig. 6; the schlieren optical equipment was kindly made available by Sawistowski (Department of Chemical Engineering, Imperial College). Polarizing membranes at current densities of 14-66 ma/cm^2 showed violent turbulence in the diluate layer near the membrane, whereas nonpolarizing membranes showed no turbulence, even at 130 ma/cm^2. Instead, a thin layer of diluate just below the membrane appeared dark on the schlieren screen and gradually increased in depth. With a current density of 66 ma/cm^2 convectional circulation in the concentrate compartment commenced after about 10 sec.

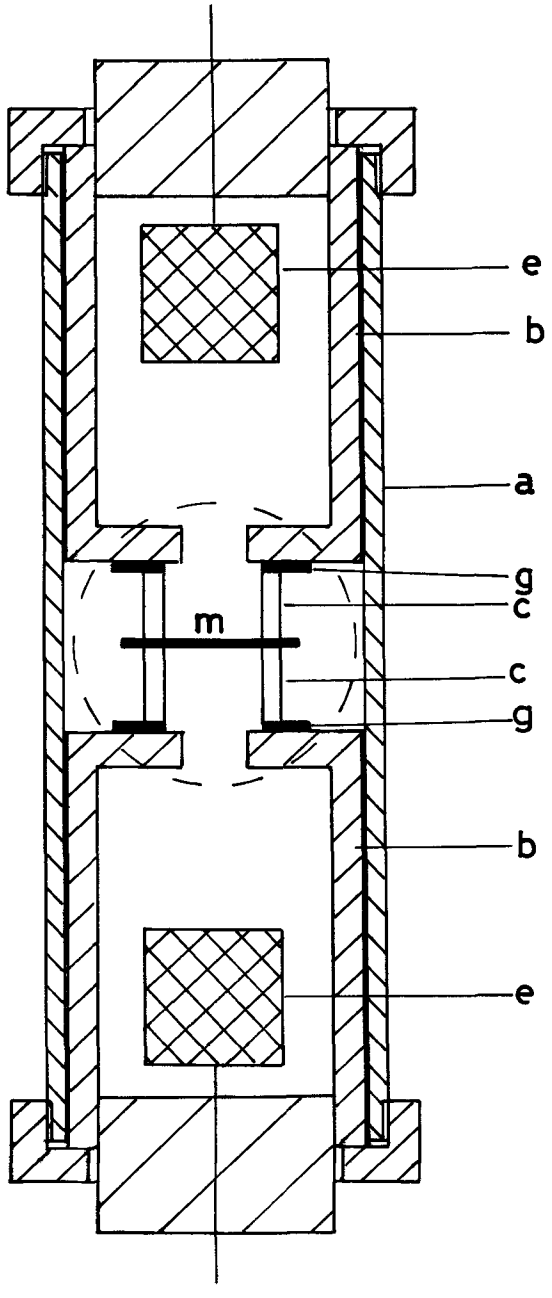

Fig. 6. Diagram of Schlieren cell: a; steel cylinder with screw ends and observation windows; b, b; "Perspex" electrode compartments; c, c; glass cylinders; m; membrane; g, g; gaskets; e, e; electrodes.

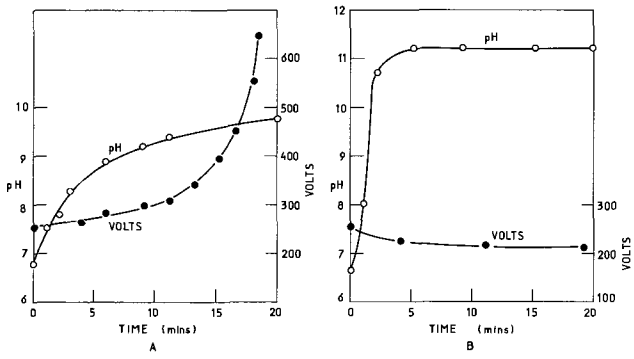

Fig. 7. Break-through of alkali with A. polarizing membrane (ACI A), and B. nonpolarizing membrane (Selemion ASG) at 66 ma/cm^2. Flow-rate across upper face of membrane: 24 ml/min. Electrolyte 0.01*N* NaCl.

pH changes during electrolysis.—To measure the amount of alkali generated during electrolysis with a nonpolarizing anion-exchange membrane, the cell was modified as in Fig. 1A so that a slow current of solution could be flowed across the top surface of the membrane and the *p*H of the effluent was determined. (To eliminate electrical disturbance of the pH-meter it was necessary to cause the effluent to fall as drops inside a polythene tube, thus electrically isolating the glass electrode vessel from the electrolysis cell.)

Results obtained with one polarizing and one nonpolarizing anion-exchange membrane at 66 ma/cm^2 are shown in Fig. 7. Both membranes passed considerable amounts of alkali, but the latter possessed a more facile conduction path and a steady state could be reached. In the steady state, the amount of alkali being released was sufficient to maintain the *p*H of the upper solution, flowing at 24 ml/min, at about 11.2; this corresponds to a transport number for OH^- of 0.93. It is certain, therefore, that practically all the current passing through the nonpolarizing membranes is carried by OH^- ions.

With the polarizing anion-exchange membrane of Fig. 7A, a steady state could not be reached, but, clearly, far less alkali had been generated for the same quantity of current passed. The *p*H was still rising after 19 min, but up to this time the bulk of the current must have been carried by other ions. Similar results were obtained with cation-exchange membranes (all polarizing): at most, only 6% of current was ever obtained in the form of H^+ transport, even at 66 ma/cm^2. The problem is therefore to account for the current that does pass in the highly polarized condition of the membrane. Several possible theories were tested by direct experiment (see below).

Leakage of co-ions.—The transport number for co-ions through commercial ion-exchange membranes is normally only a few per cent, but it seemed possible that under high polarization the value might increase. Measurements of transport of Na^+ and Cs^+ through four different anion-exchange membranes were therefore made, by means of ^{22}Na and ^{137}Cs, with 0.01*N* solutions of NaCl and CsCl as electrolytes and a current density of 66 ma/cm^2. The duration of the electrolysis ranged from 1.5 to 16 min.

The results showed co-ion transport numbers around 0.01 (ranging from 0.002 to 0.03, with results for Cs^+ being 2-3 times those for Na^+). Therefore, conductance by co-ions is a negligible factor in the polarization current.

These conclusions were supported by experiments in which a long-chain amine, "Hyamine 1622" (Rohm

and Haas Company), and a basic dye, methylene blue, both being cations too large to migrate through the membrane, were used as anolyte; the polarization response of the membranes was unaffected. These experiments show that the diluate side is rate-controlling.

Electroosmotic flow.—It seemed possible that nonpolarizing membranes might contain small pores through which solution streamed under high potentials, with consequent disturbance of the diffusion layers. Tests for electroosmotic flow were made by adding glucose, labelled with ^{14}C, to the catholyte and determining, by the method of Edwards and Kitchener (12), the amount of glucose transported into the anolyte. The assumption was made that glucose would diffuse through homogeneous membranes at a negligible rate, would be little adsorbed by the membrane, but would indicate any hydrodynamic streaming of catholyte through capillaries. The glucose tracer was at 10^{-5}M in 10^{-4}M inactive carrier; for analytical convenience, 0.01*N* NaOH was used as carrier electrolyte. A current of 66 ma/cm^2 was passed for 30 min. These experiments were done with a U-tube apparatus, with vertical membrane, in order to make it possible to continue electrolysis at high current density. It was argued that if pores were present in some but not other membranes, they should lead to differences of electroosmotic transport of glucose tracer.

The results showed transference of about 3×10^{-5} moles of glucose per Faraday, the values being of the same order for polarizing as for nonpolarizing membranes. Therefore, differences of electroosmotic flow could not be the explanation of the difference of polarization properties.

Stratified heterogeneity.—It seemed possible that the surface layer of a membrane might vary in properties, depending on whether it was cast on glass or exposed to air, as has been reported for cellulose acetate membranes by Sourirajan (13) and Keilin (14). Furthermore, membranes are known to be sensitive to surface contamination; therefore a membrane might behave in different ways when clean or when fouled during manufacture or handling. A further possibility with membranes made by introducing ionogenic groups into preformed hydrophobic plastic sheets is a chemical difference across the thickness of the sheet, if the reaction is not carried to completion (for example, to prevent the membrane becoming too brittle). The polarizing character of a membrane might be affected by such structural factors.

However, these expectations were not borne out by experiment, despite the fact that some of the membranes presented, surprisingly, a hydrophobic exterior, for neither abrasion of the surface with glass-paper nor creation of fresh surfaces by scraping with a scalpel changed the polarizing character.

Effect of hair-line cracks.—It was noticed that certain brittle membranes (containing reinforcing meshes), when subjected to gentle bending, developed microscopic cracks on the convex faces. These were practically invisible to the naked eye, but could be seen clearly under the microscope if the specimen was stained with a dye that did not diffuse into the resin matrix, for example, "Chlorazol Sky Blue" (I.C.I. Ltd.) for anion-exchange membranes. The cracks were seen to penetrate only as far as the reinforcement, the concave side being free from cracks.

A remarkable observation was made on the polarizing properties of these membranes, namely, that when a noncracked membrane or a cracked membrane with the cracked side uppermost (*i.e.*, facing the concentrate) was subjected to current, it polarized strongly. Correspondingly, in the schlieren cell violent convection was observed prior to boiling of the diluate. On the other hand, when the very same cracked specimens were tested with the cracks facing the diluate, nonpolarizing characteristics were observed; for example, a current of 66 ma/cm^2 could be passed for 30 min without marked heating or variation of voltage with time once the steady state had been reached. This behavior was reproducible with anion-exchange membranes made by different companies (*viz.*, Selemion AMG, ASG and AST: TOSO A; Ionics 111BZL).

The change from polarizing to nonpolarizing response could not be brought about by abrading the surface, by forming a fresh surface by means of a scalpel, by cutting vertical lines in the surface with a razor blade, or by applying wetting agents (anionic, cationic, or non-ionic) to generally hydrophobic membranes. A possible explanation of these phenomena is proposed later.

"Poisoning" by colloids.—"Orange G," an anionic dye of small molecular size, diffused into nonpolarizing membranes and had a small effect. But "Chlorazal Sky Blue," a larger dye that did not diffuse in, was found to restore the polarizing character of a deliberately microcracked brittle membrane. Apparently, the freshly formed surfaces within the microcracks were blocked as transport paths because of sorption of the dye. Similarly, treatment of inherently nonpolarizing membranes with an alkaline solution of an anionic polyelectrolyte (a high mol. wt vinyl acetate—maleic anhydride copolymer flocculant) converted them into polarizing membranes. As such polyelectrolytes certainly cannot penetrate into ion-exchange resins, their effects are confined to exposed functional groups. Not only are such groups eliminated as anion-exchangers, but the surface layer may be converted into a thin cation-exchanger which acts as a Donnan barrier to anions.

Discussion

The main facts requiring explanation are as follows: (*A*) Certain commercial anion-exchange membranes were found capable of carrying large currents (in the experimental set-up described) largely by means of OH^- ions, while others were not; (*B*) None of the cation-exchange membranes tested was found able to sustain substantial currents under comparable conditions.

These observations appear surprising only when considered in conjunction with the fact that all the membranes possessed high permselectivity and low resistivity in electrolyte solutions; therefore the development of concentration polarization should follow the same path, in all cases, as indicated by Sand's theory, as, indeed, it does, so far as transport of Cl^- or Na^+ ions is concerned. The auxiliary experiments reported show that the anomalies do not arise from differences of co-ion transport, leakage, or electroosmotic streaming. Furthermore, they appear to be confined to virtually salt-free membranes.

The only hypothesis that has been found to fit all the facts is the admittedly tentative suggestion that all the cation-exchanger membranes tested are relatively poor conductors of H^+ ions, that all the nonpolarizing anion-exchangers are good conductors of OH^-, and the polarizing anion-exchangers are relatively poor. As H^+ and OH^- are normally the most mobile cation and anion, respectively, this hypothesis seems, at first sight, improbable, but there is some evidence (discussed below) in favor of the idea. Furthermore, although the curves in Fig. 4A and 4B appear strikingly different, a quite small change of conditions (*e.g.*, the introduction of microcracks) sufficed to cause a switch from one class to another, and it is therefore likely that a delicate dynamic balance exists (under the test conditions) which requires only small differences of transport to upset it. Schlieren observations showed considerable convection in all the tests at high current density, and disturbances would presumably vary with transport rate.

It is generally accepted that the reason for the high mobility of H^+ and OH^- ions is their special transport mechanisms, the Grotthus chain, by which a charge is passed along a chain of hydrogen-bonded water molecules without actual migration of atoms. Now it has been found [Block (15)] by microscopic staining methods that all commercial membranes are highly heterogeneous and many are patchy and even partially hydrophobic. The manufacture of certain membranes by incomplete chemical attack on both sides of a sheet of polymer already introduces the probability of a greater concentration of exchange sites near the surfaces than at the center, where hydrophobic barriers might be present. Indeed, recent diffusion experiments have suggested the existence of such barriers [Crabtree and Glueckauf (16)]. Furthermore, the plastic sheets from which membranes of this type are made almost certainly contain amorphous and crystalline regions which would exhibit differential resistance to penetration of reagents. Therefore it seems very likely that the Grotthus chains are interrupted, more or less frequently, by hydrophobic barriers, through which ions have to migrate by a jump mechanism. Thus the advantage normally held by H^+ and OH^- would be reduced and might conceivably be reversed if these jumps required dehydration of the ions.

This theory cannot apply to truly homogeneous resins, and, indeed, conductance measurements on phenolsulfonic acid condensation resins show that H^+ retains its usual high mobility in highly swollen resins [Jakubovic, Hills and Kitchener (17)]. None of the commercial membranes available for test was homogeneous. However, Gregor and Peterson (18) have recently reported unique results obtained with a commercially obsolete membrane ("Nalfilm I", Nalco Chemical Company, Chicago). This membrane showed a transport number for H^+ ions above the initial current density of 0.4-0.7. The membrane is believed to have been of the polymer mixture type which are cast from a solution in dimethylformamide or dimethyl sulfoxide [Gregor (19)]; evaporation of solvent leaves the polyelectrolyte (polystyrenesulfonic acid) entangled with a water-insoluble plastic. These membranes were thin (96μ) and of low permeability, but it seems possible that continuous conduction paths for the Grotthus mechanism would be present.

Accurate conductance data for the various commercial membranes in counter-ion forms including H^+ (or OH^-), in absence of internal salt, would provide a check of the hypothesis that heterogeneity handicaps the ions of water by breaking Grotthus chain conduction paths; but unfortunately no suitable data are available at present. (Although the experiments reported here were in 0.01*N* NaCl, the membrane must presumably be virtually salt-free after a very short time.)

The influence of microcracks on the diluate side might also fit into the same model, as follows.

Application of Sand's equation for the concentration of electrolyte in the plane of electrolyte just above the membrane, namely, $c = c_o + 2F\sqrt{t/\pi D}$, shows an increase in salt concentration from 0.01 to 0.6*N* in 10 sec and 1.5*N* after 1 min at the current density of 66 ma/cm^2 generally used. The concentration of sodium hydroxide would be somewhat smaller, and would apply after exhaustion of the diluate layer adjacent to the membrane. Glueckauf and Watts (20) have shown that when an ACI A membrane sample was transferred from 0.01*N* sodium chloride to 0.4*N*, the equilibrium concentration of electrolyte within the membrane increased 160-fold and in the case of 1.0*N* solution increased 600-fold. It is therefore probable that the upper part of a polarized membrane has lost its permselectivity and that the critical zone is that part of the membrane adjacent to the diluate.

Therefore, if hydrophobic barriers are the limiting factor, microcracks through these barriers may be sufficient to maintain the current. When, however, such paths are poisoned, the membrane as a whole reverts to polarizing type.

Acknowledgments

This work was carried out in the Department of Mining and Mineral Technology, Imperial College, London, by kind permission of Professor M. G. Fleming. The authors thank G. and J. Weir Ltd., for a research studentship awarded to M.B. They are grateful to Professor R. S. Silver, Professor G. J. Hills, and Dr. H. C. Simpson for helpful discussions. They are also indebted to the many firms who freely supplied samples of membranes for examination.

Technical Notes

A Dynamic Method of Determining the Internal Resistance of Fuel Cells and Batteries

L. Reid, D. Cole, and I. Trachtenberg

Texas Instruments Incorporated, Dallas, Texas

Current interruption techniques (1, 2) have been used successfully to study fuel cells and batteries. One important parameter which can be measured by these techniques while the cell is on open circuit or under a steady d-c drain is the internal resistance. These interruption techniques permit use of reference electrodes without requiring a cumbersome Luggin capillary. However, all of these techniques are limited by the time required to interrupt the current and measure the voltage change. Errors as large as several tenths of a volt can occur if polarizations, other than ohmic polarization, have relatively short time constants compared with the time required for the measurement.

The previously reported single current interruption technique (1) utilized a mechanical relay which depended on mercury wetted contacts to give reproducible opening and closing without appreciable relay chatter. The make-before-break condition of this relay introduces an error in determining the exact current and voltage immediately prior to interruption. Also, some difficulty is always encountered in adjusting the oscilloscope delay circuits because of slight variations in the make-before-break time of the relay. One usually looks at only the voltage change at the break time on the shortest possible time scale. With the single current interruption methods, time scales shorter than 1 μsec/cm on an oscilloscope could not be used. Most internal resistance measurements with this technique can be made within 2-5 μsec after current interruption.

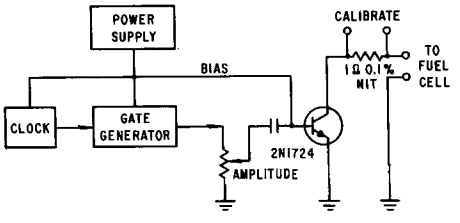

Fig. 1. Block diagram of circuit used for current interruption studies.

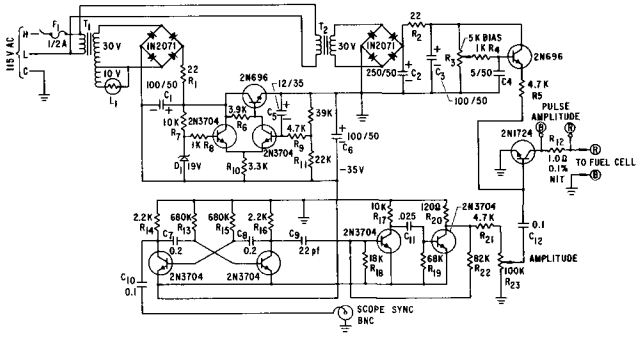

Fig. 2. Schematic diagram of circuit used for current interruption studies.

The method described here employs an electronic switch to interrupt a constant current which is imposed on the cell in its steady-state condition (open circuit or a steady d-c drain).

A block diagram of the circuit is shown in Fig. 1, and a detailed circuit diagram is given in Fig. 2. The power source is 115-v 60-cycle, and the only auxiliary piece of equipment is a fast rise oscilloscope such as the Tektronix 545B with a type W high gain differential plug-in preamplifier. This system has a rise time of 44 nsec on the most sensitive ranges. The clock circuit generates a 250 cps square wave pulse approximately 100 μsec long with a rise and fall time of less than 0.1 μsec. It also provides a trigger signal for the oscilloscope which allows the operator to view the leading edge of the pulse. By proper synchronization a fixed display on the scope is achieved. The clock frequency and pulse duration were arbitrarily chosen. No provisions were made in this design to vary these parameters; however, with suitable circuit modifications, they could be made variable without affecting the system performance.

The gate circuit amplifies and shapes the pulse, which is then coupled through an amplitude control potentiometer to the base of a passing transistor. This transistor is a high-frequency silicon power device in series with the fuel cell or battery. The electrochemical cell provides the collector voltage to the transistor. Bias is adjusted so some known direct current will flow. The magnitude of this current is determined by measuring the voltage drop across the 1-ohm precision resistor at the "calibrate" terminals.

Current levels as low as a few milliamperes and as high as several hundred milliamperes have been used with equally good results.

If polarizing the electrochemical cell to a greater extent by drawing larger currents is desired, a parallel external load may be connected. This allows a static load of any reasonable magnitude to be drawn from the electrochemical cell while only a hundred milliamperes or so is interrupted.

When the amount of d.c. flowing is set with the bias control, the oscilloscope is connected directly to the electrochemical cell terminals; and the pulse ampli-

Table I. Comparison of battery resistance measurement techniques

Battery	Current interruptor technique		A-C bridge technique
	Resistance in ohms	Current in ma	Resistance in ohms
No. 6 cell	0.030	80	0.026
	0.031	200	
	0.031	400	
D cell	0.18	80	0.20
	0.19	200	

tude is adjusted so during the 100-μsec pulse the passing transistor is driven to cut off. This interrupts current flow. By measuring the amplitude of this pulse at the "turn-off" time one can calculate the cell's internal resistance.

Corrections need not be made for lead resistance with this technique, an advantage not offered by the a-c bridge technique.

Table I lists typical examples of resistance measurements of Leclanché cells made by current interruptions and with a General Radio Type No. 1650-A Impedance Bridge. The test data in Table I were taken on used batteries.

Figure 3 illustrates a typical oscilloscope trace for a "D" size Leclanché cell. Preinterruption current was 80 ma, and the voltage change after 1 μsec was 15 mv.

This method has been applied to fuel cells containing a slurried molten carbonate electrolyte. One apparently typical group of five such fuel cells, in which the geometric areas of the anodes and cathodes were 8 in.^{2}, had minimum resistances of 0.012-0.014 ohm. The resistances of these cells varied between 0.012 and 0.025 ohm during operation.

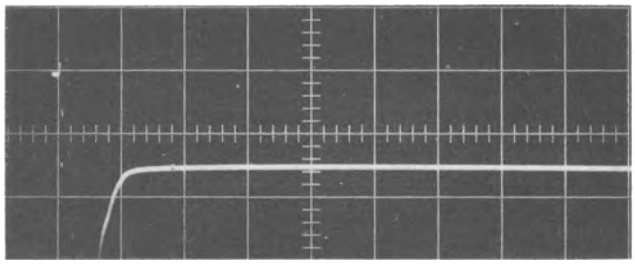

Fig. 3. Typical oscilloscope trace for "D" size Leclanché cell. Preinterruption current 80 ma; horizontal scale 1 x 10^{-6} sec/division; vertical scale 10 mv/division.

Preparation of Homogeneous HgTe-ZnTe Alloys

E. Cruceanu and N. Nistor

The Institute of Physics, the Academy of the Socialist Republic of Romania, Bucharest, Romania

In view of the interesting properties of the mixed crystals of the $Cd_xHg_{1-x}Te$ system, and especially the extremely high mobility of the electrons observed in compositions with $x \approx 0.2$ (1, 2), particular attention has been focused on this system.

Although a number of similarities exist between the CdTe-HgTe and ZnTe-HgTe systems, the latter has been studied to a lesser extent. This may be due partly to the difficulties encountered in obtaining certain compact and homogeneous alloys suitable for electrical work. These difficulties are linked not only to the comparatively high temperatures of the liquidus curve of the system, but especially to the accentuated structural differences that exist between the substituting atoms (Hg-Zn), which lead to long homogenization periods and a marked tendency to the appearance of pseudo-eutectic structures.

The possibility of obtaining solid solutions in the whole range of HgTe-ZnTe compositions was demonstrated by Woolley and Ray (3), who also established the solidus curve of the system by the x-ray method. The liquidus curve of the system has recently been determined (4) by normal cooling-curve technique, checking at the same time the solidus temperatures of several of the compositions. The electrical properties of the system have been studied up to the present only for the compositions close to HgTe (5); variations in the optical energy gap with composition have been discussed in ref. (6) for thin layers.

Here the preparation of solid $Zn_xHg_{1-x}Te$ solutions, suitable for the determination of their semiconductor properties is discussed.

Preparation of solid specimens.—In the case of the two methods considered (*a*) the Bridgman-Stockbarger method, and (*b*) slow zone recrystallization, for the preparation of $Zn_xHg_{1-x}Te$ alloys, solid solutions in the form of powders, obtained in separate experiments after very prolonged heat-treatment of the appropriate amounts of HgTe and ZnTe (3), were used.

The Bridgman-Stockbarger method.—The vertical Bridgman-Stockbarger method can be successfully employed for the preparation of compact, monocrystalline alloy ingots, with $X \leq 0.12$, provided the rate of movement of the quartz ampoules is lower than 2 mm/hr and a small temperature gradient (5°-7°C/cm) is used. In order to obtain better homogeneity, the ingots are further annealed (400-500 hr) at temperatures immediately below the relevant solidus temperature and then studied from the microstructural and x-ray viewpoints. The ingots obtained were single phase along their whole length, and the high-angle x-ray reflections were clear-cut and intense, testifying to good equilibrium conditions.

All the samples for electrical determinations, cut perpendicular to the displacement direction of the ampoules, showed a p-type conductivity, without any special heat-treatment, with carrier concentrations at 77°K (ranging in terms of the composition) of from 6.10^{18}/cm^3 for $x = 0$ to $4.4 \cdot 10^{18}$ for $x = 0.08$. The fact that, after annealing in Hg vapor at temperatures close to 200°C, the concentration of acceptors falls to 8.10^{16} cm^{-3} would suggest that the nature of the acceptors is linked to the presence of mercury vacancies in the crystalline lattice of the alloys.

With increase in ZnTe concentrations, *i.e.*, $x > 0.12$, it is difficult to obtain solid solutions by the Bridgman-Stockbarger method, because of the high working temperatures and long periods in which the quartz ampoules must be kept at these temperatures.

Slow zone recrystallization has proved, in this instance, a good method. Quartz ampoules (140-160 mm long) were used in a set-up that permits slow movement of the ampoule along the three temperature zones used. The material was melted with high-frequency currents, inducing the necessary temperatures in graphite cylinders containing the quartz ampoules. The zonal temperature was determined with an optical pyrometer and its value fixed according to the liquidus curve established in (4) and shown in Fig. 1.

Temperature values in the two lateral background temperature zones were chosen in separate experiments carried out for the determination of the vapor pressure of solid solutions at various temperatures and were fixed at 500°C for $x = 0.6$ and 550°C for $x = 0.3$.

The velocity of the ampoule along the fixed zone was approximately 1.5 mm/hr, and the length of the molten zone was maintained between 10 and 20 mm.

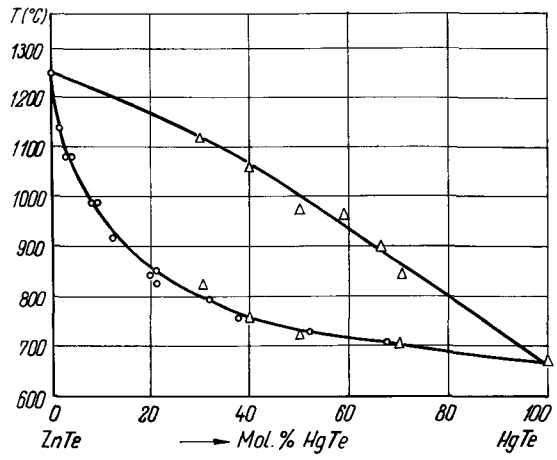

Fig. 1. Phase diagram of HgTe-ZnTe system. Liquidus curve, △-Cruceanu *et al.* (4); solidus curve, ○-Woolley and Ray (3).

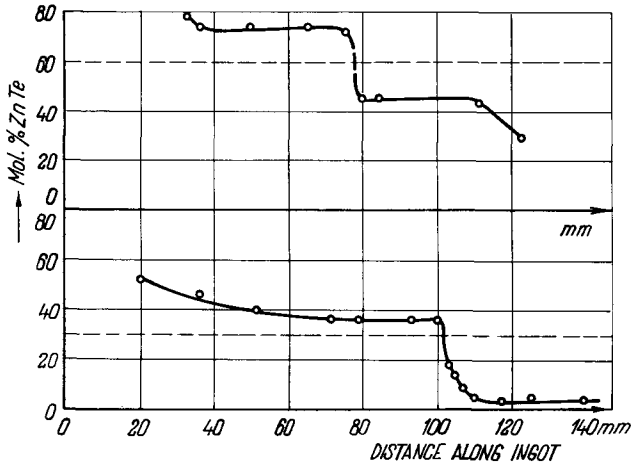

Fig. 2. Variation of composition of cross-sectional slice as a function of position in zone recrystallized ingots.

Two initial compositions were used, one with a higher molar HgTe ($Zn_{0.3}Hg_{0.7}Te$) composition, and the other with a higher molar ZnTe ($Zn_{0.6}Hg_{0.4}Te$) composition. In order to obtain better homogeneity, after moving the zone along their whole length, the ingots were annealed for approximately 300 hr at 650°C. The microstructural and x-ray analysis showed the ingots to be single phase in the center, over a length of 12-14 cm, the composition varying along the ingot according to the curves plotted in Fig. 2 [the composition was determined by the x-ray powder method in a ϕ 114 mm camera, using the data on the variation of the lattice constant with composition, obtained in (3) (4)].

It is of interest to note that although the aspect of the curves in Fig. 2 is, in general, similar to that of the InSb-InAs system curves (7), our results differ from those of Woolley and Warner in that we found one phase in the center of the ingot whereas they found the ingot to be homogeneous at the two ends. Moreover, our metallographic studies have demonstrated the existence of two phases at the ends of the ingot, over a distance of 1-2 cm, with a pseudo-eutectic structure, yielding either broader x-ray lines or two completely separate systems of lines. Hence, the composition could not be determined accurately, and in Fig. 2 the data for the ends of the ingot have been omitted.

Although the results on the electrical properties of alloys will be published elsewhere, we deem it of use to indicate that the solid solutions obtained by this method (with $0.35 \leq x \leq 0.74$) are all p-type and have extrinsic carrier concentrations of approximately 2.10^{16} cm^{-3} (at 77°K).

To conclude, zone recrystallization may be considered one of the most useful methods for obtaining massive and homogeneous HgTe-ZnTe alloys, with practically any composition, and will probably play an important role in the development of further studies on this system.

Temporary Protection of Silicon Surfaces by Iodine Films

R. Lieberman and D. L. Klein

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Silicon surfaces are normally covered with mixtures of oxide, hydroxide, and fluoride groups subsequent to chemical etching. This coverage results from the necessity of terminating the free or dangling bonds that are generated on new silicon surfaces. These terminations are responsible for the hydrophobic character observed on freshly etched silicon.

In an effort to eliminate this surface activity a barrier technique involving the formation of iodine films has been developed. The function of the iodine is to prevent formation of oxides and to displace fluoride and hydroxide terminations normally found on etched silicon. Atomically clean silicon surfaces can then be generated by removing these iodine films by sublimation.

Procedure

The procedure consists of quenching a freshly etched silicon surface in a saturated or concentrated solution of iodine in an anhydrous solvent. This quenching must immediately (~1-2 sec) follow the removal of the slice from the etchant. The anhydrous property of the solvent serves to prevent hydrolysis of the Si-I bonds formed during quenching. Several

solvents suitable for the iodine are chloroform, carbon tetrachloride, and methanol. After removing a silicon slice from the iodine solution, a gross iodine film can be observed on the surface for approximately 5 to 10 min in room ambient. A more tightly bound chemisorbed iodine layer is present on the surface and can be effectively removed by thermal treatment. In practice temperatures of about 500°-550°C have been employed to remove the chemisorbed iodine *in vacua* (*e.g.*, $\leq 10^{-6}$ Torr), or at atmospheric pressure in inert ambients. The removal of the iodine is accomplished in several minutes under these conditions.

Until the gross iodine film is removed by sublimation it is important to limit the temperature of treated surfaces to < 600°C. Otherwise, direct reaction of the silicon and iodine can occur and result in surface etching via the formation of SiI_4.

When slices must be stored subsequent to the iodine quench they can be left immersed in the iodine solution. Samples have been stored in this manner for extended periods (up to 72 hr) without loss of surface protection.

Discussion

The iodine treatment was found to produce atomically clean and well ordered silicon (111) surfaces as determined by low-energy electron diffraction studies.[1] The diffraction patterns were observed after removal of the iodine by heating the samples at pressures of $\sim 10^{-9}$ Torr. Results of the diffraction measurements indicate that the coverage of adsorbates (*e.g.*, oxygen) was less than a small fraction of a monolayer. The success of this technique may be due to several factors. These include the displacement reaction of fluorinated silicon surfaces directly with iodine as well as the physical adsorption of iodine on silicon surfaces.

The displacement of the fluorinated silicon surface probably results from the reaction of the iodine with the fluorine bonded to the silicon to form an interhalogen compound.[2] This type of reaction could account for the effective removal of fluorine from silicon surfaces. Hydroxyl groups can also be displaced, in this case, through the formation of HOI.

The physical adsorption of iodine on a freshly etched silicon surface results in the formation of a temporary barrier to other reactions.

Stronger van der Waals forces should exist between iodine and the silicon surface than between either fluorine or oxygen and the surface. The chemical formation, therefore, of Si-F and Si-O bonds will be inhibited since these reactions depend on preliminary physical adsorption of the reactants. The combination of a relatively large covalent radius (1.33Å), solubility in nonaqueous solvents and sublimation properties serve to make iodine an ideal material for a temporary barrier film.

The model that has been used to explain the effectiveness of the iodine treatment is a simplified description. A more detailed study of the interaction of silicon and iodine by means of low-energy electron diffraction has been reported by Lander and Morrison (1).

Applications

Oxide film prevention.—This process has been utilized to eliminate interfering surface oxides during closed vacuum system diffusion of arsenic into silicon. Oxide-free silicon surfaces are necessary for this type of diffusion in order that uniform junctions can be formed. Photomicrographs (Fig. 1) of angle lapped

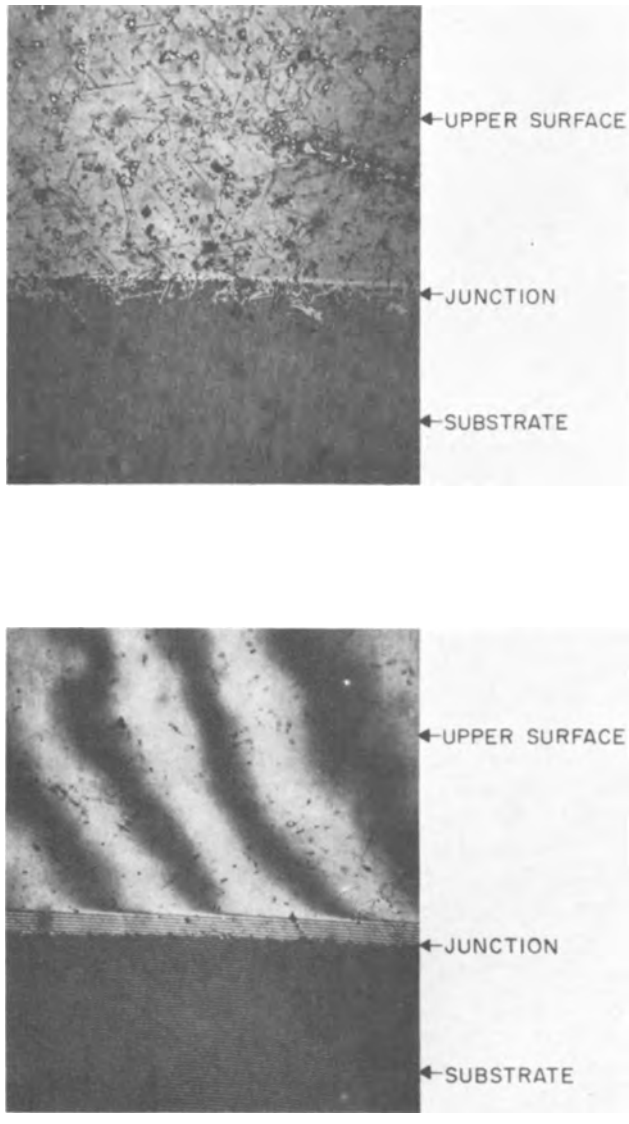

Fig. 1. Effect of I_2 quench on junction formation; double furnace diffusions, As at 600°C, Si at 1050°C. Top, without I_2 quench; bottom with I_2 quench. Angle lapped surfaces, 2° bevel. Magnification approximately 160X.

samples, with and without the use of the I_2-methanol quench, have demonstrated a marked difference in junction uniformity. The elimination of oxide on the iodine treated silicon surface prior to diffusion probably accounts for the improvement in the quality of the junction.

Control of defects in passivating films.—Normally, silicon surfaces etched in the presence of HF are initially hydrophobic. Silicon surfaces following iodine quenching and subsequent iodine removal are hydrophilic in character. The hydrophilic nature of the iodine quenched surface appears to influence the uniformity of surface oxide formation. Marked decreases of oxide defects, such as pinholes, have been demonstrated in oxide films formed by steam (1050°C, 1 atm) oxidation of silicon. Examinations of oxides on silicon surfaces subjected to the I_2-methanol quench have shown a significant decrease in the number of pinholes. These pinholes were exposed by a discriminatory water-amine-pyrocatechol etch.[2] Pinhole counts of steam oxidized (1 hr, 1 atm, 1050°C) silicon samples which were pretreated with I_2 quenches exhibited 230 pinholes/cm^2. The defect density of control samples prepared by quenching in water was found to be 900 pinholes/cm^2.

[1] The electron diffraction studies were performed by E. G. McRae and J. Morrison of these Laboratories who observed 7th order patterns.

[2] It is recognized that the Si-I bond energy (51 kcal) is considerably less than the energy of the Si-F bond (143 kcal). However, the displacement of the fluorine can probably be explained on the basis of mass action. The availability of large quantities of iodine in solution and the coordination of any labile fluorine entering the iodine solution could be expected to result in a high probability of fluorine replacement.

Influence on semiconductor junctions.—In order to investigate the possibility of deleterious effects caused by I_2-solvent quenches on devices, leakage currents of silicon detector diodes were measured following such treatment. These n-p diodes are large area, 10,000 ohm-cm resistivity mesa devices and as such are very sensitive to surface effects. Leakage currents of these diodes given either an I_2-methanol or an I_2-carbon tetrachloride quench following a 5-sec HNO_3-HF (40-1) etch displayed no degradation. Results after 10-min cycling in dry O_2 and wet N_2 did not differ from those obtained on control diodes. This would indicate that the iodine surface treatment did not degrade the electrical characteristics of these sensitive junctions.

Conclusions

The technique of I_2-nonaqueous solvent quenching has been investigated, and preliminary experiments indicate that it will temporarily prevent oxide, hydroxide, and fluoride formation normally experienced in silicon technology. This has been demonstrated by low-energy electron diffraction studies and by the application of the technique to several device processing procedures. Since the iodine films are readily removed, the procedure serves as a simple means of preparing atomically clean surfaces just prior to device processing.

Acknowledgment

Enhanced GaAs Etch Rates Near the Edges of a Protective Mask

Don W. Shaw

Materials Science Research Laboratory, Texas Instruments Incorporated, Dallas, Texas

It has been observed in the author's laboratory that holes etched into gallium arsenide through windows in a protective silica etch mask are deeper near the edges of the mask than at the center of the hole. This phenomenon is illustrated by the angle-lapped section shown in Fig. 1. It is obvious from the morphology of the hole bottoms that the etch rate was greater near the mask edges than at the centers of the holes. This "edge effect" presents a severe problem to the fabrication of device structures by selective etch and deposition techniques.

The edge effect occurs when GaAs holes are etched with such etchants as bromine-methanol (1:1000), hydrogen peroxide-sulfuric acid-water (1:5:1), and 3% sodium hypochlorite solutions. It is also observed to a lesser degree with holes formed by HCl vapor etching at temperatures up to 800°C. The magnitude of the effect tends to decrease as the hole depths increase, *i.e.*, the deeper holes have flatter bottoms. The phenomenon is independent of the window dimensions with the exception that with very small windows the regions of enhanced etch rate near opposite walls may overlap.

The enhanced etch rates near the mask edges could be due either to localized stresses occurring at the mask-GaAs interface or to surface diffusion of adsorbed molecules along the protective mask which effectively results in a greater flux of etchant at the mask edges. As will be shown below, the experimental results provide strong support for the surface diffusion explanation.

Fig. 1. Micrograph showing 5° angle-lapped section through holes etched into GaAs with an unstirred bromine-methanol (1:1000) solution.

Stresses present at the mask-GaAs interface could be related to the differences in thermal coefficients of expansion between the silica film and GaAs. They would be imposed when the silica-coated GaAs crystal is cooled from the 450°C silica deposition temperature (oxidative tetraethyl orthosilicate process) to room temperature. To investigate further the effect of stress at the mask-GaAs interface, a polymerized KMER (Kodak Metal-Etch Resist) etch mask was employed. This mask was applied to the GaAs crystal at room temperature, but in this case also the edge effect was still present at the etched holes. Later a silica etch mask obtained by a room temperature, tetraethyl orthosilicate, glow discharge process was employed. Since the holes were then etched at room temperature, the effects of stress at the mask-GaAs interface should be minimized. However the etch rates were still greater near the mask edges than toward the center of the hole.

When a masked GaAs slice is placed in contact with the etchant, the etchant molecules are striking the protective mask as well as the GaAs exposed at the windows. Some of the molecules which strike the protective film are adsorbed and migrate across the surface for some distance before desorbing. A portion of these molecules will diffuse to the exposed GaAs and may react causing dissolution. Thus the exposed GaAs near the mask edge is receiving etchant molecules from surface diffusion as well as by "direct" diffusion. If the etch rate were limited by diffusion of etchant molecules to the reaction surface, then the above-mentioned process would result in an enhanced initial etch rate near the mask edge as compared with the etch rate near the center of the hole. This explanation is supported by the shapes of the hole bottoms shown in the angle-lapped section of Fig. 1. The holes on either side of the array have unsymmetrical edge effects, *i.e.*, the etch depth is greater near the edge having the largest adjacent area of protective mask. Since these edges have greater adjacent mask areas, they receive more etchant molecules from sur-

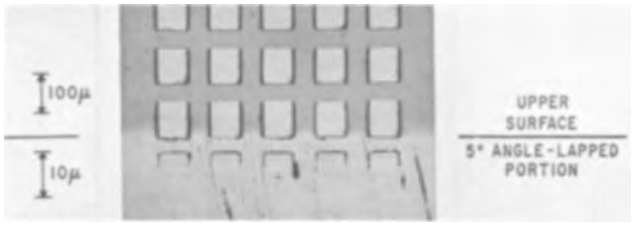

Fig. 2. Micrograph showing 5° angle-lapped section through holes etched into GaAs with a 0.7M H_2O_2-1M NaOH solution.

face diffusion. The three inner holes exhibit equal and symmetrical edge effects because they have equal adjacent mask areas. The exposed regions near the corners of the windows have the greatest adjacent mask areas and would be expected to exhibit the greatest edge effect. This is confirmed experimentally by observation of the hole bottom contours with an interferometer. It should be noted that the greatest contribution of etchant molecules due to surface diffusion would be realized at the initial stages of etching. This is in agreement with the experimental observation that the magnitude of the edge effect decreases with increasing hole depth.

It has been found that the etch rate of GaAs with a 0.7M hydrogen peroxide-1M sodium hydroxide solution is limited by the rate of chemical reaction rather than by the diffusion rate (1). If surface diffusion of adsorbed molecules along the protective mask is responsible for the enhanced GaAs etch rates near the mask edge, then the effect should be eliminated by etching with the above mentioned H_2O_2-NaOH solution. Figure 2 shows an angle-lapped section through GaAs holes formed by etching with this solution. The holes have flat bottoms, and no evidence of an enhanced etch rate near the mask edge is noted. These results provide strong support for the explanation of the edge effect based on surface diffusion of etchant molecules adsorbed on the protective mask.

Brief Communications

The Effect of Concentration on the Interdiffusion Coefficient of Chromium in Chromium-Iron Alloys

G. A. Davies, A. B. Ponter, G. C. Wood, and D. Whittle

The University of Manchester Institute of Science and Technology, Manchester, England

An investigation into the mechanism of oxide formation of chromium-iron alloys for a temperature range 800°-1200°C has resulted in determinations of the interdiffusion coefficients of chromium. The concentration profiles of chromium in the alloy were measured using an electron probe microanalyzer and metallographic techniques. The results which are presented in Fig. 1 exhibit a minimum value of diffusivity at 60% chromium concentration for a temperature of 1000°C. The values of Gorbunov *et al.* (1) for chromium concentrations of 84.5% and 29.4% Cr at 1000°C agree well with these data. Krwoglaz and Smernov (2) have indicated that the phenomenon of exhibiting minimum values is not common, but has been observed for diffusion in β-brass. Some anomalous predictions of chromium-iron behavior in their alloys may be attributed to the use of average values of interdiffusional coefficients over the range where a minimum exists. Here it is particularly important to use the discrete values reported.

Optical Phenomenon in $LiNbO_3$ Single Crystals

W. J. Croft and M. Kestigian

Sperry Rand Research Center, Sudbury, Massachusetts

Large, single crystals of $LiNbO_3$ are grown by the Czochralski technique and are oriented for physical measurements by the back-reflection Laue x-ray technique. The determination of the c-crystallographic direction presents somewhat of a problem in this rhombohedral crystal (1), as there are three pseudo-trigonal directions. It is the practice of this Laboratory to cut a slice perpendicular to the c-direction for microscopic confirmation of the axis using convergent polarized light. One crystal showed the presence of apparent oriented intergrowths with high-order interference colors (Fig. 1a), under low magnification in parallel polarized light (crossed nicols). Most of the area of the slice remains dark during rotation of the microscope stage except for the narrow bands. The bands make a triangular pattern and are perpendicular to the a-axis directions of the crystal. The dark areas of the crystal show a normal uniaxial interference figure. The bright bands in convergent polarized light show a "flash" phenomenon. A shadowy cross appears four times during complete rotation of the crystal slice. Examination of Fig. 1a and b, which are opposite sides of the same slice in parallel polarized light, show a peculiar phenomenon. On one side of the slice (Fig. 1a), the bands are sharp on the inside of the V and diffuse on the outside. On the other side of the slice (Fig. 1b), the opposite is true, and the bands are sharp on the outside of the V and diffuse on the inside.

A series of back-reflection Laue x-ray photographs were taken across one of these bands extending from one dark area to the other. All of the pictures gave the same c-axis orientation diagram.

The slices were cut from crystals which had been tightly bound with platinum wire during heat-treatment (1200°C). This phenomenon is caused by an apparent stress-induced incipient cleavage development.

From the measured thickness of the slice and the apparent width of the bands, as seen in the microscope, the plane of cleavage makes an angle of approximately 59° with the basal plane. This cleavage can be indexed to be along the {113} (hexagonal) planes.

Another phenomenon observed in Czochralski-grown $LiNbO_3$ single crystals is linear rows of fine

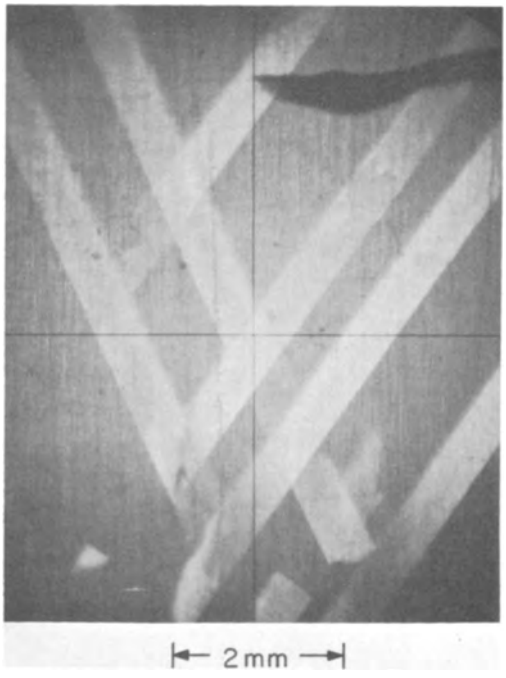

Fig. 1b. Same section viewed from the opposite surface.

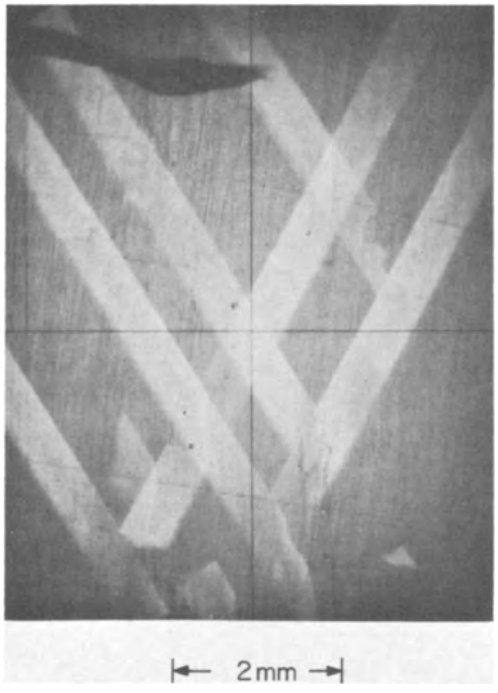

Fig. 1a. Section of $LiNbO_3$ crystal cut perpendicular to c axis and viewed in parallel polarized light.

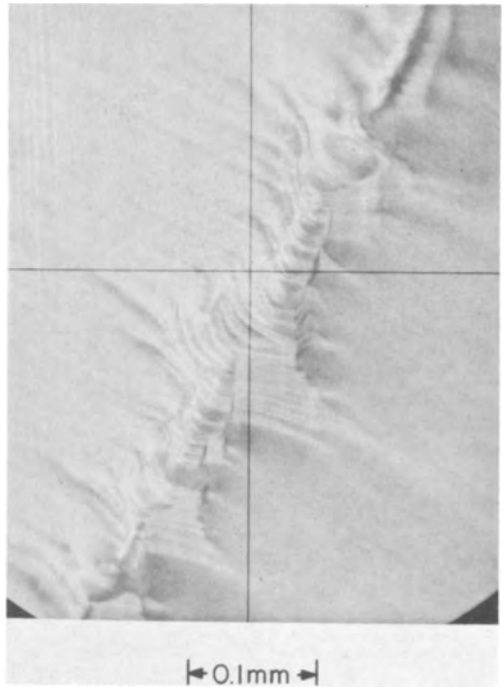

Fig. 2. $LiNbO_3$ single crystal boule showing row of growth notches

chips parallel to the growth direction of the boules (Fig. 2). These rows, to a degree, reflect the symmetry of the boule. When the growth axis is in a [0.001] direction, there are three equally spaced rows aligned with the lines joining the points at which the a axis intersects the surface of the crystal. In the case of a-axis grown crystals, there are usually four rows in sets of two and the boule forms in an orthogonal section rather than the round or trigonal section of c-axis crystals. Under the microscope these chips are curved rather than flat and probably represent some incipient face growth.

Manuscript received June 8, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

High-Speed Measurement of Reversible Electrode Potentials

T. Hagyard and K. M. Chapman

Department of Chemical Engineering, University of Canterbury, Christchurch, New Zealand

During measurements of the potential of aluminum electrodes in aqueous solutions (1), it was deduced that a quickly formed aluminum surface reached its equilibrium potential in microseconds and in ref. (2) anodic polarization curves were based on aluminum electrode potentials taken during the first 30μ. Using the same apparatus, it seemed desirable to determine if, indeed, a metal electrode could establish its usual equilibrium potential in so short a time. For this purpose a metal was needed in which hydrogen evolution would not occur at a perceptible rate at the equilibrium potential and whose rate of ionization was known to be fast. The work of Randles (3) indicated that the latter condition would be met by cadmium in equilibrium with the nitrate and, since cadmium also fulfills the first condition, metallic cadmium was tested.

Cadmium of analysis Zn 0.019, Pb 0.013, Cu 0.002, Fe 0.002% was used, but was too soft to be used exactly as described in ref. (2). The electrode used in the latter measurements was machined from ¼ in. diameter aluminum rod so that a thin insulated flange was formed and subsequently cut by impact of the ruby cutter, thereby exposing a new surface in about 6μ. For the present experiments it was not possible to use such an integral electrode. Instead, a thin cadmium disk was mounted on the end of a duralumin rod, the disk being backed by fused high-density polyethylene and the whole insulated with a fused layer of low-density polyethylene. Difficulty was still experienced due to deformation of the cadmium during cutting and lack of adhesion of the insulating layers. This resulted in most of the oscillograph traces showing irregularities ascribed to crack formation. Nevertheless, the more successful traces, such as that in Fig. 1, showed a rapid approach to a steady potential.

Figure 1 was obtained with cadmium in M/1000 $CaCl_2$ + M · KCl swept with purified hydrogen and shows at A the 10,000 cps time base and zero potential lines, at B the insulated electrode potential before cutting, at C the potential at the instant of cutting, and at D the very rapid rise to a more negative potential. This rise occurred in some 10μ, and thereafter the potential remained substantially constant except for the momentary deviation at E. The latter is characteristic of irregularities frequently met with in this work and is ascribed to defective adhesion of the insulation around the newly cut surface. In this figure, line F is the Weston cell potential calibration. Measurement of the potential of the electrode 10-30μ after cutting gives the value of —0.879v on the *N* calomel scale for this trace falling to —0.875v after 200μ and thereafter unchanged. Measurements on nine similar traces gave a mean value of —0.864 with standard deviation 0.062v.

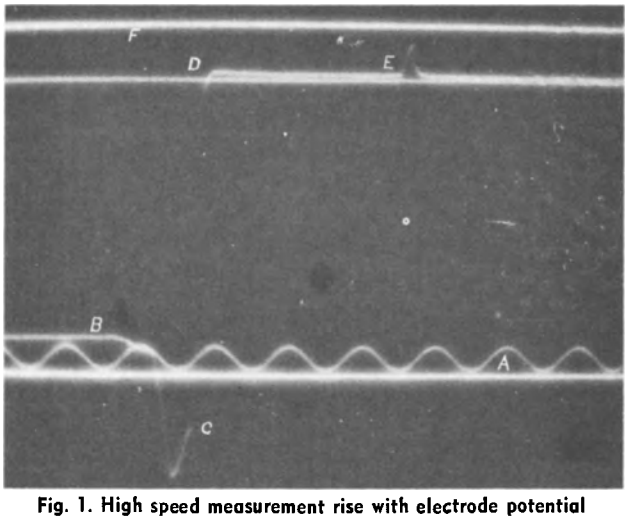

Fig. 1. High speed measurement rise with electrode potential

Static potential measurements with the same metal in massive form in the same solution swept with purified hydrogen, required about 1½ hr to reach equilibrium, presumably due to slow elimination of oxygen from the electrode surface and from the solution. Results depended somewhat on surface preparation:

Etched surface							
Time, min	20	40	60	80	95	120	140
Potential v N.C. scale	−0.817	0.842	0.854	0.852	0.864	0.865	0.865
Abraded with emery							
Time,	10	40	55	70	85	115	130
Potential	−0.843	0.849	0.850	0.850	0.851	0.850	0.851

It is considered that agreement between the 10-30μ oscillographic observations and the static observations is reasonably good.

With nitrate solutions the oscillograph traces for the fast measurements were much more irregular than for the chloride solutions, and a similar comparison with static measurements was less satisfactory possibly because of the metastability of nitrate solutions in the presence of hydrogen. Nevertheless, agreement was in general within some 20 mv [for details see Chapman (4)].

It is concluded that there is reasonable agreement between measurements of the equilibrium potentials of cadmium in chloride solutions by the present oscillographic technique and by the usual static method and that the methods used in ref. (1) and (2) are reasonable for fast electrode processes.

The Electrode Potential of Evaporated Aluminum Films in Chloride Solution

T. Hagyard, W. B. Earl,[1] K. J. Kirkpatrick, and I. G. Watson[2]

Department of Chemical Engineering, University of Canterbury, Christchurch, New Zealand

Potential measurements as negative as -1.67 E_{H_2} volts in 1*N* KCl solution pH 3.2, have been measured on a freshly cut aluminum surface by a technique devised by Hagyard and co-workers (1, 2). A polythene-coated aluminum rod immersed in 1*N* KCl solution was cut by a ruby travelling at 1000 cm/sec. Potential measurements were made using a high-impedance cathode follower coupled to an oscilloscope. From the instant the cut was made into the aluminum, its potential was recorded by photographing a single traverse of the oscilloscope trace. A typical potential measurement is shown in Fig. 1.

The initial rapid potential rise to the peak was attributed to the dissolution of aluminum charging the double layer. After reaching the peak potential, only a small fraction of the electrode surface was thought to remain actively anodic while the slower hydrogen discharge process took place over most of the metal surface. The exponential fall in potential was attributed to the polarization of the anodic and cathodic processes. The information gained using this technique enabled the kinetics for aluminum dissolution and hydrogen discharge on aluminum to be studied.

The object of the present work was to confirm the validity of the measurements made by the above technique. The possible alternative explanations of the potential behavior of freshly cut aluminum that were considered by the authors were (*a*) that instantaneous high temperatures were generated at the cut surface by the shearing action of the ruby cutter; the high temperatures would be rapidly reduced by heat dissipation into the bulk of the metal, (*b*) severe stressing and dislocation of the aluminum electrode surface followed by relaxation of the surface structure; the peak in this case would be a stress potential.

Vacuum evaporated aluminum films were used in this work to obtain an uncontaminated oxide-free aluminum surface comparable with that exposed by the previous technique. The aluminum film was formed in an evacuated, degassed, Pyrex glass bulb by evaporating 99.99% aluminum from a stranded tungsten wire that was supported on tungsten leads. The target area was a smoothly ground glass button. Electrical contact with the aluminum film was made by a tungsten wire sealed through the center of the button. Figure 2 is a sectional drawing of the bulbs used. To limit the area on which the measurements were made, the shape of the button was designed so that with straight line evaporation only the front surface of the button was coated with aluminum.

The glass bulbs were evacuated to a vacuum better than 0.1μ by a two-stage G.E.C. mercury diffusion vacuum pump with liquid nitrogen trap. The bulbs were baked under vacuum for more than 2 hr at 400°C. After baking, the aluminum was evaporated rapidly (3-5 sec) to give a thick (2-10μ) nontransparent coating of aluminum over the interior of the bulb. Holland (3) recommends rapid evaporation for high quality films. At the start of evaporation aluminum vapor was relied on to act as a getter of any residual gases. Subsequent deposits of aluminum were assumed to be uncontaminated and oxide free. At the completion of the evaporation process, the bulb was sealed off from the vacuum pump.

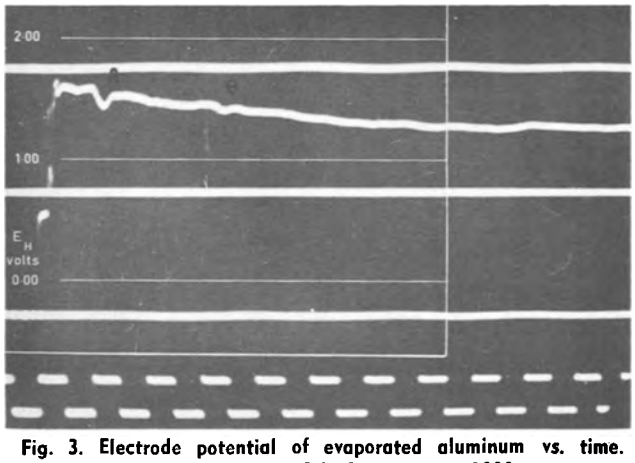

Fig. 3. Electrode potential of evaporated aluminum vs. time. Solution IN KCl + HCl to pH 3.2. Square wave 1000 cps.

Potential measurements were made in a 1*N* Analar KCl solution contained in a polythene beaker. The reference electrode was a normal calomel electrode. The electrical measuring circuit was a fast response (0.1 μsec) cathode follower, input impedance 10^7 ohms, coupled to a Cossor 1065 pulse oscilloscope. The potential of the evaporated aluminum film was measured by breaking the evacuated bulb under solution with a polythene-coated steel cutter. The cutter was driven through the bulb by a spring-loaded hammer device. A continuous photographic record of the potential change was obtained for the 10 msec following contact between the aluminum film and the KCl solution.

Figure 3 is an example of the potential-time trace obtained from evaporated films. Each trace reached a peak potential of -1.67 E_H volts then decayed in a similar but not entirely reproducible manner to the trace shown. The potential could be measured to better than ±0.05v. The authors believe that the difference in the potential decay characteristics between the two techniques is associated with the different mode of wetting the electrode surface. With the previous technique the electrode was a small v notch that was driven past the solution. The total time to cut and wet the electrode surface in this case was of the order of 10 μsec. The electrode area for the evaporated film method was approximately 1 cm^2. In this case the electrode was wet by the solution rushing into the evacuated glass bulb. It seems probable that the relatively large electrode area is wet progressively over possibly a millisecond or more. A peak potential was to be expected the instant the solution made electrical contact with the solution. Thereafter until the total electrode surface was wetted a mixed potential would result between that part of the electrode surface being wetted and that part already wet. The two jumps in potential at A and B, (shown in Fig. 3) were quite reproducible and could be associated with shock waves. A vigorous discharge of gas bubbles from the aluminum surface was observed immediately after the bulb was broken. It was strongly suspected that the gas discharged was hydrogen.

The conditions for the alternative explanation of the peak potentials obtained by the previous technique were absent from the evaporated aluminum films. When exposed to solution the films were neither at a high temperature nor in a severely stressed condition. The fact that the same peak potential has been obtained by two independent techniques is strong evidence that potential measurements by the earlier technique are valid.

Double Layer Studies

Paul Delahay

Department of Chemistry, New York University, New York, New York

ABSTRACT

This paper covers four investigations dealing with hitherto neglected or hardly studied aspects of the electrical double layer. Topics are: (*a*) specific adsorption of inorganic cations; (*b*) resolution of simultaneous anion and cation specific adsorption; (*c*) double layer in media of low electrical conductivity; (*d*) interpretation of double layer capacity measurements for electrodes with a charge transfer reaction.

Double Layer with Specific Adsorption of an Inorganic Cation

This study was made for the particular case of thallium fluoride and followed the same general approach of similar work for inorganic anions exhibiting specific adsorption. No such detailed investigation has been made before to the writer's knowledge although the possibility of rather strong specific adsorption of some inorganic cations on mercury was conclusively shown some time ago (1). Details are given elsewhere (2), and only the essential points will be mentioned.

The TlF/Hg system was selected for the following reasons: specific adsorption of Tl^+ is quite pronounced even at potentials at which there is virtually no Tl deposition; specific adsorption of F^- can reasonably be neglected; complexation in solution does not interfere.

Electrocapillary curves and differential capacity data were interpreted in three steps: (*a*) thermodynamic calculation of the charge density q on the electrode and of the relative surface excesses Γ_+ and Γ_- of Tl^+ and F^-; (*b*) application of the Gouy-Chapman theory on the assumption of no F^- specific adsorption and calculation of the amount of specifically adsorbed Tl^+ and of the potentials in the outer plane of closest approach and across the compact double layer; (*c*) examination of isotherms.

Both Γ_+ and Γ_- were positive over the range af q being covered (2-12 microcoulombs · cm^{-2}) and varied linearly with q. Γ_+ reached up to 10 μcoul · cm^2. Such positive values of Γ_+ for markedly positive q's result from cation specific adsorption since Γ_+ for KF tends toward an asymptotic negative value (3) (little specific adsorption of K^+). The slope $-(\partial\Gamma_+/\partial q)$ at constant TlF chemical potential μ was equal to the slope of the Esin and Markov plot $(\partial E_-/\partial\mu)$ at constant q as expected.

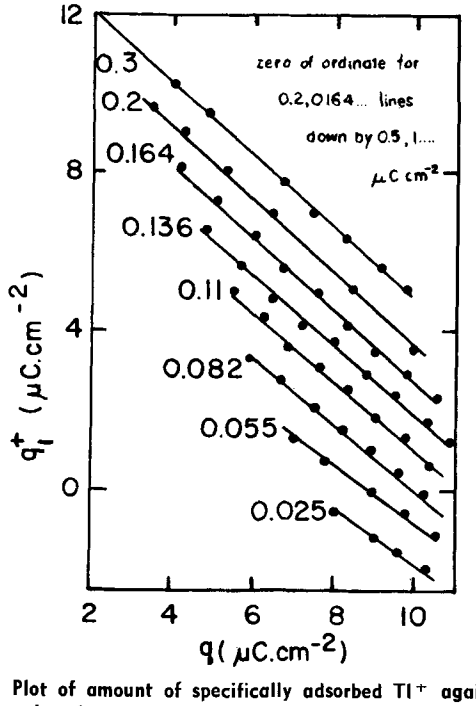

Fig. 1. Plot of amount of specifically adsorbed Tl^+ against the charge on the electrode for different concentrations of TlF (M). Vertical scale for 0.3M; all other curves equally spaced downward by 0.5 unit for 0.2M, by 1 unit for 0.164M, etc. (2).

The charge q_1^+ corresponding to specifically adsorbed Tl^+ was computed from the amount of Tl^+ in the diffuse double layer according to Grahame's method (3). The bulk dielectric constant was used for the diffuse double layer (not a source of serious error). Plots of q_1^+ against q are essentially linear (Fig. 1) much as for I^- specific adsorption (4). Note, however, that the highest q_1^+ (=12.3 μcoul · cm^{-2}) for Tl^+ was lower than $q_1^- \approx 40$ μcoul · cm^{-2} for I^-. Deposition of Tl prevented exploration at more negative q's where specific adsorption is enhanced.

The computation of q_1^+ involved as an intermediate step the calculation of the potential ϕ_2 in the outer plane of closest approach (from Γ_- and the Gouy-Chapman theory). The resulting ϕ_2's were all positive, and their dependence on E appeared quite normal. The difference of potential $\phi_M - \phi_2$ across the compact double layer could now be computed at constant charge in the scale of rational potentials. $\phi_M - \phi_2$ was then divided into two parts (5), $q_1^+/K_a + q/K_b$ where the K's are integral capacities. Thus $K_a \approx 16$ to 17 and $K_b \approx 32$ to 34 μf/cm^2. These values are about one-half those for (4, 5) Cl^- and I^-. It is believed that the formal division of $\phi_M - \phi_2$ into these two components, according to electrostatics, is open to question in this particular case. Using K_a and K_b for what they are worth one finds $(x_2 - x_1)/x_2 = K_b/K_a \approx 0.5$ to 0.6, where x_1 and x_2 are the distances of the inner and outer plane, respectively, to the electrode. Since this ratio equals 0.4 for I^- and 0.2 for Cl^- it would seem that Tl^+ approaches the electrode more closely than I^- and certainly more than Cl^-.

The last step in the interpretation dealt with the isotherm for Tl^+. If one assumes that this isotherm is of the form $f(q_1^+) = \beta a_+$ where a_+ is the activity of Tl^+ and β is solely a function of the charge on the electrode one can deduce the dependence of β on q. [See Parsons (6) for an approximate treatment and Parry and Parsons (7) for a more rigorous approach.] The corresponding plot of log β against q is linear (Fig. 2), and this seems to indicate that the standard free energy of adsorption $\overline{\Delta G}^\circ$ for Tl^+ varies linearly with q [$\beta = \exp(-\overline{\Delta G}^\circ/RT)$]. A similar dependence holds for other inorganic cations, *e.g.*, I^-. (The dependence for uncharged adsorbates is not the same and will not be discussed here.)

Among the various criteria which can be applied to isotherm assignment the one recently used by Parsons (8) was selected, namely, the plot of $(1/C) - (1/C_b)$ against log a_+ at constant q (C is the differential capacity of the compact double layer, C_b the same datum in the absence of specific adsorption; C_b can be computed from data on NaF.) This plot should

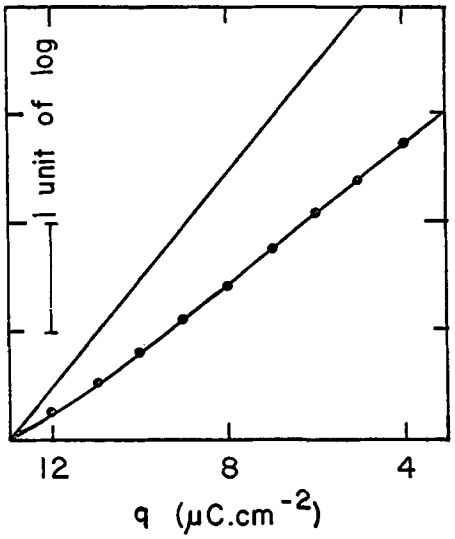

Fig. 2. Variation of the standard free energy of adsorption of Tl^+ with the charge on the electrode. Line with points corresponds to calculation with correction for diffuse double layer. Other line is without this correction (2).

be symmetrical for the Frumkin isotherm as was essentially the case. The Flory-Huggins isotherm (with a Frumkin interaction factor), also tested by Parsons (9), might provide a better approximation, but the data obtained here did not justify this approximation. The numerical value of the interaction parameter in the Frumkin isotherm ($A = 9.6$ for the isotherm written with $\log_{10}$) indicated a strong repulsion between Tl^+ ions.

The following conclusions can be drawn from this study: (*a*) Tl^+ specific adsorption can be described by the Frumkin isotherm; (*b*) the standard free energy of adsorption appears to vary linearly with the charge on the electrode; (c) Tl^+ ions approach the electrode more closely than Cl^- or I^-.

Double Layer with Simultaneous Specific Adsorption of Inorganic Anion and Cation

Analysis of simultaneous specific adsorption of anions and cations is the next logical step after the study of separate anion or cation specific adsorption. This problem has not received a detailed analysis to the writer's knowledge. Thallium nitrate was selected for this study because of available relevant information on Tl^+ (see above) and NO_3^- (10) [see also Frumkin (1)]. Complexation is minor ($pK_1 = 0.33$ for $TlNO_3$) and easily corrected for. Detailed results are available elsewhere (11), and only the essential points will be covered.

Thermodynamic analysis yielded Γ_+ and Γ_- for Tl^+ and NO_3^- and indicated the enhancement of Tl^+ adsorption by NO_3^- specific adsorption. This effect is shown in Fig. 3 in which the $\Delta\Gamma_+$ between the (Γ_+)'s for $TlNO_3$ and TlF for the same electrolyte concentration is plotted against q. Moreover, the plot of Γ_- for $TlNO_3$ against q exhibited a minimum (0.1 to 0.2M) caused by increased specific adsorption of Tl^+ as q decreased. [Γ_- in the absence of cation specific adsorption increases uniformly with q; see KNO_3 (3).]

The separation of $F\Gamma_+$ into the specifically adsorbed charge q_1^+ and the charge q_{2-s}^+ in the diffuse double layer and the similar separation of $F\Gamma_-$ into q_1^- and q_{2-s}^- is not possible by Grahame's method (3). We adopted the following approach based on the Gouy-Chapman theory and a simple electrostatic model, already used [*e.g.*, (12, 13)] in other problems. We write

$$\phi_M - \phi_1^+ = (4\pi/\epsilon)\, q x_1^+ \qquad [1]$$

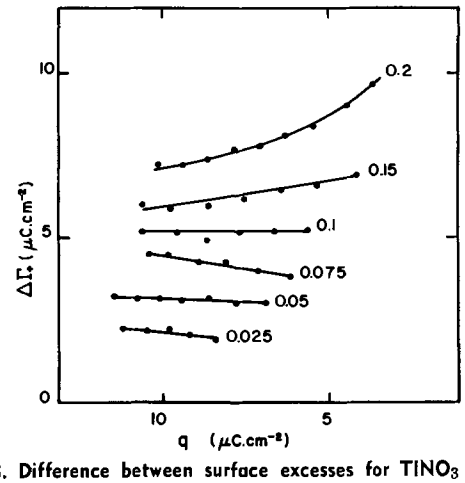

Fig. 3. Difference between surface excesses for $TlNO_3$ and TlF, at constant concentration of Tl(I) salt, against charge on the electrode.

$$\phi_1^+ - \phi_1^- = (4\pi/\epsilon)\,(q + q_1^+)\,(x_1^- - x_1^+) \qquad [2]$$

$$\phi_1^- - \phi_2 = -(4\pi/\epsilon)\, q_{2-s}\,(x_2 - x_1^-) \qquad [3]$$

where the superscript + corresponds to Tl^+, the superscript — to NO_3^- and ϵ pertains to the compact double layer. Note that we assume two inner planes at distance x_1^+ and x_1^- from the electrode ($x_1^+ < x_1^-$). We also write three other equations expressing the charge q_{2-s} as a function of ϕ_2 in the outer plane (Gouy-Chapman); the electroneutrality of the interface and the equality between $F\Gamma_+$ and $q_1^+ + q_{2-s}^+$. A system of six independent equations with the six unknowns is obtained: ϕ_1^+, ϕ_1^-, ϕ_2, q_1^+, q_1^-, and q_{2-s}. Resolution by interaction is possible provided x_1^+, x_1^-, and ϵ are known. An alternative approach would be to write three additional equations based on a more detailed model, *e.g.*, one taking into account discreteness effects. The method involving an *a priori* selection of x_1^+, x_1^-, and ϵ has the merit of simplicity and is not as arbitrary as might appear. (A more detailed model might not be free either of adjustable parameters.)

We selected $x_1^+ = 2A$, $x_1^- = 3.15A$, and $\epsilon = 6$, 8, or 9.6 for the compact double layer. (We used the bulk value of ϵ in the Gouy-Chapman theory.) It turned out that self-consistent results were obtained for $\epsilon = 6$ which is precisely the dielectric constant chosen by Macdonald and Barlow in a recent paper (14) on discreteness effects. The choice of x_1^+ was prompted by previous work of TlF, and we verified that this choice was not critical for $1.8 \leq x_1^+ \leq 2.2A$. The value of $x_1^- = 3.15A$ was selected on the basis of discreteness effect analysis (13) we made of Payne's results (10) for NO_3^- specific adsorption at low concentrations ($\leq 0.05M$). Variations of x_1^- from 3 to 3.5A did not affect the results considerably.

The charge q_1^+ at constant $TlNO_3$ concentration varied quite linearly with q except at the more positive q's (≈ 15 μcoul/cm^{-2}) where it tended to approach zero. The enhancement of Tl^+ specific adsorption caused by NO_3^- specific adsorption is shown in Fig. 4. (Negative Δq_1^+'s, which are small anyhow, probably result from the uncertainty of calculation.) The charge q_1^-, plotted against q, exhibited a minimum just as the comparable plot of Γ_- against q (see above).

Values of ϕ_2 were negative (between —0.045 and —0.075v) and showed qualitatively a normal dependence on q and $TlNO_3$ concentration. Negative ϕ_2's, instead of the positive ϕ_2's found for TlF, are to be expected since NO_3^- undergoes stronger specific adsorption than Tl^+ in the conditions prevailing in this work. It turned out that ϕ_2 (and also ϕ_1^+ and ϕ_1^-) was much more sensitive to the selection of ϵ than q_1^+ and q_1^-. In fact calculated ϕ_2's for $\epsilon = 8$ and $\epsilon = 9.6$

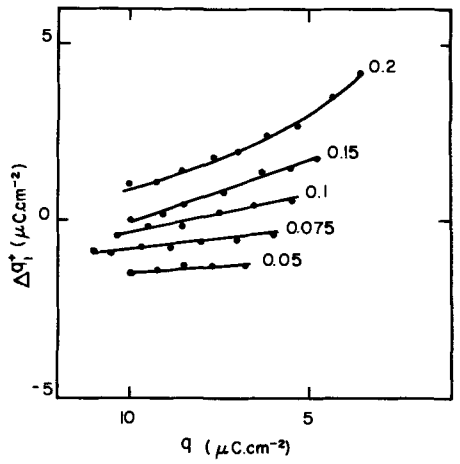

Fig. 4. Difference between the amounts of specifically adsorbed Tl^+ for $TlNO_3$ and TlF, at constant concentration of Tl(I) salt, against charge on the electrode.

were completely abnormal in their dependence on q and $TlNO_3$ concentration. This influence of the choice of ϵ is also evident for Fig. 5 showing ϕ_1^+ against q. The potential ϕ_1^+ appeared quite independent of $TlNO_3$ concentration for $\epsilon = 6$ and varied quite linearly with q_1. The same remark applied to the ϕ_1^- *vs.* q plot although there was some concentration dependence.

Adsorption was interpreted by means of two simultaneous Frumkin isotherms of the types proposed by Parry and Parsons (24). By using the $Tl^+ - Tl^+$ interaction parameter $A_{11} = 9.6$ from our TlF study, we found that the $NO_3^- - NO_3^-$ interaction parameter A_{22} varies from 2.0 to 5.5 for $4 \leq q \leq 10$ μcoul · cm^{-2} and that the $Tl^+ - NO_3^-$ interaction parameter A_{12} ($\equiv A_{21}$) varies from -6 to -9 for $4 \leq q \leq 10$ μcoul · cm^{-2}. The magnitude and sign of these parameters indicate repulsion between NO_3^- ions and strong association between Tl^+ and NO_3^-. The results cannot be regarded as quantitative, but they probably describe qualitatively interactions.

In conclusion, a relatively simple method is tentatively proposed for resolution of simultaneous cation and anion specific adsorption. This approach does depend on an *a priori* selection of parameters, but self-consistency of results imposes rather severe restrictions in the selection, particularly with respect to the dielectric constant in the compact double layer. A more detailed model analysis would be desirable, but might prove quite involved.

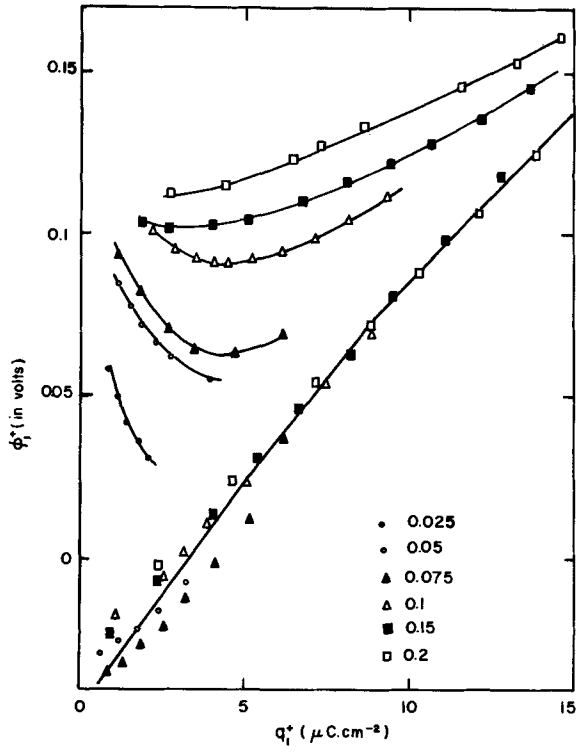

Fig. 5. Potential in the plane x_1 against charge on the electrode for different $TlNO_3$ concentrations (M). Lower curve calculated for $\epsilon = 6$; group of curves calculated for $\epsilon = 8$ (11).

Double Layer in Media of Low Electrical Conductivity

This phase of our work, in a very different vein from the previous two investigations, covers an aspect of the double layer which has not been touched on, namely, the electrical double layer for media of low conductivity, *e.g.*, for a metal in contact with very dilute (below 10^{-3}M) aqueous solution of strong electrolytes, electrolytes in nonaqueous solvents of low dielectric constant, solids with ionic conductivity (*e.g.*, ice), etc. The main problem, aside from theory, is the development of a suitable technique for the measurement of the double layer differential capacity. The conventional bridge fails, even at low frequencies, because the cell resistance is very much higher than the electrode impedance. This problem was solved by the following differential coulostatic method (15).

Two identical electrodes e_1 and e_2 (but not necessarily of the same area) are coupled with a reference electrode in a single cell. The potential of e_1 and e_2 is set at a known, identical value with a potentiometer. The potentiometer circuit is opened, and a small known charge is supplied to e_1 by discharge of a small capacitor ($|\Delta E| <$ 5-10 mv). The difference of potential across e_1 and e_2 is recorded (electrometer and oscilloscope or fast recorder) against time and extrapolated back to zero time. Extrapolation is necessary because small spurious faradaic processes cause a drift of potential at open circuit. This source of interference is minimized by the above differential technique.

Application was made to Hg/NaF system in the 10^{-3} to 10^{-5}M range. The electrodes were hanging mercury drops expelled from microsyringes. This system was selected because capacities can be computed from Grahame's data in the 1 to 10^{-3}M range on the basis of two reasonable assumptions: (*a*) the Gouy-Chapman theory is valid; (*b*) the differential capacity of the compact double layer at constant q is independent of the electrolyte concentration. Agreement between theory and experiment for 10^{-3}, 10^{-4}, and 10^{-5}M is good (Fig. 6). These are the first measurements of double layer capacity in very dilute solution of which we know.

Measurements at lower concentrations and with distilled water were still entirely feasible although the cell resistance reached several megohms, but two difficulties were encountered: lack of purity of water and drift of potential at the junction with the reference electrode. It is expected that these two difficulties will be eliminated.

This method is less accurate than the bridge method because it is direct reading, and faradaic processes (*e.g.*, reduction of residual oxygen) interfere more. (Interference by a fast process is also serious with the bridge because of the resulting pseudocapacity.) A detailed study of residual oxygen was also made (16) in this connection. Finally, electrodes of constant area are more easily contaminated than the dropping mercury electrode. Application of the latter type of electrode to the present method is complicated by the variation of potential resulting from variation of the electrode area at open circuit (17).

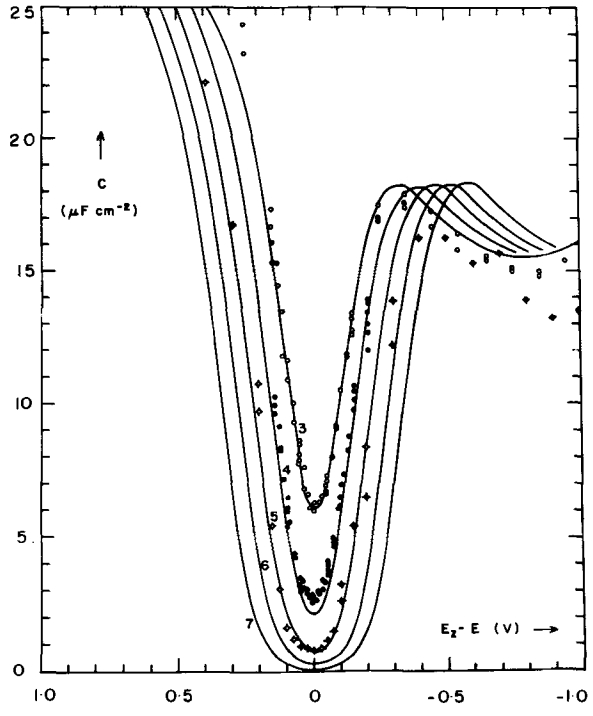

Fig. 6. Differential capacity of double layer for 10^{-n}M NaF in contact with Hg at 25°C. Values of n on each curve; points are experimental, curves are calculated (15).

In conclusion, a method is available for measuring double layer capacities with media of low conductivity. Further application is now being planned (distilled water, ice) or has actually been made [0.5 to 10^{-3}M potassium acetate in anhydrous acetic acid (18)]. Mass transfer generally poses no problem as an approximate treatment (unpublished) showed, but this aspect is now being reexamined more rigorously.

Double Layer for Electrodes with a Charge Transfer Reaction in Nonsteady-State Measurements

The double layer at an electrode on which a charge transfer reaction occurs has attracted little attention since emphasis has been placed over the last two decades on the ideal polarized electrode. Correction for charging of the double layer in kinetic measurements, *i.e.*, in presence of a large excess of supporting electrolyte, is generally made on the assumption that the double layer capacity is essentially unaffected by the presence of the reactants and products at low concentration. It is only recently that Sluyters and co-workers developed (19) a method for separating the double layer capacity from the electrode impedance in electrode impedance measurements. (See his series of papers in *Rec. trav. chim.* since 1960.) These workers showed that the foregoing empirical correction for double layer charging is not satisfactory in some cases because the double layer capacity is strongly affected by the reactants and/or products even with a large excess of supporting electrolyte. In view of this very interesting result, it seems necessary to question what is actually measured in charging of the double layer under such "dynamic" conditions as in impedance measurements or any other relaxation or perturbation method for fast processes (in contrast to the "static" conditions in electrocapillary curve measurements). This problem was recently examined by us (20), and our conclusions will be reviewed here.

There is no problem from the thermodynamic point of view since this question was settled long ago [see Grahame's review (21)] and was re-examined more recently (22, 23). Thus, the derivative or the interfacial tension with respect to potential, all other variables being kept constant, *e.g.*, for the reversible electrode $M^{+z} + ze = M$, is $q + zF\Gamma_+$ where Γ_+ is the relative surface excess of M^{+z}. This derivative is equal to q for an ideal polarized electrode. Interfacial tension measurements for a reversible electrode thus yield $q + zF\Gamma_+$. The question is whether this is also the case for dynamic measurements.

The essential idea is the recognition that *a priori* separation of faradaic and charging processes, as generally assumed [including Sluyters (19)], is not justified or physically conceivable for a nonideal polarized electrode under nonsteady-state conditions. Impossibility of *a priori* separation arises because there is, in addition to charging by ionic transfer of M^{+z}, charge separation or recombination at the interface without external current. The latter process occurs according to the reaction $M^{+z} + ze = M$ and depends on the kinetics of this reaction. If the exchange current i_o for this reaction is sufficiently low, charging occurs almost entirely by ionic transfer, just as for an ideal polarized electrode, and the differential capacity of the double layer is essentially dq/dE. Conversely, when i_o is sufficiently high, charging occurs almost entirely by charge separation or recombination, and the differential capacity is then that of a reversible electrode, namely, $d(q + zF\Gamma_+)/dE$ for a metal ion-pure metal electrode. [The expression is different for a metal ion-amalgam electrode (25).] Any capacity between these two values can be obtained for intermediate values of i_o and, furthermore, the capacity is then frequency- or time-dependent in nonsteady-state measurements. Correction for double layer charging, based on a constant capacity, is then in error to an extent that can be serious.

These ideas led (20) to three general equations which, after solution for any particular conditions, allow the detailed analysis of nonsteady-state and periodic electrode processes. The three equations are very general and apply to metal ion-pure metal electrodes, metal ion-amalgam electrodes, redox electrodes, etc. Detailed analysis has already been completed for impedance measurements (25) and for the usual relaxation methods and the interrupter method (26).

No *a priori* separation of faradaic and charging processes is postulated in the writing of the three general equations. *A posteriori* separation of the charging process is feasible by elimination of the faradaic component corresponding to the usual treatment (no double layer charging). This *a posteriori* separation is purely formal, but it has the advantage of explaining double layer charging in terms of a familiar model. It is found in this way that, at time zero, (or for infinite frequency) charging occurs as an ideal polarized electrode for any finite exchange current. (This is because there is no time for charge separation or recombination to occur.) Conversely, for time approaching infinity (or for zero frequency) charging occurs as an ideal reversible electrode for any finite exchange current. If the exchange current is supposed to be infinite, charging occurs always as an ideal reversible electrode. The transition from one behavior to the other occurs in a range of time or frequency which frequently corresponds to actual experimental conditions. Furthermore, the difference between the two limiting values of the capacity can be significant, even in the absence of specific adsorption. This may account, at least in part, for some discrepancies in kinetic parameters obtained by different methods. It is suggested some of the results obtained by different methods be re-examined and possibly revised in the light of the foregoing ideas and treatments derived from them. In some cases, correction will turn out to be negligible but in other cases the error resulting from *a priori* separation of faradaic and charging processes may be serious.

ΔG^o	standard free energy of adsorption, cal · mole^{-1}
i_o	exchange current density, amp · cm^{-2}
K	integral capacity of double layer, μf · cm^{-2}
N	number of electrons corresponding to a given energy level
q	charge density on electrode, μcoul · cm^{-2}
$q_1^\pm$	charge density of specifically adsorbed cations (q_1^+) or anions (q_1^-), μcoul · cm^{-2}
q_{2-s}	charge density in diffuse double layer, μcoul cm^2
R	gas constant
t	time, sec
T	absolute temperature or transmission coefficient (no confusion)
x	distance from electrode, cm
x_1	distance from electrode to the inner plane of closest approach, cm
x_2	distance from electrode to the outer plane of closest approach, cm
W	energy, ergs
W_a	sum of the Fermi level energy and the work function, ergs
z	ionic valence on ion
β	defined by $\beta = \exp(-G^o/RT)$
γ	interfacial tension dynes · cm^{-1}
$\Gamma_\pm$	relative surface excess of cations (Γ_+) or anions (Γ_-), mole · cm^{-2}
ϵ	dielectric constant
η	overvoltage, v
μ	chemical potential, cal · mole^{-1}
ϕ_M	potential in metal, v
ϕ_1	potential in inner plane of closest approach, v
ϕ_2	potential in outer plane of closest approach, v

Discussion

Roger Parsons: I would like to suggest that the assumed constancy of the distances x_1^+ and x_1^- and the dielectric constant of the inner region ϵ is only a first approximation. From the data we already have on systems involving only a single specifically adsorbed species it seems likely that these parameters are charge dependent.

Hence I believe it is important that the calculation of specific adsorption in a mixed system should be done without making such approximations. This can be done following the method proposed independently by Hurwitz[1] and by Dutkiewicz and myself[2] and used by us for the KI + KF system. For the $TlNO_3$ system this would involve measurements in two series.

(*a*) say $(1-x)MTlF + xMTlNO_3$

(*b*) say $(1-x)\ MKNO_3 + xMTlNO_3$

In (*a*) the appropriate form of the Gibbs equation at *T,p* constant is

$$-d\gamma = qdE^+ + \Gamma_{F^-}\,d\mu_{TlF} + \Gamma_{NO_3^-}\,d\mu_{TlNO_3}$$
$$= qdE^+ + RT\Gamma_{F^-}\,d\ln(1-x) + RT\Gamma_{NO_3^-}\,d\ln x$$

if activity coefficients may be assumed constant in a medium of constant ionic strength. Hurwitz treated a more elaborate situation. Hence

$$-d\gamma = qdE^+ + RT\left\{\Gamma_{NO_3^-} - \frac{x}{1-x}\Gamma_{F^-}\right\} d\ln x$$
$$= qdE^+ + RT\Gamma'_{NO_3^-}\,d\ln x$$

since the term $(x/1-x)\Gamma_{F^-}$ is just equal to the surface excess of NO_3^- in the diffuse layer only. Thus this experimental series gives the specifically adsorbed amount of NO_3^- subject to the approximation that F^- and NO_3^- have equal distances of closest approach to the electrode in the nonspecifically adsorbed state. This approximation may cause trouble if the diffuse layer is negatively charged but will be very good if it is positively charged.

Similarly in series (*b*) the Gibbs equation becomes

$$-d\gamma = qdE^- + \Gamma_{Tl^+}\,d\mu_{TlNO_3} + \Gamma_{K^+}\,d\mu_{KNO_3}$$
$$= qdE^- + RT\Gamma_{Tl^+}\,d\ln x + RT\Gamma_{K^+}\,d\ln(1-x)$$
$$= qdE^- + RT\left\{\Gamma_{Tl^+} - \frac{x}{1-x}\Gamma_{K^+}\right\} d\ln x$$
$$= qdE^- + RT\Gamma'_{Tl^+}\,d\ln x$$

It should now be possible to extrapolate the result in each series of experiments to $x = 1$ to obtain Γ'_{Tl^-} and $\Gamma'_{NO_3^-}$ in 1M $TlNO_3$, and other measurements would lead to similar results at other total ionic strengths.

[1] H. R. Hurwitz, *J. Electroanal. Chem.*, 10, 35 (1965).

[2] E. Dutkiewicz and R. Parsons, *ibid.*, 11, 100 (1966).

Also in connection with the results in $TlNO_3$ I would like to ask whether there is any evidence for $Tl^+NO_3^-$ ion-pair formation. This would be expected in the low dielectric constant medium of the inner layer since pK is 0.33 in bulk water.

Paul Delahay: Dr. Parsons' suggestion is a very good one. At first sight I have no objection to it except perhaps the possibility of difference in behavior similar to that found by Dr. Payne for adsorption of NO_3^- in pure KNO_3 solution and in mixtures of $NH_4NO_3 + NH_4F$. However, the experiments should be run.

With regard to your question about ion pairs, there is indeed strong association between Tl^+ and NO_3^-, as shown by the magnitude and sign of the corresponding interaction parameter for two simultaneous Frumkin isotherms of the type you advocated ($r = 1$ to simplify matters). I shall present some results on this point after presentation of your paper, and detailed data are given in ref. (11) of my paper.

B. E. Conway: In regard to your second charge-separation effect involving no transfer of electrons in the external circuit, would this not be equivalent to the reverse of what occurs on open-circuit decay of emf of electrodes which are not ideally polarizable, *e.g.*, as treated in the theory of Butler and Armstrong[3] for emf decay at Hg? If this is so, it may help to clarify the significance of the effect you propose.

Paul Delahay: Your comparison is interesting but I see there more an analogy than an equivalence. It is generally stated that, in open circuit decay, discharge of the double layer provides the faradaic current. You consider, I suppose, the opposite proposition, namely, that faradaic current charges the double layer. Actually, the situation is more complex because of the interplay of ionic fluxes, variations of the Γ's, and finally the faradaic current. One really should consider charge separation or recombination in the analysis of open potential decay (at least when the exchange current is high enough to warrant the analysis). This we have already done. This is why I think that your suggested equivalence is misleading.

F. C. Anson: I have not been able to follow all of Professor Delahay's very stimulating arguments and I hope to clarify my own thinking by asking him to comment on the following thought experiment.

Suppose one has a reversible, well-poised metal-metal ion electrode at equilibrium at potential E_1 in a sodium fluoride supporting solution. With an all but perfect potentiostat the electrode potential is stepped to a more cathodic potential, E_2. The charge-potential characteristic for the electrode in sodium fluoride is known so that the electronic charge on the metal electrode is known to be q_1 at E_1 and q_2 at E_2. Thus the total electronic charge that will have to be supplied to the electrode to change its potential from E_1 to E_2 will be $q_2 - q_1$.

I had thought that all of this charge, $q_2 - q_1$, would be supplied to the electrode from the potentiostat. However, as I understood Professor Delahay, he believes that some part of this charge may be supplied to the electrode by the faradaic reaction of the electrode itself according to

$$M \rightarrow M^{n+} + ne^- \qquad [1]$$

What I cannot understand is how such a net anodic reaction could have been induced to proceed by the application of a cathodic potential step. Furthermore, even if this reaction did somehow occur, the metal cations it produced would not help to satisfy the cationic charge required by the diffuse layer to match the negative electronic charge injected into the electrode by the potentiostat because each metal action produced by this reaction releases n electrons into the electrode so that the relative charges on the electrode and in the diffuse layer would remain unchanged.

Paul Delahay: First I must correct a statement made in Professor Anson's question, and then I shall answer his question.

If the potential of the electrode $M^{+z} + ze = M$ is changed from the equilibrium potential E_1 to some other value E_2 by an ideal potentiostat, one should not consider the charge density q on the electrode but some function of q and Γ_+ (of M^{+z}). Under ideal reversible behavior one has a variation of $(q + zF\Gamma_+)_{E_1}$ to $(q + zF\Gamma_+)_{E_2}$ where q and Γ_+ at E_2 correspond to the activity of M^{+z} just outside the diffuse double layer at E_2. This point, however, does not change the gist of Professor Anson's question.

The answer is a simple one: I always referred to charge separation or recombination, and by this meant that the reaction $M^{+z} + ze = M$ can occur in the forward (recombination) or backward (separation) directions.

When E varies from E_1 to E_2, q may either increase or decrease depending on the values of E_1 and E_2. Likewise Γ_+ can vary in either direction. Let us assume that

$$(\Gamma_+)_{E_1} > (\Gamma_+)_{E_2}$$

and that Γ_+ is positive at these two potentials (the situation Professor Anson wants, I believe). Variation from E_1 to E_2 causes recombination (and not separation), and consequently the ionic flux of M^{+z} at the electrode is greater than if recombination did not occur. Hence, recombination must be considered.

At $t = 0$, charging occurs as an ideal polarized electrode for a finite exchange current. Charge recombination comes into play for $t > 0$. If the exchange current is supposed to be infinite, charging occurs as an ideal reversible electrode for $t \geq 0$. This problem has already been worked out in collaboration with Mr. Susbielles (unpublished work).

In conclusion, I think that Professor Anson's question indicates that he considered only charge separation and not the opposite effect. I never made a suggestion along these lines.

F. C. Anson: Professor Delahay has stressed that the separation of a measured current into faradaic and nonfaradaic components cannot be made rigorously. I wonder if this difficulty could not be partially overcome if the total charge that passes, rather than the current, were the measured parameter. The total nonfaradaic charge which passes as a result of a potential step, for example, should be calculable *a priori* in favorable cases from a knowledge of the charge-potential characteristic of the pure supporting electrolyte.

Paul Delahay: The answer to Professor Anson's question is "No". Integration of the current is only a mathematical transformation of the signal which does not modify the basic premises on which theory is based. Integration (or differentiation, etc.), however, may facilitate analysis of results, minimize errors, etc.

It turns out that integration may minimize errors of results obtained by classical analysis based on *a priori* separation of faradaic and charging current. The reason is as follows.

The double layer charging contribution, as calculated by *a posteriori* separation, often depends on the derivatives, with respect to potential, of q and the Γ's. The Γ's in particular, can vary very rapidly with E over a narrow interval of potential. Hence, the derivatives can be high. Use of a technique in which

[3] J. A. V. Butler and G. Armstrong, *Proc. Roy. Soc. London*, 137A, 604 (1932).

the signal depends on the Γ's (and other factors) over a wide interval of E rather than on the $d\Gamma/dE$'s over a narrow interval of E may then be advantageous. In this sense, integration may help, but it does not remove the basic difficulty. I believe that the real answer is to solve a particular problem without assuming charge separation or recombination, and then compare the solution with the one obtained with *a priori* charge separation. The error can then be evaluated.

H. Gerischer: It is certainly very necessary to reconsider the basic concepts of our approaches to the study of electrode reaction kinetics as Professor Delahay has done in the fourth part of his paper. But to my regret, I have not yet understood why he assumes that the heretofore used concepts of discussing transients are not adequate. These concepts have been developed for describing nonequilibrium conditions. In principle the derivative of interfacial tension with respect to potential, all other variables being kept constant, cannot be measured for a reversible electrode since the potential in a reversible system can only be changed by variation of the composition of one of the two phases in contact (at constant T and p) without leaving equilibrium conditions. This derivative is therefore basically associated with the concept of the ideal polarized electrode. In kinetics, one studies the question of what goes on when we depart from equilibrium conditions? This is reached for electrode reactions by bringing additional electrical charges from an external current source to the electrode interface. This charging process can be done very fast (in principle with an infinitely high voltage source infinitely fast). If the reactants in the electrode process are ions, and this is always true for at least one of the reactants, the accumulation of charge in the double layer can be due partially to these ions themselves depending on their relative concentration and their specific charge, but I cannot see that this makes questionable the concept of distinguishing between faradaic and charging currents.

As a limiting case, the double layer can be charged by an extremely high external current pulse momentarily without noticeable faradaic discharge of the interface condenser. The deviation from this idealized charging behavior indicates to us the faradaic loss. The purely electrostatic part of such a charging process is defined by the assumption that the charge distribution is changed without chemical reaction; that means without any chemical change in the composition of the electrode half-cell as a whole. In this picture, the change in distribution of those ions which take part in the electrode reaction is assumed to occur by movement of ions already present in the electrolyte. It is further assumed that the distribution of charges in the double layer reaches equilibrium immediately.

All current flowing of a faradaic nature through the electrode interface is combined with changes in chemical composition. The products of the chemical reactions will change the composition of the electrolyte and (often of the electrode also) at and next to the phase boundary. We are accustomed to describe this as concentration polarization when we ask how this chemical change alters the driving force for the faradaic process. This change in composition includes also a change in the distribution of ionic charges in the double layer. But this means only, I believe, that the electrostatic capacity may vary somewhat. All this has to be included in the model as concentration polarization and this can be done by introducing into this model the kinetics of diffusion processes, adsorption, and formation of intermediates inside and outside the double layer. We all know that this can become extremely complicated.

It is obvious that this model of distinguishing between electrostatic and chemical effects can only be verified experimentally when the energy barriers for the transfer of charge through the double layer are essentially higher than those for the transport of ions in solution over the same distances. Only then do we have the chance to apply the electrostatic force at the electrode interface faster than the chemical reaction can follow. Otherwise we come immediately to a situation which is controlled only by the other rate processes which are involved, such as transport and chemical reactions. These cases will be found and are found, I think, but this is already included in the assumptions hitherto made.

I would like to add that this problem of distinguishing between the effects of electrical forces and chemical forces on the electrode reaction is closely related to the problem of distinguishing between electrical and chemical potentials for ionic species in electrolytes. We assume in our usual treatment that equilibrium is preserved in the double layer with respect to the electrostatic interaction in spite of nonequilibrium conditions with respect to the electrode reaction. This is certainly a somewhat dubious assumption when we discuss the influence of the concentration distribution in the double layer on kinetics. It seems to me that it is this problem which Professor Delahay tries to avoid. But at the moment I have not yet understood in what way this can be done without relying on any mechanistic interpretation of these indeed very complex processes.

Paul Delahay: To answer Professor Gerischer's question I shall consider two points: (*a*) Is the approach I suggest justified? (*b*) Does this approach lead to results that are significantly different from those obtained by the usual *a priori* separation of faradaic and charging processes.

I shall begin with the first question and try to answer it in two ways: (*i*) by introducing the concept of charge-separation or charge recombination without external current; (*ii*) by considering the three general equations I proposed (and without use of the charge-separation concept). The answer is the same by both methods. To simplify matters, I shall consider only a metal ion-pure metal electrode ($M^{+z} + ze = M$), but the analysis can be transposed to other types of electrodes. I hope to refute in this way, Professor Gerischer's arguments, inasmuch as I understand them. Further details can be found in a recent paper,[4] and application to electrode impedance measurements is made in another paper.[5]

Consider the electrode $M^{+z} + ze = M$ at equilibrium and assume that some perturbation is applied (current, potential, etc.). Further, assume that the double layer is at equilibrium with respect to the ionic concentrations (activities) just outside the diffuse double layer. (This is reasonable provided the time scale of measurements is large in comparison with the relaxation time of the double layer.) Finally, let us first suppose that all ions needed in the charging of the double layer are supplied (or removed) by ionic transfer. Then, the charging current is proportional to the charge density q on the electrode or the differential capacity dq/dE (E potential) depending on the charging conditions. (More complicated dependence need not be considered here.) This follows from the definition of q

$$q = -\Sigma z_j F \Gamma_j \qquad [1]$$

where z_j is the ionic valence of each ionic species with sign, Γ_j the corresponding surface excess (relative $\approx$ absolute; dilute solution) and F the faraday. This behavior is characteristic of an ideal polarized electrode and has been assumed in previous treatments of nonsteady-state processes. I believe there is no disagreement here.

[4] P. Delahay, *J. Phys. Chem.*, in press.

[5] P. Delahay and G. G. Susbielles, *J. Phys. Chem.*, in press.

Consider now the same electrode and assume that all ions but M^{+z} are supplied by ionic transfer. Let us leave for a moment the reason for making this assumption (see below), and let us proceed as before. The current for charging of the double layer is now proportional to $-\sum_{j \neq M^{+z}} z_j F_j \Gamma_j$ or to the derivative of this quantity with respect to E. One has by definition of q in Eq. [1]

$$-\sum_{j \neq M^{+z}} z_j F \Gamma_j = q + zF\Gamma_+ \qquad [2]$$

where z is the ionic valence of M^{+z} and Γ_+ is the surface excess of M^{+z}. We see that the charging current is now different from that of an ideal polarized electrode. Also note that the quantity $q + zF\Gamma_+$ is that appearing in the equation for the electrocapillary curve for an ideal reversible electrode (metal ion-pure metal). More about this point later.

I now return to the assumption I made, namely, that M^{+z} ions are not supplied (or removed) by ionic transfer. This assumption amounts to stating that there is charge separation or recombination by the reaction $M^{+z} + ze = M$ without external current. Thus a M^{+z} ion is supplied by this reaction, and the electronic charge $-|ze|$ is left on the electrode. This concept follows directly from the idea of exchange current. If we assume that the exchange current is infinite, any driving force, no matter how small it is, will cause some charge separation or recombination. When we disturb the system from equilibrium, some driving force is exerted, and the above mechanism must be considered. The contribution to charging by this mechanism, as compared to ionic transfer, depends on the exchange current and also on mass transfer characteristics. Hence, time or frequency must be considered.

I have used thermodynamics as guiding posts, but I like to stress that the problem is a kinetic one. This brings me to the second approach in which we simply consider balance conditions (1 equation for a metal ion-pure metal electrode; 2 equations for amalgam, redox electrodes, etc.). In writing the third equation I simply recognize that only ionic fluxes (converted to an electronic current at the counter electrode) can be measured. I make no assumption, in the writing of the first two equations, about the explicit form of the faradaic current. Of course, in applying these equations one needs some specific form for the faradaic current in terms of overvoltage, exchange current, concentrations, etc. Models then come into play, but only at that stage. No mention need be made of charge separation without external current, but the previous transition from ideal polarized to ideal reversible electrode follows naturally from the general equations.

One also finds from this treatment that at $t = 0$ (or at infinite frequency), charging occurs as an ideal polarized electrode provided the exchange current is finite. (If the exchange current is supposed to be infinite, the ideal reversible electrode behavior always prevails.) I agree with Professor Gerischer on this point, but I like to emphasize that behavior as an ideal polarized electrode prevails only for $t = 0$ (or infinite frequency). For $t > 0$ (or a finite frequency) there is a progressive transition toward ideal reversible electrode as t increases after the initial perturbation.

I hope these arguments are quite convincing, but anyhow let me now consider the second point, namely, is the effect significant? It turns out that it is more often than one might think, especially when the charging current is proportional to the potential derivatives of the quantities I mentioned. If one assumes no specific adsorption, one can show from diffuse double layer theory and the Nernst equation that $zF(d\Gamma_+/dE)$ can easily be larger than dq/dE. Specific adsorption may make the difference larger or smaller.

In conclusion, I shall restate what I said before: *a priori* separation of faradaic and charging processes is not justified in nonsteady-state electrode processes. Such a separation is not needed in the detailed treatment of nonsteady processes. The difference between the results obtained by the method I outlined and the classical one can be significant. Of course, there may be many cases (concentrated supporting electrolytes, *i.e.*, 1 M of 1-1 electrolytes) in which the difference is not particularly great. Finally, I might add that I explicitly separated the charging process in the discussion to express myself in terms of a familiar model.

I shall not discuss the separation of chemical and electrochemical forces, Professor Gerischer considered, as I do not see how it is directly relevant to the problem, at least as I treated it. However, I do not see there a refutation of the ideas I put forward.

G. C. Barker: I have a number of comments to make on Professor Delahay's interesting paper. First it should be mentioned that strong adsorption of metal on mercury ions often is observed with halide solutions, and there is now evidence in many cases that the adsorption is due either to the interaction of the metal ions with specifically adsorbed halide ions or to simple extraction by the interface of ion pairs or complex ions present in the solution. As it is known that Tl^+ is fairly readily complexed by NO_3^- is would seem likely that the enhanced adsorption for nitrate solution is partly if not entirely due to the presence of undissociated $TlNO_3$ in the interfacial region, and I wonder what the consequences of such adsorption may be when it comes to analyzing the data.

The adsorption which is observed with fluoride solutions seems more unexpected and may be connected with weak formation of an intermetallic compound between mercury and thallium. There is evidence for such compound formation in the case of platinum. It would be of interest to study the dependence of the adsorption on temperature in the mercury case to eliminate the slight possibility that the adsorption is connected with pair formation. Usually when there is strong adsorption arising from complex ion formation the surface excess falls rapidly as the temperature rises whereas there is some (not wholly conclusive) evidence[6] suggesting that the temperature coefficient, when the adsorption is due to the formation of intermetallic compounds, is relatively small.

My next point has to do with mass transport effects when double layer capacities are measured in solutions of low ionic strength by the coulostatic method described by Professor Delahay. Some studies of the mass transport problem made a few years ago led us to believe that the equivalent circuit for the double layer is not purely capacitative, but contains also a transmission line connected in series with the zero-frequency capacity.[7] Thus when charge is injected the potential should at first overshoot its final value and, provided the subsequent decay is small compared with the potential excursion, the amount by which the potential exceeds the equilibrium value should be inversely related to the elapsed time to the power 1/2. It would be of interest to know whether this theoretical expectation is realized, but even more important is the fact that the overshoot is dependent on the rate of change with potential of the surface excesses of anions and cations at the interface. Thus there is a slight possibility of using the dynamic technique developed by Professor Delahay to study surface excesses. This might provide a check on the data currently obtained by less direct methods.

Finally I would like to make a comment on the stimulating paper dealing with the influence of changes in reactant concentration caused by a faradaic

[6] G. C. Barker, Unpublished.

[7] G. C. Barker, "Transactions of the Symposium on Electrode Processes," E. Yeager, Editor, John Wiley & Sons, Inc., New York (1961).

process on the apparent double layer capacity of the interface. I understand the points that Professor Delahay is making, and I fully agree that changes in reactant concentration (regardless of whether the reactant is specifically or nonspecifically adsorbed) do influence the double layer charge and hence affect the apparent differential double layer capacity. My comment is that this effect has been taken account of in an earlier paper by myself and in one by Delahay and Senda,[8] although I would agree that the implications of interactions between faradaic and nonfaradaic phenomena have not been previously discussed adequately. I believe that it would be well to emphasize that generally errors resulting from neglect of the dependence of double layer charge on reactant concentration are small compared with the errors which occur when one neglects the influence of nonspecific or specific adsorption on the faradaic impedance or on the aperiodic equivalent circuit for the faradaic part of the interfacial impedance. Thus when studying the kinetics of fast or slow reactions by any linear or nonlinear relaxation technique one should always first give regard to the latter complication. To omit doing this and to apply only corrections for the dependence of double layer charge on reactant concentration would be disastrous in many instances, but I suspect that this is not what Professor Delahay is advocating in the paper which he has described briefly. One final point may be mentioned which I am sure Professor Delahay will agree with; this is that when one considers the aperiodic circuit for the interface, it is evident that the influence of changing reactant concentrations on double layer charge can be allowed for by a current generator shunting the differential double layer capacity for constant reactant concentration. Specific or nonspecific adsorption of the reactant in question can be allowed for with a high degree of accuracy, if the integral adsorption coefficient changes slowly with potential, by capacity shunting the diffusion impedance for the reactant in question. One can see intuitively that, when the surface excesses are small and the system at equilibrium is linear as regards reactant adsorption at constant potential, the current associated with the aforementioned current generator [see Fig. 8, ref. (2)] is linearly related to the current flowing through the capacity shunting the diffusion impedance. All therefore turns on the magnitude of the two currents, and I believe that in the majority of experimental systems the former current is much smaller than the latter largely because adsorption coefficients (nonspecific or specific) change only slowly with potential whereas the reactant concentration may change relatively rapidly with potential. However, there undoubtedly are exceptions (organic reactants), and in these cases due regard must be given to interaction between the faradaic and nonfaradaic parts of the interfacial impedance. Professor Delahay is to be congratulated on drawing attention to these involved matters.

Paul Delahay: I completely agree with your suggestion that $TlNO_3$ is formed, *i.e.*, that there is strong $Tl^+ - NO^-_3$ association between specifically adsorbed Tl^+ and NO^-_3. This is shown, at least qualitatively, by analysis on the basis of simultaneous isotherms. (Cf. my reply to Dr. Parsons' question.)

With respect to your comment on the coulostatic method, I believe that an answer is provided by analysis on the basis of the three general equations I gave in the discussion of my paper. This problem has now been solved, and one can show that there is a progressive transition from behavior as an ideal polarized electrode at $t = 0$ to an ideal reversible electrode at $t \to \infty$. The situation is similar to the one I discussed for impedance measurements. You are quite right in stating that one cannot regard the double layer as that of an ideal polarized electrode (except at $t = 0$, and there we disagree I believe), but I believe that we approach the problem in different ways. It would be of interest to see whether our conclusions are similar or identical.

I shall now take up your point about previous treatments of how to modify the equivalent circuit to account for adsorption (specific or not). These treatments have indeed been developed. My present position is that the problem can be attacked from a different point of view without *a priori* separation of double layer and faradaic processes. One can develop models for the writing of the faradaic current and solve the three general equations I presented. The effect of adsorption then comes out naturally from the treatment (frequency dependence) rather than from some modification of the equivalent circuit. On the basis of our calculation, I disagree with your statement that small effects can be expected in most cases. Detailed analysis of actual systems and measurements will provide the best answer.

D. M. Mohilner: Why is it that for the case of the reversible (very fast) charge transfer you attribute the entire change in the surface excess of the electroactive species to charge separation-recombination? I should have thought that even for this species a part of $zFd\Gamma_+$ required in time dt could be furnished by ion transport.

Paul Delahay: If we consider dynamic conditions, as prevailing in nonsteady state measurements, ideal reversible behavior implies an infinite exchange current. Hence, any driving force (*e.g.*, concentration gradient), no matter how small it is, causes charge separation or recombination. The contribution to charging, as far as M^{+z} is concerned, by ionic transfer in solution can then be neglected for a finite diffusion coefficient of M^{+z}.

I could also answer your question in another way by considering the charging process and showing that by assuming pure charge separation or recombination ($M^{+z} + ze = M$), one indeed finds that the charging current depends on $q + zF\Gamma_+$ (or the derivative of this quantity with respect to E depending on charging conditions) for a pure metal-metal ion electrode. Details are given in my paper [ref. (20)].

Richard Buck: The thermodynamic arguments for coupling of an exchange current-controlled Faradaic process and the double layer charging process in an over-all reversible process under nonsteady state conditions should be reinforced by an electrostatic treatment of this problem. The paper by Bass[9] may provide the necessary formalism although neither Bass nor Levich[10] treated the transient state. By combining Poisson's equation with the Nernst-Planck flux equations for each ion of a binary salt, Bass was able to give the potential distribution from the interior of the solution (where electroneutrality prevails) to the inner Helmholtz plane both for the case of zero current (Gouy-Chapman result) and for finite current. Presumably the potential distribution for the nonsteady state could be treated this way perhaps with the aid of a computer. From the potential distribution, the charge and capacitance can be found.

It would be surprising if this calculation gave anything different from the previously assumed result, *e.g.*, that charging occurs early in time and is not complicated by the faradaic process. It seems to me that Professor Delahay's suggestion implies that the divergence of the flux (divergence of the quantity-Dgrad$C$ $\pm zeuEC$ where D is the diffusion coefficient, C the

species concentration, z the ionic charge, e the electronic charge, u the mobility, and E the electric field strength) is not zero at the electrode surface (even for zero not current as was assumed by Bass) for an ion which can exchange electrons with the electrode. This means that a volume source of strength proportional to the exchange current density must be added.

It would be interesting to follow through with the above assumptions to see whether or not there is a verification of the coupling of faradaic and charging processes suggested by Professor Delahay. Would Professor Delahay care to comment on these points?

Paul Delahay: Dr. Buck may be quite right, and I only wish to correct a statement he made, namely that I developed the analysis by thermodynamic means. I did introduce thermodyanmic considerations to show the need for a transition from an ideal polarized electrode to an ideal reversible electrode. However, the three general equations I gave are of kinetic rather than thermodynamic character. This point is further discussed in my reply to Dr. Breiter.

James N. Butler: We have attempted, in our studies of gallium and gallium amalgam electrodes[11] (Cleveland Meeting) to measure the surface charge directly by observing current-time curves at a dropping electrode whose potential is held constant. Under the assumption that there is no interaction between the charging process and the faradaic process, a theoretical form of this dependence may be predicted, and this has been verified experimentally for double layer charging of gallium in the presence of hydrogen evolution, and on Ga-Hg alloys in the presence of gallium dissolution. These results are consistent with Professor Delahay's theoretical arguments in spite of his suggestion that for some situations there may be strong deviations from the approximation of independent double layer and faradaic currents.

In the case of simultaneous double layer charging and hydrogen evolution in 0.1M $HClO_4$ solutions, the faradaic process can contribute only a cathodic current. The reaction rate in the opposite direction is so slow that the electrode behaves as an ideally polarized electrode except for the discharge of hydrogn ions; and the charging current and faradaic current are strictly additive.

In the case of gallium dissolution, the time-dependence of the current indicates that the double layer charging current is independently additive to a diffusion-controlled anodic current. Because of the minute concentrations of Ga^{+3} in the solutions, the reverse reaction is probably very slow, and thus the currents are again independent.

The effects which Professor Delahay has predicted are important in systems where the reaction occurring at the electrode has approximately the same time scale as the transient measurement. We have observed deviations from strictly additive behavior under conditions where the concentration of gallium ions in the solutions becomes large enough so that the relaxation time of the $Ga \leftrightarrows Ga^{+3}$ reaction is probably comparable to the time scale of the measurements, about 0.01-1 sec. Such conclusions would have to be verified by direct measurements of the rate of this reaction, but could provide an important test of this theory.

Paul Delahay: There is no problem for the processes you refer to because the exchange current, under conditions of your measurements, is very low. I pointed this out precisely in my paper in some detail and showed a plot of the double layer capacity (*a posteriori* separation) as a function of frequency for different exchange currents. The same order magnitude for the time scale applies to other techniques than impedance measurements.

In your paper[12] you implicitly assumed algebraic additivity of the faradaic and charging currents at a dropping mercury electrode. You give no hint that this might not be the case. You may expect trouble in some of the applications you predict in your note, particularly for thallium amalgam, whenever the potential is such that the exchange current is high.

We independently developed the same technique, as you did, and made extensive measurements[13] on the $Hg^{+2} + 2e = Hg$ system while I was still at Louisiana State University (spring of 1965). It was this work (and also that of Sluyters) which led me to think about the whole problem of double layer charging with concomitant charge transfer reaction. The analysis of the type of analysis you used is now being worked out on the basis of the three general equations I presented.

Your last comment is in agreement with the views I expressed in the paper.

M. W. Breiter: It appears that the distinction resulting from the thermodynamic treatment of the "ideally polarizable electrode" and the "reversible electrode" is not useful here. In the absence of specific adsorption of ions a capacitance may be due to the amount of potential-determining ions in the diffuse double layer under certain experimental conditions. If adsorbed intermediates are formed in an adsorption reaction (for instance, H-atoms in the Volmer reaction), a large capacitance of up to several thousand $\mu F/cm^2$ may be measured at low frequencies. This capacitance has been designated as "faradaic capacitance," and the thermodynamics of this case is treated by Frumkin and co-workers in a paper which follows.

Paul Delahay: One can approach the problem in two ways (which I used): (*a*) Point out the difference between charging of an ideal polarized electrode and an ideal reversible electrode and then examine the transition from one case to the other for nonsteady-state measurements; (*b*) write the three general equations which I gave and deduce implications by solving the problem for the particular conditions prevailing in any given method.

The writing of the first two equations involves only balance considerations. The third equation, however, is a little more subtle and, to arrive at it, I found it useful to introduce the concept of charge separation or recombination without external current.

I agree with your comments on the hydrogen electrode, but I wish to point out that the three general equations also apply to this case. The treatment of this electrode for impedance measurements ought to be reexamined but the difference between the result and the one now used may not be significant (except for high exchange currents). We have plans for examining this and similar problems.

Finally, I believe the term "faradaic capacity" is misleading because of the impossibility of *a priori* separation of charging and faradaic processes. It is better to refer to electrode capacity, resistance, or impedance.

G. J. Hills: Professor Delahay's proposals, if correct, require the revision of many electroanalytical procedures. His faradaic charging term is written as

$$zF\Gamma_-$$

and the associated current as

$$zF\frac{d\Gamma_+}{dt}$$

[11] Abstract No. 171, Cleveland Meeting, May 1966.

[12] J. N. Butler and M. L. Meehan, *J. Phys. Chem.*, 69, 4051 (1965).

[13] G. Tessari, J. Murphy, R. de Levie, and P. Delahay, Unpublished work.

This can be equated to

$$zF\frac{d\Gamma_+}{d\mu_\pm}\cdot\frac{d\mu_i}{dE}\cdot\frac{dE}{dt}$$

where μ_i is the chemical potential of the potential-determining species. For a reversible electrode

$$\frac{\partial\mu_i}{\partial E}=\frac{zF}{RT}$$

and for a particular frequency or time-scale the significance of the faradaic charging current depends therefore on $\partial\Gamma_+/\partial\mu_+$ which will be small for nonspecifically adsorbed ions in the presence of excess supporting electrolyte. The faradaic admittance of adsorbable species is already taken care of.

Paul Delahay: First, I did not say or suggest that electroanalytical procedures ought to be modified as a result of my work. The difference between my approach and the classical one may be of no particular significance as far as analytical procedures are concerned. Further thought is required on that point. What I did say, however, was that the determination of kinetic parameters by nonsteady-state methods ought to be reexamined.

Now to your question. I am not sure I understand what you mean by "faradaic charging term," but anyhow your point is that $d\Gamma_+/d\mu_+$ is small in the absence of specific adsorption, *i.e.*, that the effect I discussed ought to be small. This conclusion is not correct as you can ascertain by calculating $zF\frac{d\Gamma_+}{d\mu_+}\frac{d\mu_+}{dE}$ $\left(\text{or more simply } zF\frac{d\Gamma_+}{dE}\right)$ from diffuse double layer theory and the Nernst equation. The calculation is given in the treatment of the faradaic impedance[14] based on the ideas I expressed. One easily reaches 100 $\mu f\cdot cm^{-2}$ for realistic conditions in 0.1M of a 1-1 electrolyte (no specific adsorption). Hence this term cannot be neglected in comparison with dq/dE or the capacity component of the usual faradaic impedance. I should add that in 1M supporting electrolyte, for the same conditions as above, the effect is less pronounced (about 7 $\mu f\cdot cm^{-2}$). This may explain why abnormal behavior has escaped attention in experimental work. Workers were simply not looking for it, and the temptation to ascribe abnormal behavior to kinetic complications (often real!) could not be resisted I suppose.

Finally, I do not understand what you mean by "The faradaic admittance of adsorbable species is already taken care of." I did not make any distinction between specifically and nonspecifically adsorbed ion in writing Γ's. These are surface excesses in the thermodynamic sense.

H. D. Hurwitz: It is interesting to note the importance of the influence of the diffuse layer composition (cf. the work of Dr. R. Payne). In this respect the method of mixed electrolytes at constant ionic strength[15,16] appears to be able to throw further light in this direction and to correct some earlier assumptions based upon the model of Gouy-Chapman.

It is also noteworthy that such results may be obtained from measurements of double layers in media of low electrical conductivity as shown by Professor Delahay in his paper. One must, however, stress the point that even at very low concentration the theory of Gouy-Chapman is inconsistent unless a linearization of Poisson-Boltzmann equation is performed, the solution of which does not yield a cosh behavior of the differential capacity. Nevertheless, some less rigorous approach [17] may lead to some stimulating results. For example, the smaller experimental values of C near the maximum on the cathodic side of Fig. 6 in Professor Delahay's work could be interpreted as resulting from electrostrictive effects of the adsorbed Na^+ in the diffuse layer.[17] In this respect, it is advisable to repeat such experiments with different cations.

Discreteness-of-Charge Adsorption Micropotentials

III. Dielectric-Conductive Imaging

J. Ross Macdonald and C. A. Barlow, Jr.

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

A convenient general method for calculating potentials and fields arising from planar arrays of discrete adions under a variety of imaging conditions is described and illustrated. Adions are perfectly imaged by one conducting plane (single imaging) and are also imaged by a dielectric constant discontinuity at a plane on their other side. The method employs only solutions of the single imaging problem, is readily applied without a computer, and is pertinent to the usual electrolyte compact layer adjoining either an electrode or a dielectric material, which may be air. The single image solutions used in calculating more complex imaging results may be exact values obtained from a previous rather complicated approach, or for ease in calculation, may frequently be approximate but quite accurate values calculated by a simple method described herein. Using the exact approach, one can calculate, for the full range of the dielectric reflection parameter, fields and potentials along any line perpendicular to the conducting plane. Here we are primarily concerned with potentials and fields along the line through a removed adion, and the approximate single imaging solution is especially useful. Although we apply the method to regular hexagonal arrays, in the latter case it is equally applicable to arrays described by Grahame's partially smeared, cut-off model for single imaging. Some comparison with the results of this model is presented. In addition to calculating and illustrating the variation of field and potential within the compact layer and the adjoining dielectric medium, we have examined in detail the difference between the micropotential and the macropotential for many different imaging situations. The present study includes the previously treated single conductive plane imaging and also the (infinite) conductive-conductive imaging situations as special cases. It is found that special care is needed to describe the latter situation by the present model. Finally, the effect of possible conductive imaging by the electrolyte diffuse layer is considered qualitatively.

The system we shall consider in this paper is the electrolyte compact double layer (1). We shall assume it consists of a monolayer of ions (effective charge $z_v e$ and average surface charge density q_1) bounded on one side by a plane interface which we shall call the electrode-surface plane (ESP), generally (but not always) associated with an adsorbing conductor, and on the other side by an imaginary plane marking the points of closest approach of the charge centroids of ions in the electrolyte, or diffuse layer. The plane of closest approach is known as the outer Helmholtz plane (OHP), and the plane passing through the charge centroids of the adions in the monolayer is the inner Helmholtz plane (IHP). We shall define γ to be the distance between the OHP and the IHP and β to be the IHP-ESP separation; $d \equiv \beta + \gamma$ is therefore the total thickness of the compact layer.

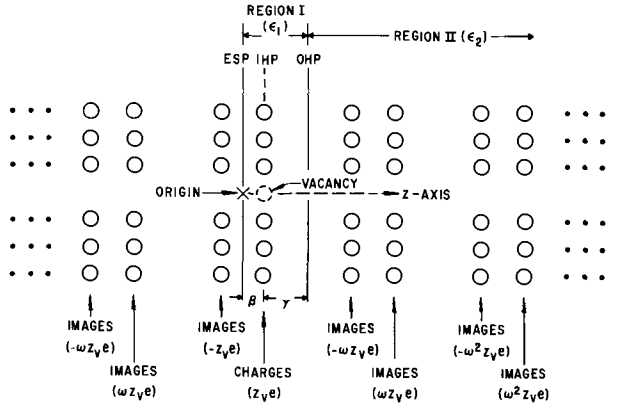

Fig. 1. Cross-sectional diagram of the double layer region showing charges, and some of their images applicable for calculating potential in region I, and the distances β, γ, and z.

The situation is illustrated in Fig. 1. The circle centers denote the positions of adion charge centroids. The diagram is not to scale since β is roughly equal to an ionic radius, and the minimum distance between spherical adions in the plane is thus approximately 2β. The present treatment of course applies for adsorption on a curved electrode surface such as a mercury drop provided, as is the case in practice, that the radius of curvature of the surface is much greater than the characteristic microscopic distances involved in the situation such as d and the effective Debye length in the diffuse layer.

The possibility immediately arises that other material besides the ions, such as adsorbed water molecules, may reside in the compact layer; to represent this possibility approximately as well as to take into account to the same degree of approximation the finite polarizability of the adions themselves, we regard these ions as point charges lying on the IHP and take the dielectric constant of the compact layer in which they reside to be ϵ_1. We have discussed the introduction of such an ϵ_1 in some detail elsewhere (1-4).

The present paper is concerned primarily with the determination of the electrical potential within the compact layer; this is because the potential's behavior is centrally related to virtually every measurable electrochemical property of the system (5). As it turns out, the potential within the system is sensitively dependent on certain structural aspects of the system; not only is it necessary to take the discreteness of the elements into account (6), but correspondingly one may only do so if reasonable models are used for the spatial distribution of the discrete adions within their plane (7). What is "reasonable" depends, it seems, on the temperature, the surface density of the monolayer, the quantities z_v, β, and γ, and other, more subtle, characteristics of the system. In the present work we shall usually assume that the ions form a perfect hexagonal array with lattice

constant r_1, although our general analysis is applicable even without this specific restriction. This is a popular model (3, 4, 7a, 8); and even though it is by no means applicable under all conditions (7), it seems to be a model which is approximately valid for many conditions of interest. As might be suspected, the hexagonal model begins to become inapplicable at low surface densities and/or high temperatures; further discussion of the applicability of this and other models appears elsewhere (7).

There is one other major consideration involved before one can determine the potential in the compact layer: What is the effect of those charges outside the compact layer on the potential? If one of the bounding planes is the surface of a conductor, the effect of those charges on and beyond this plane is straightforward; the conductor acts as an electrical imaging plane, and charges on the conductive surface in excess over those (proportional to q_1) involved in the imaging process set up an additional uniform electric field in the compact layer. If one or both of the bounding surfaces is that of a neutral dielectric insulator, then again a type of imaging is involved. A more difficult question, one which is responsible for much of the variety in the various theories of double layer structure and whose solution has significant impact on the expected properties of such systems, is the effect of the diffuse layer on the potential in the compact layer. One possible approximation is simply to neglect any variation in charge density or polarization within the diffuse layer along directions parallel to the OHP; that is, to assume that these quantities vary only in the direction perpendicular to the OHP. That this is not strictly true is a result of the discreteness-of-charge in the compact layer; that this assumption might still be a good approximation rests on the thermal motion of the ions in the diffuse layer, motion which tends to disrupt any "shadowing" within this layer of the charge density variations on the IHP through pairing of adions with counterions in the diffuse layer. If one makes this approximation, the explicit effect of the diffuse layer goes to nought, and the potential within the compact layer is determined completely by the monolayer ions and the boundary conditions at the other interface. Several more or less correct, exact or approximate, treatments of this model have appeared in print (4, 8c-f, 9, 10). The above situation, with a metal electrode, has been termed by the present authors the "single-imaging" case in a treatment (4) hereafter referred to as II.

At the extreme opposite end of things, another model of the diffuse layer's effect has been proposed and treated (3,7b, 8b-f, 11). This might be termed the "Ershler model" after its first proponent; the present authors have dealt with this model in some detail and have termed it the "infinite-imaging" case in a treatment (3) hereafter referred to as I. As the latter terminology implies to some of us, this model assumes that mobile diffuse-layer ions are capable of arranging themselves so as to make the OHP an equipotential surface. Effectively then, the OHP becomes a second conductive-imaging plane (exactly as though it were a metal surface) and the outcome of this is an infinite set of images, as in a hall of mirrors.

Unfortunately it has not been possible to establish unequivocally, either experimentally or theoretically, which of these two models more nearly represents the actual behavior of the diffuse-layer ions. An adequate treatment of the diffuse layer in the vicinity of the OHP, where the influence of the discrete compact-layer ions is greatest and the usual approximations most hazardous, may be as yet an unfinished assignment. The most promising approaches have been those of Stillinger and Kirkwood (12) and some of the Russian workers (13); however, even these treatments invoke expansions involving the ratio of electrical energy to thermal energy in the diffuse layer, and for concentrations of interest the validity of such theories is uncertain. The experimental problems are almost as sticky: The quantities actually measured are only related to local potentials after an "interpretive process" which is somewhat questionable; for example, isothermal measurements leading to adsorption coverages (q_1) only yield adsorption potentials *vs.* coverage if the form of the isotherm is known. Furthermore, it is possible that the state of ionization of the monolayer elements may change over certain ranges of surface coverages for some systems (2, 14, 15).

Returning to the refuge of our idealized situation, however, there is one diffuse-layer effect which should exist independent of the behavior of the diffuse-layer ions: In most situations there is a fairly abrupt change in the dielectric constant in going across the OHP. If we denote the dielectric constant of the bulk electrolyte, containing no excess ions, by ϵ_2, the difference $\epsilon_2 - \epsilon_1$ will induce dielectric imaging at the OHP. [We should note that the major dielectric constant change may not occur precisely at the OHP, so that the imaging plane may lie somewhat within the compact layer (16). This possibility will be neglected here.] When this imaging is accompanied by metallic imaging at the ESP, resulting in an infinite set of imperfect images, as though in a hall of imperfect mirrors, we have described this dielectric-conductive situation as the "partial-imaging" case. This case has the following features of particular interest. First, this type of imaging should be present in most systems, whatever additional effect may be present due to the diffuse-layer ions. The dielectric discontinuity, or an approximation thereto, would be expected in most cases, forming a "background effect" for any additional action by the diffuse-layer ions. In view of this effect, it is in fact difficult to construct an electrolytic system which displays "single imaging," and we now regard this case to be of interest only in reference to nonelectrolyte systems or as a least-imaging limiting case for electrolytes.

Since we plan to compare many of the theoretical single, partial, and infinite imaging discreteness-of-charge treatments mentioned above in a forthcoming review (17), we shall omit much of such cross-comparison from the present paper. It is perhaps worth mentioning that the present work contains in a certain sense all the results of the limiting cases I and II and also yields a continuous bridge between them. Although the present paper does not include a treatment of dielectric-dielectric imaging, a case treated to some extent by Levine *et al.* (7b), our present, easily applied methods require, as we shall show elsewhere, only simple modifications to apply to this situation as well.

General Analysis

In the remainder of this paper we shall be primarily concerned with the potential which results when a single vacancy is present in an otherwise perfect hexagonal array of adsorbed ions. As has been discussed in I and II, this leads to the interesting part of the micropotential; the effects of omitted self-images are independent of q and q_1 and may be subsumed into the "chemical" part of the adsorption potential. The potential ψ in our present work consists of two contributions: a discrete-charge contribution ψ_a which is always present whatever the charge on the ESP and a uniform-displacement component ψ_e which results from an additive constant D field normal to the ESP and vanishing when the ESP is grounded so its charge q becomes equal to $-q_1$ for dielectric-conductive imaging. We first determine the discrete-charge contribution ψ_a. The basic method is to replace the ESP and OHP interfaces with a system of fictitious "image charges;" the particular system depends on whether we seek the potential on the metal side or the solution side of the OHP. Thus, referring to Fig. 1, the potential between the metal and the OHP (region I) will derive from an infinite

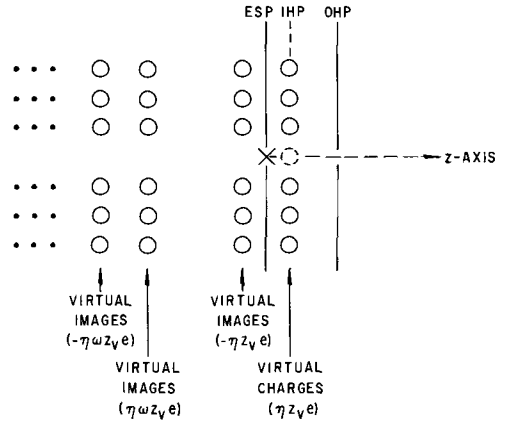

Fig. 2. Cross-sectional diagram of the double layer region showing effective charges and some of their virtual images applicable for calculating potential in region II.

set of images (for each charge on the IHP) as though the whole space were of dielectric constant ϵ_1; referring to Fig. 2, the potential on the solution side of the OHP (region II) will likewise involve an infinite set of images, and the whole space of region II is to be regarded as having dielectric constant ϵ_2. The sets of images for each charge on the IHP are chosen so that the resulting potentials satisfy the appropriate conditions on the ESP and OHP. In particular, the resulting potential should be zero on the ESP, continuous across the OHP, and result in a continuous variation in the normal component of electric displacement across the OHP. It may be verified by inspection that the set of images indicated in Fig. 1 and 2 lead to potentials satisfying these conditions.

We shall set up a coordinate system as follows: The positive z-axis is taken normal to the ESP, extending outwards towards the OHP. The x and y axes lie in the ESP, and the origin of coordinates is on the ESP and the normal line passing through the vacancy. Although the methods of the present paper may be readily extended to give potentials for positions other than $x = y = 0$, in the following we shall only be concerned with actually calculating the potential (and field) along this line.

Let us now define $\omega \equiv (\epsilon_2 - \epsilon_1)/(\epsilon_2 + \epsilon_1)$, and $\eta \equiv 1 + \omega = 2\epsilon_2/(\epsilon_1 + \epsilon_2)$. Referring to Fig. 1, we see that the array of adions and their images giving rise to ψ_a in region I form sheets of nonideal dipoles whose centers lie on the planes $z = z_n \equiv 2nd$ where n is an integer. The separation between the positive and negative charge of each nonideal dipole is 2β, and the strength of the dipole sheets drops off as $\omega^{|n|}$. Similarly, referring to Fig. 2, it may be seen that the potential ψ_a in region II derives from a set of nonideal dipoles similar to those pertaining to region I. The differences between the sets for the two regions are that the positive-n sheets are missing for the region II calculation and the dipole strengths are all multiplied by the factor η.

If we now define $\psi_{ao}(x,y,z)$ to be the potential produced at (x,y,z) by our array of adions in the single-image regime (the quantity known as ψ_a in II) we may take the foregoing into account and write

$$\psi_a(x,y,z) = \psi_{ao}(x,y,z) + \sum_{n=1}^{\infty} \omega^n \{\psi_{ao}(x,y,z + 2nd) - \psi_{ao}(x,y,2nd - z)\} \quad [1]$$

in region I, and in region II

$$\psi_a(x,y,z) = (\eta\epsilon_1/\epsilon_2) \sum_{n=0}^{\infty} \omega^n \psi_{ao}(x,y,z + 2nd) \quad [2]$$

where $\eta\epsilon_1/\epsilon_2 = 1 - \omega$. Thus, we have expressed the partial-image potential in terms of a single series (instead of the double or triple series used by others) involving the accurately known (4) single-image potentials. Levine *et al.* (7b, 11) have employed a similar approach (for the infinite imaging case), in which they used Grahame's cut-off model (8c) for the single image potential $\psi_{ao}(0,0,z)$. Similarly, defining $\mathcal{E}_a$ as the electric field associated with ψ_a in the present regime and $\mathcal{E}_{ao}$ as the field associated with the single-imaging potential ψ_{ao}, one obtains in regions I and II, respectively

$$\mathcal{E}_a(x,y,z) = \mathcal{E}_{ao}(x,y,z) + \sum_{n=1}^{\infty} \omega^n \{\mathcal{E}_{ao}(x,y,z + 2nd) + \mathcal{E}_{ao}(x,y,2nd - z)\} \quad [3]$$

$$\mathcal{E}_a(x,y,z) = (\eta\epsilon_1/\epsilon_2) \sum_{n=0}^{\infty} \omega^n \mathcal{E}_{ao}(x,y,z + 2nd) \quad [4]$$

These single-summation expressions for ψ_a and $\mathcal{E}_a$ converge quite rapidly; even for $\omega = 1$, the expression for potential in region I converges well. As ω approaches unity, the value of ψ_a in region II is bounded

$$\psi_a \leq (\eta\epsilon_1/\epsilon_2) \sum_{n=0}^{\infty} \omega^n \psi_\infty = \eta\epsilon_1\psi_\infty/\epsilon_2(1 - \omega) = \psi_\infty$$

where the upper bound, ψ_∞, is defined as in II; thus $\psi_\infty \equiv 4\pi\beta q_1/\epsilon_1$. In carrying out the sums for $\psi_a(0,0,z) \equiv \psi_a(z)$ it was usually found to be more convenient to use an approximate but highly accurate analytic expression for $\psi_{ao}(0,0,z) \equiv \psi_{ao}(z)$ than to use the exact results obtainable from II. The approximation used and its accuracy is discussed further in ref. (18) and in the Appendix. Calculation of $\psi_{ao}(z)$ by this approximation is far simpler than by the lengthy expressions given in II, yet yields adequate accuracy. The accuracy of the results in the present paper have, in fact, been checked by calculating many of them with both exact and approximate values for $\psi_{ao}(z)$.

To complete the potential, we must add the uniform D field part, ψ_e. The boundary conditions at the ESP require that, if the total surface charge density on the ESP is q, then the uniform field produced is simply $4\pi(q + q_1)$. Taking the zero of ψ_e to lie on the ESP, we obtain $\psi_e = -(4\pi/\epsilon_1)(q + q_1)z$ for region I and $\psi_e = -4\pi(q + q_1)[(d/\epsilon_1) + \{(z - d)/\epsilon_2\}]$ for region II. We note, incidentally, that if ψ_{aic} and $\mathcal{E}_{aic}$ (see II) are substituted for ψ_{ao} and $\mathcal{E}_{ao}$ in the foregoing equations, the resulting potentials and fields are the ones pertaining to a complete adion array.

Before presenting detailed results of our calculation of potentials, fields, and other quantities of interest, we point out an interesting feature pertaining to the limit $\omega \to 1$. Intuitively one might expect ψ_a (in region I) to approach the infinite-image (conductive-conductive) ψ_a as ω approaches unity. As it turns out, however, this preconceived notion is entirely wrong: The limiting behavior of the present ψ_a is distinctly different from the ψ_a determined in I, which we shall here denote as ψ_{acc}. Thus one cannot simply take $\omega = 1$ herein and directly obtain ψ_{acc}. What does occur for given q and q_1 is that the limiting value of the present $\psi = \psi_a + \psi_e$ is identical to the value of $\psi_{acc} + \psi_e$ obtained by redefining ψ_e (in I) so as to place its zero on the ESP (as has been done with our present partial-imaging ψ_e). In other words, the actual limiting behavior of the present ψ_a is given by $\lim_{\omega\to 1} \psi_a = \psi_{acc} + (4\pi q_1 z\beta/\epsilon_1 d)$. In particular, at the OHP where ψ_{acc} is zero, $\lim_{\omega\to 1} \psi_a = \psi_\infty$. This behavior represents a real physical effect and not just a trivial definition of the zero of potential. The physical origin of the effect lies in the fundamental difference between

a dielectric, no matter how "strong," and a conductor. Only the conductor allows charge to build up on its surface so as to render the field inside exactly zero.

Normalized Equations

For presentation and comparison purposes, it is convenient to deal with normalized equations whenever practical. We shall normalize potentials with the ψ_∞ introduced above and shall denote such quantities as ψ_{ao}/ψ_∞ and ψ_a/ψ_∞ as $\psi_{ao}{}^N$ and $\psi_a{}^N$, respectively. Note that since ϵ_1 occurs in ψ_∞, a potential such as ψ in region II, where $\epsilon = \epsilon_2$, is still normalized by a quantity involving ϵ_1, not ϵ_2, in this convention. It will prove convenient to normalize fields in an equivalent way, using $\mathcal{E}_\infty \equiv -4\pi q_1/\epsilon_1$. Finally, we will normalize electric displacements with $\mathcal{D}_\infty \equiv -4\pi q_1$.

From now on let us take $x = y = 0$ and define $Z \equiv z/\beta$ and $R_1 \equiv r_1/\beta$. Further, let $\gamma/\beta \equiv \Gamma$, $Z_o \equiv 1 + \Gamma \equiv d/\beta$, and $\rho \equiv 2Z_o$. Then the IHP occurs at $Z = 1$ and the OHP at $Z = Z_o$. For some purposes, as we shall see, it is useful also to use the normalized variable $\xi \equiv Z/R_1 \equiv z/r_1$.

We may now omit reference to x and y and write in place of [1] and [2]

$$\psi_a{}^N \equiv \psi_a{}^N(Z;R_1) = \psi_{ao}{}^N(Z;R_1) + \sum_{n=1}^{\infty} \omega^n\{\psi_{ao}{}^N(n\rho + Z;R_1) - \psi_{ao}{}^N(n\rho - Z;R_1)\} \quad [5]$$

(region I, $0 \leq Z \leq Z_o$)

$$\psi_a{}^N \equiv (1-\omega) \sum_{n=0}^{\infty} \omega^n \psi_{ao}{}^N(n\rho + Z;R_1) \quad [6]$$

(region II, $Z \geq Z_o$).

Equations following from [3] and [4] may be similarly written; instead, since it proves more convenient to plot displacements than fields, we give equations for $\mathcal{D}_a{}^N \equiv \mathcal{D}_a/\mathcal{D}_\infty$, equal to $\epsilon_1\mathcal{E}_a/\epsilon_1\mathcal{E}_\infty$ in region I and to $\epsilon_2\mathcal{E}_a/\epsilon_1\mathcal{E}_\infty$ in region II. To obtain $\mathcal{E}_a{}^N$ in region II, we need only multiply $\mathcal{D}_a{}^N$ in this region by $(\epsilon_1/\epsilon_2) = (1-\omega)/(1+\omega)$. The results for $\mathcal{D}_a{}^N$ are

$$\mathcal{D}_a{}^N = \mathcal{E}_{ao}{}^N(Z;R_1) + \sum_{n=1}^{\infty} \omega^n\{\mathcal{E}_{ao}{}^N(n\rho + Z;R_1) + \mathcal{E}_{ao}{}^N(n\rho - Z;R_1)\} \quad [7]$$

(region I)

$$\mathcal{D}_a{}^N = (1+\omega) \sum_{n=0}^{\infty} \omega^n \mathcal{E}_{ao}{}^N(n\rho + Z;R_1) \quad [8]$$

(region II)

For use in comparing with experimental results, it is frequently useful to have available complete potentials and fields which include the uniform D field contributions. We may write

$$\psi^N = \psi_a{}^N + \psi_e{}^N \quad [9]$$

$$\mathcal{E}^N = \mathcal{E}_a{}^N + \mathcal{E}_e{}^N \quad [10]$$

where $\epsilon_a{}^N = \mathcal{D}_a{}^N$ and $\{(1-\omega)/(1+\omega)\}\mathcal{D}_a{}^N$ in regions I and II, respectively, and

$$\psi_e{}^N = -\{1 + (q/q_1)\}Z \quad [11]$$

$$\mathcal{E}_e{}^N = -\{1 + (q/q_1)\} \quad [12]$$

$(0 \leq Z \leq Z_o)$

$$\psi_e{}^N = -\{1 + (q/q_1)\}[Z_o + \{(1-\omega)/(1+\omega)\}(Z - Z_o)] \quad [13]$$

$$\mathcal{E}_e{}^N = -\{1 + (q/q_1)\}[(1-\omega)/(1+\omega)] \quad [14]$$

$(Z \geq Z_o)$

There is, of course, no average D field contribution when $q = -q_1$ and the ESP is grounded.

The micropotential ψ_1 is related to the energy required to move an ion at the OHP to its adsorbed position at the IHP. This definition does not include the small p. d. V_2 in the diffuse layer between the OHP and the bulk of the solution. It is actually $\psi_1 + V_2$ which appears in an adsorption isotherm, but we shall neglect V_2 hereafter since it depends on q and q_1 and can be added in whenever pertinent. Remark, however, that unless the OHP is taken as an equipotential surface, which implies conductive imaging there, the usual one dimensional diffuse-layer theory is inconsistent with the requirement that the potential be continuous across the OHP. On the other hand, even when the OHP is not an equipotential, the value of V_2, now a function of x and y, will probably be quite close to that predicted by the usual one-dimensional theory.

From the above discussion, we have $\psi_1 \equiv \psi(\beta) - \psi(d)$. We wish to compare this p. d. to the average p. d., V_1, across the inner region. The average potential itself, $V(z)$, may be written in normalized form as (3)

$$V^N(Z) = -[Z(q/q_1) + (Z-1)] \quad [15]$$

for $Z \geq 1$. It is taken zero at $Z = 0$. $V_1{}^N$ is then $-V^N(Z_o)$. It will be convenient to introduce the normalized quantity $\lambda \equiv \gamma/d = \Gamma/(1+\Gamma) = \Gamma Z_o{}^{-1}$. For $\psi_1{}^N$ we readily obtain

$$\psi_1{}^N = \psi_a{}^N(1) - \psi_a{}^N(Z_o) + \Gamma\{1 + (q/q_1)\} \quad [16]$$

As in II, let us form the ratio (applicable for $Z_o \geq 1$)

$$\Lambda \equiv \psi_1/V_1 = -\psi_1{}^N/V^N(Z_o) \equiv \lambda(1+\Delta) = \frac{\Gamma\{1 + (q/q_1)\} + \Delta\psi_a{}^N}{\Gamma + (1+\Gamma)(q/q_1)} \quad [17]$$

where Δ is defined in [17] and $\Delta\psi_a{}^N \equiv \psi_a{}^N(1) - \psi_a{}^N(Z_o)$. The quantity Δ, which measures the deviation from linear proportionality of the micropotential to V_1, follows from [17] and may be written

$$\Delta = \frac{1 + \lambda^{-1}\Delta\psi_a{}^N}{\Gamma + (1+\Gamma)(q/q_1)} \quad [18]$$

When $q = 0$, we define $\Delta \equiv \Delta_o$, where

$$\Delta_o = \Gamma^{-1}[1 + \lambda^{-1}\Delta\psi_a{}^N] \quad [19]$$

Discussion of Results

Conducting ESP

In this section, we shall consider the usual electrolyte situation shown in Fig. 1 of a conducting electrode, a compact inner layer, and a diffuse layer extending beyond the OHP. We shall, for the time being, ignore effects arising from moveable ions in the diffuse layer and shall only be concerned with the effect of the $\epsilon_1 - \epsilon_2$ dielectric discontinuity at the OHP.

Suggested values of ϵ_1 in the compact layer have ranged from 6 to about 15 [see ref (1)]. The value of ϵ_2 for an aqueous electrolyte can be no greater than 81 at room temperature and will likely be appreciably reduced in the diffuse layer because of dielectric saturation arising from the average field there and the effects of closely neighboring ions (1, 19, 20). A reasonable approximate lower value for ϵ_2 might therefore be 50. Those combinations of the above values of ϵ_1 and ϵ_2 which give the smallest and largest ω's lead to $\omega_{min} \sim 0.54$ and $\omega_{max} \sim 0.86$. The smaller is ω, the less is dielectric imaging alone likely to approximate well to the actual electrolyte situation including diffuse layer conductive imaging. In the succeeding figures, however, we have shown results for a variety of values of ω between +1 and −1, for completeness, for comparison with the results of I and II, and because some of the negative values are pertinent to the situation discussed in the next section.

Figures 3 and 4 show the dependence of normalized potential and displacement on normalized distance from the ESP, ξ, for a number of ω values for the choice $R_1 = 5$ and several values of Γ. These values of Γ probably cover the experimentally likely possibilities for such electrolytes as KI. We have used

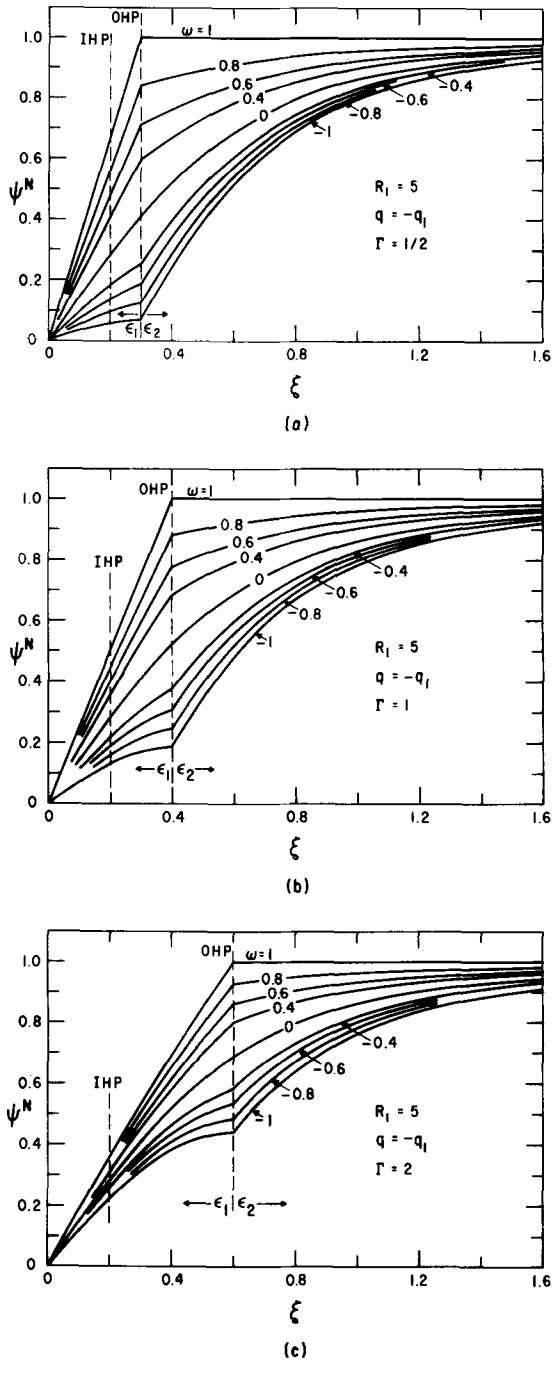

Fig. 3. Normalized discrete potential $\psi^N = \psi_a{}^N$ vs. normalized distance from ESP, $\xi \equiv Z/R_1$, for $R_1 = 5$ and $\Gamma \equiv \gamma/\beta$ equal to ½, 1, and 2. The parameter is $\omega \equiv (\epsilon_2 - \epsilon_1)/(\epsilon_2 + \epsilon_1)$.

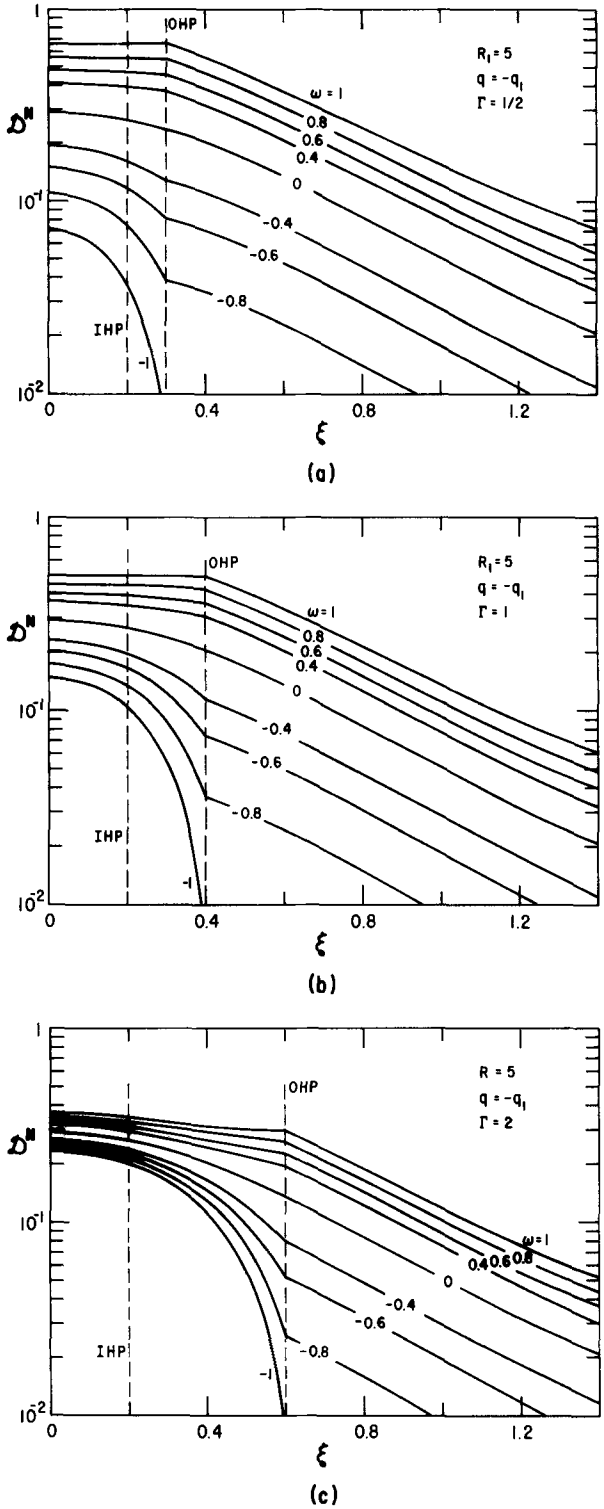

Fig. 4. Normalized discrete displacement $\mathcal{E}^N = \mathcal{E}_a{}^N$ vs. ξ for $R_1 = 5$, $\Gamma = ½, 1, 2$, and a variety of ω values.

the parameter ξ here instead of Z itself because we have found elsewhere (4, 18) that for single imaging ($\omega = 0$) $\psi_a{}^N = \psi_{ao}{}^N$ is a function primarily of ξ and depends only slightly on R_1 separately. The present curves may thus be compared directly with others plotted *vs.* ξ. Unfortunately, when $\omega \neq 0$, such virtual independence of R_1 is less marked, as we shall demonstrate elsewhere.

For greatest clarity and distinction between curves, we have taken $q = -q_1$ in Fig. 3 and 4. This choice has the effect of making $\psi^N = \psi_a{}^N$ and $\mathcal{D}^N = \mathcal{D}_a{}^N$. Although q seldom equals $-q_1$ in electrolyte situations of the kind discussed in the present section, ψ^N and $\mathcal{D}^N$ for $q \neq -q_1$ may be readily derived from the curves given through the use of Eq. [9] and [10], [11], and [12], and the known relations between $\mathcal{E}^N$ and $\mathcal{D}^N$. We have elected to plot $\mathcal{D}^N$ in Fig. 4 rather than $\mathcal{E}^N$ to avoid the discontinuities which would otherwise appear at the OHP. It is interesting to note that discontinuities still appear in the first derivative of $\mathcal{D}^N$ except when $\omega = 0$. Because of the infinite discontinuities which occur in some quantities at $\omega = 1$ and -1, our present results do not serve to yield $\mathcal{E}_a{}^N$ for $Z_o \geq 1$ when $\omega = -1$, but they do show that $\mathcal{E}_a{}^N = 0$ for $Z_o \geq 1$ when $\omega = 1$. The missing $\mathcal{E}_a{}^N$ portion for $\omega = -1$ can be readily calculated directly from Eq. [8], however, by first multiplying it by $(1 - \omega)/(1 + \omega)$ and then letting $\omega = -1$.

Although the present method of calculating ψ^N and $\mathcal{D}^N$ for any pertinent values of ω, Z, and R_1 is suffi-

ciently simple that no computer need be used to achieve 1% or better accuracy, we have required for this paper so many values of these and other related quantities that we have, in fact, used a computer for their calculation. We have made a careful comparison between the results of the approximate formulas for $\psi_{ao}{}^N$ and $\mathcal{E}_{ao}{}^N$ given in the Appendix and very accurate values of these quantities calculated as in II. This comparison shows, for example, that $R_1 = 5$ the use of the (3/3) approximant for $p(\xi)$ given as (a) in Table I of the Appendix yields values of $\psi_a{}^N$ for any reasonable Z, Γ, and ω choices which generally differ from the accurate ones by only a small amount in the fifth significant figure. The results for $\psi_a{}^N$ are thus at least as accurate as those for $p(\xi)$ itself and are usually more accurate. This approximant, or an even simpler one given in ref. (18), can be used in calculating results such as those shown in Fig. 3 and 4. An approximant such as the (2/3) one given for $F(\xi)$ in the Appendix is also required in calculating $\mathcal{D}_a{}^N$ by the modified cut-off method. When an approximant for $p(\xi)$ derived for $R_1 = 5$ is used to calculate values for $\psi_{ao}{}^N$ or $\mathcal{E}_{ao}{}^N$ when $R_1 \neq 5$, almost as high accuracy as with $R_1 = 5$ can be expected when $R_1 > 5$ since, as stated, $\psi_{ao}{}^N$ depends very little on R_1 alone but primarily on ξ. In particular, $R_1 = 5$ values are very close to $R_1 = \infty$ values of $\psi_a{}^N$ for a given ξ (18). When R_1 is < 5, there is somewhat more dependence on R_1, although the difference is still small even for $R_1 = 2$, the smallest value of R_1 that usually need be considered (18). For example, using the $R_1 = 5$ (3/3) $p(\xi)$ approximant to calculate values of $\psi_a{}^N$ for $R_1 = 4$ leads to deviations between accurate and approximate values of $\psi_a{}^N$ which usually occur in the fourth significant figure and rarely in the third. As discussed and listed in ref. (18), even simpler approximants than those given here in the Appendix may ordinarily be used to obtain adequate accuracy in calculated fields and potentials.

In order to achieve high accuracy in the present computer results, we summed such series as those of Eq. [5] to [8] to fairly high order and/or used the epsilon algorithm (21) to extrapolate to accurate final values when necessary. The series are all very rapidly convergent when $\omega << 1$. They are generally most slowly convergent when $\omega = 1$ so we examined this limit. When $\omega = 1$, the series of Eq. [5] is only conditionally convergent. Even so, it generally converges quite rapidly. Thus for $R_1 = 5$, $\Gamma = 1$, and $Z = 1$ we find that $\psi_a{}^N$ is within 1.7% of its final value when only three (accurate) terms of the series are used. With five terms the percentage is 0.71, and if the epsilon algorithm is used on these five terms, the percentage drops to 0.28.

Since [5] is only conditionally convergent when $\omega = 1$, rearrangement of its terms should change its value. We have found that this circumstance can be put to good use in calculating $\Delta\psi_a{}^N \equiv \psi_a{}^N(1) - \psi_a{}^N(Z_o)$ in the infinite imaging case where $\omega = 1$ and convergence is slowest. Ordinarily this quantity would have to be calculated by two separate evaluations of $\psi_a{}^N$ using [5]. After a slight rearrangement of the terms of [5], we find the surprising result, however, that

$$\Delta\psi_a{}^N = \psi_{ao}{}^N(1; R_1) - \psi_{ao}{}^N(\rho - 1; R_1) + \sum_{n=1}^{\infty} \{\psi_{ao}{}^N(n\rho + 1; R_1) - \psi_{ao}{}^N[(n+1)\rho - 1; R_1]\} \quad [20]$$

($\omega = 1$ only)

a series whose convergence is still generally good. The above is a lucky result; even it is unnecessary, however, if we note that when $\omega = 1$, $\psi_o{}^N(Z_o) \equiv 1$. Thus, when $\omega = 1$, $\Delta\psi_a{}^N$ can still be calculated using [5] only once to first obtain $\psi_a{}^N(1)$.

In II, we noted the extraordinary constancy of $\mathcal{E}(d)$ for $\beta = 3$Å, $\omega = 0$, and $\Gamma = 2/3$ over a wide range of q. There, Grahame's (22) values for q_1 as a function of q, determined from measurements on a 1N KI electrolyte at 25°C, were used in calculating $\mathcal{E}$. The above result suggested to us that it would be worthwhile to examine the field at the IHP, $\mathcal{E}(\beta)$, for several Γ and ω values. Results are shown in Fig. 5. We have chosen to look at the field at $Z = 1$ since its value at the site of a removed ion is pertinent to ionic polarization, dielectric saturation, and ionic compressibility

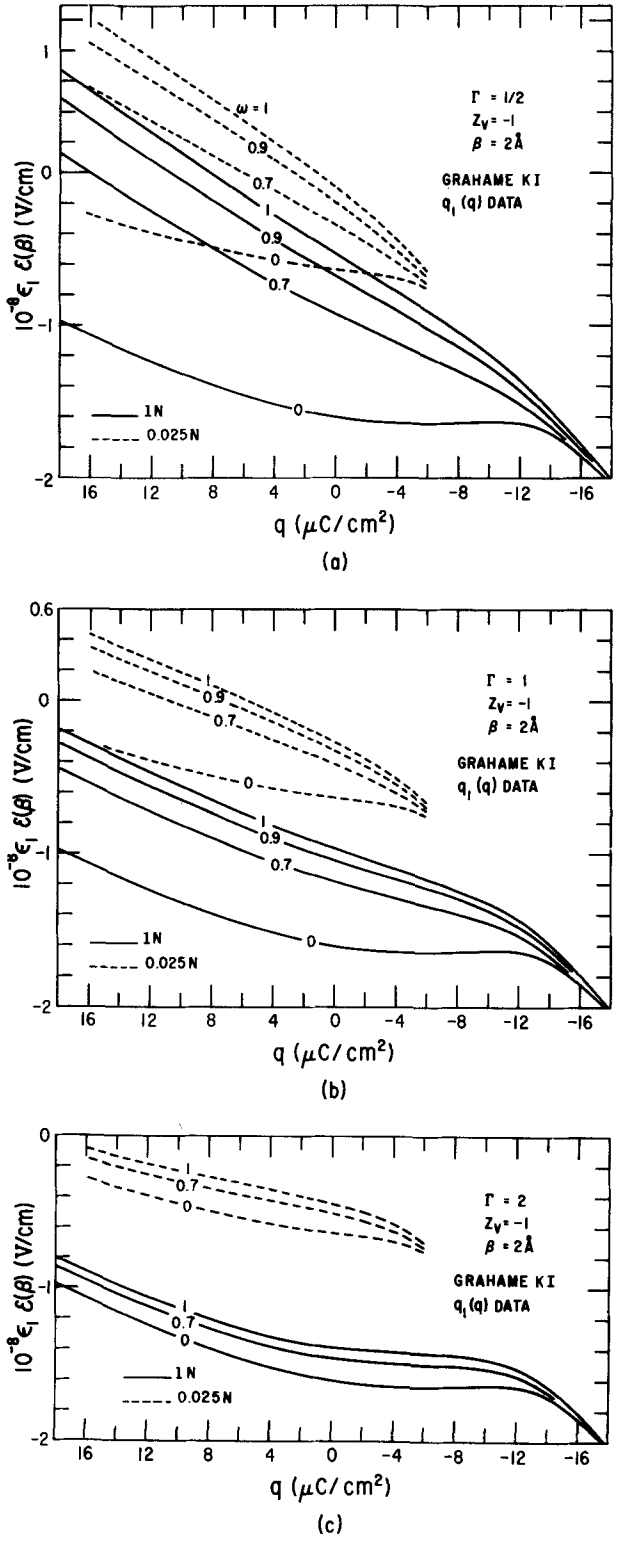

Fig. 5. Full electric field at the IHP, $\mathcal{E}(\beta)$, vs. average electrode charge density, q, using Grahame's KI $q_1(q)$ data for 1N and 0.025N concentrations; $\Gamma = \frac{1}{2}, 1, 2$; $\beta = 2$Å; and several values of ω.

effects (1). We show results in Fig. 5 using Grahame's $q_1(q)$ data for both $1N$ and $0.025N$ concentrations for the choice $\beta = 2$Å, which we now believe is a more likely value than the 3Å used in II. The results in Fig. 5 were calculated using the (b) and (c) approximants of Table I in the Appendix. The (b) approximant for $p(\xi)$ is particularly appropriate here since Z is fixed at one for these calculations and R_1 varies. The resulting approximant is therefore somewhat superior to that in (a) where R_1 is fixed at 5 and Z varies to produce changes in ξ. Since $F(\xi)$ is a small correction term, its $R_1 = 5$ approximant is quite adequate in the present case.

It will be seen from Fig. 5 that $\mathcal{G}(\beta)$ remains quite constant when $\omega = 0$ and remains so also even when $\omega \sim 1$ for $\Gamma = 2$. For $\Gamma = 1$, $\mathcal{G}(\beta)$ for the $0.025N$ concentration goes through zero in the experimental range of q when ω is about 0.4 or greater. Finally, when $\Gamma = \frac{1}{2}$, all of the curves shown change sign in the experimental range except those for $\omega = 0$. If we assume that the Γ appropriate to the actual experimental situation is 1 or less and that $0.7 < \omega \leq 1$, then it is evident that $\mathcal{G}(\beta)$ will vary sufficiently over the q range, for either $1N$ or $0.025N$ concentrations, that it will not be a good assumption to take ϵ_1 completely saturated and equal to 6 over the entire q range. For $\Gamma = 1$, $\omega = 0.9$, and this constant value of ϵ_1, the appropriate curve shows that $\mathcal{G}(\beta)$ varies from about 3.5×10^7 v/cm to 4×10^6 v/cm as q goes from -18 to $+18$ μC/cm^2. With ϵ_1 becoming less saturated and thus larger as $\mathcal{G}(\beta)$ decreases (20), $\mathcal{G}(\beta)$ at $q = 18$ μC/cm^2 might be as small as 2×10^6 v/cm. We remark again, however, that the introduction of an ϵ_1 at all in the present situation is a considerable approximation, making any conclusions about its variation uncertain.

Figure 6 shows the nonlinearity parameter Δ_0 for the usual values of Γ and many positive values of ω. These results form a bridge between the $\omega = 1$ results of I and the $\omega = 0$ results of II. Here and elsewhere in this paper all $\omega = 1$ and $\omega = 0$ results agree excellently with those previously given in I and II. We can now follow in detail the continuous change from one limiting case to the other, however. It should be noted that in the present paper the ω values 0 and 1 represent only limiting situations and are not examined in detail; more results for these specific values thus appear in I and II than are given here.

It will be noted from Fig. 6 that, except for ω values equal to or very near unity, Δ_0 is by no means negligible over most of the range of R_1 shown. At the top of Fig. 6a is shown a q_1 scale following from the R_1 scale when $\beta = 2$Å, probably a reasonable value for the KI system. The $R_1 = 2$ value, which is the smallest possible R_1 for close-packed spherical adions, corresponds to a q_1 of 115.6 μC/cm^2 for this choice of β. On the other hand, the largest value derived from Grahame's (22) experiments is about 43 μC/cm^2 (corresponding to $R_1 \simeq 3.3$ for $\beta = 2$Å), indicating a maximum adion surface coverage of about 37% for these experiments.

The dashed and dotted lines of Fig. 6b are calculated for the usual cut-off model of the inner region (8c, 18), not for a hexagonal array. They use values of $\psi_{a_0}{}^N$ obtained from Eq. [A-1] with constant p values, and [A-1] is applied for all Z and R_1 combinations since [A-4] is only applicable to the hexagonal array. The dotted-curve value $p = (\sqrt{3}/2\pi)^{1/2} \cong 0.5250376$ is Grahame's original figure. It is the value appropriate for a smeared array of charges and is thus also the value for the fixed hexagonal array when $\xi \to \infty$. It is the smallest value of p possible for such an array. The dashed-curve value $p = 4\pi/\sigma\sqrt{3} \cong 0.65752059$, where $\sigma \cong 11.034175$, is the value appropriate for an array of ideal dipoles when $\xi \to 0$ [see ref. (18)]. This p is thus the largest value possible with a hexagonal array. It is interesting that over much of the R_1 scale of interest, the accurate

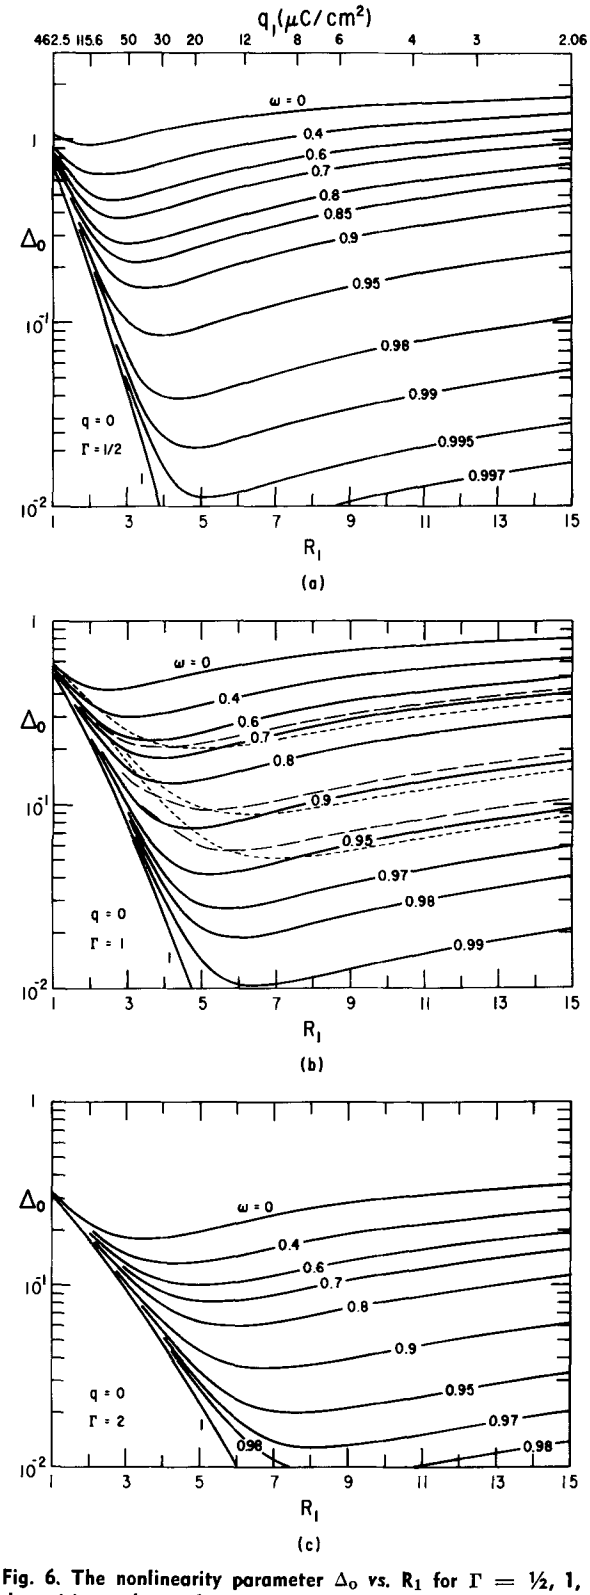

Fig. 6. The nonlinearity parameter Δ_0 vs. R_1 for $\Gamma = \frac{1}{2}$, 1, 2 and positive values of ω. Dotted lines were calculated using Grahame's cut-off model involving the constant value of p, $p_\infty \cong 0.5250376$. Dashed lines were calculated similarly with p again constant and equal to $p_0 \cong 0.65752059$. The nonlinear q_1 scale at the top of (a) is applicable for the choice $\beta = 2$Å only.

hexagonal-array results lie between those obtained with the above two limiting values of p. On the other hand, in the region of appreciable IHP charge density, say $2 \leq R_1 \lesssim 6$, where the fixed hexagonal array model is most appropriate at room temperature, we note regions of very appreciable deviation of the

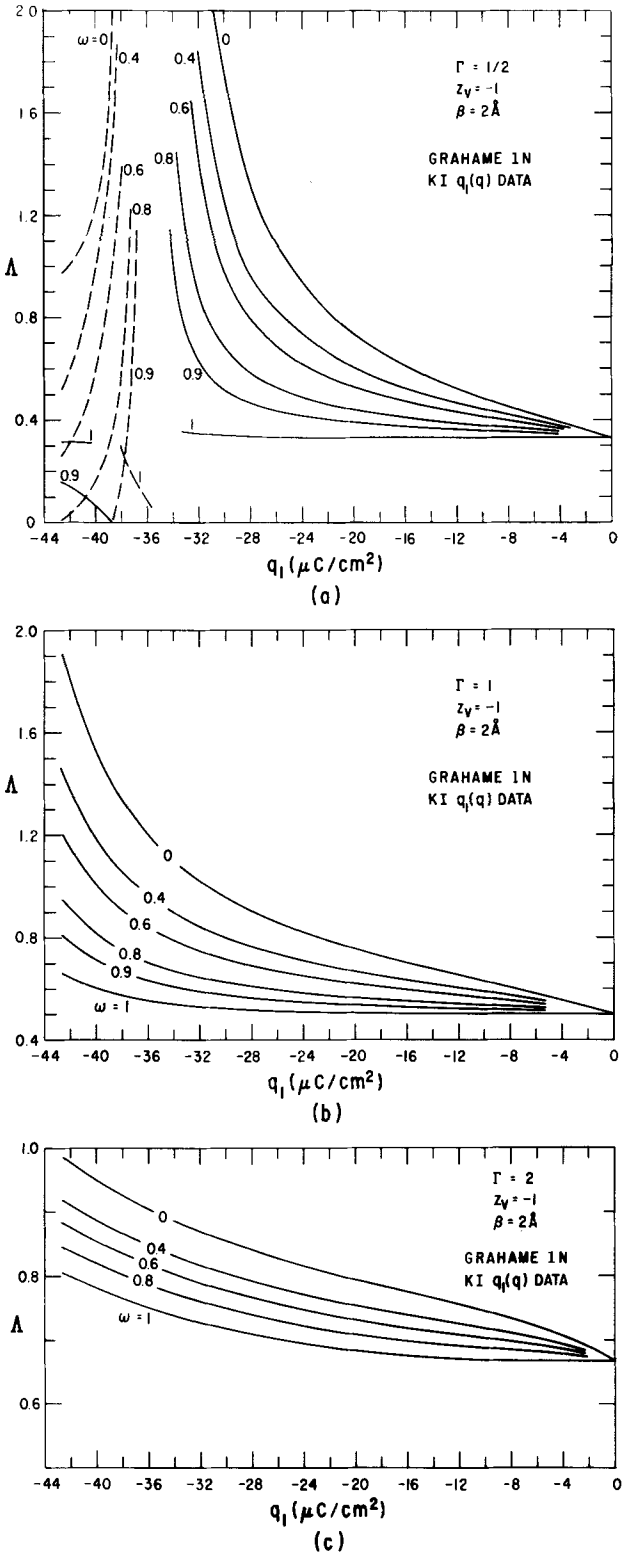

Fig. 7. Quantity $\Lambda \equiv \psi_1/V_1$ *vs.* Grahame's derived $q_1(q)$ for $\beta = 2$Å, $\Gamma = \frac{1}{2}$, 1, 2, and several positive values of ω. Dashed lines denote negative values.

fixed-p results from the hexagonal array results. In such a region, the hexagonal model is definitely preferable to a constant-p cut-off model. The exact charge density where the latter might be more preferable is difficult to determine [see (7, 17)], however.

Figure 7 shows the ratio of the micropotential to the macropotential, $\Lambda \equiv \psi_1/V_1$, *vs.* q_1 for $\Gamma = \frac{1}{2}$, 1, and 2, and several values of ω. Here again Grahame's (22) $q_1(q)$ values for 1N KI were employed in calculating Λ from Eq. [17]. For a given q, the corresponding q_1 was used to calculate R_1, using $\beta = 2$Å, then $\Delta\psi_a{}^N$ was calculated and was finally used in Eq. [17]. This calculation of $\Delta\psi_a{}^N$, and also most of those for Δ_o in Fig. 6, used the $R_1 = 5$ (3/3) approximant for $p(\xi)$ discussed in the Appendix together with Eq. [A-1] and [A-4]. We do not show Λ curves for the 0.025N concentration, but calculations for this case showed them to be quite similar to the 1N curves. We have elected to show Λ curves here instead of the corresponding Δ curves given in I and II because Δ turns out to be very appreciable for most of the curves (nonlinear distance dependence of ψ^N) and the ratio Λ is itself then of most direct interest.

Equation [17] shows that when $\Delta = 0$, $\Lambda = \lambda$. This is, of course, the case at the right of the Λ curves in Fig. 7 where $q_1 \approx 0$. Dashed lines are used in Fig. 7a to indicate negative values of Λ. These arise because V_1 may change sign, leading to a pole in Λ near $q_1 = -35$ μC/cm². Although both ψ_1 and V_1 are continuous, their ratio need not be. The peculiar behavior of the $\omega = 1$ curve in Fig. 7a is evidently produced by a zero in ψ_1 near but not at that of V_1.

The quantity of most interest for adsorption isotherms is ψ_1 itself. It can, of course, be readily obtained from the Λ values given here by multiplying by calculated values of V_1. In this paper, we shall not be directly concerned with adsorption isotherms and with the ψ_1 which enters them, reserving such discussion for another place (17). It is worthwhile to point out, however, that when Δ is neglected (often a good approximation for infinite imaging) and ψ_1 is then taken as λV_1, Grahame (22) and Grahame and Parsons (23) have found that the ψ_1 derived by using experimental results in a simple adsorption isotherm leads to a variable λ. Although this specific approach can probably be improved, it does lead to λ variation with q or q_1 of much the same form as that of Λ in Fig. 7b and c. In particular, λ is found to increase continuously for KI as q increases from −18 μC/cm² to 18 μC/cm². Reasonable values of Γ and ω can even be selected that lead to Λ variation quantitatively very similar to that found for λ, but we do not wish to stress this agreement even though the Grahame-Parsons $\lambda(=\psi_1/V_1)$ determined as above is formally fully equivalent to our Λ and they both equal the constant λ (a ratio of distances) of the present paper when $q_1 = 0$.

Dielectric ESP

While in the foregoing work metallic imaging is assumed to occur at a conducting electrode and dielectric imaging at the OHP, our mathematical model also pertains approximately to an entirely different system: At an electrolyte-dielectric interface, we may also have a surface phase in which ions are hexagonally arrayed on an "IHP." Separating this phase from the bulk electrolyte would be an "OHP;" separating it from the bulk dielectric would be an "ESP." While external charged electrodes might be present near the surface layer, producing a uniform field ψ_e, these electrodes need only be a microscopically large distance removed from the layer (a probable situation here) for their effect upon ψ_a to be negligible.

Our model in the present situation is that the OHP approximates to a metallic imaging plane and the ESP forms a dielectric imaging plane. Clearly, the OHP will approximate better and better to a conductive imaging plane the higher the concentration of ions in the diffuse layer. To maintain our previous equations with minimum change requires that we now define β as the IHP-OHP separation, γ as the IHP-ESP separation, q as the total surface charge density on the OHP, that we measure z from the OHP (thus $z = \beta + \gamma$ at the ESP), and that we define ϵ_1 and ϵ_2 to be the effective dielectric constants of the surface phase and bulk dielectric, respectively (see Fig. 8).

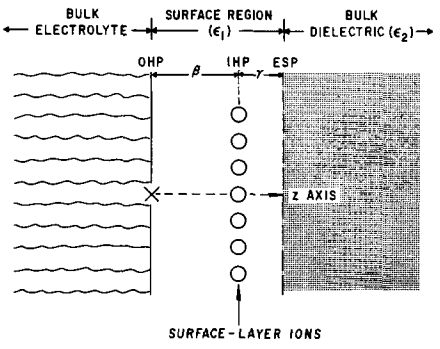

Fig. 8. Cross-sectional diagram showing appropriate situation and distances when the OHP is taken as a conducting plane.

There still remain certain differences between our system and the original compact layer for which our equations were derived. Most important of these is that the adion density on the IHP will now depend on the potential difference between the IHP and the conductive plane; thus, $\psi_1 \equiv \psi(\beta) - \psi(0) \equiv \psi(\beta)$, where "$\beta$" here is probably numerically equal to the "γ" of our original system. The reason for the present involvement of the conductive plane potential, which is of course zero, is that in this system the ions are presumed to originate (again neglecting V_2) from the conductive (outer Helmholtz) plane whereas earlier they originated from the dielectric imaging plane, and there the finite potential at the dielectric discontinuity had to be incorporated in the micropotential. Finally, apart from the numerical differences expected between new and old β's, γ's, q's, and so forth, we may now obtain with greater likelihood negative values for the parameter ω. Levine *et al.* (7b, 11) have discussed, to some extent, a situation where ϵ_2 is taken as 15, pertaining to silver chloride, and ϵ_1 taken as 10 or 15. In these cases, $\omega = 0.2$ and 0, respectively. On the other hand, the important air-electrolyte interface is a more common situation. For $\epsilon_1 = 10$ and 5, ω is about -0.82 and -0.67, respectively, for such a boundary.

We have already plotted in Fig. 3 and 4 normalized discrete potentials and displacements for $q = -q_1$ and negative values of ω. To make use of these curves in the present situation, however, we must interpret the plane marked OHP in those figures as being the ESP, and the plane $\xi = 0$, in the earlier case the ESP, as the OHP. The IHP is the same in both situations. The different interpretations now given to β and γ result in probable changes in the numerical values appropriate to these quantities; correspondingly, the numerical value of ψ_∞ is likely to be different. Note that if the numerical values of γ and β are simply interchanged in going from a conductive ESP to a dielectric ESP situation, then Γ in the dielectric situation has a magnitude which is just the reciprocal of that in the usual situation. Although we have only shown curves of potential and field applying when $q = -q_1$, the extension to the more general case is straightforward. The expression for ψ_e in the present situation is identical to that given for the case of a conducting electrode.

Finally, we wish to define and calculate a quantity Λ analogous to that defined for our original system. In the present situation, we shall again define

$$\Lambda \equiv \psi_1/V_1 = \psi(\beta)/V_1 = \psi^N(1)/V^N(Z_o) = \frac{[1 + (q/q_1)] - \psi_a{}^N(1)}{\Gamma + (1 + \Gamma)(q/q_1)} \quad [21]$$

This equation shows that when $q_1 \neq -q$ $\Lambda \to (1 + \Gamma)^{-1} = Z_o{}^{-1} = \Gamma^{-1}\lambda$ as $R_1 \to \infty$ for fixed q. Specializing now to the case most interesting and pertinent for the present situation, $q = -q_1$, we find $\Lambda = \psi_a{}^N(1)$, just the discrete-charge contribution to the normalized potential at the IHP. The choice $q = -q_1$ means that the charge on the IHP is entirely balanced by that in the diffuse layer, here taken to be on the (conducting) OHP. One would only expect $q \neq -q_1$ in the present situation when the inner layer was exposed to an externally applied field.

We have plotted curves for Λ *vs.* R_1 in Fig. 9. For completeness and because some authors have taken

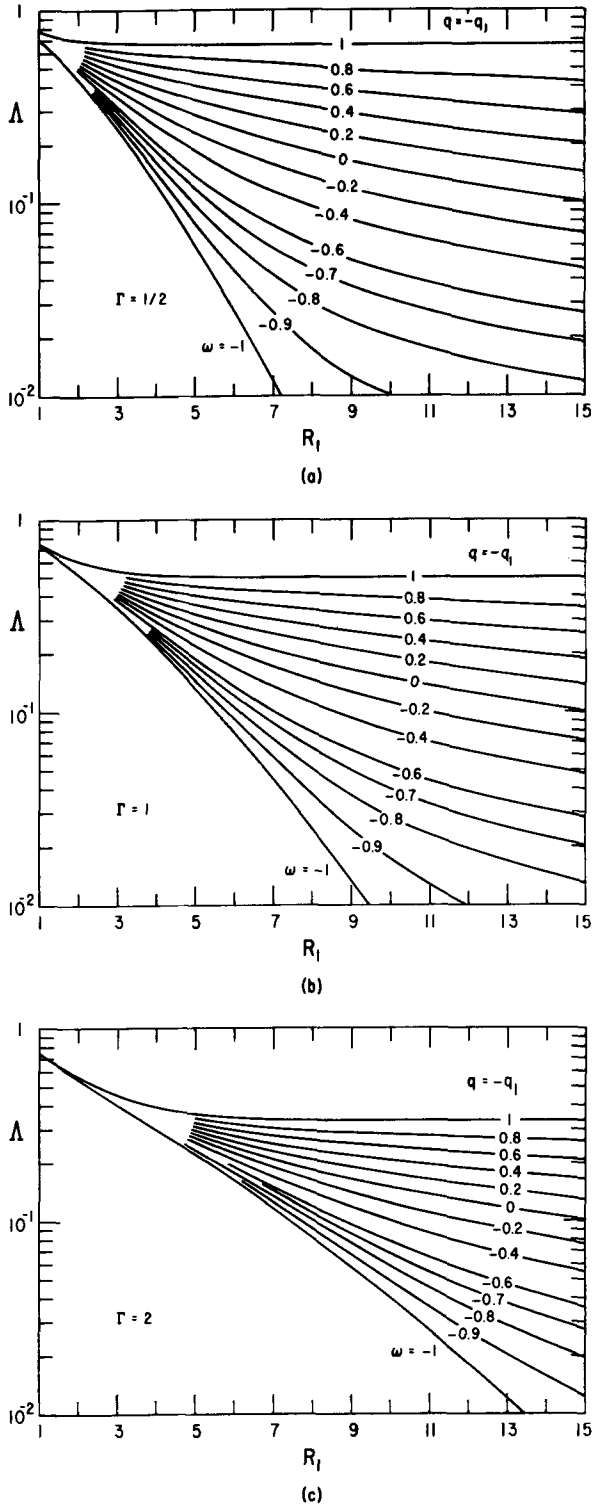

Fig. 9. Quantity $\Lambda \equiv \psi_1/V_1$ appropriate when the OHP is taken conducting *vs.* R_1 for $\Gamma = \frac{1}{2}$, 1, 2 for a full range of ω values. Here $q = -q_1$ and $\Lambda = \psi_a(\beta)/\psi_\infty$, pertinent to the conducting ESP case as well.

the OHP to be a metallic imaging plane in situations where the material beyond the ESP may lead to a positive value for ω, we show curves for positive ω values as well as negative ones. It will be noted that as R_1 increases all the $\omega = 1$ curves approach the limiting value $(1 + \Gamma)^{-1} = \beta/(\beta + \gamma)$. In this situation, $\psi_1 = \psi_a(\beta)$ is just the proper linear proportion, $\beta/(\beta + \gamma)$, of $V_1 = \psi_\infty$ and Δ, here defined through $\Lambda \equiv \Gamma^{-1}\lambda(1 + \Delta)$, would be zero as it should be. Again, we have presented curves of Λ rather than Δ since we believe Λ to be more significant in the present case.

The curves of Fig. 9 are particularly valuable since when $q = -q_1$, $\Lambda = \psi_a(\beta)/\psi_\infty$, and the curves show immediately how large the discrete-charge potential at the IHP is compared to the total potential (at large distances) set up by the array, ψ_∞. These results for $\psi_a{}^N(1)$ are, of course, just as appropriate for the situation of a conducting ESP discussed in the last section since they immediately give the relative ψ_a at the IHP in this case as well. Note further that since the average potential at the IHP, $V(\beta)$, is also ψ_∞ for $q = -q_1$, the curves show in addition how $\psi_a(\beta)$ differs from the average potential at the IHP.

In the present paper, we have made calculations based on a model in which there is one conductive imaging plane and one dielectric imaging plane (and have also included results appropriate for two conducting planes). These calculations were referred to two physical situations. In the first situation treated, the electrolyte was assumed to behave like a simple dielectric, mobile ions in the diffuse layer were not explicitly taken into account, and the OHP therefore was considered a dielectric imaging plane. In the second situation, the OHP was considered effectively to be a conductive imaging plane, and the dielectric imaging occurred elsewhere, at the surface of a true dielectric. How valid is our model for these two situations?

The theoretical difficulties associated with the first system have already been discussed somewhat and preclude a precise answer to this question for this case. However, we may make some reasonable guesses as follows. Inasmuch as the ions in the diffuse layer will cause the OHP to become to some extent a conductive imaging plane, we anticipate that the present model will not accurately portray the first system except possibly at ionic concentrations so low that the effective Debye lengths are larger than other characteristic dimensions of the system (*e.g.*, β and r_1), concentrations which are often lower than those of most interest. Note that the Debye length for $0.025N$ at 25°C is about 20Å. If $\beta = 2$Å, this corresponds to $R_1 = 10$, and complete neglect of any diffuse layer conductive imaging would probably then only be justified for R_1 values appreciably smaller than 10 for this bulk concentration. Although one might be tempted to apply the present model by using an effective ω, larger than that calculated on the basis of dielectric constants alone, which hopefully would approximately take into account the mobile ions, we do not here advocate this procedure as an entirely satisfactory solution to the problem for two reasons: Our own estimates of the importance of conductive imaging at the OHP for ionic concentrations such as $1N$ would imply effective ω values exceedingly close to unity, for which the Ershler model is appropriate. Furthermore, any actual small difference between the predictions of the Ershler model and those of the present model with $\omega \approx 1$ would probably be no larger than the errors introduced into the present treatment by the attempt to subsume the action of the diffuse-layer ions into an effective ω. Nevertheless, the present approach adequately illustrates for the first time the effects of the ever-present underlying dielectric imaging.

Concerning the second system considered, where the OHP is taken to be a conductive imaging plane, our evaluation of the model validity is accordingly considerably higher. The foregoing arguments which favor taking the OHP as just such an imaging plane are as encouraging in this situation as they were discouraging in the former one. We therefore feel that the present treatment pertains to a dielectric ESP (for the usual appreciable ionic concentrations) fairly well. If an accurate future theory should demonstrate that our present opinions are overestimates of conductive imaging at the OHP, then we would have to interchange our evaluations of the applicability of the present model to the two situations.

Acknowledgment

The authors greatly appreciate the help of Marilyn White and Charles Ratliff in writing the several computer programs used in this work.

APPENDIX

In another paper (18), we have discussed in some detail how Grahame's (8c) cut-off approximation for single imaging discreteness-of-charge potential calculations can be modified in a simple way to yield highly accurate results for hexagonal planar arrays of ideal or non-ideal dipoles. Here, we thus shall only quote results used in the present work.

For $\psi_{ao}{}^N$ and $\mathcal{E}_{ao}{}^N$ we may write

$$\psi_{ao}{}^N = \tfrac{1}{2}\{[(pR_1)^2 + (Z+1)^2]^{1/2} - [(pR_1)^2 + (Z-1)^2]^{1/2}\} \quad [A\text{-}1]$$

$$\mathcal{E}_{ao}{}^N = \tfrac{1}{2}\left\{\frac{Z+1-[(pR_1)^2/Z]F}{[(pR_1)^2+(Z+1)^2]^{1/2}} - \frac{Z-1-[(pR_1)^2/Z]F}{[(pR_1)^2+(Z-1)^2]^{1/2}}\right\} \quad [A\text{-}2]$$

In these equations, p and F (which are constant and zero, respectively in Grahame's work) are primarily functions of $\xi \equiv Z/R_1$ but depend slightly on R_1 as well (18). Here $F \equiv -d\ln p/d\ln\xi$. Using Chebychev rational function approximation methods, we obtained in ref. (18) very accurate, yet simple, approximations of the p and F functions which make [A-1] and [A-2] exact for hexagonal arrays. This method of approach was used because it was found that p changed only over a limited range for any fixed R_1 when ξ varied from 0 to ∞ and F was small over most of the range, reaching a maximum of about 0.14 near $\xi = 1$.

The rational function approximations for p and F are all of the type

$$f(\xi) = \sum_{i=0}^{n} a_i\xi^i \Big/ \sum_{i=0}^{m} b_i\xi^i \quad [A\text{-}3]$$

and may be termed (n/m) approximants. Note that $b_m \equiv 1$. In Table I we give the coefficients of (3/3) and (0/2) approximants for $p(\xi)$ and of a (2/3) approximant for $F(\xi)$. Coefficients of other simpler approximants are given in ref. (18). Here, we have used more complicated approximants than would normally be necessary in order to ensure accuracy of at least several decimal places in all the results calculated. In Table I, (a) values are for a fit which min-

Table I. Rational function coefficients for (a) $p(\xi)$ ($R_1 = 5$ fit), (b) $p(\xi)$ ($Z = 1$ fit) and (c) $F(\xi)$ ($R_1 = 5$ fit)

		(a) $\delta_R = 1.355 \times 10^{-4}$ (b) $\delta_A = 1.261 \times 10^{-3}$ (c) $\delta_A = 3.965 \times 10^{-3}$	
i		a_i	b_i
0	(a)	−41.607035	−63.857680

imized the absolute value of the relative deviations, δ_R, while (b) and (c) values were for fits which minimized the absolute values of the absolute deviations, δ_A, between accurate values and approximate predictions. Values of the pertinent δ_R and δ_A's are shown in the table and illustrate the high accuracy of the approximants.

We have used the above expressions for $\psi_{ao}{}^N$ and $\mathcal{E}_{ao}{}^N$ for a hexagonal array for $Z < 1 + 3R_1$. When $Z \geq 1 + 3R_1$, however, the results of II reduce to

$$\psi_{ao}{}^N \cong 1 - (\sqrt{3}/4\pi)\,[R_1{}^2/(Z^2 - 1)] \qquad [A\text{-}4]$$

and

$$\mathcal{E}_{ao}{}^N \cong (\sqrt{3}/2\pi)\,[ZR_1{}^2/(Z^2 - 1)^2] \qquad [A\text{-}5]$$

accurate to about eight figures when $Z = 1 + 3R_1$ and becoming even more accurate as Z/R_1 increases further. Therefore, these simple expressions were employed in place of [A-1] or [A-2] when $Z \geq 1 + 3R_1$.

GLOSSARY

Basic Parameters of System

e	Charge of proton
q_1	Average surface charge density on IHP
q	Total surface charge density on conductive plane
z_v	Effective valence of surface-layer ions
ϵ_1	Effective dielectric constant of surface region
ϵ_2	Effective dielectric constant of dielectric region
β	Distance from IHP to conductive plane
γ	Distance from IHP to dielectric imaging plane
d	$\beta + \gamma$ = thickness of surface region
r_1	Lattice spacing of surface-layer ions
ω	$(\epsilon_2 - \epsilon_1)/(\epsilon_2 + \epsilon_1)$
η	$1 + \omega = 2\epsilon_2/(\epsilon_2 + \epsilon_1)$
λ	$\gamma/(\beta + \gamma)$
Γ	γ/β
ρ	$2d/\beta$
(x,y)	Coordinates in a plane parallel to IHP, generally set to zero here
z	Coordinate of position normal to ESP
Z	z/β
R_1	r_1/β
Z_o	$1 + \Gamma = d/\beta$
ξ	$Z/R_1 = z/r_1$

Unnormalized Potentials and Fields

ψ	$\psi_a + \psi_e \equiv$ actual potential at a point (x,y,z)
ψ_e	Portion of potential arising from a uniform electric displacement
ψ_a	Portion of potential arising from discrete system of charges and images
ψ_{ao}	Discrete potential in single image regime
ψ_{acc}	Discrete potential in infinite image regime
$\mathcal{E}$	Actual electric field, associated with ψ
$\mathcal{E}_a$	Field associated with ψ_a
$\mathcal{E}_{ao}$	Field associated with ψ_{ao}
$\mathcal{D}_a$	Displacement associated with ψ_a

Potential Differences, Average Quantities, and Normalizing Factors

ψ_1	Micropotential $\equiv \psi$(at IHP) $- \psi$(at OHP)
V_1	Average potential drop across surface layer
V_2	Potential drop across diffuse layer
$V(z)$	Average potential in a plane $z =$ constant
ψ_∞	$(4\pi\beta q_1/\epsilon_1)$ = average potential drop arising from discrete array of charges and images; used as a normalizing factor
ϵ_∞	Normalizing quantity for fields $\equiv -\psi_\infty/\beta$
ϕ_∞	Normalizing quantity for displacements $\equiv \epsilon_1\mathcal{E}_\infty$

Normalized Potentials and Fields

ψ^N	ψ/ψ_∞
$\psi_a{}^N$	ψ_a/ψ_∞
$\psi_{ao}{}^N$	ψ_{ao}/ψ_∞
$\psi_e{}^N$	ψ_e/ψ_∞
$\psi_1{}^N$	ψ_1/ψ_∞
$V_1{}^N$	V_1/ψ_∞
$V^N(Z)$	$V(z)/\psi_\infty$
$\Delta\psi_a{}^N$	$\psi_a{}^N(1) - \psi_a{}^N(Z_o)$
$\mathcal{E}^N$	$\mathcal{E}/\mathcal{E}_\infty$
$\mathcal{E}_a{}^N$	$\mathcal{E}_a/\mathcal{E}_\infty$
$\mathcal{E}_{ao}{}^N$	$\mathcal{E}_{ao}/\mathcal{E}_\infty$
$\mathcal{E}_e{}^N$	$\mathcal{E}_e/\mathcal{E}_\infty$
$\mathcal{D}_a{}^N$	$\mathcal{D}_a/\mathcal{D}_\infty$

Other Quantities

Λ	$\psi_1/V_1 \equiv$ a quantity measuring ratio of micropotential to full surface layer average p.d.
Δ	A quantity measuring departure from a strict proportionality between ψ_1 and V_1. When the ESP is conductive, $\Lambda \equiv \lambda(1 + \Delta)$; when the ESP is dielectric, $\Lambda \equiv \Gamma^{-1}\lambda(1 + \Delta)$
Δ_o	Value of Δ for $q = 0$
p,F	Quantities used in our modified cut-off approximation for ψ_a and $\mathcal{E}_a$

Discussion

H. D. Hurwitz: It must be stressed that the value of the micropotential is not sufficient to account for the total coulombic interaction among adsorbed particles. This is shown easily by deriving, as indicated next, the total coulombic energy of interaction for a set of charges of species α adsorbed at the inner Helmholtz plane (IHP), assuming as usual that: 1, the interaction α-solvent is implicitly stated in the definition of the local dielectric constant ϵ_0 and of the pair correlation function $g1,2$ introduced below; 2, the interaction α-diffuse layer charge is described by a simple average electrostatic effect in which the ionic distribution in the diffuse layer is smeared out over parallel planes to the electrode; 3, the dielectric discontinuity near the outer Helmholtz plane (OHP) leads to partial or total reflection of the charge e_α of α.

Under these conditions we assume that the surface density of α is p_α. Hence $p_\alpha 1$ gives the probability to find α at one given position, 1, of the IHP. The probability to encounter a neighbor to α at position 2 is then by definition $g1,2\ p2$ where $g1,2$ is the radial distribution function. The coulombic interaction between these two particles is $(e^2_\alpha/\epsilon_0)\gamma 1,2$ where $\gamma 1,2$ represents the reduced coulombic potential at 2 corresponding to an isolated charge located at the IHP at 1. The quantity $\gamma 1,2$ includes the effects of partial or total infinite reflections into the dielectric discontinuities of the model.

The probable pair interaction for positions 1 and 2 is

$$\frac{e^2_\alpha}{\epsilon_0}\gamma 1,2\, g1,2\, p_\alpha 1\, p_\alpha 2 \qquad [1]$$

Let us sum over all particles on the IHP considered to interact with α at 1 and over all central positions, 1, in order to get finally the total interaction energy

$$\frac{e^2_\alpha}{2\epsilon_0}\sum_1\sum_2 \gamma 1,2\, g1,2\, p_\alpha 1\, p_\alpha 2 \qquad [2]$$

(Because of symmetry of $\gamma 1,2\ g1,2$ the quadratic sum is divided by 2.) Instead of summing over all 1 and 2 we may integrate over-all distances s_{12} between 1 and 2 and over-all positions 1 in order to get finally

$$\Omega\frac{e^2_\alpha}{2\epsilon_0}\int g1,2\,\gamma 1,2\, p^2_\alpha\, ds_{12} \qquad [3]$$

where Ω is the total area of the IHP.

The change of interaction energy on introduction of one particle α is obtained through differentiation of [3]. Therefore

$$\frac{e^2_\alpha}{2\epsilon_0}\int \gamma(s_{12})\,\frac{\partial}{\partial p_\alpha}\,(g(s_{12})\,p^2_\alpha)\,ds_{12} \qquad [4]$$

It is clear that [4] is the contribution of coulombic interactions among specifically adsorbed charges to the change of potential energy of adsorption. A more convenient way to write [4] is to decompose this expression in the following manner

$$e_\alpha\left[p_\alpha\frac{e_\alpha}{\epsilon_0}\int\gamma(s_{12})ds_{12} + p_\alpha\frac{e_\alpha}{\epsilon_0}\int\gamma(s_{12})[g(s_{12})-1]ds_{12}\right] + \tfrac{1}{2}\,p^2_\alpha\frac{e^2_\alpha}{\epsilon_0}\int\gamma(s_{12})\,\frac{\partial}{\partial p_\alpha}\,g(s_{12})\,ds_{12} \qquad [5]$$

In view of the fact that the first term in [5] corresponds to the effect at [1] of charges uniformly distributed over the IHP, it is readily inferred that by definition this term pertains to the average electrostatic potential (macroscopic potential).

The second term is then a correction which results from discreteness-of-charge effects [$g(s_{12})$ is different from unity] and the first and second term together represent the so-called micropotential.

At this point we have to realize that whenever we introduce in our system at position 1 an ion α we do not alter only the local density p_α, but we modify simultaneously the radial distribution of particles. This in turn gives rise to some interaction energy. The last term of [5] reflects such an effect of radial redistribution. The contribution of this effect to the free energy of adsorption has yet been considered only from a qualitative viewpoint[1,2] and is generally neglected. However, a careful evaluation based on a simple model for $g1,2$ has led[3] to the conclusion that such work of redistribution is not negligible at all and may even be of the order of magnitude of the discreteness-of-charge correction as given by the second term in expression [5]. In the crude hexagonal lattice approximation of Ershler, in which no allowance is made for thermal motion, the $g1,2$ functions are represented by delta Dirac functions.

C. A. Barlow, Jr.: Three points seem to have been raised here. First, "that the value of the micropotential is not sufficient to account for the total coulombic interaction among adsorbed particles;" second, "that the work of redistribution is not negligible at all and may even be of the order of magnitude of the dicreteness-of-charge correction;" and third, that the hexagonal lattice approximation is crude, the use of exact two-particle correlation functions being preferable.

We disagree with the first point; however, the disagreement possibly stems merely from a different use of words: We assert[4] that the total coulombic energy $U(N)$ of a system of N charges is given by a sum over all particles of the local potential times one-half the charge; in other words, we agree entirely with Dr. Hurwitz's Eq. [2] within the approximation of the model. Now except for a contribution, V_2, from the diffuse layer, the "local potential" occurring above is just the micropotential. To equate the two involves the neglect of V_2 in the micropotential, to be sure, but this is discussed in our present paper just after Eq. [14], and this doesn't seem to be Dr. Hurwitz's objection. His objection, as seen from the second point raised, is that we are somehow neglecting rearrangement energy. This is not true; in the first place, in the present paper we did not need to calculate the energy of adsorbing one additional ion, $\Delta U \equiv U(N+1) - U(N)$. We have shown explicitly[4] that, having found the micropotential, we have a means of calculating the related quantity $U(N)$ in accordance with the foregoing. In the second place, our approach does lead to the redistribution energy in essentially the same way that it arises in Dr. Hurwitz's discussion when one finally gets down to the business of calculating ΔU, the energy of adsorption. The only difference in approach is that we initially calculate $U(N)$ and save the differencing with respect to N until the very last (as may be seen from our papers[5,6] where we determine the total energy for adsorbing an additional

ion). We agree with Dr. Hurwitz's statement about orders of magnitude; we were, in fact, the first to make a correct quantitative study of redistribution energy in the present system. Indeed, although this question was considered quantitatively by us in the work cited by Dr. Hurwitz[4] and a curve plotted to show the numerical magnitude of the effect for a wide range of surface coverages, in his discussion Dr. Hurwitz only references his own unpublished work to support "the conclusion that such work of redistribution is not negligible at all and may even be of the order of magnitude of the discreteness-of-charge contribution." It is of interest to note that in our previously published work[4] we explicitly state that the work of redistribution is of the same order of magnitude as the full adsorption energy and is not at all negligible. Dr. Hurwitz seems to have missed noticing the significance of the quantity η in our paper,[4] since he refers to this paper as considering the question "only from a qualitative viewpoint." Further quantitative treatment of this matter will soon appear.[5]

Finally, that the hexagonal model may be "crude" cannot be denied. We have already presented a discussion of just how crude it may be under some conditions.[6] If the proper correlation functions were known, they would certainly be preferable to the δ-function lattice model. They are not known, however, so our approach has been to try to keep the following statement (concerning statistical physics) of Richard Feynman[7] in mind:

"Anyone who wants to analyze the properties of matter in a real problem might want to start by writing down the fundamental equations and then try to solve them mathematically. Although there are people who try to use such an approach, these people are the failures in this field; the real successes come to those who start from a physical point of view, people who have a rough idea where they are going and then begin by making the right kind of approximations, knowing what is big and what is small in a given complicated situation. These problems are so complicated that even an elementary understanding, although inaccurate and incomplete, is worth while having. . . ."

We believe the hexagonal array approach to be the "right kind of approximation" for a q_1 range of practical importance.[6]

Richard Payne: According to the results in Fig. 7, the ratio of ψ_1/V_1 is uniformly larger for the single imaging limit than for the infinite imaging limit. This does not seem consistent with the Esin and Shikov and Grahame calculations for the single imaging case which overexplained the Esin and Markov effect (*i.e.*, ψ_1/V_1 too small); whereas Ershler's treatment of the infinite imaging case gave larger values of ψ_1/V_1. It seems, therefore, that the trend in Fig. 7 as ω varies is inverted.

J. Ross Macdonald and *C. A. Barlow, Jr.*: The apparent discrepancy pointed out by Dr. Payne is not significant for several reasons. First, the single-imaging treatments of Esin and Shikov and Grahame not only treat a physically very different situation than the present single-imaging one but the situation treated is much less physically appropriate than is ours. Second, we properly include the uniform D field contribution to the single-imaging micropotential, omitted by other authors. The Esin-Shikov and Grahame treatments are not really single-image ones at all since they consider fixed arrays of adsorbed ions each with a rigidly paired counterion in the diffuse layer. The counterions are not taken as images of the adions but as real associated ions a fixed perpendicular distance from the adions. Ershler has modified this approach by considering single imaging of the adions in the diffuse layer, a preferable assumption. This is indeed a single-imaging treatment, but it necessarily still disagrees with our $\omega = 0$ results in Fig. 7 since there we take imaging in the electrode instead of the solution, take q variable, and include the D field contribution.

The significant point regarding Fig. 7 is that for reasonable Γ values the $\omega = 1$ curves generally yield micropotential values which are smaller than they should be to explain the Esin-Markov effect (Λ too small) while the $\omega = 0$ results yield micropotentials which are too large to explain it. For an appropriate value of Γ, it appears possible to pick a ω value near but less than unity which will lead to results which will explain the Esin-Markov effect (within the limitations of the present treatment) better than will results with either $\omega = 1$ or 0.

Richard Payne: It is not clear why grounding of the electrode should affect the charge on the metal since the whole system is electrically neutral. If the effect of grounding the electrode were to eliminate the uniform displacement component ψ_e, then it would be possible to determine the point of zero charge simply by measuring the potential of the grounded electrode with respect to a reference electrode.

J. Ross Macdonald and *C. A. Barlow, Jr.*: Actually one could not measure the ecm potential in this way without additional information about the system: The condition that the electrode is grounded is not the same as the condition of zero charge. The charge on the electrode which produces the ground condition depends on the imaging situation which applies, as well as the adsorbed surface charge density. Specifically, for single and for dielectric imaging the condition is that $q = -q_1$, whereas for infinite-conductive imaging we have $q = -\dfrac{\gamma}{\beta + \gamma} q_1$ at the ground condition. However, if one knew the physical (imaging) situation and measured q_1 with the electrode grounded, one might be able to infer from the average potential drop across the compact layer what the ecm potential is.

Richard Payne: I think it is important to point out that λ in the Grahame-Parsons analysis is not fully equivalent to ψ_1/V_1 in this treatment as stated by the author for the following reason. In the Grahame-Parsons analysis λ is obtained from the experimental results by investigating the concentration dependence of the adsorption energy at constant charge in the electrode. λ is therefore an average value over a range of concentrations and amounts adsorbed. In other words, the imaging conditions in the diffuse layer are not kept constant during the calculation whereas the calculations given here refer to definite imaging conditions in the solution.

J. Ross Macdonald: Our $\Lambda \equiv \psi_1/V_1$ is formally equivalent, as stated, to Grahame and Parson's $(\psi^i - \psi^o)/\psi^u$, which they set equal to λ on the basis of an approximate infinite-imaging treatment. Experimental results seem to indicate that the ratio $(\psi^i - \psi^o)/\psi^u$ depends only slightly, if at all, on the concentration. It therefore seems reasonable to compare our theoretical results, which assume a definite degree of dielectric imaging at the OHP, with experimentally derived results obtained using various concentrations. We do not expect much change of ω with concentration, and the change in the average charge density in the diffuse layer apparently does not affect the ratio with which we compare appreciably. The comparison thus appears useful even though there are approximations involved which preclude perfect agreement between theory and experiment.

[7] R. Feynman, R. B. Leighton, and M. Sands, "The Feynman Lectures on Physics," Vol. I, p. 39-2, Addison-Wesley, Reading, Mass. (1963).

Richard Payne: The authors have pointed out that the value of λ (and hence ψ_1) obtained in the Grahame-Parsons analysis is dependent on an assumed form of the isotherm which I think is an important point. Incidentally, I would also like to point out that λ also depends on whether the anion activity or the salt activity is used in the isotherm.

In this context, it seems to me that the Frumkin isotherm or better the Flory-Huggins modification of the Frumkin isotherm introduced by Parsons offers an excellent starting point for the experimental study of discreteness of charge effects for the following reasons. If we write down the Stern form of the isotherm,

$$\frac{\theta}{1-\theta} = a_{\pm} \exp\left[(\psi_1 + \Phi)F/RT\right] \qquad [1]$$

and compare this with the Frumkin isotherm in the form

$$\frac{\theta}{1-\theta} = \frac{a_{\pm}}{\Gamma_s} \exp\left[-\frac{\Delta G^{\circ}}{RT} + f(q) - A\theta\right] \qquad [2]$$

it seems reasonable to equate the specific adsorption potential Φ with the standard free energy of adsorption at zero coverage $-\Delta G^{\circ}$, *i.e.*

$$F\Phi = -\Delta G^{\circ} - \ln \Gamma_s \qquad [3]$$

and to write ψ_1 as

$$\frac{F\psi_1}{RT} = f(q) - A\theta \qquad [4]$$

where $f(q)$ is the form of the charge dependence of the standard free energy of adsorption at zero coverage and A is the lateral interaction coefficient of the adsorbed anions. I think it is clear from [4] that the Frumkin isotherm with a constant value of A represents the infinite imaging limit to a close approximation since the adsorption energy is linearly dependent on the amount adsorbed. Deviation from the linear θ dependence of the lateral interactions, *e.g.*, a $\theta^{3/2}$ dependence for single imaging should show up as variation in A when the Frumkin isotherm is applied. It is interesting to note that apparent variation of A is often found for adsorption of anions from solutions of a single salt.

A further point I would like to make here is that the infinite imaging case also leads to linear charge dependence of $-\Delta G^{\circ}$ providing the effect of replacement of oriented solvent dipoles is neglected and providing the dielectric constant is assumed constant:

$$\psi_1 = \frac{\gamma}{\beta+\gamma} V_1 = \frac{\gamma}{\beta+\gamma} \cdot \frac{4\pi}{\epsilon}\left[q + \frac{\gamma}{\beta+\gamma} \cdot q^1\right]\beta + \gamma$$

$$= \frac{\tau\pi\gamma}{\epsilon} q + \frac{4\pi}{\epsilon} \cdot \frac{\gamma^2}{\beta+\gamma} \cdot q^1$$

Deviations from the linear charge dependence of $-\Delta G^{\circ}$ can arise (*i*) from replacement of oriented dipoles which would contribute a term $4\pi n\bar{\mu}/\epsilon$ to V_1 where n is the number of dipoles replaced by each ion and $\bar{\mu}$ is the mean normal component of the dipole moment and (*ii*) through deviations of ψ_1/V_1 from constancy resulting from imperfect imaging in the solution.

J. Ross Macdonald and *C. A. Barlow, Jr.*: We do not agree that ψ_1 is given by $\frac{\gamma}{\beta+\gamma} V_1$ only that the uniform field part is given by this quantity in the infinite-conductive imaging situation. The linearity of ψ_1 with charge on the electrode, q, is independent of this, however, and in fact does not depend on the type of imaging present. We only refer to the explicit dependence of ψ_1 on q. Since evidently as q changes q_1 will generally change as well, we do not include all q-dependence in the present discussion. We are in fact referring to the linearity of ψ_1 with q under hypothetical circumstances where the constitution of the compact layer is held fixed and only q is allowed to change. Accordingly, we agree with the statement that ψ_1 will be explicitly linear with q, but disagree with the reasoning which led to this conclusion and with the comments concerning causes for "deviations from the linear charge dependence of $-\Delta G^{\circ}$." On the other hand, the remarks about "deviations . . . (etc.)" are interesting and pertinent if by "charge dependence" is meant "dependence on q_1." Note, however, that if one is concerned with the dependence of ψ_1 on q_1, he must include the contribution from the discrete ions and their images (ψ_a), and that such inclusion will itself destroy the linearity without the additional help of the two effects cited by Dr. Payne.

Roger Parsons: I think it is fair to say that the general idea of the discreteness of charge effect is widely accepted and is supported by several pieces of experimental evidence. However, it is much more difficult to demonstrate experimentally the fine details of the models proposed, *e.g.*, whether imaging is partial or infinite, whether the hexagonal lattice or the disordered models provide the closest approximation to reality. I should emphasize the importance of attempting to verify these models by experimental test. We have tried to examine imaging in the diffuse layer recently[8] and suggest that it is not complete. However, this work does not test the efficiency of imaging in the dielective jump.

In connection with the problem of thermal motion, is it correct to say that some of the difference between you and Levine *et al.* is due to the fact that you assume a lower dielective constant in the inner layer? A value of 6 or 7 seems more reasonable than 15.

I would like to point out that the variable λ obtained by Grahame and Parsons was further analyzed by Parry and Parsons[9] and an improved model suggested.

Finally, I think it is interesting to note that the elegant method of summation proposed in this paper has some relation to the intuitive way in which David Grahame discussed the potential drop in the inner layer[10].

J. Ross Macdonald and *C. A. Barlow*: We believe this difference of opinion as to the proper value of the dielectric constant to use in these circumstances is the only significant disagreement between Levine and his co-workers and ourselves although there are small perturbations on the final numbers for lattice stability coming from slight differences in stability criteria, etc. In a recent paper by Bell, Mingins, and Levine[11] the inner-layer dielectric constant is taken to be 10. As you have pointed out we have generally taken 5 or 6 to be more typical of the inner-layer dielectric constant, to the extent that one can define such an object. This choice was motivated by our prior work on differential capacitance in the electrical double layer. However, in later theoretical studies on electrode work function change, we calculate that the dielectric constant in some systems may be completely different from bulk values insofar as work function effects are concerned. The significant phrase is "insofar as work function effects are concerned." It turns out that the use of a single dielectric constant to characterize dielectric effects in the inner layer is incorrect, since this region is so completely different from three-dimensional bulk matter. We have re-

cently estimated the dielectric constant effective in reducing the lateral interaction between adions and find that it is no greater than 2, and more likely to be closer to unity. So you see the question of the proper dielectric constant to use is a rather confused one. It seems to us that all previous estimates of lattice stability in the inner-layer (including our own) have employed a dielectric constant which is at least 3 times too large, and possibly much worse than that.

It is completely correct that our image summation method stems from that originally used (for $\omega \equiv 1$) by Grahame. We have generalized the approach to include the $|\omega| < 1$ case. In this connection, we think it is interesting to note a certain difficulty not fully appreciated by Grahame which troubled us for a while: Whereas the summation technique used here is absolutely convergent for all $|\omega| < 1$, the series is only conditionally convergent for $\omega = 1$. As it happens, the particular arrangement of terms employed by Grahame and ourselves in the $\omega = 1$ case leads to the potential appropriate for $q = -q_1$. Since this does not coincide with the condition $q = -\gamma q_1/(\beta + \gamma)$ obtaining when both imaging planes are at zero potential, this accounts for Grahame's conclusion that the infinite set of images and the adions contribute to the total p.d. across the inner layer, an incorrect conclusion for the model with conductive imaging at the OHP.

The Adsorption of Aromatic Sulfonates at a Mercury Electrode

II. Sodium p-Toluenesulfonate—An Example of Two-Position Adsorption

J. M. Parry[1] and R. Parsons

Department of Physical Chemistry, The University, Bristol England

ABSTRACT

The adsorption of the p-toluenesulfonate ion on a mercury surface from aqueous solution has been studied by measuring the interfacial tension and the capacity of the electrode as a function of concentration. An interpretation of the results is proposed in terms of two orientations of the adsorbed ion. A simple model of this type of system is proposed, at first neglecting interaction between adsorbed ions other than due to their space-filling properties. A very approximate allowance for interaction is introduced, and it is concluded that consideration of interaction is essential for a full description of the system.

In the previous paper of this series (1), we described the adsorption of the benzene m-disulfonate (BMDS) ion which may be treated by methods closely analogous to those used for simple ions such as the halides. This is essentially because adsorption of this ion occurs with the plane of the benzene ring oriented parallel to the plane of the mercury solution interface over the whole of the experimentally accessible range. As we mentioned previously, the behavior of the p-toluenesulfonate (PTS) ion is more complicated and, as we shall show in the present paper, it cannot be analyzed by using the surface pressure in a simple way. This is due to the existence of the adsorbed species in more than one orientation, and we believe that this system provides a clear-cut example of two position adsorption. This problem has been discussed in a qualitative way by Damaskin *et al.* (2); here a more quantitative description is attempted.

Experimental

Measurements of differential capacity and interfacial tension were carried out as described previously (1). Sodium p-toluenesulfonate was recrystallized three times from equilibrium water; it crystallizes as the hemihydrate from concentrated solutions. The water content was determined by heating and weighing and also volumetrically after exchanging the Na^+ for H^+ on an ion exchange resin.

Results

The concentration dependence of the capacity at constant temperature is shown in Fig. 1. It is evident from these data that the behavior of PTS is qualitatively different from that of BMDS as shown in Fig. 1 of ref. (1). At the lower concentrations up to 0.1M the capacity curves for both ions are similar in showing a marked peak at a potential of about −0.6v (SCE). However, as the concentration is increased above 0.1M this peak is lowered, eventually being replaced by a minimum, while a higher and narrower peak develops at more negative potentials (up to −1.4v *vs.* SCE). These results suggest that at low bulk concentrations the PTS ion is lying flat on the mercury surface like the BMDS ion while at higher concentrations re-orientation occurs to allow closer packing of the PTS ion.

Potentials are measured with respect to the saturated calomel electrode at the temperature of the experiment.

diameter in the region of the maximum. The agreement between the integrated capacity curves and the experimental electrocapillary curves was within the experimental accuracy expected (approximately 0.5 dyne cm^{-1}) except at negative charges where the discrepancy rises to about 3.5 dynes in the most concentrated solution. This may be due to the measured capacity in the region of the cathodic peak being somewhat lower than the true equilibrium value, although no frequency dependence or increase of series resistance was observed. In this region, therefore, the electrocapillary measurements were used in preference to those derived from capacity curves.

The measured potentials were converted to an E^+ scale assuming that the liquid junction potential between the test solution and saturated potassium chloride is independent of the concentration of the test solution. Activity coefficients for sodium p-toluenesulfonate (4) were extended to concentrations below 0.1M using the values for KNO_3 as a guide (5). Values of the function (6) $\xi_+ = \gamma + qE^+$ were calculated and plotted against $(2RT/F) \ln a_\pm$ ($a_\pm$ is the mean activity of the salt) for integral values of q. These plots were differentiated graphically to obtain the component of charge (q_-) on the solution side of the double layer due to the anion. The cation was assumed not to be specifically adsorbed, and the surface charge contributed by it was used to calculate the charge due to anion in the diffuse layer. Classical diffuse layer theory (7) was used as it causes little error in this type of calculation (8). The resulting values of the charge due to the specifically adsorbed anions are shown in Fig. 2. It is not possible to obtain more accurate values by fitting the $\xi_+ - \log a_+$ curves with an integrated adsorption isotherm as described

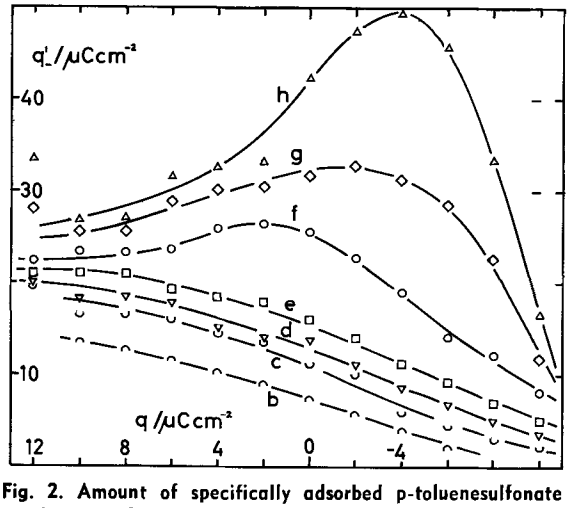

Fig. 2. Amount of specifically adsorbed p-toluenesulfonate ion per unit area of a mercury electrode expressed as charge plotted against the charge on the mercury electrode at 30°C. Letters have the same significance as those in Fig. 1.

previously because the adsorption isotherm for this system is too complex owing to the change in orientation of the adsorbed species.

We may note from Fig. 2 that at the lower concentrations the adsorption behavior is very similar to that of BMDS as noted above. As the charge on the metal becomes more positive, the amount adsorbed appears to approach a limit corresponding to complete coverage by flat adsorbed ions. The limiting charge of about 30 $\mu C\ cm^{-2}$ corresponds to an area per ion of 53 A^2, close to the calculated area of the flat ion. We may also note that the monotonic rise in the adsorption as q increases in this concentration range is consistent with a standard free energy of adsorption which is linearly dependent on the electrode charge. In contrast at the highest concentration studied the adsorption rises to 50 $\mu C\ cm^{-2}$ corresponding to an area per ion of 32 A^2 which is too small for ions lying flat, but is consistent with an orientation of the benzene ring with its plane perpendicular to that of the interface. Further, the existence of a maximum in the amount adsorbed in Fig. 2 is similar to the behavior of neutral molecules and suggests that the vertically oriented molecules have a standard free energy of adsorption which depends on the square of the charge.

Further evidence for the orientation of the adsorbed ion may be obtained from the relation between the potential drop across the inner layer (ϕ^{m-2}) and the amount of specifically adsorbed ion. ϕ^{m-2} was calculated in the usual way by subtracting from the measured potential difference the potential drop across the diffuse layer and a constant which is the potential of the point of zero charge in the absence of specific adsorption. The resulting plot is shown in Fig. 3. Two regions again may be distinguished: at low amounts adsorbed the lines are approximately parallel and the slope corresponds to a capacity $(\partial q_-^{-1}/\partial \phi^{m-2})_q$ which is several times the inner layer capacity. This is similar to the behavior of BMDS (and indeed to that of halides, etc.) and may be taken as characteristic of the flat orientation. At higher adsorbed concentrations the lines become much flatter and even begin to slope in the opposite direction when the electrode is positively charged. Thus the capacity $(\partial q_-^{-1}/\partial \phi^{m-2})_q$ becomes infinite or negative. An infinite value of this capacity would be expected if the distance $x_2 - x_1$ between the inner and outer Helmholtz planes became zero, *i.e.*, the charge on the spe-

cifically adsorbed ion was located on the outer Helmholtz plane or actually within the diffuse layer. This is consistent with orientation of PTS with the methyl group toward the electrode and the sulfonate group toward the bulk of the solution.

However, if the only change in structure of the double layer were the movement of the charge into the diffuse layer ($x_2 - x_1 \to 0$) the lines in Fig. 3 should become horizontal and remain parallel at high coverages. The actual divergence of these lines can best be understood in terms of the other component of the inner layer capacitance $(\partial q/\partial \phi^{m-2})_{q-1}$ which is inversely proportional to the vertical distance between adjoining lines in Fig. 3. With the charged head group of the molecule outside the inner layer this capacity is determined by the ratio of the average dielectric constant to the thickness of the inner region: ϵ^{m-2}/x_2 just as in a system in which neutral organic molecules are being adsorbed. The integral capacity at constant amount of adsorbed PTS ion is shown in Fig. 4, which shows that there is very little effect on this capacity up to a surface coverage of 20 μC cm^{-2} in which region the ion is lying flat. On the other hand, the lowering between 20 and 30 μC cm^{-2} is marked in agreement with the proposed reorientation of the adsorbed ion. Results for surface concentrations above this are very limited, and the lowering of capacity could be reasonably interpreted either as an increase in thickness, as a decrease in dielectric constant of the inner layer, or as a combination of both. Perhaps the predominant effect is the increase of thickness since the dielectric constant might tend to increase as the proportion of molecules oriented perpendicularly increases because the polarizability of the benzene ring is greater in directions parallel to the ring than in the perpendicular direction (9).

A simple two-position adsorption isotherm.—We have shown above that the experimental results on PTS require the assumption of at least two different orientations of the adsorbed species. We now investigate the properties of a simple model allowing for two orientations having different areas per molecule. It has become evident recently (10) that the most useful basis for an adsorption isotherm is the equation derived originally by Zhukovitskii (11) which is also known as the Flory-Huggins isotherm by analogy with the equations for polymer solutions: when the adsorbed species forms a monolayer at the electrode and replaces r molecules of the solvent the adsorption isotherm may be written

$$\frac{\theta}{r(1-\theta)^r} = \beta a \qquad [1]$$

where θ is the fraction of surface covered by the adsorbate, a is the latter's activity in the bulk of the solution, and β is the adsorption coefficient; $-RT \ln \beta = \Delta G^\circ$ the standard free energy of adsorption, the standard states being unity activity in the bulk of the solution and θ^* on the surface where $\theta^* = r(1-\theta^*)^r$ while the reference states are infinite dilution for both surface and bulk. Equation [1] assumes that the adsorbate and solvent are noninteracting, and a suggestion was made previously (12) of a way in which interaction could be introduced approximately.

The derivation of Eq. [1] may easily be extended to the adsorption of more than one species, for example by the quasi-chemical method (13). This leads to the expression for the fraction of surface covered by the i'th species

$$\frac{\theta_i}{r_i(1-\sum_i \theta_i)^{r_i}} = \beta_i a_i \qquad [2]$$

If the surface, in the absence of adsorbed species, is covered with N_s solvent molecules then the surface excess of the i'th species is

$$\Gamma_i = N_s\theta_i/r_i - (x_i/x_s)N_s(1-\Sigma\theta_i) \qquad [3]$$

from the usual definition of this quantity, where x_i and x_s are the mole fractions of i and of s, respectively, in the bulk of the solution.

We now consider a system in which one adsorbed species is present in the adsorbed state in two different orientations, flat in which it replaces r_1 solvent molecules and perpendicular in which it replaces r_2. Then we may write adsorption isotherms for the two forms

$$\frac{\theta_1}{r_1(1-\theta_1-\theta_2)^{r_1}} = \beta_1 a \qquad [4]$$

and

$$\frac{\theta_2}{r_2(1-\theta_1-\theta_2)^{r_2}} = \beta_2 a \qquad [5]$$

where β_1 and β_2 are the adsorption coefficients for the flat and perpendicular forms, respectively, and the bulk activity for both forms is of course identical. The total coverage due to adsorption of both forms is

$$\theta = \theta_1 + \theta_2 \qquad [6]$$

and the surface excess is

$$\Gamma = N_s\theta_1/r_1 + N_s\theta_2/r_2 - (x/x_s)N_s(1-\theta) \qquad [7]$$

where x is the mole fraction of the adsorbate in the bulk.

We now require to solve the adsorption isotherms [4] and [5] to obtain the surface excess. From Eq. [4], [5], and [6] we can obtain an equation for θ in the form

$$\theta = ar_1\beta_1(1-\theta)^{r_1}\left\{1 + \frac{r_2\beta_2}{r_1\beta_1}(1-\theta)^{r_2-r_1}\right\} \qquad [8]$$

To solve this equation for θ we must first describe the relation between β_1 and β_2.

We have suggested above that the PTS ion in its flat orientation behaves like the BMDS ion and therefore that the free energy of adsorption for this orientation, $-RT \ln \beta_1$, is approximately a linear function of the charge on the electrode. On the other hand, the perpendicularly oriented ion behaves like a neutral molecule and, therefore, $-RT \ln \beta_2$ may be taken to be quadratic in the charge on the electrode. Using the form of equations for these two cases derived previously (20) we write

$$-\ln\beta_1 = \frac{\Delta G_1^\circ}{RT} + aq \qquad [9]$$

and

$$-\ln\beta_2 = \frac{\Delta G_2^{max}}{RT} + b(q^{max} - q)^2 \qquad [10]$$

It is convenient to express β_2 in terms of β_1 which may then be used as the variable representing the charge dependence. Let

$$-\ln \beta_1^{max} = \frac{\Delta G_1^{o}}{RT} + aq^{max} \quad [11]$$

and

$$-\ln \beta_2^{max} = \frac{\Delta G_2^{max}}{RT} \quad [12]$$

so that Eq. [9] may be written

$$-\ln\left(\frac{\beta_2}{\beta_2^{max}}\right) = H\left(\ln\frac{\beta_1}{\beta_1^{max}}\right)^2 \quad [13]$$

where $H = b/a^2$. Equation [13] expresses the relationship between the adsorption coefficients of the two forms as they vary with the charge on the electrode. To substitute this relation into Eq. [8], we need the ratio of β_2/β_1, *i.e.*

$$\frac{\beta_2}{\beta_1} = \frac{\beta_2^{max}}{\beta_1}\exp\left\{-H\left(\ln\frac{\beta_1}{\beta_1^{max}}\right)^2\right\} = \frac{\beta_2^{max}}{\beta_1^{max}}\left(\frac{\beta_1^{max}}{\beta_1}\right)\exp\left\{-H\left(\ln\frac{\beta_1}{\beta_1^{max}}\right)^2\right\} \quad [14]$$

in terms of the ratio (β_1/β_1^{max}). The parameters which characterize the form of the relation between the two adsorption coefficients may thus most conveniently be taken as $\beta_2^{max}/\beta_1^{max} = S$ which represents the relative strength of adsorption of the two forms at the point where the perpendicular form is most strongly adsorbed and H which represents the rate at which the free energy of adsorption of this form falls off on either side of this point. Now Eq. [8] may be solved for θ as a function of log $(a r_1 \beta_1)$ with the given values of the parameter β_1^{max} r_1, r_2, S, and H. This is best done by iteration on a digital computer owing to the awkward form of Eq [8]. Once θ is obtained θ_1 is found from Eq. [4] in the form

$$\theta_1 = a r_1 \beta_1 (1-\theta)^{r_1}$$

and θ_2 from Eq. [6]. Finally Γ is calculated from Eq. [7], most simply by assuming dilute solutions, so that the last term may be neglected.

Some typical results are shown in Fig. 5 where Γ/N_s is plotted against $\log_{10}\beta_1$ for constant values of the activity of the adsorbate in the bulk of the solution. They were obtained with the aid of an IBM 1620 computer. It is clear from these results that, as the bulk activity increases, the shape of the curve changes from the monotonic rise with log β_1 characteristic of simple adsorption to one with a rapid rise to a high value of Γ followed by a fall to a lower limiting value.

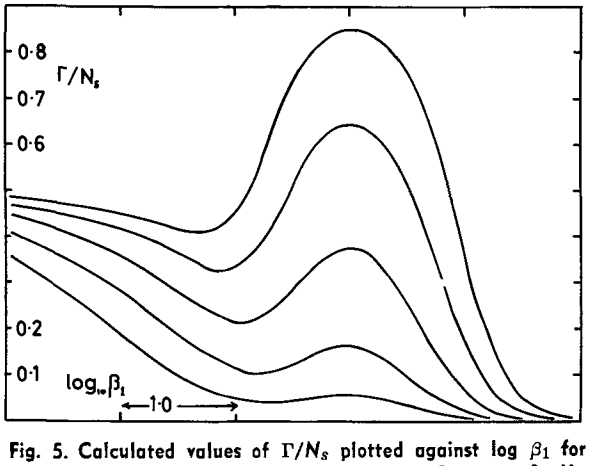

Fig. 5. Calculated values of Γ/N_s plotted against log β_1 for a two-position isotherm without interaction. $r_1 = 2$; $r_2 = 1$; H = 0.434; S = 12. The interval of $\log_{10}a$ between successive curves is 0.5.

In fact the general shape of the curves in Fig. 5 is quite similar to those in Fig. 2. However, there are quantitative differences which may be expressed by saying that the change in shape of the curves occurs over a narrower range of concentration than is found with the theoretical curves. This appears to be true over a wide range of parameters used for the calculated curves.

This discrepancy may be further explored by using the model to calculate the potential across the inner layer due to adsorption and thence the double layer capacity. In doing this, we must first note that the simple routes described previously (14) for this type of calculation cannot be used because this adsorption isotherm is not congruent, *i.e.*, it is not of the form $\Gamma = \Gamma(\beta a)$. Nevertheless, it is possible to start from the general relation [15]

$$\left(\frac{\partial E^+}{\partial \mu}\right)_q = -\left(\frac{\partial \Gamma_-}{\partial q}\right)_\mu \quad [15]$$

The potential of the mercury electrode with respect to a reference electrode reversible to the cation in solution may be expressed

$$E^+ = \phi^{m-2} + \phi_2 - \phi^{o}_{ref} - (RT/F)\ \ln a_+ \quad [16]$$

where ϕ^{m-2} is the potential across the inner layer and ϕ_2 that across the diffuse layer of the mercury electrode, ϕ^{o}_{ref} is the standard potential across the reference electrode and a_+ the activity of the cation in solution. If the variation of ϕ_2 is neglected and a_+ is put equal to the mean activitiy $a_\pm$, we may write Eq. [15] in the form

$$\frac{1}{RT}\left(\frac{\partial \phi^{m-2}}{\partial \ln a_s}\right)_q - \frac{1}{2F} = -\left(\frac{\partial \Gamma_-}{\partial \ln \beta_1}\right)_\mu \left(\frac{\partial \ln \beta_1}{\partial q}\right)_\mu = a\left(\frac{\partial \Gamma}{\partial \ln \beta_1}\right)_\mu$$

using Eq. [9] also,
thence

$$\phi^{m-2} - \phi^{m-2}\ (a_s = 0) = N_s RTa \int_0^{a_s} \frac{\partial(\Gamma/N_s)}{\partial \ln \beta} d\ln a_s + \frac{RT}{2F}\ln a_s \quad [17]$$

and the differential capacity of the inner layer can be found from

$$\frac{1}{C} - \frac{1}{C^b} = \left(\frac{\partial \phi^{m-2}}{\partial q}\right) - \left(\frac{\partial \phi^{m-2}}{\partial q}\{a_s = 0\}\right) = N_s RTa \frac{\partial}{\partial q}\int_0^{a_s} \frac{\partial(\Gamma/N_s)}{\partial \ln \beta_1} d\ln a_s = -N_s RTa^2 \frac{\partial}{\partial \ln \beta_1}\int_0^{a_s} \frac{\partial(\Gamma/N_s)}{\partial \ln \beta_1} d\ln a_s \quad [18]$$

Values of $\partial(\Gamma/N_s)/\partial \ln \beta_1$ were calculated from data like that shown in Fig. 5 and were then numerically integrated to obtain the reduced reciprocal capacity change, *i.e.*, $\{(1/C) - (1/C^b)\}/N_s RTa^2$ which is plotted in Fig. 6 against log β for various bulk concentrations. This theoretical calculation of the capacity curve is compared with the experimental results in the form of $1/C$ against q in Fig. 7. The comparison may be made directly since C^b does not vary much with q as seen in Fig. 4. Although some qualitative similarities can be seen it is again evident that the predictions of the simple theory show a less rapid change of the form of the curve with concentration than is found experimentally. There is also the important qualitative difference that the calculated capacity curve is more like that of a neutral compound than the experimental curves for PTS.

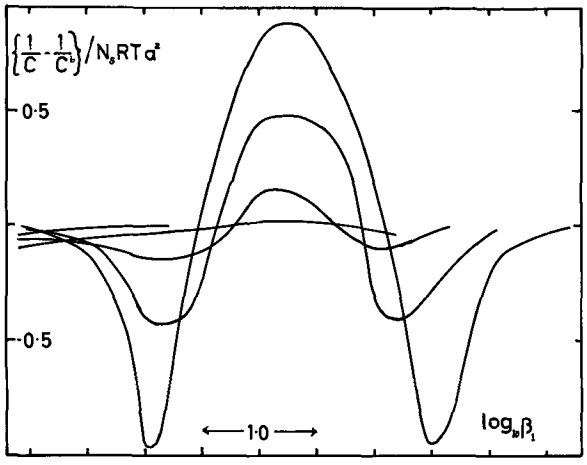

Fig. 6. Calculated reduced capacity curves for the two-position isotherm without interaction. The parameters have the same values as in Fig. 5, but the interval of $\log_{10}a$ between the successive curves is 1.0.

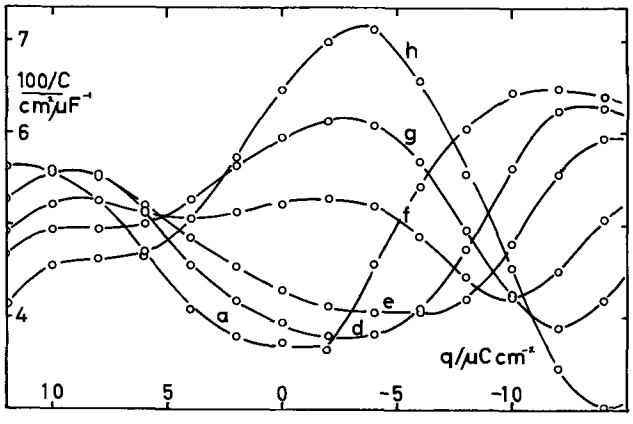

Fig. 7. Experimental curves of reciprocal capacity plotted against charge on the mercury electrode for aqueous sodium p-toluenesulfonate at 30°C. Letters on the curves have the same significance as those in Fig. 1.

A two-position adsorption isotherm with crude allowance for interaction.—The discrepancies between experiment and the simple theory described in the previous section cannot be overcome by variation of the parameters r_1, r_2, S, and H, so that it must be concluded that one of the postulates of this theory is incorrect. The one most likely to cause errors is the assumption that the adsorbed ions do not interact with one another. However, the difficulties in allowing for interaction in any realistic way are great. It has been suggested previously (12) that Eq. [1] could be modified to allow for interaction by introducing an exponential dependence on θ by analogy with Frumkin's modification (16) of Langmuir's isotherm

$$\frac{\theta}{r(1-\theta)^r}e^{A\theta} = \beta a$$

where A is a coefficient depending on interaction between adsorbed particles which may be interpreted as related to the two-dimensional second virial coefficient (17). The extension of such an equation to mixed adsorption would lead to [cf. Temkin (18)]

$$\frac{\theta_i}{r_i(1-\sum_i\theta_i)r_i}\exp\left(\sum_j A_{ij}\theta_j\right) = \beta_i a_i \qquad [19]$$

where A_{ij} expresses the interaction between adsorbed particles of the i'th and j'th type, and both summations are over all types of adsorbed particles except the solvent, although the effect of the latter must be included in the calculation of the A_{ij}. Even with the analogues of Eq. [4] and [5]

$$\frac{\theta_1}{r_1(1-\theta_1-\theta_2)^{r_1}}\exp\left(A_{11}\theta_1 + A_{12}\theta_2\right) = \beta_1 a \qquad [20]$$

and

$$\frac{\theta_2}{r_2(1-\theta_1-\theta_2)^{r}}\exp\left(A_{21}\theta_1 + A_{22}\theta_2\right) = \beta_2 a \qquad [21]$$

which might be applied to the present system the solution is difficult.

We have attempted to assess the effect of interaction on the two-position adsorption isotherm by simplifying [20] and [21]. It seems likely that the interaction between two PTS ions oriented flat will be repulsive, *i.e.*, A_{11} is positive, because the ionic groups are entirely within the inner layer, while the interaction between two vertically oriented ions will be attractive, *i.e.*, A_{22} is negative, since it is known that adsorbed hydrocarbon chains attract one another (19) and the ionic groups are in the diffuse layer where they are screened by the counter ions. The interaction between flat and vertically oriented ions may be weakly attractive due to polarization interactions; we shall assume that $|A_{21}| = |A_{12}| << |A_{22}|$ and $|A_{11}|$ and shall neglect their interactions. We also note that, owing to the opposite signs of A_{11} and A_{22}, the inclusion of both has the same qualitative effect of favoring the adsorption of the vertical form as its adsorption increases, while adsorption of the flat form is hindered. We shall, therefore, be able to investigate the effect of this interaction on the shape of the adsorption curves by introducing the coefficient A_{22} only, although its value will be larger (and negative) to allow for the other, neglected interaction coefficients. From Eq. [6], [20], and [21] $A_{11} = A_{12} = A_{21} = 0$, we obtain (20)

$$\theta = ar_1\beta_1(1-\theta)^{r_1}\left\{1 - \frac{r_2\beta_2}{r_1\beta_1}\exp^{-A_{22}\theta_2}(1-\theta)^{r_2-r_1}\right\} \qquad [22]$$

which differs from Eq. [8] only in the exponential factor in the last term. This equation may be solved using the results of the previous section and a simple graphical construction. Equation [8] is solved as described, for a series of values of S and θ_2, calculated. Log S is then plotted against θ_2. On this plot the value of θ_1 satisfying [22] is given by the intersection of this line with a straight line of slope $-A_{22}$. The position of this straight line can be characterized by the parameter S_o, *i.e.*, the value of S in the absence of interaction.

A set of curves of Γ_s/N against log β, calculated in this way with one set of parameters β_1^{max}, r_1, r_2, S_o,

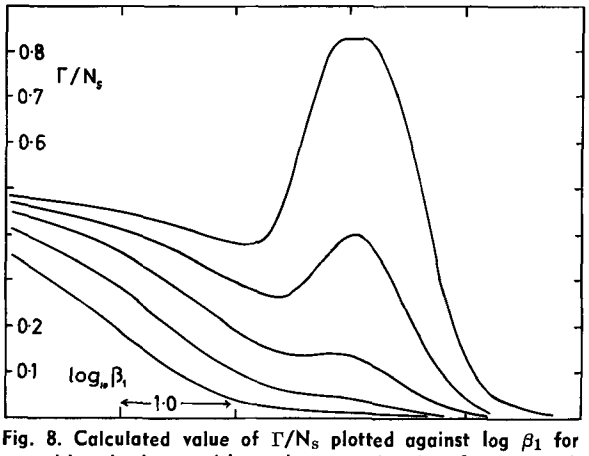

Fig. 8. Calculated value of Γ/N_s plotted against log β_1 for a two position isotherm with crude approximation for interaction. $r_1 = 2$; $r_2 = 1$; $H = 0.434$; $S_0 = 2$; $A_{22} = -2$. The interval of $\log_{10}a$ between successive curves is 0.5.

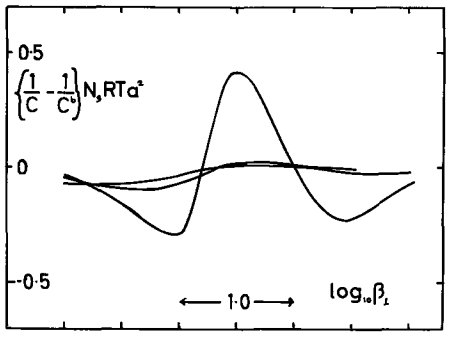

Fig. 9. Calculated reduced capacity curves for the two-position isotherm with crude approximation for interaction. The parameters have the same values as in Fig. 8, but the interval of $\log_{10}\alpha$ between the successive curves is 1.0.

H, and A_{22} is shown in Fig. 8. It is evident from this that the introduction of interaction in this way improves the agreement with experiment in that the change of shape of the curve occurs more rapidly with concentration. Capacity curves calculated by the route described in the previous section are shown in Fig. 9. Again there is some improvement in the agreement between the shape of these curves and those found experimentally as shown in Fig. 7. Nevertheless one major qualitative difference remains clearly expressed. This is the left-hand minimum in Fig. 9 at the highest concentration which would correspond to a marked peak at the left-hand side of Fig. 1. Comparing Fig. 8 and 2, we can see that this discrepancy is due to the fact that the displacement of the vertically oriented ions by flat ones at high concentrations occurs too rapidly. This may be ascribed to our neglect of the cross-coefficients $A_{12} = A_{21}$ which, as we suggested above, will correspond to an attractive force. This will act so as to stabilize the predominant form and will therefore lower the slope of the curve on the left-hand side of the maximum in Fig. 8. Little effect is to be expected on the right-hand side of the maximum owing to the fact that the concentration of the flat form is negligible in this region.

We therefore conclude that to account fully for the form of the experimental curves it is necessary to use the complete pair of Eq. [20] and [21].

Discussion

In this paper we have compared the predictions of a simplified model allowing adsorption of an ion in two-positions with experimental results for a system in which simple behavior of this type is observed. There seems little doubt that the general features of the model are correct and that proper allowance for interaction between the adsorbed ions would lead to a semiquantitative account of this system. However, apart from the practical difficulties of obtaining a solution for the simultaneous transcendental equations, it must be noted that the model based on Eq. [20] and [21] together with [9] and [10] would require at least 9 parameters to be fixed for a given set of curves even if no account is taken of deviations from [9] and [10] or variation of q^{max} with concentration. It therefore seems scarcely profitable to pursue the quantitative evaluation of the model further at present. Further experimental work on systems showing similar behavior may permit us to establish trends which may be correlated with the variation of individual parameters. The investigation of this type of model also provides a basis for the general problem of mixed adsorption which is of great importance in electrode kinetics.

Finally, we should note that this system provides a very clear example of an adsorption isotherm whose shape changes with change of the electrical parameter, *i.e.*, the isotherms at different charges are not congruent, because of the varying proportions of the two forms. Thus, the only satisfactory method for the calculation of surface concentrations is the direct use of the thermodynamic equations by graphical, or another type of, differentiation.

Acknowledgment

We should like to thank the Science Research Council (U.K.) for a maintenance grant (to J.M.P.) during the course of this work and also to thank the University of Bristol Computer Unit for facilities.

Discussion

P. Delahay: My main comment on this paper pertains to the application of simultaneous isotherms (Eq. [19]) to the simultaneous adsorption of Tl^+ and NO_3^- in $TlNO_3$ solution in contact with mercury. The results, which are summarized in my paper at this meeting, will now be discussed more fully.

Calculations were made by assuming that the parameters r for Tl^+ and NO_3^- are equal to unity. An attempt to determine these parameters did not seem justified because of the uncertainty on the amounts of specifically adsorbed Tl^+ and NO_3^-. Furthermore, data fitting with a rather large number of adjustable parameters would not have been very convincing. Our results cannot be regarded as quantitative, but they do indicate a strong attraction between specifically adsorbed Tl^+ and NO_3^- ions. The NO_3^- — NO_3^- repulsion is significant and will be discussed in connection with Dr. Payne's on KNO_3 adsorption.

I would now like to ask Dr. Parsons a question he may not find surprising, namely, is one justified in using the concepts of average charge and potential in dealing with a surface that is partially covered with rather large ions? Dr. Parsons pointed out in 1959[1]

[1] K. M. Joshi and R. Parsons, *Electrochim. Acta*, 4, 129 (1961).

the need for a three-dimensional solution of the Poisson equation. Moreover, one would also have to consider other interactions than purely electrostatic ones. The case corresponding to $x_2 - x_1 < 0$ certainly should give some trouble. What is then the significance of $\phi_M - \phi_2$? I realize that an answer to my question could well be, you give us a better way of treating such cases, but Dr. Parson's thoughts on this question should be of interest.

Finally, I would like to ask Dr. Parsons his present position on the selection of the electrical variable, charge on the electrode *vs.* potential, in the treatment of adsorption. The dust has not settled, and this question has led to rather spirited discussion. It is unfortunate that Professor Frumkin is not present, as he certainly would also have had something to say on this point. Anyhow, the arguments of one school of thought should be of general interest.

Roger Parsons: The analysis of the $TlNO_3$ system is most interesting, and the interaction coefficients seem reasonable. Use of both r parameters equal to unity seems likely to be fairly near to the correct value.

In the case of flat orientation of large ions I do not think that the errors in the use of average potentials and charges are more serious than in the case of small ions at the same adsorbed charge density. I agree that the vertical orientation gives more trouble, and this is included in a very qualitative way in the idea of screening the sulfonate charge in the diffuse layer. Undoubtedly a more sophisticated model is desirable, but not much progress has been made in this direction as far as explaining experimental results is concerned.

I believe that there is some degree of agreement that charge is the preferable variable for ionic adsorption, but this is not so for neutral molecule adsorption. I still retain the opinion that it is preferable in the latter case, but it is very difficult to make a conclusive test of this or the opposite view. Tests can be devised for congruent isotherms (those for which the interaction parameters are independent of electrical conditions), but there is no *a priori* reason to assume that the isotherm for a given substance is congruent.

E. Gileadi: Equation [1] in this paper takes into account the obvious activity coefficient of the species in solution, but seems to neglect activity coefficients on the surface. Apart from lateral interaction effects which cause a change in the free energy of adsorption, there is an important entropy term which must be introduced when an adsorbed species occupies more than one site on the surface ($r > 1$). This accounts for the nonrandom distribution of occupied (and free) sites on the surface. Calculations of this type have been given by Miller[2] for the relatively simple case of $r = 2$, but as far as I know none have so far been published for higher values of r. Some preliminary calculations by Hurwitz and Gileadi for $r = 4$ show that this effect can be quite substantial and can alter the shape of the isotherm. The additional difficulty which arises here is that the form of the entropy term depends not only on the value of r but also on the shape of the adsorbed molecule.

It would seem therefore that the isotherms given here are applicable mainly for liquid electrodes and would not apply to solid electrodes with well-defined and localized adsorption sites.

Roger Parsons: Yes, I agree that Eq. [1] is likely to be useful only for liquid electrodes where there are no definite sites on the metal surface. In this case the entropy contribution is included according to the Flory-Huggins model.

[2] A. R. Miller, *Proc. Cambridge Phil. Soc.*, 35, 293 (1939).

Richard Payne: I think several important points arise from this paper.

1. It is stated that the lines in Fig. 3 are approximately parallel at low coverages, whereas in actual fact, they diverge. The slope at $q = -10\ \mu C/cm^2$, for example, is 0.019 $cm^2/\mu F$; whereas at $q = 8\ \mu C/cm^2$, it is 0.0043 $cm^2/\mu F$. This suggests strongly that the standard free energy of adsorption of the flat form falls off from the linear charge dependence assumed in the analysis. I think this is confirmed by the discrepancy between the measured and calculated charge dependence of the amount adsorbed which the authors attribute to neglect of cross-interaction coefficients. The discrepancy could also be attributed to decrease of $d \ln \beta_1/dq$ with q which would mean that the flat form would not replace the vertical form as rapidly as predicted by the theory.

2. I would also like to make two other points in connection with the peaks in Fig. 3. It is suggested that the lines should become horizontal if the center of charge of the adsorbed species is in the diffuse layer. I disagree with this, since it neglects the contribution to ϕ^{m-2} of replaced solvent dipoles. I think it would be difficult to explain the charge dependence of the amount adsorbed for many neutral adsorbates without taking this factor into account. Second, the authors state that the divergence of the lines in Fig. 3 at high coverages can be explained in terms of $(\partial q/\partial \phi^{m-2})_{q'}$, the capacity measured at constant amount adsorbed which I think is only partially true. It is not possible to explain the zero and negative slopes of ϕ^{m-2} *vs.* q' at constant q without taking into account the contribution of the replaced solvent dipoles.

3. The value of the parameters used in the calculation which are listed under Fig. 5 seem unrealistic in certain respects. If the area occupied by a solvent molecule is taken as 10Å^2 then according to the experimental saturation areas of the two forms, *i.e.*, 53 and 32 Å^2 in the corresponding values of r_1 and r_2 should be roughly 5 and 3, respectively, rather than the 2 and 1 assumed in the calculation. How sensitive is the calculation to the values chosen for r_1 and r_2?

I think the value $\beta_1^{max} = 1$ should read $\ln \beta_1^{max} = 1$. This leads to $\Delta G_1^{max} = 576$ cal/mole which is more than an order of magnitude lower than the usual values found for ionic adsorption ($\sim$ 20 kcal/mole). Using the value $S = 12$ we find $\Delta G_2^{max} = -1.43$ kcal which again is much too low. It seems that with this value of S the difference between ΔG_1^{max} and ΔG_2^{max} is also unrealistically large (*i.e.*, a factor of 2.303 log $12 \simeq 2.5$). Can the authors comment on this point?

Roger Parsons: 1. This explanation is certainly a possible one. I had assumed that the flat orientation of the toluene sulfonate would behave in the same way as the benzene in disulfonate reported previously. In fact, the number of points in this low coverage region in Fig. 3 is rather small (4 concentrations or so), and the slopes of these plots cannot be given with complete confidence.

2. I do not entirely agree. As I suggest in the remarks on your paper, it is possible to obtain the quadratic dependence of free energy of adsorption on charge if only the thickness of the inner layer is increased by the adsorption. Then the change of sign of the slope of ϕ^{m-2} *vs.* q' follows with the charge corresponding to zero slope (maximum adsorption) depending on dipolar or ionic properties. An alternative explanation is in terms of the average dielectric constant of the inner region in which the dipoles may also play a part. In the real system it may well be that all these phenomena contribute.

3. I have discussed the value of the parameter r for some single adsorption systems briefly elsewhere[3] and suggested that the value found was smaller than would be expected from the known size of the water

[3] Roger Parsons, *J. Electroanalyt. Chem.*, 8, 93 (1964).

molecule and that this might be due to the existence of clusters of water molecules on the mercury surface. Variation in the relative values of r_1 and r_2 changes some features of the curves such as those in Fig. 5. In particular, the limit at large positive changes (left-hand side of Fig. 5) is $\theta = r_2/r_1$ so that this ratio determines the relative heights of the peak and the saturation coverage at positive charges.

The caption under Fig. 5 should read ln β_1^{max}. This value is arbitrary, and the actual value would depend on the concentration range for which the curves in the figure apply. The difference between ΔG_1^{max} and ΔG_2^{max}, however, does have real significance. In the absence of similar analyses for simpler systems, it is only possible to express an opinion about the magnitude used here, but I believe this difference is not too large; if it were much smaller it would become close to RT, and there would be no clear predominance of the vertical form over any range of the variables.

J. R. Macdonald: Your implicit assumption that there are no stable intermediate states for the adsorbed molecules between completely flat and standing-up straight conditions seems reasonable to me. On the other hand, in the situation where there are appreciable concentrations of molecules in both these two stable states, one would expect thermal equilibrium between them; thus a proportion of them at any instant should be undergoing transitions from one state to the other. Should not your treatment include the effects of the molecules in these intermediate positions?

Roger Parsons: It is indeed true that under conditions where the energies of the two forms of adsorbed species are comparable intermediate orientations must also have similar energies. However, the solution of the complete problem of the energy of the system as a function of orientation of each toluene sulfonate ion would be difficult. It seems likely that the main features of the present simplified solution would still be present since in most regions one form or the other would predominate.

B. E. Conway: It may be of interest to note that a two-position treatment for adsorption also applies to the neutral molecule, pyridine. This is indicated by the fact that (*a*) the apparent standard free energy of adsorption of pyridine on Hg decreases in a discontinuous manner with increasing coverage θ expressed to the power $\theta^{3/2}$ to allow for dipole repulsion effects;[4] and (*b*) by the fact that the surface pressure ϕ-surface excess Γ relation shows two linear regions with different slopes which can best be interpreted in terms of a disorientation-orientation transition in the double layer.[5] Similar effects are observed in the sorption of pyridine in montmorillonite.[6]

In regard to the Flory-Huggins type of treatment you mentioned in which the different areas of the adsorbate molecules (solvent and solute) are taken into account, it may be mentioned that Shinoda and Hildebrand[7] have found for the analogous lattice problem in three-dimensional solutions of spherical molecules of different sizes that the required volume-fraction statistics represent the solution behavior less satisfactorily than do mole fraction statistics. This may be due to the shapes of the molecules involved. However, for tetraalkylammonium salts the size factor can be significant in the activity coefficients.[8] The lattice theory may be quantitatively applicable only to those solutes that approach the ideal condition of occupying some simple multiple number of the solvent sites laterally (as in polymer solutions, or diphenyl in benzene). Similar problems would, it seems, arise in the case of the Flory-Huggins type of treatment for a two-dimensional phase.

The Structure of the Mercury-Solution Electrical Double Layer in the Presence of Adsorbed Oxyanions

Richard Payne

Air Force Cambridge Research Laboratories, L. G. Hanscom Field, Bedford, Massachusetts

ABSTRACT

The unusual adsorption characteristics of oxyanions are described with special reference to the adsorption of nitrate ions from KNO_3 solutions. The adsorption energy is shown to be linearly dependent on the charge in contrast to the behavior previously found for mixed solutions of NH_4NO_3 (and also NH_4ClO_4) with NH_4F at constant ionic strength where the dependence is approximately quadratic. The reasons for the differences are discussed in terms of the structure of the inner region of the double layer. The capacity of the inner region of the double layer is analyzed and related to the form of the adsorption isotherm and the Esin and Markov coefficient. Arguments are advanced in favor of using the mean ionic activity rather than the salt activity in the isotherm.

The unusual electrocapillary properties of inorganic oxyanions like nitrate and perchlorate were first recognized by Grahame and Soderberg (1) in a systematic study of the specific adsorption of anions. They concluded from their measurements that the nitrate ion is relatively weakly adsorbed, probably by Van der Waals-type adsorption forces rather than the stronger forces characteristic of the adsorption of the iodide ion for example. This viewpoint seemed to be confirmed by recent measurements of the adsorption of nitrate (2) and perchlorate (3) ions from mixed solutions of NH_4NO_3 and NH_4ClO_4, respectively, with NH_4F at constant ionic strength, which suggested that specifically adsorbed anions are replaced by solvent molecules at sufficiently positive values of the electrode charge in much the same way that weakly held organic adsorbates are desorbed at the extremes of polarization. However, studies of KNO_3 and $HClO_4$ solutions appear to indicate fundamental differences in the characteristics of the ad-

sorption process for a given anion depending on the nature of the solution. Thus the adsorption of nitrate ions from pure KNO_3 solutions more closely resembles that of the strongly adsorbed iodide ion than the adsorption of nitrate ions from the mixed ammonium salt solutions. This result is somewhat surprising and apparently casts some doubt on the validity of Grahame's analysis (4). The problem is here reconsidered with special reference to the behavior of the KNO_3 system.

Experimental

The differential capacity of the double layer at a dropping mercury electrode was measured for seven concentrations of KNO_3 ranging from 0.01-1M using the a-c bridge method described previously (5). The internal precision of the measurements was better than 0.05%. The potential was measured with a precision of 1 mv with respect to a calomel reference electrode in 0.1M KCl. In order to minimize uncertainties due to variations in the liquid junction potential (LJP), a 0.1M KNO_3 solution was always maintained in contact with the reference electrode. The liquid junction was made in a solution-sealed stopcock and was left undisturbed throughout the measurements. As before, a second liquid junction of the type KNO_3 (0.1M) $|KNO_3(x\text{M})$ was deliberately introduced. The junction was again maintained in a solution-sealed stopcock. The LJP in this case could be calculated from the Henderson equation using published values (6) of t^+, the cation transference number. Since t^+ is close to 0.5 for KNO_3 solutions, the LJP is small and can be accurately computed. The reproducibility of this arrangement was repeatedly checked by measuring the potential of zero charge (pzc) using the streaming mercury electrode method (7), and also by checking the pzc against published values (8) and the value found independently (9) for 1M KNO_3 using a 1M KCl calomel reference electrode in direct contact with the KNO_3. The agreement found was usually better than 1 mv.

Solutions were prepared volumetrically from permanganate distilled water and AR grade KNO_3 previously recrystallized from the same water. No trace of electroreducible or surface active impurities was detected during the measurements. Mercury was purified in the usual way by extraction with dilute HNO_3 followed by multiple distillation *in vacuo*. Capillaries were prepared and silicone treated as described previously (10). Solutions were freed from oxygen by bubbling with filtered and presaturated oxygen-free nitrogen. The pzc was measured for each solution by the method of the streaming mercury electrode (7). All measurements were made in a water thermostat controlled to ±0.05°C.

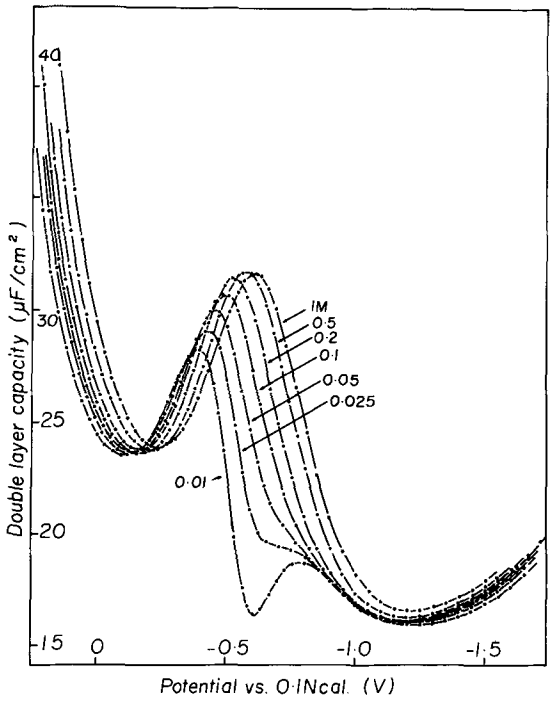

Fig. 1. Differential capacity of the electrical double layer at a mercury electrode in contact with aqueous KNO_3 solutions at 25°C.

Results

The differential capacity of the double layer is shown as a function of the potential for seven concentrations of KNO_3 in Fig. 1. The characteristic capacity hump which occurs close to the pzc decreases in height as the bulk concentration of KNO_3 decreases due to the effect of the diffuse layer capacity at the lower concentrations. The occurrence of specific adsorption at the pzc, even in the most dilute solution, is suggested by the fact that the capacity minimum due to the effect of the diffuse layer capacity occurs at a potential of ~60 mv more negative than the pzc owing to the effect of the superimposed steeply rising inner layer capacity. It will be shown, however, that most of the concentration dependence of the capacity in Fig. 1 is due to the effect of the diffuse layer, in contrast with the behavior of the halide anion systems where the concentration dependence of the inner layer capacity is much more important.

The capacity was integrated twice with respect to the potential using a digital computer (Elliot 803) as described previously (10). Integration constants were taken from the measured zero charge potentials and published interfacial tension data of Gouy (11). The measured potentials were converted to an E^- scale with the aid of published values of the mean activity coefficient and cation transference number (6). The computed data were in the form of values of the capacity (C), potential measured with respect to a hypothetical anion reversible electrode (E^-), interfacial tension (γ) and the function $\xi^- = \gamma + qE^-$ all interpolated to integral values of the surface charge density on the metal (q). The capacity potential and interfacial tension for each solution at the pzc are recorded in Table I.

The surface excess of cations (Γ^+) was calculated in the usual way (12) by plotting ξ^- against $2RT/F$ ln $a_\pm$ for constant values of q and differentiating graphically according to the thermodynamic equation

$$-d\xi^- = 2RT/F \cdot \Gamma^+ \, d \ln a_\pm - E^- \, dq \qquad [1]$$

where $a_\pm$ is the mean activity and constant temperature and pressure are understood.

The charge dependence of Γ^+ is shown for several concentrations of the salt in Fig. 2. The flatness of the variation on the anodic side first noted by Grahame and Soderberg (1) distinguishes this system from systems like KCl and KI where Γ^+ goes through a well-defined minimum (13). This difference is due to the smaller charge dependence of the specific adsorption of the nitrate ion as will be shown. The flat maximum

in Γ^+ for the 1M solution close to $q = 4\mu C/cm^2$ suggests that the anion adsorption approaches saturation coverage (14), although this effect may be an artifact resulting from errors inherent in the graphical differentiation. Since Γ^+ is close to zero for $q \gtrsim 4\mu C/cm^2$ in the 0.01M solution, the charge on the solution side of the interface (q^s) is almost wholly due to specifically adsorbed anions in this region if specific adsorption of cations is discounted. Although measurements in solutions more dilute than 0.01M were not made, the results in Fig. 2 suggest that a plot of Γ^+ *vs.* log $a_\pm$ would be asymptotic to $\Gamma^+ = 0$ at infinite dilution, in which case a similar plot of the surface excess of anions (Γ^-) would be asymptotic to the value $-q/F$. Since there is no diffuse layer charge all of q^s is made up of the charge due to specifically adsorbed anions (q^1) so that q^1 apparently approaches the value $-q$ at infinite dilution. This is somewhat surprising since q^1 should presumably approach zero when the bulk concentration of anions is zero. Because of the uncertainty in the diffuse layer calculation under conditions where Γ^+ is close to zero (15), it could be assumed that this effect is due to errors in the measurements or the analysis. This point is discussed in more detail below.

The values of Γ^+ were used to calculate the surface excess of anions (Γ^-) by difference from q^s/F

$$\Gamma^- = q^s/F - \Gamma^+ \qquad [2]$$

The charge due to diffuse layer anions (q^d) was then calculated from Gouy-Chapman diffuse layer theory assuming no specific adsorption of cations. The charge due to specifically adsorbed anions was found by subtracting the diffuse layer concentration from the total surface excess of anions

$$q^1 = F\Gamma^- - q^d \qquad [3]$$

The values of q^1 obtained in this way were then used directly in the subsequent analysis which was developed by Parsons (12) and Grahame (4).

In Fig. 3 q^1 is shown as a function of q for several concentrations of KNO_3. It is evident that the curves are approximately linear and parallel for $q \geq 4\mu C/cm^2$, the slope of the linear segment being

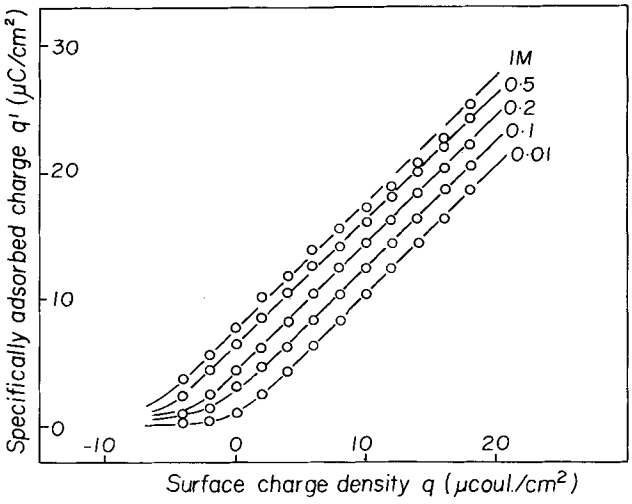

Fig. 3. Charge due to specifically adsorbed nitrate ions as a function of the charge on the metal and concentration of KNO_3.

close to 1.0 in good agreement with the result found by Grahame and Soderberg for 0.1M KNO_3. The systematic deviations from the line of unit slope for the most concentrated solution can be reasonably attributed to errors of graphical differentiation which are most serious at the extremes of the concentration range. The maximum deviation is $\sim 0.8\ \mu C/cm^2$, which is probably within the experimental error. The potential difference (ϕ^{m-2}) generated across the inner region of the double layer by specifically adsorbed anions was calculated by subtracting RT/F ln $a_\pm$ and the potential difference across the diffuse layer (ϕ_2) from E^-. The resultant values of ϕ^{m-2} were then plotted against q^1 for integral values of q. The results of this plot are shown in Fig. 4. As was found previously for KCl (16) and sodium benzenedisulfonate solutions (14) the data can be represented by a series of parallel straight lines. The appreciable scatter of the points is again attributable to errors introduced by the graphical differentiation. This is particularly troublesome at the lower concentrations where Γ^+ is close to zero. Under these conditions the calculation of ϕ_2 and q^d from diffuse layer theory is extremely sensitive to errors in Γ^+.

The capacity was analyzed with the aid of diffuse layer theory and values of dq^1/dq obtained by graphical differentiation of the plots in Fig. 3. The capacity of the inner region (C^i) was first obtained through the relationship

$$1/C = 1/C^i + 1/C^d(1 + dq^1/dq) \qquad [4]$$

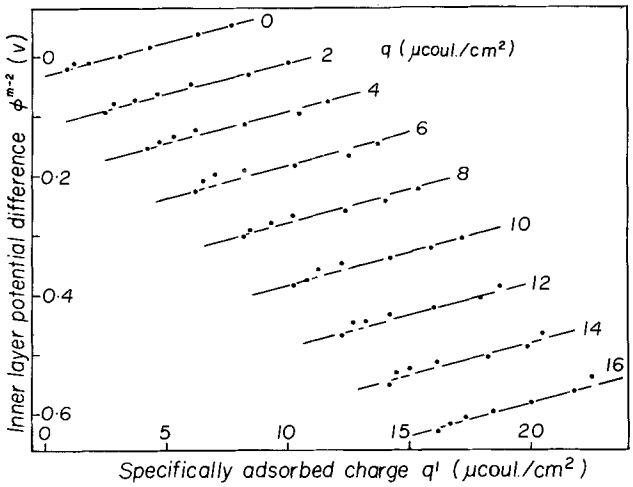

Fig. 4. Potential difference generated across the inner region of the double layer by specifically adsorbed anions.

where C^d is the capacity of the diffuse double layer. C^i was then further resolved into components measured at constant charge and at constant amount adsorbed through the identity

$$1/C^i = 1/{}_qC^i + 1/{}_{q1}C^i \cdot dq^1/dq \quad [5]$$

where ${}_qC^i$ the capacity of the inner layer measured at constant amount adsorbed and ${}_{q1}C^i$ the capacity measured at constant charge on the metal are defined by

$${}_qC^i = (\partial q/\partial \phi^{m-2})_{q1} \quad [6]$$

and

$${}_{q1}C^i = (\partial q^1/\partial \phi^{m-2})_q \quad [7]$$

As in all previously studied systems ${}_{q1}C^i$ is independent of the amount adsorbed (in view of the linearity of the plots in Fig. 4) and can therefore be replaced by the corresponding integral capacity ${}_{q1}K^i$. The value of ${}_{q1}K^i$ in the present system is 96 $\mu F/cm^2$.

The total inner layer capacity C^i and the capacity at constant amount adsorbed ${}_qC^i$ are shown as a function of q for several concentrations of KNO_3 in Fig. 5 and 6. The curves in both cases are almost independent of the salt concentration. This is somewhat surprising since C^i is expected to depend strongly on specific adsorption of the anion and hence on the bulk concentration of KNO_3. It appears that most of the concentration dependence of the measured capacity in Fig. 1 can be attributed to variation of the diffuse layer capacity. The constancy of ${}_qC^i$ is to be expected

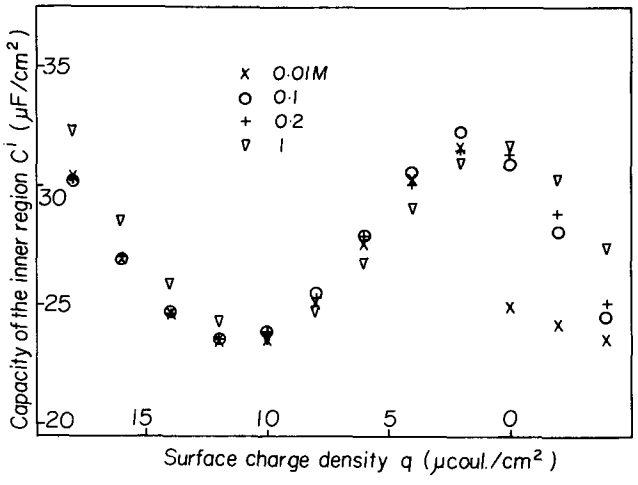

Fig. 5. Differential capacity of the inner region of the double layer as a function of the charge on the metal and concentration of KNO_3.

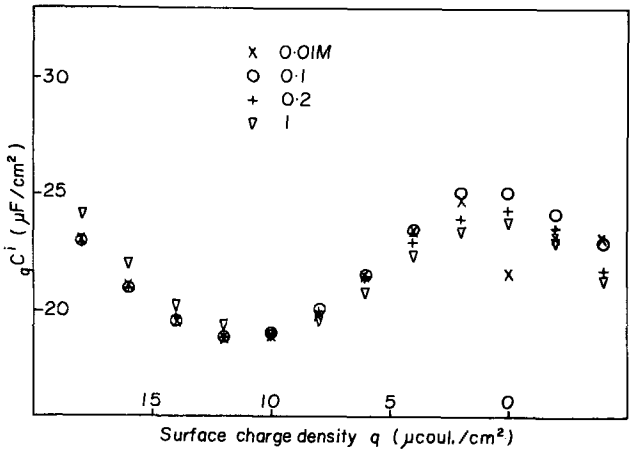

Fig. 6. Component of the inner layer capacity measured at constant amount adsorbed as a function of the charge on the metal and concentration of KNO_3.

since the plots of ϕ^{m-2} *vs.* q^1 in Fig. 4 are parallel. ${}_qC^i$ could also have been calculated for each experimental point in Fig. 4 by interpolating ϕ^{m-2} at the appropriate value of q^1 and then differentiating the corresponding values of q with respect to ϕ^{m-2}. Since the lines are parallel, the results of this calculation are independent of q^1.

Discussion

Adsorption Isotherm

The data were fitted to a single constant charge isotherm using the method described by Parry and Parsons (14). In order to test the correctness of maintaining constant charge rather than constant potential in this system the criterion devised by Frumkin et al. (17) was applied. According to Frumkin the charge (q) and potential (ϕ) in the case of a constant charge isotherm are related by the equation

$$q = (\phi - \theta\phi_N)/[(1-\theta)/C_o + \theta/C'] \quad [8]$$

where ϕ_N is the pzc corresponding to a coverage $\theta = 1$. ϕ and ϕ_N are measured with respect to the pzc for $\theta = 0$. C_o and C' are the capacities corresponding to $\theta = 0$ and $\theta = 1$, respectively. When $q = 0$; *i.e.* at the pzc, Eq. [8] reduces to

$$\phi_{q=0} = \theta\phi_N \quad [9]$$

so that the pzc should be a linear function of the coverage if a constant charge isotherm is obeyed. Figure 4 shows that this is so for the present system as was found previously for nitrate and perchlorate ion adsorption from mixed solutions of NH_4F with NH_4NO_3 and NH_4ClO_4, respectively. However, it should be pointed out as mentioned by Frumkin *et al.* that if $C_o = C'$ the corresponding equations for constant potential adsorption

$$q = C_o\phi(1-\theta) + C'(\phi - \phi_N)\theta \quad [10]$$

$$\phi_{q=0} = \phi_N\theta/[C_o/C'(1-\theta) + \theta] \quad [11]$$

also reduce to Eq. [9]. Although this condition seldom occurs in adsorption of organic compounds, it appears in view of the small dependence of C^i on concentration (Fig. 5) in this system that C_o and C' may be similar so that the value of the test is correspondingly reduced. It is possible within the limitations of the somewhat crude approximations of Frumkin's treatment to extend the argument to consider adsorption at constant values of q other than zero. In this case the constant charge equation, Eq. [8], can be rearranged to give

$$\phi = q/C_o + \theta[\phi_N + q(1/C' - 1/C_o)] \quad [12]$$

whereas the constant potential equation, Eq. [10], gives

$$\phi = [q + C'\theta\phi_N]/[C_o(1-\theta) + C'] \quad [13]$$

According to Eq. [12] ϕ should be a linear function of θ with a slope that increases (or becomes less negative) with increasing q by an amount $(1/C' - 1/C_o)$, whereas Eq. [13] predicts a more complex dependence. The relationship of Eq. [12] to the plots of ϕ^{m-2} *vs.* q^1 in Fig. 4 is obvious. Since these plots are parallel it follows that $C' \approx C_o$ in this system as was shown earlier (Fig. 5). Again this does not necessarily confirm the correctness of the constant charge isotherm since both [12] and [13] reduce to the common equation

$$\phi = q/C_o + \theta\phi_N \quad [14]$$

when $C' = C_o$. However, in the $NH_4NO_3 + NH_4F$ system C' and C_o are not equal and the plots of ϕ^{m-2} *vs.* q^1 (or θ) are linear with a slope which becomes increasingly positive with q in agreement with Eq. [12]. It appears, therefore, that a constant charge isotherm is appropriate to this system, and in the ab-

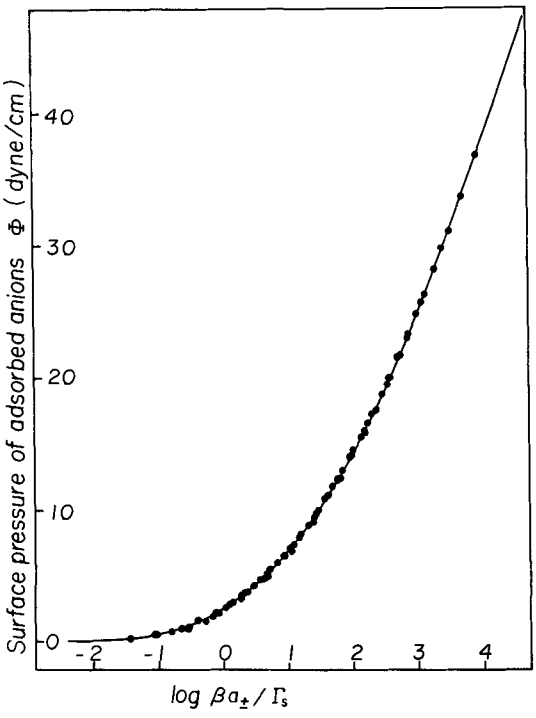

Fig. 7. Composite curve of the surface pressure of nitrate ions specifically adsorbed from KNO_3 solutions. The range of q covered is 0-18 $\mu C/cm^2$.

sence of any indications to the contrary it seems reasonable to assume that the same is true for the present system.

The surface pressure (Φ) of specifically adsorbed anions was calculated as described elsewhere (14, 18). The individual curves of Φ *vs.* log $a_\pm$ for various constant values of q were fitted together to give the composite curve shown in Fig. 7. The solid line was calculated from a Frumkin isotherm (19),

$$\ln[\theta/(1-\theta)] + A\theta = \ln(\beta a_\pm/\Gamma_s) \qquad [15]$$

with the following constants

$$\begin{aligned} &A/2.303 = 3 \\ &\left\{\begin{array}{l} \Gamma_s = 1.59 \times 10^{14}\ \text{molecule/cm}^2 \\ q_s^1 = 25.4\ \mu C/cm^2 \end{array}\right. \\ &\log\beta = 14.83 + 0.205\,q \end{aligned} \qquad [16]$$

where A is the dimensionless lateral interaction coefficient, Γ_s the saturation coverage, q_s^1 is equal to $F\Gamma_s$, and β is related to the standard free energy of adsorption at zero coverage (ΔG°) by

$$\beta = \exp(-\Delta G^\circ/RT) \qquad [17]$$

The variation of ΔG° with q (Fig. 8) showed a slight sigmoid tendency which was regarded as small enough to be neglected. The largest deviation of Φ from the common curve in Fig. 7 was no more than 0.3 dyne/cm.

The constants of the isotherm are remarkably similar to those previously found for the adsorption of nitrate ions from NH_4NO_3 + NH_4F solutions (2) which also obeys a Frumkin isotherm with $A/2.303 = 1$, $q_s^1 = 24.7\ \mu C/cm^2$ and $\log\beta = 14.95 + f(q)$[1]. Thus the anomalously large apparent area of the adsorbed nitrate ion (~60 Å^2) is again emphasized. The lateral interaction coefficient is larger by a factor of 3 for the KNO_3 system. This has the effect of spreading the adsorption over a wider concentration range in the lower and intermediate range of coverage. This suggests that the lateral interactions may be screened out to some extent by the constant high electrolyte concentration in the mixed electrolyte system. The same factor would lead to variation of the interaction coefficient with concentration in the KNO_3 system which would mean that the adsorption could not be represented by a single isotherm.

[1] $f(q)$ in this system is nonlinear.

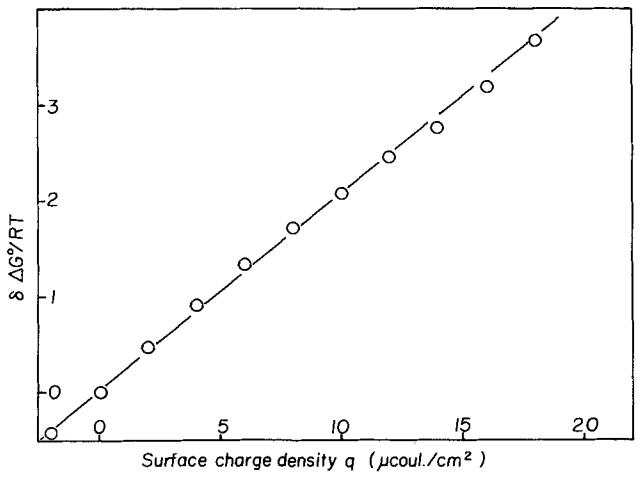

Fig. 8. Charge dependence of the standard free energy of adsorption of nitrate ions from KNO_3 solutions.

It is interesting to note that the plot of ϕ^{m-2} *vs.* q^1 at $q = 0$ in Fig. 4 does not extrapolate to $\phi^{m-2} = 0$ at $q^1 = 0$ but to a value which is ~25 mv positive. When the isotherm values of q^1 are used to calculate the diffuse layer potential difference, the same plot is curved but now properly extrapolates to the origin, suggesting therefore that the isotherm values of q^1 may be more accurate than the values obtained by graphical differentiation. The source of this discrepancy appears to be the diffuse layer potential difference which, according to the graphical analysis, does not approach zero at low concentrations. This is another way of stating that the specifically adsorbed charge appears to be asymptotic to a value of $-q/F$ rather than zero at infinite dilution as was discussed earlier. The divergence of the ϕ^{m-2} *vs.* q^1 plots calculated directly and from the isotherm at $q = 0$ can

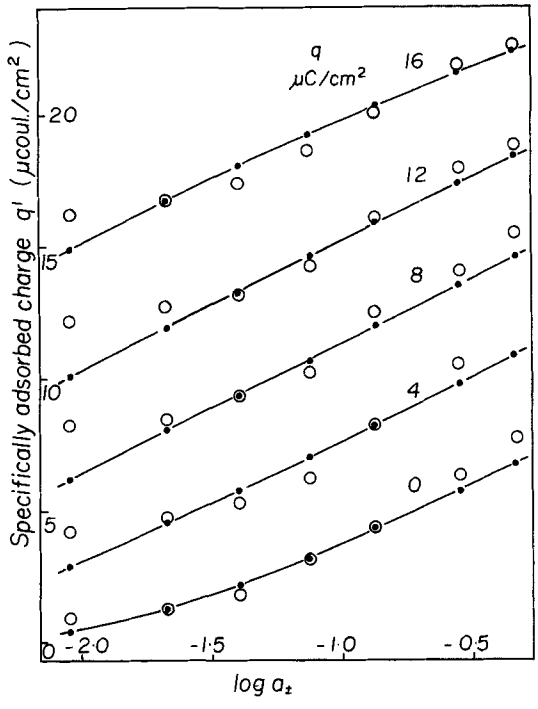

Fig. 9. Comparison of the charge due to specifically adsorbed ions calculated directly according to Eq. [1] (open circles) with values calculated from the isotherm (closed circles).

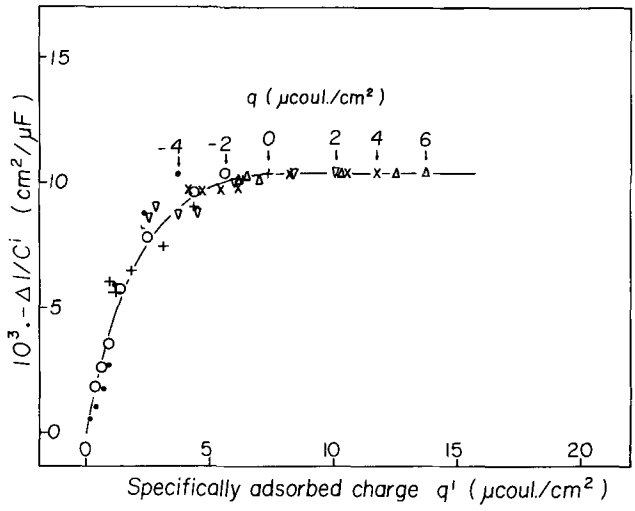

Fig. 10. Change of the inner layer capacity produced by adsorption of nitrate ions from KNO_3 solutions as a function of the amount adsorbed.

evidently be accounted for by a systematic error in ξ^- of no more than 0.2 dyne/cm. This is due to the extreme sensitivity of the calculation of ϕ_2 from diffuse layer theory to the value of q^1 under these conditions. In Fig. 9 are compared the values of q^1 calculated by the two methods. It is apparent that the directly calculated values are asymptotic to a value close to $q^1 = -q$ at the low concentration end whereas the isotherm values are asymptotic to $q^1 = 0$ (as they clearly must be if they are to fit a single common isotherm). This behavior is also evident in other systems.[2] Thus, although the deviations in Fig. 9 could be accounted for by very small errors in the measurements, they are nevertheless believed to be real and represent a small dependence of the isotherm constants on the charge or concentration or both. For this reason the directly calculated values of q^1 were used in the analysis.

As is well known, the change of the capacity produced by adsorption is characteristic of the adsorption isotherm and under favorable circumstances can be used to identify the isotherm and evaluate its constants (20, 21). The change of the inner-layer capacity ($-\Delta 1/C^i = 1/C^i - 1/{}_qC^i$) is shown as a function of q^1 in Fig. 10. As mentioned earlier, $\Delta 1/C^i$ reaches a limiting value as was found previously for the adsorption of iodide ions from formamide solutions (18). Now according to Eq. [5]

$$-\Delta 1/C^i = 1/{}_{q1}K^i \cdot dq^1/dq \qquad [18]$$

or

$$-\Delta 1/C^i = 1/{}_{q1}K^i \cdot d \ln \beta/dq \cdot dq^1/d \ln \beta \qquad [19]$$

The last factor on the R.H.S. of Eq. [19] is characteristic of the adsorption isotherm. Since ${}_{q1}K^i$ and $d \ln \beta/dq$ are constant in this system, it follows that the shape of the $-\Delta 1/C^i$ *vs.* q^1 curve is the same as that of $dq^1/d \ln \beta$ *vs.* q^1. It is easily shown that the Frumkin isotherm leads to the relationship

$$dq^1/d \ln \beta = q^1{}_s\{[(1-\theta)]^{-1} + A\}^{-1} \qquad [20]$$

leading to a maximum value of $dq^1/d \ln \beta$ at $\theta = 0.5$ whereas a virial type of isotherm gives

$$dq^1/d \ln \beta = (1/q^1 + 2B/F)^{-1} \qquad [21]$$

where B is the second virial coefficient leading to the limiting value of $F/2B$ when $2B >> F/q^1$. It appears, therefore, that the present system might be better described by a virial form of isotherm. The value of B given by Eq. [19] and [21] is 440Å²/mol.

[2] See for example ref. (16).

As was pointed out previously, this ambiguity between the Frumkin and virial forms of the adsorption isotherm can arise when the lateral interaction coefficient A is large because under these conditions (and at sufficiently small values of θ) the Frumkin isotherm reduces to the virial equation. However, it follows from Eq. [18] that where the plots of ϕ^{m-2} *vs.* q^1 (Fig. 4) are linear and plots of q^1 *vs.* q (Fig. 3) are also parallel at the high concentration end, $\Delta 1/C^i$ must reach a limiting value which in general will be different for each value of q. This behavior was noted by Parsons (20) for the aq. KI system in which the charge dependence of the limiting value of $\Delta 1/C^i$ is evidently due primarily to the variation of ${}_{q1}K^i$ reported by Grahame (4) for this system. Where ${}_{q1}K^i$ is also independent of q (parallel plots of ϕ^{m-2} *vs.* q^1 in Fig. 4) and the q^1 *vs.* q plots are both linear and parallel at the high concentration end, $\Delta 1/C^i$ will reach a common limiting value for all values of q as found in the present system.

A modification of isotherms based on the Langmuir isotherm to take into account the different sizes of the adsorbing particles and the solvent molecules they replace was recently proposed by Parsons (22). The modified Frumkin isotherm is

$$\beta a = \theta e^{A\theta}/r(1-\theta)^r \qquad [22]$$

where r is the number of solvent molecules replaced by one adsorbate molecule. This isotherm leads to a maximum in $d\theta/d \ln \beta$ when $\theta = (1 + \sqrt{r})^{-1}$ so that when r is large the curve of $d\theta/d \ln \beta$ (or $-\Delta 1/C^i$) against θ is highly asymmetric. This seems likely to be the case in this system in view of the low saturation coverage and may account for the apparent limiting value of $-\Delta 1/C^i$. In other words the descending branch of the curve to the right of the maximum may have been eliminated by the assumptions mentioned previously. In this case the fit to a simple Frumkin isotherm would have to be regarded as empirical. From the value of 59Å² previously deduced for the saturation area and a value of 6Å² taken as the area occupied by a water molecule we obtain a value for r of ~10 leading to a maximum in $-\Delta 1/C^i$ when $\theta \approx 0.25$ or $q^1 \approx 7$ μC/cm². According to Fig. 10 $-\Delta 1/C^i$ indeed reaches its maximum value close to this point. It therefore seems reasonable to conclude that Parsons' modification of the Frumkin isotherm will describe the adsorption and that the limiting value of $-\Delta 1/C^i$ found is due to small errors introduced by the simplifying approximations necessarily made in the analysis.

Capacity of the Inner Region

The component of the capacity of the inner region measured at constant amount adsorbed (${}_qC^i$) is independent of the amount adsorbed within the experimental error. Similar behavior has been observed for all previously studied systems of anion adsorption from solutions of a single salt (4, 14, 16, 18). A small charge dependence of ${}_{q1}K^i$ (the reciprocal slope of the plots of ϕ^{m-2} *vs.* q^1 in Fig. 4) observed for the adsorption of iodide ions from both aqueous and formamide solutions of KI is of doubtful significance.

The behavior of the KNO_3 system contrasts sharply with that of mixed solutions of NH_4NO_3 and NH_4F at constant ionic strength (2) in which the adsorption of the nitrate ion results in a marked decrease of ${}_qC^i$ with increasing amount adsorbed. The same behavior was also found for perchlorate ion adsorption under similar conditions (3). The change in the total inner layer capacity produced by the adsorption of nitrate ions from the mixed solutions is shown as a function of concentration and electrode charge in Fig. 11. As was noted previously, these curves closely resemble those frequently found in the adsorption of neutral organic substances [see for example ref. (23)] and, as shown by Parsons (21), are characteristic of a quadratic charge (or potential) dependence of the

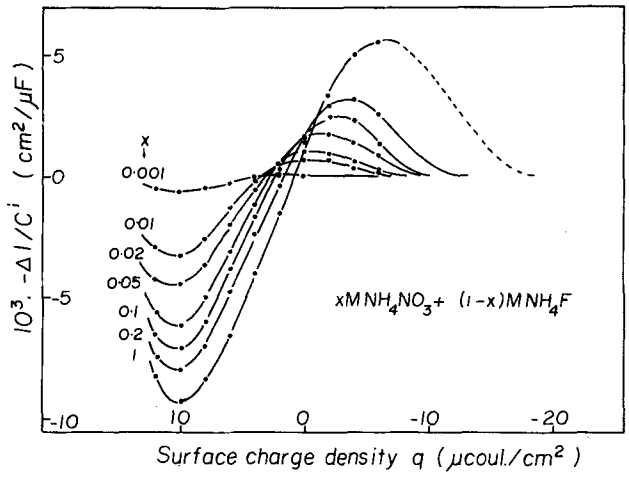

Fig. 11. Change of the inner layer capacity resulting from adsorption of nitrate ions from mixed solutions of NH_4NO_3 and NH_4F as a function of the charge on the metal and composition of the solution.

standard free energy of adsorption. They can be compared with the corresponding curves for the KNO_3 system in Fig. 12 which apparently exhibit the limiting value of $-\Delta 1/C^i$ characteristic of a virial form of the adsorption isotherm with a linear charge dependence of the adsorption energy as discussed earlier.

Since the specific adsorption of ions presumably results in the replacement of adsorbed solvent molecules it seems reasonable to assume that the capacity will depend on the amount adsorbed and, because the ions will in general be less polarizable than the replaced solvent molecules, the capacity would be expected to decrease. At the same time the average effective thickness of the layer will depend on the amount adsorbed and also on the size of the ion. For an ion like the nitrate ion which presumably adsorbs in a flat position on the electrode, the thickness of the layer should be little affected. It seems unlikely, therefore, that the expected decrease in the dielectric constant (ϵ^i) of the inner layer resulting from the adsorption would be compensated by a corresponding decrease in the thickness (x_2) as suggested by Grahame (4). Certainly the general occurrence of this effect in both aqueous and nonaqueous solutions (which of course was not known to Grahame) makes the possibility of accidental compensation of this kind seem unlikely. It is suggested, therefore, that the behavior of the mixed electrolyte system rather than

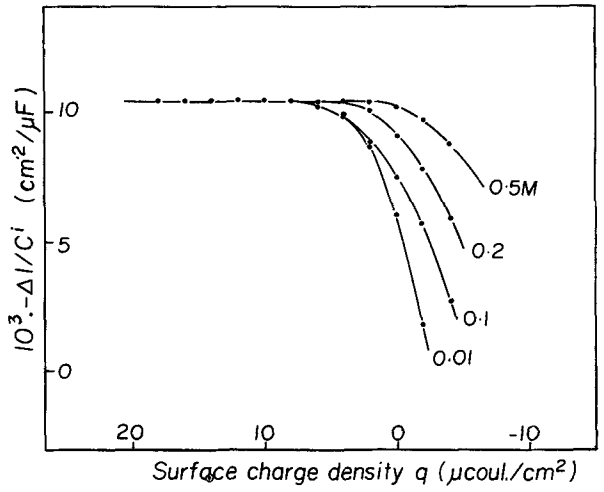

Fig. 12. Change of the inner layer capacity resulting from adsorption of nitrate ions from KNO_3 solutions as a function of concentration and the charge on the metal.

that of the KNO_3 system is more consistent with a realistic physical model of the inner region.

The fundamental change in the character of the adsorption of ions like nitrate and perchlorate when the composition of the solution is changed is difficult to understand. The quadratic charge dependence of the adsorption energy found for the mixed electrolyte system was previously attributed, by analogy with the adsorption of organic substances, to competitive adsorption of the ion with solvent dipoles. However, the fact that the pure KNO_3 solutions behave differently suggests that the fluoride ion, which is supposedly nonspecifically adsorbed, rather than the solvent is the competing species. It seems likely that the fluoride ion is specifically adsorbed to some extent at extreme positive polarizations although this possibility unfortunately can only be inferred, as in the case of inorganic cations (24), from indirect evidence because of the gross uncertainties in the diffuse layer correction mentioned earlier. It does not seem likely on the other hand that fluoride ions could be sufficiently strongly adsorbed under any conditions to replace adsorbed nitrate ions. The curves in Fig. 11 tend to confirm the original interpretation since the quadratic charge dependence of the adsorption energy is already well developed close to the pzc where specific adsorption of fluoride ions can almost certainly be discounted. It is therefore necessary to look elsewhere for an explanation of the difference between the two types of systems.

Grahame (4) wrote the part of the potential difference across the inner region resulting from the specifically adsorbed charge as

$$_{q1}\phi^{m-2} = \frac{-4\pi n^i e^o (x_2 - x_1)}{\epsilon^i} \qquad [23]$$

where x_1 is the distance of the center of the ion from the metal surface, n^i is the number of singly charged specifically adsorbed ions and e^o is the electronic charge. It is clear, however, as Frumkin indicated in his theoretical treatment for the adsorption of neutral substances (25), that Eq. [23] should include a second term to account for the contribution of solvent dipoles replaced in the adsorption process. $_{q1}\phi^{m-2}$ should therefore be written

$$_{q1}\phi^{m-2} = \frac{-4\pi n^i}{\epsilon^i}[e^o(x_2 - x_1) - n_w\bar{\mu}] \qquad [24]$$

where n_w is the number of solvent dipoles of average moment in the direction of the field $\bar{\mu}$ which are replaced by one specifically adsorbed ion. At sufficiently positive values of q (the electrode charge) the solvent dipoles will be oriented by the field with the negative end of the dipole facing the metal so that their removal will result in a positive shift of the electrode potential. The effect should also increase with increasing q as the degree of orientation, and hence $\bar{\mu}$ increases.

It was noted previously that the plots of ϕ^{m-2} *vs.* q^1 for the mixed electrolyte system are not parallel: the slope decreases with q and eventually reverses sign close to the limit of anodic polarization. This is a further manifestation of the quadratic charge dependence of the adsorption energy in view of the approximate relationship (26)

$$(\partial\phi^{m-2}/\partial q^1)_q = 2RT/F \cdot d\ln\beta/dq \qquad [25]$$

If it is assumed that the main contribution to variation of ϕ^{m-2} at constant q is through $_{q1}\phi^{m-2}$ as defined by Eq. [24] it follows that the condition for $(\partial\phi^{m-2}/\partial q^1) = 0$ is

$$e^o(x_2 - x_1) = n_w\bar{\mu} \qquad [26]$$

It would not be possible to explain these experimental results in terms of Grahame's expression for $_{q1}\phi^{m-2}$

(Eq. [23]) which would require an infinite value of the dielectric constant or zero or negative values of x_2—x_1, which seem to have no physical significance. It is clear therefore that Eq. [23] is only valid for the limiting case where the ion becomes a point charge and the dielectric a structureless continuum, neither of which are likely to be good approximations to the real situation. It therefore seems more reasonable to interpret the charge independent values of $(\partial\phi^{m-2}/\partial q^1)_q$ found for KNO_3 and other single salt systems in terms of Eq. [24] in preference to Eq. [23]. The constancy of $(\partial\phi^{m-2}/\partial q^1)_q$ would then reflect the constancy of $1/\epsilon^i(\epsilon^o(x_2 - x_1) - n_w\bar{\mu})$ in Eq. [24]; $x_2 - x_1$ would therefore have to increase with q in order to offset the expected increase in $\bar{\mu}$ according to which the results for the mixed electrolyte system were interpreted. It is not, however, clear why this should occur for the single salt and not for the mixed electrolyte system.

The slope of ϕ^{m-2} *vs.* q^1 for the mixed electrolyte system becomes approximately constant at 0.0051 $cm^2/\mu F$ for small negative values of q suggesting that the contribution of oriented dipoles to ϕ^{m-2} is small in this region as would be expected. The corresponding slope for pure KNO_3, however, is 0.0104 $cm^2/\mu F$ which is larger by a factor of 2. Therefore, $x_2 - x_1$ is apparently larger for the KNO_3 system over the whole range of polarization which suggests that imperfect imaging in the diffuse layer of the adsorbed ions occurs, leading to apparently increased values of x_2 as suggested by Dutkiewicz and Parsons (27). Certainly the most important difference between the KNO_3 and the NH_4NO_3 + NH_4F systems lies in the composition of the diffuse layer. Some evidence for the effect of this on the adsorption process is found in the smaller value of the lateral interaction coefficient in the isotherm for the mixed electrolyte system which suggests that the mutual repulsion of the adsorbed ions is being partially screened out by the high electrolyte concentration in the diffuse layer. The indication of a small concentration dependence of the isotherm constants for the KNO_3 system also tends to confirm this. Further studies of mixed electrolyte systems will be required to resolve this problem.

Distance Ratio

According to the Grahame-Parsons analysis of the inner layer capacity the distance ratio $(x_2 - x_1)/x_2$ is given directly by the capacitance ratio

$$ {}_qK^i/{}_{q^1}K^i = (x_2 - x_1)/x_2 \qquad [27] $$

It can easily be shown that when the effect on ϕ^{m-2} of the replaced solvent dipoles is taken into account according to Eq. [24] the capacitance ratio now gives

$$ {}_qK^i/{}_{q^1}K^i = (x_2 - x_1)/x_2 - n_w\bar{l}/x_2 \qquad [28] $$

where $\bar{l}$ is the mean component of the length of the solvent dipole in the direction of the field. The capacitance ratio therefore no longer gives the distance ratio directly.

As was discussed at length in the previous section ${}_qK^i$ and ${}_{q^1}K^i$ are independent of the amount adsorbed for the KNO_3 system and since K^i also does not vary much with q the capacitance ratio is almost independent of q and q^1, and has a value close to 0.25 in close agreement with the value reported by Parry and Parsons for the benzenedisulfonate ion. The capacitance ratio for NH_4NO_3 + NH_4F solutions on the other hand is much lower; it also decreases with q from a value of 0.12 at $q = 0$ to zero at $q = 10$ $\mu C/cm^2$ and is negative for larger values of q as would be expected from the earlier discussion.

The distance ratio can be calculated by an alternative method devised by Grahame, but subsequently modified by Parry and Parsons, in which the adsorption energy is arbitrarily expressed as the sum of a "chemical" term ($F\Phi'$) analogous to the Stern specific adsorption potential and an electrical term ($F\phi_1$) where ϕ_1 is the potential at an anion site. The isotherm is written

$$ \theta/1 - \theta = a_{\pm} \exp(\Phi' + \phi_1) F/RT \qquad [29] $$

By expressing the difference in potential between the inner and outer Helmholtz planes $\phi_1 - \phi_2$ as a fraction $\gamma/(\beta + \gamma)$ of ϕ^{m-2} Eq. [29] can be used to determine a distance ratio $\gamma/(\beta + \gamma)$ as a function of q and q^1. Replacement of ϕ_1 in Eq. [29] by $\gamma/(\beta + \gamma)$. ϕ^{m-2} + ϕ_2 leads to the equation which is plotted in Fig. 13. Values of $\gamma/(\beta + \gamma)$ calculated from the slopes are compared with the corresponding values of $(x_2 - x_1)/x_2$ calculated from Eq. [27] in Fig. 14. $\gamma/(\beta + \gamma)$ is also almost independent of q and as found in all other systems of this type is larger than $(x_2 - x_1)/x_2$. This was previously attributed (14) to breakdown of the constant field approximation in Grahame's method of calculation due to discreteness of charge effects as a result of which a fraction of ϕ^{m-2} greater than the distance ratio is dropped between the IHP and OHP. An alternative explanation is possible however in terms of the contribution of the displaced solvent dipoles to the capacitance ratio (Eq. [28]) previously neglected in the calculation of $(x_2 - x_1)/x_2$. It may be significant that for both KI (4) and KCl (16) $\gamma/(\beta + \gamma)$ approaches the value of $(x_2 - x_1)/x_2$ calculated from Eq. [27] close to the pzc but increases rapidly with increasing q. This is consistent with Eq. [28] since the contribution of the second term should be small close to the pzc, but should increase with q to give values of the capacitance ratio smaller than the true distance ratio. The KNO_3 results which do not show this con-

vergence of $\gamma/(\beta + \gamma)$ and $(x_2 - x_1)/x_2$ are probably unreliable close to the pzc because of the scatter in the plots in Fig. 13 resulting from errors in ϕ_2 values calculated from diffuse layer theory.

Values of the specific adsorption potential Φ' obtained from the intercepts in Fig. 13 are recorded in Table II. $F\Phi'/2.303RT$ in this system is evidently close to 1.0 compared with ~2.8 found for the system KI in formamide (18).

In a recent paper Dutkiewicz and Parsons (27) compared the adsorption of iodide ions from pure KI solutions with that from mixtures of KI and KF at constant ionic strength from which they conclude that the salt activity rather than the anion activity (*i.e.*, the mean ionic activity) should appear in the anion adsorption isotherm. This, however, seems inconsistent since it amounts to equating the chemical potential of adsorbed anions to the chemical potential of the salt in solution. Further, it does not seem possible to consider the adsorption of neutral salt, since not only are the anions specifically adsorbed into the inner layer whereas the cations are in the diffuse layer, but also because the ions are adsorbed to different extents except at the pzc. As was pointed out previously (18), this argument also affects the constants of the isotherm deduced by fitting the experimental surface pressure of adsorbed anions to the integrated isotherm. The surface pressure measured at constant charge as defined by Parsons (12) is

$$\Phi = \xi^+ - \xi^+_0 = \int \Gamma^- d\mu \qquad [30]$$

where ξ^+ is equal to $\gamma + qE^+$, μ is the chemical potential of the salt, and ξ^+_0 is the limiting value of ξ^+ at infinite dilution. According to Eq. [30] differentiation of Φ with respect to ln $a_\pm^2$ gives the surface excess of anions, but it is clear that what is actually being measured is adsorption of neutral salt since, if q is kept constant, adsorption of anions must be accompanied by adsorption of an equal number of cations. Φ, therefore, cannot be regarded as the surface pressure of anions because it contains a contribution from adsorption of cations. This is another way of stating that the anion adsorption isotherm should contain $a_\pm$ rather than $a_\pm^2$ because differentiation of Φ as defined by Eq. [30] when plotted as a function of ln $a_\pm$ will obviously give values of Γ^- which are too large by a factor of two. Thermodynamically the adsorption of a given number of ions resulting from a given change in the chemical potential of the ion in solution will produce the same decrease in the interfacial tension irrespective of the state of the adsorbed ions; it seems, therefore, reasonable to assume that Φ as defined by Eq. [30] contains equal contributions from cations and anions. This appears to be equivalent to the assumption of equal activities of anion and cation in the solution, *i.e.*, $a_+ = a_- = a_\pm$. The plot of $\Phi/2$ *vs.* ln $a_\pm$ has the correct slope and is now consistent with the anion adsorption isotherm based on the mean ionic activity rather than the salt activity. The surface pressures of adsorbed anions shown in Fig. 7 were calculated in this way with small corrections for the contribution of diffuse layer anions. It should be mentioned that the value of the lateral interaction coefficient in the isotherm and also the standard free energy of adsorption calculated from the curve fitting procedure depend on the choice of the activity of the adsorbate in solution. The amounts adsorbed and the saturation coverage, however, will be correct in any case if the fit has been made correctly.

In view of the experimental evidence described by Dutkiewicz and Parsons in support of the idea of using the salt activity in the adsorption it is of interest to make a similar comparison for the KNO_3 system and the mixed NH_4NO_3 + NH_4F system. This is done in Fig. 15 and 16 where the amounts of specifically adsorbed nitrate ions are plotted against log $a_\pm$ and log $a_\pm^2$, respectively. It appears that the agreement is better when log $a_\pm$ rather than log $a_\pm^2$ is used in disagreement with the result found for the KI and KI + KF systems. The agreement of the log $a_\pm$ plots for the nitrate systems is less satisfactory than that of the log $a_\pm^2$ plots found for the iodide systems, as might be expected in view of the weaker adsorption of nitrate and the fact that different cations were involved in the two systems compared. Furthermore, the agreement is much better at the lower values of q and only deteriorates at the more positive values which were not reached in the iodide system. It would, therefore, be of considerable interest to extend the iodide measurements to positive values of q and also

to study other systems in order to determine the effect of the supporting electrolyte on the adsorption process.

Esin and Markov Coefficient

Equation [1] can be written in the alternative form

$$-d\xi^+ = \Gamma^- d\mu - E^+ dq \qquad [31]$$

where E^+ is now the potential measured with respect to a cation reversible electrode and ξ^+ is correspondingly defined as $\gamma + qE^+$. Cross differentiation in Eq. [31] gives a form of the Esin and Markov coefficient (28)

$$(\partial E^+/\partial\mu)_q = -(\partial\Gamma^-/\partial q)_\mu \qquad [32]$$

The surface excess of anions can be divided into the contributions of specifically adsorbed and diffuse layer anions so that Eq. [32] can be written

$$(\partial E^+/\partial\mu)_q = -1/F\,[(\partial q^1/\partial q)_\mu + (\partial q_-{}^d/\partial q)_\mu] \qquad [33]$$

In the present system the diffuse layer concentration of anions does not vary much with q for positive values so that the second term on the right-hand side of Eq. [33] can be neglected. The Esin and Markov coefficient is therefore equal to $-1/F(\partial q^1/\partial q)_\mu$. E^+ is shown as a function of the salt chemical potential for integral values of q in Fig. 17. The plots are evidently linear for $q \geq 2$ μC/cm^2 with slopes which are similar and close to unity (see Table II). This is in agreement with the $\partial q^1/\partial q$ values obtained from plots of q^1 *vs.* q (Fig. 3). However, this does not constitute independent confirmation of the correctness of the values since the uncertainties introduced into the calculation of q^1 by the diffuse layer correction are inherent in the assumption that $(\partial q_-{}^d/\partial q)_\mu = 0$ in Eq. [33]. It is interesting to note that the Esin and Markov coefficient is close to unity at the extreme of anodic polarization which suggests that diffuse layer behavior is obeyed. The reason for this is that Γ^+ is actually almost independent of q although the (constant) value of Γ^+ is positive for all but the most dilute solutions, whereas diffuse layer behavior predicts limiting repulsion. The Esin and Markov coefficient therefore cannot be regarded as a reliable criterion of the occurrence of specific adsorption under these conditions. However, the occurrence of specific adsorption is confirmed by the fact that the slope of the plots in Fig. 17 does not decrease to the theoretical value of 0.5 at $q = 0$ predicted by diffuse layer theory. The curvature at the low concentration end for $q = 0$ indicates the approach to diffuse layer behavior at low concentration but specific adsorption of anions is not completely absent at all concentrations until the charge reaches -12 μC/cm^2.

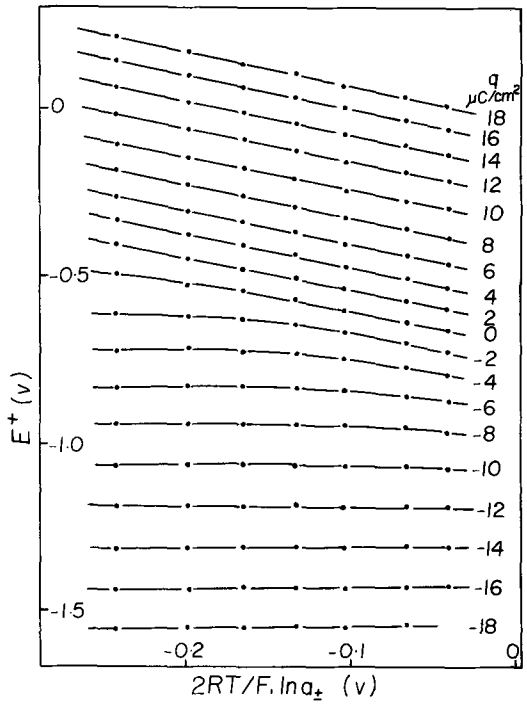

Fig. 17. Esin and Markov plots for aqueous KNO_3 solutions at 25°C.

The Esin and Markov is directly related to the anion adsorption isotherm since

$$(\partial E^+/\partial\mu)_q = (\partial q^1/\partial \ln\beta)_\mu \cdot d\ln\beta/dq \qquad [34]$$

As pointed out by Parsons (20) $(\partial q^1/\partial \ln\beta)_\mu$ is characteristic of the adsorption isotherm. Since $\ln\beta$ is evidently a linear function of q in this system (Fig. 8) it would appear that a Langmuir type of isotherm is incorrect since this would predict a maximum value in $(\partial q^1/\partial \ln\beta)_\mu$, and hence in the Esin and Markov coefficient, at $\theta = 0.5$ which is not found (see Table II). Although this conclusion is again dependent on the approximations involved in neglecting the diffuse layer contribution in Eq. [33] and possible deviations of $d\ln\beta/dq$ from constancy, a virial type behavior or more likely the modified Langmuir behavior of Eq. [22] is suggested.

The plots in Fig. 17 for extreme cathodic values of q show a small but apparently significant positive slope in contrast with the predictions of diffuse layer theory according to which the slope should be zero as anions undergo limiting repulsion. This suggests that anions are being readsorbed as the electrode charge becomes more negative. Similar behavior has been observed in other aqueous solutions (9) and cannot apparently be completely explained by specific adsorption of cations. Further study and analysis of these results will be required before the possibility of systematic experimental errors can be eliminated.

Discussion

Roger Parsons: I would like to suggest that the main reason for the difference of behavior of NO_3^- ion in mixtures with F^- compared with pure nitrate solutions is the fact that the inner layer thickness x_2 for F^- is smaller than that for NO_3^-. This is suggested by the fact that the inner layer capacity in pure fluoride solutions at positive charges is higher than that in nitrate solutions in spite of the greater specific adsorption in the latter which would tend to raise the capacity.

The tendency for quadratic dependence of adsorption free energy on electrode charge follows then from the fact that the introduction of nitrate ions to a fluoride solution tends to increase the inner layer thickness. The resulting quadratic behavior was discussed previously,[1] and this would automatically lead to ϕ^{m-2} $-q_-^{1}$ plot whose slope changed sign. It is also possible that the reduction in the interactive parameter in the NO_3^- isotherm is due to the lowered value of x_2 in the system containing fluoride.

The KF + KI system seems to be simpler because as Grahame[2] showed x_2 seems to be very similar for F^- and I^-. Hence, this system is a more satisfactory one for examining the functional dependence of adsorption on bulk activity. Nevertheless, it is certainly true that the comparison of single and mixed systems should be extended to more positive charges than we have so far studied.[3]

The significance of the dipole term in Eq. [24] is not very clear. If such a term is introduced, it is probably necessary to use a different value for ϵ^i, the apparent dielectric constant of the inner layer.

Finally, I would like to ask why there is no evidence of an approach to saturation in the adsorption isotherm of Fig. 3 which extend to charges equal if not higher than the value calculated as the maximum in the Frumkin isotherm. Similarly, do the results at more positive charges show a descending branch of the curve in Fig. 10 which again would be expected from this analysis?

Richard Payne: I agree with Dr. Parsons that the results for the mixed fluoride and nitrate solutions could be explained in terms of a variation in thickness of the inner layer as the amount of adsorbed nitrate increases rather than the replacement of oriented dipoles or decrease in the dielectric constant. However, it does not seem likely that the mean thickness of the layer would be appreciably increased by specific adsorption of nitrate ions in the flat orientation especially at the low coverages involved. Also, since the diffuse layer charge changes sign in the middle of the concentration range, it does not seem possible to attribute any thickness variation to variation in composition of the diffuse layer, *i.e.*, at concentrations above $\sim 0.1N$ the diffuse layer is populated by cations at all charges. It is therefore not possible to conclude with certainty that a thickness change will accompany the adsorption process. On the other hand, if it is assumed, as seems extremely likely, that the solvent dipoles in the inner layer are oriented at positive charges then the replacement of dipoles by adsorbed ions must result in a potential shift of the kind observed.

I also agree that the KF + KI system would be more appropriate as a test of the bulk activity factor, insofar as the iodide ion is simpler than the nitrate ion. On the other hand, the fluoride ion will be more strongly solvated than iodide so that there is really no reason to believe that the similarity between F^- and I^- will be any greater than that between F^- and NO_3^- in their effect on the thickness of the inner layer.

It seems appropriate to introduce the dipole term in Eq. [24] under conditions where it can be assumed that the dipole is permanently oriented. Under these conditions, there can be no orientational contribution to the dielectric constant although the oriented dipole will of course generate a potential difference. It seems more realistic to make this approximation in which the dipoles are fixed in a dielectric medium the polarizability of which is the sum of the contributions of the atomic and molecular polarizabilities of all the species present with no contribution of permanent dipoles, which should be almost independent of the potential. In Dr. Macdonald's paper, it is assumed that the high-frequency value of $\epsilon^i = 6$ is appropriate with the possibility of a variable contribution from orientation of permanent dipoles which may or may not be present. The assumption in Eq. [24] is that its effect is small.

The reasons for the apparent discrepancy between the plots in Fig. 3 and the saturation coverage given by the isotherm are given in answer to Professor Delahay's question. The absence of the descending branch in Fig. 10 predicted by the Frumkin isotherm is due to the fact that $-\Delta 1/C^i$ was calculated directly rather than from the isotherm values of q^1 as explained in my paper. It was pointed out that insofar as the plots in Fig. 3, 4, and 8 can be regarded as linear the value of $-\Delta(1/C^i)$ in Fig. 10 must be constant as it is at sufficiently positive values of q where the curvature of q' *vs.* q disappears. If we assume instead that the first two terms on the RHS of Eq. [19] are constant as given by the analysis, but that the last term $dq^1/d \ln \beta$ is given by the Frumkin isotherm, then the plots of $-\Delta C^i$ would have a maximum value occurring at half coverage. In actual fact although the surface pressure data fits a Frumkin isotherm closely, it appears that the fit is approximate and that the apparent limiting value is more like the actual behavior, which has also been observed for the adsorption of iodide ions from aqueous solutions[4] and formamide solutions.[5]

Paul Delahay: First, I would like to note that the relative weak dependence of the amount of specifically adsorbed NO_3^- on the concentration for KNO_3 is also observed for $TlNO_3$. The spread between 0.01 and 1M solution is of the order 6 $\mu C/cm^2$ in both cases.

In Eq. [16] Dr. Payne uses a saturation coverage of 25.4 $\mu C/cm^{-2}$. How does he justify this value since no saturation coverage of that order is apparent from Fig. 3. The plot in Fig. 3 is still quite linear up to 25 $\mu C/cm^{-2}$. The value used by Dr. Payne corresponds to the ratio of $3H_2O/NO_3^-$, but does not seem justified by experiment.

Second, I note that Dr. Payne's value of $A = 3$ is of the same order as the value of A we found for NO_3^--NO_3^- interaction in $TlNO_3$, namely, 2-5.5 (depending on the charge on the electrode). The question is, How does he account for the difference between $A = 1$ for $NH_4NO_3 + NH_4F$ and $A = 3$ for KNO_3?

Finally, why does Dr. Payne seem to rule out cation specific adsorption to explain the anomalous feature of the Esin and Markov?

Richard Payne: The apparent absence of the approach to saturation in Fig. 3 is partly due to the fact that

[1] Roger Parsons, *J. Electroanal. Chem.*, 5, 397 (1963).

[2] D. C. Grahame, *J. Am. Chem. Soc.*, 80, 4201 (1958).

parallel straight lines have been drawn through all the points including the 1M points which actually begin to fall off above $q \approx 10$ $\mu C/cm^2$. The approach to saturation is more apparent in the curves shown in Fig. 9. Also, as I have stressed in my paper, the values of q^1 have been calculated directly rather than by the isotherm fitting method, whereas the saturation coverage of 25.4 $\mu C/cm^2$ was found from the isotherm. Although the fit of the experimental surface pressures to the theoretical curve (Fig. 7) derived from the isotherm is well within the experimental error I have still preferred to use directly calculated values of q^1 because of the uncertainty of the diffuse layer correction in this system. I have also stressed that I believe the fitting of data of this kind to an isotherm by the surface pressure method is an insensitive procedure and that the result tends to obscure much of the fine detail. It seems likely that both the interaction parameter and the saturation coverage depend on the charge on the metal so that the value given by the isotherm should be regarded as an averaged quantity.

In reply to the question concerning specific adsorption of cations and the Esin and Markov coefficient, the effect referred to was observed only in dilute solutions. In other words, the system is close to limiting repulsion of anions for the higher concentrations as predicted by diffuse layer theory, whereas at the lower concentrations, there appears to be positive adsorption of anions which increases with the negative charge on the metal. The effect has been observed with KNO_3, Na_2SO_4, and NaOH solutions and also appears in the electrocapillary data of Oldfield[6] for NaOH, LiOH, and KOH solutions. Since the effect is only apparent in dilute solutions, it does not appear possible to explain it in terms of specific adsorption of cations. The effect appears to be real, but the possibility that it is due to some defect in the experimental method has not yet been eliminated.

The question of the difference between the lateral interaction parameters for KNO_3 and $NH_4NO_3 + NH_4F$ is difficult to answer. First, it should be pointed out that these parameters probably vary with the charge and composition of the solution as mentioned earlier. The difference could be attributed to partial screening of the electrostatic charge by fluoride ions in the mixed electrolyte system. Alternatively, the difference could be due to difference in the diffuse layer composition and the effects that this might exert on the lateral component of the polarizability of the solvent dielectric or on the nature of the imaging of ions and dipoles in the OHP.

B. E. Conway: I wish to comment on some aspects of the specific behavior exhibited in the adsorption of cations and anions in the double-layer. In two dimensions, the concentrations of ions in the double-layer under most conditions are equivalent to concentrations in three-dimensional solutions of several molar. At such high concentrations, three-dimensional electrolyte solutions exhibit rather specific variations in their activity coefficients connected with the hydration of the ions and the close interaction of such hydrated ions. The specificity of such effects is believed to be connected with the structure forming or structure breaking influence of such ions in the water solvent.[7] In two dimensions in the double-layer, it appears that more attention must be paid to the possible role of such solvent-structure effects if specificities in ion adsorption are to be accounted for. The presence of oriented or dielectrically saturated water in the interphase will, however, make the detailed consideration of such effects a somewhat different problem from that involved in bulk aqueous solutions. The orientation of solvent by the electrode field[8] may occur competitively or cooperatively with that caused by the ions in the double-layer, depending on their charge and that of the electrode.

Richard Payne: In reply to Professor Conway's comments, it does not seem likely to me that the solvent structural effects he mentions will be important in the interphase since the structure of the solvent layer will presumably be determined primarily by the large field due to the electrode charge rather than by lateral solvent-solvent interactions. There is no evidence to suggest that any of the unusual structural properties of bulk water are retained in the adsorbed state, and indeed calculations of the electrostatically generated pressure in the double layer together with the known effects of pressure on the structure of bulk water lead one to the same conclusion.[9] The structure of the solvated ion in the bulk solution will, of course, affect the adsorption inasmuch as the solvation energy contributes to the adsorption energy. Bockris, Müller and Devanathan[10] in fact regard the solvation energy as a major factor in the adsorption process. However, this factor obviously does not affect the charge (or potential) dependence of the adsorption which is due to a variety of other factors. It seems to me that specific metal-ion and metal-solvent forces, ion size, ion and solvent polarizability and other purely electrostatic effects are likely to be more important than the structural effects mentioned by Professor Conway.

J. Ross Macdonald: While I agree that one should take account of the effect of the dipole moment of displaced solvent molecules, as you have done, I question the appropriateness of your method of doing so. For one thing, the ion which replaces one or more solvent dipoles will have an induced dipole moment and, in addition, its charge and the image of this charge in the conducting electrode will form a nonideal dipole. I do not see where you have taken account of these partially compensating effects.

Second, in a treatment of adsorption of ions from gas onto a conducting electrode, Barlow and I found that inclusion of images and induced polarization did, in fact, lead to an infinite effective dielectric constant under some conditions. Perhaps a discrete charge and dipole treatment of the present situation might lead to the same possibility here. Do you have any comments on this point?

Richard Payne: I agree with Dr. Macdonald that the introduction of the dipole term in Eq. [24] is a crude approximation and that other terms involving induced polarization of both solvent molecules and ions and the images of these induced dipoles in the metal and in the solution should be taken into account in any calculation of ϕ^{m-2}. However, no attempt was made to calculate the dipole term in Eq. [24] using the ordinary dipole moment of water. This term was included as a first order correction to the potential generated by the adsorbed ions. μ can be regarded as the effective dipole moment taking into account the contribution of the dipole imaging and other effects on ϕ^{m-2} of removing the dipole. It seems likely in any case that these effects will be second order, as was in fact assumed by Macdonald and Barlow[11] in a previous paper.

Some Aspects of the Thermodynamics of the Platinum Hydrogen Electrode

A. N. Frumkin, N. A. Balashova, and V. E. Kazarinov

Institute of Electrochemistry, Academy of Sciences of the USSR, Moscow and Moscow State University

ABSTRACT

The presence of adsorbed hydrogen results in essential differences in the thermodynamics of the surface phenomena on the platinum electrode compared to the mercury one. Thus in this case the point of zero charge (in the conventional sense) does not coincide with the maximum of the electrocapillary curve. The value of the potential difference between the electrode and the solution depends not only on the surface charge but also on the amount of adsorbed hydrogen. Additional complications arise in the presence of specifically adsorbed cations and anions in the solution. The experimental data used in this paper have been obtained by the charging curves method, by direct determinations of anion and cation adsorption, and by the measurements of the potential shift with changing composition of the solution under isoelectric conditions.

A platinum electrode obtained by platinization or activation of smooth platinum by alternating anodic and cathodic polarization in the potential range of ψ_r from $\psi_r = 0$ to $\psi_r = 0.5$-0.6, as referred to hydrogen electrode in the same solution, can be considered a reversible system in acid solutions. Therefore, in interpreting its surface properties, it is possible to make use of Gibbs thermodynamics. Thereby, it should be taken into consideration that, in addition to free charges and ions forming the electric double layer, there is adsorbed hydrogen on the electrode surface. It can be assumed that within the potential range indicated no adsorbed oxygen is present on the electrode surface. In the presence of strongly adsorbed anions or cations (I^-, Cd^{2+}), the condition of reversibility of adsorption processes may be violated. In that case a thermodynamic treatment would give only approximate results.

In the case of alkaline solutions, the above assumptions seem to be valid only within a narrower potential range and only for solutions containing singly charged cations of alkali metals. In the presence of doubly charged cations, such as Ba^{2+}, complications may arise (1)

Let us consider first the case of an acidified or alkalized solution of a binary electrolyte (2), assuming the concentration of the H^+ or OH^- ions to be small compared to that of the salt ions.[1] At constant temperature and pressure, the state of the system is determined by the chemical potentials of hydrogen μ_H, of the hydrogen ion μ_{H+} and of the salt ions μ_s, which we shall express in electric units. We shall set the interface in such a way that the Gibbs adsorption of water $\Gamma_{H_2O} = 0$. Then for $d\sigma$, where σ is the surface density of the free energy, we shall have

$$d\sigma = -\Gamma_H d\mu_H - \Gamma_{H+} d\mu_{H+} - (\Gamma_{C+} + \Gamma_{A-}) d\mu_s \quad [1]$$

where Γ_H, Γ_{H+}, Γ_{C+}, and Γ_{A-} are Gibbs surface densities of hydrogen, hydrogen ion, cation and anion of the salt, respectively, also expressed in electric units.

Evidently

$$\psi_r = (\mu_H)_o - \mu_H \quad [2]$$

where $(\mu_H)_o$ is the value of μ_H in equilibrium with molecular hydrogen at given temperature and pressure. Now

$$\Gamma_{H+} = \Gamma_{A-} - \Gamma_{C+} \quad [3]$$

The quantity Γ_{H+} can be considered to be the density of the electrode surface charge ϵ, assuming that with an excess of C^+ cations, the presence of H^+ ions in the ionic part of the double layer can be neglected (see footnote 1) and that being adsorbed, all hydrogen ions give off their charges to the metal and change to H atoms. In other words, we assume that the potential determining H^+ ions are not adsorbed specifically or that jointly the specifically adsorbed H^+ ion and the negative surface charge can be identified with an H atom. Equating Γ_{H+} with ϵ is somewhat conditional. In fact, specifically adsorbed ions, such as I^- or Cd^{2+}, are shown by experiment to form covalent bonds with the electrode surface (4). Therefore, it could be assumed that in Cd^{2+} adsorption, some of the Cd^{2+} ions change to atoms, giving off positive charges to the surface. Hence two separate quantities Γ_{Cd+} and Γ_{Cd} could be introduced, just as it was done in considering the electrocapillarity of thallium amalgams (5). However, since in the case under consideration we cannot vary independently μ_{Cd} and μ_{Cd2+}, such separation would be aimless. Therefore, within the frame of the thermodynamic treatment it would be reasonable to consider formally all ions disappearing from the solution, except the H^+ ions, to be adsorbed as ions, although such an assumption would have to be essentially corrected in developing a molecular theory of the electric double layer on the Pt electrode (see below).

Let us designate by A_H the amount of hydrogen adsorbed per unit surface. The quantity A_H is not identical with Γ_H, as part of the hydrogen disappearing from the bulk of the solution, when a unit surface is formed, is ionized and expended in its charging. Obviously the following relationship exists between A_H and Γ_H

$$\Gamma_H = A_H - \Gamma_{H+} = A_H - \epsilon \quad [4]$$

From Eq. [1], [2], [3], and [4] it is possible to deduce some relationships between measurable quantities (2, 6). No allowance will be made for hydrogen solubility in the metal and the possible effect of dissolved hydrogen on the electrode process. We shall also assume the quantity μ_{H+} to remain constant with changing ψ_r, that is that the changes in the value of

[1] In practice, the last condition was often not fulfilled, since in an experimental determination of ionic adsorption the use of solutions with a low concentration of H^+ or OH^- ions makes it difficult to keep the pH of the solution constant. However, at least in the case of Cs^+ ions, this could not lead to a significant error in the determination of the charge of adsorbed cations, since when the ratio $[H^+]:[Cs^+]$ is decreased 10 times, adsorption of Cs^+ from $0.01N$ Cs_2SO_4 solution at $\psi_r = 0$ increases only by 30% (3), as it follows also from Fig. 1. Even at the same concentration, the Cs^+ ions seem to displace considerably the H^+ ions from the ionic side of the double layer.

$[H^+]$ caused by those in A_H are small compared to $[H^+]$.[2]

Let us consider the case of a solution of a constant salt composition (μ_s = const). Since

$$\left(\frac{\partial\Gamma_H}{\partial\mu_{H+}}\right)_{\mu_H} = \left(\frac{\partial\Gamma_{H+}}{\partial\mu_H}\right)_{\mu_{H+}} \quad [5]$$

or

$$\left(\frac{\partial\Gamma_H}{\partial\mu_{H+}}\right)_{\psi_r} = -\left(\frac{\partial\Gamma_{H+}}{\partial\psi_r}\right)_{\mu_{H+}} \quad [5a]$$

$$\left(\frac{\partial\Gamma_{H+}}{\partial\psi_r}\right)_{\mu_{H+}} = \left(\frac{\partial\psi_r}{\partial\mu_{H+}}\right)_{\Gamma_H}\left(\frac{\partial\Gamma_H}{\partial\psi_r}\right)_{\mu_{H+}} \quad [6]$$

The quantity Γ_{H+} can be determined experimentally directly from the change in the hydrogen ion concentration in the solution in contact with the electrode polarized to the potential ψ_r, or, according to Eq. [3], from the difference between the anion and cation adsorptions. Some examples of the dependence of Γ_{H+} upon ψ_r are given in Fig. 1 and 2 (7).

The curves in these figures, as well as in others, are extended into the oxygen region, which, however, will not be discussed in the present paper. Now, evidently

$$\left(\frac{\partial\Gamma_H}{\partial\psi_r}\right)_{\mu_{H+}} = -\left(\frac{\partial Q}{\partial\psi_r}\right)_{\mu_{H+}} \quad [7]$$

where Q is the quantity of electricity to be supplied to the electrode per unit surface to shift its potential from some initial value to the value ψ_r, assuming that the quantity of hydrogen dissolved in the bulk of the solution, which is in equilibrium with the electrode, can be neglected compared to the amount of adsorbed hydrogen. Finally, the quantity $\left(\frac{\partial\psi_r}{\partial\mu_{H+}}\right)_{\Gamma_H}$ is determined from the change in the electrode potential, as referred to hydrogen electrode in the same solution, with changing $[H^+]$ under isoelectric conditions, *i.e.*, at open circuit (constant Γ_H).[3] Thus Eq. [6] can be verified quantitatively. A roughly approximate verification of this kind has already been carried out (2). There the quantity $\left(\frac{\partial\psi_r}{\partial\mu_{H+}}\right)_{\Gamma_H}$ was determined from the change in ψ_r when passing from acidified to alkalized solutions, *i.e.*, μ_{H+} was changed within too wide limits. The values of the derivatives in Eq. [6] were equated with the half-sum of the values obtained experimentally for the lowest and the highest *p*H. At present similar measurements are made using improved technique.[4]

Of interest is another deduction from Eq. [1] and [4]. With the solution composition constant

$$\frac{\partial\sigma}{\partial\psi_r} = \Gamma_H = A_H - \epsilon \quad [10]$$

Thus, the maximum of the "electrocapillary curve" of the platinum hydrogen electrode lies not at $\epsilon = 0$, but at $A_H - \epsilon = 0$ and does not coincide with the point of zero charge in the usual sense of this term, *i.e.*, the potential at which the quantity $\epsilon = \Gamma_{A-} - \Gamma_{C+}$ vanishes. According to (2), the point of zero charge of platinum in solution of N NaCl + 0.01N HCl lies at $\psi_r = 0.16$, whereas the quantity $A_H - \epsilon$ vanishes at $\psi_r \approx 0.3$. Such a discrepancy may seem to be unexpected if we proceed from the derivation of Lippman's equation, suitable for the concept of an ideal polarizable mercury electrode, *e.g.*, in the form given by Grahame (10) or Parsons (47). However, Lippman himself understood perfectly well that what the right-hand side of his equation expresses is the capacitance of a unit surface at constant potential (11). Evidently, in the case of a hydrogen-adsorbing metal, the last quantity cannot coincide with the surface charge in the sense of the electrostatic theory of the double layer. In 0.01N Cs_2SO_4 + 0.01N H_2SO_4 the point of zero charge lies at $\psi_r = 0.30$ (3, 7) (0.19 *vs.* NHE) and is close to the potential of the maximum of σ. This coincidence is, however, an accidental one.

The platinum electrode potential ψ, measured against a constant reference electrode, such as the normal hydrogen electrode, depends not only on Γ_{H+}, but on A_H as well. In fact

[2] When the above conditions are fulfilled, the state of the system at a given initial solution composition is completely determined by the quantity of electricity Q supplied to the electrode from some initial moment of time. In this sense, the behavior of the electrode does not differ from that of an ideal or completely polarized electrode, although in this case, the condition of the absence of the exchange of charges between the electrode and the solution, which is usually considered to be the criterion of ideal polarizability, is not fulfilled.

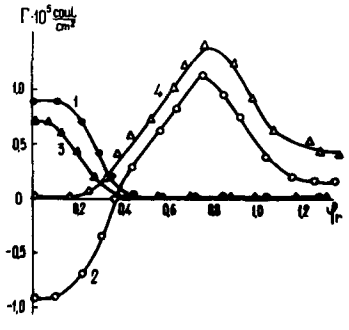

Fig. 1. Dependence of Γ_{Cs+} (1) and Γ_{H+} (2) in 0.018N Cs_2SO_4 + 0.002N H_2SO_4 and Γ_{Cs+} (3) and $\Gamma_{SO_4 2-}$ (4) in 0.01N Cs_2SO_4 + 0.01N H_2SO_4 on ψ_r.

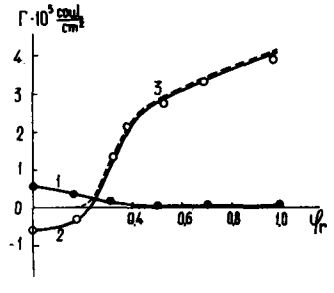

Fig. 2. Dependence of Γ_{Na^+} (1), Γ_{H+} (2) and Γ_{Br-} (3) in 10^{-3}N NaBr + 10^{-3}N H_2SO_4 on ψ_r.

[3] Changes in the electrode state in which the quantity Γ_H, determining the total amount of electricity stored on the electrode, remains constant were suggested to be called isoelectric (8). Isoelectric measurements can be carried out readily in the case of electrodes with developed surface (platinized platinum, activated carbon), for which the condition Γ_H = const. can be fulfilled easily in practice when replacing the solution. These measurements have something in common with the coulostatic method developed by Delahay and collaborators (46), since in both cases changes in the electrode potential at open circuit are observed. The problems to be solved in the two cases were, however, different.

[4] From Eq. [6] by simple transformations (9) it is possible to obtain the relationship

$$\left(\frac{\partial\psi_r}{\partial\mu_{H^+}}\right)_{\Gamma_H} = 1:\left[\left(\frac{\partial A_H}{\partial\Gamma_{H^+}}\right)_{\mu_{H^+}} - 1\right] \quad [8]$$

or

$$\left(\frac{\partial\psi}{\partial\mu_{H^+}}\right) = \left(\frac{\partial A_H}{\partial\Gamma_{H^+}}\right)_{\mu_{H^+}}:\left[\left(\frac{\partial A_H}{\partial\Gamma_{H^+}}\right)_{\mu_{H^+}} - 1\right] \quad [9]$$

where ψ is the potential measured against normal hydrogen electrode.

Equations [8] and [9] determine the dependence of the hydrogen electrode potential on the *p*H of the solution with Γ_H remaining constant, *i.e.*, under isoelectric conditions. The quantity $\left(\frac{\partial A_H}{\partial\Gamma_{H^+}}\right)_{\mu_{H^+}}$ is negative in most cases; if $\left|\left(\frac{\partial A_H}{\partial\Gamma_{H^+}}\right)_{\mu_{H^+}}\right| >> 1$, Eq. [9] turns into the usual relationship for the reversible hydrogen electrode.

$$d\psi = d\mu_{H+} - d\mu_H \quad [11]$$

Now, let us put (2)

$$d\psi = \left(\frac{\partial\psi}{\partial A_H}\right)_{\Gamma_{H+}} dA_H + \left(\frac{\partial\psi}{\partial\Gamma_{H+}}\right)_{A_H} d\Gamma_{H+}$$

$$= X dA_H + Y d\Gamma_{H+} \quad [12]$$

From [11] and [12] it follows

$$X\left(\frac{\partial A_H}{\partial\mu_H}\right)_{\mu_{H+}} + Y\left(\frac{\partial\Gamma_{H+}}{\partial\mu_H}\right)_{\mu_{H+}} = -1 \quad [13]$$

$$X\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H} + Y\left(\frac{\partial\Gamma_{H+}}{\partial\mu_{H+}}\right)_{\mu_H} = 1 \quad [14]$$

From [13], [14], [4], and [5] we obtain

$$X = -\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H} : Z \quad [15]$$

$$Y = \left[\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H} + \left(\frac{\partial A_H}{\partial\mu_H}\right)_{\mu_{H+}}\right] : Z \quad [16]$$

where

$$Z = \left(\frac{\partial\Gamma_{H+}}{\partial\mu_{H+}}\right)_{\mu_H}\left(\frac{\partial A_H}{\partial\mu_H}\right)_{\mu_{H+}} - \left(\frac{\partial\Gamma_{H+}}{\partial\mu_H}\right)_{\mu_{H+}}\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H}$$

$$= \left(\frac{\partial\Gamma_H}{\partial\mu_H}\right)_{\mu_{H+}}\left(\frac{\partial\Gamma_{H+}}{\partial\mu_{H+}}\right)_{\mu_H} - \left(\frac{\partial\Gamma_H}{\partial\mu_{H+}}\right)^2_{\mu_H} \quad [17]$$

If $\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H} = 0$, *i.e.*, atomic hydrogen adsorption does not depend on the composition of the solution, according to Eq. [15], $X = 0$. In this case, the presence of adsorbed hydrogen has no effect on the potential difference. In actual fact, however, the value of A_H depends on pH, increasing when passing from acid to alkali at small and medium coverages and decreasing at large coverages (2, 6). As all the quantities appearing in the right-hand sides of Eq. [15], [16], and [17] are measurable, it is possible to calculate from these equations the contribution of atoms and ions to the potential difference at the electrode-solution interface. Unfortunately, there are no sufficiently accurate values of the quantities $\left(\frac{\partial A_H}{\partial\mu_{H+}}\right)_{\mu_H}$ and $\left(\frac{\partial\Gamma_{H+}}{\partial\mu_{H+}}\right)_{\mu_H}$ available at present. The results of a roughly tentative calculation from the data obtained in (2) are presented in Fig. 3. Since in this case the measurements of Γ_{H+} were made in N NaCl + 0.01N HCl and in N NaCl + 0.05N KOH, the results of the calculation can give an approximate idea of the quantities X and Y for the intermediate value of pH, *i.e.*, for a neutral solution. More accurate measurements of this kind are to be made at a later date. In spite of the tentative nature of the data in Fig. 3, it is possible to draw some conclusions from them regarding the mechanism of the appearance of the potential difference on the platinum hydrogen electrode. At small coverages, the quantity X is positive, *i.e.*, in the atomic hydrogen coverage the negative dipole end is turned toward the solution. With increasing coverage, the sign of polarity changes, the effect continuing to increase in absolute value as $\psi_r = 0$ is approached. As already pointed out in the literature,

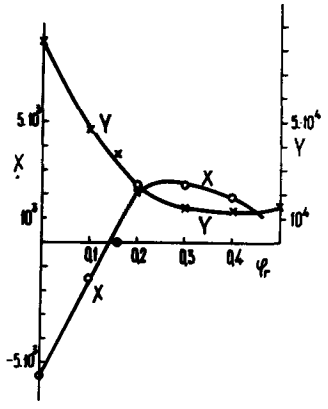

Fig. 3. Dependence of the quantities $X = \left(\frac{\partial\psi}{\partial A_H}\right)_{\Gamma_{H+}}$ and $Y = \left(\frac{\partial\psi}{\partial\Gamma_{H+}}\right)_{A_H}$ on ψ_r in N NaCl solution. Ordinates in farads^{-1} x cm^2.

the change in polarity with increasing coverage is in agreement with the results of the work function measurements (12). It follows from a comparison of the X and Y curves that the contribution of the adsorbed hydrogen atom to the establishment of the potential difference is approximately by an order of magnitude less than that of the adsorbed ion. The quantity Y^{-1} is the electrode capacitance at constant A_H. At ψ_r = 0.3-0.5, it is equal to *ca.* 70 μf/cm^2 and decreases to 12 μf/cm^2 with ψ_r approaching zero. The decrease in capacitance can be partially due to the substitution of cations for anions in the ionic side of the double layer, but the effect of the increasing surface coverage with adsorbed hydrogen on the capacitance should be taken into consideration as well. In actual fact, as is clear from Fig. 3, the increase in Y with decreasing ψ_r becomes appreciable beginning with ψ_r = 0.3, whereas the point of zero charge, as is evident from Fig. 6 in Frumkin and Slygin's work, in neutral N NaCl should lie at ψ_r = 0.18. It should be noted that within the range of ψ_r = 0.3-0.5 the capacitance values are high. Numerous a-c measurements on smooth electrodes at sufficiently high frequencies give capacitance values of 15-20 μf/cm^2 in the double layer region. It is possible that this value should be even smaller if allowance is made for the roughness factor. The reliability of the values obtained from the adsorption measurements depends on the correct estimation of the platinized electrode surface. The calculation of adsorption per cm^2, and hence of the quantities X and Y, given in this paper is based on the assumption that at ψ_r = 0, there is one H atom for each Pt atom, and 1.31 x 10^{15} atoms/1 cm^2 of the Pt surface.[5] The determination of the surface area by this method leads to values which are in agreement with the Pt surface measurements by the BET method (14, 15). Thus, the discrepancy between the results of the capacitance determination from adsorption measurements and from impedance is a real one. The most probable explanation would be to suppose the establishment of equilibrium between the adsorbed anion and the platinum surface to be a slow process, which is in agreement with the covalency of the Pt-anion bond under equilibrium conditions. It should be noted that the capacitance of the Pt electrode in the double layer region in a 0.1N H_2SO_4 solution, determined from adsorption measurements (without control however of the condition A_H=const being

[5] There are some discrepancies in the estimation of the latter value. Thus, Fisher, Chon, and Aston (13) give the value 1.195 x 10^{15}. These discrepancies are too small, however, to account for those between the results of the two methods of the capacitance determination.

observed) amounts to as little as 36 ± 5 μf/cm² (3), *i.e.*, is much less than in solutions of halides.

If the establishment of the potential difference at the platinum electrode-solution interface cannot be understood without taking into account the contribution of the atomic coverage, it is not possible either to assume, as Bowden and Rideal (16) did some time ago, the total potential difference established to be determined by the dipole moment of the adsorbed atoms. As pointed out by Frumkin (17), it is impossible to fulfill the conditions of equilibrium between electrode, solution, and adsorbed gas at a given electrode potential without taking into consideration the electric double layer. Let us explain this for the simplest case of the equilibrium hydrogen electrode. Under the assumption made, the quantity A_H depends only on μ_H and hence on ψ_r

$$A_H = f(\psi_r) \qquad [18]$$

On the other hand, if we designate the effective dipole moment of the Pt-H bond as d, we shall have

$$\psi = \psi_r - (\mu_{H+})_o + \mu_{H+} = \frac{4\pi A_H d}{e} + \text{const} \qquad [19]$$

where e is the elementary charge and $(\mu_{H+})_o$ the value of μ_{H+} at molar concentration of the H^+ ions. It is evident that the quantity A_H, determined from [19], in the general case cannot be the solution of Eq. [18]. This conclusion remains valid if, under the assumption about the equilibrium state of the system, we assume O_{ads} to be present on the surface along with H_{ads}. At the first glance, the results of the adsorption measurements of the cations from dilute NaOH and CsOH solutions seem to be at variance with this conclusion (18) (Fig. 4). In this case the cation adsorption practically does not depend on ψ_r. In other words, the change in the potential difference seems to be due to that in the atomic coverage, a decrease in the amount of adsorbed H and an increase in that of adsorbed O. In actual fact, however, the constancy of Γ_{C+} is probably of a random nature, since the adsorption effect in alkaline solutions is made up of two items: cation adsorption, associated with H_{ads} ionization, and adsorption by hydrated surface oxide groups, which are of a weakly acid nature and take up cations in alkaline solutions. With increasing ψ_r, the first effect decreases, whereas within a certain potential range, the second effect increases, resulting in the approximate constancy of Γ_{C+}. Such an explanation is supported by the following observations. In the presence of Br^- or I^- ions (as well as of Cl^- ions at higher concentrations, which displace oxygen from Pt surface) in alkaline solutions at not too small ψ_r, Γ_{C+} decreases with increasing ψ_r (Fig. 5) (7, 18, 19). In $Ca(OH)_2$ and $Ba(OH)_2$ solutions containing doubly charged cations Ca^{2+} and Ba^{2+}, which seem to be strongly chemisorbed by hydrated surface oxides, with increasing ψ_r in the hydrogen region Γ_{C+} increases (Fig. 6) (1). Of particular interest is the approximate constancy of Γ_{C+} in the hydrogen region, which is also observed, although within a narrower range of ψ_r values, in

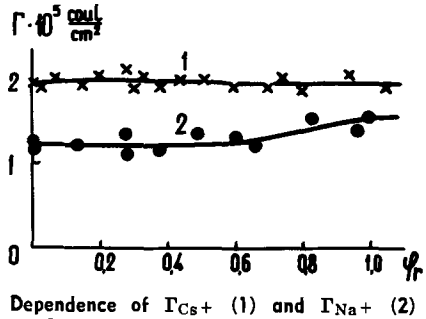

Fig. 4. Dependence of Γ_{Cs+} (1) and Γ_{Na+} (2) in 10^{-2}N CsOH and 10^{-2}N NaOH on ψ_r.

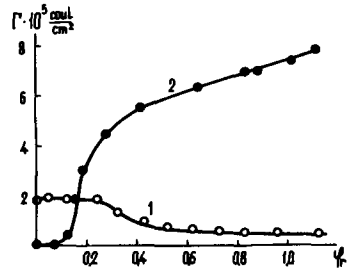

Fig. 5. Dependence of Γ_{Cs+} (1) and Γ_{I-} (2) in 10^{-2}N CsOH + 10^{-2}N CsI on ψ_r.

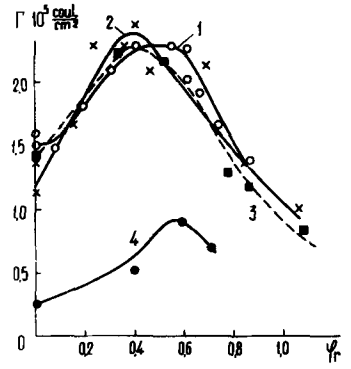

Fig. 6. Dependence of adsorption values on ψ_r: 1, Ca^{2+} in 10^{-3}N $Ca(OH)_2$; 2, Ba^{2+} in 10^{-3}N $Ba(OH)_2$; 3, Ba^{2+} in 10^{-3}N $Ba(OH)_2$ + 1N NaOH; 4, Ca^{2+} in 10^{-3}N $Ca(OH)_2$ + 1N NaOH.

acidified solutions of sulfates (Fig. 1). In this case, the change in ψ_r at a practically constant Γ_{C+} is partly determined by that in the effective dipole moment of the Pt-H bond. As pointed out earlier, at small coverages the dipole of this bond is turned toward the solution with its negative, at large coverages—with its positive end. Another factor leading to an increase in the absolute value of the negative potential difference at constant Γ_{C+} in the range of small ψ_r, which we have also mentioned earlier, is the decrease in the capacitance of the electric double layer with increasing A_H.

The thermodynamic theory outlined here can be extended to other hydrogen adsorbing metals. As shown by Tyurin and Tsybulevskaya (20), who studied the dependence of the charging curves of disperse rhodium on the *p*H of the solution, an empiric relationship is valid in the case of the rhodium electrode

$$A_H = f_1 (pa^{-0.52}) \qquad [20]$$

where p is the equilibrium pressure of molecular hydrogen, a is the activity of hydroxonium ion, and f_1 is some functional dependence. Equation [20] can also be written as

$$A_H = f_2 (\mu_H - 0.26\,\mu_{H+}) \qquad [21]$$

whence from [11], [15], and [16] it follows

$$\left(\frac{\partial A_H}{\partial \Gamma_{H+}}\right)_{\psi} = -\left(\frac{\partial \psi}{\partial \Gamma_{H+}}\right)_{A_H} : \left(\frac{\partial \psi}{\partial A_H}\right)_{\Gamma_{H+}}$$

$$= \left[\left(\frac{\partial A_H}{\partial \mu_H}\right)_{\mu_{H+}} + \left(\frac{\partial A_H}{\partial \mu_{H+}}\right)_{\mu_H}\right] : \left(\frac{\partial A_H}{\partial \mu_{H+}}\right)_{\mu_H}$$

$$= -\frac{1 - 0.26}{0.26} = -2.8$$

The relatively low value of $\left|\left(\frac{\partial A_H}{\partial \Gamma_{H+}}\right)_{\psi}\right|$ (com-

pared to platinum) can be partly due to the Rh surface which apparently always carries a positive charge in the hydrogen region (21). It also points to a considerable and constant polarity of the Rh-H bond, with the negative dipole end turned toward the solution.

Let us consider some other possible changes in the composition of the solution.

Adsorption of cations and anions of the electrolyte, on one hand, and hydrogen adsorption, on the other, exert a mutual influence (6). It follows from [1], [3], and [4] that

$$\left(\frac{\partial A_H}{\partial \mu_s}\right)_{\psi_r,\mu_{H^+}} = \left(\frac{\partial(\Gamma_{A^-} - \Gamma_{C^+})}{\partial \mu_s}\right)_{\psi_r,\mu_{H^+}} - \left(\frac{\partial(\Gamma_{A^-} + \Gamma_{C^+})}{\partial \psi_r}\right)_{\mu_s,\mu_{H^+}} \quad [22]$$

Equation [22] can be verified experimentally, although this has not been done yet. In fact, adsorption of cations and anions on platinum can be directly estimated from experiment, primarily by the method of radioactive tracers (7). Then, by the charging curves method, it is possible to find the quantity $\left(\frac{\partial \Gamma_H}{\partial \mu_s}\right)_{\psi_r,\mu_{H^+}}$, and hence $\left(\frac{\partial A_H}{\partial \mu_s}\right)_{\psi_r,\mu_{H^+}}$. From [22], by elementary transformations, we obtain

$$\left(\frac{\partial \psi}{\partial \mu_s}\right)_{\epsilon,\mu_{H^+}} = -\left[\frac{\partial(\Gamma_{A^-} + \Gamma_{C^+})}{\partial \epsilon}\right]_{\mu_s,\mu_{H^+}} - \left(\frac{\partial \psi}{\partial \epsilon}\right)_{\mu_s,\mu_{H^+}} \left(\frac{\partial A_H}{\partial \mu_s}\right)_{\psi_r,\mu_{H^+}} \quad [23]$$

With $\frac{\partial A_H}{\partial \mu_s} = 0$, Eq. [23] changes to a relation which is well known from the thermodynamics of electrocapillary phenomena (22, 27).

At the present time, experimental data are available on the adsorption on platinum of the cations Na^+, Cs^+, Ca^{2+}, Ba^{2+}, Cd^{2+}, Tl^+ and the anions SO_4^{2-}, $H_2PO_4^-$, Cl^-, Br^-, I^- from acid and partly from alkaline solutions (1, 3, 4, 7, 18, 19, 23) which, however, will not be presented here. Let us consider briefly only a few of the specific features of this adsorption.

The behavior of adsorbed Na^+ and Cs^+, as well as of Ca^{2+} and Ba^{2+} in acid solutions is on the whole similar to their behavior at the mercury-solution interface.[6] But the difference in their adsorptivities, which increases in the sequence: $Na^+ < Cs^+ < Ca^{2+} < Ba^{2+}$ is much greater. The maximum charge of adsorbed cations remains within 5 — 10 x 10^{-6} coul/cm^2 for acid and 10 — 25 x 10^{-6} coul/cm^2 for alkaline solutions at the bulk concentrations of the order of 10^{-2} mol. The cations Cd^{2+} and Tl^+ show a pronounced specific adsorptivity (to a lesser degree also Zn^{2+} and Pb^{2+}). In the case of Cd^{2+} the maximum charge reaches the value 60 x 10^{-6} coul/cm^2, and the coverage reaches large fractions of a monolayer. The adsorptivity of anions increases in the sequence $SO_4^{2-} < Cl^- < Br^- < I^-$; the maximum charge of adsorbed anions increases in this sequence from 15 to 140 x 10^{-6} coul/cm^2. Some specific adsorptivity is observed also in the case of the least adsorbable ion SO_4^{2-}, since the adsorption of SO_4^{2-} and Cs^{2+} maintains a small, but still measurable, value at the point of zero charge in acidified Cs_2SO_4 solution as well. One of the characteristic differences between specific adsorption of ions on Pt and that on mercury is that in the former

[6] Added in proof: New data show that the difference in the behavior of Ba^{2+} at both interfaces is much greater than it was supposed earlier.

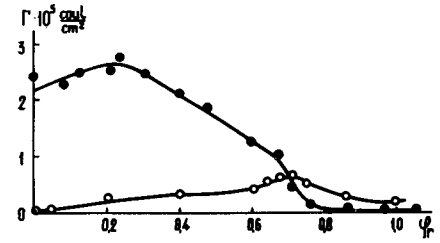

Fig. 7. Dependence of $\Gamma_{Cd^{2+}r}$ and $\Gamma_{SO_4^{2-}}$ in 10^{-2}N $CdSO_4$ + 10^{-2}N H_2SO_4 on ψ_r.

case the phenomenon of superequivalent adsorption is much less pronounced. Considerable adsorption of halogen ions on platinum is accompanied over a wide potential range by slight adsorption of cations only (Fig. 2). The same holds true in the case of adsorption of the anion SO_4^{2-} in the presence of the Cd^{2+} ion (Fig. 7). In the latter case, however, it is this small quantity of adsorbed anions and the positive charges on Pt corresponding to them which determine the ultimate positive sign of the potential difference between metal and solution to be observed at potentials more positive than the point of zero charge of platinum in absence of specific adsorption. Hence it follows that the effective charge of specifically adsorbed cations Cd^{2+} must be very small. It would be possible to estimate this charge quantitatively by measuring, *e.g.*, $\left(\frac{\partial \psi}{\partial \Gamma_{Cd}}\right)_{\Gamma_{A^-}}$ and $\left(\frac{\partial \psi}{\partial \Gamma_{A^-}}\right)_{\Gamma_{Cd}}$ in $CdSO_4$ + H_2SO_4 solutions with varying concentration of both components. At the present time, however, such data are not available. The results of an attempt to estimate the effective charge of adsorbed Tl^+ ions in (23) cannot be agreed with.

Adsorptivity of ions can also be determined from the potential shift on introduction of an ion under isoelectric conditions into a solution containing only weakly, or not at all, specifically adsorbable ions.[7] Such "adsorption" potentials of anions (24) (Cl^-, Br^-, I^-) and cations (25) (Tl^+, Cd^{2+}, Zn^{2+}, Pb^{2+}) were determined by Obrucheva on platinized and smooth platinum [see also (26)]. A supporting electrolyte was used, *e.g.*, *N* H_2SO_4. Let us designate the chemical potential and the surface density of the surface active ion by μ_i and Γ_i, respectively. We assume its concentration to be so small, compared to that of other ions in the solution, that it can be varied, maintaining the chemical potentials of the other ions in the solution practically constant. Under these conditions, the variables to be taken into consideration are μ_H and μ_i. From the relation

$$d\sigma = -\Gamma_H d\mu_H - \Gamma_i d\mu_i \quad [24]$$

it follows

$$\left(\frac{\partial \Gamma_H}{\partial \mu_i}\right)_{\mu_H} = \left(\frac{\partial \Gamma_i}{\partial \mu_H}\right)_{\mu_i} \quad [25]$$

whence

$$\left(\frac{\partial \psi_r}{\partial \mu_i}\right)_{\Gamma_H} = -\left(\frac{\partial \psi_r}{\partial \Gamma_H}\right)_{\mu_i} \left(\frac{\partial \Gamma_H}{\partial \mu_i}\right)_{\mu_H} = \left(\frac{\partial \psi_r}{\partial \Gamma_H}\right)_{\mu_i} \left(\frac{\partial \Gamma_i}{\partial \psi_r}\right)_{\mu_i} = \left(\frac{\partial \Gamma_i}{\partial \Gamma_H}\right)_{\mu_i} \quad [26]$$

Taking into consideration Eq. [4], Eq. [25] can be written as

$$\left(\frac{\partial \psi_r}{\partial \mu_i}\right)_{\Gamma_H} = 1 : \left[\left(\frac{\partial A_H}{\partial \Gamma_i}\right)_{\mu_i} - \left(\frac{\partial \epsilon}{\partial \Gamma_i}\right)_{\mu_i}\right] \quad [27]$$

[7] Evidently, the isoelectricity condition cannot be fulfilled at potentials which are so close to the reversible hydrogen potential that the hydrogen content in the bulk of the solution becomes comparable to the amount of hydrogen adsorbed on the electrode surface.

We shall assume the adsorptivity of the ion i to be so large that, in spite of small concentration, it will displace from the ionic part of the double layer other ions with charges of the same sign. Then in the case of the surface-active anion

$$\epsilon = \Gamma_{i-} - \Gamma_{C+} \qquad [28]$$

and the surface-active cation

$$\epsilon = \Gamma_{A-} - \Gamma_{i+} \qquad [28a]$$

where C^+ and A^- are cation and anion which do not show significant specific adsorptivity. From [27], [28], and [28a], it follows for the case of anion adsorption[8]

$$\left(\frac{\partial\psi_r}{\partial\mu_i}\right)_{\Gamma_H} = 1 : \left[\left(\frac{\partial A_H}{\partial\Gamma_{i-}}\right)_{\mu_i} - 1 + \left(\frac{\partial\Gamma_{C+}}{\partial\Gamma_{i-}}\right)_{\mu_i}\right] \qquad [29]$$

and for the case of cation adsorption

$$\left(\frac{\partial\psi_r}{\partial\mu_i}\right)_{\Gamma_H} = 1 : \left[\left(\frac{\partial A_H}{\partial\Gamma_{i+}}\right)_{\mu_i} + 1 - \left(\frac{\partial\Gamma_{A-}}{\partial\Gamma_{i+}}\right)_{\mu_i}\right] \qquad [29a]$$

The expressions in square brackets determine the sign and value of the potential shift under isoelectric conditions with increasing concentration of the i ion, assuming the adsorption equilibrium to be maintained all the time. These expressions differ from those obtained in the case of the mercury electrode not only in that they contain the term $\left(\frac{\partial A_H}{\partial\Gamma_i}\right)_{\mu_i}$, but also in that the quantity $\left(\frac{\partial\Gamma_{C+}}{\partial\Gamma_{i-}}\right)_{\mu_i}$ and, accordingly, $\left(\frac{\partial\Gamma_{A-}}{\partial\Gamma_{i+}}\right)_{\mu_i}$ are small (unless the potential lies in the immediate vicinity of the point of zero charge). The latter fact is due to the insignificance of the value of superequivalent adsorption on the Pt electrode, already mentioned earlier.[9] In the expression in square brackets in Eq. [29] all items are always negative. Therefore, the quantity $\left(\frac{\partial\psi_r}{\partial\mu_i}\right)_{\Gamma_H}$ should be negative, as would be expected in the case of anion adsorption, and less than unity in absolute value, approaching unity on complete displacement of adsorbed hydrogen by the anion. The last conclusion is at variance with some results of Obrucheva (24), since, when the concentration of Br^- and I^- was increased ten times, with H_2SO_4 used as a supporting electrolyte, under certain conditions adsorption shifts of the potential in the direction of more negative values equal to 0.12v or even larger were observed, which would correspond to $\left(\frac{\partial\psi_r}{\partial\mu_i}\right)_{\Gamma_H} \sim -2$. It is possible, however, that in more dilute solutions adsorption equilibrium was not established. In the case of cation adsorption (Eq. [29a]), the second and the third items in square brackets are always positive. Usually, the first item is also positive, and the positive value of the sum determines in the case of cation adsorption the shift of ψ_r in the direction of higher values. In some cases, however, *e.g.*, in adsorption of Cd^{2+} from acid solution of $CdSO_4$, at small values of ψ_r, Γ_{i+} increases with increasing ψ_r (7). Probably, this is the result of the competition between Cd^{2+} and H for sites on the platinum surface (Fig. 7). At large enough negative values of $\left(\frac{\partial A_H}{\partial\Gamma_{i+}}\right)_{\mu_i}$, the quantity $\left(\frac{\partial\psi_r}{\partial\mu_{i+}}\right)_{\Gamma_H}$ may become negative, and the adsorption of the cation may cause a potential shift toward more negative values. Such effects were actually observed in the case of the adsorption of the Tl^+ ion in the vicinity of the reversible hydrogen potential and were explained by the displacement of adsorbed hydrogen (25). It should be emphasized, however, that these data are of a strictly qualitative nature, and the verification of the quantitative theory of adsorption shifts of potential in the case of specific ion adsorption on platinum necessitates further study.

Measurements of adsorption shifts of potential also give an independent method of determination of the changes in the shape of the charging curve with changing composition of the solution since all the values of ψ_r obtained in passing from the values $\mu_i = (\mu_i)_1$ to $\mu_i = (\mu_i)_2$ at Γ_H = const. evidently can give a charging curve corresponding to the solution with $\mu_i = (\mu_i)_2$, provided the charging curve of the solution with $\mu_i = (\mu_i)_1$ is known (28).

Recently much attention has been given to adsorption of organic substances on electrodes of the platinum type, and valuable results have been obtained by Bockris and co-workers (29). Assuming that this kind of adsorption can be considered to be a reversible process, which does not seem to be true in all cases, the following relation can be used for a system with constant concentration of all components except adsorbed hydrogen and organic substance

$$d\sigma = -\Gamma_H d\mu_H - \Gamma_{org} d\mu_{org} \qquad [30]$$

where Γ_{org} and μ_{org} are adsorbed amount and chemical potential of the organic substance (30).

Taking into consideration Eq. [4], it follows from [30] that

$$\left(\frac{\partial A_H}{\partial\mu_{org}}\right)_\psi - \left(\frac{\partial\epsilon}{\partial\mu_{org}}\right)_\psi = -\left(\frac{\partial\Gamma_{org}}{\partial\psi}\right)_{\mu_{org}} \qquad [31]$$

whence

$$\left(\frac{\partial\mu_{org}}{\partial\psi}\right)_{\Gamma_{org}} = -\left(\frac{\partial\mu_{org}}{\partial\Gamma_{org}}\right)_\psi \left(\frac{\partial\Gamma_{org}}{\partial\psi}\right)_{\mu_{org}} = \left(\frac{\partial A_H}{\partial\Gamma_{org}}\right)_\psi - \left(\frac{\partial\epsilon}{\partial\Gamma_{org}}\right)_\psi \qquad [32]$$

Equation [32] can also be written in the form

$$\left(\frac{\partial\Delta G_{org}}{\partial\psi}\right)_{\Gamma_{org}} = -\left(\frac{\partial\epsilon}{\partial\Gamma_{org}}\right)_\psi + \left(\frac{\partial A_H}{\partial\Gamma_{org}}\right)_\psi \qquad [33]$$

where ΔG_{org} is the standard free energy of adsorption of organic substance. In the case of the mercury electrode, the change in adsorptivity of organic substance with the potential is determined by the first term in the right hand side of Eq. [33]. To compare the values of the first and of the second terms, let us put it as it is usually done (31)

$$\epsilon = \epsilon_1\left(1 - \frac{\Gamma_{org}}{\Gamma_\infty}\right) + \epsilon_2\frac{\Gamma_{org}}{\Gamma_\infty} \qquad [34]$$

where Γ_∞ is the limiting adsorption of organic substance and ϵ_1 and ϵ_2 the charge per unit surface on uncovered and covered parts of the surface, respectively. Similarly, we can put

[8] If $A_H = 0$, Eq. [29], as it is easy to show, becomes identical with the relation deduced recently by Dutkievicz and Parsons (48) (loc. cit., Eq. [14]) to determine the shift of the potential of a mercury electrode in a KF solution, caused by the adsorption of I- ions at constant charge.

[9] For the mercury electrode in the case of specific adsorption of anions, the quantity $\left(\frac{\partial\Gamma_{C^+}}{\partial\Gamma_{i^-}}\right)_{\mu_i}$ is close to 0.3 (27).

$$A_H = (A_H)_1 \left(1 - \frac{\Gamma_{org}}{\Gamma_\infty}\right) + (A_H)_2 \frac{\Gamma_{org}}{\Gamma_\infty} \quad [35]$$

It follows from [34] and [35] that

$$\frac{\partial \epsilon}{\partial \Gamma_{org}} = \frac{1}{\Gamma_\infty}(\epsilon_2 - \epsilon_1) \quad [36]$$

$$\frac{\partial A_H}{\partial \Gamma_{org}} = \frac{1}{\Gamma_\infty}[(A_H)_2 - (A_H)_1] \quad [37]$$

For many organic substances and over a wide potential range, in the case of the mercury electrode $|\epsilon_2|$ is known to be several times less than $|\epsilon_1|$, which fact determines the desorbing action of the electric field. Judging by the few experimental data available (32), a similar relation should exist between $(A_H)_2$ and $(A_H)_1$. Thus, the relative importance of the first and the second terms in the right-hand side of Eq. [33], as the factors determining the value of $\left(\frac{\partial \Delta G_{org}}{\partial \psi}\right)_{\Gamma_{org}}$, depends in order of magnitude on the ratio of A_H and $|\epsilon|$. Taking into consideration that the maximum value of A_H in the hydrogen region is $\sim 2 \times 10^{-4}$ coul/cm^2, and the maximum value of ϵ for the Pt electrode, *e.g.*, in acid sulfate solutions, is of the order of 10^{-5} coul/cm^2, it is evident that the second term in the right-hand side of Eq. [36] is of great importance. Even at the positive boundary of the hydrogen region and within the so-called "double layer" region, in which in the case of solutions without surface-active anions the amount of hydrogen adsorbed on platinum surface, small as it is, is not equal to zero, ϵ and A_H can be of the same order of magnitude and the presence of the term $\left(\frac{\partial A_H}{\partial \Gamma_{org}}\right)_\psi$ should be taken into consideration in determining the dependence of ΔG_{org} on ψ. Hence it follows that the relations deduced for the mercury electrode are not applicable for the determination of the position of the adsorption maximum of neutral molecules relative to the point of zero charge in the case of the platinum electrode. Whereas the point of zero charge of platinum at low pH values lies in the hydrogen region, due to the desorbing action of hydrogen, the potential of maximum adsorption should be shifted into the double layer region. The magnitude of this shift is limited by the appearance on the platinum surface not only of positive charges, but also of adsorbed oxygen. The mutual influence of adsorption of organic substance and oxygen cannot be considered using thermodynamic methods owing to the irreversibility of oxygen adsorption, but there is no doubt that the presence of the latter also reduces the adsorption of organic molecules. The shift of the potential of maximum adsorption in the direction of more positive values relative to the point of zero charge must decrease in the presence of surface-active anions, since at not too small ψ_r the latter decrease A_H and increase ϵ.

It should be noted that in considering the thermodynamics of adsorption of organic substances on the Pt electrode, we assumed the molecule to be adsorbed without dissociation. In actual fact, the adsorption of many compounds, e.g., aliphatic alcohols, involves dehydrogenation (33), which makes the treatment of the process somewhat more complicated. This case should be considered separately.

A suggestion was made to determine the point of zero charge of platinum from the potential at which adsorption of organic substance does not depend on the electrolyte concentration (34). This conclusion could be considered to be justified only if the quantity A_H were proved to remain unchanged with changing electrolyte concentration.

Finally, it should be noted that Eq. [33] is applicable not only to adsorption of a neutral molecule, but also to that of the surface active cations and anions, present as an addition to the supporting electrolyte, provided their concentration is so small that it can be varied, keeping the concentration of the supporting electrolyte practically constant. In this case, the quantity Γ_{org} in Eq. [33] should be substituted by the surface density of the ion being adsorbed Γ_i.

ADDENDUM

Of essential importance for the development of the theory of the double layer on platinum is the determination of the potential of zero charge $\psi_{\epsilon=0}$. The following methods were used for this purpose: direct determination of the quantity Γ_{H^+} from the changes of the hydrogen ion concentration caused by the adsorption process (I); determination of the potential at which anion and cation adsorptions, expressed in electric units, become equal (II); determination of the deviation of a thin platinum wire in an electric field (III); determination of the dependence of the force which must be applied in order to establish a contact between two crossed platinum wires on the potential (IV); determination of the potential corresponding to the maximum contact angle (V). The last method is a roughly approximate one. Some results obtained by the above methods are listed in Table I.

As it is evident from Table I, the data obtained by different methods are in fair agreement. In the case of minimum specific adsorption $\psi_{\epsilon=0} = 0.16$-0.19. This quantity shifts in the direction of more negative values in adsorption of the anions Cl^- and Br^- and in the direction of more positive values in adsorption of the ion Cd^{2+}.

In addition to investigations by the above mentioned methods, attempts have been made to determine the value of $\psi_{\epsilon=0}$ from the position of the minimum on the differential capacitance-potential curve, this minimum being assumed to correspond to the maximum diffusivity of the electric double layer. The use of this method, which gives reliable results for metals that do not adsorb hydrogen, such as mercury (38), gallium (39), silver (40), lead, tin, etc. (41, 42), involves, however, considerable difficulties in the case of the platinum electrode, on whose surface adsorbed hydrogen and oxygen are present, since in this case the pseudocapacity of ionization of these gases is superimposed on the double layer capacity. Additional difficulties arise due to the slowness of the process of adsorption equilibrium establishment during the formation of the double layer on platinum, which was discussed earlier. Although, in principle, measurements carried out in dilute solutions at sufficiently high frequencies should give correct values of $\psi_{\epsilon=0}$, the difficulties arising in such measurements do not seem to have been overcome as yet. The values of $\psi_{\epsilon=0}$, obtained by various investigators from the capacitance measurements of the Pt electrode (43, 44), show great divergences. Moreover, the potential corresponding to the minimum observed on the differential capacitance curve greatly depends on pH, which has been recently confirmed by Gileadi, Rubin, and Bockris (45). As already shown by Frumkin and Slygin, due to the polarity of the Pt-H bond, a dependence of $\psi_{\epsilon=0}$ on pH should exist. But the linear rela-

tionship between the supposed value of $\psi_{\epsilon=0}$ and pH, established in (45), cannot be explained on the basis of the theory and makes it probable that the minimum observed reflects to some extent the minimum coverage of the surface with adsorbed hydrogen and oxygen rather than the maximum diffusivity of the double layer (44). This is in agreement with the relation between the slopes of the $\Gamma_{H^+,\psi}$ and the $\Gamma_{H,\psi}$ curves in solution containing the SO_4^{2-} ion (3, 7), which shows that in this case, in the so-called double layer region the amount of adsorbed hydrogen and oxygen on the surface is commensurable with the double layer charge. Thus, in 0.1*N* H_2SO_4, within the potential range 0.3-0.8, the value of $\partial\Gamma_{H^+}/\partial\psi$ is equal to 36 ± 5 μf/cm^2, whereas the value of $-\partial\Gamma_H/\partial\psi$, determined from the slope of the charging curve, is ~70 μf/cm^2 at ψ = 0.3-0.5 and 150 μf/cm^2 at ψ = 0.5-0.8 (3). An even greater discrepancy is observed at higher pH (2). Only in the presence of specifically adsorbed anions, such as Cl^- and Br^-, the capacitance values, determined from the adsorption measurements and the charging curves coincide over some potential range, *i.e.*, the surface is practically free of adsorbed H and O.

It should be also kept in mind that a certain lowering of the differential capacitance values with increasing dilution is not necessarily connected with increased diffusivity of the double layer and can be caused by an exclusion of a part of the surface, which is especially pronounced if the surface is not perfectly smooth or markedly inhomogeneous.

On the whole we think that the capacitance minimum of the platinum electrode, corresponding to the maximum diffusivity of the double layer, has not yet been established. It appears therefore doubtful whether the value of $\psi_{\epsilon=0}$ equal to 0.48 at pH = 3 obtained by capacity measurements (45) really corresponds to the point of zero charge of platinum. The question of the relationship between the potential of zero charge and that of maximum adsorption of neutral molecules in the case of the Pt electrode was discussed earlier.

Discussion

M. W. Breiter: The paper stresses the important aspects in which the adsorption of inorganic and organic species on platinum differs from that on mercury because of simultaneous adsorption of hydrogen atoms or oxygen atoms. The general predictions of the thermodynamic treatment given first by Frumkin and Slygin[1] are in good agreement with the numerous results of direct measurements of ion adsorption on platinum by the above authors. The influence[1] of the composition of the electrolyte on hydrogen adsorption is also reflected by the heats of hydrogen adsorption[2,3] at the same coverage in different electrolytes. The heat decreases with increasing adsorbability and concentration of the anion. The decrease of the heat is paralleled[4,5] by less negative values of the corresponding entropy change at small hydrogen coverage ($\theta < 0.1$). If organic species are chemisorbed, the resulting decrease of hydrogen adsorption may be used as a measure of the coverage with organic species. A quantitative method was suggested recently.[6]

An attempt was made some time ago to apply the thermodynamic treatment[1] to the determination of halide ion adsorption from the measurements[7] of hydrogen adsorption on smooth platinum in 1M $HClO_4$ with additions of HCl or HBr at halide ion concentrations of 10^{-3} and 10^{-2}M. However the changes of Q (see Eq. [7] in the paper) with the chemical potential of HCl and HBr, respectively, were not large enough to warrant a computation under the condition of having the same surface state at different anion concentrations. The technique developed by Gilman[8] appears useful for the study of halide ion adsorption on platinum.

S. Schuldiner: This paper gives an excellent thermodynamic treatment of the Pt hydrogen electrode. Many useful relations are derived which are of value. The initial assumption of the authors that the potential range from 0 to 0.5-0.6v *vs.* the hydrogen electrode in the same solution can be considered as a reversible system in acid solution is open to question. Work at the U. S. Naval Research Laboratory has shown that the reversible H^+/H_2 reaction determines potential on a Pt electrode in acid solution only up to 0.18v *vs.* NHE. Furthermore this work and others has shown that a large part of the hydrogen associated with a Pt electrode is irreversibly sorbed. Thus, the potential range Frumkin, Balashova, and Kazarinov assume to be valid for the reversible hydrogen electrode appears to be much less than claimed.

A. N. Frumkin (communicated): It is not important for the theory developed by us whether the equilibrium of the reaction H^+/H_2, to which Dr. Schuldiner's remark refers, is realized in practice. The theory presumes only the existence of an equilibrium for the ionization reaction of adsorbed hydrogen. The existence of this equilibrium is proved by the complete reversibility of the charging curves in the potential range indicated and by the independence of the length and shape of the charging curves from the time of measurement, which varied from 10 to 100 min, when employing our method (platinized platinum electrodes with 5-10 mg Pt-black/cm^2 of visible surface).[9] Apparently, owing to the wide use of fast pulse methods in recent years it has become unusual to treat the surface of the platinum hydrogen electrode as an equilibrium system.

F. G. Will: In Eq. [7] of the thermodynamic treatment, it is assumed that the amount of charge supplied to the electrode to shift its potential from one to another value in the hydrogen adsorption region is not substantially affected by molecular hydrogen in the electrolyte. With the lightly platinized electrodes used in this study, this assumption can lead to significant errors, depending on the particular conditions of charging. Recent, still unpublished calculations show that an even more significant error may be introduced by neglecting the diffusion of atomic hydrogen from the surface of the electrode into its interior. The magnitude of this error will again depend on transition times, surface roughness, and the size of the platinum black grains.

With regard to the relative contributions of adsorbed atomic hydrogen and of hydrogen ions to the potential difference at the platinum solution interface, it seems surprising that the contribution of the ions should be an order of magnitude larger. While it is granted that this would be true for the particular electrolytes (1N NaCl + 0.01N HCl and 1N NaCl + 0.05N KOH) considered in this study, it appears highly unlikely that it is also true for many acid electrolytes. In the case of the latter, a near 1:1 ratio between surface platinum atoms and adsorbed hydrogen atoms is found. From studies in the gas phase[10,11] it is known that the work function of platinum is changed by as much as 1 electron volt when hydrogen is adsorbed. Certainly, then, the effect of adsorbed ions cannot be one order of magnitude larger.

E. Gileadi: I would like to agree with Dr. Will that the surface area measured from a hydrogen charging curve at very low current densities may be substantially in error due to hydrogen diffusion from the bulk of the metal. On the other hand, the authors find agreement between their area measurement and B. E. T. measurement so that their hydrogen charging method probably cannot be very much in error.

A. N. Frumkin (communicated): Contrary to Dr. Will's comments, the data presented by Marvet and Petry[12] also show that hydrogen solubility in the electrolyte and the metal could not affect the results obtained. The question as to how the presence of dissolved hydrogen could be taken into consideration in the equations derived by us, should this be necessary, will be dealt with elsewhere.

Dr. Will's remark regarding the relationship between the quantities designated by us X and Y seems to be founded on a misunderstanding. The contribution of the adsorbed H atoms to the potential difference set up at the interface is by an order of magnitude less than that of the adsorbed Na^+ and Cl^- ions per one adsorbed particle. The maximum amount of adsorbed Na^+ and Cl^- ions is, however, in about the same proportion less than the maximum amount of adsorbed hydrogen atoms. As the result, the contribution of the ions and of the atoms to the potential difference being set up become comparable, which deter-

mines the shape of the charging curves observed. In the case of ions with pronounced specific adsorptivity, such as Tl^+ ions, when maximum ion adsorption becomes comparable with hydrogen adsorption owing to the covalent bond between the metal and the adsorbed ion, Y should approach X.

E. Gileadi: I would like to refer to two of the topics mentioned in this paper, namely, the position of the potential of zero charge on Pt and the interpretation of the potential dependence of organic adsorption on Pt.

The potential of zero charge on platinum has been investigated in our laboratory in some detail by two methods.[13] One method depends on the study of the effect of natural salt concentration on the potential dependence of organic adsorption[14] and the other is the well-known measurement of differential double layer capacity as a function of potential in highly purified dilute solutions of $HClO_4$. Results obtained by the two methods were found to be in good agreement, and I would like to concentrate on those obtained by the capacitance method.

Fig. EG 1 shows a typical C-V plot in highly purified, dilute $HClO_4$ solution. The pretreatment of the electrode was found to be of very great importance, and in particular the absorption of hydrogen into the bulk of the metal must be controlled. The curve marked "without H" in Fig. EG 1 was obtained on an electrode which has been treated for 3 hr at 450°C in an atmosphere of purified argon. Calculations based on independent measurement of the diffusion coefficient of hydrogen in Pt carried out in our laboratory[15] confirmed that under these conditions all the hydrogen was eliminated from the metal. Prolonged heating (overnight) had no further effect. The curve marked "with H" was obtained after keeping the electrode at a potential of 0.2v r.h.e. for 5 min, allowing for hydrogen diffusion into the metal. Figure EG 2 gives similar results in alkaline solutions.

Fig. EG 3. Variation of the shape of the C-V plots with increasing $HClO_4$ concentration.

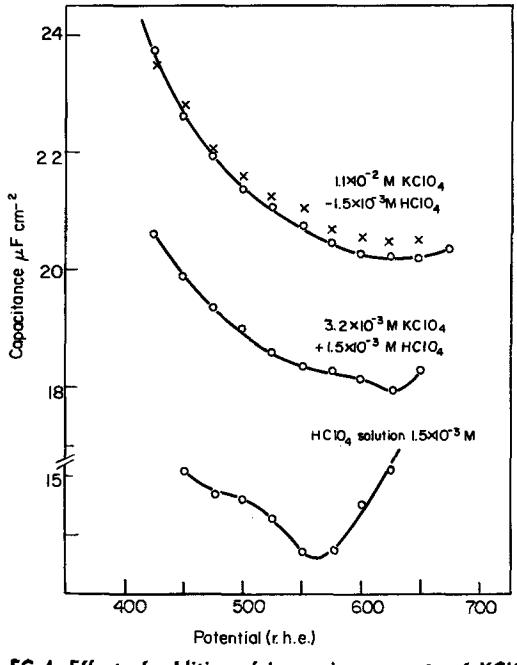

Fig. EG 4. Effect of addition of increasing amounts of $KClO_4$ on the shape of the C-V curves.

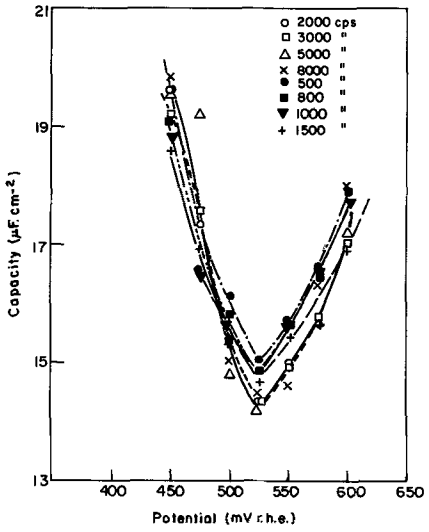

Fig. EG 5. Differential capacity measurements on platinum in 0.001N $HClO_4$ solution as a function of frequency.

Two types of experiments were performed to prove that the capacitance minimum observed here does in fact correspond to the maximum diffusivity of the double layer, *i.e.*, to the potential of zero charge. Figure EG 3 shows the variation of the shape of the C-V plot with increasing concentration of $HClO_4$. In Fig. EG 4, the effect of increasing the total ionic strength by addition of $KClO_4$ is shown. In both cases the capacitance minimum characteristic of the potential of zero charge in dilute solutions disappears as soon as the total concentration of electrolyte exceeds $5 \times 10^{-3}N$.

In Fig. EG 5, the effect of frequency on the C-V plot in the vicinity of the potential of zero charge is given for a frequency range of 0.5×10^3 to 8×10^3 cps. A very small frequency variation is observed, which can be attributed to the lack of complete symmetry between the working and counter electrode, and to a certain extent to a possible slight roughness of the surface.

On the basis of the effect of concentration and frequency on the C-V plot we then conclude that the capacitance minimum observed in our measurements in very dilute solution corresponds to the potential of zero charge. The value of the potential of zero charge, measured *vs.* a constant reference electrode, varies linearly with pH to an extent of 60 mv/pH unit and has a value of $V_{pzc} = 0.56 \pm 0.025$v independent of pH when measured *vs.* a reversible hydrogen electrode in the same solution.

The disagreement between the results presented by Frumkin *et al.* in this paper and our own recent result may be at least in part due to the different pretreatment of the electrode. Our values refer to a "hydrogen free" Pt electrode, while the results of Frumkin *et al.* and probably all other results reported so far refer to a "hydrogen loaded" electrode. Figures EG 1 and EG 2 indicate that the effect of hydrogen in the metal is at least in the right direction to resolve this discrepancy.

I would like to turn now to the question of the interpretation of the potential dependence of adsorption of neutral organic molecules on Pt. In several publications from our laboratory in recent years[16-19] this dependence has been interpreted in terms of a "competition with water" model while according to the present papers of Frumkin *et al.*, this is more likely due to essentially a competition with hydrogen and oxygen adsorbed on the surface.

We are in agreement with the relevant Eq. [33] in this text, which gives the variation of the free energy of adsorption of organic with potential at constant Γ_{org} as a function of the derivatives of the charge and the hydrogen coverage A_H with respect to Γ_{org} at constant potential

$$\left(\frac{\partial \Delta G_{org}}{\partial \psi}\right)_{\Gamma_{org}} = -\left(\frac{\partial \epsilon}{\partial \Gamma_{org}}\right)_{\psi} + \left(\frac{\partial A_H}{\partial \Gamma_{org}}\right)_{\psi}$$

The relative importance of the two terms on the r.h.s. of this equation for the Pt system is, however, disputed. Moreover, to explain the decrease of coverage with potential above 0.5v a similar equation would have to be assumed for adsorbed oxygen. It is doubtful if such an equation would be valid, due to the irreversible nature of oxygen adsorption, as pointed out by Frumkin in a previous publication.[20]

Several experimental facts do not seem to be in agreement with the theory proposed here by Frumkin.

1. Peak adsorption on Pt occurs at about 0.45v (NHE) in $1N$ H_2SO_4. The coverage decreases roughly symmetrically on either side of V_{max}, yet at 0.2v, $\theta_H = 0.5$ while at 0.7v (*i.e.*, at an equal distance on the anodic side of V_{max}) the coverage by oxygen is probably not more than 0.05.

2. In a study of hydrocarbon adsorption on Pt on open circuit it was found[21] that ethylene displaced hydrogen from the electrode surface. On the other hand, it was found to have essentially no effect on oxygen coverage in the same system.[22] Thus

$$|(\partial A_H/\partial \Gamma_{org})_\psi| >> |(\partial A_o/\partial \Gamma_{org})_\psi|$$

and an unsymmetrical $\theta - \psi$ relationship would be predicted.

3. In the adsorption of naphthalene and n-decylamine on Ni an increase of coverage with increasing cathodic potential occurred in a region where coverage by hydrogen also increased.

In conclusion, we agree that hydrogen adsorption may have an effect on the potential dependence of organic adsorption in certain systems. However, it appears highly unlikely that our results for *e.g.*, ethylene[17] and benzene[18] adsorption can be interpreted even partially on this basis.

The pH dependence of the potential of zero charge and the effect of pH on organic adsorption are consistent with our interpretation of the $\theta - V$ relationship. Figure EG 6 shows $\theta - V$ plots for the adsorption of benzene on Pt from mixtures of H_2SO_4 and Na_2SO_4 maintaining a constant concentration of $SO_4^=$ ions.[18] A plot of the potential of zero charge and the potential of maximum adsorption *vs.* pH is given in

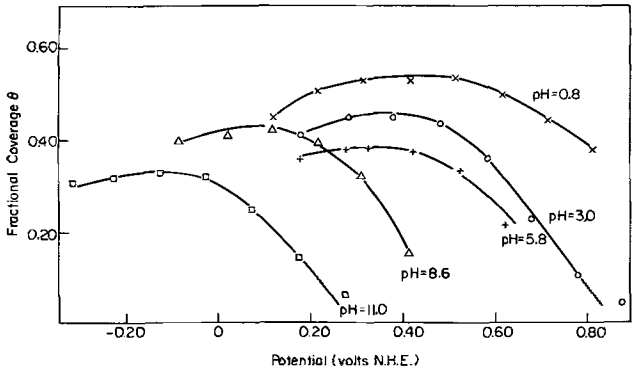

Fig. EG 6. The adsorption of benzene on Pt as a function of potential and pH.

A. N. Frumkin (Communicated): A number of attempts have been made at the Institute of Electrochemistry to use for the platinum-hydrogen electrode the method of the point of zero charge determination from the capacitance minimum in dilute solutions, first proposed by one of the authors.[23] Although Birintseva and Kabanov[24] observed at $\psi = 0.18$v the appearance of a minimum on the C, ψ curves in 0.01 and 0.001*N* H_2SO_4, which disappeared with increasing concentration (C, the capacitance per unit electrode surface; other designations, the same as in our paper), *i.e.*, in agreement with the point of zero charge determination, in our paper we pointed out with good reason, as it seems to us, that the difficulties involved in these measurements have not yet been overcome. Recently Burshtein, Pshenichnikov, and Shevchenko, of the same Institute, apparently obtained more reliable results. The experiments were carried out with a smooth Pt electrode, which after reduction in hydrogen at 450°C and outgassing *in vacuo* at 900°, had been activated in the solution by the application of sawtooth cathodic and anodic pulses in the interval of ψ_r values from 0.0 to 1.6v. As can be seen from Fig. AF 1, at higher concentrations a minimum is observed at $\psi \sim 0.55$v, which is, undoubtedly, a pseudocapacity minimum due to ionization of adsorbed hydrogen and oxygen. As the solution is diluted, however, a deeper minimum appears at $\psi = 0.23$v, *i.e.*, close enough to the pzc determined by direct adsorption measurements. The position of this minimum on the ψ-axis does not change when the concentration of the acid is changed from 0.01 to 0.002*N* and appears therefore to be pH independent. Further measurements will show how far this result can be considered conclusive.

Comparing the results of his measurements by the differential capacitance method with the data on the pzc given in our paper, Dr. Gileadi suggests that the difference in the surface state of the electrode is one of the reasons for the discrepancy observed. In Dr. Gileadi's opinion, his own data refer to a "hydrogen free" electrode, whereas our data are for a "hydrogen loaded" one. In this connection, we would like to make two observations. The term "hydrogen loaded" does not correctly describe the surface state of the electrodes used by us, as under cathodic polarization the electrode can be loaded with hydrogen to various degrees. In actual fact, our aim was to establish the conditions for the equilibrium relative to the ionization reaction of adsorbed hydrogen as given by Eq. [2]. Such conditions, as will be shown below, really can be established. As regards the surface treatment carried out by Dr. Gileadi, there is no doubt that no equilibrium is established on the surface of a smooth electrode deactivated by prolonged heating at 450°C without subsequent activation by alternating anodic and cathodic polarizations. Measurements of the electronic work function of platinum, however, performed at the Institute of Electrochemistry by Fokina, Shurmovskaya, and Burshtein have shown that in order to remove strongly adsorbed or dissolved gases from the surface of solid smooth platinum it is necessary to carry out degassing *in vacuo* at 900°C. In addition, as it follows from a series of studies by Bagotsky and collaborators,[25] previously degassed platinum absorbs appreciable amounts of oxygen from the solution already at the potential $\psi_r \sim 0.4$v. Therefore, we suppose that the minimum observed by Dr. Gileadi in the experiments with 0.001*N* $HClO_4$ is likely to be connected with the position of the pzc of a somewhat oxidized platinum surface. In fact, according to the data of Balashova and Frumkin,[26] in dilute H_2SO_4 the pzc of oxidized platinum lies at $\psi \sim 0.5$v, *i.e.*, it is strongly shifted in the positive direction.

At any rate, the shift in the minimum on the capacitance curve along the ψ-axis with changing pH of the solution, observed by Dr. Gileadi, as well as by Kheifets and Krasikov,[27] shows adsorbed oxygen (or hydrogen) to be present on the metal surface, since otherwise it would be impossible to account for this pH dependence by means of any theory. Unfortunately, Dr. Gileadi does not mention whether he observed the dependence of the depth of this minimum

Fig. AF 2. Dependence of Γ_{H+} on ψ_r for a platinized platinum electrode in *N* KCl + 0.01*N* HCl. The full drawn curve has been calculated from Eq. [6]; the circles represent experimental values (Frumkin, Petry, and Marvet).

on the concentration of the solution only in acid solutions or at other pH as well. This point is an important one.

From our point of view, it was most important to show that under the conditions of our experiments, the surface of the platinum electrode could really be treated as an equilibrium system, so that Gibbs thermodynamics could be applied to it. At present, Frumkin, Petry, and Marvet have been able to prove experimentally the correctness of this assumption, at any rate for the case of a platinized platinum electrode. In Fig. AF 2 the values of Γ_{H+} in the function of ψ_r determined experimentally in *N* KCl + 0.01*N* HCl solution are compared with those calculated by means of Eq. [6] of our paper from the values of $\left(\frac{\partial \Gamma_H}{\partial \psi_r}\right)_{\mu_{H+}}$ and $\left(\frac{\partial \psi_r}{\partial \mu_{H+}}\right)_{\Gamma_H}$.

The calculated values were obtained by the integration of the $\left(\frac{\partial \Gamma_{H+}}{\partial \psi_r}\right)_{\mu_{H+}}$ curve determined from Eq. [6] using the value of Γ_{H+} at $\psi_r = 0$ found experimentally. Good agreement between calculated and experimental values corroborates the correctness of our assumption as well as of the determination of the pzc by the method designated in our paper as method I.

In the second part of his discussion, Dr. Gileadi presents some arguments against the thermodynamic treatment of the dependence of the adsorption of organic substances on the potential, which was suggested by one of the authors.[28] According to Dr. Gileadi, the relations like our Eq. [33] are quantitatively inapplicable to the oxygen region of the charging curve owing to the irreversibility of oxygen adsorption. This is quite correct and was emphasized in our paper. It is not clear, however, how a model based on "competition with water" can be quantitatively used in this potential range when the measurements of the anion adsorption show that in the case of anions, which are not adsorbed specifically, the tension of the electric field of the double layer, due to positive surface charges and negative charges of adsorbed anions, decreases rather than increases with rising ψ_r.[29] The increase in the latter quantity depends completely on that in the number of adsorbed oxygen atoms and on the dipole nature of the Pt — O bond.

Our treatment refers to the idealized case of organic substance adsorption when an equilibrium relative to adsorption of all components is established on the surface. Naturally in the case of chemisorption of such substances as ethylene, when adsorbed hydrogen [30,31] appears on the platinum surface and methane and ethane can be detected in the gas phase,[31] it is not possible to explain all the phenomena observed in terms of a thermodynamic theory. The general parallelism, however, between the position of the potential of maximum adsorption and the supposed pzc determined as it has been done by Dr. Gileadi, follows from our interpretation of the physical significance of this potential and the relationship between the adsorption of organic substances and that of electrochemically active gases.

Hideaki Kita: 1. According to the statement on the fourth paragraph, the H^+ ions in the ionic part of the double layer are adsorbed giving off their charges to the metal and changing to H atoms. Thus, the quantity Γ_{H+} is identified with the charge density on the electrode.

If we extend this identification further, Γ_{H+} can also be the quantity of adsorbed hydrogen atoms thus formed. Since Γ_H is the symbol for the surface density of hydrogen atom, these quantities, Γ_{H+} and Γ_H, appear not to be separated definitely from each other.

On the other hand, if we understand the quantity Γ_{H+} as the surface density of hydrogen ion as defined in paragraph 3, the charge density of electrode surface would be negligibly small according to the statement in paragraph 4 that the presence of H^+ ions in the ionic part of the double layer can be neglected at the conditions of an excess of C^+ cations.

2. Equation [2] can be taken as applicable only for the case where the step, $H^+ + e^- = H(ads)$, is in equilibrium, since the hydrogen electrode reaction occurs irreversibly at the polarization of ψ_r. Hence, the quantity A_H, which is understood to be the amount of hydrogen disappeared from the bulk of solution according to the statement in paragraph 5 cannot be the equilibrium quantity and must not be introduced in the thermodynamical equations.

In short, interrelations among Γ_{H+}, Γ_H, and A_H do not seem to be clear enough.

A. N. Frumkin (Communicated): 1. The quantities Γ_H and Γ_{H+} may become equal (but opposite in sign) if no measurable amount of adsorbed hydrogen in the atomic form is present on the electrode surface. Such case was considered by one of the authors earlier.[32]

2. The exchange current of the reaction $H^+ + e^- \rightleftarrows H_{ads}$ at $[H^+] = 10^{-2}N$ is of the order of 10^{-1} amp/cm^2. The maximum current density, used by us in the measurements of the charging curves, calculated per cm^2 of true electrode surface, did not exceed 10^{-6} amp/cm^2. Thus, the equilibrium conditions for the above reaction were realized.

S. Gilman: It was suggested that the discrepancy between the results of capacitance determination from adsorption measurements and from the impedance might be explained on the basis of slow establishment of equilibrium between the adsorbed anion and the platinum surface. While the observation need not be general for all anions, evidence has been found[33]

that (at potentials below *ca.* 0.8v in acid solution) the adsorption-desorption of chloride and phosphate ions is rapid and reversible. An alternative explanation for low capacitance is naturally surface contamination,[34] although it is not altogether certain that the high values measured at clean smooth Pt electrodes [34,35] are entirely free of pseudocapacitance.

A. N. Frumkin (Communicated): Our paper was concerned with the discrepancy between the calculated value of $Y^{-1} = \left(\frac{\partial \Gamma_{H^+}}{\partial \psi}\right)_{A_H}$ and the capacitance determined by the a-c measurements at a high enough frequency, the former quantity proving to be much larger than the latter. Since the presence of pseudocapacity of the ionization reaction of adsorbed hydrogen could have affected only the second quantity, taking it into consideration would have resulted only in the increase in this discrepancy.

In the case of I^- adsorption from NaI solutions on a platinized Pt electrode, it takes hours for the equilibrium to be established.[36] Such a delay was not observed in the case of ions without specific adsorptivity, which shows that it cannot be caused by the diffusion difficulties or by the presence of impurities in the solution. The effect of the latter moreover could not be of great importance in the case of platinized electrodes with a highly developed surface. The adsorption process of such anions as I^- on platinum is in many respects similar to that of oxygen chemisorption from the solution. Slow establishment of the equilibrium in this case is a well known fact and has been the object of a number of investigations (*e.g.*[37]). In the case of the chlorine anion, these phenomena are much less pronounced, but hardly absent altogether. The technique used by Dr. Gilman is probably not quite suitable for the investigation of very slow processes.

G. C. Barker: I do not question any of the experimental facts reported by Professor Frumkin and his co-workers. I merely wish to point out that the specific adsorption of certain metals on platinum is an effect far more striking than might be suspected from adsorption potential measurements. Our unpublished work, based largely on studies of the rate of increase of the part of the interfacial impedance connected with the reduction of hydrogen ions and the oxidation of adsorbed hydrogen atoms, suggests that hydrogen adsorption sites are readily occupied by adsorbed metal atoms sometimes even when the solution concentration of the ion metal is as low as 10^{-8}M. The adsorption for potentials in the range in which hydrogen is adsorbed is very marked for Cd and Tl and strong adsorption of the ions of Pb, Bi, and Sn in the same potential region is also observed with strongly acid solutions (HCl, $HClO_4$). Generally the adsorbed metal is displaced when the platinum electrode is anodically polarized and this displacement (due to oxygen adsorption) rather than the oxidation of organic matter is usually the main reason why platinum electrodes are "activated" by anodic polarization. Often the solutions used in studies of the kinetics of the formation and oxidation of molecular hydrogen contain copper and lead ions at concentrations up to 10^{-7} — 10^{-6}M and such concentrations are sufficient to rapidly displace a substantial amount of the adsorbed hydrogen from a smooth platinum electrode and so greatly lower the activity of the electrode. The fall in activity is generally accelerated in stirred solution as the adsorption usually seems to be a diffusion-controlled process. It might also be mentioned that, if a smooth platinum electrode is suspended in a sealed glass cell lined with platinum, the surface of which has been platinized, after saturating the solution with hydrogen and subjecting the electrode to brief anodic polarization occasionally during the first few days, the activity of the electrode (studied by a-c means) remains almost constant for months without further activation. This shows clearly that if adequate precautions are taken to remove from the solution organic matter and ions tending to be strongly adsorbed, a spontaneous fall in activity such as has been suggested from time to time in the literature does not occur. Clearly such falls are due to faulty experimental techniques. Professor Frumkin states that adsorbed Cd is covalently bound to the electrode, and it seems likely that the same may be true in other cases where almost complete coverage (judging from the effect on the impedance) is obtained at potentials considerably more positive than that for bulk deposition of the metal. As has been suggested earlier by Professor Frumkin, the strong adsorption is presumably connected with the formation of a two-dimensional intermetallic compound. Mössbauer studies of the bonding of specifically adsorbed tin on platinum made recently by Bowles and Cranshaw at Harwell suggest that the adsorbed tin is very strongly bound to the electrode.

Reply by *M. W. Breiter*: Study of the deposition of copper ions on smooth platinum from acidic solutions (1M $HClO_4$) was carried out by me at potentials more anodic than the potential of copper deposition about two years ago. The results were not published because of the presence of small amounts of organic impurities leading to an anodic wave in the oxygen region during an anodic sweep. It was observed that copper ions may be deposited at potentials up to 0.25v more anodic than the deposition potential. The layer formed is less than a monolayer and considered by me as an adsorbed layer of Cu atoms. Thicker layers are formed at the potential of copper deposition. The layers can be removed by anodic stripping.

H. D. Hurwitz: Without using the original method of Gibbs, it seems to me that we may formulate the problem of the nonideal polarized interphase in an equivalent manner starting from the equation of Gibbs-Duhem and the electroneutrality condition

$$\Gamma'_{H^+} + \epsilon = \Gamma_{A^-} - \Gamma_{C^+} \qquad [1]$$

At constant T one has

$$(d\sigma)_T = -\Gamma_{A^-} d\mu_{A^-} - \Gamma_{C^+} d\mu_{C^+} - \Gamma'_{H^+} d\mu_{H^+} - A_H d\mu_H - \epsilon d\psi \qquad [2]$$

In [1] and [2] one has stated that the Gibbs surface defined by $\Gamma_{H_2O} = 0$ is permeable to H^+ and H. The quantities Γ_{A^-}, Γ_{C^+}, A_H and the charge ϵ have been defined in the paper. As for Γ'_{H^+}, the surface excess of H^+, it has been assumed to vanish in the model of Frumkin *et al.* in order to fit with the interpretation of the value of ϵ.

For the condition of electrochemical equilibrium respectively at the working electrode and at the reference electrode, one has

$$\mu_{H^+} - F\psi = \mu_H \qquad [3]$$

$$\mu_{H^+} - F\psi^{ref} = (\mu_H)_0 \qquad [4]$$

and

$$\psi_r = \psi + \frac{(\mu_H)_0 - \mu_{H^+}}{F} \qquad [5]$$

with ψ_r the cell potential.

From Eq. [2] and [3] one deduces easily that

$$(d\sigma)_T = -\Gamma_{A^-} d\mu_{A^-} - \Gamma_{C^+} d\mu_{C^+} - [\Gamma'_{H^+} + \epsilon] d\mu_{H^+} - [A_H - \epsilon]\, d\mu_H \qquad [6]$$

[34] S. Gilman, *Electrochim. Acta*, 9, 1025 (1964).

[35] M. Breiter, *J. Electroanal. Chem.*, 7, 38 (1964).

[36] N. Balashova and V. Kazarinov, *Elektrokhim.*, 1, 512 (1965).

[37] V. Nesterova and A. Frumkin, *Zhur. Fiz. Khim.*, 26, 1178 (1952).

Another way to write [2] is obtained in making use of [1], [3], and [4], thus

$$(d\sigma)_T = -\Gamma_{A-}d\mu_{AH} - \Gamma_{C+}d\mu_{COH} - F[\epsilon - A_H]d\psi_r \quad [7]$$

in which

$$d\mu_{AH} = d\mu_{A-} + d\mu_{H+};\ d\mu_{COH} = d\mu_{C+} - d\mu_{H+}$$

According to the definition $\epsilon = \Gamma_{H+}$ and assumption $\Gamma'_{H+} = 0$, Eq. [6] transforms into Eq. [1] of Frumkin *et al.*, and relations [3] and [4] of this work are readily inferred and may be extended to the case where H^+ is not only in state of contact adsorption ($\Gamma'_{H+} \neq 0$).

From [6] it is observed that at μ_{A-} and μ_{C+} constant, $[\Gamma'_{H+} + \epsilon]$ and $[A_H - \epsilon]$ are thermodynamically independent variables. Therefore, by exact differential property, $d\psi$ could be written in terms of these coordinates, or by introducing an analytical change of coordinates* in terms of either $[A_H + \Gamma'_{H+}]$ and $[\Gamma'_{H+} + \epsilon]$ or A_H and Γ_{H+}, according to the approximation of Frumkin. Equation [12] of Frumkin with X^{-1} the pseudocapacitance of adsorption and Y^{-1} a capacitance of the double layer suggests that such change of coordinates has been used.

Equation [10] of Frumkin *et al.* may be easily shown to follow from Eq. [7] given above.

* With $X = [A_H - \epsilon]$; $Y = [\Gamma'_H + \epsilon]$ and $U = X + Y$; $V = Y$ the Jacobian $J(X,Y/U,V)$ of the transformation $X,Y \rightarrow U,V$ is unity.

Ion Pairing Mechanisms in Electrode Processes

L. Gierst, L. Vandenberghen,[1] E. Nicolas, and A. Fraboni

Free University of Brussels, Brussels, Belgium

ABSTRACT

The influence of "bulk" ion pairing on electrode processes is easily detected when its main effect is to decrease the activity of the depolarizer. On the other hand, when association with the adsorbed ions of the supporting electrolyte forms a more electroactive entity, it is known that it can be more difficult to distinguish between direct discharge, or via ion pairs. However, a broad intercomparison (under strictly identical experimental conditions) of the influence of the nature and concentration of the supporting cation (Li^+, Na^+, K^+, Cs^+, Mg^{2+}, Ca^{2+}, Ba^{2+}) on depolarizers of various electronic charge, allows to detect the abnormal behaviors, which are not determined by the pure "static" ψ effect. An indirect method has also been used, which essentially consists in modifying the double layer profile by adding, at constant concentration, increasing amounts of tensioactive ions having the same charge as the electrode, *e.g.*, iodide at not too negative charge densities.

The occurrence of chemical ion pairing as a concomitant rate-determining factor in electrode processes is generally easily detected from the effect of suitable composition changes at constant double layer structure: a typical case is the action of the sulfate ion on cation reduction, recently studied in our laboratory (15). However, it has been pointed out (1, 2) that, in the case of anion reduction proceeding at sufficiently negative potentials in not too concentrated solutions, the variations of the apparent rate constant produced by changing the concentration of the supporting electrolyte can be referred either to the usual ψ effect acting on the "bulk" species or to a prior charge-decreasing process involving ion-pairing with the supporting cations, which helps to circumvent the repulsive interaction with the electrode. In some cases, sudden changes in α_0 values (for want of more definite proof) seem even to suggest that each mechanism could be rate-determining within separate potential ranges (3).

Exact diagnosis of the type of mechanism unfortunately is made more difficult by the conjunction of three circumstances:

1. Since no double layer model of sufficient accuracy is available (if it should be, it would probably be hardly adaptable to electrode kinetics), the fact that a given electrochemical reaction follows closely the predictions derived from the Frumkin relation coupled with for instance the Gouy-Chapman theory, does not constitute in itself an overwhelming argument (2).

2. There is some tendency to focus the investigations on electrochemical reactions which present quite abnormal characteristics, without paying enough interest to reactions more apt to bring clearer information. Some of these latter reactions have occasionally received only superficial attention, or have been investigated with inadequate methodology, enough however to hinder their reexamination.

3. Most of the available data cannot be directly compared, since experimental conditions (such as drop time, compositions, temperature) and measured quantities (average or instantaneous currents, 45° tangent of half-wave potentials, etc. . . .) are highly variable.

The method adopted here consists in reassessing the basic characteristics of a sufficient number of these reactions, under strictly standardized conditions.[2]

The systematic intercomparison of the results obtained allows the identification of the various types of behavior and relates them specifically to their corresponding rate-determining mechanisms. Additional evidence may be gained from a more general comparison considering other data relative to behaviors which are known to be affected by ion pairing.

The present study is limited to concentrated solutions (0.1 and 1*N*) of supporting electrolytes with the most common mono- and divalent cations. As far as the charge of the depolarizer is concerned, it is worthwhile to distinguish: (*a*) the "formal" charge z^0 calculated from valencies and stoichiometry; (*b*) the "bulk" charge z_B which prevails in solution and may vary with the concentration of the supporting electrolyte [for highly charged anions, z_B is generally close to −2 in 1*N* solutions (8)]; (c) the "apparent" charge z_K which best fits the Frumkin equation if it is assumed that there is no prior labile association with the supporting cation, and when ψ is controlled by the supporting electrolyte concentration; (*d*) the "actual" charge z_δ of the electroactive entity itself.

[1] Excerpts from dissertations to be submitted to the Faculty of Sciences as partial fulfillment of the requirements for Ph.D. degree.

[2] Since no claim for originality is made, the extended list of references pertaining to each of the various depolarizers used has been deliberately omitted. Such references are easily available in systematic polarographic surveys (6, 7).

The connection between z_K and z_δ constitutes one of the problems dealt with in this paper.[3]

A first approach consists in modifying the ψ potential without affecting the cationic composition. Besides the use of amalgam electrodes already used successfully (2), this result may be achieved by suitable substitution of the anion of the supporting electrolyte, using anions of increasing adsorbability, and as far as the potentials at which measurements are made are not too negative with respect to the point of nul charge. A more indirect way, usable through the whole potential range, is based on the substitution of the supporting cation itself; it can indeed be presumed that the specific interactions with the electrode (affecting ψ values), and with the depolarizer [controlling the prior chemical step(s)], are not following the same sequence.

Instrumentation and Reagents

All the data presented have been derived from the analysis of instantaneous maximum current-time polarographic curves, obtained with a controlled drop-time of 4 sec. The experiments were carried out at 25° ± 0.2°C, in a conventional three-electrode cell, with a separate high-impedance circuit for the measurement of potentials. The I-E curves were recorded at slow scanning rates, with at least a hundred drops for the rising section of each wave.

Triply distilled water and doubly distilled mercury were used. The various supporting electrolytes were made from A.R. products (after recrystallization, when needed, and calcination each time it was possible). In the particular case of the pyrophosphate ion fresh solutions were prepared daily, to avoid appreciable hydrolysis. It has been verified, for each supporting electrolyte, and after careful deoxygenation, that the residual current recorded at high sensitivity, was devoid of any waves or steps indicative of the presence of significative amounts of electroactive or adsorbable foreign species.

The depolarizers were generally determined according to standard procedures and used without further purification, at concentrations of the order of $10^{-3}N$. Sodium chlorite was purified following the procedure of Weiner (9).

Processing Data and Presentation of Results

Each depolarizer has been systematically studied in supporting electrolytes of Li^+, Na^+, K^+, Cs^+, Mg^{++}, Ca^{++}, Ba^{++} each in 0.1 and 1N (as long as solubility or pH incompatibilities were not insuperable).

After graphical deduction of the charging current component (evaluated separately with the supporting electrolyte alone), I/I_d plots were constructed, and the diffusional character of the limiting current, was checked by conventional means. Log $\chi = f(E)$ plots were then established, using the values tabulated by Koutecky (10).

In most of the cases, for which first order surface reactions were encountered, the apparent rate constants v can be calculated from the well-known relation (10)

$$\log v = \log \chi + \log \sqrt{\frac{7}{12}\frac{D_o}{t_d}} + \eta(E) \qquad (a)$$

where D_o is the diffusion coefficient in $cm^2\ sec^{-1}$ t_d the drop-time (4 sec)

$$\eta(E) = -\log\left[1 - \sqrt{\overrightarrow{D}/\overleftarrow{D}}\exp \cdot (F(E-E_o)/RT)\right] \qquad (b)$$

being a positive correction term to be added only when the process is not entirely irreversible ($Eu^{+++} + \epsilon \rightleftharpoons Eu^{++}$ and $Cr^{+++} + \epsilon \rightleftharpoons Cr^{++}$ for instance). However, as only relative changes of log v are of interest, and since D_o values are slightly generally affected by composition changes,[4] insignificantly anyway with respect to the χ variations themselves, intercomparison of the rate constants has been based mostly on log χ values.

In the few cases (NO_3^-, NO_2^-) where reduction was proceeding at very negative potentials, thus preventing the evaluation of the diffusion current (which merged into the reduction wave of the supporting cation), relatively large concentrations of the depolarizer were used, and the foot of the wave was recorded at high sensitivity. After proper correction, if any was needed, for the supporting cation current, the apparent rate constants were obtained from the classical steady-state relation

$$v = \frac{I}{nF[C]_\infty A_d} \qquad (c)$$

which is sufficiently accurate in the case where I values do not exceed a few per cent of the diffusion current (A_d being the electrode area at the drop time).

Intercomparison of Data

Comparison of half-wave potentials, the easiest and most precise quantities to obtain, has been discarded, because the mere fact that potentials are shifted with composition makes it more difficult to evaluate the influence of the double layer structure (which of course varies both with composition and potential). It has been preferred to select, for each system, a "median" potential[5] for which all v or χ values have been calculated. When E shifts or α slopes are large, some extrapolation may be required, the extent of which was never found objectionable, in view of the reasonable straightness and parallelism of the Tafel plots.

The next step was to calculate, for each system and each supporting electrolyte, values of the purely formal quantity $\Delta\psi'$ defined by

$$\Delta\psi' = \frac{RT}{F}\frac{\Delta \ln (\chi \text{ or } v)}{z_K - \alpha_0 n_\alpha} \qquad (d)$$

using as reference level the (χ, v) values observed in the 1N sodium solution.

$\Delta\psi'$ represents the change in ψ potential which would account for the recorded variations, with the *a priori* assumption that the system obeys the Frumkin relation strictly. As shown later, although sometimes completely incorrect, such an arbitrary calculation is however useful, because it allows easy intercomparison, and the immediate diagnosis of any "atypical" behavior.

Within defined pH and potential ranges, some oxygenated anions are electroreducible only after undergoing a fast protonation reaction, which, among other things, leads to a decrease of the negative charge of the "bulk" particles (more rarely, this prior chemical step is sufficiently slow to give rise to a decrease in the limiting current, which becomes then kinetically controlled). Such cases will be presented and discussed later.

$\alpha_0 n_\alpha$ was calculated from the experimental $d \ln v/dE$ slopes, with a correction $\Delta\alpha_\psi$ for $d\psi/dE$, estimated on the basis of thermodynamic and not of "actual" ψ' values. Typical correction terms were, respectively, about +0.1 and +0.2, for z_B being −1 and −2.

[3] For the sake of clarification, the case of the uranylcarbonate ion in N sodium carbonate could be considered briefly as an example. Its formal charge z_o is −4 [$UO_2(CO_3)_3^{4-}$], while the "bulk charge" z_B is of the order of −2 [$UO_2(CO_3)_3Na_2^{2-}$]. If [Na^+] is modified, the corresponding variation of the apparent rate constant leads to $z_K = -2$, by applying the Frumkin relation. However, if a fast prior association with Na^+ is required before discharge may occur, the actual z_δ value may be only −1.

[4] H_3O^+ ions excepted, typical extreme deviations never exceeded 10%.

[5] The "median" potential is chosen in order to have $O < i < id$ for all compositions.

All $\Delta\psi'$ values[6] are finally fitted into the ψ_R—E diagram, using the ψ_R curve calculated for $Na^+ = 1N$ as reference line (for ψ_R see "Thermodynamic Data"). The actual ordinate ψ'' is thus equal to ψ_R (Na^+ $1N$) $+\Delta\psi'$. This way of presentation (purely arbitrary again) does not mean that any special consideration is given to the validity of the ψ_R curve: it is merely dictated by the fact that (*i*) experimental results in $1N$ sodium solutions were the most abundant, and that (*ii*) $\Delta\psi_R$ variations when Na^+ is replaced by 0.1 and $1N$ divalent cations are small, allowing thus a better detection of non-ψ effects.

Thermodynamic Data

It is well known that negatively charged mercury surfaces are characterized by charge density-potential curves which are very little affected by the nature of the cation and its charge (11). In accordance with this fact, the few measurements of charge distribution based on the Gibbs equation tend to fail to show any significant amount of "specific" adsorption.[7] This results in part from the low intrinsic sensitivity of the method.

"Reference" ψ_R values have been calculated by assuming that the charge density of the diffuse part of the double layer equals that of the electrode, save in the sign. ψ_R has been calculated using the classical Gouy-Chapman relation (13), neglecting thus all second-order effects (which are by no means easily amenable to quantitative evaluation).

Such $\psi_R - E$ plots have been constructed (Fig. 1) for $Z = 1$, $Z = 2$, and $N = 1$ and 0.1, on the basis of Grahame results (11). Z and N are, respectively, the electronic charge and the normality of the supporting cation.

It should be stressed that no particular confidence is placed in these curves (they are, for instance, grossly incorrect for Cs^+), which will be merely used as a canvas delineating trends more than describing actual behavior. In fact, one of the aims of the present paper is to check by kinetic measurements to what extent ψ_R values may be used to explain or predict the influence of composition.

The same graph includes (interrupted line) the ψ potentials relative to $1N$ iodide solutions, as calculated by Grahame (14), and the corresponding $\Delta\psi$ curve, which represents the ψ_R-lowering due to the iodide adsorption.

[6] For IO_3^-, the $\Delta\psi'$ values have been increased by 15 mv. This procedure will be justified in the Discussion.

[7] We mean by "specific" : "depending on the species," without relating this expression to any particular hypothesis on the nature of the forces involved.

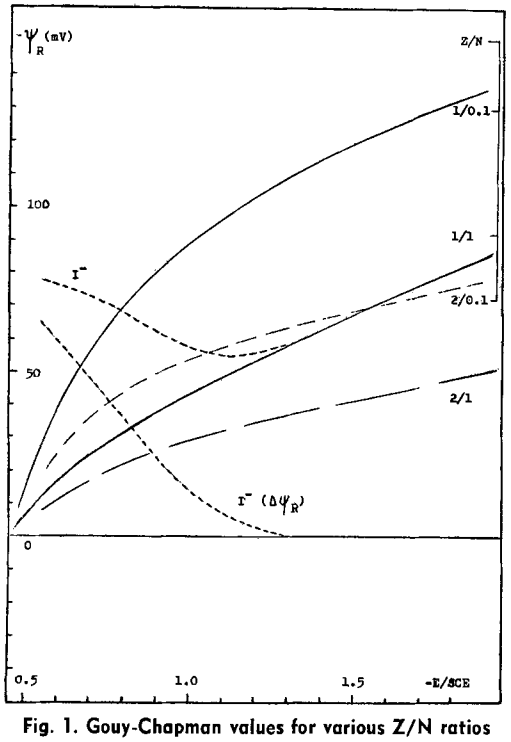

Fig. 1. Gouy-Chapman values for various Z/N ratios

Experimental

Depolarizers with formal electronic charge varying between +3 and —8 have been investigated. The behavior of neutral species will not be discussed here, since ψ effects are generally small, as compared with salting out interference.

Cationic depolarizers.—The selection of suitable cations was determined by the following requirements (besides the obvious condition of nonreversibility).

The cation must be present in its true cationic form. Possibility of complexation with the supporting anion has thus to be recognized. Perchlorate medium unfortunately cannot be used systematically, since potassium and cesium salts have low solubilities. In the particular case of multicharged cations in sulfate medium, ion pairing may be important and leads then to a significant decrease of the activity coefficient. [A systematic study, conducted at constant cationic strength with variable amounts of sulfate, has shown, for all the cations studied (Eu^{+++}, Cr^{+++}, Co^{++}, Ni^{++}, H^+) that changes in rate constants with composition are quantitatively accounted for, assuming fast dissociation of ion pairs prior to discharge itself, with reasonable *p*K's values for association (15)].

Another possible complication results from the presence of hydrolyzed species, which are generally more electroactive than the cation itself (possibly in part through specific adsorption). This situation may be avoided by sufficient *p*H lowering, which, in turn, restricts the range of usable potentials, prohibiting *inter alia* the study of ions like Ga^{+++}, Al^{+++}, and most of the rare earth trivalent cations. Fe^{++}, too, is preferentially reduced under the form $Fe(OH)^+$, as shown by Ivanov and Jofa (16), and reconfirmed by our own results.

Generally speaking, the over-all discharge process has to be devoid from kinetic complications like any slow prior chemical step or change in the surface reactivity by electrodeposition. In the particular case of Ni^{++}, for which the limiting current is controlled by a nonelectrochemical step involving rearrangement of the water-shell (17, 18), it is still possible to draw reliable conclusions, if small relative values of current are compared, in which case the prior step is kept under conditions of labile equilibrium.

These considerations have so far limited the exploration to the ions Eu^{+++} and Cr^{+++} (slightly acid perchlorate solutions), Ni^{++} and H^+ (chloride and perchlorate solutions), and Co^{++} (sulfate and perchlorate solutions). Some limited information is also at hand for Zn^{++} (nitrate medium) (19), Fe^{++} and Mn^{++} (perchlorate solutions).

Tables Ia and b, and Fig. 2 embody all the kinetic data now gathered. They will be analyzed and compared with the other corresponding results in the Discussion section.

Anionic depolarizers (Tables IIa, IIb, and III; Fig. 3-5).—The study of mononegative anions is of considerable interest, because association with the supporting cation can be expected to be the smallest, at least when $Z = +1$. Consequently this could afford the opportunity of disentangling, from the complex pattern of behaviors, the basic features of the "pure" ψ effect when it acts on anions.

Under such circumstances, comparison with kinetic ψ'' values obtained with cations can be worth-

while, in order to appreciate the magnitude of the deviations, and their possible origin.

The following anions were studied, under controlled conditions, for which their reduction is pH-independent: BrO_3^- and IO_3^- (at pH) > 11.5, to avoid occurrence of the prior protonation mechanism), ReO_4^- (at pH ≥ 13, to suppress the catalytic water discharge), ClO_2^- (at 9 < pH < 13, to eliminate both the protonation mechanism and the prewave which occurs in strongly alkaline medium), NO_2^- and NO_3^- (these reactions are pH-insensitive within a large range). The reduction of palladite (PdO_2^-) and periodate ($H_3IO_6^=$) have been investigated at pH 13. The fact that these reactions are pH-dependent, with d ln v/d pH ≃ −1 at constant double layer structure, with no indication of any "kinetic" limiting current, leads to the conclusion that the electroreduction itself is preceded by a fast protonation step

$$(PdO_2^= + H^+ \rightleftharpoons PdO_2H^- \qquad (e)$$

$$H_3IO_6^= + H^+ \rightleftharpoons H_4IO_6^-) \qquad (f)$$

and involves mononegative particles. This deduction is confirmed by the order of magnitude of the ψ effects. However, since composition changes may alter the protonation equilibrium, these reactions will be discussed separately.

Similarly, some mononegative anions (like O_2H^- or SbO_2^-), although predominating in solution at the

pH values which were used, were found to be only reducible under their neutral monoprotonated form. Since pH and supporting electrolyte concentration can be varied independently, the identification of the apparent charge of the dischargeable species presents no difficulties. However, if hydroxides are used as supporting electrolyte, both effects combine and the overall kinetics may appear quite complex.

A few multicharged anions have been studied: $CrO_4^=$ (at pH > 13, to suppress the protonation mechanism), $S_4O_6^=$ (in neutral unbuffered solutions), $UO_2(CO_3)_3^{4-}$ (0.1N in carbonate, to stabilize the complex), $(UO_2)_2(P_2O_7)_3^{8-}$ (0.1N in pyrophosphate, for the same reason). These two last systems were carefully investigated, in order to delineate compositions for which direct discharge of the complex is the rate-determining step, without any prior decomplexation reaction.

Supporting cations.—pH requirements have very often precluded the use of Mg^{++} (and sometimes Ca^{++}). It was essential to check whether the buffering action of Mg^{++}, Ca^{++}, and even Ba^{++} (second pK) was not influencing the electrode processes. Precipitation between multicharged species ($|z_B Z| \geqq 4$) imposed another rather strict limitation.

Results Obtained with Anion Substitution

As pointed out earlier, difficulties which may arise when trying to distinguish between ψ-effect and a prior association stem from the fact that varying the supporting cation affects both mechanisms the same way, when the depolarizer is an anion. It is therefore obvious that this obstacle might be evaded, if the double layer structure could be modified in a controlled way, without appreciably shifting the chemical equilibriums under consideration. For that purpose, the simplest method consists in replacing the usual supporting anion (ClO_4^-, F^-, OH^-) by another which is as tensioactive as possible. Iodide is thus the best choice.

For 1N solutions, this substitution brings a negative variation $\Delta\psi_R$, which persists at rather negative potentials (see Fig. 1). Such a method, however, must be used with caution, since the relative smallness of $\Delta\psi_R$ values which occur at negative potentials, tend to render objectionable any second order factor capable of blurring the resulting "pure" ψ effect. In particular, the anion substitution is accompanied by a variation of the mean activity coefficient $\gamma^{\pm}$, which can act both on the activity of the depolarizer, and on the double layer. As far as the former effect is concerned, it is

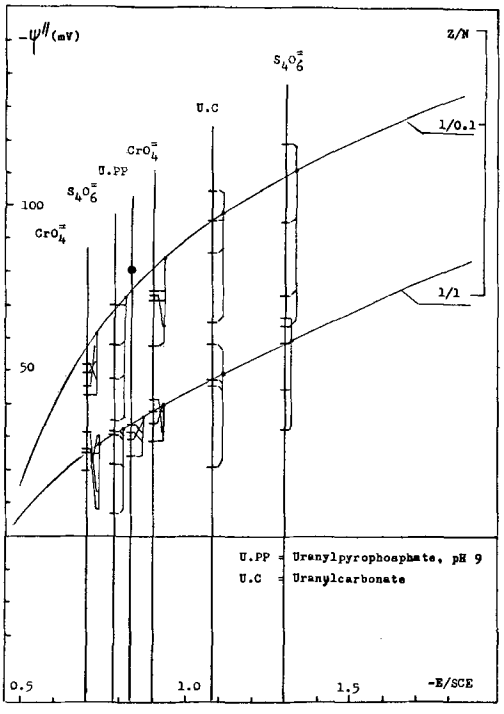

Fig. 5. Behavior of multicharged anions with supporting electrolytes with monopositive cations, expressed in terms of ψ''. (See details under Symbols and Units.)

safe to assume as a first approximation that the depolarizer activity coefficient simply follows $\gamma^{\pm}$ (20). Such a trend has been confirmed experimentally, by measuring the χ values for the reduction of uranylcarbonate (at —0.92v) and comparing them (Table IV) to the corresponding $\gamma^{\pm}$ of the various supporting electrolytes selected in view of the inactivity of their anions.

The fact that rate constants vary more than $\gamma^{\pm}$ suggests that the simultaneous double layer modification acts cooperatively (as it can be inferred from the Gouy-Chapman theory, amended with the crude first approximation that activities must replace concentrations). As a matter of fact, when working at constant activity with the same supporting electrolytes, the χ values (Table V) are practically identical (with the exception of the perchlorate medium, for which a positive deviation is observed).

As a result of these experiments, it appears necessary to make the substitution of the inactive anion for iodide, by using a salt having the closest mean activity coefficient to it. In N solutions, sodium acetate is the best choice ($\gamma_{(NaI)} = 0.736$ *vs.* $\gamma_{(NaAc)} = 0.757$).

Table IV

Supporting* electrolyte	$\gamma^{\pm}$	χ (−0.92v)
NaAc	0.757	1.115
$NaClO_4$	0.629	1.00
$NaClO_3$	0.589	0.71
$NaNO_3$	0.548	0.508

* Each 0.9N + 0.05M in Na_2CO_3.

Table V

Salt*	χ (−0.92v)
NaAc	0.485
$NaClO_4$	0.875
$NaClO_3$	0.55
$NaNO_3$	0.51

* Concentrations adjusted for $\gamma^{\pm} = 0.548$.

Table VI

Depolarizer	$\Delta \log \chi(-0.82v)$	$(z_A - \alpha_o n_\alpha)$ calc.	$z_A(\pm 0.3)$
$CrO_4^=$	−0.85	−1.57	−2.2
$S_4O_6^=$	−0.87	−1.61	−1.8
$UO_2(CO_3)_3^{4-}$	−0.45	−0.83	−1.4
$(UO_2)_2(P_2O_7)_3^{8-}$	−0.33	−0.61	−1.0

These solutions have thus been used, with small additions of tensio-inactive complexing agents, when required.

The depolarizers were chosen in order to allow measurements of $\Delta\chi(Ac^- \rightarrow I^-)$ at the same potential (—0.82v/SCE, for which $\Delta\psi_R$ (I^-) amounts to —32 mv). Table VI embodies the $\Delta \log \chi$ value, together with values found for $(z_A - \alpha_o n_\alpha)$, and the derived corresponding electronic charges z_A themselves (the subscript A refers to charges found in the anion substitution method).

Comparative Analysis of Results

Intercomparison of Fig. 1, 2, 3, 4, and 5 permits one to draw some direct conclusions regarding the effect of the various supporting electrolytes investigated. In this respect, it should be recalled (*i*) that all ψ'' values have been normalized by equalization of ψ'' (Na^+ 1N) to the corresponding ψ_R and (*ii*) that ψ'' is nothing but a purely formal quantity which expresses in terms of potential the resultant of all the actual rate-determining factors, even if some are nonelectrical in nature.

Cationic depolarizers.—Comparison between ψ'' and ψ_R (Fig. 2) is of special interest, since non-ψ effects can be expected to be minor, as the depolarizers are not capable of ion pairing with the supporting cations. Despite the fact that too few systems are available to draw definite conclusions, it appears that both concentration and potential changes exhibit the trends predicted by the Gouy-Chapman theory (crossing of the 2/0.1 and 1/1 curves in particular), although the absolute values of the variations are generally lower than expected (for 1/0.1 data in particular). Closer examination of the figure proves that in some cases factors specific to the depolarizers themselves are determining.

On the other hand, as far as the nature of the supporting cation is concerned, excellent regularity in sequences is always observed, the rate constants decreasing in the orders $Li^+ > Na^+ > K^+ > Cs^+$ and $Mg^{++} > Ca^{++} > Ba^{++}$. It is noteworthy that (*i*) Cs^+ is markedly retarding all reactions (Co^{2+}, H^+), and that (*ii*) divalent cations do not show very large differences (less than the corresponding for Li^+, Na^+, and K^+).

Most of these findings are not new (4): it was however useful to restate them in a "standardized" way in view of rendering intercomparison with the other cases more coherent.

Anionic depolarizers.—Mononegative anions in presence of supporting electrolytes with monopositive cations (1/0.1 and 1/1).— Reduction potentials for the various anions investigated happen to be more negative than —1.1v. Although rate constants obtained for periodate and palladite reductions are within the potential gap, they will be presented later, for the reason given above.

Examination of Fig. 3 shows that most of the ψ'' values are in satisfactory agreement with the corresponding ψ_R curves, except for Cs^+. There is a good concordance between the sequential intervals, Na^+ and K^+ being usually the closest together.

However, iodate presents a completely abnormal behavior [already discovered before this work, ref. (5, 21)]. Instead of being $Li^+ < Na^+ < K^+ < Cs^+$, the sequences are $K^+ < Na^+ < Li^+$, Cs^+ (1N) and $K^+ < Na^+ < Li^+ < Cs^+$ (0.1N), and they remain perturbed even in 0.01N solutions. Li^+ and Na^+ media

are obviously characterized by abnormally high rate constants. It is this fact which leads us to shift downward all iodate ψ'' values, in order to give a reasonable position for Cs^+ (see discussion part for further arguments).

A closer inspection of Fig. 3 discloses that, although not inverted, Li^+ (0.1N) values for BrO_3^- and ClO_2^- are somewhat too low. This tendency is exalted in 1N medium for ClO_2^-, but vanishes with BrO_3^-. It should be noted that Cs^+ 0.1N seems to be the most accelerating with ReO_4^-, the only anion for which 0.1 Cs^+ ψ'' overtakes 1N Na^+ ψ_R. These slight deviations, as insignificant as they may look, will however find definite correspondences with relevant data presented in the next section.

Mononegative anions in presence of supporting electrolytes with divalent cations.—For most of the depolarizers, Mg^{++} was not utilizable, in view of *p*H prerequisites. Figure 4 reveals that large positive deviations from the ψ_R curves, varying from system to system, are systematically observed.

When the deviation is important (IO_3^-, BrO_3^-, ClO_2^-, NO_2^-), the normal sequence $Ba^{++} > Ca^{++}$ is reversed. On the other hand, the concentration effect (0.1 → 1N) is in reasonable agreement with the calculated (0.1N/1N)ψ_R differences, though generally somewhat smaller.

Multicharged anions with $Z = 1$ supporting electrolytes.—As a result of solubility and *p*H incompatibilities, not enough information is now available when $Z > +1$, and, even for $Z = 1$, relatively few comparable data have been obtained up to date.

Inspection of Fig. 5 shows that $S_4O_6^=$ and uranylcarbonate ions present a "normal" behavior, in marked contrast with $CrO_4^=$ and uranylphosphate ions (*p*H 9.1) for which the Li^+ inversion is again observed. Comparison of chromate ψ'' values at the two potentials indicated, reveals that the extent of deviation seems to decrease with more negative potential.

Cationic effects on "complex" electrochemical reactions.—A number of electrochemical reaction schemes include concentration- or rate-controlling steps (*e.g.*, decomplexation, protonation, etc.), easily distinguished from ψ effects. When they involve anions, such reactions generally respond to cationic effects. Diagnosis of the relevant mechanisms is of interest, since it may sometimes help to devise appropriate mathematical corrections, allowing the deduction of the undesirable chemical effect from the main electrochemical step, with the resulting possibility of obtaining usable ψ'' values. A few pertinent examples will be briefly discussed.

Occurrence of a prior fast nonelectrochemical reaction.—Two typical cases are afforded by the electroreduction of periodate (22) and palladite ions in alkaline medium. For both processes, the study of the influence of variable *p*H at constant double layer structure, and vice versa, shows conclusively that a labile protonation step occurs before the discharge which involves a mononegative particle (Eq. *e*, *f*).

The net pseudomonomolecular rate constants can then be affected by any shift undergone in the prior equilibrium. For periodate in 0.1N alkaline hydroxides, all the polarization curves are practically coincident around the potential of nul charge. However, in 1N solutions, differences in rate constants become obvious, the equilibrium (*f*) being shifted forward from Li^+ to Cs^+ (for LiOH, this is mostly due to incomplete dissociation). As a result, 1N ψ'' values calculated without taking this circumstance into account, are in error. After proper correction, however, the ψ'' values are cogent with the others so far obtained.

Palladite reduction (25) will be considered with some more detail, since, in contrast with periodate, Ba^{++} and Ca^{++} salts are sufficiently soluble (Ca^{++} however is useless for our purposes, in view of its *p*H buffering action).

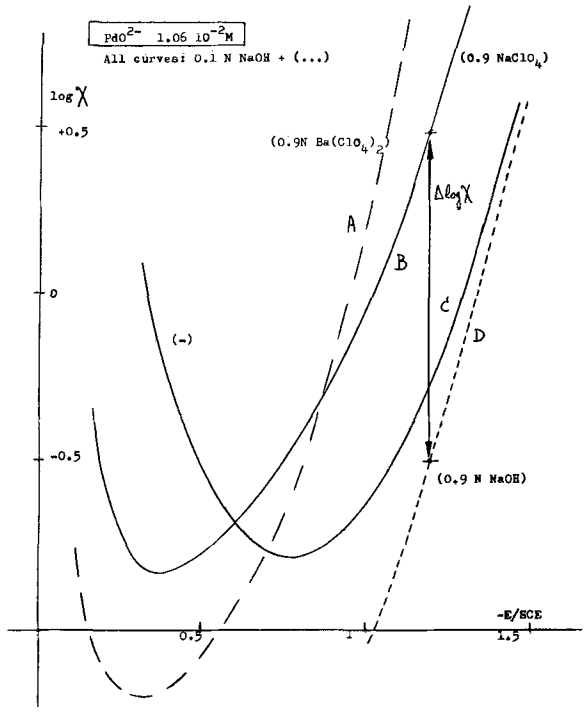

Fig. 6. Effect of composition on the polarization curves for palladite reduction.

Examination of Fig. 6 (which embodies only a few selected polarization curves) leads to the following conclusions.

1. At the same sodium concentration (1N : curves B and D), the over-all apparent rate constants decrease by an order of magnitude when *p*H is raised by one unit, independently of the potential. This fact demonstrates the existence of a prior protonation step (which is fast, as evidence by the attainment of the true diffusion current in all cases).

2. At the same *p*H (13), and variable [Na^+] (0.1 and 1N : curves C and B), the usual ψ effect predominates, with the resulting crossing of the two curves near the point of nul charge, at which ψ reverses itself. The order of magnitude of the effect corresponds to $z_k \simeq -1$ (with $\alpha_o \simeq 0.25$).

3. Comparison between curves C and D (NaOH 0.1 and 1N) is instructive because it shows the complex behavior which is observed when *p*H influence is studied without controlling ionic strength : pure *p*H effect around the point of null charge, and, at sufficiently negative potentials, nearly complete compensation between retarding *p*H- and accelerating ψ effects [periodate reduction behaves the same way under similar condition (22). As it is with periodate, the series $Li^+ \rightarrow Cs^+$ is also somewhat perturbed by shifts in the prior equilibrium in 1N alkaline hydroxides].

4. When equinormal Ba^{++} is substituted for Na^+ (curves A and B), conflicting effects are observed : the net rate constant increases at negative potentials, but drops to attain a nearly constant lowering ($\Delta \log \chi \simeq -0.3$) at potentials more positive than the point of nul charge.

This behavior may be explained assuming that the prevailing bulk species $PdO_2^=$ is appreciably associated with Ba^{++} (*p*K's for 2-2 ion-pairing are currently over 2), thus bringing a shift toward deprotonation for the prior chemical step. Simultaneously, the same Ba^{++} ions are increasing the discharge rate constant of PdO_2H^-, the more as the potential is made negative. It results from this that $\Delta\psi''$ calculated for Ba^{++} are cogent only if a suitable correction is made for the first chemical effect. The proposed mechanism

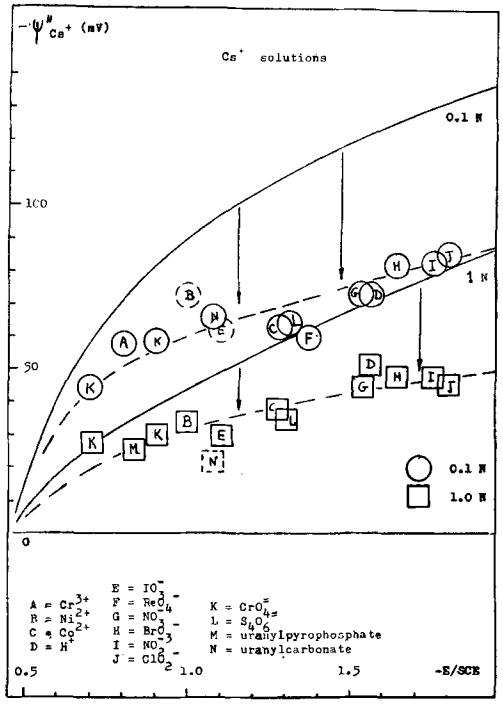

Fig. 7. Effect of Cs^+ as supporting cation on electrode reactions involving depolarizers of various charges expressed in terms of ψ''.

also indicates that $BaPdO_2$ ion pairs are not electroactive (probably for want of any hydroxyl groups, a rather common behavior in oxyanion reduction).

Occurrence of rate-limiting steps.—The existence of large cationic effects has already been demonstrated in the case of the "kinetic" prewave presented by ClO_2^- in very alkaline media (23, 24).[8]

A different example, now under study in this laboratory, is afforded by the reduction of ReO_4^- at $pH \geq 13$.

It is well known (26) that perrhenate waves are generally exalted and distorted by simultaneous catalytic hydrogen evolution. However, at *p*H 13 and before the start of the hydrogen wave, a relative well-defined limiting current is observed, which corresponds to a net 7-8 electron process. This current was observed to fall with increasing *p*H, the easier as the supporting cation is changed according to the series $K^+ < Na^+ < Li^+ << Ba^{++}$. In all cases, the amplitude decreases to a limiting value coresponding to a net 3-electron reduction. Meanwhile, the wave is shifted along the potential axis, in accordance with the expected behavior of a "normal" mononegative anion. These characteristics are explainable, by assuming that :

1. The rate-determining step is always the slow transfer of the first electron.

2. The following steps include a purely chemical process (possibly a disproportionation mechanism involving Re^{IV}), which, although usually too fast to allow detection, slows down by the increase in *p*H, and is notably affected by selective cationic effects (probably of the ion-pairing type).

These few examples illustrate the multiplicity of situations where cations may exert specific influence. Fortunately, such behaviors present peculiarities which permit their easy distinction from the simplest cases first considered above.

The Discussion Section will be devoted essentially to these latter cases, for which mechanism diagnosis remains to be debated.

Discussion

Results obtained with cationic depolarizers show that their behavior generally follows predictions from the Frumkin theory, using the simple Gouy-Chapman model, although some systematic deviations are indicated. For all of the systems, dilution of $Z = 1$ supporting electrolytes does not quite bring the expected increase in apparent rate constants. These deviations, however, remain marginal and would perhaps reflect some specific adsorption (or size effect) of the depolarizers themselves. The decelerating effect of Cs^+ is noticeable; it presents the same order of magnitude for all depolarizers, irrespective of their charge (Fig. 7). For 1*N* Cs^+ solutions, ψ'' varies very little with potential, with the consequence that experimental α values observed in that medium need hardly any correction for the double layer effect.[9]

In the case of multicharged anions, the supporting anion substitution method shows that z_A (which can be expected to equal z_δ) is close to —2 for the chromate and tetrathionate ions, and that, accordingly, no prior association is needed. [Using thallium amalgams, Frumkin (2) found the same result for persulfate.]

For uranylcarbonate, however, $z_K \simeq -2$ and $z_A \simeq -1.4$, a discrepancy which suggests some limited prior interaction with Na^+. In the case of the rather bulky uranylpyrophosphate anion z_A is around —1, while $z_K \simeq -3$. These conflicting values are indicative of an extensive amount of prior labile ion pairing. Besides, the surprisingly low value of z_A is perhaps explainable in terms of a size effect and the subsequent lowering of the effective ψ value acting on the anion.

Regarding the mononegative depolarizers (the only ones for which it was possible to compare mono- and divalent supporting cations), examination of the ψ'' values reveals that the extent of deviation observed in Li^+ medium is closely related to (*a*) the amount of "abnormal" acceleration due to divalent cations, and (*b*) the reversal in the usual Ba^{++}-Ca^{++} series (as found with cationic depolarizers).

Figure 8 in which the relative $\Delta\psi''$ charges resulting from the substitution $Na^+ \rightarrow Li^+$ have been plotted *vs.* the same quantities for $Ba^{++} \rightarrow Ca^{++}$, illustrates this correlation, and shows furthermore that the extent of deviation from the normal behavior increases according to the sequence

$$ReO_4^- < NO_3^- < NO_2^- < BrO_3^- < ClO_2^- < IO_3^- \quad (g)$$

The contrasting behavior of ReO_4^- and IO_3^- appears clearly in Fig. 9 which embodies a larger number of monopositive supporting cations. It should be noted that these intercomparisons are vitiated to some extent by the fact that the various depolarizers have been studied at their "median" reduction potentials which vary from —1.1 to —1.8v. (The potential depend-

[8] We recently found (37) that this prewave results from the catalytic reduction of ClO_2^- by minute amounts of ferrite ions, electrogenerated by reduction of ferrate. The so-called "desorption dip" observed about —1.6 v/SCE coincides with further reduction to metallic iron. The large cationic effects previously observed are essentially linked to the fact that each particular sample of any hydroxide is differently contaminated by iron traces. Recent experiments conducted with rigorous control of the ferrate content have shown that the catalytic wave depends in fact very little on the cationic composition (as can be expected for such a mechanism).

[9] Using the average cesium ψ'' values, it is possible to compute the charge densities for the diffuse part of the double layer. After algebraic addition to the corresponding electrode charge densities, the amount of specific adsorption may finally be evaluated. Such work is now extended to a larger concentration range and complete results will be published later.

For Cs+ 1*N*, "kinetic" q_i can be compared to independent thermodynamical data recently obtained (q_i') (12). The agreement between the two sets of results is satisfactory, in view of the inherent imprecision of the Gibbs method at low q_i', and the approximations involved in the Gouy-Chapman theory for the diffuse part, which affect our q_i values.

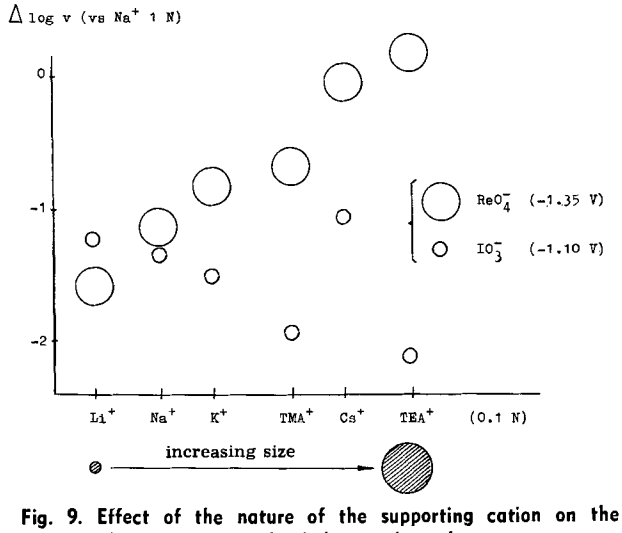

Fig. 9. Effect of the nature of the supporting cation on the variations of rate constants for iodate and perrhenate.

ence of the observed effects is demonstrated the best with the palladite system, Fig. 6, curves A, B, which permits the measurements of rate constants over a large potential interval, due to the particularly low α value. It can be shown from that figure that the charge-reducing effect of Ba^{++} is only effective when ψ is repulsive enough.) The fact, however, seems of relatively secondary importance, and affects the deductions drawn later only slightly (more particularly, IO_3^- and ReO_4^- median potentials are relatively close).

It is of particular interest to note that there is a remarkably close correlation between series (*g*) and many other sequences which characterize other types of anion behavior, as exemplified by: (*a*) B coefficients of viscosity in aqueous solutions (27); (*b*) adsorption potentials at the water-air interface (38, 39); (c) selectivity coefficients of anionic exchange resins of the Dowex 1 or 2 type (40); (*d*) effect on salting out chromatography (41); (*e*) coadsorption with tetrapropylammonium ions at the air-water interphase (42); (*f*) coadsorption with tetraalkylammonium ions on negatively charged mercury (32); (*g*) distribution coefficients between water and an organic phase (chloroform) in the presence of a large cation as extractant (*e.g.*, tetraphenylarsonium) (34, 35).

Table VIII permits direct intercomparison between these different sequences which, for this purpose,

have been "normalized" with respect to the halide ions (horizontal double lines), except for the series found in this work, for which IO_3^- and ReO_4^- have been chosen as reference levels, since halides cannot be investigated.

The obvious conclusion that stems from inspection of Table VIII is that the deviations observed in the electrochemical behavior are merely a new aspect of a more general phenomenon. There is at present a growing amount of evidence supporting the concept (originated by Gurney) that interaction between oppositely charged ions increases if they both exert the same type of structural influence on the water molecules that surround them (27). These order-making or order-destroying effects are related to thermodynamic quantities like the partial ionic entropies, or the B coefficient of viscosity. Recent works by de Jong (30), Bregman (33), Ling (43), Eisenman (29), and Diamond (28), among others, may be considered to a certain extent as attempts to quantify the Gurney concept, in terms of quantities like ion field strength, polarizability, and suitable spatial configurations.

Table IX lists several ions, tentatively positioned according to their charge and the extent of their water-ordering character. According to the Gurney concept, association can be expected to prevail mostly between oppositely charged ions of the same type. Association (or pairing, the two words being taken as equivalent) between water-ordering ions is typified by $MgSO_4$ or LiOH. On the other hand, entities like Et_4NI or Ph_4AsClO_4 are examples of the inverse type of interaction (essentially pairing by "cavity-sharing," or, in other words, "cavity pairing").

In the case of a cavity-type water-depolymerizing anion like ClO_4^- or ReO_4^-, the other interacting cavity may be a cation of the same type (free or part of

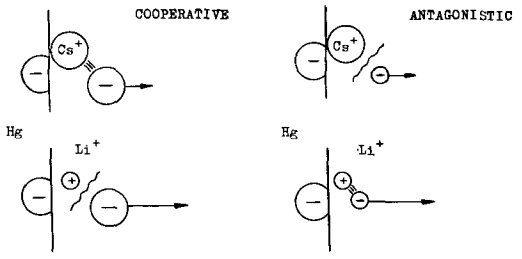

Fig. 10. Coupled ψ and pairing effects. Anion discharge on negatively charged mercury: ≡ interaction; ~ lack of interaction; → amount of ψ repulsion.

an exchange resin, Table VIII, col. 3, 6) or any weakly charged interphase (col. 1). Columns 2, 4, 5 correspond to a more complex situation for which three different "cavities" interact together. The unexpected order-making of the iodate ion results essentially from the fact that its oxygen atoms have very small π-bonds with the central iodine atom and are thus able to interact strongly with water.

Regarding the reactions considered in the present work, the characteristics of the deviations or reversals observed indicate that the responsible factor is linked with ion pairing of the first type (water-ordering partners). Negatively charged mercury acts itself as a "cavity" macro-ion (more or less similar to ClO_4^- at very negative potentials) and, as such, specifically adsorbs cavity-type cations like Cs^+. In this case, ψ is accordingly lowered and so is the repulsion between mercury and the anionic depolarizer. However, if the latter is also of the cavity-type, interaction with adsorbed Cs^+ ions contributes to increase its local concentration, and significant increase of the apparent rate constant is observed (Fig. 9 and 10).

On the other hand, when lithium is the supporting cation, ψ is more repulsive (due to the lack of interaction with mercury). However, if the reducible anion is of the water-ordering type (IO_3^-, *e.g.*), the local ion pairing tends to circumvent the repulsion, and sequence reversal may be observed. Figure 10 illustrates schematically the four limiting cases which can be encountered.

Although little doubt exists about the fact that occurrence of ion pairing and deviating behaviors are linked, it still remains to be established whether the association affects only the local concentration of the depolarizer, or whether its reactivity itself is enhanced.

Experiments now under way using proton-donor cations (NH_4^+, $CH_3NH_3^+$, etc.) and electrodes other than mercury (Pt, Au) show further sequences of the same type which strongly suggest that reactivity may indeed be enhanced provided that the reduction requires a protonation step. It is believed that the transition complex involved a water-molecule which can be subjected to considerable electrostriction when ion pairing occurs, the effect of which being to decrease the activation energy of the rate-determining step. This concept will be presented and discussed later.

Conclusions

Within the range of compositions and concentrations to which the present study is restricted, deviations from the "average" ψ effect appear to be intimately related to the extent of association. Although "mostly electrostatic" ion pairing is the most frequent factor responsible for the increases in rate constant, a cavity ion pairing mechanism is indicated in the case of perrhenate in tetraalkylammonium solutions. The direction and the amplitude of the observed effects can be accounted for on the basis of the Gurney concept which stresses the importance of the water-ion interaction.

The present investigation points out that specific conclusions about rate-determining factors require the preliminary intercomparison of as many systems as possible, in order to allow the definition of a "standard" type of behavior, regardless of any *a priori* assumption for the double layer model. It appears, however, that the simple Gouy-Chapman, despite its intrinsic defects, predicts values which are in rather reasonable agreement with the order of magnitude of the kinetic effects observed, as far as the cases for which specific adsorption or deviating mechanisms occurs are carefully excluded.

Discussion

F. C. Anson: Professor Gierst should be complimented on providing so much valuable new information on double layer structure in a very large number of supporting electrolytes. I would like to ask three questions about this work.

1. Do you regard the departure of any particular reactant from the "normal" behavior established for each supporting electrolyte as a sufficient or merely a necessary indication of the occurrence of ion pairing?

2. Whenever ion pairing is invoked to explain rate enhancement must it not also be assumed that the ion paired species, which has a lower charge and can therefore more readily cross the diffuse layer, has at least as large a standard electrode reaction rate constant as the unpaired starting material?

3. Is any commitment made or intended as to where the ion pairing takes place, *i.e.*, in the bulk of the solution, only within the diffuse layer, or both?

L. Gierst: 1. Any departure from the "normal behavior" is of course in itself not automatically indicative that ion pairing is the responsible factor. What we have shown, however, is that the sequence of results found in our experiments are very similar to many others, for which there is clear evidence that ion pairing is the controlling factor. Furthermore, all these sequences follow the order which can be predicted from such thermodynamic quantities as ionic entropies or B coefficient of viscosity, if we accept Gurney's views about the water structure effect.

2. The influence of pairing on the intrinsic reducibility of a given anion is difficult to assess. Present experiments indicate that enhancement in reactivity is in fact observed at least for oxyanions of the "water-organizing" type, when their reduction involves protonization. This matter will be presented in detail in a later paper.

3. Since the supporting cation concentration is increased in the diffuse part of the double layer, the amount of ion pairing is accordingly larger there, especially if cationic specific adsorption occurs. It remains difficult at present to delineate the role of the local electrical field since it acts on both electrolytic dissociation and water structure (cf. the recent contributions to that topic by Hurwitz and Sanfeld[1] and by Nürnberg[2]).

[2] H. Nurnberg, *Discussions Faraday Soc.*, 1965, 39.

H. B. Urbach: Professor Gierst, have you made calculations of the ion recombination from Brönsted's theory and have you correlated your results with these calculations?

L. Gierst: No, since our experiments were carried out in nonideal solutions and some vital parameters are not available. It should perhaps be mentioned that the sequence of results found are following the order for "effective" radii of hydrated ions, proposed by Nightingale[3] on the basis of his phenomenological theory of ionic solution.

G. J. Hills: Ion association is a well-established general phenomenon in electrolyte solutions, although it is seldom possible, except in dilute nonaqueous solutions of low permittivity, to specify the nature and degree of the association. In concentrated aqueous solutions, the variety of local ion and solvent interactions is large, and in the absence of any obvious discriminating procedures, it is often necessary and desirable to express the total interaction in purely thermodynamic terms which contain all of the general and specific interactions of any pair of ionic species. These thermodynamic features will inevitably influence the ionic distribution at the interface, and this paper is concerned to delineate the way in which this influence occurs.

Just how far this can be done in terms of ion pairing is doubtful. These are complex concentrated systems in which the electrostatic interactions cannot yet be quantified. The term "ion pair" implies a long-lived species, the electrochemical characteristics of which are not taken into account here. It is not easy to see how far the effects described can be further quantified except perhaps by using more dilute solutions, *e.g.*, without supporting electrolyte, or by using cation reversible (membrane) electrodes to take into account the effective lowering of γ_+.

I should be glad of some further clarification of the "median potential" and some further reassurance that (*a*) no specific adsorption took place (IO_3^-) and (*b*) that the charging current was successfully eliminated. Indeed the broad sweep of results presented here could usefully be complemented by a detailed description of the procedures and results of a single system in which all the approximations could be assessed.

[3] E. Nightingale, *J. Phys. Chem.*, **63**, 1382 (1959).

L. Gierst: 1. Concentrated ionic aqueous solutions are not easily amenable to thermodynamic analysis and, besides, there are still many conflicting views about the water structure, and the way it is affected by ions (see Kavanau's[4] monograph, for example). We do not believe, however, that this fact should be a sufficient reason to abandon the field. One of the main conclusions we draw from the present work is that a general picture of what happens starts to emerge. In that respect, intercomparison of as many types of behavior as possible must be pursued in order to pinpoint the responsible factors. Quantitative thermodynamic explanations will probably follow, but must be based on sufficient prior experimental evidence (see also 1. in our reply to Dr. Anson).

2. IO_3^- is not adsorbed at the potentials under consideration (—0.65v *vs.* e.c.m.).

3. Capacity currents were carefully deduced, of course.

4. Procedures used were based on the classical Koutecky theory.[5] We did not find it useful to produce the polarization curves themselves, which would have increased the size of the paper considerably.

H. Hoffmann: Dr. Gierst presents a wealth of excellent experimental data which may be used for further improvement of the Gouy-Chapman theory of the double layer.

The authors use the procedure of anion substitution of the supporting electrolyte to distinguish between ψ-effects and effects which are due to ion association. The substitution certainly should also influence the association equilibrium of the anion depolarizer with the supporting cations since I^- ions will form complexes with the cations and two coupled association equilibria will result.

The existence of water structure enforced ion pairs is concluded from the data which is of particular interest since such associates are normally not considered and have not yet been discovered by other techniques. Therefore these data should stimulate investigations with different methods which are directly sensitive to ion pair formation.

L. Gierst: The mentioned difficulty was circumvented as far as possible by using two anions (iodide and acetate), the sodium salts of which have very close mean activity coefficients.

B. E. Conway: In regard to the interesting ion-pairing effects discussed by Professor Gierst, it may be useful to record that we have recently[6] determined the components of charge Γ_{K^+} and Γ_{Cl^-} for KCl adsorption in aqueous solutions containing various concentrations of pyridine, the surface excess (Γ_{Py}) of which could be independently determined from the derivative $-(\partial\gamma/\partial\mu_{Py})_{E,\mu_{KCl}}$ by means of appropriate electrocapillary measurements. In the presence of adsorbed pyridine, both Γ_{K^+} and Γ_{Cl^-} increase almost equally both on the cathodic and anodic branches as the Γ_{Py} increases. The effect is largest in the strongest KCl and pyridine solutions. The parallel increase of the Γ_{K^+} and Γ_{Cl^-} seems to be most easily explained by supposing that ion pairing in the double layer is enhanced by the presence of adsorbed pyridine. The concentration of pyridine in the bulk was insufficient to lower the bulk dielectric constant significantly so that the species in solution were still presumedly free hydrated K^+ and Cl^- ions.

L. Gierst: The observed enhancement is very interesting. It could perhaps reflect the fact that the transition between the pyridine layer and the "bulk" water is not really sharp, and that the boundary region (including the hydrated nitrogen groups) possesses a rather low "microscopic" dielectric constant, favoring local ion pairing. There is some similitude between this behavior and the fact that large organic cations, when they are specifically adsorbed, also tend to pair with anions of suitable type.[7]

Panel Discussion on Adsorption at Solid Electrodes

I. The Application of Multipulse Potentiodynamic Sequences to the Study of Surface Intermediates in the Electrochemical Oxidation of Organic Substances

S. Gilman

General Electric Research and Development Center, Schenectady, New York

In the electrochemical oxidation of complex organic molecules on platinum electrodes, it may be anticipated that parallel and sequential reaction steps will occur. Such complex systems do not lend themselves well (1) to study by the steady-state treatments of classical kinetics. However, through the use of pulse techniques, it is often possible to isolate individual reaction steps and to characterize surface intermediates. Early application of such techniques was made in the study of the adsorption and oxidation of methanol (2, 3).

In this paper, I shall discuss the manner in which some particular aspects of the adsorption and reaction of organic compounds (encountered in the study of C_2 hydrocarbons) were examined by means of the "multipulse potentiodynamic" method first developed in connection with the study of CO adsorption (4).

Experimental

The electronic instrumentation, test vessel, etc., have been described previously (4). The test electrode used in most of the measurements, was a length of C.P. grade smooth platinum wire. A platinized wire was used only in the last section as indicated. All potentials are referred to that of a reversible hydrogen electrode in the adsorbate-free electrolyte.

Discussion

Study of the Mechanism and Kinetics of Activated Adsorption (of Ethane)

Use of a linear anodic sweep in the measurement of adsorption kinetics.—The organic adlayer may be "stripped" by means of a linear anodic sweep (l.a.s.) and the coverage determined from the corresponding charge. In the sequence of Fig. 1, steps A-C serve to clear the surface of previously adsorbed material. Step *D* (which is optional) serves to prereduce the surface, but the low potential prevents the adsorption of ethane in the allotted time. In step E, atomic hydrogen is rapidly removed from the surface and the

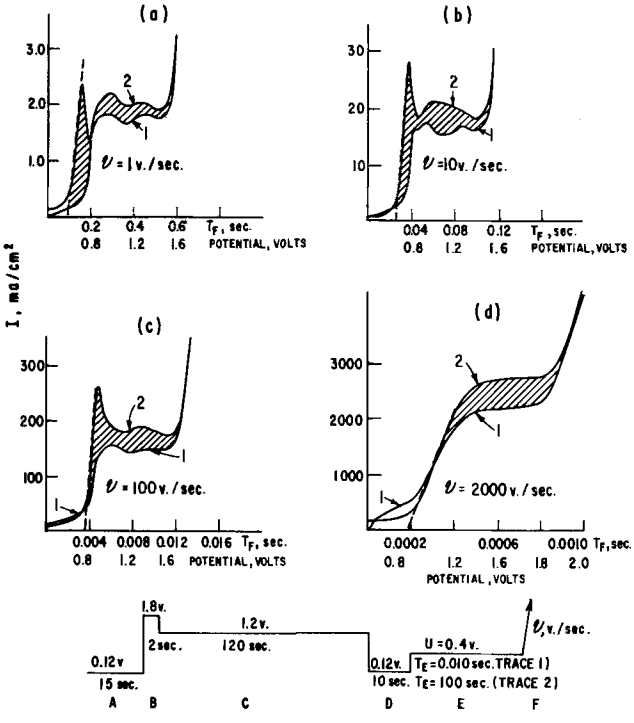

Fig. SG1. Linear anodic sweep traces corresponding to the "clean" surface (traces "1") and to the surface partially covered with ethane (traces "2"). The 1*N* $HClO_4$ solution was saturated with ethane at 60°C. The electrode was smooth, having a "roughness factor" (R.F.) of 1.5 based on hydrogen adsorption. After Gilman, ref. (5).

adsorption of ethane occurs at 0.4v for 100 sec. The potential sequence was chosen in such a way at the beginning of step E, the solution adjacent to the surface was well equilibrated with the bulk solution and transport of the hydrocarbon was by ordinary diffusion (5). Traces "1" of Fig. SG1a-SG1d were obtained in the absence of hydrocarbon and correspond to the "clean" surface. The current corresponds mainly to surface oxidation until copious evolution of molecular oxygen sets in at *ca.* 1.6v.[1] Traces "2" correspond mainly to combined oxidation of the surface and of adsorbed ethane.[2] Let us call the difference in areas under curves 1 and 2, Q_E' (hatched areas). Let us also assume the existence of a charge, Q_E which bears the following relationship to the absolute coverage with ethane

$$Q_E = nF\,\Gamma_E \qquad [1]$$

where Γ_E is the coverage of the surface with various adspecies (in moles/cm²), and n is the average number of electrons required for oxidation and desorption of an ethane adspecies. Then Q_E may be used as a measure of absolute coverage if n is known and remains constant; Q_E is a measure of relative coverage if n is constant, but the value of n is not known.

The experimental charge $Q_E' = Q_E$ if the following conditions hold:

1. All organic material is desorbed by the time traces 1 and 2 (Fig. SG1) merge.
2. Capacitive corrections are negligible.
3. Traces "1" and "2" comprise identical surface oxidation charges.
4. Negligible readsorption and/or oxidation of ethane occurs during the sweep.
5. The desorption of organic material is entirely oxidative (not due to electrostatic repulsion).

An indirect test of the validity of such assumptions is made by exploring the dependence of Q_E' on the sweep speed. It was found (5) for ethane that Q_E' remains constant for sweep rates ν as small as 1 v/sec to somewhat under 100 v/sec (with dependence on surface coverage, as well as on ν). Decreasing charge at higher values of ν was found to correspond to retention of a portion of the adlayer past the region of oxygen evolution. A more direct test of the equality of Q_E' and Q_E may be made for rapidly adsorbed substances. For CO (4), ethylene and acetylene (6) a plot of the anodic stripping charge *vs.* the square root of adsorption time is linear until high coverages are achieved. This suggests diffusion-controlled adsorption. The slopes of such plots were found in excellent agreement with a diffusion law if it was assumed that the values of n (of Eq. [1]) correspond to complete oxidation of the adlayer to CO_2 and H_2O (as in the steady-state situation). Hence the method has been validated for these quite diverse compounds. Similar validation has been reported for even more complex molecules (7, 8).

An explanation may now be offered for the apparent equality of the surface oxidation charge (by the end of the sweep) both in the presence and absence of an adsorbed organic substance.[3] The kinetics of oxidation of the surface is such that the charge (after the first small fraction of a second) depends strongly on the potential, but only slightly (approximately on the logarithm) of the time (9). The organic material may be regarded as blocking sites temporarily and hence slightly decreasing the time of surface oxidation. This causes a negligible error.

Correction for surface oxidation might also be made by cathodically reducing the surface and measuring the corresponding charge. This is, however, best avoided where possible since reduction is sluggish (9) and may lead to error through incomplete reduction or through simultaneous oxidation of dissolved organic material (both lead to positive error in determination of surface coverage with the organic material).

It is to be noted that in this application, the l.a.s. trace is used only to derive the charge, Q_E, corresponding to the adsorption process preceding the sweep (other wave forms may be used but are generally not as satisfactory). Hence variations (with sweep speed) of such characteristics of the trace as peak voltage, current, etc., have no bearing on the problem. This seems a point previously misunderstood by other investigators [see, for example ref. (11, 12)].

Results of the kinetic measurements.—The kinetics of ethane adsorption may be examined through recording Q_E or the hydrogen codeposition charge (see below) as a function of time at various constant potentials. Over a range of several tenths of a volt, the "true" rate of adsorption was found (5) to follow the law

$$\frac{d\theta_E}{dt} = KC(1-\theta_E)^2 \qquad [2]$$

or the integral law

$$1/\theta_F = KCt + 1 \qquad [3]$$

where $\theta_F = 1 - \theta_E$, and C is the concentration of dissolved ethane. Equation [2] implies an adsorption step which is second order in unoccupied[4] (by ethane) surface sites and relatively field-independent. A reasonable mechanism is

[1] There may be considerable IR drop (due to residual resistance between the Luggin capillary and the working electrode) included in the nominal potential at high sweep speed. This, however, does not effect the measured charge which is the only quantitative consideration in such measurements.

[2] By "adsorbed ethane" we mean "the adlayer resulting from the adsorption of ethane" which may have a composition quite different from that of the parent molecule.

[3] The charge corresponding to oxidation of the surface is not necessarily identical in presence and absence of the organic adsorbate at constant potentials less than *ca.* 1.6v.

[4] The possibility that such sites are occupied by inorganic species (*e.g.*, H_2O) is not ruled out.

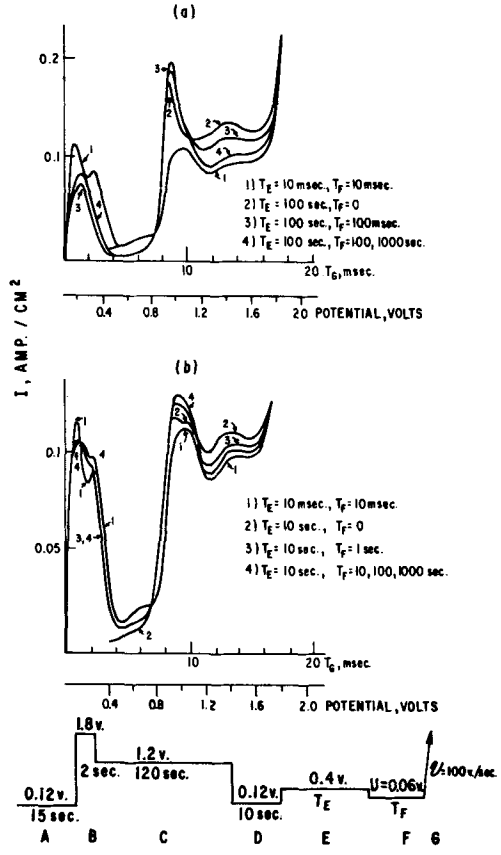

Fig. SG2. Linear anodic sweep traces obtained during desorption of adsorbed "ethane." The 1*N* $HClO_4$ solution was saturated with ethane at 60°C; the smooth Pt electrode had a R.F. = 1.5. T_E and T_F are adsorption and desorption time intervals, respectively. After Gilman, ref. (13).

$$C_2H_6 \text{ (dissolved)} \rightarrow \underset{|}{\overset{C_2H_5}{S}} + \underset{|}{\overset{H}{S}}$$

$$H \rightleftarrows H^+ + e^- + S$$
$$|$$
$$S$$

where S = Surface site.

Study of the Kinetics and Mechanism of Desorption (of Adsorbed Ethane)

Figure SG2 presents traces corresponding to desorption of a portion of the ethane adlayer. As in Fig. SG1, adsorption was allowed to occur at 0.4v (step E). In step F the desorption proceeded under the influence of (low) potential U and the desorption process could be followed as a function of time (T_F) by application of l.a.s. (G). In Fig. SG2a, trace 1 corresponds to the clean surface. Trace 2 corresponds to 100 sec of adsorption, with no desorption. Traces 3 and 4 correspond to 100 sec of adsorption, followed by 100 msec and 100-1000 sec of desorption, respectively. We see that the material desorbing (type II) corresponds mainly to the portion of the adlayer which oxidizes at relatively high potentials during the l.a.s., while the nondesorbable residue (N.D.R.) (type I) corresponds mainly to the more electrochemically reactive material. The N.D.R. is retained at potentials as low as —0.2v (13). Hence this experiment serves to characterize two types of surface intermediates.

By measuring (from traces such as those of Fig. SG2) the charge, ΔQ_E corresponding to desorption, it was possible (13) to establish the kinetic law

$$\frac{-d\theta_E}{dt} = H' \exp\left[(\alpha n' FU/RT) + m\theta_E\right] \qquad [4]^5$$

[5] In ref. (13) the "+" was accidentally omitted between the two terms in the exponential term of Eq. [4].

where $\alpha = 0.5$ and $n' = 2$ electrons. Equation [4] suggests the following mechanism for the desorption

C_2H_2 (adsorbed) + $2e^-$ + $2H^+ \rightarrow C_2H_4$ (adsorbed)

$C_2H_2 \rightarrow$ Further hydrogenation (to ethane) and desorption.

The first step is rate-determining. A similar chemical hydrogenation (involving hydrogen atoms) step is also permissible.

Identification of Surface Intermediates

Type I intermediates.—The adsorption of C_1 "oxygenated" molecules (HCOOH, CO_2, etc.) results in nondesorbable adlayers resembling the "type I" ethane oxidation intermediate (14, 15). The "type I" intermediate is therefore believed to comprise one or more C_1 oxygenated surface structures.

Type II intermediates studied with linear anodic sweeps.—Figure SG3 presents traces obtained in the adsorption of ethylene and acetylene. The traces for both adsorbates are similar to those for the type II oxidation intermediate of ethane. Also, (temperatures under 60°C) the adlayers of all three substances may be hydrogenated and desorbed as ethane (16). When ethylene is adsorbed at potentials of 0.4v or less, a current flows corresponding to the abstraction of (approximately) 2 hydrogen atoms/molecule. These results suggest that at moderate potentials and temperatures, the type II intermediate, and adsorbed ethylene and acetylene have a common average stoichiometry corresponding to C_2H_2.

Type II intermediate studied by linear cathodic sweeps.—Figure SG4 presents linear cathodic sweep traces corresponding to the codeposition of hydrogen on a surface partially covered with adsorbed ethylene. Trace I corresponds to H-deposition on the "clean" surface. The area above the trace (preceding large-scale evolution of molecular hydrogen) corresponds to approximately a monolayer of hydrogen atoms. Traces 2-6 correspond to the hydrogen required to complete a mixed monolayer of hydrogen atoms and organic material. A rather high sweep speed is required to prevent desorption of the organic material (5, 6, 13). The areas defined by trace 1 and any sub-

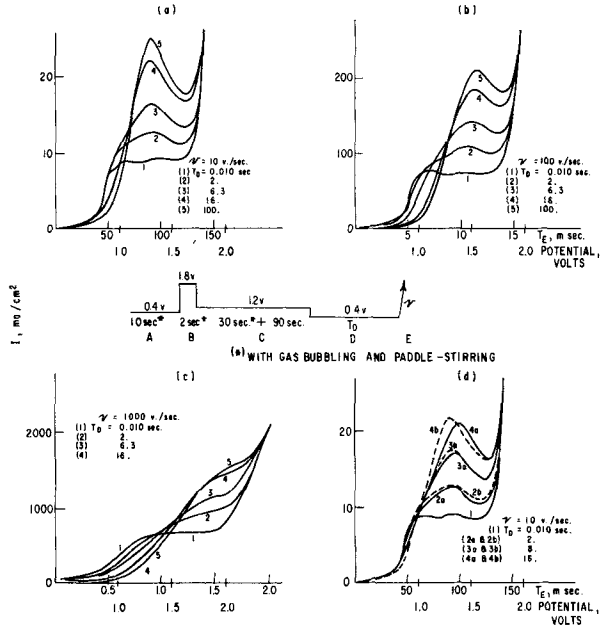

Fig. SG3. Linear anodic sweep traces for adsorbed ethylene and acetylene. The traces were recorded during l.a.s. E of the specified sequence. T_D is the adsorption time. The solid traces (a-c) and the dashed traces (d) were obtained in 1N $HClO_4$ saturated with a gas mixture of 1.08% ethylene + 98.92% argon (30°C). The solid traces (d) were obtained in 1N $HClO_4$ saturated with a gas mixture of 0.105% acetylene + 99.985% argon (30°C). Electrode roughness factor = 1.4. After Gilman, ref. (6).

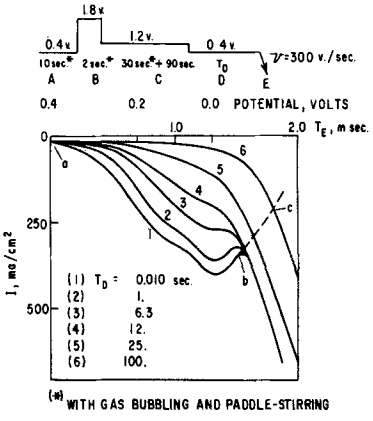

Fig. SG4. Linear cathodic sweep traces corresponding to codeposition of hydrogen on a surface partially covered with ethylene. The traces were measured during sweep E of the specified sequence. T_D is the adsorption time. The solution was 1N $HClO_4$ saturated with a gas mixture of 1.08% ethylene + 98.92% argon (30°C). After Gilman, ref. (6).

sequent trace, represents a charge, $\Delta(sQ_H)$ corresponding to (hydrogen) sites blocked by organic material. This is related to the absolute coverage with the ethylene by

$$\Delta(sQ_H) = mF\,\Gamma_{ENE}\ (ENE = \text{ethylene}) \qquad [5]$$

Analogous to Eq. [1]

$$Q_{ENE} = nF\,\Gamma_{ENE} \qquad [6]$$

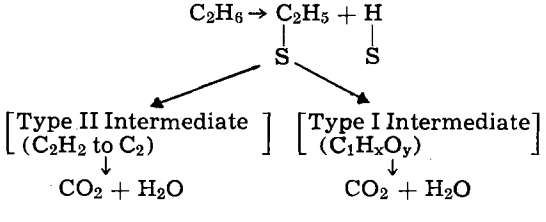
Combining Eq. [5] and [6]

$$\Delta(sQ_H)/Q_{ENE} = m/n \qquad [7]$$

The quantity m/n (sites/electron) may serve as an indication of the number of valences per adspecies for simple molecules [*e.g.*, for CO, acc. to ref. (4)]. For the more complex hydrocarbons, it may serve, at least, as a characterization of the structure. For ethylene and acetylene at low potentials, m/n was found constant with a value (*ca.* 0.3) corresponding to 3 valences/adsorbed entity, based on simple assumptions. At higher potentials, m/n (ethylene) was found to increase to values that would correspond to ultimate dehydrogenation to adsorbed carbon (17).

Interconversion of Surface Intermediates

The skeletal oxidation scheme for ethane may be represented by



Possible conversions of the type II to type I intermediate were investigated by means of the pulse sequence appearing in Fig. SG5. Higher temperatures were examined to favor conversion. A platinized surface was employed to minimize the rate of transport (per geometric cm^2) during the time allotted for conversion. The functions of the various steps in the sequence of Fig. SG5 are:

A-C. Pretreatment
D. Adsorption at 0.3v
E. Oxidation of adlayer at 0.8v [to reduce the ratio, (type I)/(type II)].

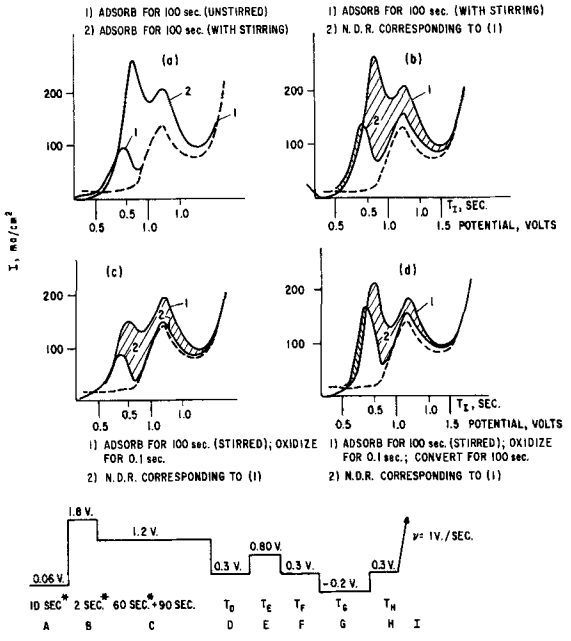


Fig. SG5. Use of linear anodic sweep traces for determination of the nondesorbable residue during readsorption of acetylene. Electrode B (R.F. = 138) was used. The electrolyte was 85% phosphoric acid saturated with ethylene at 120°C. The dashed trace corresponds to the clean surface and was obtained in the absence of adsorbate with T_D = 1 sec, $T_E = T_F = T_G = T_H = 0$. (a) Trace 1, corresponds to ethylene adsorbed for T_D = 100 sec (quiescent solution). $T_E = T_F = T_G = T_H = 0$. Trace 2, corresponds to ethylene adsorbed for 100 sec (stirred solution). $T_E = T_F = T_G = T_H = 0$. (b) Trace 1, corresponds to ethylene adsorbed for T_D = 100 sec (stirred solution) + 90 sec (quiescent solution) $T_E = T_F = T_G = T_H = 0$. Trace 2, corresponds to the nondesorbable residue for the conditions of trace 1. T_D = 100 sec (stirred solution + 90 sec (quiescent solution) $T_E = T_F$ = 0, T_G = 1 sec (to desorb), T_H = 0.1 sec (to reduce concentration of adsorbed and dissolved hydrogen). (c) Trace 1, corresponds to ethylene adsorbed for T_D = 100 sec (stirred solution) and 90 sec (quiescent solution), and partially oxidized for T_E = 0.1 sec with $T_F = T_G = T_H = 0$. Trace 2, corresponds to the nondesorbable residue for the conditions of trace 1. T_D = 100 sec (stirred solution) + 90 sec (quiescent solution), T_E = 0.1 sec, T_F = 0, T_G = 1 sec (to desorb), T_H = 0.1 sec (to reduce concentration of adsorbed and dissolved hydrogen). (d) Trace 1, Corresponds to ethylene adsorbed for T_D = 100 sec (stirred solution) + 90 sec (quiescent solution), partially oxidized for T_E = 0.1 sec and readsorbed for T_F = 100 sec. $T_G = T_H = 0$. Trace 2, Corresponds to the nondesorbable residue for the conditions of trace 1. T_D = 100 sec (stirred solution) plus 90 sec (quiescent solution) T_E = 0.1 sec, T_F = 100 sec, T_G = 1 sec, T_H = 0.1 sec.

F. Possible conversion (type II → type I) step at 0.3v
G. Desorption step: remove type II at —0.2v so that separate amounts of types I and II may be determined.
H. Preoxidation step (0.1 sec): to decrease the concentration of hydrogen, hence preventing the corresponding oxidation current during the sweep.
I. Linear anodic sweep: for alternative determinations of type I and of total I + II.

The durations of the various steps was adjusted to provide the conditions listed with Fig. SG5a-SG5d. The dashed traces of the figure correspond to the "clean" surface. The traces marked N.D.R. correspond only to the nondesorbable residue (type I). The other traces correspond to the entire adlayer (1 + II).

In Fig. SG5a, traces 1 and 2 correspond to the entire adlayer obtained after 100 sec (quiescent solution) and 100 sec (stirred solution). The traces of Fig. SG5a acts as control experiment for the conversion step of Fig. SG5d. In Fig. SG5b, trace 1 corresponds to the total

adlayer after 100 sec (with stirring) and 90 sec (quiescent solution) which is the "original condition" for the remaining experiments of Fig. SG5b-SG5d. Trace 2 corresponds to the N.D.R. portion of trace 1. The difference between areas under 1 and 2 (large hatched area minus small hatched area) is the charge corresponding to the type II portion of the adlayer. In Fig. SG5c, adsorption for 100 sec (stirred solution) + 90 sec (quiescent solution) was allowed and then the ratio of type II/type I was increased by briefly oxidizing at 0.8v. The total remaining adlayer is characterized by trace 1 of Fig. SG5c and the type I fraction of that adlayer is characterized by trace 2 of the figure. In Fig. SG5d, time is allotted for conversion of type II to type I in the adlayer containing a high ratio of type II/type I. Trace 2 of Fig. SG5d reveals that there is accumulation of appreciable additional type I compared with trace 2 of Fig. SG5c. This increase is approximately twice that which would have accumulated from the solution during the time allotted for conversion (twice the charge corresponding to trace 1 of Fig. SG5a). However, this possible conversion is approximately 1/5 the amount which could be accumulated from the solution in the absence of a "reservoir" of type II (1/5 the amount represented by trace 2 of Fig. SG5b). Hence one may conclude that the conversion of type II to type I is not an important path of the over-all reaction of ethane to yield $CO_2 + H_2O$.

Discussion

E. Gileadi: Dr. Gilman claims that C_2H_6, C_2H_4, and C_2H_2 all give rise to the same surface species on adsorption on a bright Pt electrode through partial dehydrogenation of ethane and ethylene. Two types of experiments carried out in our laboratory indicate that this is not the case.

1. The kinetics of the anodic oxidation of ethylene and acetylene have been studied by Bockris and coworkers in recent years.[1-3] A fundamentally different behavior was observed for the two compounds, indicative of different reaction paths and different rate determining steps. If ethylene were to dehydrogenate on the surface spontaneously, as claimed by Dr. Gilman, and give rise to an acetylenic residue, both compounds should behave kinetically in an identical manner.

2. An experiment has been performed[4] in which a Pt electrode was allowed to reach its rest potential in 1*N* H_2SO_4 and was then potentiostated at this potential (with obviously no current flowing through the circuit). Ethane or ethylene was then rapidly introduced into the cell and the current transient was recorded. In the case of ethane (and similarly for propane), an anodic current transient was observed, corresponding to a surface dehydrogenation followed by ionization of the hydrogen atom produced. No current was produced upon addition of ethylene to the solution, indicating that no dehydrogenation occurred. This is further confirmed by results of Niedrach published in 1964[5] where hydrogen was found on the surface of Pt electrodes in solutions containing saturated hydrocarbons at open circuit, but not in the case of ethylene.

The difference in the adsorption behavior of unsaturated and saturated hydrocarbons can be easily understood in a tentative manner. An unsaturated hydrocarbon can be chemisorbed on the surface by opening an ethylenic or acetylenic bond and using the orbitals thus made available for the formation of covalent bonds to the surface. In the case of saturated hydrocarbons the required orbital can only be made available by rupture of some of the existing C-H or C-C bonds, the former being usually the case.

The various peaks of current obtained during anodic stripping of organic compounds are often interpreted in terms of various species formed on the surface during the adsorption process which takes place at a lower potential. This is a prime example of a case in which the measuring technique may influence the system and cause major errors in the interpretation of results.

The anodic oxidation of a hydrocarbon molecule on the surface involves several steps, giving rise to intermediates associated with one or more adsorption pseudocapacitance peaks. The occurrence of several peaks is indicative of the existence of several different species on the surface during the anodic sweep. This in itself, however, does not constitute sufficient proof that the same species existed on the surface at the potential at which adsorption was taking place, before the sweep was started.

S. Gilman: The suggestion of similar adlayers in the adsorption of ethylene and acetylene is based on three types of evidence:

1. The traces obtained when the adlayer is "stripped" by means of a linear anodic sweep (Fig. SG3) are almost identical for the two adsorbates when comparison is made at equal surface coverage.

2. The number of hydrogen sites obscured per mole-

[5] L. W. Niedrach, *This Journal*, 111, 1309 (1964).

cule adsorbed is almost the same for the two adsorbates.[6]

3. When ethylene is adsorbed at 0.4v (30°C) under conditions of diffusion control, an anodic current contribution is observed.[6] This current corresponds approximately to that calculated for abstraction of two hydrogen atoms per molecule adsorbed. Because adsorption is diffusion-controlled, it is not possible that this current corresponds to partial or complete oxidation of additional nonadsorbed molecules, but this is possible in the study of ethane, in ref. (4). Since the presumed hydrogen abstraction charge for ethylene is only 1/6 the total charge for complete conversion of the adlayer to CO_2 and H_2O, it may easily be overlooked through compensation [*e.g.*, by O_2 reduction, as may have been the case in ref. (4)] or through slow hydrogenation of additional ethylene ("self-hydrogenation"). The latter possibility is suggested by the observation that the open-circuit potential goes through a minimum in the lengthy equilibrations studied by Niedrach.[5]

While the evidence suggests that acetylenic structures are present in the adlayers of ethane, ethylene, and acetylene, the evidence also suggests that the adlayers at "steady state" are by no means identical. The ethane adlayer contains additional species (type I) which cannot be removed by hydrogenation.[7] The steady-state coverages for ethylene and acetylene are significantly different[8] presumably because of the different steric requirements of the two different parent molecules. Hence it would be anticipated that the steady-state rates of oxidation of the three different adsorbates would differ, as found in footnotes 1 and 3.

The question of whether ethylene is associatively or dissociatively adsorbed in the absence of electrolyte has been a controversial subject for over thirty years.[9] The results are probably sensitive to the experimental conditions.[10] In view of the complexity of the problem area, Dr. Gileadi's attempt to predict the structure of the adlayer from the electronic structure of the parent molecule is therefore probably an oversimplification.

I agree with Dr. Gileadi's argument that the appearance of "waves" during a linear anodic sweep is not conclusive evidence for the existence of structurally different adspecies before the application of the sweep. It is for this reason that I do not rely on such evidence in my own work. In Fig. SG2 and SG5, for instance, the distinction between type I and type II species is made on the basis of whether the material may be desorbed (presumably through hydrogenation) at low potentials (a chemical differentiation). It happens that the chemically differentiated species also seem to be represented by two waves (with considerable overlap) in this particular case.

E. Gileadi: We find that the adsorption of ethylene and benzene on platinized Pt in 1*N* H_2SO_4 is reversible with respect to a change of potential in the range of 0.1-0.7v re. RHE. This observation in fact serves as our main criterion for reversibility of the adsorption process in these systems and makes the study of adsorption isotherms here meaningful.

S. Gilman: In the experiments of Dr. Gileadi and coworkers, only the surface concentration of radioactive carbon is determined. The method is not very sensitive (precise) and provides no information on the structure of the adlayer. Voltammetric measurements reveal[8] that the ethylene adlayer changes in structure at potentials above *ca.* 0.5v (probably corresponding to increasing dehydrogenation) and that this results in a dependence of steady-state surface coverage on the path taken to reach the potential of interest. It seems possible that Dr. Gileadi's isotherms do not have the usual thermodynamic significance (a balance between reversible adsorption and desorption) but represent a balance between rates of adsorption and hydrogenation (at low potentials) or between rates of adsorption and oxidation to CO_2 and H_2O (at high potentials).

II. Structure and Composition of Organic Adsorption Layers on Pt Electrodes—Relation to Reaction Kinetics

S. B. Brummer

Tyco Laboratories, Inc., Waltham, Massachusetts

The study of organic adsorption on Pt electrodes has been stimulated recently by interest in the mechanism of the reactions at the anode in fuel cells. Work from our own laboratory has been concerned with the HCOOH reaction (1-4), which one might hope to be a simple model system, and with a more complex reaction, the oxidative adsorption of C_3H_8 (5, 6). The aim of these continuing studies is to investigate the nature of the adsorbate and to relate the findings to the overall reaction kinetics of the parent compound.

The measurement of θ on solid electrodes is a difficult experimental problem. The capacity method, which has been so useful for the Hg-solution interface, is inappropriate and one has to adopt other procedures. An obviously appealing method, because of its directness, is the radioactive tracer technique (7, 8) where the amount of adsorbed fuel is "counted" without any apparent uncertainty. The disadvantage of this technique is the long time scale required for the counting and the necessity to use very rough electrodes to achieve sufficient sensitivity.

Another fairly direct method which has been widely used to estimate θ is anodic stripping. This was originally done after removing the electrode from the solution of the adsorbate (9). This procedure has the advantage of not having complications due to charge from readsorption during the stripping transient. Also, because the stripping may be done very slowly, no correction for contemporaneous electrode oxidation is necessary. The disadvantages are the cumbersomeness of the technique and the likelihood of removing loosely adsorbed material. *In situ* anodic stripping is then to be preferred, particularly where the adsorption process is complex and the adsorbate may comprise more than one material. This procedure has been used extensively by Breiter (10), Gilman (11), and Giner (12) as well as in our own work. The usual disadvantage of the procedure is the large correction which must be made for electrode oxidation. The main advantage is the high versatility of the method for complex adsorbate analysis. Within certain limits, the method may be thought of as "direct."

Another method, which is particularly useful for Pt electrodes but not so direct, is H-atom deposition. Here, adsorption is permitted to occur, and a cathodic charging curve (galvanostatic or linear potential sweep) is applied to estimate the fraction of the electrode which is available for H-atom deposition. This fraction, $\theta_H{}^c$, is assumed to be equal to that part of the electrode not occupied by the organic adsorbate ($\theta_H{}^c = 1 - \theta_{org}$). This assumes that $\theta_H{}^c$ is less than unity only for steric reasons (*i.e.*, site blockage) and

that no desorption occurs during the $\theta_H{}^c$ measurement. The latter is easy to verify experimentally; the former is less certain for it is well known that the heat of adsorption of H atoms depends on their coverage (13). Thus different interactions between H atoms and the organic adsorbate than between H atoms might lead to inclusion of a nonsteric effect on the measured value of $\theta_H{}^c$. Opposing such an effect is the observation that for finite θ_{org}, the hydrogen overpotential is higher than for a clean surface so that the possible effects of any H-organic interactions would be opposed by the more cathodic potential of the electrode. Recently (14), we have investigated this problem by comparing θ_{org} obtained above with those obtained using anodic hydrogen charging. Here, after allowing adsorption (at E_{ads}), the potential is lowered to a potential positive of the reversible hydrogen potential (E_1) so as to deposit H atoms onto part of the surface. These are then stripped to yield $\theta_H{}^{anodic}$, which is the ratio of the charge found for H_{ads} compared to that found at the same potential (E_1) on a clean electrode. Since the H atom concentration on a clean electrode decreases with increasing potential, we can adjust the amount of hydrogen on the electrode for a given θ_{org} by adjusting the potential E_1. We find a good 1:1 correlation between $\theta_H{}^{anodic}$ and $\theta_H{}^c$ over the whole range from 0-1 in θ. Since nonsteric effects, if they were significant, would show up strongly in the $\theta_H{}^{anodic}$ data, this is good evidence that the main effect in the cathodic measurement is steric.

In any complex system, it is strongly advised to use more than one of the above methods. Thus for the hydrocarbon case (5, 6). we found that the average oxidation state of the adsorbate varies with time and potential of adsorption. Any conclusions about the kinetics and the steady-state extent of adsorption, drawn solely from anodic charging data would, then, be in error. Conclusions drawn from other methods would not be affected but, by combining anodic stripping with one of the other methods much more detailed information about the adsorbate and its participation in the electrode reaction can be obtained.

Identity of adsorbed species.—The major point to be made here is that very often the adsorbed species do not have the same chemical composition as the original adsorbate. This view has attained wide acceptance for a number of fuels. Thus for HCOOH (1, 2, 15), methanol (15, 16), and for saturated hydrocarbons (5, 6, 17, 18) there can be little doubt that the adsorbate is either a reaction-intermediate or the product of a side-reaction. In addition, in some instances, the situation is more complex in that the adsorbate is not a single species, but consists of a number of materials of varying oxidation state, perhaps none of which is the original fuel.

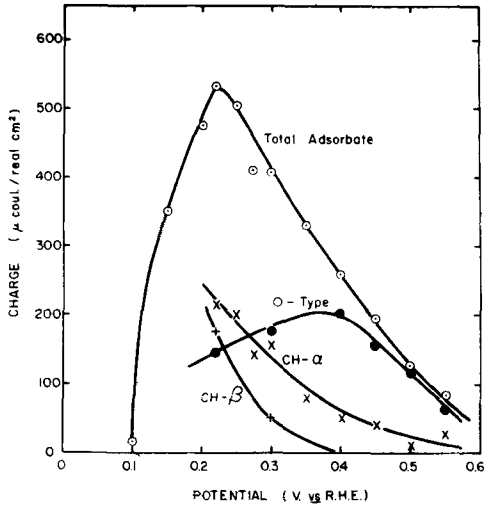

Fig. SB1. Adsorption of C_3H_8 on smooth Pt from 13M H_3PO_4 solution at 130°C.

An example is given in Fig. SB1 (14) for the adsorption of C_3H_8 on Pt from H_3PO_4 solutions at 130°C. The method of examining the structure of the adsorbate and of discriminating the different species was indicated in part earlier (6) and will be described more fully later (14). We see that while the total adsorbate concentration appears to show a fairly simple dependence on potential (Q *vs.* E is almost linear above 0.2v suggesting a Temkin isotherm) the adsorbate actually consists of at least three species. We divide these species into two broad classes, the O-type and the CH-type. The basis of this distinction is whether we judge that most of the C-H bonds in the original fuel have been replaced by C-O bonds (14). The oxidation state of these adsorbed species is very different. Thus the O-type has an $[e]$ value[1] of 1.3 ± 0.05 whereas, for example, the CH-β type releases ~4 electrons per site when oxidized. Because of these variations in oxidation state, Fig. SB1 is not a true representation of the relative amounts of the various species. Thus for example, at 0.3v, $\theta_o \simeq 0.65$, $\theta_{CH\text{-}\beta} \simeq 0.1$ and $\theta_{CH\text{-}\alpha} \simeq 0.25$; total coverage ~1. At 0.2v, total coverage is also about unity, but there is a larger amount of charge to oxidize the adsorbate because of the larger contribution of CH-species.

The important conclusion that we can draw from the above data is that measuring "isotherms" for the adsorption of the parent fuel is not likely to be very helpful in analyzing the kinetics of the reactions of the fuel.

Relation of adsorbed species to over-all reaction.—Earlier, we suggested that $HCOOH_{ads}$ is not HCOOH itself. An important reason for this suggestion was the observation that the oxidation current decreases as θ increases (1). Similarly, Giner (15, 18) has reported a decline in oxidation rate with time for a number of organic oxidations which he related to the accumulation of an adsorbed species. The frequently observed variations of oxidation rate with time seem to be the result of the accumulation of relatively refractory adsorbed species. Giner (15, 18) has suggested that this species is similar to "reduced CO_2" (12). The exact relationship of this species to the general mechanism of the oxidation of organic species must vary from compound-to-compound but its frequent presence is very suggestive. Two basically different mechanisms involving reduced CO_2 can be postulated, *e.g.*

$$\text{Fuel} \xrightarrow[\text{steps}]{\text{sequence of}} \text{reduced } CO_2 \xrightarrow{\text{slow}} CO_2 \quad [1]$$

$$\left.\begin{array}{l} \text{Fuel} \longrightarrow CO_2 \\ \downarrow \text{ "reduced } CO_2\text{"} \xrightarrow{\text{slow}} CO_2 \end{array}\right\} \quad [2]$$

In [2], the main reaction proceeds on that part of the surface not occupied by reduced CO_2; in [1], the oxidation of reduced CO_2 is the rate-limiting step. For HCOOH, at low E, [2] is probably applicable. For C_3H_8, [1] appears to be the mechanism [here we tentatively equate O-type material with reduced CO_2; more information on this point will be published later (14)].

The important conclusions we can draw from the above data are:

1. Simple current-potential curves should be interpreted with extreme caution and only in the context of adsorption data.
2. Application of isotherm theory is only of marginal relevance in these complex systems.
3. We must use experimental methods which can can give us information on the chemical composition of the adsorbates and on their relation to the original fuel and to the over-all reaction.

[1] $[e]$ is the number of electrons released per covered site when the adsorbate is completely oxidized to CO_2.

In these ways, we can expect to continue the significant improvement in our understanding of these complex reactions.

The author is pleased to acknowledge support by the U. S. Army Engineer Research and Development Laboratories, Fort Belvoir, Va.

Discussion

M. W. Breiter: The conclusion that intermediates and not formic acid molecules are adsorbed on platinum in acidic solutions at room temperature appears very doubtful on the basis of my recent studies[1] in which small amounts of formic acid were quickly added to 1*M* $HClO_4$ at 0.2v under conditions such that only a small amount of intermediates can be formed anodically. At concentrations C $\geq$ 0.01*M* HCOOH the adsorbed amounts of formic acid agreed well with the corresponding amounts of previous measurements made under repetitive cycling between 0.05v and about 1.5v at 0.03 v/sec. Decomposition of formic acid molecules into intermediates and hydrogen atoms can be ruled out at 30°C on smooth platinum on the basis of the small rates observed by Giner[2] and Gottlieb[3] at room temperature. The question of the adsorbed intermediate is open in the more complex case of methanol. Our techniques do not allow us to distinguish between adsorbed species of a different nature and the same species adsorbed with different heats of adsorption on the heterogeneous platinum surfaces. The conclusions on the nature of the adsorbed species are mainly based on the interpretation of kinetic data, not on direct evidence.

S. B. Brummer: The experiment of Breiter[4] showed that at 0.2v, $HCOOH_{ads}$ could not simply be an intermediate of the oxidation reaction since too little charge apparently flowed after he introduced HCOOH into the solution. One possible alternative to his conclusion that $HCOOH_{ads}$ is HCOOH itself is the presence of reduction reactions to give an adsorbed species which is more reduced than HCOOH itself. Then, $i_{obs} = (i_a - i_c)$, where i_a is the current for oxidation (to CO_2) of HCOOH and i_c is the current for reduction of HCOOH to an adsorbed product. Then

$$Q_{obs} = \int (i_a - i_c)\, dt \qquad [1]$$

Such a process cannot be excluded on the basis of Breiter's data. Another possibility to obtain an adsorbed product which is not HCOOH itself is from the chemical decomposition of HCOOH on the electrode. Breiter rules this out on the basis of the HCOOH decomposition rate as reported by Gottlieb.[5] This rate, he says, is too slow, which indeed it is. However, this decomposition rate refers to a "poisoned" catalyst, *i.e.*, the Pt already has a full layer (about 0.75 of a monolayer[6]) of $HCOOH_{ads}$. The current for HCOOH oxidation decreases with increase in θ[6,4] and it seems extremely probable that the chemical decomposition rate is also much faster on a clean electrode, as used by Breiter.[7] Thus, the evidence is not conclusive.

The reasons for our view that $HCOOH_{ads}$ is not HCOOH are to some extent kinetic in origin. Thus i_a decreases with increase in θ.[6] Additional evidence on this point arises from the work of Giner[8,9] and also from our measurement of the charge to oxidize $HCOOH_{ads}$. We found[10] 285 μC/real cm^2, in good agreement with Breiter's own value.[11] This is too much to correspond to a close-packed monolayer of HCOOH (230 μC/real cm^2) and yet this material only occupies ~75% of the available surface. Incidentally, this species cannot be $COOH_{ads}$, which is sometimes suggested, since a compact monolayer of this material only provides 115 μC/real cm^2.

E. Gileadi: I would like to make two remarks to Dr. Brummer's presentation. First, I cannot agree with Dr. Brummer's point of view just made in his talk that the study of adsorption isotherms is useless. It is perhaps the most important single measurement one can make in adsorption studies and can lead to very valuable information regarding the state of the adsorbed species on the surface, its surface bond energy, and the type and magnitude of lateral interactions on the surface. In addition this kind of measurements can lead to better understanding of the anodic oxidation process involved, as has been demonstrated in the case of ethylene[12,13] and benzene.[14,15] It is clear, on the other hand, that adsorption isotherms can only be considered when the adsorption process is reversible. This was shown to be the case for ethylene[13] and benzene[15] which were studied in our laboratory. For

the system studies by Dr. Brummer, rapid surface reactions clearly occur and adsorption equilibrium is not maintained. An attempt to obtain adsorption isotherms for such a system would obviously be futile.

My second point refers to the need to study adsorption always by several methods. Here I am in complete agreement with Dr. Brummer. A comparative study of adsorption of several compounds by the radiotracer method and by two electrochemical methods is under way in our laboratory, and we hope to be able to report these results in the near future.

S. B. Brummer: I understand Dr. Gileadi's concern to elaborate the adsorption isotherm. My main point is that where the adsorbate is not chemically identical with the adsorbing fuel or where there is more than one adsorbate, this is not a particularly useful thing to do. In this instance, the main concern must be to find out the composition of the adsorbates, their distribution-with-potential and their relation to the overall reaction. This appears to be the approach which is most relevant to the study of the anodic reactions of organic fuels.

H. B. Urbach: I am in agreement with Dr. Brummer's observation in his talk that the adsorption isotherms of many molecules described in the literature have not taken into account the fact that a Faradaic current is generally present. This would indicate that the observed values of surface coverage represent a steady state rather than an equilibrium. I would like to propose the following quantitative relation (based on the assumption of a Langmuir isotherm) between the observed coverage, θ, the theoretical equilibrium value, θ_{eq}, and the current, i

$$\frac{\theta}{\theta_{eq}} = \left(1 - \frac{i}{i_L} - \frac{i}{i_A}\right)\left(1 - \theta_{eq}\frac{i}{i_L}\right)^{-1}$$

where i_L is the diffusion limited current and i_A is the adsorption limited current defined by

$$i_A = nFk_a a_o$$

where n is the number of electrons, F is the faraday, k_a is the adsorption rate and a_o is the bulk activity of the adsorbed species.

S. B. Brummer: The presence of faradaic current certainly does necessitate a correction to the concentration of the adsorbate at the electrode-solution interface. However, one must be cautious in the application of simple models to calculate the concentration of the electroactive species at the interface, since this frequently is not the original adsorbing material, but is the product of a (number of) irreversible surface reactions. In such a case, it would not be appropriate to derive a θ_{eq} from the observed θ and the faradaic current.

S. Schuldiner: An assumption is made that organic and H atom adsorption is additive to one monolayer. This does not take into account that both the adsorption and absorption of H atoms can be influenced by the presence of organic species.

S. B. Brummer: In analyzing the structure of the adsorbed species, we have made use of cathodic H-atom deposition and we have assumed that $\theta_{org} = 1 - \theta_H$. ($\theta_H$ is the fraction of H-atom deposition charge compared with an organic-free surface, and θ_{org} is defined as the fraction of the surface occupied by organic.) This procedure assumes:

(*a*) That the organic is not desorbed or reduced during the cathodic H-atom charging. Conditions can be chosen to ensure that these assumptions are true.

(*b*) That at finite θ_{org}, the only reason that θ_H is < 1 is because of site coverage by the organic. Thus we assume that the interaction energy (or whatever determines the fall of H-atom adsorption energy with increase in coverage) is similar in magnitude between H-organic as between H-H. This is of course not likely to be true in general. One factor which tends to help this to be more probable, *i.e.*, to ensure that all the surface not occupied by organic is charged with H-atoms during the charging process, is that in presence of organic the H_2-overvoltage is higher. This helps to deposit H-atoms on the organic-free surface, despite unfavorable energy considerations. In recent experiments, we have compared the values of θ_{org} obtained above with those obtained from anodic H-atom stripping. In the latter case, the effect of interactions would be more deleterious because the potential (say in the range $+0.03$ to $+0.1$v *vs.* R.H.E.) can be changed so as to alter the initial (organic-free) H-atom coverage considerably. We appear to get good ($< 10\%$) agreement for values of θ_{org} determined cathodically and those determined anodically from potentials where the H-atom coverage on a clean electrode is as low as 0.6 of a monolayer. This we regard as good evidence that in this case (C_3H_8 in H_3PO_4) the assumption of only steric hindrance is reasonable.

(*c*) The assumption that the surface of the Pt is just as much or as little receptive to H-adsorption is not necessary. We only assume that in the short time involved in the cathodic measurement the difference between the behaviors with or without the organic adsorbate is negligible. In experiments we have recently carried out with the adsorption of n-hexane, we find no difference whether or not we allowed the possibility of H-adsorption. Hence, in this case at least, this possibility does not have to be considered.

A. Reed and E. Yeager: We are attempting to use infrared attenuated total reflection methods to examine the adsorption of organic species from aqueous solutions on germanium. The intensity of the C-H stretching frequency ca. 2900 cm^{-1} is used as a measure of the amount of adsorption. Particular systems under study include the Tritons, octanol, and stearic acid. D_2O has been used as the solvent rather than H_2O since the O-H stretching frequency of ordinary water masks the C-H absorption band.

Several difficulties are involved in such studies. First is the difficulty of differentiating between optical absorption due to the adsorbed species and that due to species in the bulk solution. Another problem is the preparation of a clean, well-defined surface without destroying the optical quality of the germanium surface. Presently the method is limited by signal-to-noise ratio, but some improvement of this appears possible.

In the case of stearic acid, we have cast monolayer films on the germanium by a modified Langmuir-Blodgett technique. With the germanium plate in contact with solution containing negligible stearic acid, the monolayer spectrum is quite evident. Work is continuing in this area, and we hope to report data under controlled conditions in the near future.

Technical Notes

Effect of Polarization Field on Electroluminescence

S. Kawashima

Broadcasting Science Research Laboratories, Japan Broadcasting Corporation, Setagaya, Tokyo, Japan

Many investigations about brightness waves of electroluminescence (EL) have been published (1). Generally speaking, in the brightness waves produced by sinusoidal wave excitation, two emission peaks, primary and secondary, appear for each half-cycle of the applied voltage. Since their emission mechanisms are considered to be different (2), analyses of them are rather complicated.

On the other hand, in the case of excitation by using pulse voltage, emission peaks appear only at the rise and fall of the pulse voltage, and the secondary peak usually does not appear. Hence, analyses of the phenomena become rather easy. Nudelman and Matossi (3) observed the brightness waves of ZnS:Cu,Pb, separately, on blue and green emissions by using pulse voltage and analyzed the decay curve of the brightness waves. They concluded that the excitation process is due to inelastic collision of accelerated electrons with luminescence centers and that the green emission is due to the electronic transition via the conduction band, while the blue emission is due to the one within the luminescence centers. ,Briggs (4) observed the brightness waves of Zn(S, Se) phosphors, also separately on blue and red emissions, by the use of pulse voltage having pulse width of 2 to 40 μsec, and found that the voltage dependence of emission intensity can be expressed as $B = B_0 \exp(-C/V^{1/2})$ in the same way as in the case of sinusoidal voltage excitation. Tanaka (5) measured the brightness waves of ZnS:Cu, Pb phosphor by using a pulse voltage having very short rise and fall times. He found that the decay curve of the emission at the fall of pulse voltage follows bimolecular law and that the time constant of the decay curve increases with increase of temperature.

In the present work, build-up of brightness waves under excitation by pulse voltage superposed with d-c voltage were studied and compared with steady-state brightness waves.

Experimental Method
