The prints shown in Fig. 5 were obtained with specimens pretreated in various ways and heated to 500°C for 5 min in stationary air.

Annealed foil gave completely clear prints when unheated (print 5.1), but when heated, the prints frequently revealed a number of localized electronically conducting sites (print 5.2). Uniformly distributed electronic current, however, was not observed. With foil of highest purity we found no e.c. either with or without thermal oxidation.

When chemically polished foil was used, we obtained prints without e.c. if taken with the unheated foil (print 5.4). When the same foil was heated in air we obtained prints with little e.c. if the specimen was rinsed in water for a short time only (print 5.5) while rather high e.c. was observed after extended rinsing in cold or boiling water (print 5.6). When rinsed for short time only it was difficult to avoid drying marks which always became centers of high e.c. They account for the nonuniform pattern in print 5.5 Dipping in conc. HCl for 10 min after chemical polishing and a 10 sec HF dip led to clear prints without thermal oxidation (print 5.7), prints reflecting very little e.c. after short rinsing in water (print 5.8), and uniform e.c. after a 10 min rinse (print 5.9). Treatment of annealed

(print 5.3) or chemically polished (prints 5.10-5.12) foil in alkaline solutions produced an effect similar to treatment in HF whereas dipping in concentrated acids like HNO_3, H_2SO_4, H_3PO_4, etc., did not produce films with e.c. either with or without thermal oxidation.

Print 5.14 was obtained from a vacuum annealed specimen previously oxidized in phosphoric acid to 100v followed by a 5 min thermal treatment in air at 500°C. It shows a pattern of electronic conductivity which was not observed when an unheated specimen was tested (print 5.13). With chemically polished instead of annealed foil, considerably more localized e.c. was observed after heating (print 5.15).

The e.c. of crystalline anodic tantalum oxide was found to be too low for detection with our method when we took prints of various specimens which had been crystallized anodically for 1 hr at 90°C in 2% HNO_3 (12) and which showed a high density of crystalline areas. Some e.c. was found when scintillation associated with the formation of crystalline oxide had taken place.

Plastic deformation of tantalum sheet by bending.—Since plastic deformation is a consequence of all mechanical surface treatments, we had to consider its effect on the e.c. of oxide films formed on plastically deformed substrates.

Chemically polished sheet was bent up to 10 times at four different positions. One specimen was used for taking prints after bending, the other one after it was submitted to thermal oxidation in air at 500°C for 2 min. Figure 6 shows that along the bends a few localized marks indicating e.c. were found being both more numerous and intense after thermal oxidation. Vacuum annealed sheet showed few conducting sites, highly contaminated sheet showed more uniform e.c. along the bends.

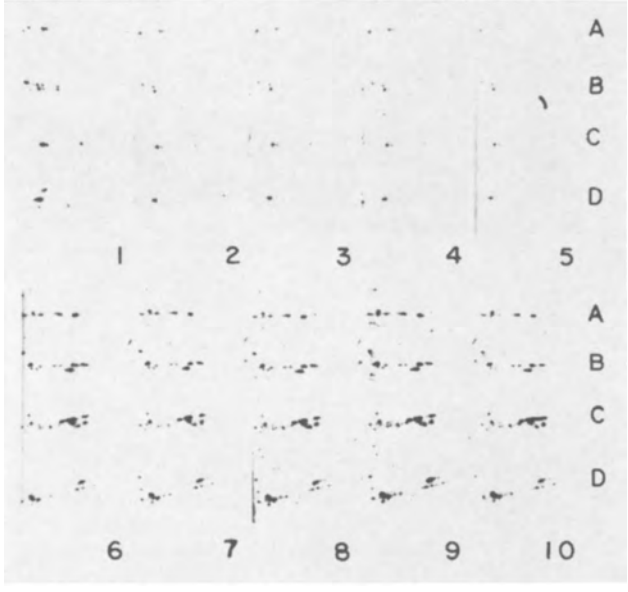

Fig. 6. Anodic prints of vacuum annealed Ta sheet deformed plastically by repeated bending at positions A-D. The second series shows prints of a specimen that was thermally oxidized in addition to bending. See Table VI.

Surface topography—roughness.—The surface topography of mechanically treated surfaces, their roughness, was held responsible for the electronic conductivity of oxide films on supposedly clean surfaces. Two mechanisms were proposed to explain the e.c. (1, 2, 7): (*i*) The field at sharp points and ridges was thought to be higher than the average giving rise to field emission effects which eventually would lead to breakdown; and (*ii*) oxide formation at asperities would produce highly stressed films which would crack and expose the bare metal. Electronic conduction would be due to a local field increase or due to changes in the oxide film as a consequence of local heating following high local currents at bare spots. Oxygen bubbles were thought to play a role in stabilizing active pores and microfissures.

Since it is difficult to produce roughness by other than mechanical means, and since all such attempts are likely to introduce side effects, we could not study rough surfaces *per se*. However, we prepared specimens with sharp edges by tearing thin foil and by electrochemical etching. The foil was 0.0005 in. thick and had very jagged edges after etching. The radii of curvature of such edges were a few microns after etching. Prints taken from such specimens never showed any trace of electronic current along the edges up to the sparking potential of the printing electrolyte. Even when some of the jags tore off while changing the printing medium the next print would still show no blackening at those sites. Surfaces with a high degree of surface roughness could also be produced by sintering tantalum powder to tantalum foil. Prints taken from such specimens did not reveal any electronic conductivity which, by its distribution, could have been attributed to roughness. The particle size was less than 10μ; sintering time and temperature were such that no significant change of the particle shape could have taken place during sintering.

Electronic conductivity of blasted tantalum surfaces.—Abrasion can lead to contamination of the surface layers of a specimen in various ways: by the transfer of impurities from the abrasive to the substrate and the embedding of abrasive particles. Also, impurities present in the substrate can become exposed, for example, when the abrasive removes the softer material while leaving the harder precipitates on the surface.

The blasting of tantalum with tantalum, alumina, and dolomite powder was found to produce similar surface conditions as far as the e.c. of anodic oxide films was concerned. The degree of surface damage depended on the relative hardness of substrate and abrasive and the intensity and duration of blasting. Dolomite powder was chosen because of the ease with which it could be dissolved in acids. Particles of abrasive which adhered to the surface did not give any e.c. as long as the abrasive was of high purity and itself an insulator. Scratches produced with tantalum on the same specimens were used as a standard for comparisons since contamination by the abrasive was least likely to have occurred in this case. Figure 7 shows dynamic prints obtained with blasted specimens. Prints 7.1-7.3 taken at constant current reveal how a pattern of electronically conducting sites developed. Initial specks in print 7.1 became somewhat fainter in the following two prints with many more appearing in the center portion of the blasted area. A closer comparison shows the continued presence of most of the specks initially present. Higher current densities brought forth more specks in print 7.4, but print 7.5 was practically identical with print 7.3 except for its intensity. The following series of prints was taken at a higher current density in voltage intervals of 20v.

The e.c. decreased rapidly once the first few volts of formation had been achieved at a high current density and continued to decrease more slowly above 20v. The

spots were made up of a large number of tiny specks which remained the same over most of the range of anodic oxidation covered in the prints. Only within the first 10v had there been a pronounced change in the relative intensity of the specks. The specks persisted over a sufficiently large voltage range to exclude their being transients. Prints 7.5 and 7.10 may serve as an illustration of the decrease in the e.c. from the initial stages of film formation to its later stages. The total charge that had been passed in print 7.10 was 72 mcb/cm^2 compared to only 0.75 mcb/cm^2 in print 7.5 even though the electronic charge passed was several times larger in the latter print.

The second half of Fig. 7 shows a series of prints taken from a similarly pretreated specimen that was heated in air at 500°C for 2 min after the blasting. In this case, the e.c. started out very high in the first print and decreased rapidly in the following ones. This behavior was the opposite of what was found with the unheated specimen where the e.c. had shown an increase in a similar series of prints. The voltages reached in comparable prints of the unheated and heated samples were slightly higher in the case of the latter since a thermal oxide film was present. The following series of prints in 20v intervals revealed very strong e.c. in the interval to 20v. Apart from an intensive blackening of the blasted area a pattern was also found around it. The e.c. decreased slightly in the higher formation voltage intervals, but remained several times higher than with the unheated specimen. The blasted area itself was so intensely blackened that no details could be observed except when a short time print was taken (not shown) that revealed localized specks indicating discrete sources of e.c.

Additional information concerning the origin of the e.c. of blasted areas was obtained when the oxide formed on blasted specimens during printing was removed with HF before another series of prints was taken. Results are shown in Fig. 8. Removal of the oxide and printing were repeated three times. Thermal oxidation after oxide removal was applied in the last

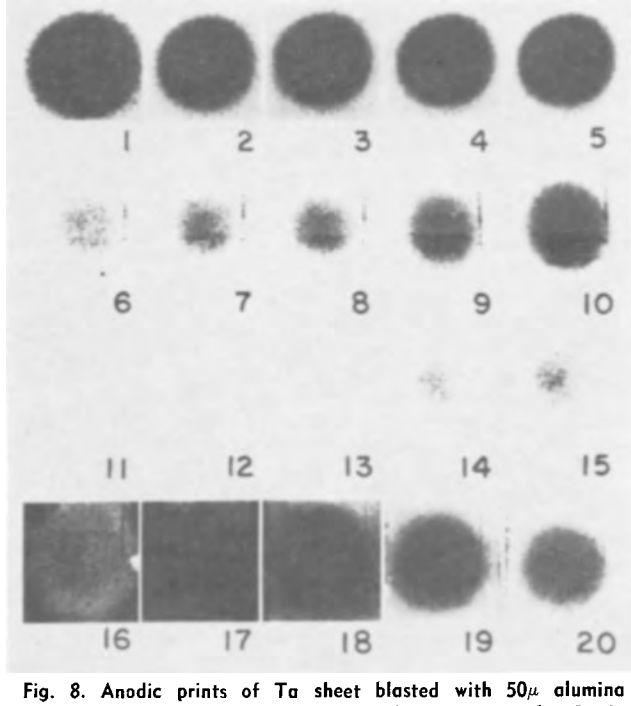

Fig. 8. Anodic prints of Ta sheet blasted with 50μ alumina powder. First row: as after blasting; second row: repeat, after 1-min dip in conc. HF; third row: repeat, after 1-min dip in conc. HF; fourth row: repeat, after 1-min dip in conc HF and thermal oxidation at 500°C in air for 2 min. See Table VIII.

series of prints (prints 8.16-8.20); the specimen had been blasted with alumina powder.

The first series of prints (prints 8.1-8.5), similar to parts of Fig. 7, again showed the high initial e.c. followed by a sharp decrease after the first formation interval and a very slight increase on further oxidation. After removal of the initial oxide film by dipping in concentrated HF a second series of prints (prints 8.6-8.10) showed an e.c. gradually increasing with an increase in the formation voltage. The pattern of the e.c., being at first highly nonuniform, became more and more uniform while the size of the print approached the size of the total blasted area.

The oxide was dissolved in conc. HF after oxidation to 50v and a third series of prints (prints 7.11-7.15) was taken. The intensity of the e.c., at a much reduced level compared to the last series, shows the same tendency to increase gradually with an increase in formation voltage. The oxide was again dissolved in conc. HF after formation to 50v. The specimen was then rinsed in triple-distilled water, dried in an air stream, and heated at 500°C for 5 min. Prints 7.16-7.20 were taken after this treatment. The blasted area initially showed lower e.c. than the surrounding area, but with increasing formation voltage the blasted area showed an increasing e.c., whereas the surroundings became less conducting.

Discussion

The effects of bulk contamination on the e.c. of anodic oxide films on Ta were demonstrated by taking anodic prints of Ta alloyed with Fe, Ni, and C. The effects of surface contamination were shown for Ta that was scratched with Ta, Ni, Fe, and C. With alloys of Ni and Fe the e.c. was either strong from the beginning with a tendency to increase further, as indicated by the first series of prints obtained with Fe, or it started out low and increased gradually with progressing film growth until it reached very high values as in the case of Ni and with Fe after HF treatment. The e.c. was affected by chemical treatments of the oxidized specimen in the case of the Ta-Ni alloy where aqua regia, for example, removed the cause for e.c., at least temporarily. The e.c. was not noticeably affected by chemical treatments of the oxide covered specimen in the case of Fe and C alloys as long as fluorides and hydrofluoric acid were absent. After prolonged HF treatment of the Ta-Fe alloy, which dissolved Fe rich portions of the alloy, oxides were formed on anodic oxidation exhibiting e.c. that was removed by conc. HCl.

It appears that in the case of Ta-Ni alloys a Ni rich oxide at the oxide-electrolyte interface was responsible for the e.c. The e.c. of the oxide film on the Fe-Ta alloy must either be due to an oxide film which in itself is highly doped with Fe, or a highly doped surface film that still shows the chemical reactivity of Ta_2O_5 rather than of any of the iron oxides. In any case, the e.c. was not affected in the same way it was in the case of the Ta-Ni alloy.

Without discussing in detail the possible mechanism of the anodic oxidation of tantalum alloys we shall briefly consider some aspects that may help to understand the characteristics of the e.c. of alloy oxides. Assuming a thin initial oxide layer consisting mainly of tantalum oxide, we are likely to have a competition between tantalum and foreign ions in regard to their transport through the already existing oxide film under high field conditions. In case the foreign ions migrate at a higher rate than the tantalum ions they will accumulate at the oxide-electrolyte interface unless they dissolve in the electrolyte. Depending on the *p*H of the solution and the particular anions present, a layer will be formed on the tantalum oxide, this layer being either insulating or electronically conducting, or porous and permeable to the electrolyte. In case the migration rate of the foreign ions is less than that of Ta ions, or if the transport number for the cations is less than one, intermediate situations may be found where oxide layers rich in foreign ions are formed inside the oxide film or at the metal-oxide interface.

The valency of the ions as they arrive at the oxide/electrolyte interface will depend on the nature of the ions and their environment. In the case of Fe or Ni the valency could be two, three, or even higher. These high valency ions may then react with the electrolyte and be reduced by any redox system with a sufficiently negative redox potential. It is conceivable, therefore, that the redox indicator system that we used (iodide/iodine-starch) reacted with these ions, leading to a blackening of our prints which was not due to electronic conductivity of the film. However, the result of this reaction would be the same as with truly electronic charge transport.

In order to determine whether oxidation of iodide by higher valency ions could have contributed to our results to any appreciable degree, we used the printing technique with indicators for Fe^{2+}, Fe^{3+}, and Ni^{2+} ions, respectively. The sensitivity of these color reactions was about as high as for the iodine-starch reaction. The test indicators were $K_3Fe(CN)_6$ for Fe^{2+}, KSCN for Fe^{3+}, and dimethyl glyoxim for Ni^{2+}. In no case did we observe more than a trace of any of the low valency ions and no trace at all of the higher valency ions. These tests were conducted under conditions where very strong coloration of the iodide-starch prints would have been observed.

An additional test showed beyond doubt that no high valency ions were formed in a concentration that could have affected our results. Prints were taken as usual except that the printing electrolyte did not contain any potassium iodide. The tantalum alloy to be tested was anodized through at least 10v (it would have given a very strong blackening of the prints with iodide). Since no iodide was present in this test, the prints were absolutely clear. If any higher valency ions had been formed, they should have reacted immediately with a drop of potassium iodide solution brought onto this print. Neither with Ta-Fe nor with Ta-Ni alloys did we observe any positive reaction. This showed that the blackening of our prints was indeed a result of the electronic conductivity of the anodic oxide film. It also showed that practically no corrosion of the Fe and Ni was taking place during printing since even low valency ions could only be found in trace concentrations at the most.

The observation that with aqua regia we could remove something from the surface of oxides on Ta-Ni alloys which caused the prints to become black showed that a Ni containing compound was present at the oxide-electrolyte interface; however, this compound did not cause blackening of the printing medium without the passage of current. The over-all mechanism of electron transfer is not known, but it does not seem to go via a consecutive homogeneous redox reaction, at least with Fe and Ni alloys of Ta.

It is clear that further studies of the structure and composition of the mixed oxide films and their kinetics of growth are required before final conclusion can be drawn.

With carbon the behavior was very different. The e.c. started out high, decreased subsequently, and increased again on approaching voltages around 100v. Above 120v the anodic oxide film was destroyed by a process which led to excessive e.c. A behavior of this kind can be understood qualitatively by assuming that the original substrate surface contained both tantalum and carbon (in the form of tantalum carbide) and that the initially formed oxide film was electronically conducting due to the carbon. As more film was built up, the e.c. decreased since the new film consisted mainly if tantalum oxide, carbon having been left behind. This eventually led to the formation of a layer of carbon underneath the insulating oxide film, at the

irregularities of which the dielectric would break down at high fields.

Areas on the Ta sheet where carbon had reacted incompletely with the substrate showed strong activity which in some cases did not exhibit the same exponential current-field characteristics that we observed with most other defects (13). The resistance of these areas appeared to be ohmic with the current being limited by diffusion in the electrolyte, or interrupted by gas evolution. A similar situation arose when tantalum was scratched and contaminated with carbon. Direct contact between sufficiently large areas of metal and carbon was believed to have prevented the growth of tantalum oxide thus maintaining active areas on the substrate. But in most cases of surface contamination the anodic oxide appeared to have grown underneath, above, and around the impurities thereby establishing the characteristics typical for most defects in anodic oxide films.

The results obtained with Ta specimens that were pretreated in various ways and then oxidized thermally (500°C in air, for 5 min) are summarized below. Vacuum annealed Ta foil was used as the standard for comparisons. As was shown in Fig. 5, no e.c. was observed whenever prints were taken from foil that was annealed in vacuum or polished chemically, as long as the specimens were not oxidized thermally. Occasionally, chemically polished material would give rise to nonuniform e.c. which could be traced to gross impurities.

After thermal oxidation, vacuum annealed foil tended to show some nonuniform e.c. with a distribution typical for contamination. No uniform e.c. was found either after short oxidation at 500°C or after oxidation up to several hours at 2-400°C. Thermal oxide, either amorphous or crystalline, does not give rise to e.c. of the subsequently formed anodic oxide within the sensitivity of the printing method. Thermal oxidation brings out impurities, however, which would not have been apparent before. It can be used as a means to amplify their effect. Thermal oxidation in connection with anodic printing is an effective means to test the purity of tantalum foil.

Chemical treatment of vacuum annealed foil prior to thermal oxidation led to more or less uniform e.c. of the anodic oxide film if alkaline reagents were used. Mineral acids had only a minor effect. The effect of concentrated HF depended strongly on the duration of subsequent rinsing in water: very little e.c. was observed if the specimen was blown dry after dipping in Hf, without rinsing in water, while high e.c. was found after several minutes of rinsing in cold or hot triple-distilled water. Further rinsing did not change the intensity of the e.c. once it was established.

Chemically polished foil, that was given the usual 10-min rinse in conc. HF, behaved similarly to vacuum annealed foil with HF treatment. Besides more or less uniform effects of the chemical treatments, nonuniform e.c., probably due to impurities, was more frequently observed with chemically polished material.

Uniformity of the e.c. could not be achieved when chemical treatments were used. It was difficult to avoid drying marks, especially after very short rinsing times, even though triple-distilled water was used. Drying marks, fingerprints, etc., always led to e.c. after thermal oxidation. But even if the preparation and handling of the specimens was done with great circumspection we obtained a considerable degree of nonuniformity. Extended rinsing in water after chemical treatments usually gave the most uniformly distributed e.c. The conditions characteristic of vacuum annealed foil were most closely approached by washing chemically polished foil in conc. HCl and short rinsing in water. Practically no uniform e.c. was observed except for the almost unavoidable drying marks.

These observations are tentatively explained in the following way. Tantalum oxides formed by thermal oxidation are insulating and do not cause subsequently formed anodic oxide films to become electronically conducting. If, however, a tantalum hydroxide film is present initially, thermal oxide may be formed which exhibits a higher e.c. due to the hydroxyl ions replacing oxygen ions, transforming the tantalum oxide into a highly conductive n-type semiconductor. A similar reaction would be expected to take place with fluoride; however, it seems likely that tantalum fluorides, being rather volatile, may be removed during the thermal oxidation. This would explain why HF treated specimens showed e.c. only after washing in water for several minutes or after short treatment in conc. KOH.

It is not clear why thermal oxidation should be required to produce these effects. Apparently, the hydroxyl ions, if responsible for the electronic conductivity, are not incorporated in sufficiently high concentration as would be the case if a thin pre-existing surface film with high anion concentration was being oxidized thermally.

If specimens anodized in dilute phosphoric acid were heated in air after the same chemical pretreatments, similar effects were observed. By comparing vacuum annealed and chemically polished specimens, more localized defects were observed in the latter case. This again suggested the printing method combined with thermal oxidation as a means to evaluate the effectiveness of purification techniques and the quality of Ta foil.

Plastic deformation (bending) of Ta sheet did not produce e.c. attributable to this treatment. Usually a few localized centers with high e.c. were found, but they were probably caused by impurities which became exposed due to slip within grains and the displacement of neighboring grains relative to one another. Thermal oxidation after bending produced increased e.c. which again was localized in a limited number of sites. It seems most likely that impurities became exposed at the surface by the combined action of bending and thermal oxidation. Since the sheet was bent back and forth ten or more times, plastic deformation was so extensive that a uniform effect along the bends should have been seen if the strain associated with plastic deformation had an effect on the e.c. at all. This result is interesting in that it reveals a strong secondary effect of a particular treatment that was induced by the primary effect of this treatment; the primary effect was inoperative in producing e.c. directly.

The experiments with foil having torn and highly jagged edges produced by electrochemical etching and of foil with powder sintered onto it did not give any indication of e.c. due to surface geometry. Likewise, the reformation of cracked anodic oxide films at high local current densities gave no indication of any electronic current due to excessively high local fields.

These tests cannot be considered a sufficient proof that the geometry of the substrate has no effect at all on the e.c., but they suggest that it is so.

In discussions of the e.c. of "rough" surfaces in the literature (1, 2, 6, 7) it has been maintained, after other possible causes were thought to have been excluded, that the geometry alone could be responsible for electronically conducting sites on the surface. Several mechanisms by which this could happen were suggested. They were all based on the assumption that for one reason or another the field strength was increased locally with the consequence of electronic current due to field emission. This current could be the precursor of local breakdown which in turn might lead to local heating, destruction of the dielectric, and crystallization.

These mechanisms require that an increase in the field strength lead to an exponential increase in the electronic conductivity. While the field strengths encountered in these thin film dielectrics under the test conditions are such that field emission may occur,

we must take into account the ionic conductivity as a stabilizing factor for the field strength. If the e.c. was due to high fields only, then the electronic current should have been transitional since the field would have caused the ionic current to rise as well and this would have led to film repair and a corresponding drop in the local field towards average values. Therefore, if the e.c. was caused by cracking, as suggested by Young (1, 2), then we should see changing patterns on the prints. According to Young, the cracks should also become more numerous with increasing film thickness. Neither phenomenon was observed by us. On the contrary, the conductive sites were found to be active over rather large formation intervals starting at low voltages with their intensity staying constant or even decreasing with increasing film thickness. No increase in the number of specks or a radical change in pattern were observed with mechanically treated specimens towards higher formation voltages once the initial maximum in the e.c. in the first 10v interval was overcome.

Sudden, high, local currents, either ionic or electronic, could have damaged the oxide film through local heating either by causing the film to crystallize, or at least to nucleate crystalline oxide. Again, these changes would most likely have resulted in ephemeral bursts of electronic current since at least partial healing of the damage would have followed any catastrophic event. In addition, it had been found that the e.c. of thermal and anodic crystalline oxides was below the sensitivity of the printing method. In no case did we find electronically conducting defects with an initial burst and a trail of disappearing electronic current which we would expect in all of these cases.

Vermilyea (7) found roughness to be one of the causes for flaws which in his model took the form of a thin oxide film separated from the substrate by an air gap. No direct reference was made to their e.c.; it was even thought that they were passive electrically contributing to the capacity only. However, in an earlier paper (6) Vermilyea had found gassing to take place when rough surfaces were anodized. The question arose whether the flaws were responsible for the e.c. which should have been distributed rather uniformly on a macroscale since the number of flaws had been found to be very high in scratches and nowhere lower than $10^4/cm^2$ on the best smooth specimens.

Vermilyea's flaws seemed to have appeared under a multitude of conditions. Our studies showed the most distinct flaws to be caused by thermal crystalline oxide and tantalum carbide precipitates. The e.c. of individual flaws was below the sensitivity of our method, but even very high concentrations of flaws caused by thermal oxide did not give an imprint. Higher carbide concentrations on the other hand gave prints as the ones shown in Fig. 3. Mechanically treated specimens developed a varying number of flaws depending not only on the kind of abrasive used, but even more on the substrate material and its and the abrasive's purity.

The pattern of e.c. which we observed within blasted areas and along scratches indicated that the sources of e.c. could not be distributed uniformly on a macroscopic scale as would have been expected if the flaws had been responsible for the observed e.c. At least the predominant sources of electronic current were few compared with the number of flaws or even the number of blasting marks. Also, we found very few electronically conducting sites along tantalum scratches on tantalum. This led us to conclude that the e.c. in mechanically treated areas of tantalum could not be related to the flaws that were observed by Vermilyea, and, in some cases, by us.

If we consider tantalum scratches on carefully purified tantalum as the closest approach to a rough surface, eliminating at least contamination, we have to explain the observation of e.c. in the initial print, the absence of e.c. in the range from 10 through 120v and the appearance of uniform but very low e.c. above 120v. In case the specimen was thermally oxidized after scratching the same general picture was observed with the addition of suddenly appearing higher e.c. above 140v. The initial e.c. was nonuniformly distributed along the scratch and the number of conducting sites correlated well with the number of "slivers" observed along the scratch. In this case, geometry could have played a role as a cause for e.c. However, the e.c. was observed only in the initial print and was totally absent in the following ones up to approximately 120v.

The uniform e.c. observed above this voltage is difficult to explain: The geometry would cause nonuniform e.c. while thermal oxide has been shown not to cause e.c. under these conditions. Whether strain could account for it is uncertain. The sudden appearance of e.c. above 140v in scratches that were thermally oxidized as well appear to have been caused by spontaneous crystallization accompanied by a disruption of the amorphous oxide film as observed when scintillation occurred. In the case of the thermally oxidized specimen a connection of the faint uniform e.c. with flaws is likely since thermal oxidation of plastically deformed tantalum led to a very high density of flaws and anodic crystals. However, in the case of the specimen which was scratched only, no flaws were observed which could have accounted for the faint uniform e.c.

The interpretation of the prints from blasted specimens will be based on the results obtained for the individual factors contributing to the effects of mechanical surface treatments. Abrasive particles, if by themselves insulators, did not give rise to e.c. when sprinkled on tantalum foil. Conducting powder, such as carbon, by comparison yielded excessively high e.c. It is very unlikely, therefore, that abrasive particles even if partially or completely embedded in the substrate were responsible for the effects found with blasted surfaces. By comparing series two, three, and four of Fig. 8, we found that a considerable number of individual marks in the second series could also be found in the fourth (after thermal oxidation), whereas practically no marks were found in the third series. Particles of abrasive cannot account for this behavior since they should produce marks in all three series: an embedded particle either is there, then it gives rise to e.c., or it is removed and no further treatment like thermal oxidation will bring it back.

Roughness was shown to have no or only a temporary effect: slivers along Ta scratches were found to be centers of initial e.c. which decreased rapidly on film formation. The initially very high e.c. observed in all blasting experiments (without thermal oxidation) may in part be explained by this. However, other factors, especially contamination, may have contributed substantially as well.

After the first oxide layer was removed the e.c. no longer showed the conductivity maximum in the initial printing interval. This could be explained by a decrease in the initial roughness, but also by the removal of surface impurities. The prints of the blasted areas after the removal of the initial oxide film (second series, Fig. 8) increased in size with increasing formation voltage. If roughness were responsible for the e.c. it should have been uniform over the whole area. Stress concentrations may be eliminated as a source of e.c. by virtue of the bending test results.

The strongest point in favor of impurities as the cause for the e.c. observed with blasted surfaces is the effect thermal oxidation has after repeated anodic oxidation and oxide removal. The intensity of the e.c. had become so low that it could no longer be detected with the printing technique. Thermal oxidation led to renewed strong e.c. in the blasted area, with some localized marks which had been present in previous series before deactivation. Thermal oxidation would

have removed the extreme roughness since sharp projections especially on plastically deformed surfaces oxidize more rapidly. The last series in Fig. 8 has to be seen in comparison with Fig. 5, since HF pretreatment usually led to e.c. in combination with thermal oxidation. It accounts for the e.c. surrounding the blasted area which for itself shows only considerably lower e.c., probably because the blasted area was oxidized thermally more readily than the rest. The HF effect decreased rapidly in successive prints in favor of a more pronounced effect in the blasted area.

Comparison of the results obtained with blasted surfaces and of surface and bulk contamination lead to the conclusion that the e.c. after blasting showed the characteristics of a surface scratched with contaminating material, i.e., surface contamination. The following series after surface cleaning showed the characteristics typical for bulk contamination.

Other factors discussed in this paper may contribute to the e.c. to some degree; however, their over-all contribution appears to be masked by the effect of impurities in the majority of cases.

The overwhelming contribution to the e.c. of mechanically treated areas came from a limited number of rather active sites which remained active over large formation voltage intervals. No conclusions can be drawn at this point about the structure of the electronically active sites and the conduction mechanism.

Quantitative measurements of the intensity of blackening of the prints by densitometric methods have been used to determine the field dependence of the electronic current in electronically conducting areas of tantalum oxide films. They will be the subject of a future publication.

Conclusions

1. The redox printing technique was used to study the electronic conductivity of anodic oxide films while they were being formed (dynamic behavior) and after formation under other suitable conditions.

2. The study of alloys of tantalum with nickel, iron, and carbon (bulk contamination) revealed characteristic differences in the dynamic behavior of the electronic conductivity during the formation of the oxide film. It was shown that for specific impurities the e.c. as reflected in the prints varied characteristically with increasing formation voltage.

3. Surface contamination produced by scratching with nickel, iron, and carbon was studied by comparing the e.c. of these scratches with scratches made with tantalum alone. With increasing formation voltage, a decrease in the intensity of the e.c. was observed with Ni and C compared with an increase in the case of bulk contamination.

4. Thermal oxidation led to an amplification of the effects of impurities. No e.c. was found to be associated with thermally or anodically formed crystalline oxide in the absence of impurities.

5. Plastic deformation (bending of sheet) led to e.c. which was irregularly distributed along the bends indicating that no direct correlation existed between the plastic deformation of tantalum and the e.c. The impurity content of the material was an important variable. The effect of bending was more pronounced the higher the impurity content. Thermal oxidation after bending led to an increased e.c., rather than to a greater uniformity of the e.c. along the bends.

6. Roughness as produced by extreme electrochemical etching, or by tearing of thin foil, or by sintering of powder onto foil gave no indication of e.c. due to these conditions.

7. The e.c. of mechanically treated surfaces was found to be due mainly to impurities, the contributions from other factors being not detectable. The dynamic behavior of the e.c. of blasted surfaces was similar to that of surfaces scratched with contaminating materials. After surface cleaning, the e.c. was similar to that of alloyed tantalum.

Phase Changes in Thin Reactively Sputtered Alumina Films

R. G. Frieser[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A study has been made of the preparation and properties of aluminum oxide films prepared by reactive sputtering. Deposition temperature, rate, oxygen pressure, etching characteristics in HF, and phase changes of the deposited films as a function of heat-treatment were investigated. Two phases of deposited alumina could be prepared; either an amorphous, HF soluble, or a polycrystalline form of γ-alumina, which was considerably more HF resistant. On the basis of the observed changes in HF solubility, refractive indices, and phase changes, a tentative model is proposed which could be pertinent to catalytic behavior of alumina powders.

While studying the properties of reactively sputtered oxides, thin (< 1000Å) aluminum oxide films were prepared which exhibited anomalous solubility behavior in HF. This paper describes the preparation and properties of these films and a tentative interpretation of the observed time-temperature dependence of the HF solubility of these films and a corresponding increase in their refractive index. The proposed model is based on the known phase transformations of alumina.

[1] Present address: Sprague Electric Company, North Adams, Massachusetts.

Experimental Procedures and Results

The deposition of the films was carried out in an oil-free vacuum system in order to reduce contamination from pump oil. To reduce contamination further, particularly during loading of the apparatus, the entire vacuum system was enclosed by a Whitfield-type hood. By recirculating and filtering the air in the enclosure, particulate matter of a size larger than 0.3μ was reduced to two particles in 3½ hr.

Using a combination of sorb- and ion-pumps, the pressure in the system was reduced to about 10^{-6} Torr prior to sputtering. During the deposition the system was operated as a dynamic system, keeping a constant pressure (1 to 5 x 10^{-4} Torr) in the sputtering chamber. This was accomplished by permitting a certain amount of oxygen or of an oxygen-argon mixture to enter a sputtering chamber through a controlled leak-valve while the sorb-pump continuously removed approximately the same amount of gas. The sputtering gases were used directly from tanks without further purification. The electrodes were 5 cm in diameter; their separation during the experiment was either 2.5 or 5.0 cm. The anode, which held the materials to be coated, was above the cathode which held a disk of pure aluminum (99.9999%, 5 cm diameter x 0.3 cm thick). Both electrodes were electrically shielded to prevent sputtering in undesirable directions. Electrochemically polished silicon disks were employed as substrates with a few exceptions, when mechanically polished platinum disks were employed. All disks were chemically cleaned prior to deposition, and transported in a dust free container to the sputtering chamber.

The deposited film thickness in the range of 500-7000Å was observed to be a linear function of time (Fig. 1). The deposition rate of the reactively sputtered alumina was found to vary directly with the sputtering voltage (1-2 kv), the total sputtering gas pressure (1 to 5 x 10^{-4} Torr), the current density (0.25-3.5 ma/cm^2), and inversely as the electrode separation. The deposition, however, was found to decrease as the oxygen partial pressure increased in an oxygen-argon mixture of the sputtering gas. The substrate temperature, as a result of the ion and electron bombardment of the substrates, increased as the deposition rate increased since the anode was not cooled. A range of 100°-600°C was observed.

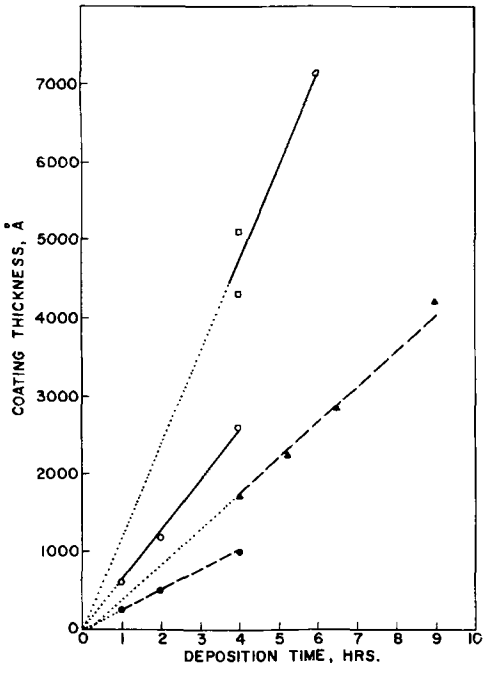

Fig. 1. Film thickness of reactively sputtered alumina as a function of deposition time at oxygen pressures (in μ, where 1 μ = 1 milliTorr), sputtering voltages (in kv) and electrode separations (in cm). Electrode separation: ———, 2.5 cm; - - - -, 5.0 cm; . . . . ., extrapolation. ●, 20μ, 1.1 kv; ▲, 50μ, 1.5 kv; ○, 20μ, 1.1 kv; □, 50μ, 20 kv.

Depending on the experimental conditions, two types of alumina films could be deposited. A polycrystalline γ-alumina film, which was difficultly soluble in HF, resulted under conditions favoring high deposition rates and substrate temperatures. At low deposition rates and substrate temperatures, an amorphous, HF-soluble film was deposited.

A coating was considered soluble in HF or ammonium bifluoride solution if, when immersed, a continuous change in the interference colors was observed. Films which showed an induction period (no change of interference colors) when immersed in HF for 1 min or longer were considered difficultly soluble. No color changes were noted but instead, after the induction period, localized dissolution of the film occurred, which spread with time over the entire surface. Under such conditions insoluble flakes of oxide could be observed to remain in the acid solution. The conditions which produced the transition from the soluble to the difficultly soluble form of reactively sputtered alumina are not well defined.

Soluble alumina films were obtained when the deposition rate was below 400 Å/hr, whereas difficultly soluble films were obtained at rates above 600 Å/hr. In the range between 400 and 600 Å/hr the solubility of the film decreased progressively as deposition time and thickness increased. Since no provision for cooling the anode existed, the higher deposition rates resulted in higher temperature. The same solubility effects could be obtained by heating the soluble films in vacuum, nitrogen, or nitrogen-oxygen ambients (no weight changes were noted), or by bombardment with an intermittent electron beam (90 kv).

Furthermore, it was noted that the loss of solubility of the films appeared to start at the free film surface and proceeded into the bulk of the film as a function of time and/or temperature on heating. The following experiment is a typical example demonstrating the existence of such a difficultly soluble skin while the bulk of the film below the skin exhibited a solubility characteristic similar to that of the original films.

A 4550Å thick alumina film (deposition rate 570 Å/hr, deposition time 8 hr) was etched in a modified ammonium bifluoride solution. This etch contained 12% concentrated H_2SO_4 and was sufficiently slow to permit thickness measurements of the films every 10 sec. Film thickness measurements were made by comparing changes in the interference colors with interference colors of prepared standards. An etch rate of 840 Å/min was estimated for the first 750Å on top of the film. The remainder of the coating (3800Å) then dissolved in 20 sec; this corresponded to an etch rate of about 11,000 Å/min. This observation suggests that a thin surface layer is responsible for the decrease of the solubility of the film and further that this results from low heat treatment. At what time/temperature conditions a soluble alumina film can be completely converted was not ascertained.

The densities of the films were determined from weight-area-thickness measurements. These were found to be 1.8 ± 0.2 g/cm^3 for either type of film. This is about ½ of the value reported in the literature for bulk γ-alumina which ranges from 3.42-3.67 (g/cm^3).

The observed refractive indices of the films varied from 1.51 ± 0.03 for the soluble to 1.62 ± 0.03 for the difficultly soluble alumina, with γ-alumina being reported as 1.76 (2). Refractive indices were measured by the VAMFO techniques (Variable Angle Monochromatic Fringe Observation) (3).

Physical homogeneity of the alumina films was examined by chlorine etching. All films were etched in ammonium bifluoride solution to remove about 500Å

from the soluble films prior to exposure to hot chlorine at 800°C for 30 min. Etch pits in the silicon substrate were then observed under a microscope. Examination of the soluble films revealed many very small pits ($> 50/mm^2$). A heat treatment of the coating, such as 4 hr at 260°C, prior to chlorine etching reduced the number of pits to 3 to $4/mm^2$. These observations support the contention that a structural rearrangement of the deposited oxide apparently occurs as a result of heat treatment. Films deposited on silicon substrates at rates above 600 Å/hr showed few (1 to $2/mm^2$) etch pits if the film was 400Å thick.

The dielectric strength of soluble and heat treated (3 hr at 100°C) alumina films on silicon substrates was examined using 25 mil gold evaporated contacts on 3400Å thick films and a voltage ramp of 5 v/min. The dielectric strengths of the films increased by a factor of 2 on heating (4 to 8 x 10^5 v/cm).

Differential thermal analysis of several representative alumina films showed only one phase transformation at about 375°C in air, in the range from 25° to 1200°C (heating rate 1°C/min). This change was irreversible and exothermic. Electron diffraction studies have shown that (*i*) the soluble alumina was amorphous, and (*ii*) that the films became progressively more crystalline on heating and that this crystalline phase was a $\gamma(\eta, \theta, \kappa)$-alumina. Formation of the γ-alumina phase was clearly a temperature-time dependent phenomenon. From line broadening it was inferred that the films were composed of crystallites, the diameter of which grew on heating from 30 to 50Å.

Prolonged (164 hr) heating of an alumina film at either 1000° or 1150°C in nitrogen did not convert the γ-alumina form to the α-form although according to the literature γ-alumina is not stable above 1100°C (4). On platinum substrates the γ-phase persisted under such drastic conditions, while on silicon substrates the films again became amorphous. This phase might be attributed to the diffusion of silicon in the γ-alumina and the formation of an amorphous aluminasilicate.

The consistently low density observed for the reactively sputtered films as compared to the literature value of alumina (1), the etching experiments, the physical inhomogeneity (revealed pinholes), and the measured crystallite size support the suggestion that the structure of the reactively sputtered alumina films is an aggregate of particles, and therefore porous.

Discussion

Studies of the refractive indices in aluminum oxide systems have shown that aluminum can exist in both 4- and 6-fold coordination in the same compound (5), and that the refractive index increases with the coordination number of aluminum (5), (from 1.5 to 1.6). Since the range of refractive indices observed in this study are the same as those cited in the literature, the observed increase in the refractive index on heat treatment of the film could be interpreted as a change from 4- to 6-fold coordination of the aluminum atom.

An acid-soluble amorphous form is mentioned by Durrant and Durrant (6). In the present work, reactively sputtered alumina can be deposited as an amorphous, HF soluble film. Such films on heating undergo crystallization resulting in γ-alumina. It should be pointed out that formation of γ-alumina by reactive sputtering does not proceed via the dehydration of gibbsite or aluminum hydroxide (7), which is the usual procedure reported in the literature. The strong time-temperature dependence of the phase transformation and the fact that no weight changes were observed on heating even in nitrogen-oxygen mixtures argues that a reconstructive transformation is taking place (8). This could be accompanied by some aluminum atoms changing their coordination number from 4 to 6 as they move from a tetrahedral to an octahedral site. The reason that the initial increase in density associated with a reconstructive transformation was not observed can be due to the porous nature of the films, since the observed density was that of a film and not that of the individual crystallites. The observed decrease in the pinhole density on heating may indicate that in the amorphous phase very small crystallites could be present, which on heating coalesce with the bigger particles. Such a process would close many of the channels, but would still leave a spongy coating having a low density.

The apparent change in observed solubility of the films as a function of the depth in the film could be explained on the basis of the low solubility of anhydrous γ-alumina forming a film on top of a layer of readily soluble amorphous alumina. This explanation would not be applicable to the reported decrease in the acid solubility of well crystallized and anhydrous γ-alumina which did not have any amorphous component. However, a mechanism proposed here could fit the data in this work as well as some data published on the study of catalysis and hydration on γ-alumina. For instance Peri (9) studying γ-alumina surfaces came to the conclusion that for anhydrous γ-alumina "some other type of strain-relieving mechanism (than hydration) apparently becomes operative on the surface of dry alumina above 500-600°C." Peri does not offer any suggestions concerning this mechanism. Solubility studies of γ-alumina powders in concentrated HCl have shown that the solubility decreases markedly as a result of prior heat exposure in the range from 600° to 1500°C (10). Similar behavior was noted for the solubility in HF of reactively sputtered alumina in this work. The observation of the induction period for the solvent attack on reactively sputtered alumina films is in accord with catalytic studies on γ-alumina powders (11-13). Here again the loss of catalytic action and the length of the induction period (hydration of the surface) was found to be a function of prior heat treatment. Recalling that the solubility decreased as the refractive index increased, it is tempting to postulate that a change in the coordination number of the aluminum atoms in the surface is responsible.

α-alumina has a hexagonal closest packed structure with all aluminum atoms located on octahedral sites. This form of alumina is known to be quite insoluble in mineral acids, and catalytically inert. γ-alumina, however, has a defect spinel structure, thus some of the aluminum atoms are located in tetrahedral sites. Aluminum atoms sitting on a tetrahedral site in a crystal would have sp^3 hybrid bonding (6). For those aluminum atoms which are on the surface in γ-alumina and would be in tetrahedral sites only two bonds remain in a rigid position. These would point into the body of the crystal. The other two bonds pointing up from the surface would not be "dangling bonds" in the usual sense of the term. With oxygen and air as ambient these bonds would most likely have hydroxyl ions attached to them. However, these would, on the surface, be mobile, and thus, it does not seem unreasonable to treat these two bonds as having somewhat the characteristic of "dangling bonds." If this can be assumed the following argument could be made. Haneman (11) has argued that on GaAs the "dangling bonds" on the cleaved surface revert to a less-hybridized form. In our case this would mean that the sp^3 character of the hybrid bonds would change to something more closely resembling an sp hybrid bond which is linear. The two oxygen atoms, bonded to the aluminum atom, would then experience a force pushing them out and away from the aluminum atoms. But they are hindered by the other oxygen atoms in the surface from moving too far. This would strain the surface. This strain could be however relieved, with little energy requirements, by the aluminum atom "flipping" over into the surface, since below each tetrahedral site is an empty octahedral site. Such a surface with all aluminum atoms in 6-fold coordina-

tion would be virtually an α-alumina surface. This film would still give an electron diffraction pattern of a γ-alumina. Because of the increasing coordination number of the aluminum atom, a hexagonal closest packed structure would result as in α-alumina, which in turn reduces the polarizability of the oxygen atoms. Such a surface could be expected to be more inert to chemical attack and would require an initiation period (5). Such a mechanism would be time-temperature dependent as well as surface initiated and presumably progress towards the oxide-substrate interface.

Acknowledgments

The author wishes to express his appreciation to Dr. E. A. Wood for reading the manuscript and helpful discussion, as well as to Mr. A. W. Smith for the preparation of the oxide films, to Mrs. A. Hunt and to Messrs. G. M. Loiacono and F. L. Worthing for the crystallographic and physical measurements.

The Relationship Between Coercivity and the Structure and Composition of Electroless Cobalt-Phosphorus Films

M. G. Miksic,[1] R. Travieso, A. Arcus, and R. H. Wright

International Business Machines Corporation, Systems Development Division, Poughkeepsie, New York

ABSTRACT

Electroless cobalt-phosphorus films were prepared under varying conditions of temperature, hypophosphite concentration, total concentration, time, and pH to determine the relationship between coercivity, structure, and chemical composition of the films. It was found that coercivity increases with increasing percentage of phosphorus content. The thickness effect on coercivity is complex and dependent upon the phosphorus concentration. The preferred orientation of the films is related to phosphorus concentration. Films with phosphorus weight per cent smaller than 2 exhibit, on the average, a normal orientation of the c-axis to the substrate; those with higher per cent phosphorus generally have the c-axis parallel to the substrate.

The magnetic properties of thin films, in general, and of cobalt, in particular, are strongly dependent upon the crystalline structure and the macroscopic structure of the film. Many properties of these films have been related to the thickness of the deposits with consideration of the deposition parameters (1, 2). In this report, we consider the variation of the magnetic properties with thickness for electroless films of constant phosphorus concentration in the range from 0.5 to 4 w/o (weight per cent) P which have been prepared under varied conditions.

The properties of bulk Co itself are a function of crystalline direction. The magneto-crystalline anisotropy of cobalt at room temperature is considerably higher than that of the other ferromagnetic elements. The curves showing the ratio of the areas under magnetization (for the c-axis the easy direction, and the a-axis the hard direction) indicate a measure of magnetic anisotropy; it is 10 times that of iron and 100 times that of nickel. Thus, it will be expected that in some cases the magnetic properties are a function of the preferred orientation of the crystallites which make up the films, but in other cases, shape anisotropy can also be of importance.

[1] Present address: Queens College, New York.

Experimental Techniques

Sample preparation.—The cobalt-phosphorus films were chemically deposited on polyethylene terephalate substrate.

The substrate was rendered hydrophilic using Koretzky treatment (3) which consists of 30 sec immersion in a 27.5*N* solution of H_2SO_4 containing 38 g/l of $Na_2Cr_2O_7 \cdot 2\ H_2SO_4$ at a temperature of 80°C. Substrate was rinsed in deionized water at 25°C for 30 sec, followed by 30 sec immersion in a 3.3*N* solution of NaOH at a temperature of 84°C and rinsed.

The sensitization and activation of the substrate was performed using Bergstrom technique (4) which consists of 30 sec immersion in an aqueous solution containing 30 g/l of $SnCl_2 \cdot 2H_2O$ and 10 ml/l of concentrated HCl at a pH of 1.0 and a temperature of 25°C. This was followed by 30 sec rinsing in deionized water at 25°C and 30 sec immersion in an aqueous solution containing 0.75 g/l of $PdCl_2$ and 10 ml/l of concentrated HCl at a pH of 1.0 and a temperature of 25°C, and rinsed.

The electroless cobalt-phosphorus deposition was made using the following modified Brenner bath (5): $CoSO_4 \cdot 7H_2O$, 35 g/l; $NaH_2PO_2 \cdot H_2O$, 20 g/l; $Na_3C_6H_5O_7 \cdot 2H_2O$, 35 g/l; $(NH_4)_2SO_4$, 66 g/l.

NH_4OH was added to adjust pH to 8.3 at a temperature of 75°C for 3 to 5 min.

To study the effect of process parameters on the structure and composition of the electroless cobalt-phosphorus films the following parameters were varied, one at a time, systematically: bath temperature, 67° to 87°C; pH, 7.3 to 9.3; $NaH_2PO_2 \cdot H_2O$, 5 to 25 g/l.

Magnetic measurements.—The coercive force was obtained by using a 60 cycle hysteresis loop tracer having a maximum driving field of 2000 oersteds.

X-ray diffraction.—A Norelco diffractometer and filtered molybdenum Kα radiation were employed for all the x-ray diffraction studies. The ratios $I(002)/I(100)$, for the films were normalized to a ratio of 1.1, calculated from the structure of hexagonal cobalt in order to avoid the error of using the literature values for polycrystalline cobalt which all show some degree of preferred orientation.

Chemical analysis.—Chemical analysis of the thin films was made only for cobalt and phosphorus. At present, these are the only elements known to have a major influence on the characteristics of the film. A General Electric vacuum x-ray emission apparatus was used for this study.

The operating conditions were as follows: *Cobalt*: x-ray target, tungsten at 40 ma and 50 kv; receiving slit, 0.005 in.; analyzing crystal, lithium fluoride; pulse height selector; detector, scintillation counter; air path. *Phosphorus*: x-ray target, chromium at 40 ma and 50 kv; receiving slit, 0.020 in.; analyzing crystal, EDDT; pulse height selector; detector, gas flow proportional counter-, P-10 gas; vacuum path, at 5μ pressure.

The standards used were previously compared with standard chemical analysis. Cobalt was analyzed colorimetrically by nitroso-R-salt method (6). Phosphorus analysis was made colorimetrically by the Heteropoly Blue method (7).

The experimental results indicated that the coercive force does not seem to be a function which depends only on thickness. It may vary independently of thickness by changing the hypophosphite concentration, the total concentration, the pH, and the temperature in the cobalt bath. The coercive force increases, in general, with increasing hypophosphite concentration and total concentration and with decreasing pH, temperature, and thickness (time of deposition).

In Fig. 1, the coercive force is plotted against the phosphorus concentration of a group of films prepared under widely varying conditions. The significance here is that the coercivity appears to be directly related to the phosphorus concentration of the film for a broad range of deposition conditions. Thus, this may not indicate ways to make a good magnetic film, an admittedly complex undertaking, but it is a step toward characterizing magnetic parameters with the film composition. The points lying below the curve in the high phosphorus range and above the curve at the low phosphorus range are films generally heavier than 0.2 mg/cm². It is now possible to consider the variation of coercive force with film thickness (or cobalt weight) for films having a constant phosphorus concentration.

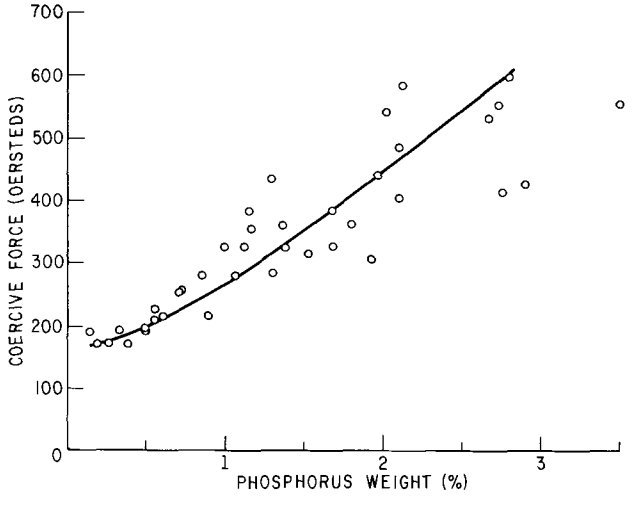

Fig. 1. Coercive force *vs.* phosphorus weight for cobalt-phosphorus films.

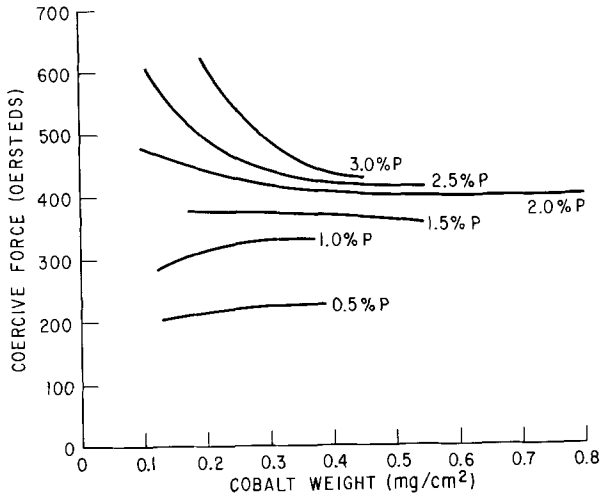

Fig. 2. Coercive force *vs.* cobalt weight for cobalt-phosphorus films

In Fig. 2, the data plotted in Fig. 1 is grouped roughly according to the phosphorus concentration. The coercive force increases with increasing cobalt weight for phosphorus concentration smaller than 2% and decreases with increasing cobalt weight for phosphorus concentration larger than 2%. The data indicates a generally smaller dependence of the coercive force on phosphorus concentration for films heavier than 0.2 mg/cm². It was observed that the phosphorus concentration decreases with increasing film thickness when deposition time is increased on a given bath. This suggests that, in general, the phosphorus concentration is higher at the initial stage of deposition. X-ray emission and electron probe measurements on selected samples have indicated that the phosphorus concentration at the substrate interface is larger than at the film surface.

X-ray diffraction data indicates that, in general, films with phosphorus concentration less than 2% have the c-axis normal to the substrate and those with phosphorus concentration greater than 2% have the c-axis parallel to the substrate. This is indicated in Fig. 3 and 4 by the value of the x-ray intensity for the reflected plane, (002) and (100), as given by the symbol I_{002}/I_{100}. A ratio of I_{002}/I_{100} larger than one indicates a c-axis preferentially oriented normal to the plane of the film, whereas a value smaller than one indicates a c-axis preferentially oriented in the plane of the film.

The aggregate size as shown by electron micrographs increases with cobalt weight at a constant phosphorus concentration (Fig. 3) and decreases with

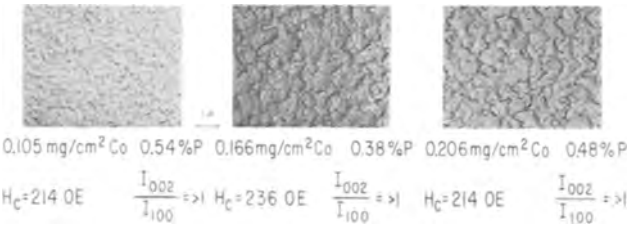

Fig. 3. Electron micrographs for cobalt-phosphorus films with increasing cobalt weight at constant phosphorus concentration. Magnification 10,000X.

Fig. 4. Electron micrographs for cobalt-phosphorus films with increasing phosphorus concentration at constant cobalt weight. Magnification 10,000X.

increasing phosphorus concentration at constant cobalt weight (Fig. 4). These micrographs also show a crevice type surface structure at a phosphorus concentration below approximately 2% and a noncrevice type surface structure at a phosphorus concentration above 2%.

Discussion

The results indicate that the magnetic properties of chemically deposited cobalt, as previously reported (1), depend on the cobalt plus hypophosphite ion concentration, the total bath concentration, the pH, temperature, and thickness (time of deposition). It seems that these process parameters affect the chemical composition of the deposits which were found to relate closely to the structural and magnetic properties. Films with phosphorus concentration smaller than 2% have their average orientation with the c-axis normal to the substrate, aggregate size larger than 0.2μ and coercive force smaller than 400 oersteds. Films with phosphorus concentration larger than 2% have their average orientation with the c-axis parallel to the substrate, aggregate size less than 0.2μ and coercive force larger than 400 oersteds. In general, the coercive force increases with increasing phosphorus concentration. The thickness effect on coercive force is shown to be complex and dependent also upon the phosphorus concentration.

Also of interest is the chemical nature of the phosphorus which is present within the film. Cobalt-phosphorus compounds have not been observed by x-ray diffraction, and in fact all diffraction traces have been identified as corresponding to α-cobalt which has a hexagonal close packed crystallographic structure.

No satisfactory model for the electroless cobalt-phosphorus films can be set forth based on the available data. However, there appears to be a correlation between coercivity of the film and the phosphorus concentration which, in turn, seems to relate to the crystallographic orientation, surface structure, and aggregate size.

Acknowledgments

The authors would like to express their gratitude to Mr. R. E. Smith for the electron microscopy studies, to Dr. J. E. Hurt for the electron transmission studies, and to Mr. R. G. Volk for the magnetic measurements.

Manuscript received May 17, 1965; revised manuscript received Dec. 4, 1965. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Kinetics of Growth of $FeSn_2$ Layers on Tinplate

H. E. Biber

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

$FeSn_2$ alloy layers were formed on unalloyed tinplate specimens heated by immersion in constant-temperature oil baths and by resistance heating. The data show that the critical factor affecting alloy-layer-growth behavior is the rate at which the unalloyed tinplate is heated. As the heating rate is decreased the average alloy-layer-growth rate decreases instead of remaining constant. With rapid heating, there is an appreciable interval during which the growth of the alloy ceases or practically ceases.

During the production of tinplate, a thin layer of $FeSn_2$ is formed at the steel-tin interface. In the hot-dip tin-plating process, this alloy layer forms while the steel strip is immersed in the molten tin bath. In the electrolytic process, it forms when the freshly plated strip is briefly heated to melt the coating and give it a high reflectance (flow brightening). Excessive amounts of this iron-tin alloy are detrimental to the physical properties of tinplate, therefore, the kinetics of its formation is a subject of interest in the tinplate industry.

Loginow and Frankenthal (1) studied the kinetics of this reaction in detail by immersing strips of matte tinplate (*i.e.*, electrolytic tinplate that had never been heated) in a constant-temperature oil bath for various times and then measuring the resultant amount of alloy. Their data for bath temperatures of 175°-316°C showed that the growth rate increased with increasing bath temperature and that a parabolic rate law was followed at all temperatures.

Seybolt (2) studied the kinetics of alloy-layer formation by immersing strips of steel in molten tin maintained at 260°, 288°, 316°, and 330°C. His data also showed that a parabolic rate law was followed at each temperature.

However, when Thwaites (3) formed alloy layers by immersing matte tinplate in oil baths heated to 175°, 200°, and 225°C, he found that the growth did not follow a parabolic rate law. In addition, he observed that when matte tinplate was heated resistively to 250°C and held at that temperature, no additional alloy was formed after the first 3 sec, even though the heating was continued for 30 sec.

This present study was undertaken to resolve the differences in the results of the previous studies of alloy-layer growth.

Experimental Work

Matte tinplate was prepared from 0.010-in.-thick Type L steel in a circulation cell with phenolsulfonic acid electrolyte. The coating weights were 0.5, 1.0, 1.5, and 2.0 lb per base box (1.3, 2.6, 3.8, and 5.1 x 10^{-4} oz/in.^{2}, respectively).

For most of the study, ½-in. squares of the matte tinplate were immersed for various times in a constant-temperature oil bath vigorously stirred by a 2-in.-diameter propeller driven at 10,500 rpm. Alloy-layer growth was measured for bath temperatures of 200°, 210°, 220°, 231°, 240°, 260°, and 300°C. Some additional measurements were made for a bath at 240°C with a less vigorous stirrer speed of 1800 rpm and without stirring. When the oil was stirred, the temperature variation was less than ±0.5°C; however, when the oil was not stirred, temperature gradients set up in the bath resulted in a variation of about ±4°C. Immediately upon removal from the oil bath, the specimen was quenched in an organic liquid.

Alloy layers were also formed by resistively heating strips of matte tinplate for various times. Alloy-layer-growth data were obtained for various potentials applied across the strip.

The heavier tin-coating weights were used for the longer times and/or higher temperatures so the amount of free tin would always be considerably in excess of the expected amount of alloyed tin. To minimize the possible effect of alloy layer formed at room temperature, no measurements were made with matte tinplate that was more than three days old.

The amount of alloy layer formed on each specimen was determined in duplicate by the coulometric method of Kunze and Willey (4).

The heating rates with different degrees of stirring of the oil bath at 240°C and with resistance heating were determined by means of an iron-constantan thermocouple welded to steel specimens identical in size to the tinplated specimens. The thermocouple was connected to a fast-response chart recorder.

Results

In the oil bath stirred at 10,500 rpm, the alloy layer grew in three distinct stages (Fig. 1). In the initial stage the alloy layer formed very rapidly. The growth followed a rate law of the form $w = kt^n$, where $n > 1$. The value of n and the total amount of alloy formed in this first stage increased with increasing bath temperature. Following this initial stage was a second stage in which little additional alloy was formed. The duration of this growth-retardation stage varied from about 15 to 200 sec at different bath temperatures; however, the changes in duration were not consistent with the changes in temperature. In the third stage the growth again followed a rate law of the form $w = kt^n$, but $n = 0.3$ at each bath temperature, Table I. This last stage comprised the main part of the growth curve.

Table I. Slope of plotted third stage alloy-layer-growth data at various bath temperatures

Bath Temperature, °C	Slope, n
200	0.31
220	0.30
231	0.32
240	0.29
260	0.30
300	0.32

Stirring the oil at 10,500 rpm causes the tinplate specimen to be rapidly heated to bath temperature. If the agitation of the oil is reduced, the heating rate is reduced (Fig. 2) and the alloy-layer-growth behavior changes. An example of this relationship is seen in the results of alloy-layer-growth measurements at 240°C in oil baths stirred at 10,500, 1800, and 0 rpm (Fig. 3). With the rapid heating rate provided by stirring at 10,500 rpm, the alloy layer grew in three stages and the initial stage persisted well beyond the time required to heat the specimen to bath temperature. With the intermediate heating rate provided by stirring at 1800 rpm, the three-stage nature was less pronounced and the slope of the third stage was increased. With the slow heating rate provided by the unstirred bath, the alloy layer grew in two stages. The initial rapid-growth stage persisted only until the specimen was heated to bath temperature. The slope of the main portion of the plotted data was greater than in the stirred baths, having a value of almost 0.5.

Thus the results for oil heating can be summarized as follows. For a given bath temperature, as the heating rate is increased three changes occur in the

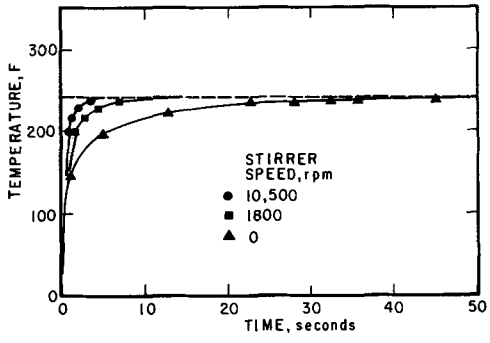

Fig. 2. Heating of ½ x ½ in. squares of black plate with different degrees of stirring of oil. Stirrer speed, rpm: ●, 10,500; ■, 1800; ▲,0.

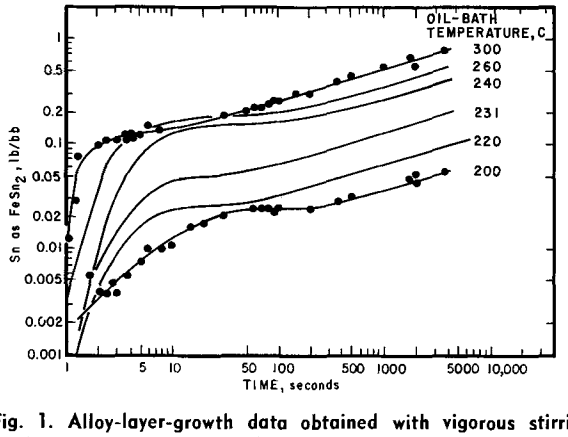

Fig. 1. Alloy-layer-growth data obtained with vigorous stirring at various bath temperatures. Note: Data points omitted from all curves except 200° and 300°C for simplification.

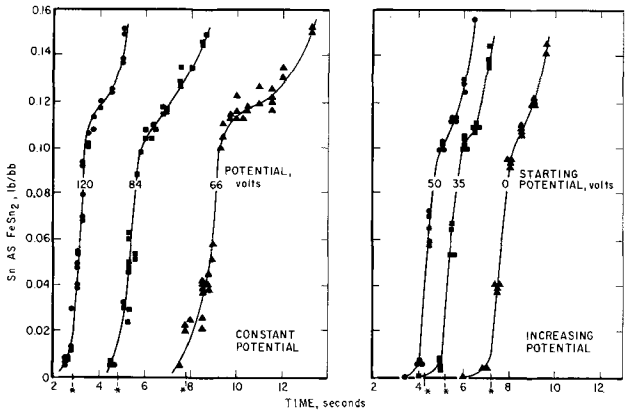

Fig. 5. Alloy-layer growth with constant or increasing potentials on resistance melter. * equals tin melting time.

plotted alloy-layer-growth data: (*i*) the slope of the main portion of the plotted data continuously decreases from a value of about 0.5; (*ii*) an initial stage of accelerated growth becomes pronounced, and (*iii*) an intermediate stage of growth retardation appears at a higher heating rate.

No explanation can be offered for the growth retardation. It was thought to indicate the formation of a new phase that could not be detected by the coulometric analysis. However, x-ray diffraction analysis showed only $FeSn_2$ in the alloy layer before, during, and after the growth-retardation stage.

This relationship between heating rate and alloy-layer-growth behavior clarifies the differences in the results of previous alloy-layer-growth studies. Loginow and Frankenthal (1) used large specimens in an unstirred oil bath, which resulted in a slow heating rate. Therefore they observed little, if any, of the initial stage of accelerated growth, and the slope of their plotted data was 0.5. Seybolt's paper (2) does not include information about the heating rate, but, because he observed only the parabolic growth, it is assumed that his specimens were also heated slowly. On the other hand Thwaites' oil-bath specimen heating rates (3) must have been faster than Loginow and Frankenthal's because his data did not indicate the parabolic rate law. His resistance-heating experiments certainly involved rapid heating rates because the specimens were heated to 250°C in 3 sec. The fact that no additional alloy was formed after the first 3 sec., even though heating was continued for 30 sec., indicates that the alloy layer was in the growth-retardation stage. In fact, Thwaites' alloy-layer-growth curves at 250° and 300°C obtained by resistance heating compare favorably with the present curves for 260° and 300°C obtained by rapid oil heating.

Oil-bath heating differs considerably from commercial practice in which the tin coating is flow-brightened by rapidly heating the strip resistively for a few seconds. The tinplate temperature increases continuously during the entire resistance-heating period, whereas with oil-bath heating it increases exponentially to the bath temperature. To obtain a better understanding of alloy-layer growth during resistance heating, alloy-layer-growth curves were prepared by heating matte tinplate resistively with three different constant potentials and three different continuously increasing potentials. The constant potentials produced heating rates that were practically linear, Fig. 4, whereas the continuously increasing potentials produced heating rates that continuously increased. For the same melting time, the growth curves obtained with either heating condition are generally the same, Fig. 5. There is very little alloy-layer growth until the tinplate temperature approaches the melting point of tin; then the growth proceeds rapidly. Each of the growth curves exhibits the arrest that is characteristic of growth during rapid heating. However, the arrest is not as pronounced as with oil-bath heating, presumably because the temperature is continuously increasing.

Discussion

In studies of the kinetics of surface reactions one is concerned with the effects of time and temperature on the amount of reaction product formed. Ideally the reactants are kept apart until the system is at the desired temperature. However with a system such as tinplate this is not possible because the reactants are always in intimate contact. Thus the reaction can occur from the onset of heating. The results of the present study show that with such a system there is

a factor other than time and temperature that affects the amount of reaction product formed.

If the growth of the iron-tin alloy layer depended only on time and temperature, with different linear heating rates, there should be an inverse proportionality between the heating rates and the relative amounts of alloy layer formed when a given temperature was reached. For example, if one heating rate were twice another, it would reach a given temperature in half the time and should cause half as much alloy-layer growth. However with either heating rate the average growth rate should be identical when evaluated at the same temperature. (The average growth rate is the amount of alloy layer that has formed when a given temperature is reached divided by the time required to reach that temperature.)

The data for linear heating rates show that the amount of alloy layer formed when a given temperature is reached is not inversely proportional to the heating rate and further that the average growth rate actually decreases as the heating rate decreases, Table IIA. The data for increasing heating rates and for exponential heating rates also show the same effects, Table IIB and IIC, respectively. The heating rates for resistance heating at increasing potentials were practically identical above about 150°C and differed considerably in the range 40°-150°C, whereas those for the 240°C oil baths were just the opposite. Thus it appears that a reduction in heating rate in any part of the temperature range up to at least 240°C produces these effects.

The cause of these effects is not known. It is possible that they can be explained on the basis of increased $FeSn_2$ crystallite nucleation rates with decreased heating rates, and this is currently being investigated.

Summary

The rate at which matte tinplate is heated strongly affects the kinetics of alloy-layer formation. For a given oil bath temperature, as the heating rate is increased, the slope of the main portion of the plotted growth data continuously decreases from a value of 0.5, an initial stage of accelerated growth becomes pronounced, and at a higher heating rate an intermediate stage of growth retardation appears. When matte tinplate is rapidly heated resistively, as in commercial flow brightening, the growth data exhibit a growth retardation, however, it is not as pronounced as with oil-bath heating.

An analysis of the growth data for both oil-bath heating and resistance heating shows that a reduced heating rate reduces the average alloy-layer-growth rate and therefore causes a smaller amount of alloy layer to be formed by the time a given temperature is reached. It appears that a reduced heating rate in any part of the temperature range to at least 240°C will cause this effect.

Acknowledgments

The author wishes to express his thanks to Messrs. L. E. Berta, E. C. Brendlinger, C. W. Cross, E. J. Masar, and J. W. Ruffner for constantly supplying fresh matte tinplate and for patiently assisting in the various resistance heating experiments. Also, the valuable assistance of Messrs. W. T. Harter and B. J. Lapinski in making numerous measurements for this study is gratefully acknowledged.

Epitaxial Synthesis of GaAs Using a Flow System

M. Rubenstein and E. Myers

Westinghouse Electric Corporation, Research & Development Center, Pittsburgh, Pennsylvania

ABSTRACT

The epitaxial synthesis of gallium arsenide utilizing a flow system was achieved using gallium trichloride, arsenic, and hydrogen as reactants, and oriented single crystals of GaAs as substrates. Under the conditions of these experiments, there is almost no difference in growth rates between the "A" orientation of the {111} surface and the "B" orientation of a $\{\bar{1}\bar{1}\bar{1}\}$ surface. The rate of growth on a {110} surface is more than twice as great as on a {111} surface, and the rate of growth on a {100} surface is slower by a factor of 1.4 than on a {111} surface.

Gallium arsenide has been prepared in a variety of manners (1-4). This paper concerns the epitaxial synthesis of GaAs using $GaCl_3$, arsenic, and H_2. The over-all reaction can be written as

$$4GaCl_3 + As_4 + 6H_2 \rightleftarrows 4GaAs + 12HCl \quad [1]$$

Since this reaction appears to be the complete hydrogen reduction of $GaCl_3$ in the presence of arsenic, one must look at the various equilibria involved in this over-all reaction (5)

$$2GaCl_3 \rightleftarrows Ga_2Cl_2 + 2Cl_2 \quad [2]$$

$$3Ga_2Cl_2 \rightleftarrows 4Ga + 2GaCl_3 \quad [3]$$

$$H_2 + Cl_2 \rightleftarrows 2HCl \quad [4]$$

$$As_4 \rightleftarrows 2As_2 \quad [5]$$

$$2Ga + As_2 \rightleftarrows 2GaAs \quad [6]$$

In the system $GaCl_3$-As_4-H_2 the sources of chlorine are in reactants [2] and [4]. The ratio of any of the three reactions is not critical. However, in the system $GaCl_3$-$AsCl_4$-H_2, the ratio of $GaCl_3$:$AsCl_3$ must not fall below unity (3). When this ratio falls below unity, not only is there no epitaxial growth, but the substrates are often attacked. This $GaCl_3$-$AsCl_3$-H_2 system has three sources of Cl_2: Eq. [2], [4], and [7].

$$2AsCl_3 \rightleftarrows As_2 + 3Cl_2 \quad [7]$$

If the Cl_2 concentration were to increase, reaction [2] would shift to the left, reaction [3] would shift to the left, reaction [6] would shift to the left and the over-all reaction [1] would shift to the left so that less or little GaAs would grow epitaxially. In the system $GaCl_3$-As_4-H_2, as long as the chlorine source is only in Eq. [2] and [4] (and not in Eq. [7]) and as long

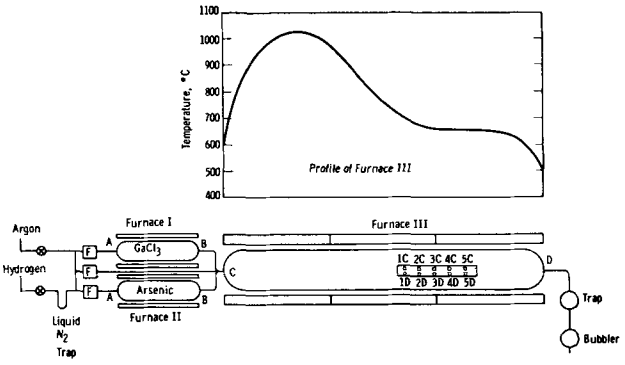

Fig. 1. Diagrammatic flow system for the epitaxial synthesis of GaAs.

as H_2 is the carrier, any combination of ratios of reactants is non-critical for the epitaxial growth of GaAs.

Experimental Procedures

$GaCl_3$ was prepared by ALCOA and AIAG from their respective 99.9999% gallium. Arsenic was 99.999+% from ASARCO. The heating was done with hinged resistance furnaces and heating tapes. The glass apparatus was quartz except for the Vycor ball and socket joints. Figure 1 shows the diagrammatic sketch of the apparatus with the temperature profile of the reaction furnace. The tube in furnace III was 45 mm OD and the length of the deposition zone (where the seeds were placed) was about 25 cm.

Furnace I was maintained at a temperature of about 70°C, furnace II was maintained at a temperature of about 450°C. Heating tapes were used from points B to C to maintain the wall temperature at a minimum of 475°C. Hydrogen and/or argon (argon for flushing the hydrogen out of the system at the end of the experiment) can flow through the system monitored by flow meters at points F. The experiments usually lasted about 5 hr.

All substrates were single crystals of GaAs sliced, lapped, and given a nonpreferential polishing etch. The dimensions of the seeds were about 1x5x5 mm. The seeds were placed on a graphite slab as indicated in Fig. 1. The flat surfaces of the substrates were oriented in {111}, {110}, and {100} planes. The seeds were placed on a graphite slab (as indicated in Fig. 1) to give relative rate growths using the "A" and "B" orientations of the {111} planes as the standard. In some runs {110} and {100} oriented substrates were placed adjacent to {111} seeds so the {111} oriented substrates could be used as a standard experiencing the same flow rates of gases, concentrations, and temperatures.

The flow rate of arsenic was about 0.13 mM/min, and the flow rate of $GaCl_3$ was between 0.2 to 0.7 mM/min, and the total flow rate was about 200 cc/min. The arsenic flow rate and the $GaCl_3$ flow rates were calculated from weight measurements of the sources before and after runs. The total flow rate was made by calibrating the flow meter settings with the gas coming out of the bubbler at the effluent end of the apparatus. The optimum temperature for the growth of GaAs on the substrates (maximum amount of GaAs deposited) was 665°-670°C. Deposits grew at the rate of between 0.07 to 0.45 μ/min. This difference in growth rates was primarily due to differences in flow rates of the $GaCl_3$. The thickness of the GaAs growth was obtained by angle lapping and decorating the junction using an aqueous solution containing $CuSO_4$ and HF (6).

Results

Table I contains data from three representative runs. Under "substrate orientation" column, the numbers and letters refer to positions of substrates as indicated in Fig. 1. The thickness of the grown layers used in this paper were obtained by angle lapping and decorating with a copper solution. Weight gain measurements of substrates before and after growth could not be used to determine thicknesses of growth since the ratio of the surface area of the tops of these substrates to the surface area of the sides varied between 1.0 and 1.5. There was very little growth on the bottom surface of these substrates.

* Hydrogen flow over $GaCl_3$ for these three runs was 125 ml/min. Hydrogen flow over arsenic for these three runs was 145 ml/min.
(a) {111} grows at about the same rate as {$\bar{1}\bar{1}\bar{1}$}.
(b) {110} grows about 134% faster than {111} or faster by a factor of 2.34.
(c) {100} grows about 26% slower than {111} or slower by a factor of 1.35.

The three runs indicated in Table I are meant to be representative of many runs. These three representative runs demonstrate a few points. One can note that the substrates downstream in EP 23 and EP 25 show smaller growth layers than substrates which are upstream. But EP 24 does not demonstrate this trend. The $GaCl_3$ flow for EP 25 was the largest flow, for EP 23 the flow was somewhat smaller, and the flow for EP 24 was appreciably smaller. The two fast flow rate experiments yielded larger growth rates and a lessening of growth on downstream substrates. Faster flow rates of $GaCl_3$ produce faster growth rates of GaAs within the limits of the flow rates in these experiments. The reduction of growth as one looks at downstream substrates is probably due to the reaction products from the upstream substrates reducing the rate of growth on the downstream substrates. EP 24 indicates that at temperatures of 674°C and greater the rate of deposition of GaAs is being reduced by the rate of transport of GaAs. EP 24 also shows a more uniform rate of deposition on upstream and downstream substrates. If the flow rate of $GaCl_3$ is slow enough the reaction products from the upstream substrates probably have enough time to diffuse away and not deter the growth rates on the downstream substrates. These same observations were noted in runs other than EP 23, EP 24, and EP 25.

The relative rates of growth on the three orientations of GaAs (under the conditions stated earlier in this paper) are {110} > {111} > {100}. The {110} surface grows faster than a {111} surface by a factor of about 2.3; and the {100} surface grows slower than a {111} surface by a factor of about 1.4. No real difference in growth rates were observed between the "A" and "B" orientations of the {111} surfaces. Many of these layers on the four orientations were checked by back reflection Laue x-ray diffraction studies and were all found to be single crystal growths with the same orientations as their respective substrates. These

layers were also lightly lapped and given a preferential etch to demonstrate that there were no grain boundaries in the grown layers.

Two runs were made in which the carrier gas was argon. No deposition was observed on the seeds and the seeds were seriously attacked. These experiments confirm that hydrogen is more than just the carrier gas but is necessary for the reaction to synthesize GaAs.

Variation was performed on the maximum temperature indicated in Fig. 1. This temperature was varied between 1150° and 900°C with no apparent effect on the rate of deposition. At temperatures lower than 850°C there was little or no deposition of GaAs on the seeds. One can conclude from this that a temperature of 900°C or higher is necessary to shift Eq. [2] to the right. The function of this high temperature zone is to allow the partial reduction of the $GaCl_3$ so that a disproportionation reaction can occur in the substrate zone.

The efficiency of growth on these seeds is between 1 and 3%. This efficiency is calculated on the basis of the amount of GaAs deposited on the seeds and the amount of arsenic or $GaCl_3$ delivered from the sources (whichever was the lesser amount). Between 15 and 50% of the $GaCl_3$ which left the tube in furnace I was recovered in the trap, after point D (see Fig. 1). The trap mentioned above was air cooled. At the flow rates used in these experiments much of the $GaCl_3$ and any Ga_2Cl_4 formed would be trapped since the melting points are 77.9° and 171°C, respectively. If the trap contained any Ga_2Cl_4 mixed with the $GaCl_3$ the recovery of gallium would be that much higher than reported here. Of course, some of the gallium halide was not trapped, so the figures of 15-50% are low figures. The variation between 15 and 50% was due primarily to the rate at which $GaCl_3$ left the tube in furnace I. The inefficiency of the growth of GaAs on the seeds can be attributed to the equilibria (Eq. [2] and [3] indicate that 1 mole out of an initial 3 moles of $GaCl_3$ must be unreacted), to GaAs which formed on the walls of the quartz tube (particularly downstream from the seeds), and to the fact that every molecule passing through the high temperature zone does not undergo reduction. This technique could be made more efficient by using more seeds in the deposition zone, by tilting the seeds from the horizontal (7) (or placing the seeds in a vertical state), and by passing the reactants through the system at optimum flow rates.

Discussion

The data on the relative rates of growth on the various orientations {111}, {$\bar{1}\bar{1}\bar{1}$}, {110}, and {100} in the literature varies tremendously (8-10) and the authors will not attempt to try to interpret why various experimental procedures used by various scientists give such varied results. However, we would like to offer an explanation for the results in this paper. The results of the experiments in this paper are consistent with the model presented by Gatos (11). A surface atom on a {100} orientation is bonded to two atoms of the crystal and has 2 unshared electrons. A surface atom on a {111}, {$\bar{1}\bar{1}\bar{1}$}, or a {110} orientation is bonded to three atoms of the crystal and has one unpaired electron.

If one assumes that these various surfaces are surrounded by gallium atoms (as Ga_2Cl_2 or GaCl) and arsenic atoms about to form bonds with the surface atoms, the probability would be greater to form such bonds if the atom in the gas would have to make one bond with one surface atom to complete the tetrahedron of the surface atom. Therefore, one would expect growth on a {100} surface to be slower than growth on a {111}, {$\bar{1}\bar{1}\bar{1}$}, or {110} surface. The {111} and {$\bar{1}\bar{1}\bar{1}$} surface consists only of gallium atoms and arsenic atoms, respectively, and the {110} surface consists of gallium and arsenic atoms. The probability of growth on the {110} should be greater since gallium and arsenic are in the gas above the surface ready to form bonds with the surface. In the case of the {111} surface, a layer of arsenic atoms must deposit before a layer of gallium atoms can deposit. Therefore, one would expect the {110} surface to accept growth faster than a {111} or a {$\bar{1}\bar{1}\bar{1}$} surface. From the above discussion one would expect the {111} surface to grow at the same rate as the {$\bar{1}\bar{1}\bar{1}$} surface.

Marinace (12) found the same relative growth rates with respect to the {110}, {111}, and {100} orientations using a sealed-tube iodine transport type growth of germanium on germanium.

Sangster (13) discussed the relative growth rates of III-V compounds. He concluded that the {110} growth rates should be greater than the {111} as this paper is reporting, but he concluded that the fastest growing orientation should be the {100}. He concluded this from the most stable and least stable planes. Experimentally he reported confirmation of his conclusions by referring to InSb {311} crystals (grown from the melt) so that the development of facets would be encouraged. The facets found in sequence of strength or prominence were {111} > {110} > {100}. The order of rates of growth should be in the reverse order. Sangster in this same reference (13) also points out that "crystals of III-V compound semiconductors are not usually grown under near-isothermal, near-equilibrium conditions, but are grown rapidly in the presence of strong temperature gradients."

This paper demonstrates the isoepitaxial synthesis of GaAs in a flow system in which the reactants are $GaCl_3$, As_4, and H_2. This paper also shows that under the conditions as set forth here, there is almost no difference in growth rates between the "A" and "B" orientations of the {111} orientations; the rate of growth on a {110} orientation is more than twice as fast as on a {111} plane; the rate of growth on a {100} orientation is slower by a factor of about 1.4 than on a {111} orientation.

Phase Shift Corrections for Infrared Interference Measurement of Epitaxial Layer Thickness

P. A. Schumann, Jr., R. P. Phillips, and P. J. Olshefski

IBM Systems Manufacturing Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Under certain conditions of wavelength and substrate impurity level, correction factors were found to be necessary for the infrared interference method of measuring epitaxial layer thickness. A general theory has been developed which relates the index of refraction and extinction coefficient to physical properties of the semiconductor and the wavelength. From these constants, a phase change at the epitaxial layer-substrate interface is calculated. This phase shift is shown to influence the measurement and a correction factor is derived.

In 1961 Spitzer and Tanenbaum (1) proposed a nondestructive technique for the measurement of the thickness of epitaxial layers deposited on heavily doped substrates of the same type. This technique relies on the reflection of infrared radiation from the epitaxial layer-air interface and from the epitaxial layer-substrate interface and subsequent interference of the two beams. Further work was done by Albert and Combs (2) and Pliskin and Grochowski (3) in expanding the technology and comparing the infrared interference method with other techniques. It was assumed in the aforementioned papers that the phase shift on reflection at the layer-substrate interface was constant and did not enter into the calculation of the layer thickness. However, it was pointed out by Albert and Combs (2) that in the transition region between low refractive index and high extinction coefficient the phase shift on reflection was a function of wavelength. In 1961, Pliskin (4) measured this phase shift showing it was a function of wavelength and proposed that this phase shift could be used to determine the substrate resistivity empirically. Albert and Combs (2) limited their discussion of the thickness measurement to the spectral region where the phase shift was small. However, the wavelength region in common use, 11-35μ, encompasses the transition region for most low resistivity substrates.

This varying phase shift is evidenced by the fact that successive peaks or valleys do not yield the same layer thickness when calculated in the standard manner.

To determine the phase shift at the epitaxial layer-substrate interface, the index of refraction and extinction coefficient must be known. This paper will present theoretical solutions for these optical constants and propose a method of correcting the thickness measurement by including the varying phase shift.

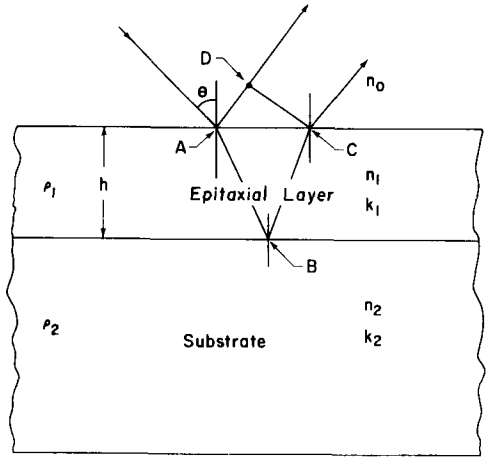

Fig. 1. Geometry of infrared interference method of measuring epitaxial layer thickness.

Theory

The geometry of the technique is illustrated in Fig. 1. Here the incident beam makes an angle, θ, with a normal to the surface. The beam is split by reflection and refraction. The reflected ray undergoes a phase shift Φ_1 at point A. The refracted ray passes through the epitaxial layer and is reflected at point B experiencing a phase shift Φ_2. The refracted and reflected ray then passes back through the epitaxial layer to point C where it is again refracted and interferes with the reflected ray. This interface is either constructive or destructive depending upon the relative phase of the two rays. The multiple reflected rays are not considered because they add nothing to the analysis.

In this analysis of the epitaxial layer thickness measurement, several assumptions have been made. First, it is assumed that there is an abrupt change in conductivity at the layer-substrate interface and that within each region the conductivity is uniform. Second, the assumption is made that the wavelength is sufficiently long so that no direct transitions can be made across the band gap. For silicon, this can be satisfied if $\lambda > 2\mu$. This is equivalent to stating that the lattice contribution to the dielectric constant is independent of wavelength. Third, it is assumed that the band structure is such that there are no interband transitions. Fourth, the assumption is made that the carrier concentration in the epitaxial layer is sufficiently low that the carriers do not contribute to the dielectric constant and only the lattice contribution need be considered. This is equivalent to saying that the extinction coefficient is zero and the refractive index is constant with wavelength. Fifth, the effects of polarization are neglected because the angle of incidence of the ray at the layer substrate interface is close to zero. The first assumption is questionable but necessary to make the analysis possible. It will be shown in the data that this condition is not too restrictive since the results are self-consistent. For normal epitaxial structures, conditions two through five are satisfied.

Equations [1] and [2] express the phases of the outgoing rays at points C and D in terms of the optical path lengths and the phase shifts the rays suffer when reflected. Because the epitaxial layer is nonabsorbing the phase shift of the transmitted ray at point A is zero and is neglected (5).

$$\Phi_C = \frac{4\pi h n_1^2}{\lambda\sqrt{n_1^2 - \sin^2\theta}} - \Phi_2 \qquad [1]$$

$$\Phi_D = \frac{4\pi h \sin^2\theta}{\lambda\sqrt{n_1^2 - \sin^2\theta}} - \Phi_1 \qquad [2]$$

The difference in phase, δ, is

$$\delta = \Phi_1 - \Phi_2 + \frac{4\pi h}{\lambda}\sqrt{n_1^2 - \sin^2\theta} \qquad [3]$$

The order of interference, P, is

$$\delta = 2\pi P \qquad [4]$$

where if $P = 0, 1, 2, 3 \ldots$ interference is constructive, and if $P = 1/2, 3/2, 5/2 \ldots$ interference is destructive.

Equations [3] and [4] can be solved for the epitaxial layer thickness, h, as

$$h = \left(P_j - \frac{\Phi_{1j}}{2\pi} + \frac{\Phi_{2j}}{2\pi}\right)\frac{\lambda_j}{2\sqrt{n_1^2 - \sin^2\theta}} \qquad [5]$$

An expression for the order, P, is obtained by writing Eq. [5] for the two different interference extremum and subtracting one from the other. The convention is adopted that $\lambda_1 > \lambda_2$, hence $P_2 > P_1$ and $P_2 = P_1 + m$. The result is given by

$$P_2 = \frac{m\lambda_1}{\lambda_1 - \lambda_2} + \frac{\Phi_{11}\lambda_1 - \Phi_{12}\lambda_2}{2\pi(\lambda_1 - \lambda_2)} - \frac{\Phi_{21}\lambda_1 - \Phi_{22}\lambda_2}{2\pi(\lambda_1 - \lambda_2)} \qquad [6]$$

where Φ_{X1} is the phase shift at λ_1 and Φ_{X2} is the phase shift at λ_2.

Equations [7a] and [7b] express the phase shifts Φ_1, and Φ_2 in terms of the indices of refraction and the extinction coefficients of mediums 0, 1, and 2 (6). For normal incidence

$$\tan\Phi_1 = \frac{2\,n_0 k_1}{n_0^2 - n_1^2 - k_1^2} = 0 \text{ as } k_1 = 0 \qquad [7a]$$

$$\tan\Phi_2 = \frac{2\,n_0 k_2}{n_1^2 - n_2^2 - k_2^2} \text{ for } k_1 = 0 \qquad [7b]$$

In order to calculate the phase shifts values of n and k must be obtained.

Moss (7), Smith (8), Spitzer and Fan (9), and Lyden (10) made various approximations to the theory of the optical constants of a semiconductor. These approximations make their solutions valid for limited ranges of wavelength and carrier concentration. The general solutions (11) for the index of refraction and extinction coefficient are given by Eq. [8a] and [8b]. These solutions have been verified by comparison with published data on the reflectivity of heavily doped semiconductors (12).

$$n = \frac{1}{\sqrt{2}}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^{1/2}\left\{1 \pm \left[1 + \frac{e^8\lambda^6 N^4\rho_0^2 g^2 [L(D)]^2}{64\pi^6\epsilon_0^2 C^6 m^{*4}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^2}\right]^{1/2}\right\}^{1/2} \qquad [8a]$$

$$k = \frac{1}{\sqrt{2}}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^{1/2}\left\{-1 \pm \left[1 + \frac{e^8\lambda^6 N^4\rho_0^2 g^2 [L(D)]^2}{64\pi^6\epsilon_0^2 C^6 m^{*4}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^2}\right]^{1/2}\right\}^{1/2} \qquad [8b]$$

where

$$J(D) = \frac{1}{\Gamma(5/2)}\int_0^\infty \frac{x^{9/2}\,e^{-x}\,dx}{x^3 + D} \qquad D = \frac{N^2 e^4 \lambda^2 \rho_0^2 \Gamma(4) g}{4\pi^2 C^2 m^{*2}}$$

$$L(D) = \int_0^\infty \frac{x^3\,e^{-x}\,dx}{x^3 + D} \qquad g = \frac{\Gamma(4)}{[\Gamma(5/2)]^2}$$

where N is the carrier concentration, ρ_0 the d-c resistivity, λ the wavelength, m^* the conductivity effective mass, e the charge on electron, and C the velocity of light. All the symbols have their standard meanings. K_L is the dielectric constant of the intrinsic semiconductor at long wavelengths, and D is a convenient parameter in the integrals. The choice of the positive or negative sign is dictated by the fact that n and k must be real.

These solutions are applied to Eq. [7a] and [7b] to calculate the phase shift. It can be shown that as the impurity concentration decreases, the index of refraction approaches the intrinsic index of refraction and the extinction coefficient approaches zero. For the first phase shift, ϕ_1, with a lightly doped layer, less than $10^{17}/\text{cm}^3$, and the wavelength region between 5 and 35μ, the phase shift is π, and not a function of the wavelength.

Since no such convenient approximation may be made for the second phase shift, these equations were programmed for an IBM 7094 computer and solved numerically (13). Figure 2 shows $\Phi_2/2\pi$ plotted as a function of wavelength for various substrate resistivities for N-type silicon. Figure 3 shows the same parameters plotted for P-type silicon. The phase shift varies from zero to π as the wavelength or carrier concen-

tration increases. These phase shifts are then used in Eq. [5] and [6] to calculate the layer thickness.

Discussion

The best and most general procedure found for calculating epitaxial layer thickness from the interference pattern is: (*I*) Knowing the resistivity of the substrate, determine the orders of the maxima and minima observed. (*II*) Calculate the thickness from the order using the phase shift correction.

Table I shows a sample order calculation for an N/N+ epitaxial layer. Φ_1 has been replaced by π and the terms factored to yield the 1/2 in the uncorrected order. In all of the calculations presented, all computations involving wavelengths are taken from the reference number zero which was the longest wavelength valley occurring in the spectrum. The calculated order generally differs from a whole integer, for a maximum, or a half integer, for a minimum by less than 0.2. This deviation is felt to be caused by small errors in reading the wavelengths of maxima or minima, which cause significant errors when the difference in wavelengths is taken. If the order calculation spans many fringes, the average error is generally less than 0.1. Because of this effect, samples with thick layers may be treated differently. By combining Eq. [5] and [6] and solving for the thickness

$$h = \frac{m\,\lambda_1\,\lambda_2}{2(n_1^2 - \sin^2\theta)^{1/2}\,(\lambda_1 - \lambda_2)}\left[1 - \frac{\phi_{21} - \phi_{22}}{2\,\pi\,m}\right] \quad [9]$$

Equation [9] may be used when the pair of wavelengths, used for the calculation, span many fringes so that the "difference" errors are small, and m is large.

When the correct order of one maximum or minimum has been determined, the orders of other maxima and minima may be assigned. Note that when the order is corrected, no difficulty is experienced in assigning whole or half integers to the peaks or valleys.

Table II shows the thickness calculations for the same sample treated in Table I. The thicknesses calculated without correction show a systematic error while the corrected values agree quite well. The uncorrected thickness. calculated by

$$h' = \frac{m\,\lambda_1\,\lambda_2}{2(n_1^2 - \sin^2\theta)^{1/2}\,(\lambda_1 - \lambda_2)} \quad [9a]$$

has a spread of 13.6% while the corrected thickness has only a 2.6% spread.

Table II. Thickness calculation for the same sample as in Table I

The average corrected thickness is 7.01μ ± 1.3% and average uncorrected thickness is 7.62μ ± 6.8%.

Reference number	λ(μ)	Order P	$\frac{\Phi_2}{2\pi}$	Corrected thickness h(μ)	Uncorrected thickness h′(μ)
−1	27.90	2.0	0.214	6.98	7.59
0	21.95	2.5	0.155	6.97	—
1	18.30	3.0	0.136	7.11	8.15
2	15.40	3.5	0.115	7.07	7.63
3	13.05	4.0	0.099	6.93	7.12

Table III. Order calculations for thin N/N+ silicon sample

An approximate thickness of 4μ was used to calculate an approximate order of 1.26. The correct order for that peak is therefore 1.0. The substrate resistivity, ρ_2 = 0.006, ohm-cm.

Reference number	λ(μ) Max	λ(μ) Min	Uncorrected order $\frac{m\lambda_0}{\lambda_0-\lambda_j}+\frac{1}{2}$	$\frac{\Phi_{2j}\lambda}{2\pi}$	Order correction	Corrected order-P_j Max	Corrected order-P_j Min
−1	28.80		1.37	6.05	0.38	0.99	
0		17.25	—	2.39	—		—
1	12.20		2.26	1.16	0.25	2.01	

It should be noted that the correction decreases the calculated thickness. The correction has its largest effect when the order is small. For $P = 2$, a typical correction is −10%. The correction improves the agreement between the staining technique and infrared technique since the infrared technique, without correction, always reads thicker. It was reported by Pliskin and Grochowski (3) that the difference between the two techniques ranged up to 11%.

Table III shows order calculations for a thin N/N+ epitaxial silicon sample. It was noted by Pliskin (4) that if the approximate thickness is known within wide limits, the order may be deduced. This is true for low orders (1, 2, and 3) as incorrect choices of the order change the thickness by at least 33%. This change is at least 50% for orders 1 and 2. Order zero, if never observed as the second phase shift (ϕ_2), never reaches π.

Table IV shows thickness calculations for the same thin sample. These data exhibit the self consistency observed on the thicker sample even when the order correction is 30% for first order. This exhibited self consistency extends the range of the infrared technique below 5μ.

Tables V and VI show similar calculations for a P/P+ epitaxial silicon sample. The data have been treated in the same manner as the N-type samples.

In conclusion, the shift in phase of infrared radiation upon reflection from an epitaxial layer-substrate interface has been calculated. When this phase shift is included in the calculation of epitaxial layer thick-

Reaction of Tantalum with Molten Cerium-Cobalt Alloys

Felix B. Litton and John C. Biery

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

The reaction of tantalum with molten cerium-cobalt was investigated by heating alloys containing from 6 to 18 w/o cobalt in sealed tantalum capsules at temperatures from 600° to 800°C and at times from 4 to 2069 hr. At 800°C, with 18 w/o cobalt-cerium alloy, reaction layers formed which varied in thickness with time from 5 to 16μ. The reaction layer consisted of two separate zones. The inner diffusion zone contained discrete particles of cerium distributed in a tantalum-cobalt alloy, TaCo or Ta_2Co. The composition of the molten cerium-cobalt alloy, temperature, and reaction time controlled the composition and growth of the reaction layer. The tantalum-cobalt phase identified as Ta_2Co was predominant in layers formed from cerium-cobalt containing 12 w/o cobalt, while either TaCo or Ta_6Co_7 was predominant in the layer formed from cerium-cobalt containing 18 w/o cobalt. The sequential steps in the formation of the reaction layer are as follows: dissolution of tantalum, precipitation of Ta-Co crystals on the Ta surface, diffusion of Co into and Ta out from an inner diffusion zone, and continued precipitation of a tantalum-cobalt alloy from the liquid cerium-cobalt melt onto the outer layer. The growth rate at long times was controlled by diffusion of tantalum and cobalt through the outer precipitation layer.

Low melting plutonium alloys have been proposed for fuels in fast breeder power reactors to eliminate the problem of irradiation damage and to simplify handling and reprocessing procedures (1, 2). Alloys of potential value occur in the Pu-Fe and Pu-Ce-Co systems (3-5). The Los Alamos Molten Plutonium Reactor Experiment (LAMPRE) was operated to determine the problems that might be encountered when these fuels are used under operating conditions. The core of the LAMPRE reactor consisted of an array of tantalum capsules containing plutonium fuel alloy (6-8). Tantalum and tungsten had been observed to be satisfactory materials for alloy containment, but tantalum was preferred because of the greater ease in its fabrication.

In out-of-pile experiments with the Pu-Co-Ce fuel and Co-Ce binary alloys held in tantalum capsules, a cobalt-tantalum reaction layer was observed to form. To understand better the mass transfer processes of tantalum in the Co-Ce-Pu fuels, a knowledge of the characteristics of the reaction layer was necessary. This study was initiated in an attempt to determine these characteristics by observing layers formed from the Co-Ce alloys.

Experimental

Materials.—Tantalum capsules, 1½ in. long, were fabricated from 0.025 in. wall x 0.430 in. O.D. seamless tubing. End caps were stamped from sheet stock. Capsules were fabricated from powder metallurgy, double arc-melted, and electron-beam-processed material. The parts were degreased and dipped in hydrofluoric-nitric acid mixture prior to attaching the end cap by welding, after which the capsule blanks were vacuum annealed for 1 hr at 1450°C.

Cerium base alloys were prepared to contain nominally 6, 12, and 18 w/o Co by heating 99.8 w/o Ce with 99.5 w/o Co to 900°C for 2 hr in tantalum crucibles under a helium atmosphere. During alloying, the melts were stirred with helium and filtered through a tantalum frit. Prior to their use, the cerium base alloys were analyzed for cobalt, then stored in a vacuum desiccator.

Procedure.—The reaction between tantalum and Ce-Co alloys was studied by heating 5g of each alloy composition in a tantalum capsule for a specified time at a given temperature. The cerium base alloys were cut, weighed, and placed in the capsules in air, and sealed in a welding box under argon. The capsules were placed in a copper block and heated under a positive pressure of 10 cm of helium. The temperature of the furnace was regulated from a thermocouple centrally located in the copper block to within ± 5°C of the desired temperature.

After heating, transverse sections were cut from the tantalum capsule for metallographic examination and chemical analysis to determine the structure and amount of cobalt in the reaction layer. The cerium-cobalt alloy was dissolved from the transverse section in dilute hydrochloric acid, and, after visually measuring the layer thickness, the weight of cobalt in the layer was determined by chemical analysis and re-

ported as milligrams cobalt per square centimeter of surface area.

Description of Reaction Layer Growth

Photographs of the reaction layer formed on tantalum in contact with 6, 12, and 18 w/o cobalt-cerium alloys for 96 hr at 800°C are shown in Fig. 1, 2, and 3. The tantalum capsules were cut longitudinally to produce the section shown at the right in each figure and the Ce-Co alloy dissolved from one-half of the capsule with dilute hydrochloric acid revealing the section shown at the left in each figure. A reaction layer was formed above the liquid meniscus in each of the capsules. However, a reaction layer was not formed along the surface in contact with the bulk liquid with 6 and 12 w/o Co-Ce alloys. With these alloys, the areas in direct contact with the melt or with heavy films above the liquid surface show an etched appearance. The reaction layer in Fig. 1 and 2 is the silvery zone above the etched areas. In Fig. 2 a fairly heavy layer of reaction layer crystals has grown immediately above the etched area. The Co-Ce alloy has climbed the walls of the capsule and has covered all surfaces with a thin liquid layer. For the 6 and 12 w/o Co-Ce alloys at this length of exposure, the reaction layer forms only on the surfaces covered with this very thin film. In contrast, as shown in Fig. 3, a reaction layer was formed above the meniscus and in the bulk liquid contact area with molten 18 w/o Co-Ce alloy.

Structure of reaction layer.—The reaction layer consists of a diffusion zone adjacent to the tantalum and a crystalline deposit in contact with the cerium-cobalt alloy. Electron microprobe analysis indicated that the diffusion zone contained cerium globules distributed in a tantalum-cobalt phase and the crystalline deposit consisted of an impurity-free tantalum-cobalt phase.

X-ray and microprobe analyses showed that two distinct tantalum-cobalt phases were included in the reaction layer zones. However, they also indicated that the exact composition of these phases varied somewhat. Therefore, in this report these phases are titled A and B. The A phase is nominally Ta_2Co while the B phase is nominally TaCo with some solubility of cobalt existing in both phases. For instance, the composition of the B phase was found to range from Ta_6Co_7 to Ta_7Co_6.

The composition of the reaction layer zones varies with changes in temperature and cobalt concentration in the melt. Two cobalt-temperature regimes exist. In the upper one B is the stable phase in contact with the melt; in the lower regime A phase is stable. The

800	15
700	18

* A phase is stable below this concentration while B phase is stable above this concentration.

temperature-cobalt concentration boundary between the regimes is shown in Table I.

The inner diffusion zone which may not be in direct contact with the melt can contain layers of both A and B phase. In the upper cobalt-temperature regime, microprobe analysis has shown the outer precipitation zone to be B phase and the inner diffusion zone to be mainly B phase with a possible thin zone next to the metal being A phase. In the lower regime, both the inner and outer zones contain only A phase.

Examples of the above phenomena are shown in Fig. 4 and 5. The two-layered structure in Fig. 4 has been emphasized by a selective etching procedure. The outer precipitation crystals resisted etching and appear much as they did in the as-polished state. The inner diffusion zone was attacked much more rapidly by the etch. This layer was produced with 18 w/o Co-Ce at 700°C in 1024 hr.

The outer precipitation layer appears to grow in horizontal platelets of relatively uniform thickness across the tantalum diffusion zone surface. The average thickness of the platelets is approximately 5-6μ, but the width of the platelet may be as great as 300μ. In Fig. 5 a very large crystal which had fallen off the tantalum surface is shown. Note the well-formed corners of 120°. This particular crystal is 330μ long and 200μ wide. These crystals were formed in 18 w/o Co-Ce at 740°C in 832 hr.

Growth Rates of Reaction Layer in Bulk Liquid Contact Area

6 w/o Cobalt-cerium.—With 6 w/o cobalt-cerium alloy no reaction layer was formed on tantalum in contact with the bulk liquid phase at temperatures from 600° to 800°C and periods of time up to 2069 hr.

12 w/o Cobalt-cerium.—Reaction layers were formed with 12 w/o cobalt-cerium alloy at 800°C but not at lower temperatures. However, even at 800°C the layers formed only after relatively long periods of time, *i.e.*, 1024 and 2069 hr. The reaction layer thicknesses observed at these times were 5.5μ and 8.5, respectively.

Fig. 4. Structure of reaction layer. Two zones are shown: the diffusion zone adjacent to the tantalum, covered by crystals identified by x-ray analyses as B phase. Etched. Magnification 420X.

Fig. 5. B phase precipitation platelet, 330μ long x 200μ wide x 5μ thick.

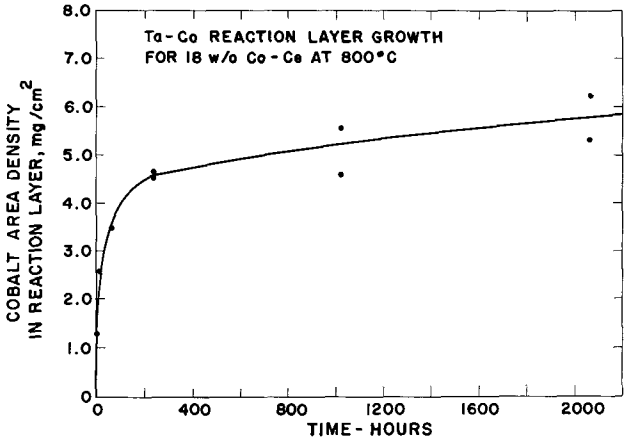

Fig. 6. Reaction layer growth as a function of time, 18 w/o Co-82 w/o Ce at 800°C.

18 w/o Cobalt-cerium.—800°C.—The growth rate data for tantalum with 18 w/o cobalt-cerium alloy at 800°C are shown in Fig. 6 and in Table II. At this temperature a reaction layer was formed in periods as short as 4 hr. The reaction layer grew very rapidly in the first 250 hr. Thereafter, the growth essentially stopped. The thickness observed after 2069 hr as estimated from the cobalt density data was 16.7μ.

The thicknesses of the reaction layer in microns as obtained from photomicrographs are also tabulated in Table II for the 18 w/o Co-Ce alloy at 800°C. Visual

Table II. Ta-Co reaction layer growth for 18 w/o Co-Ce at 800°C

Time, hr	Cobalt area density in reaction layer, mg/cm²* Experimental***	Smoothed***	Layer thickness,** μ

240	4.51	4.58	13.3
1024	4.64 4.57 5.53	5.20	—
2069	5.31 6.22	5.76	—

* Determined by chemical analysis of ring cut from capsule.
** Determined by graphical integration of layer area on photomicrograph.
*** The estimated experimental standard deviation is 6.1%. The estimated standard deviation of the smoothed curve is 2.0%, and a 95% confidence width about the smoothed curve is ± 6.6%.

Table III. Time required for reaction layer to start forming when in contact with bulk cobalt-cerium melts ($A/V = 5$ cm^{-1})

	Time to first formation, hr		
	600°C	700°C	800°C
6 w/o Co-Ce	>2069	>2069	>2069
12 w/o Co-Ce	>2069	>2069	1024
18 w/o Co-Ce	>2069	256 (Intermittent thereafter)	4

readings at 1024 and 2069 hr were not obtained. These data are not as reliable as the cobalt density data since the visual thicknesses were measured from one small area of the layer while the chemical data were obtained from the layer formed on a complete ring cut from the capsule. Comparison of the visual and chemical data indicates that the microns of thickness per milligram per square centimeter of cobalt density decreased from 3.7 at 4 hr to 2.9 at 240 hr. This variation would indicate that the composite layer was changing in cobalt composition with time and was becoming more dense.

700°C.—At 700°C with 18 w/o Co-Ce, reaction layers formed after 256 hr of contact time. However, even after this initiation period subsequent tests at longer periods did not consistently produce reaction layers. For instance, at 256 and 1024 hr the observed cobalt density in the layer was 3.94 and 6.88 mg/cm^2, respectively. But at intermediate and longer times of 625 and 2069 hr no layer was produced whatsoever. This type of behavior seems to indicate that the 18 w/o—700°C conditions represents one of the boundary points between the fast and slow reactive regimes.

600°C.—At 600°C with the 18 w/o melt no reaction layer was formed in the bulk liquid contact zone in periods up to 2069 hr.

A summary of the minimum observed times to form reaction layers in contact with the bulk liquid phase is given in Table III.

Effect of Cobalt Concentration on Reaction Layer Formation Rate

The results from the 12 and 18 w/o Co-Ce melts at 800°C show a large change in reaction layer formation rate with change in cobalt concentration. To test the effect more exactly, a series of capsules was run for 96 hr at 800°C with melt concentrations ranging from 11 to 16 w/o cobalt in 1% increments. The results are shown in Fig. 7. Up to 14 w/o cobalt no layer was formed. Then almost dramatically, the layer started to grow rapidly at 15 and 16 w/o cobalt. The measured cobalt density in the layer increased from < 0.01 mg/cm^2 at 14 w/o to 2.4 mg/cm^2 at 15 w/o. A 1% increase in cobalt concentration increased the reaction rate by a factor of 200 or more.

Effect of Surface Area to Volume Ratio on Reaction Layer Formation

The ratio of tantalum contact surface area to melt volume (A/V) greatly influences the ability of the reaction layer to form, especially in the low concentration-temperature regime. For instance, reaction layer is always found above the meniscus where a thin layer of melt, 10-20μ thick, has crept up the wall. Here the A/V ratio is 500 to 1000 cm^{-1}. In the same systems, 6 and 12 w/o cobalt at 600°-800°C, no reaction layer is formed at times up to 1000 hr on areas in contact with the bulk liquid phase where the A/V ratio is approximately 5 cm^{-1}.

To investigate the area to volume ratio effects, finely divided tantalum powder (30μ diameter particles) was added to 6 w/o Co-Ce and was run at 600°C for 96 hr. In this short period a reaction layer formed on the tantalum wall in direct contact with the powder, while no reaction layer was found on the wall where no powder resided. The A/V ratio in the powder zone was approximately 250 cm^{-1}.

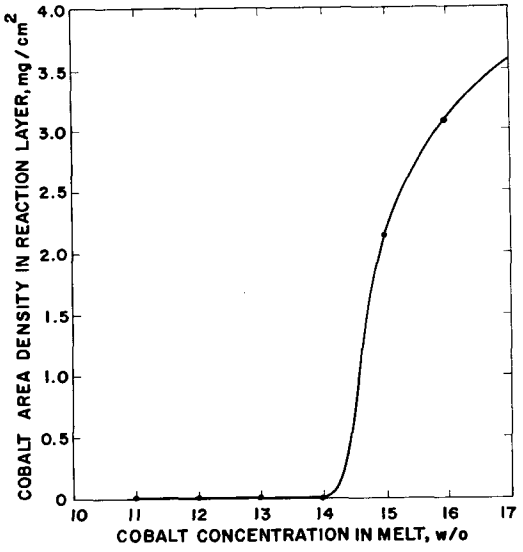

Fig. 7. Reaction layer thickness as a function of cobalt concentration in melt; 96 hr at 800°C.

Mechanical Instability of Reaction Layer

A number of experiments have been run which indicate that the outer precipitation layer cannot stand excessive mechanical or thermal shock. Temperature cycling and melt freezing cause the precipitation crystals to disengage from the diffusion zone. The crystal shown in Fig. 5 is one of many hundreds of crystals which fell off from the wall of a capsule when the melt was frozen, capsule inverted, and alloy remelted. Also, a few runs at temperatures of 900°C and above indicate that the precipitation layer grows and spalls with no obvious thermal perturbations.

The instability of the precipitation zone indicates that the over-all reaction layer might not be protective and self-healing if it is thermally perturbed. The layer growth is slowed by the formation of the precipitation zone. If it falls off, then the total layer can continue to grow until more crystals cover the surface. A worse case which could cause catastrophic failure is one in which the precipitation crystals detach but loosely hang onto the wall. The dissolving tantalum can precipitate on the detached crystals which now serve as a local sink. The dissolution process is unimpeded since the precipitation zone is not re-formed to inhibit the diffusion of cobalt into and tantalum out from the diffusion zone.

Mechanism for Formation of Reaction Layer

The following stepwise mechanism is proposed to explain the observed phenomena.

1. Dissolution of tantalum into the melt. Before the layer can grow tantalum must dissolve into and saturate the melt. The rate of dissolution appears to be a strong function of cobalt concentration. In the high cobalt-temperature regime, the rate is very fast while in the low regime the rate appears to be quite slow. During this period cobalt does not diffuse into the tantalum wall. The cobalt does attack the tantalum and probably forms Ta-Co A or B phase molecules or subcritical sized crystallites on the surface. While the melt is unsaturated, these crystallites are unstable and immediately dissolve. In this manner tantalum and cobalt transfer back into the liquid metal.

2. Supersaturation of the melt and precipitation of stable crystals on the tantalum surface. The melt becomes supersaturated with respect to the A or B phase crystals and precipitates these crystals on the tantalum surface. The melt is not saturated with respect

to the tantalum metal since the tantalum is in a higher energy state in the metal wall then in the Ta-Co crystals.

3. Formation of diffusion zone. With the precipitation of the crystals, the diffusion zone immediately starts to form. The cobalt attacks the tantalum surface and forms the A or B phase crystallites. Now, however, stable crystals of A or B phase are in direct contact with the reactive surface, and the new crystallites are stabilized in the local area of the precipitate. The newly formed reaction compound does not dissolve into the melt since the melt is now saturated with respect to the stable crystals.

As the reaction proceeds, the reactive zone moves inward into the metal. Also, the growth can move out radially from the initial precipitation crystal. (Note: Circular colonies of crystals and reactive zones have been noted on tabs immersed in the Co-Ce alloy.)

By observing growth on thin foils of known thickness, the original tantalum surface is readily identified as the boundary between the precipitation zone and the diffusion zone. Therefore, as the Ta-Co reaction zone is formed, tantalum must diffuse outward toward the melt to maintain volume and mass continuity since the Ta-Co compounds are less dense than tantalum itself. The outward current of tantalum can dissolve into the melt because the melt is saturated with respect to the A or B phase crystals and not with respect to the tantalum metal.

4. Continued growth of the A or B phase crystals. The tantalum which is dissolving into the melt from the diffusion zone precipitates on the crystals which are near by. The A or B phase crystals then continue to grow in platelets on the surface and to move laterally across the surface. Figures 8 and 9 show two stages in this development of the crystalline layer as grown from 18 w/o Co-Ce at 800°C.

5. Slowing down of layer growth as precipitation crystals cover the surface. Since the precipitation crystals are well-formed flat platelets, they present a diffusion barrier to the diffusing cobalt and tantalum. Therefore, the process is essentially terminated when the crystals cover the surface. Slow growth can occur since there must be a small but finite diffusivity for the cobalt and tantalum in the precipitation layer.

Summary

Observed phenomena.

1. For temperatures and cobalt concentrations below 18 w/o at 700°C and 15 w/o at 800°C, a reaction layer forms in contact with the bulk fluid only after long incubation periods of 1000 hr or more. (A/V = 5 cm^{-1}).

2. For temperature-cobalt conditions above the limits in 1, the reaction layer forms at short times of 4 hr or less in the bulk phase contact area.

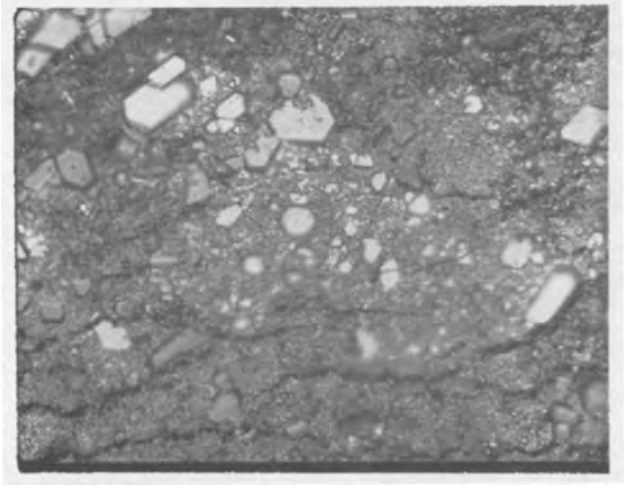

Fig. 8. Hexagonal B phase crystals in an early stage of development

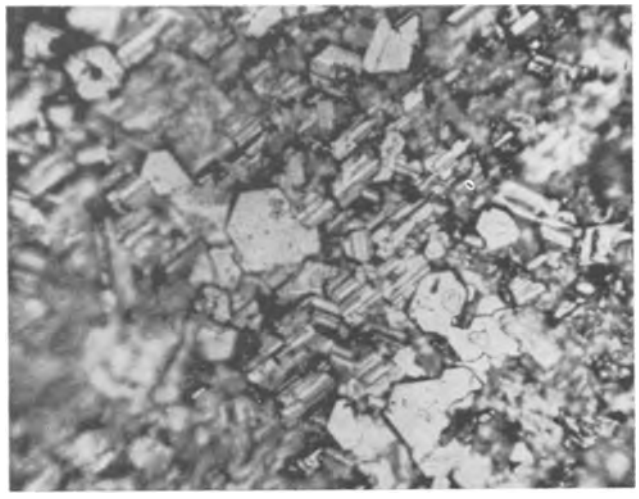

Fig. 9. A heavy layer of B phase crystals as developed at long times

3. For all concentrations and temperatures tested (6-18 w/o Co and 600°-800°C) the reaction layer formed in contact with the thin liquid layer above the meniscus in periods of 4 hr or less. (A/V = 500-1000 cm^{-1}).

4. Microprobe and chemical analysis show crystals in equilibrium with the melt to be A phase (approximately Ta_2Co) for the low temperature-cobalt conditions and to be B phase (approximately TaCo) for the high temperature-cobalt conditions.

5. Microprobe and chemical etching indicate that two layers form, one on the outside of the original surface and one inside the original surface. The outer layer appears to be crystals precipitated from the melt since they are well formed and contain no impurities. The inner layer appears to be a diffusion zone of Co in Ta since it etches easily and contains impurities of cerium. The outer crystals are A or B phase as indicated in item 4 above. The matrix of the inner layer is nominally A phase for the low temperature-concentration cases and B phase for the high temperature-concentration systems.

6. Evidence indicates that crystal precipitation must occur first before the cobalt diffusion zone can form.

Proposed Mechanism

The reaction layer appears to grow with the following sequence of events.

1. Tantalum dissolves into the melt.
2. The melt becomes supersaturated and precipitates A or B phase intermetallic crystals.
3. The cobalt diffusion zone starts to form.
4. Tantalum diffuses out of the diffusion zone, dissolves into the melt, and back precipitates on the A or B phase crystals.
5. The layer growth almost terminates when the diffusion zone is completely covered with thick crystals.

Proposed Cobalt Effect

1. The tantalum is attacked by the cobalt. The main effect is to form Ta_nCo nuclei which immediately dissolve into the melt.
2. The reverse reaction of Ta_nCo precipitation does not occur until the melt is supersaturated and can grow crystals above a critical size.
3. As temperature and cobalt concentration are lowered, the cobalt reaction produces Ta_2Co instead of TaCo. The Ta_2Co reaction proceeds much more slowly than does the TaCo reaction.

Stability of Layer

1. The precipitated crystals are not securely affixed to the tantalum surface. These crystals tend to spall off with thermal or physical shock. With spallation the cobalt-tantalum reaction is allowed to continue.

Acknowledgment

The authors wish to thank Carl Cushing for his help in obtaining data on the stability of the reaction layer. Also, the help of Marguerite Coleman and Doreen Bourne in preparing the manuscript is greatly appreciated.

Standard Molar Free Energy of Formation of Uranium Dicarbide and Uranium Sesquicarbide by Electromotive Force Measurements

W. K. Behl and J. J. Egan

Brookhaven National Laboratory, Upton, New York

ABSTRACT

The free energy of formation of UC_2 and U_2C_3 has been determined by means of the following solid state galvanic cells operated between 700° and 900°C

$$U,UF_3(s)\,|\,CaF_2(s)\,|\,UF_3,UC_2,C \qquad [A]$$

$$U,UF_3(s)\,|\,CaF_2(s)\,|\,UF_3,U_2C_3,C \qquad [B]$$

Although UC_2 is in metastable equilibrium with carbon in cell A, results are significant. Experimental details are presented and results are compared with values obtained by other techniques.

In many cases electromotive force measurements provide a useful method for an accurate determination of the free energy of formation of compounds in liquid or solid state. In this laboratory, solid state galvanic cells

$$U,UF_3(s)\,|\,CaF_2(s)\,|\,UF_3,UC_2,C(s) \qquad [A]$$

and

$$U,UF_3(s)\,|\,CaF_2(s)\,|\,UF_3,U_2C_3,C(s) \qquad [B]$$

were employed to determine the free energy of formation of uranium dicarbide and uranium sesquicarbide, respectively, in the temperature range 700°-900°C. It has been observed from the phase diagram (1) that UC_2 is in equilibrium with carbon only at temperatures above about 1500°C. At lower temperatures, U_2C_3 is the stable phase in equilibrium with carbon. Thus in the temperature range 700°-900°C, cell A is in a metastable state. However, studies of several workers (2, 3) indicate that the transformation of UC_2 to U_2C_3 and carbon is an extremely slow process. In one experiment in this laboratory a sample of UC_2 was heated to about 900°C for more than a week, at which time an x-ray of the experiment showed no U_2C_3 in the sample. As this study has shown, despite the metastable nature of cell A, meaningful results for the free energy of formation of uranium dicarbide were obtained from this cell.

In cell A at the left-hand electrode

$$U = U^{+3} + 3e$$

and at the right-hand electrode

$$3e + U^{+3} + 2C = UC_2$$

and the over-all reaction on passing $3F$ is

$$U + 2C = UC_2$$

with the CaF_2 conducting F^- ions from right to left. Thus

$$\Delta F^\circ_{UC_2} = -3FE \qquad [1]$$

Likewise in cell B

$$2U = 2U^{+3} + 6e$$

$$6e + 2U^{+3} + 3C = U_2C_3$$

and over-all

$$2U + 3C = U_2C_3$$

with

$$\Delta F^\circ_{U_2C_3} = -6FE \qquad [2]$$

Experimental

Uranium dicarbide was prepared by mixing finely filed uranium metal with an excess of carbon powder, pressing the resulting mixture into a pellet, and heating the pellet in a graphite crucible under vacuum at 1600°-1700°C for 30-40 min in an induction furnace. An x-ray of the sample identified UC_2 and carbon.

The following procedure was employed to prepare uranium sesquicarbide. Equivalent amounts of uranium metal and carbon to form UC_2 were mixed together and heated in a graphite crucible under vacuum at 1600°C in an induction furnace for 2 hr. To this a calculated amount of uranium metal was added to yield a composition corresponding to U_2C_3. Two pellets were made of the mixture and placed in a molybdenum

crucible (one over the other) and heated at 1450°C under vacuum for 5 hr. The top pellet was then removed, crushed, and again made into a pellet and placed over the other pellet in the molybdenum cup and heated for 12 hr under vacuum. The procedure was repeated once more and finally the pellets heated at 1450°C under vacuum for 18 hr. The bottom pellet in immediate contact with molybdenum was discarded and the top pellet used for experiments. An x-ray of the sample identified it as U_2C_3.

The uranium carbides so prepared were separately crushed and mixed with UF_3, and again pressed into a pellet. A similar pellet was obtained by mixing finely filed uranium with uranium fluoride.

All the above mixing operations were performed under carbon tetrachloride to prevent uranium metal or the carbides from coming in contact with the air. Also the mixture under CCl_4 resulted in a paste, from which it was easier to obtain the pellets. Carbon tetrachloride was later pumped off by evacuating the assembled cell.

A calcium fluoride single crystal, which has been shown to conduct entirely through fluoride ions, served as the auxiliary electrolyte; molybdenum disks were used to provide the leads. The cell was then quickly assembled and evacuated for a few hours. The cell arrangement was similar to the one reported by Egan, McCoy, and Bracker (5). The cell was then filled with argon gas that provided the inert atmosphere during the course of the experiment. The temperature was gradually raised to 800°C and the cell allowed to come to an equilibrium value (generally 2-3 days); this was indicated by a steady value of emf. The emf of the cell was then measured at various temperatures. Temperature cycling did not affect the values of the cell potentials. In all cases, the cells were operated for a period of 1 month.

Results

The cell potential *vs.* temperature plots for cells A and B are presented in the curves shown in Fig. 1. The measurements for cell A were carried out between 700° and 900°C while those for cell B were carried out up to 800°C.

The free energies of formation for uranium dicarbide and uranium sesquicarbide at various temperatures calculated from Eq. [1] and [2] are shown on the right of the figure. They are also given by the equations

$$U(\beta) + 2C(gr) = UC_2(s)$$
$$\Delta F^o = -15{,}820 - 8.2T \text{ (kcal)} \quad [3]$$

$$U(\gamma) + 2C(gr) = UC_2(s)$$
$$\Delta F^o = -18{,}980 - 5.2T \text{ (kcal)} \quad [4]$$

$$2U(\beta) + 3C(gr) = U_2C_3(s)$$
$$\Delta F^o = -43{,}860 - 7T \text{ (kcal)} \quad [5]$$

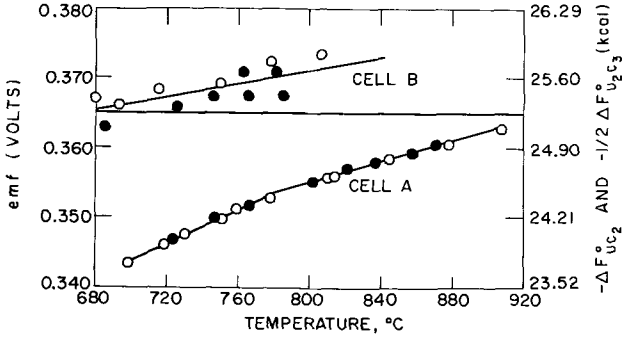

Fig. 1. Curves of emf measurements taken on cells of type A and B. Results from two separate cells are shown in each case (closed and open circles).

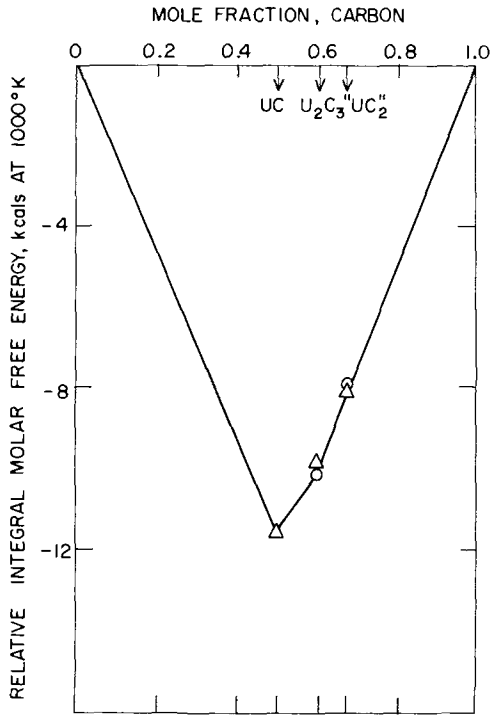

Fig. 2. Relative integral molar free energy *vs.* composition in the U-C system. The triangles represent values compiled in ref. (4). The circles represent values taken from the measurements reported here.

in the temperature range of the experiments. The precision between different cells was of the order of ±2 mv for UC_2 and ±4 mv for U_2C_3. Thus the accuracy is estimated as ±200 cal for the values reported here.

In curve A of Fig. 1, a break is observed at 780°C. This corresponds to the phase transformation of β-uranium to γ-uranium, which is known (6) to occur at 772°C.

Alcock and Grieveson (7) have measured the free energy of formation for the reaction

$$U(l) + 2C(s) = UC_2(s)$$

by measuring the uranium dissociation pressure of the carbide in equilibrium with pure carbon in the temperature range 1700°-1800°C. The free energy of formation (—27.54 kcal) extrapolated from these measurements to 1132°C (the melting point of uranium) compares very well with the value (—26.28 kcal) obtained by extrapolation from the present measurements.

An idea about the stability of the different phases in a binary system can be obtained (8) from a plot of relative integral molar free energy *vs.* mole fraction. Such a plot for the uranium-carbon system is shown in Fig. 2, in which the values of relative integral molar free energies of U_2C_3 and UC_2 obtained from the present measurements are plotted along with the literature (4) values for UC, U_2C_3, and UC_2. These values are from a thermochemical assessment using previous results from calorimetry, phase equilibria, vapor pressures, and other methods. The agreement is quite close between these values and the experimental values reported here. It is clear from the plot that at 1000°K, U_2C_3 is the stable phase in equilibrium with carbon. This is in agreement with the earlier phase diagram studies (1) for the U-C system.

Acknowledgment

The authors would like to thank Mr. John Bracker for preparing the UC_2 and U_2C_3 and for his help in assembling the cells. They are also indebted to Dr. Richard Wiswall for helpful discussions, and to Mr.

Bernard Sturm of the Reactor Division of Oak Ridge National Laboratory for supplying them with the UF_3 used in these experiments.

The Ductile-Brittle Transition in Tantalum Carbide

H. A. Johansen and J. G. Cleary

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Tantalum carbide was prepared in the composition range $TaC_{0.73}$ to $TaC_{1.26}$ and consolidated by hot pressing. Compositions at ends of the range were two phase. A modified cantilever-beam test method was used to determine the ductile-brittle transition temperature (T_{db}) at a given strain rate and for this geometry as a function of carbon content. The T_{db} range from $TaC_{0.98}$ was 1825°-1925°C, and the median nominal bend stress in this range was 23,000 psi (1617 kg/cm²). At $TaC_{0.90}$ the median nominal bend stress was at a minimum of 14,000 psi (984 kg/cm²) for the T_{db} range 1750°-1850°C. T_{db} increases approximately 150°C with increasing x across the single-phase cubic region of TaC_x.

Information concerning the high-temperature mechanical properties of refractory "hard metals" is of direct importance to their use as structural materials and to an understanding of the metallicity and mechanism of deformation of the general class of transition metal interstitial compounds.

Tantalum carbide, because of its very high melting point and good resistance to thermal decomposition, has long been of interest for many high-temperature applications, but the extreme brittleness and the absence of data on the mechanical properties at elevated temperatures have limited its consideration. In particular, knowledge has been lacking concerning the transition temperature (T_{db}) from brittle to ductile behavior, and its dependence on composition and other factors. While the T_{db} is not as well defined a physical quantity as, say density or melting point, because surface condition, porosity, second phase content, and other factors may influence T_{db}, nevertheless such information is of practical importance in understanding the limits of gross plastic flow. This work supplies new information on the ductile-brittle transition of well-characterized tantalum carbide under specific conditions.

Previous work in this field has been reported by Williams and Schaal (1) and by Williams (2) who carried out compression tests on single crystal TiC as a function of temperature, composition, and other parameters. Single crystal ZrC and NbC were also examined by Williams (2), and the behavior was found to be similar to that of TiC, although NbC was reported to have a higher hardness than either TiC or ZrC.

Experimental

Preparation of TaC_x.—Tantalum carbide compositions were prepared by direct reaction of the elements under argon in a graphite resistor furnace according to the reaction

$$Ta + xC \rightarrow TaC_x$$

for nominal values of $x = 0.8$ to 1.0. This is approximately the single-phase cubic NaCl structure region. In addition, compositions in the two-phase cubic plus hexagonal Ta_2C region, and in the cubic plus excess carbon region were prepared for comparison with the cubic single-phase TaC.

The materials used were metallurgical grade tantalum powder (Kawecki) and spectroscopic grade graphite powder (National Carbon). The tantalum metal was of 99.8% purity with oxygen the chief nonmetallic impurity (0.1%) as determined by vacuum fusion, and silicon and niobium the principal metallic impurities at 100 ppm each determined spectrographically.

Preparation of test specimens.—The tantalum carbide powders were consolidated by hot-pressing in graphite dies with 4 w/o cobalt as binder. The cobalt used was high-purity (99.999%) sponge (United Mineral). Hot-pressing was carried out by direct heating of the die by means of R. F. induction to 2000°C, and applying a pressure of 1.5 tons/in.² (211 kg/cm²). Densities obtained were between 90 and 95% of theoretical. Close to stoichiometry, dense compositions were somewhat more difficult to obtain. The compositions prepared of TaC_x were $x = 0.73$, 0.84, 0.90, 0.98, and 1.26 (1.0 + 0.26 free carbon). After compaction by hot pressing, rectangular cross-section specimens were prepared by diamond sawing to produce a rod 2 to 3 mm on a side and 5 cm long. The sawn rods were then decobalted by heating to 2000°C in vacuum to leave a cobalt content less than 0.1 w/o as determined by x-ray fluorescence analysis.

To insure homogeneity prior to testing, preliminary analysis for carbon content of the sawn specimens was made by x-ray diffraction using a 114.6 mm camera, and CuKα radiation with nickel filter. The patterns were single phase except for $TaC_{1.26}$ which showed free carbon lines, and $TaC_{0.73}$ which showed Ta_2C. The lattice parameters for the single-phase compositions were $a_o = 4.4540$Å for $TaC_{0.98}$, $a_o = 4.4427$Å for $TaC_{0.90}$, and $a_o = 4.4356$Å for $TaC_{0.84}$. The parameters are in good agreement with those reported by Bowman (3).

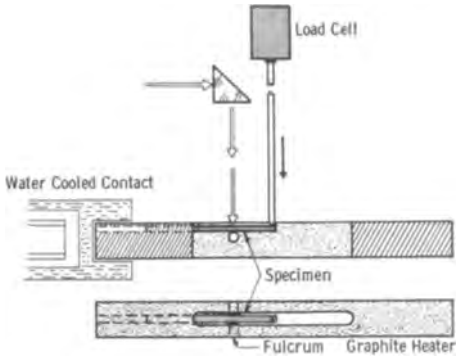

Fig. 1. Modified cantilever-beam tester (schematic)

All carbon contents were determined after the bend tests by analysis of the individual specimens for carbon by combustion. The total carbon analyses found were: carbon (in w/o) 4.57, 5.23, 5.60, 6.10, and 7.84; corresponding to x values in TaC_x of 0.734, 0.84, 0.90, 0.98, and 1.26, respectively. Analysis for free carbon was made metallographically, and, except for the composition $TaC_{1.26}$ where a deliberate excess was added, the microstructures showed no graphite. Oxygen and nitrogen were not determined, but, as found by difference on ignition, were estimated to be less than 200 ppm each in all compositions.

Test method.—A modified cantilever-beam test method was selected as the best means to compare high-temperature strength properties. The most desirable method is the standard tensile test, but this was considered too difficult and costly. The compression test was also considered, but interpretation of data is difficult and gives, finally, only the behavior in compression.

The modified cantilever-beam test apparatus is shown in Fig. 1 and consisted of a slotted graphite resistor drilled in one end to receive the specimen. The specimen was heated by radiation when a current was passed through the graphite resistor. A graphite push rod transmitted the bending force to the free end of the specimen and bending (or fracture) occurred at the graphite fulcrum. A Schaevitz-Bytrex load cell and a Brown recorder were used to record the data. All tests were conducted under flowing argon atmosphere.

The temperature was read with a Micro-optical Pyrometer and the optics corrected by checking the melting points of nickel, molybdenum, tantalum, and tungsten. Temperatures were read on the specimens at the point of maximum stress directly above the fulcrum. No correction was made for emissivity of TaC since the dependence of the spectral emissivity on carbon content was not known. The apparent temperatures reported here are lower than the true specimen temperatures by an estimated 25°-50°C, depending on the temperature range of the test.

The test specimens were brought to a predetermined temperature under no-load conditions, then the drive of the test machine was started. The test proceeded (when ductile) to a total deflection of 2.5 mm (0.1 in.) at a deflection rate of 0.9 mm/min (0.0354 in./min). The moment arm in all tests was 1 cm (0.394 in.). The deflection of 2.5 mm was selected because this deflection gave only a 3% change, due to downward motion of the end of the specimen, in the length of the moment arm.

Ductile bend specimens are shown in Fig. 2. The top specimen is before test, the middle specimen is to the 2.5 mm deflection, and the bottom specimen bent to approximately 45° without failure.

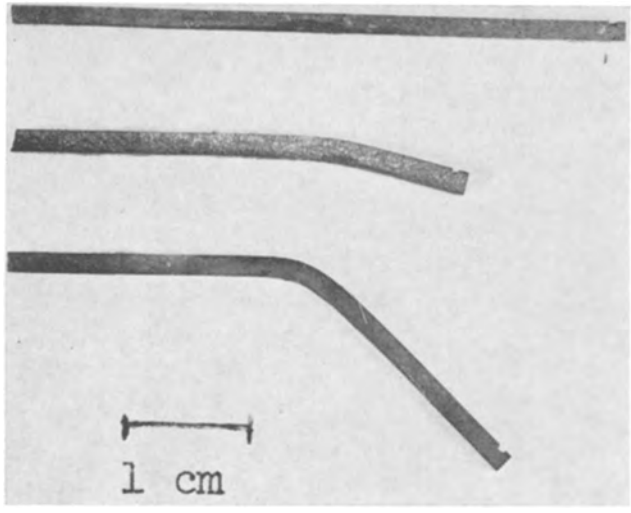

Fig. 2. Bend specimens

Results and Discussion

The maximum load obtained at brittle fracture, or at 2.5 mm (0.1 in.) deflection in ductile bending, was used in the standard beam stress formula to calculate the nominal bending stress, σ, *i.e.*, the maximum tensile strength and maximum compressive stress

$$\sigma = \frac{Mc}{I} \text{ and } M = fl,\ c = \frac{h}{2},\ I = \frac{bh^3}{12}$$

where f is load, l is specimen arm length, h is specimen cross-section height, and b is specimen cross-section width.

Since the beam formula for bending stress is properly applicable only in the elastic region, the results reported here, which include both elastic and ductile deformation, are designated nominal bending stresses. The values should be used only for comparison within the TaC_x compositions. However, tungsten rod tested in this equipment showed a value of bending stress of 16,410 psi (1153 kg/cm²) at 2270°C, in reasonable agreement with published values of tensile stresses in tungsten at elevated temperature (4).

It should be pointed out that a positive influence of strain rate on critical resolved shear stress for TiC was found by Williams (2). TaC should show the same behavior. Values for the nominal bending stress reported here refer only to the specific experimental conditions and particularly to the specific deflection rate of 0.9 mm/min (0.0354 in./ min).

Stresses for each composition were plotted against temperature, and results are shown in Fig. 3. For the compositions x = 1.26, 0.98, 0.90, and 0.84, a T_{db} transition region of about 100°C width was obtained. That is, at temperatures above the region all tests gave ductile behavior, and below, all brittle. Within the region both ductile (D) and brittle (B), as well as ductile-brittle (DB) behavior occurred. The last type of deformation (DB) was characterized by initial ductile bending, followed by brittle failure before the 2.5 mm (0.1 in.) deflection was obtained. For the composition x = 0.73 a narrow transition region of 100°C could not be defined; instead, the transition occurred over the temperature interval 1500°-1950°C and was all (DB) behavior. Nominal stress values averaged about 27,000 psi in this region. This high value was attributed to the presence of the subcarbide Ta_2C in the composition $TaC_{0.73}$. Values for the room temperature bend stresses were for values of x: 0.73 = 56,694 psi (3986 kg/cm²), 0.84 = 16,906 psi (1189 kg/cm²), 0.90 = 23,418 psi (1646 kg/cm²), 0.98 = 20,236 psi (1423 kg/cm²), and 1.26 = 43,498 psi (3048 kg/cm²).

A specimen of $TaC_{1.26}$ was polished with 6μ diamond powder on copper, but no particular effect of polishing on bend behavior was noted for this composition. This is not surprising since the presence of internal defects due to a large excess of free graphite in the microstructure would override the influence of purely surface defects.

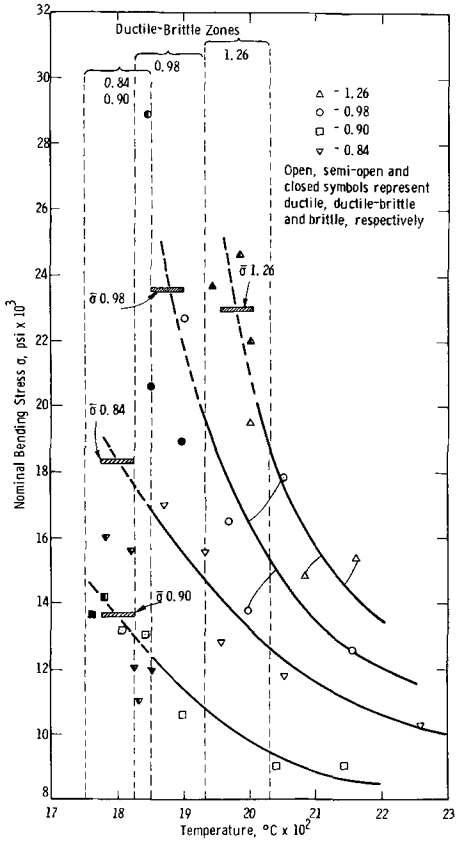

Fig. 3. Stress *vs.* temperature for $TaC_{0.84}$ to 1.26

A gas-carbided specimen of TaC showed a brittle fracture at 2030°C, which was a higher temperature than for $TaC_{1.26}$. The only discernible difference between gas-carbided TaC and the hot-pressed material close to stoichiometry ($TaC_{0.98}$) was a slightly smaller grain size of the gas-carbided TaC. However, a variation in grain sizes between 3 and 14 ASTM (70-5μ) of hot-pressed TaC in compositions near stoichiometry showed no particular effect in either bending stress or T_{db}.

If for each composition a curve be drawn from the ductile region and extrapolated into the midpoint of the ductile-brittle zone, then a median stress, $\bar{\sigma}$, as shown in Fig. 3, is obtained. A plot of the median stress data, $\bar{\sigma}$, *vs.* the carbon content x in TaC_x is shown in Fig. 4. The curve is seen to be nearly constant between $\bar{\sigma}_{0.98}$ and $\bar{\sigma}_{1.26}$ with a slight falling off in stress possibly due to excess carbon in the two-phase composition $TaC_{1.26}$ The curve then falls sharply from $TaC_{0.98}$ to a minimum at $\bar{\sigma}_{0.90}$ and rises sharply to $\bar{\sigma}_{0.84}$ and is shown directed toward the higher average values (~27,000 psi) in the Ta_2C-TaC two-phase region.

A minimum in the room temperature ultimate tensile and transverse rupture strength has also been reported at $TaC_{0.8}$ by Santoro (5). The shift in the minimum to $TaC_{0.90}$ shown in our work may be due to the difference between room temperature and elevated temperature measurement. The implications of a pronounced minimum well within the cubic single-phase region are not readily understood, but as suggested by Santoro (5), this effect may be connected with a transition in the electronic structure.

Figure 5 shows the results of plotting the mid-point temperature of the ductile-brittle transition region for each composition against the carbon content x in TaC_x. An increase in T_{db} of approximately 150°C is found with increasing x across the single phase cubic region of TaC_x.

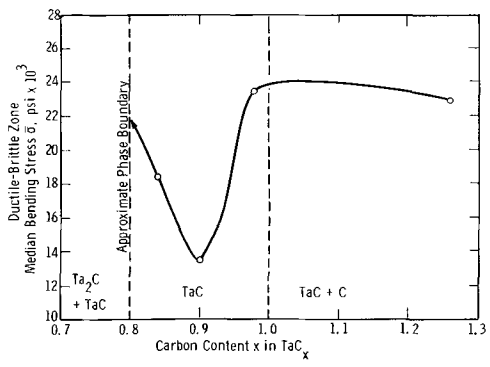

Fig. 4. Median bending stress $\bar{\sigma}$ in ductile-brittle zone *vs.* carbon content x in TaC_x.

The data show that the ductile-brittle transition range for polycrystalline TaC at or near stoichiometry is between 1850° and 1950°C, and the average nominal bending stress in this region is 23,000 psi (1617 kg/cm²). This is in reasonable agreement with a value of 17,600 psi (1237 kg/cm²) at 2000°C reported by Shaffer (6).

Examination of the microstructures of ductile, ductile-brittle, and brittle deformation and fracture showed no discernible differences in the region of stress. Brittle fracture was entirely intergranular.

Cobalt was used as a sintering aid as it is one of the best for this purpose, and its use allowed much lower hot-pressing temperatures and shorter sintering times at high temperature. Carbon pick-up from graphite dies was thus avoided or minimized. Residual cobalt (less than 0.1 w/o after vacuum decobalting) could have had a possible influence on the deformation at high temperatures. However, the existence of a carbide skeleton in various carbides such as TiC-WC-Co at cobalt contents up to 15% has been reported by Kreimer, Vakhorskaya, and Baranov (7), and the bending strength was reported to be independent of the cobalt content between 20° and 500°C. A continuous carbide skeleton was found for WC-Co containing less than 10% Co by Dawihl (8). Klimenko (9) reported that Cr_3C_2 with even 30% Ni preserved a carbide skeleton, and specimens with 5% and 15% Ni had considerable bending strength up to 1100°C. It should be reasonable to conclude that, on the basis of the evidence for strong carbide skeletons formed in various other systems as well as TaC_x, and for the change in T_{db} with change in carbon content, the effect of residual Co was removed, or at least minimized.

Williams and Schaal (1) have discussed the influence of increasing the C/metal ratio in single crystal TiC_x. They found the critical resolved shear stress to

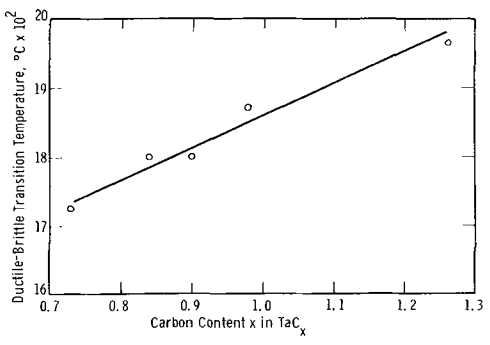

Fig. 5. Ductile-brittle transition temperature *vs.* carbon content x in TaC_x.

increase with increasing x. This also appears to be the case with TaC_x where the nominal bending stress increases with x above $x = 0.90$. The T_{db} for polycrystalline TaC_x of 1725°-1980°C is much higher than the 800°-1100°C range reported for single crystal TiC_x. At 1100°C all compositions of single crystal TiC_x were reported to exhibit plastic flow independent of the Ti/C ratio (1).

Tantalum carbide, in common with the other transition metal carbides, shows a high melting point and high hardness. This indicates some degree of covalent or other tight bonding. On the other hand, the high electrical and thermal conductivity indicate some degree of metallic-type bonding. Plastic deformation in metals occurs by dislocation movement, and the presence of vacancies in TaC due to substoichiometry might be expected to lead to the strengthening of the TaC lattice by a dislocation-vacancy mechanism. This strengthening behavior is observed in TaC_x for x values less than 0.9. Since, however, the TaC_x lattice is strengthened above $x = 0.9$ by addition of carbon (or decreasing carbon vacancies) in a fashion similar to that of TiC, we may conclude with Williams and Schaal (1) that a vacancy-dislocation interaction is less important as a strengthening mechanism in this composition range than an increase in Peierls stress (or other source of lattice resistance).

Above the ductile-brittle transition temperature the strength does not appear to depend as strongly on the C/Ta ratio as in the ductile-brittle region. This may indicate that once the source of lattice resistance is thermally removed, the material tends to react in a uniform manner, regardless of carbon content.

Summary

1. Polycrystalline TaC_x has been examined by a modified cantilever-beam test method to obtain the ductile-brittle transition temperature (T_{db}) as a function of x.

2. Nominal bend stresses as a function of temperature and carbon content were determined. An average value in the ductile-brittle transition region for $TaC_{0.98}$ (1850°-1950°C) was 23,000 psi (1617 kg/cm²).

3. T_{db} falls with decreasing carbon content to $TaC_{0.90}$, where the median bend stress is at a minimum of 14,000 psi (984 kg/cm²) for the temperature range 1750°-1850°C.

4. Below the cubic single phase boundary (x approx. 0.80) the presence of the second phase Ta_2C drastically alters the ductile-brittle transition to give a broad range of 1500°-1950°C. The nominal bend stress is raised to as high as 32,000 psi (2250 kg/cm²) at 1600°C.

5. A minimum in the median bending stress was found at $x = 0.90$. A vacancy-dislocation interaction does not appear to be the principal strengthening mechanism in $TaC_{x>0.9}$. A high Peierls stress for dislocation movement is expected.

The Potentiostatic Method as Applied to the Anodic Oxidation of the Valve Metals, and the Field Dependence of the Tafel Slope for Aluminum

M. J. Dignam and D. Goad

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The potentiostatic method for determining the steady-state parameters for anodic oxidation of the valve metals is examined in relation to present models for the conduction properties of the oxides. It is shown that despite the fact that potentiostatic conditions correspond to nonsteady-state conditions, the steady-state field coefficient (reciprocal Tafel slope) may be determined accurately, and relatively easily, from such measurements. Data for aluminum are presented in illustration and found to be in accord with an equation of the form $i = \alpha \exp[\gamma E - \delta E^2]$, where i is the current density, E the field strength, and α, γ, and δ positive constants for isothermal conditions. The values of γ and δ obtained are in good agreement with values obtained previously using a method in which steady-state conditions were maintained during measurement. The agreement lends further support for the inclusion of the term in E^2 in the conduction equation.

Previous workers have carried out experiments on anodic oxidation of valve metals, in which the oxide was formed under steady-state conditions to a given overpotential, which was then held constant (1, 2). By following the current decay during the potentiostatic condition, kinetic data were obtained. It is important to emphasize that potentiostatic conditions are not steady-state conditions for this system, since the field is changing as the film grows. It is, therefore, not valid to analyze such data using a steady-state ionic conduction equation as has been done previously, but rather they must be interpreted using a model which makes allowance for transient behavior. At present, there are two such models: the high field Frenkel de-

fect model (1) and the recent "dielectric mosaic" theory (3). It is not necessary to discuss these theories here; a full discussion may be found in the references cited. This paper presents an analysis of the potentiostatic method in relation to both of these theories. The two theories give rise to essentially the same result, which is tested against new data for the anodic oxidation of aluminum.

Theory

The purpose of this section is to derive an equation giving the current density as a function of time for an experiment carried out as outlined in the introduction. This will be done first and in some detail with reference to the dielectric polarization theory, the high field Frenkel defect theory being treated briefly later.

The relevant equations for the dielectric polarization model are recorded below

$$\frac{\mu dEe}{dt} - \frac{\mu_1 dE}{dt} = Bi(\mu_s E - \mu Ee) \quad [1]$$

$$i = io \exp(-\phi/kT) \exp\left[\frac{\mu Ee}{kT}\left(1 - \frac{\mu Ee}{C\phi}\right)\right] \quad [2]$$

The various parameters are defined as follows: E, Ee are the applied field and the effective field strength respectively; t is the time; μ is the activation dipole (effective charge activation distance product); μ_1, μ_s are the effective activation dipoles for transient and steady-state conditions, respectively; B is a kinetic parameter with the dimensions reciprocal charge times area; i is the ion current density; io is a temperature independent constant with the dimensions of current density; ϕ is the activation energy at zero field strength, and C a constant whose value depends on the shape of the potential energy surface for the activation process.

A further relationship required is that between the applied field and the effective field under steady-state conditions

$$\left(ie\frac{di}{dt} = 0 = \frac{dE}{dt}\right)$$

$$\mu Ee = \mu_s E \text{ at steady-state} \quad [3]$$

Equation [1] may now be solved for the conditions of the experiment in question. Accordingly setting

$$i = dq/dt$$

the solution to [1] becomes

$$\left[Ye^{Bq}\right]_o^q = (\mu_1 - \mu_s)\int_o^q e^{Bq}\frac{dE}{dq}dq \quad [4]$$

where $Y = \mu Ee - \mu_s E$ represents the deviation of the effective field from its steady-state value. The boundary conditions used to obtain Eq. [4] are that $\mu Ee = \mu_s E$ at $q = 0$.

Setting

$$E = \frac{V}{X} = E_o\left(1 + \frac{fq}{X_o}\right)^{-1} \quad [5]$$

we obtain

$$\frac{dE}{dq} = \frac{-E_o f}{X_o}\left(1 + \frac{fq}{X_o}\right)^{-2} \quad [6]$$

where V is the potential across the oxide film assumed to be equal to the overpotential; Xo, the film thickness at $t = 0 = q$; X, the film thickness at time t; Eo, the field strength at time $t = 0$.

$$f = \frac{dX}{dq} = \frac{W_e}{\rho F}$$

where W_e and ρ are the electrochemical equivalent weight and density of the oxide, respectively, and F is Faraday's constant.

Substituting [6] in [4] we now obtain

$$Ye^{Bq} = (\mu_s - \mu_1)\frac{E_o f}{X_o}\int_o^q \frac{e^{Bq}}{(1 + fq/X_o)^2}dq \quad [7]$$

Although the integral in [7] may be expressed explicitly in terms of the exponential integral, a more useful expression results on integration by parts. Accordingly, the integral may be written

$$I = \int_o^q \frac{e^{Bq}\,dq}{(1 + fq/X_o)^2} = \frac{1}{B}\left[\frac{e^{Bq}}{(1 + fq/X_o)^2}\right]_o^q + \frac{2f}{BX_o}\int_o^q \frac{e^{Bq}\,dq}{(1 + fq/X_o)^3} \quad [8]$$

It is clear that the error in I introduced by neglecting the remainder integral on the right-hand side is less than $2f/Bx_o$ in unity. For alumina, $f = 5.6 \times 10^{-5}$ cm³/coul; $B = (1.22 \pm 0.07) \times 10^4$ cm²/coul (4); so that neglect of the remainder term will introduce an error in $I \gtrsim ½\%$ for $X_o \gtrsim 170$Å. Since the first term is already very small, representing the deviation from steady state, neglect of the remainder integral is of no consequence.

Accordingly, [7] becomes

$$Y = (\mu_s - \mu_1)\frac{E_o f}{BX_o}\left[\frac{1}{(1 + fq/X_o)^2} - e^{-Bq}\right] \quad [9]$$

When sufficient charge has passed such that Bq is appreciably greater than unity we will have

$$\exp(-Bq) << 1$$

and hence

$$Y = (\mu_s - \mu_1)\frac{E_o f}{BX_o}\frac{1}{(1 + fq/X_o)^2} \text{ for } q > \frac{4}{B} \quad [10]$$

From Eq. [10] we see that following a transition period corresponding to a charge past of $4/B$, Y remains essentially constant (since $fq/Xo << 1$). This means that following the transient period the effective field strength lags behind the steady-state effective field strength by a constant amount. Combining this result with the conduction Eq. [2], we conclude that to a first approximation the current density will lag behind its steady-state value by a constant factor. To show this we start by replacing Eq. [2] by an approximation which will be valid over a sufficiently narrow range of the effective field. Accordingly we write

$$i = A \exp \beta Ee \quad [11]$$

where

$$A = i_o \exp\left[\frac{-1}{kT}\left(\phi - \frac{2(\mu\overline{Ee})^2}{C\phi}\right)\right] \quad [12]$$

$$\beta = \frac{\mu}{kT}\left(1 - \frac{2\mu\overline{Ee}}{C\phi}\right) \quad [13]$$

and $\overline{Ee}$ is the mean effective field strength over the range of interest. Eliminating Ee from Eq. [9] and [11] and substituting for E according to [5] we obtain

$$\ln i/A = \frac{\beta_s E_o}{(1 + fq/Xo)} + \beta_s\frac{(\mu_s - \mu_1)}{\mu_s}\frac{Eof}{BXo}\left[\frac{1}{(1 + fq/X_o)^2} - e^{-Bq}\right] \quad [14]$$

where β_s is the steady-state reciprocal Tafel slope at a field strength equal to the mean field strength over the region of interest, and is given by

$$\beta_s = \frac{\mu_s}{kT}(1 - 2\mu_s\overline{E}/C\phi) \quad [15]$$

where $\overline{E}$ is the mean external field strength for the region of the experiment being considered.

From Eq. [14] we may now see that at $t = 0 = q$ the second term on the right is 0 and hence, the current density is simply the steady-state current density for the initial field strength Eo as indeed it must be since this represents the starting conditions. As q increases, however, the term on the right increases and reaches a limiting value which changes only very slowly with time; thus when $\exp(-Bq) << 1$ the current density lags by an almost constant factor behind the steady-state value for the field in question.

For comparison with experimental data a more useful equation is obtained on differentiating Eq. [14] with respect to time after setting $\exp(-Bq) << 1$.

$$\frac{d}{dt}\left(\frac{1}{i}\right) = \frac{\beta_s E_o f}{X_o}\frac{1}{(1+fq/X_o)^2} + 2\beta_s\frac{(\mu_s-\mu_1)}{\mu_s}\frac{E_o f^2}{BX_o^2}\frac{1}{(1+fq/X_o)^3} \quad [16]$$

Thus a plot of $1/i$ *vs.* t will be nearly a straight line, there will be an initial deviation with a "time constant" corresponding to $Bq = 1$, then a nearly straight line with slope $\beta_s E_o f/X_o(1+fq/X_o)^2$ (the second term in [16] is negligible by comparison). The initial points corresponding to $Bq < 1$ will fall below this straight line. From Eq. [14], extrapolation of the straight line portion following the initial transient will give an intercept i'_1 at $t = 0$, which is related to the actual initial current, i_1, by

$$\ln\frac{i'_1}{i_1} = \beta_s\frac{(\mu_s-\mu_1)}{\mu_s}\frac{E_o f}{BX_o} = \frac{\mu_s-\mu_1}{\mu_s}\frac{f}{BX_o}\frac{\ln i_1}{A} \quad [17]$$

The treatment based on the Frenkel defect model is similar and begins with equation (1)

$$\frac{\partial m}{\partial t} = (No-m)\,v_1\exp\left\{-\left[\frac{W_1-ea_1E}{kT}\right]\right\}\frac{-i'\sigma m}{e}$$

$$i = 2ea_2mv_2\exp\left\{-\left[\frac{W_2-ea_2E}{kT}\right]\right\}$$

where W_1 and W_2 are activation energies, a_1 and a_2 are activation distances, v_1 and v_2 vibration frequencies, No the concentration of lattice sites, m the concentration of Frenkel defects, e the charge on the mobile ion, and σ' capture cross-section of vacant sites.

To obtain a solution for these equations appropriate to the problem at hand is more difficult since they are nonlinear. It can be shown, however, that after sufficient charge has passed such that $\exp(-2\sigma' q/e) << 1$, the concentration of charged defects m lags its corresponding steady-state concentration by a nearly constant factor, leading to the same type of current dependence as given by [14]. Thus the two theories predict substantially the same behavior for this experiment, and oscilloscope techniques to record the initial transient are required to differentiate between them. As such measurements were not carried out here, we shall not pursue the Frenkel defect theory further.

The conclusion which may be drawn from these analyses are as follows: both the dielectric polarization theory and the high-field Frenkel defect theory when applied to constant voltage experiments of the type outlined earlier predict that the current density will lag behind the steady-state current density by approximately a constant factor, following an initial transient. For films which are not too thin, however, tangents to a plot of reciprocal current density against time have almost precisely the same slope as would be obtained from a hypothetical plot of the reciprocal of the true steady-state current density against time. It would appear to be safe, therefore, to use constant voltage experiments to obtain information about the steady-state field coefficient (steady-state reciprocal Tafel slope).

In the following section data for the anodic oxidation of aluminum under potentiostatic conditions are presented in order to test the validity of the principle Eq. [16] and [17].

Experimental Method

Details of the cell design, glycol-borate[1] electrolyte, etc., may be found in a previous publication (6). For the present experiments the previously described reference electrode was replaced by a mercury mercuric oxide electrode (7) immersed in a 20% solution of aqueous ammonium pentaborate. The electrolytes were separated by a thin membrane permeable to cations only.

The experiment was carried out by forming the film at a constant current density of $2.09_5 \times 10^{-4}$ amp/cm^2 to a fixed constant potential of the anode with respect to the reference electrode. From this potential the anode overpotential V may be found. Since

$$V = V' - Vrev + Vref$$

V' is the measured difference in potential between anode and reference electrode, $Vrev$ the calculated potential of a hypothetical reversible aluminum-aluminum oxide electrode with respect to a hydrogen electrode in the same solution, and $Vref$ is the potential of reference electrode with respect to a hydrogen electrode in the electrolyte.

$Vrev$ was calculated as -1.386v, $Vref$ was measured as 0.567v, and $V' = 26.79$v, thus $V = 27.61$v. Because of space charge and interfacial potentials, the uncertainty in V may be as much as 2v. The importance of this may be minimized by using thicker films.

Using the data of Bernard and Cook (9) in the manner previously described (6), the formation field strength, E_o, has the value 0.085_6 v/Å so that the initial film thickness, X_o, is 27.61/0.0856 = 312Å.

Results

Figure 1 shows a plot of $1/i$ *vs.* t for the first few seconds and after several hours, showing clearly a difference in slope. Least squares straight lines were fitted to six sets of data, obtained by taking points covering factors of about 4 fall in the current during the same run. The intercept on the $t = 0$ axes obtained from the data for the first few seconds differs from the reciprocal of the initial steady-state current density by the amount $(1.88 \pm 0.23) \times 10^3$ cm^2/amp. The difference is statistically significant, being in fact, 8 times the standard deviation of the intercept. The shift predicted from Eq. [17], using the values of f, B, X_o given earlier and setting $\mu_s = 23.5$; $\mu_1 = 7.8$ eÅ (4); and $\beta_s = 374$ v/Å (see below) is 1.58×10^3 cm^2/amp in excellent agreement with the experimental shift.

[1] This is the only known electrolyte for which close to 100% current efficiencies for the formation of anodic oxide films on aluminum are obtained at low current densities.

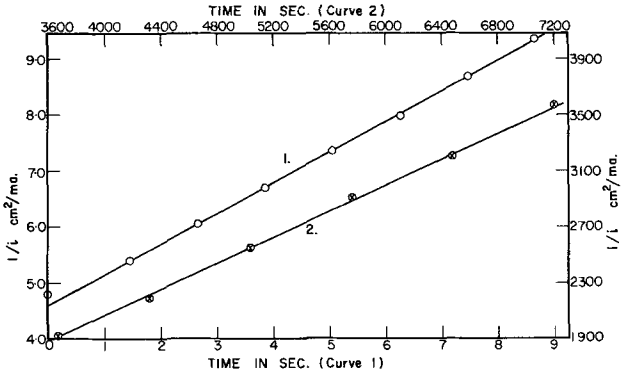

Fig. 1. Plot of $1/i$ *vs.* t for first few seconds and after several hours

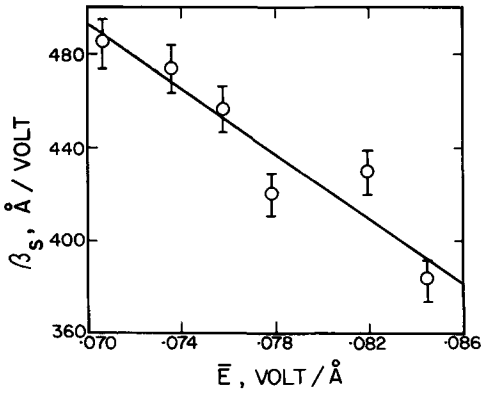

Fig. 2. Results of calculation of values of β_s

Neglecting the very small final term, Eq. [16] may be written

$$\frac{d}{dt}\left(\frac{1}{i}\right) = \beta_s f E^2/V \qquad [18]$$

The slopes of the lines as determined above were assumed to be equal to the derivative of $1/i$ with respect to t at the mean field value. Values of E were calculated by numerical integration of the charge passed, assuming 100% current efficiency with respect to film formation. Values of β_s were then calculated as a function of the mean field strength $\bar{E}$ using Eq. [18]. The results are shown in Fig. 2, the vertical lines representing ± 2 standard deviations of β_s. It should be noted that E^2 changes by several per cent for a decade change in current so that it is not a good approximation to regard it as constant as Dreiner (2) has done.

The solid line in Fig. 2 represents the least squares regression line and corresponds to the following values for the parameters in Eq. [15] and their standard deviations

$$\mu_s = 25.0\ e\text{Å};\quad \sigma = 10\%$$

$$C\phi = 7.08\ ev;\quad \sigma = 5\%$$

These values are in good agreement with those found previously using a different method (6).
vis:

$$\mu_s = 23.8\ e\text{Å},\quad \sigma = 14\%$$

$$C\phi = 7.65\ ev,\quad \sigma = 3\%$$

Discussion

The present analysis and data confirm the validity of the potentiostatic method for obtaining values of the steady-state field coefficient. In addition, the existence of a quadratic term in the field in the net activation energy, reported previously (6), has been verified.

Some comment on the papers by Dreiner (2, 8), who employed the potentiostatic method to determine the field coefficient for the anodic oxidation of tantalum, is in order, since he purports to find the steady-state field coefficient independent of field strength and inversely proportional to temperature, in direct contrast to the findings of Young (10). As he was unable to detect any curvature in a plot of $1/i$ *vs.* t he concluded that β_s was independent of field strength. Using Young's values for the relevant parameters, however, it can be shown that the decrease in β_s with increasing field cancels to a large degree the increase in E^2 with increasing field [18], so that the slope $d(1/i)/dt$ remains almost independent of time. Furthermore, contrary to the conclusion stated in the paper, Dreiners' results do indeed indicate an anomalous temperature dependence of the field coefficient. The temperature dependence of the field coefficient predicted by the simple equation which omits the term in E^2, is that the field coefficient be proportional to $1/T$ (*i.e.*, β_s *vs.* $1/T$ is a straight line with zero intercept). Dreiner's results, however, indicate a very substantial positive intercept. In order to obtain proportionality between β_s and $1/T$ the slope of the straight line representing variation of β_s with $1/T$ presented by Dreiner would have to be approximately doubled. Such an adjustment in the equation for the straight line falls well outside the experimental scatter in his data. Thus, his data indicate beyond any reasonable doubt the presence of an anomalous temperature dependence for the field coefficient. As an adequate explanation for this anomalous behavior has been presented previously by one of us (5) the matter will not be discussed further here.

Kinetics of the Chemical and Electrochemical Reduction of Platinum Black Surface Oxides

Jaspal S. Mayell

Central Research Division, American Cyanamid Company, Stamford, Connecticut

ABSTRACT

A comparative study of the reductions of platinum black surface oxides by electrochemical (at constant current) and chemical means (by propane) has been made. From the nature of the rates of the chemical reduction, from potential-time behavior, and from the two breaks observed in potential *vs.* logarithm coulombs for reductions at <1.60v oxidation, two types of surface oxides at the platinum black electrode have been observed. The chemical reduction of the platinum black surface oxide, when the electrode is oxidized to a potential in the range of 1.30-1.60 v *vs.* hydrogen electrode, is zero order with respect to oxide formation and has a rate of 7.1×10^{-7} equivalent/sec/cm^2 or "67 ma/cm^2." The zero order reaction observed suggests that the oxygen is strongly adsorbed. The chemical reduction rate of the surface oxide formed at potentials less than 1.30v, is not constant, and the oxygen is held loosely at the platinum surface.

In many reactions, it is quite often observed that the products obtained by chemical or electrochemical oxidation or reduction are the same. However, their comparative kinetic behavior is not well understood. Recently, Schuldiner and Warner (1) have studied the chemical reduction of surface oxides of smooth platinum with hydrogen saturated sulfuric acid. They have shown that the most likely rate controlling step is the migration of O_{ad} atoms to platinum active sites, where they react with hydrogen. They also have observed that the chemical reaction rate is independent of the surface coverage of platinum from a monolayer up to about two layers of oxygen per platinum atom.

In this study, known amounts of the surface oxides are formed on the platinum black molded electrodes by anodic oxidation at constant current density to predetermined potentials. The chemical reduction of the surface oxides by propane is compared with the electrochemical reduction at constant current.

Experimental

The working electrode was platinum black (30 mg/cm^2) having 15% polytetrafluoroethylene (P.T.F.E.) as a binder. It was placed in a shielded polychlorotrifluoroethylene electrode holder as shown in Fig. 1. The shield was only ¼ in., and the electrode was backed by a gas permeable but liquid impermeable porous P.T.F.E. The area of the electrode in contact with the electrolyte was 0.462 cm^2. Propane (3 ml/min) atmosphere in large excess of the stoichiometric amount required was kept over the porous P.T.F.E. The blank runs were performed with a nitrogen atmosphere.

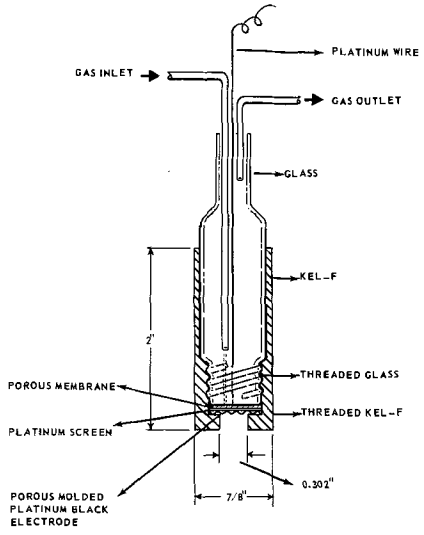

Fig. 1. Gas permeable liquid impermeable molded platinum black-P.T.F.E. porous electrode assembly.

The auxiliary electrode was also platinum black separated from the working compartment by a sintered glass disk. The reference electrode was hydrogen gas bubbled through 85% H_3PO_4 over a molded platinum black P.T.F.E. electrode contained in a Vycor tube (No. 7900) having a porous tip of Vycor 7930. The Vycor tube was placed in 85% H_3PO_4 so that the porous tip was completely submerged in the acid. Nitrogen was bubbled continuously through a sintered disk in order to remove any hydrogen leaking through the Vycor tube. The hydrogen reference electrode assembly was kept at room temperature. The connection to the working compartment of the cell was made by means of a bridge of small bore tubing. All potentials mentioned in this work are referred to the above hydrogen electrode which differs from the hydrogen electrode in 1M $HClO_4$ by about +30 mv. The apparatus used has already been described (2, 3).

The propane was allowed to flow at a high rate, far in excess of the stoichiometric amount required, directly over the porous P.T.F.E. The structure of the test electrode shown in Fig. 1 was such that there was always an excess of propane available at the electrode surface for the reduction of surface oxides. The water proofed porous gas electrode caused a considerable decrease in the average effective diffusion layer thickness. Propane was thus easily available at the reaction sites. The rate of chemical reduction of the surface oxides of platinum black was not dependent on the diffusion of propane but was similar to that of constant current reduction as will be shown in the results.

Results and Discussion

Mayell and Langer (2) oxidized platinum black electrodes in 2*N* H_2SO_4 at a constant current density to different potentials. They observed from coulometric reduction that the oxidation sequence for platinum black electrode was Pt → $Pt(OH)_2$ → $Pt(O)_2$ → $Pt(O)_{2.5(approx.)}$. Complete formation of the monolayer of $Pt(OH)_2$ occurred when the electrode was oxidized to a potential of 1.24v while the monolayer of $Pt(O)_2$ occurred at 1.54v. Above 1.60v, the amount of surface oxide formed remained constant, corresponding to $Pt(O)_{2.5(approx.)}$.

In the present work, similar results were observed when a platinum black electrode was oxidized in 85%

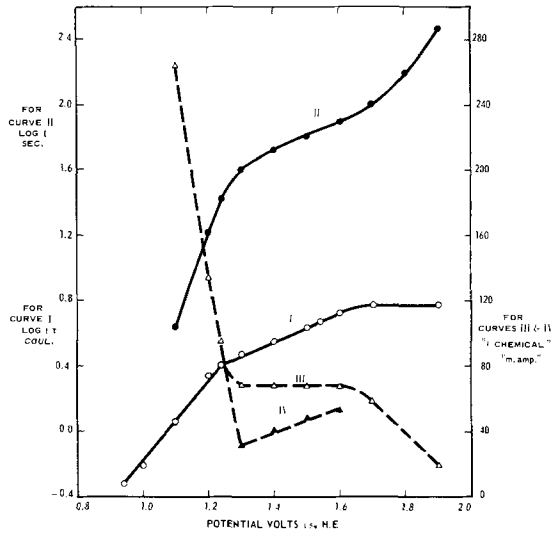

Fig. 2. Plot of potential to which the platinum black electrode was oxidized at constant current density in 85% H_3PO_4 *vs.* Curve I, log coulombs required to reduce, electrochemically, the oxidized surface at 130°C (oxidation and reduction were performed at 40.5 ma/cm^2); curve II, log seconds required for propane to reduce the electrode at 150°C, after the electrode was oxidized at 134 ma/cm^2 to different anodic potentials; curve III, the chemical reduction rate, $i_{chemical}$, by propane to reduce the total surface oxides formed at different potentials at 134 ma/cm^2; curve IV, $i_{chemical}$ of the second oxygen layer alone, by propane, when the electrode is oxidized to a potential in the range of 1.30-1.60v at 134 ma/cm^2.

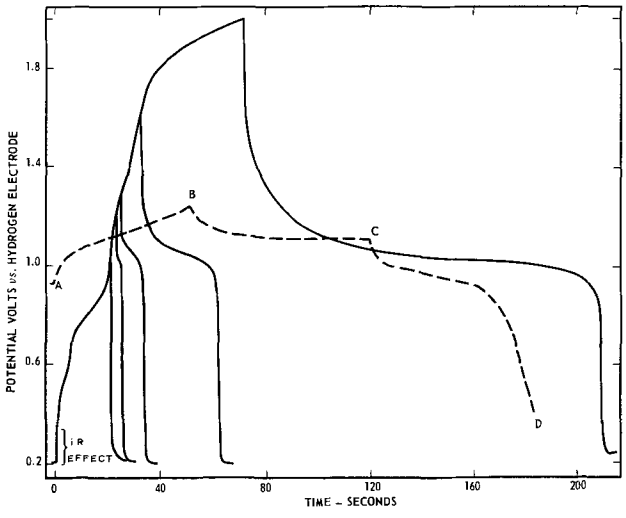

Fig. 3. Plots of potential *vs.* time when a platinum black electrode, over which propane is flowing at the rate of 3 ml/min, is oxidized at 134 ma/cm^2 to predetermined potentials (rising part of the curve) at 150°C in 85% H_3PO_4 and then put on open circuit (declining part of the curves). Dotted lines are a blank run under nitrogen atmosphere. AB is oxidation and CD is reduction, both at 40.5 ma/cm^2 of the platinum black electrode. BC is open circuit decay potential before reduction.

H_3PO_4 (H_2O_2 treated)[1] at 130°C at a constant current density of 40.5 ma/cm^2 to predetermined potentials. The cell was put on open circuit for 3 min, during which the oxygen evolved was removed by bubbling with nitrogen and then the electrode was reduced at the above current density. The number of coulombs required to reduce the platinum black surface oxides was plotted against the potential to which the electrode had been oxidized, as shown in curve I, Fig. 2. This will serve as a reference to compare the results obtained in the reduction of surface oxides by propane.

The current density used to oxidize the platinum black electrode in the blank experiment (nitrogen atmosphere) was 40.5 ma/cm^2. When propane was allowed to flow (3 ml/min) over the porous P.T.F.E., the potential did not rise above 0.8v when currents up to 130 ma/cm^2 were utilized to oxidize the electrode in 85% H_3PO_4 at 150°C. It thus appeared that the electrochemical oxidation of propane occurred predominantly as compared to the formation of surface oxides at currents less than 130 ma/cm^2 (and potentials $<$0.8v). When the current density was increased to 134 ma/cm^2, the electrode could be oxidized to about 2v. Above approximately 1v the formation of surface oxides and above 1.60v the evolution of oxygen predominated over the oxidation of propane. It could be assumed in this work that the chemical reduction of Pt surface oxides by propane during their anodic formation (at constant current) is negligible.

The electrode was oxidized to predetermined potentials and on open circuit, the potential dropped to 0.2v as seen in Fig. 3. The time τ required for the potential to reach 0.4v was taken as that corresponding to complete reduction of the surface oxides. An increase in the time for chemical reduction was observed as the electrode was oxidized to higher potentials. When the electrode was oxidized to potentials in the range of 1.30 to 1.60v, normalization of the open circuit potential decay curves with respect to time indicated an identical shape for all of the experimental curves.

[1] 0.2 ml of 30% H_2O_2 was added to a liter of 85% H_3PO_4 and heated in water condenser at 150°C for 6 hr to remove excess of H_2O_2 (tested by decolorization of $KMnO_4$).

One very characteristic feature of the open circuit decay in Fig. 3 was the very sharp transition from about 0.9 to 0.2v. When platinum surface oxides (formed in the absence of propane) were reduced at constant current, the transition was not sharp as seen in curve CD of Fig. 3. The quick drop to near the thermodynamic potential of the propane oxidation ($E^\circ_{C_3H_8 \rightarrow CO_2(25°C)} = 0.15$v), suggested that the chemical reduction of surface oxides was not limited by mass transport of propane. In another experiment in which a saturated solution of propane was used under identical oxidation conditions, the drop in potential was gradual showing mass transport limitation.

A plot of log time (decay of open circuit potential to 0.4v) by propane (Fig. 3) *vs.* the potential (iR corrected) to which the working electrode was oxidized is shown as curve II, Fig. 2. The close similarity of curves I and II suggested that the nature of the chemical reduction of surface oxides by propane is very similar to that of electrochemical reduction and that the surface oxide reduction is rate controlling in both cases. Also, the shape of curve II is further evidence for the existence of two different surface oxides at potentials lower than 1.60v, a conclusion drawn from previous work on cathodic reduction of surface oxides (2).

The data above 1.60v in curves I and II of Fig. 2 were difficult to compare because of oxygen evolution. Previously (2), oxygen was removed by a nitrogen purge before electrochemical reduction. This was not possible in the experiments with reduction by propane, as the electrode must be continuously in contact with propane in order to obtain meaningful results.

Kinetics

Since surface oxides are present at the platinum black electrode at all times, diffusion of the electroactive species does not occur and the reduction is controlled by Faraday's law.

The over-all complete reduction of the platinum black surface oxides at constant current density occurs according to the equation

$$Pt(O)_x + 2x\,H^+ + 2x\,e \rightarrow Pt + x\,H_2O \qquad [1]$$

while the over-all chemical reduction by propane follows the equation

Table I. Kinetic data for the reduction of platinum black surface oxides

	"Oxidation potential" volts *vs.* H. E.						
	1.10	1.20	1.24	1.30	1.40	1.50	1.60
Number of equivalents of platinum surface oxide/cm² $\Gamma \times 10^7$ determined electrochemically.	118.4	229.6	260.0	305.6	375.2	452.8	546.0
Time, t, required by propane to reduce the total surface oxide in sec/cm² of electrode.	4.34	16.4	26.6	40.7	53.2	65.0	79.0
Chemical reaction rate, k, equivalents/sec/cm² $\times 10^7$ for the reduction of total surface oxides.	27.32	13.98	9.78	7.52	7.08	7.00	6.92
Chemical reaction rate, k', equivalents/sec/cm² $\times 10^7$ for the reduction of second oxygen layer only.	—	—	—	3.24	4.32	5.00	5.48

$$\frac{10}{x}\,Pt(O)_x + C_3H_8 \rightarrow \frac{10}{x}\,Pt + 3\,CO_2 + 4\,H_2O \quad [2]$$

Propane oxidizes completely to CO_2 as has been shown by Grubb (4) in a fuel cell. In the present study the propane electrode is exactly similar to a fuel cell anode compartment and thus a similar over-all oxidation of propane occurs.

The chemical reaction rate, k in equivalents/sec/cm² for the reduction of total surface oxides as shown in Table I is determined as follows

$$k = \frac{\Gamma}{t} \quad [3]$$

where t is time required for propane to reduce the oxides and Γ is the number of equivalents of the surface oxide. Γ is calculated by using Faraday's law

$$\Gamma = \frac{i\tau}{F} \quad [4]$$

where $i\tau$ is the number of coulombs required to reduce the surface oxide electrochemically in the presence of nitrogen. From the values of k as shown in Table I and the curves in Fig. 2, it appears that the oxygen is adsorbed differently on the platinum black surface, when the electrode is oxidized to a potential in the range of 1.30-1.60v than at <1.30v.

If it is assumed that the adsorption of oxygen in the surface oxide formed in the potential region of 1.30-1.60v is similar to that formed at <1.30v, then the rate of the chemical reduction of the second oxygen layer, k' in equivalents per sec/cm², is determined as below

$$k' = \frac{\Gamma_{\text{determined at 1.30-1.60v}} - \Gamma_{\text{determined at 1.24v}}}{t_{\text{at 1.30-1.60v}} - t_{\text{at 1.24v}}} \quad [5]$$

since a monolayer of oxygen is complete at 1.24v (2).

The rate should decrease if the nature of the surface oxide is similar to that formed at potentials <1.30v, as shown in Fig. 2. However, the value of k' increases, as seen in Table I, when the electrode is oxidized to higher potentials, which contradicts the above assumption. Thus, the oxygen atoms of the two platinum black electrode surface oxides are arranged differently.

The reduction rates determined above could be expressed in terms of constant current

$$i_{\text{"chemical"}} = \frac{i\tau\,(\text{electrochemical})}{t\,(\text{chemical})} \quad [6]$$

The values of $i_{\text{"chemical"}}$ for the reduction of total surface oxides and second oxygen layer alone are plotted as curves III and IV, respectively, in Fig. 2. The three distinct regions observed in curve III show a similar trend as seen in the other two curves of the same figure. The decrease in $i_{\text{"chemical"}}$ above 1.60v is caused by the inability to remove oxygen and so is not considered for comparison purposes.

It is quite clear from the data in Table I and curve III of Fig. 2, that the chemical rate for the reduction of total surface oxides formed in the potential range of 1.30-1.60v is independent of the amount of surface oxide formed. The over-all reduction is thus zero order, and the rate constant is 7.1 x 10^{-7} equivalents/sec/cm² of the electrode which is equivalent to "67 ma/cm²."

A zero order reaction is strongly suggestive of strong adsorption of oxygen (5) when the electrode is oxidized to a potential in the range of 1.30-1.60v. It has been suggested (1) that oxygen atoms could go into the interstitial holes in the Pt lattice (especially in the 110 plane) after a monolayer of oxygen atoms have been formed.

Potential-Time Behavior

Comparison of the chemical reduction by propane and electrochemical reduction at constant current of the platinum black surface oxides formed by oxidation at constant current in the potential range of about 1.30-1.60v can be made by assuming a quasi-equilibrium hypothesis. It is supposed that all steps prior to the rate-determining one in the reaction sequence are almost in equilibrium, *i.e.*, the rate constant of the rate-controlling step is at least ten times smaller than all other antecedent steps in both directions. Conway (6) determined the kinetics for consecutive reactions (using constant current) assuming the above hypothesis and derived the following equation

$$E = a + \frac{2.303\,RT}{F}\log\frac{\tau - t}{t} = a + \frac{2.303\,RT}{F}\log\frac{\theta}{(1-\theta)} \quad [7]$$

where E is the potential on open circuit after oxidation to predetermined potential; a is a constant; τ is the time in seconds for complete reduction of $Pt(O)_x$ taken at 0.4v; θ is the fraction of the surface covered with $Pt(O)_x$ at any time t after the electrode has been oxidized to predetermined potential. $\theta = 1$ refers to oxide coverage at $t = 0$ in a given experiment; $(1 - \theta)$ is the fraction of the surface covered by the potential determining intermediate at any time t as in Eq. [8]; while F, R, and T have their usual values.

It has been found that the plots of E *vs.* $\log(\tau - t)/t$ gave straight lines when the surface oxide formed in the potential region of 1.30-1.60v was reduced chemically by propane (curve I) and electrochemically at constant current (curve II) as shown in Fig. 4. The experimental slopes of 0.085 (curve I, Fig. 4) for chemical reduction at 150°C and 0.081 (curve II, Fig. 4) for the electrochemical reduction at 130°C compare very well with the theoretical slopes ($2.3\,RT/F$) of 0.084 and 0.080, respectively.

The first step could then be a quasi-equilibrium reaction. One possibility for electrochemical reduction may be

$$Pt(O)_x + H^+ + 1e \underset{k_b}{\overset{k_f}{\rightleftharpoons}} [Pt(O)_{x-1}\,(OH)] \quad [8]$$

while for chemical reduction may be

$$Pt(O)_x + H^+ \underset{k_b}{\overset{k_f}{\rightleftharpoons}} [Pt(O)_{x-1}\,(OH)] \quad [9]$$

followed by the rate determining step in both the cases. The electrochemical equilibrium condition is

$$k_f\,\theta\,C_{H^+}\,e^{-\frac{\alpha FE}{RT}} = k_b\,(1-\theta)\,e^{\frac{(1-\alpha)FE}{RT}} \quad [10]$$

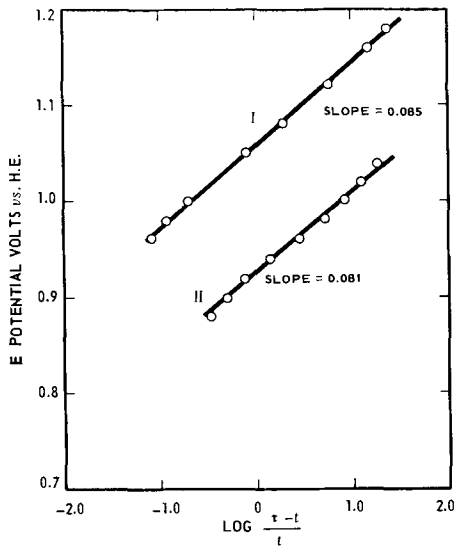

Fig. 4. Plot of potential vs. log $\left(\frac{\tau - t}{t}\right)$ for the reduction of surface oxide formed in the potential region of 1.30-1.60v in 85% H_3PO_4. Curve I, chemical reduction by propane at 150°C when the electrode was oxidized at 134 ma/cm^2 to 1.3v; curve II, electrochemical reduction at constant current density of 40.5 ma/cm at 130°C when the electrode was oxidized to 1.54v at 40.5 ma/cm^2.

$$\frac{\theta}{1-\theta} = K\, C_{H^+}\, e^{\frac{FE}{RT}} \qquad [11]$$

where α is the transfer coefficient; C_{H^+} is the concentration of H^+ which is in large excess and so is constant; and $K = k_b/k_f$.

The above equilibrium expression (6) is a thermodynamic equation for the surface species and is independent of α and any possible double layer effect.

Although the slopes of the two curves in Fig. 4 are the same, their potential displacement of about 0.13v is quite remarkable. The ease of the chemical reduction by propane is evident from the small "over potential" required to reduce the surface oxide formed in the potential region of 1.30-1.60v although the equivalent "current density" is about 1.5 times that of the electrochemical reduction.

Curves I and II of Fig. 4 and the potential-time curves for electrochemical and chemical reduction in Fig. 3 again demonstrate the similar nature of electrochemical and chemical reduction of the platinum black surface oxides.

E *vs.* log $(\tau - t)$ is linear when the surface oxides formed at potentials <1.30v are reduced at constant current density. However, E *vs.* log $(\tau - t)/t$ is not linear in the above range. It thus appears that the surface oxides formed at potentials <1.30v are reduced by a mechanism different from that operative when the oxide is formed in the potential range of 1.30-1.60v. The experimental slope (2.3 $RT/\alpha F$) of 0.25 at 130°C gives a value of 0.33 for α. This mechanism may involve a simple electrochemical reaction. One possibility may be the following mechanism

$$Pt(OH)_2 + H^+ + 1\,e \underset{\longleftarrow}{\overset{\text{slow}}{\longrightarrow}} [Pt\,OH] + H_2O \qquad [12]$$

$$[Pt\,OH] + H^+ + 1\,e \xrightarrow{\text{fast}} Pt + H_2O \qquad [13]$$

The formation of Pt OH intermediate has also been postulated by Laitinen and Enke (7) during the oxidation of Pt electrode surface.

From the different rates and apparent reaction orders of the chemical reduction; from the potential-time behavior, and from the two breaks observed in curves I and II of Fig. 2 below 1.60v, two types of surface oxides at a platinum black electrode are proposed; one formed at less than 1.30v and the other at 1.30-1.60v. The difference in the two surface oxides is not only in the amount of oxygen held per platinum atom but also in the nature of the surface oxide (relative degree of adsorption) formed. It is quite likely that the platinum surface oxides below 1.30v (oxygen loosely held) could play a significantly different role in electrochemical reactions than the surface oxides above 1.30v (oxygen strongly adsorbed).

Concentration Gradients at Horizontal Electrodes

R. N. O'Brien

Chemistry Department, University of Alberta, Edmonton, Alberta
and Inorganic Materials Research Division, Lawrence Radiation Laboratory,
University of California, Berkeley, California

ABSTRACT

Interferograms of the transient condition of concentration gradient build-up have been recorded with a motion picture camera for horizontal electrodes in the cathode-over-anode position. The appropriate solution of Fick's second law for the unsteady state has been shown to predict the concentration gradient at times of the order of 150 sec or greater. The interference fringes can be integrated as time dependent concentration contours and, hence, a measure of the diffusion current obtained. Logically, at $t=0$ sec, $i_{diff} = 0$. Experimental data show that i_{diff} reaches a maximum at times greater than 150 sec in the diffusion layer, and t goes from 0 to some value close to one during the same time. It has been impossible to decide on a definite value for the transference number and diffusion coefficient that would be appropriate.

Concentration gradients at working electrodes were difficult to obtain until the advent of the modern optical methods of Schlieren patterns (1) and interferometry (2). The recording system has always been a still camera until very recently when a motion picture camera was used (3). This recording technique should provide sufficient data of good quality to establish quantitatively the dependence of concentration changes in the electroactive species with time.

A series of interferograms of an experiment with the electrodes in the cathode-over-anode position were recorded on motion picture film and the results analyzed and compared to the theory of ionic transport. To the best of the author's knowledge this is the first recording of such transient concentration changes.

Fig. 1. Exploded view of the cell without the thermostating clamp

Experimental

A 0.5M $CuSO_4$ solution, *p*H 4.5, made up in the usual way was electrolyzed in an interferometer (Fig. 1) which has been described in detail elsewhere (4). Briefly, the cell had two copper electrodes 0.2 cm thick and 4 cm long sandwiched 0.313 cm apart between two coated glass flats. The flats were held in a specially shaped Teflon cylinder which was placed in a clamp with which an appropriate wedge angle between the flats could be produced. Collimated sodium vapor light produced wedge fringes which were recorded by a Bolex Paillard 16 mm motion picture camera on Ansco Hypan film at 24 frames/sec. The film was underexposed, and therefore required overdeveloping by a factor of 2 to 4. The developed film was then projected at a magnification factor of 80, and from frames at selected times representative fringes were sketched

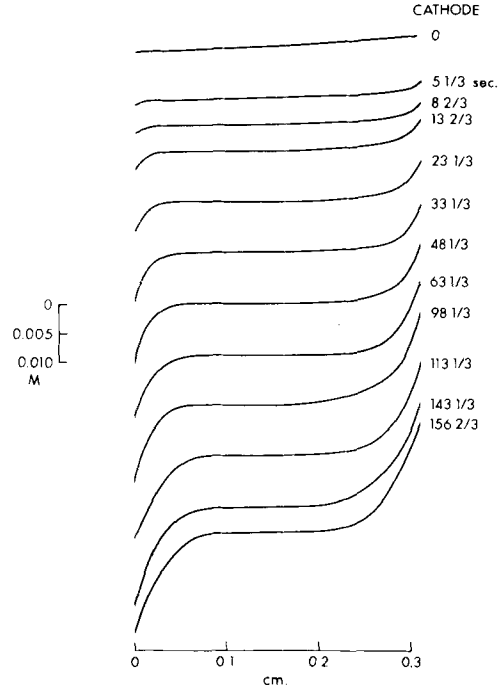

Fig. 2. Interference fringes (as sketched from 16 mm film) at various times after the beginning of electrolysis in the system $Cu/CuSO_4/Cu$. Electrolyte concentration 0.1*N*, *p*H 4.5.

on graph paper (Fig. 2). Details of the type of fringes obtained and adjustments made to them appear in Appendix I.

Carefully prepared pure polycrystalline copper electrodes were used in the cell which was thermostated at 25°C. When a suitably oriented fringe system had been produced, the motion picture camera was started, then a preset constant current passed through the cell, in this case 0.9022 ma/cm^2.

Theory

The theory of ionic mass transport in electrolysis has been reviewed by Tobias, Eisenberg, and Wilke (5). They give for the rate of transfer of ions in the x direction (x perpendicular to the plane of the electrode)

$$N_t = CU\frac{\partial\psi}{\partial x} - D\frac{\partial C}{\partial x} + VC$$

where N_t = total rate of transfer, gram ions/cm^2-sec; C = concentration in gram ions/cm^3; U = mobility, cm^2/sec-volt; ψ = potential, volts; x = distance in direction of transfer, cm; D = diffusion coefficient, cm^2/sec; and V = velocity for steady-state conditions. In the experimental set-up here used, horizontal electrodes, cathode-over-anode; $V = 0$ since convection is absent leaving only electromigration and diffusion, represented by the first and second terms on the right side. Tobias *et al.* then give an expression for the rate of ionic transport by diffusion $N_d = N_t - N_m = I(1 - t_+)/nF$ where N_m = rate of migration, gram ions/cm^2-sec; t_+ = cation transference number, and the other symbols have their usual meanings. Again this expression is for steady-state conditions.

Considering the unsteady state, the solution of the equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2}$$

for the boundary conditions $\Delta C = 0$ at $t = 0$, $x = 0$ and $\Delta C = 0$ at $t \neq 0$, $x = l$ is

$$\Delta C_{(x,t)} = \frac{\sqrt[2]{Dt}/l^2\, I\, l\, t-}{nF\, D}\ \text{ierfc}\ \frac{1 - x/l}{\sqrt[2]{Dt}/l^2}$$

as given by Carslaw and Jaeger (6), using only the first term of the complete series solution since ierfc $z \to 0$ as $z \to \infty$. It is worth noting that the expression is independent of 1, only requiring that $\Delta C \to 0$ as $x \to 1$ ($2l$ = electrode separation). Inclusion of the anion transference number in the pre-error function coefficient ($t-$), is to be expected and as in the steady state is intended to make allowance for the migration current. ierfc is the complement of the integrated error function (6).

The present experimental results should permit a testing of the efficacy of this treatment since the number of coulombs discharged at any time can be calculated by considering the number of ions required to be removed (discharged) to produce the observed concentration gradient. This can be done by a form of graphical integration which makes only the assumptions that the fringe selected is a typically average fringe for the whole electrode surface, that the diffusion coefficient is known and constant over the concentration range considered, and that all refractive index changes are due to $CuSO_4$ concentration changes.

Results

The initial attempts to fit the interference fringe selected as typical at 150 sec were made using the diffusion coefficient of $CuSO_4$ as reported by Eversole (7) and co-workers and the transference number for SO_4^{2-} according to Fritz and Fuget (8). The diffusion coefficient and transference number for the concentration at the selected x were used for each point calculated. Results are shown in Fig. 3. The agreement with the anode side of the interferogram is quite good, but for the cathode the prediction is everywhere short of that found. The predicted values for 15 sec are almost 50% too high and so are not plotted.

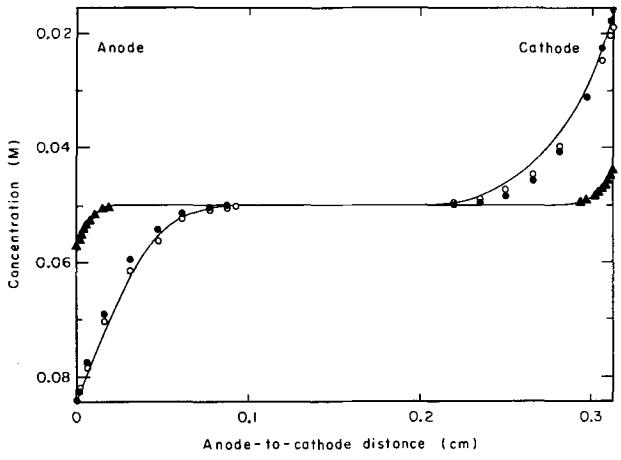

Fig. 3. Comparison of calculated and experimental values at 15 and 150 sec. ○ calculated using best literature values of D and t- for each concentration; • calculated using D = 4.4 x 10^{-6} cm^2 sec^{-1}, appropriate literature t- and current densities from Fig. 4; ▲ calculated using D = 4.4 x 10^{-6} cm^2 sec^{-1} appropriate literature t- and current densities from Fig. 4.

Realizing that the results of other studies (9) of the Cu/$CuSO_4$/Cu system have shown values for the diffusion constant of about 4.4 x 10^{-6} cm^2/sec, the requisite current densities to give agreement at ΔC_{max} using D = 4.4 x 10^{-6} were calculated, and are shown in Fig. 4 to suggest that eventually a potential gradient will be produced such that $N_d = N_t$. If instead the diffusion constant is calculated for each time and using the appropriate transference number such that $\Delta C_{calc} = \Delta C_{exp}$ at the electrode ($x = 0$), D obviously approaches 4.4 x 10^{-6} cm^2/sec at some time greater than 150 sec (Fig. 5).

Using the calculated required current density for D = 4.4 x 10^{-6} cm^2/sec and average literature transference numbers, values at selected distances from the electrodes were plotted on Fig. 3 and for 15 sec is quite good. The agreement is worse than the first attempt, but not much worse. Figure 4 shows the results of graphical integration to obtain the number of coulombs of charge required to discharge the necessary number of ions to form the concentration gradient found at various times. The successive current densities plotted in Fig. 4 are again plotted here in a different way. Beginning at 3 1/3 sec the value found is plotted from zero time to ½ the distance to the next calculated value, in this case 4 1/16 sec since the next time is 5 sec. The 5-sec value is now plotted to join at

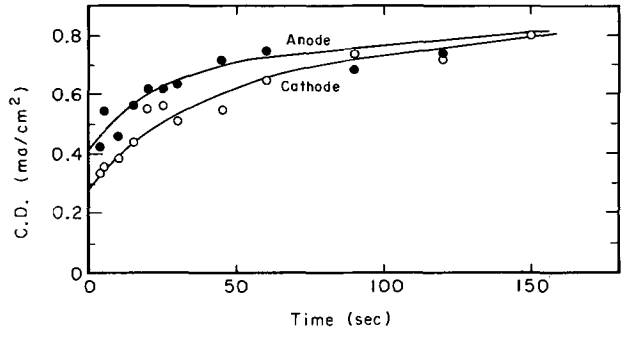

Fig. 4. Current densities calculated at various times, using D = 4.4 x 10^{-6} cm^2 sec^{-1} and appropriate literature t- such that the concentration change found experimentally at x = 0 is equal to the calculated concentration change; • anode; ○ cathode.

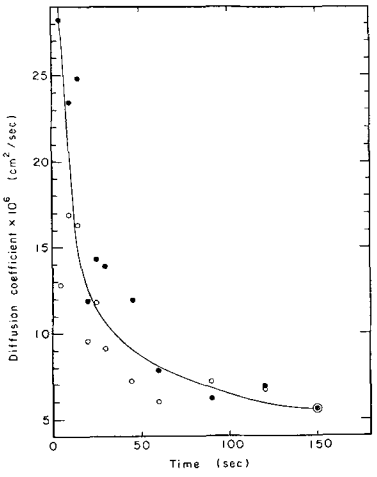

Fig. 5. Diffusion constants calculated to give agreement with concentration change found at the electrode using appropriate literature t- values; • anode; ○ cathode.

this point and is drawn half-way across the next time interval. Plots for both the anode and cathode were made. The line drawn for the anode appears to be generally too high, but the cathode plot is reasonably representative of the charge-carried points. The current density plots appear to be approaching the same slope as the externally measured current density.

Assuming the diffusion constant to be fixed at 4.4×10^{-6} cm^2/sec the transference number necessary to give agreement at $x = 0$ and $t = 150$ sec is $t- = 0.58$ for 15 sec $t- = 0.298$. This suggests that $t-$ goes to zero at $t = 0$, when of course $N_t = N_m$ since there is no diffusion gradient to support a diffusion current.

Conclusions

The quality of the fit of calculated points using

$$\Delta C_{(x,t)} = \frac{\sqrt[2]{Dt}/l^2\, I\, l\, t-}{nF\, D}\ \text{ierfc}\ \frac{1 - x/l}{\sqrt[2]{Dt}/l^2}$$

is sufficiently good that, apart from the theoretical reason for selecting it, it obviously is the correct form to represent the physical process considered, that is the sudden imposition of a constant current density between parallel, plane, horizontal electrodes in the absence of convection.

However, the problem of deciding on the values of the basic constants to use has not been solved. The assumption that a concentration contour, calculated from a refractive index contour with no allowance for pH change or extraneous reactions is probably as good as the data. If this is so, then the problem becomes one of deciding what D and $t-$ to use, again assuming that the externally measured current density must be used unmodified. These problems can probably be resolved by electrolysis for longer times so that plots like Fig. 4 and 5 could indicate the steady-state diffusion constant and diffusion current. Electrolysis at the limiting current density should also give helpful information regarding these two quantities.

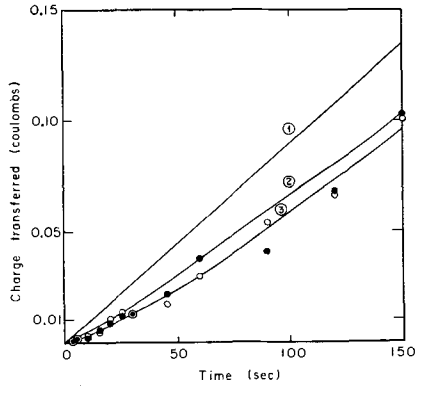

Fig. 6. Charge transferred vs. time. Line 1 is the externally measured current density; line 2 is the calculated required value of the current density at the anode from Fig. 4; line 3 is the same value for the cathode. • number of charges transferred at the anode at a given time found by integrating under the concentration contour. ○ cathode values obtained in the same way.

Acknowledgment

The author wishes to acknowledge the suggestion of E. J. Casey that the data be subjected to this type of analysis, the efforts of K. Kinoshita, who did most of the experimental work, and of John Newman for interesting and advisory conversations on the theoretical aspects. This work was supported in part by the National Research Council of Canada and the Inorganic Materials Research Division of the Lawrence Radiation Laboratory, University of California, Berkeley.

Manuscript received Dec. 7, 1964; revised manuscript received Jan. 18, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

APPENDIX I

Fringes of equal inclination: Brewster's fringes.— Tolansky has given an excellent treatment of fringes of equal inclination (10). However the difference between wedge or fizeau-type fringes and Brewster's fringes will be considered briefly.

Figure 7 shows schematically the light path and how Brewster's fringes are produced. If the incident light is at an angle to the wedge whose angle is small (about 2 min of arc), instead of getting wedge fringes, that is, a continuous set of equally spaced parallel fringes, rings of fringes are produced. In this experiment it was intended to use wedge fringes, but since

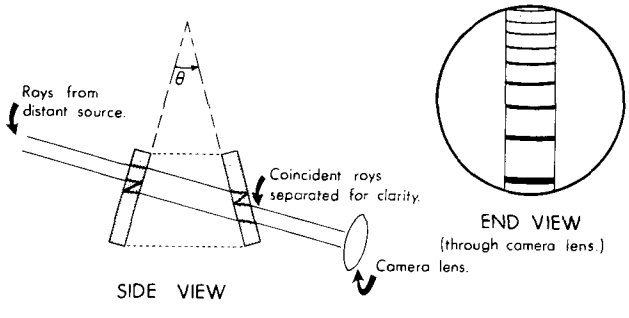

Fig. 7. Production of Brewster's fringes

the radius of curvature of the fringes is relatively large and the two types can exist simultaneously, it is easy to confuse the two. The error was not discovered until a large number of tedious hand measurements had been made.

For wedge fringes, the fringes appear on a uniform wedge at positions where the thickness of the wedge is an integral multiple of the wavelength of the monochromatic light, that is since $n\lambda = 2\mu t \cos \phi$, whenever the thickness has increased by $\lambda/2$ from the last fringe, bright or dark, a new fringe appears. n is the order of interference, μ the refractive index, t the thickness, and ϕ the angle of incidence of the light. If ϕ becomes a very little less than 90° for thick wedges, Brewster's fringes result.

Brewster's fringes are located at infinity and appear on the wedge as rings. The fringes will appear at positions governed by $n\lambda = \mu t$(cosine of the angle of refraction in the first glass flat minus cosine of the angle of refraction in the second glass flat) assuming $\cos \phi$ is about equal to 1, since the light passes only once through the cell.

Variations in the refractive index of the wedge of electrolyte cause displacement of the fringes up and down the wedge (toward the apex if the change is an increase in concentration) which takes the form of a perturbation to the arc of the circle seen between the electrodes. The fringes measured for the S/V position were a 2° 35′ arc of a circle of 3.43 cm radius and those for the C/A position had a similar radius of curvature. A detailed account of how to relate wedge fringe perturbation to concentration has been given by O'Brien and Rosenfield (7) and complete review of the theory by O'Brien (9).

To allow plots of concentration changes to be made on cartesian coordinates, these arcs had to be converted to straight lines. Frequently the increments at successive positions at which measurements were made were smaller than the expected precision of measurement. However, to ensure that some systematic method of correction for fringe curvature was used, a transparent plastic template whose plotting edge was cut in the mirror image of the curve was used in replotting the uncorrected values read from the display of the original fringes. In this way the curvature was plotted out and also any rotation of axis needed to correct the angle of the fringes to the electrode to 90°. Of course since both the plastic template and the pencil point had thickness, a further, but it is thought, random scatter of points resulted. A smooth curve was then drawn through the points. A scale in which fringe perturbations are shown as concentration change in moles per liter has been added to the figures where necessary. The limit of accuracy of the measurements is that with which the center of any fringe can be located relative to the center of another fringe. In this case it is thought from the results of repeated measurements to be about ±1/20th of a fringe width or about $\pm 7 \times 10^{-4}$M. Details of this type of calculation have been given previously (4).

Faradaic Impedance of Polarized Porous Electrodes

I. First Order Kinetics

R. Darby[1]

LTV Research Center, Ling-Temco-Vought, Inc., Dallas, Texas

ABSTRACT

The a-c impedance characteristics of polarized porous gas-diffusion electrodes are calculated on the basis of a simplified dual-layer model. It is shown that the consideration of a region within the electrode wherein simultaneous diffusion and reaction occur can result in either an inductive or capacitive reactance, depending on the magnitudes of dimensionless frequency and d-c current density parameters. The absence of such a region, which corresponds to the limiting case at high reaction rates, results in capacitive reactance only.

Recently, Gutmann (1) discussed the experimental observation of lagging currents in electrochemical systems and proposed an explanation of this inductive effect by analogy with viscoelastic phenomena. A number of authors have considered the a-c impedance of electrode systems [*e.g.*, (2)-(18)], although none of their results account for the effects described by Gutmann. It will be shown that inductive reactances arise naturally from a consideration of the Faradaic impedance of a polarized porous electrode in which mass transport and electrochemical reaction can proceed simultaneously over a distributed region of the electrode.

[1] Present address: Chemical Engineering Department, Texas A & M University, College Station, Texas.

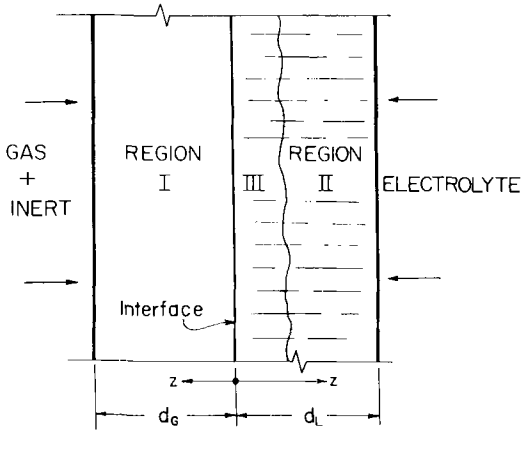

Fig. 1. Schematic diagram of dual-layer model

The Model

A simplified dual-layer model is considered for analysis and is schematically illustrated in Fig. 1. One face of the electrode is exposed to a binary gas phase containing a reactant and an inert component, and the other face is exposed to a liquid (electrolyte) phase, also considered to be a binary mixture of a reacting (ionic) component and an inert. The porosity of the two layers and the differential pressure is assumed to be such that the gas-liquid interface is maintained at the junction of the two layers. The resistivity of the electrode matrix will be neglected in comparison with that of the electrolyte so that the electrode matrix will be essentially at a uniform potential.

The electrode is assumed to be operating in a polarized condition, resulting in a d-c current I and d-c polarization E. The electrode reaction will thus proceed irreversibly and will be represented by the general expression

$$gG + lL + ne^- \rightarrow pP \qquad [1]$$

The corresponding rate equation relating current,

polarization, and concentration can thus be written as

$$I = I_o \left(\frac{G}{G_o}\right)^{g'} \left(\frac{L}{L_o}\right)^{l'} \exp\left(\frac{\alpha n' F}{RT} E\right) \quad [2]$$

where G and L are the concentrations at the reaction site, while G_o and L_o are those in the bulk phases, which are constant. The reaction orders g', l', and n' may or may not be the same as g, l, and n of [1], depending on whether or not [1] represents the true kinetics of the electrode reaction.

In order to determine the a-c impedance of the electrode, we consider an a-c component of potential superimposed upon the d-c (constant) value. If the amplitude of this a-c component is small compared with the value of $(\alpha n'F/RT)$, correspondingly small a-c components of polarization, current, and concentration will result. Thus rewriting [2] in terms of total (a-c plus d-c) quantities, gives

$$I + i = I_o \left(\frac{G + \zeta}{G_o}\right)^{g'} \left(\frac{L + \lambda}{L_o}\right)^{l'} \exp\left[\frac{\alpha n' F}{RT} (E + \eta)\right] \quad [3]$$

Recognizing that

$$\left(\frac{\zeta}{G}, \frac{\lambda}{L}, \frac{\alpha n' F}{RT} \eta\right) << 1$$

and neglecting terms of second order in these quantities, [3] can be written in the linearized form

$$i = I\left[g'\left(\frac{\zeta}{G}\right) + l'\left(\frac{\lambda}{L}\right) + \frac{\alpha n' F}{RT}\eta\right] \quad [4]$$

Equation [4] is the kinetic rate equation relating the a-c components of current, polarization, and concentration.

Mass transport through the porous layers of the electrode is assumed to occur by a diffusional type of mechanism, so that Fick's second law applies

$$\frac{\partial c}{\partial t} = D_{AB} \frac{\partial^2 c}{\partial z^2} \quad [5]$$

Here, D_{AB} can be thought of as a "pseudo" diffusion coefficient for transport through the porous medium. For diffusion paths which are large compared with pore size, the relation between gaseous binary molecular diffusivity and the porosity and tortuosity of the medium is (19)

$$D_{AB} = \mathcal{D}_{AB} \frac{\sigma}{\tau} \quad [6]$$

For transport of the electrolyte through the pores, an equivalent mechanism will be assumed. In this case, the "pseudo" diffusivity will also include the effects of migration. For dilute electrolytes, this is accomplished simply by multiplying the molecular diffusivity by the factor $(1 + Z_1/Z_2)$ as shown by Levich (20), where Z_1 and Z_2 are the charge numbers of the reacting and nonreacting ions, respectively. For very concentrated electrolytes, the effect is much more complicated, and the diffusion coefficient can no longer be considered a constant.

We shall consider three regions within the electrode. Region I includes the entire gas-filled pore layer, in which the only rate process is diffusion of the gaseous reactant in accordance with Fick's law. Region II includes the major portion of the liquid-filled pore layer, in which the only rate process is diffusion of the liquid reactant in accordance with Fick's law (with the appropriate "pseudo" diffusion coefficient). Region III is that portion of the liquid filled pore layer adjacent to the gas-liquid interface in which the catalyzed electrochemical reaction is assumed to occur. Hence simultaneous diffusion and reaction occur in this region, by the following assumed mechanism. The gaseous reactant dissolves in the liquid electrolyte at the interface, resulting in a concentration C_i at the electrolyte interface as given by Henry's law

$$C_i = G_i \frac{c_t RT}{H} \quad [7]$$

The dissolved reactant diffuses through the liquid-filled pores, and reacts simultaneously at catalytic sites on the pore walls as it diffuses. For small values of the pore diameter to length ratio, the problem is essentially one dimensional. Thus for region III, Eq. [5] is replaced by

$$\frac{\partial c}{\partial t} = D_{AB} \frac{\partial^2 c}{\partial z^2} - r = D_{AB} \frac{\partial^2 c}{\partial z^2} - i\left(\frac{ag}{nF}\right) \quad [8]$$

Since the concentration of dissolved gaseous reactant will be small compared with that of the liquid (electrolyte) reactant, L, the reaction zone (region III) will be small compared with the total diffusion path (d_L) of L. Hence the concentration of L will be assumed constant over this region at a value of L_i, as determined by solution of the diffusion equation for region II.

In summary, the appropriate dependent variables within the three regions, and their respective dependence on time and spatial coordinates are:

Region I:

$$z = 0;\ G = G_i,\ \zeta = \zeta_i(t)$$

$$0 < z < d_G;\ G = G(z),\ \zeta = \zeta(z,t)$$

$$z = d_G;\ G = G_o,\ d\zeta/dz = -\frac{ig}{nFD_{GG}}$$

Region II:

$$z = 0;\ L = L_i,\ \lambda = \lambda_i(t)$$

$$0 < z < d_L;\ L = L(z),\ \lambda = \lambda(z,t)$$

$$z = d_L;\ L = L_o,\ d\lambda/dz = -\frac{il}{nFD_{LL}}$$

Region III:

$$z = 0;\ C = C_i = G_i \frac{c_t RT}{H},\ \gamma = \gamma_i(t) = \zeta_i(t) \frac{c_t RT}{H}$$

$$z > 0;\ C = C(z),\ \gamma = \gamma(z,t),\ L = L_i$$

These conditions are expressed in terms of concentrations at the interface, which are dependent variables and hence are not known *a priori*. However, in solving the appropriate equations these conditions are essentially replaced by the following boundary conditions involving the total current density I_t, produced by the electrode

$$I_t = -\frac{nFD_{GG}}{g}\left(\frac{dG}{dz}\right)_{z=0} = -\frac{nFD_{LL}}{l}\left(\frac{dL}{dz}\right)_{z=0} = -\frac{nFD_{GL}}{g}\left(\frac{dC}{dz}\right)_{z=0} \quad [9]$$

with equivalent expressions for the total alternating current density, i_t, in terms of the flux of alternating concentration components.

It is noted that [2] can be written

$$E = \frac{RT}{\alpha n' F}\{\ln(I/I_o) + g'\ln(G_o/G) + l'\ln(L_o/L)\} \quad [10]$$

i.e., the total polarization can be expressed as the sum of three terms which are determined by the current production ("activation polarization"), and the change in reactant concentrations from bulk values ("concentration polarization"). The same interpretation can be made from [4] for the alternating components. Since L is assumed constant at L_i over the

reaction zone, for a given total current the term involving L is essentially a linearly additive constant (the same being true for λ). Thus the contribution of L and λ to d-c polarization and a-c impedance, respectively, results in an additional additive term dependent only on the total current and Fick's law over region II. Furthermore, since the calculation of this term is analogous to that for gas phase polarization (region I), the resulting gas and liquid phase terms are analogous, so that nothing new is learned by including the L term. Henceforth, it will be omitted, with the knowledge that it could later be included by simple linear addition for a given total current. This is equivalent to saying that setting $l' = 0$ results in no loss of generality for the present model.

Steady D-C Analysis

The solution for the steady d-c component of concentration has been given elsewhere (21). The results, for a first order ($g' = 1$) reaction and considering the effect of the inert gas phase component are

$$C = C_i \exp(-z\sqrt{K}) \quad [11]$$

where

$$C_i = \frac{c_t P_o}{H}\left[1 - (1 - G_o/P_o)\exp(I_t/A_2)\right] \quad [12]$$

$$K = [I_t g/(nFD_{GL}C_i)]^2 \quad [13]$$

$$A_2 = (nF\,P_o\,D_{GG}/g\,RT\,d_G) \quad [14]$$

and

$$E = \frac{2RT}{\alpha n'F}\ln(I_t/A_3C_i) \quad [15]$$

where

$$A_3 = [anFD_{GL}I_oH/(gG_oc_t)]^{1/2} \quad [16]$$

In Eq. [11]-[16], G_o refers to the partial pressure of the gaseous reactant in the bulk gas phase, P_o is the total pressure, and D_{GG} and D_{GL} refer to the pseudo-diffusivities of the gas reactant component within the gas filled and liquid filled pores, respectively. These equations are exact only if the liquid filled region is effectively semi-infinite relative to the reaction zone. As seen from [11], the effective penetration depth of the reaction zone is of the order of $1/\sqrt{K}$, which is quite small for normal values of current density (*i.e.*, significant polarization values). Hence the assumption of a semi-infinite liquid filled layer for the purpose of applicability of these equations should be quite adequate under polarized conditions.

Impedance Calculations

The electrode impedance is defined as the ratio of the alternating components of polarization (η) and current density (i_t), for a sinusoidally varying input. This involves the simultaneous solution of Eq. [4] and [8] for the appropriate alternating components, together with the condition

$$i_t = -\frac{nFD_{GL}}{g}\left(\frac{d\gamma}{dz}\right)_{z=0} \quad [17]$$

The steady d-c component also enters through I in Eq. [4].

Taking the LaPlace transform of [8] and combining with [4] (for $l' = 0, g' = 1$) gives

$$\frac{d^2\bar{\gamma}(s)}{dz^2} - \bar{\gamma}(s)\,K\left(1 + \frac{s}{KD_{GL}}\right) = \Delta\bar{\eta}(s)\exp(-z\sqrt{K}) \quad [18]$$

where

$$\Delta = \alpha n'FC_iK/RT \quad [19]$$

The solution to [18] is

$$\bar{\gamma}(s) = \left[\bar{\gamma}_i(s) - \frac{\Delta\bar{\eta}(s)}{K(1-\beta)}\right]\exp(-z\sqrt{K\beta}) + \frac{\Delta\bar{\eta}(s)}{K(1-\beta)}\exp(-z\sqrt{K}) \quad [20]$$

where

$$\beta = 1 + s/KD_{GL} \quad [21]$$

and $\bar{\gamma}_i(s)$ is given by the solution [5] for region I, relating $\bar{\gamma}_i(s)$ and $\bar{\zeta}_i(s)$ by Henry's law [7]:

$$\bar{\gamma}_i(s) = \bar{i}_t(s)\frac{A_4}{d_G\sqrt{s/D_{GG}}}\left[\frac{1 - \exp(d_G\sqrt{s/D_{GG}})}{1 + \exp(d_G\sqrt{s/D_{GG}})}\right] = \bar{i}_tA_4\Gamma(s) \quad [22]$$

where

$$A_4 = \frac{gc\,RT\,d_G}{nF\,H\,D_{GG}} \quad [23]$$

Substituting the derivative of (the transform of) [2] into [17], employing [22] for $\bar{\gamma}_i(s)$, and solving for $\bar{\eta}(s)/\bar{i}_t(s)$ gives

$$Z(s) = \bar{\eta}(s)/\bar{i}_t(s) = \sqrt{K}[(g/nFD_{GL}) - A_4\Gamma(s)\sqrt{K\beta}][1 + \sqrt{\beta}]/\Delta \quad [24]$$

Now if the substitution $s = j\omega$ is made in [24], the result is the complex impedance, $Z(j\omega)$. Separating this into real and negative imaginary parts gives the resistance (R) and capacitive reactance (X_c) of the electrode, as a function of frequency, ω. From [22] and [21], the frequency dependence of Z is seen to be a function of the following two dimensionless groups

$$\xi = d_G\sqrt{\omega/2D_{GG}} \quad [25]$$

and

$$\psi = \frac{\omega}{D_GK} = \frac{2D_{GG}}{KD_G}\left(\frac{\xi}{d_G}\right)^2 \quad [26]$$

The group ξ is essentially the square root of the ratio of the characteristic diffusion time through the gas pore layer to the angular period of the alternating voltage. The group ψ represents essentially the ratio of the characteristic reaction (relaxation) time to the angular alternating period.

Evaluation of $Z(j\omega)$ as a function of ξ was done with the aid of a computer for the representative system parameters shown in Table I. The results are expressed as impedance attenuation, $(DB)_z$, and phase angle, θ defined as follows

$$(DB)_z = 20\log(Z/Z_o) \quad [27]$$

$$\theta = \tan^{-1}(X_c/R) \quad [28]$$

Figures 2 and 3 show $(DB)_z$ and θ as functions of ξ for various values of ϕ, the ratio of current density to the gas phase diffusion limited current density

$$\phi = I_t/I_{lim};\ I_{lim} = A_2\left(\frac{1}{1 - x_o}\right) \quad [29]$$

It is pointed out that negative values of θ correspond to inductive reactances.

Figure 4 shows the Argand diagram (X_c *vs.* R) for the impedance components. The familiar semicircular form is seen, which blends into a 45° line as ξ increases. At sufficiently large values of ξ the reactance becomes inductive, and the curves approach a line with a negative slope of 45°.

Table I. Parameter values used in calculations

Gas phase: $x_o = 0.21$ mole fraction, $P_o = 1$ atm
Henry's law constant: $H = 3.95 \times 10^4$ atm/mole fraction
Porous medium: $\Phi = 0.5$, $\tau = 15$, $d_G = d_L = 0.1$ cm
Diffusivities: $D_{GG} = 0.2$ cm²/sec, $D_{LL} = 2 \times 10^{-5}$ cm²/sec
$D_{GL} = 1 \times 10^{-5}$ cm²/sec
Kinetic parameters: $I_o = 10^{-5}$ amp/cm², $n = n' = 4$, $\alpha = \frac{1}{2}$
$(aI_o) = 5 \times 10^{-5}$ amp/cm³, $T = 25$°C

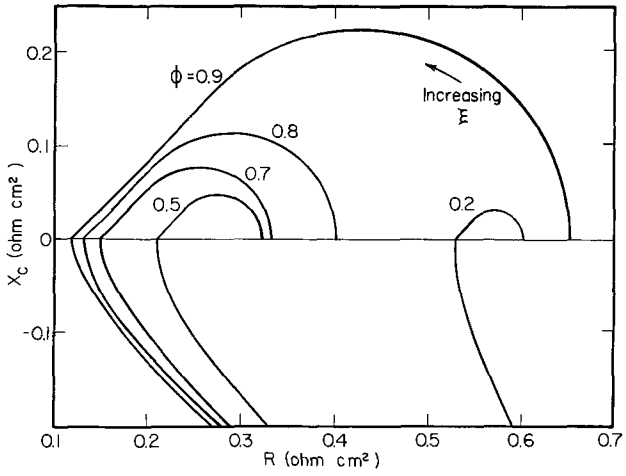

Fig. 4. Argand diagram

Limiting (Uncoupled) Behavior

As previously noted, the above analysis is valid for reaction penetration depths $(1/\sqrt{K})$ less than d_L. However, [as shown in (19)], when the reaction rate (I_t) is sufficiently large so that $1/\sqrt{K}$ is of the order of the pore diameter, this approach is not valid, since it will not then be possible to introduce a "pseudo" diffusion coefficient as per Eq. [6]. Further, it will not be possible to define an effective rate constant per unit volume, represented by $(I_o a)$. However, in this case the penetration depth would be so small that the reaction takes place essentially at the plane of the interface located at the junction of the two layers, and there will be no region of simultaneous reaction and diffusion represented by region III. Thus this condition is equivalent to a planar nonporous electrode, with finite but independent diffusion paths for each reactant.

In this event, the d-c and a-c characteristics will be determined by the sum of three separate terms, as given by Eq. [4] and [10]. Here, the values of G, L, γ and λ are those at the interface which result from the solution of the diffusional flux equations, while I and i represent total values since the current is not distributed as before. This condition is treated in (21) as the "uncoupled" model.

Again assuming $l' = 0$, the resulting complex impedance becomes,

$$Z(j\omega) = \frac{RT}{\alpha n' F}\left(\frac{1}{I_t} - \frac{gg' d_G \Gamma(j\omega)}{n F D_{GG} G_i}\right) \quad [30]$$

The impedance is thus composed of a purely resistive term, which is inversely proportional to total d-c current ("activation impedance"), and a complex term due to diffusion ("concentration impedance"). The contribution to $(DB)_z$ and θ from the concentration impedance term only is shown as the dashed curve on Fig. 2 and 3. As expected, the results for the total $Z(j\omega)$ (*i.e.*, the sum of both activation and concentration terms) for the uncoupled case approach the previous results for the coupled case very closely for larger values of ϕ. At smaller values, the $(DB)_z$ and θ curves approach zero, the inductive characteristic being absent. Likewise the Argand diagram for the concentration impedance is a semicircle blending into a 45° line through the origin. The addition of the resistive activation term merely serves to shift the entire curve along the real axis. No negative (inductive) reactance is predicted for this limiting (uncoupled) condition.

Restrictions

The analysis of electrode impedance presented here does not include the non-Faradaic effects of ohmic resistance and double layer capacitance, both of which contribute to the total impedance. The former is quite often negligible in comparison with mass transport effects, as pointed out by Austin and Lerner (22), and in any event can be independently measured and separated from polarization data [*e.g.*, Brodd (23)]. The double layer capacitance, on the other hand, can be quite significant, especially in porous systems. Although in principle it too may be determined independently in the absence of reaction, this is not easily done in practice. However these factors should not affect the qualitative picture of electrode impedance presented here, inasmuch as the inductive effects appear only at relatively high frequencies, and capacitive reactance effects from the double layer should be small at these frequencies.

Potassium Distribution in Nickel-Oxide Electrodes

Frederick P. Kober and Paul Lublin

General Telephone & Electronics Laboratories, Inc., Bayside, New York

Various authors have considered the role and distribution of potassium ion in the electrochemical oxidation of nickel-oxide electrodes in alkaline solution. Bourgault and Conway (1) were able to relate extrapolated values of the "reversible" electrode potential to the activity of H_2O and KOH in the electrochemical oxidation reactions using the data of Akerlof and Bender (2). Their results indicate the association of hydrated KOH with the charged state. A formal reaction is given and shows the discharged state to be free of any adsorbed KOH. These results are in qualitative agreement with the previous work of Kornfeil (3). Neither of these authors has considered the inclusion of potassium into the crystal structure of the active materials.

Experimental

The potassium content of sintered nickel electrodes impregnated with nickel hydroxide was investigated by means of electron probe analysis.[1] A Norelco AMR/3 electron probe analyzer equipped with two channels and a beam scanner, operating at 30 kv, was employed. The electrodes to be investigated were cycled in 31% KOH at the 3-hr rate and then thoroughly washed with deionized water in a continuous extractor for at least 48 hr. This elaborate washing procedure was employed to insure the complete removal of any adsorbed electrolyte. The electrodes were then potted in epoxy resins and polished in alcohol in order to reduce the tendency for the re-distribution of the potassium ions.

Beam scanning techniques were used to survey the samples. Since the specimen current is a function of atomic number as well as mass density, the specimen current scans are indicative of both average atomic number and porosity. Consequently, any interpretation of the results must be tempered by a consideration for the porous structure of the samples. Potassium x-ray scans were used to reveal the relative distribution of potassium in a given area under examination. As additional information, concentration profiles were obtained by positioning the goniometers on selected po-

tassium and nickel lines and mechanically translating the specimen under the electron beam.

Results and Discussion

The specimen current scan of a charged and discharged electrode revealed the highly porous nature of the electrode surface. Because of the porosity of the surface, quantitative analysis of the potassium content is not possible. However, qualitative generalizations can be made concerning the concentration and distribution of potassium in the electrode.

Figure 1 shows the potassium x-ray scans of sintered nickel-oxide electrodes. In general, the charged state appears to have a higher potassium content than the discharged state. The highest potassium concentration is observed during the initial charging of an electrode (Fig. 1a). Upon subsequent cycling the concentration

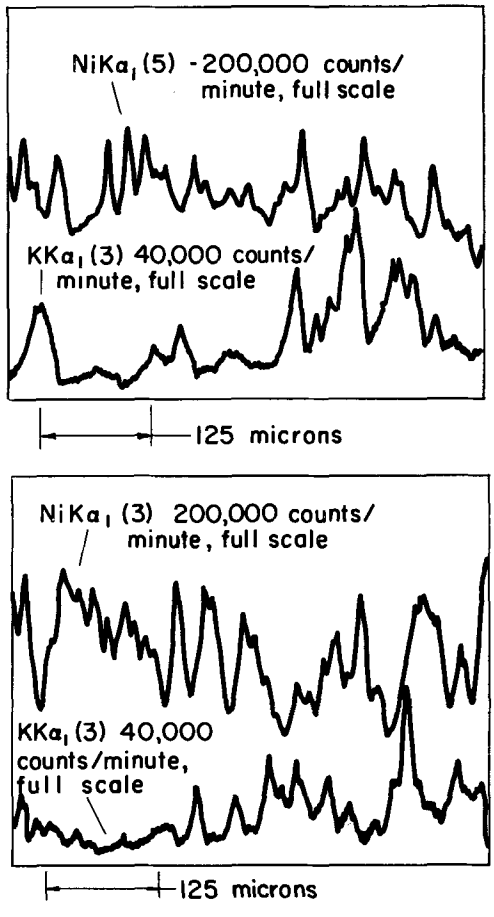

Fig. 2. Nickel and potassium concentration profiles. (a, top) Charged, 50 cycles, (b, bottom) discharged, 50 cycles.

slowly decreases to a stable limiting value (Fig. 1c and e). This increase in potassium concentration during charging is in qualitative agreement with the results of Bourgault and Conway (1) and Kornfeil (3). However, it is also observed that potassium is associated with the $Ni(OH)_2$ structure of the discharged state. It appears that although potassium is exchanged between the solid-phase and the electrolyte during the course of electrochemical reaction, a residual amount always remains incorporated within the crystal structure.

Perhaps more interesting than the changes in potassium concentration which occur during electrode reaction is the distribution of potassium within the solid phase. The x-ray scans (Fig. 1) reveal agglomerates of potassium, *i.e.*, localized areas of high potassium concentration. This result is further evidenced by the concentration profiles shown in Fig. 2. The exact meaning of this result is, at present, not well understood with respect to the role of potassium ion in the overall reaction mechanism.

Electron probe analysis is easily extended to a study of the effect on electrode reactions of cations other than potassium. There is, however, one notable exception. The analysis of lithium ion is, at present, beyond the capabilities of the electron probe.

Acknowledgment

The authors wish to thank Mr. M. A. Aia for his many helpful discussions during the course of this investigation.

Red Emitting Al_2O_3 Based Phosphors

Virgil D. Mochel[1]

Technical Staffs Division, Corning Glass Works, Corning, New York

Two new Al_2O_3-containing phosphors which emit in the red and near-infrared have been prepared.

The first type is prepared by thoroughly mixing Al_2O_3, Li_2CO_3, and Fe_2O_3 and firing in air at a temperature between 1100° and 1550°C. A bright red or fuchsia photoluminescence (PL) results when they are irradiated with 254 mμ radiation. Only a weak red emission is observed if they are excited at 366 mμ.

Reagent grade materials are satisfactory for the preparation. PL is observed for concentrations of Li_2O varying between 0.05 and 20.8% in weight per cent. A concentration of 5.0% Li_2O is optimum. Li_2O was usually added as Li_2CO_3, but other compounds of Li could be used as well. Fe_2O_3 concentrations varied between 0.013 and 1.3% by weight with 0.13% being optimum.

The best firing temperature was found to be about 1450°C although bright PL is observed from any of these phosphors fired in the range 1100°-1550°C. Firing time is not critical above 1200°C, but at 1100°C a marked improvement in PL is noticed in firing at 1 hr as compared to 30 min. The phosphors were fired in oxidizing reducing, and neutral atmospheres with no differences noted in the PL.

[1] Present address: Central Research Laboratories, The Firestone Tire and Rubber Company, Akron, Ohio.

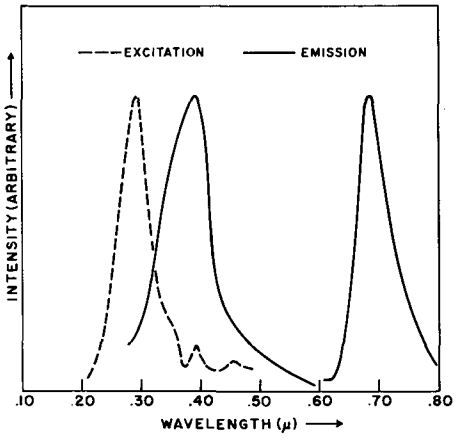

Fig. 1. Emission and excitation spectra for $Li_2O \cdot 5Al_2O_3$:Fe phosphor. Curves are normalized.

According to x-ray diffraction analysis, Li_2O serves to form the crystalline phase, lithium spinel ($Li_2O \cdot 5Al_2O_3$) otherwise known as lithium zeta alumina (1,2). The Fe_2O_3 is an activator, apparently. There is enough Fe impurity in reagent grade Al_2O_3 to activate the phosphor, but the PL is enhanced by further Fe_2O_3 additions.

Figure 1 shows the excitation and the emission spectra of these phosphors. The spectra were obtained with an Aminco-Bowman Spectrophotofluorometer. The solid curves are the emission spectra in the visible and the near-infrared regions when excited with 254 mμ radiation. The emission peak in the visible region centered at 390 mμ was obtained with a 1P28 photomultiplier tube, and the peak centered at 682 mμ was obtained with a 7102 photomultiplier tube. Because of the lack of calibration, the relative intensities of the two peaks could not be determined. All curves are normalized. The dotted curve is the excitation spectrum for the 682 mμ peak.

Figure 2 shows a direct comparison of the red emission with that of Sylvania No. 235 phosphor, which is

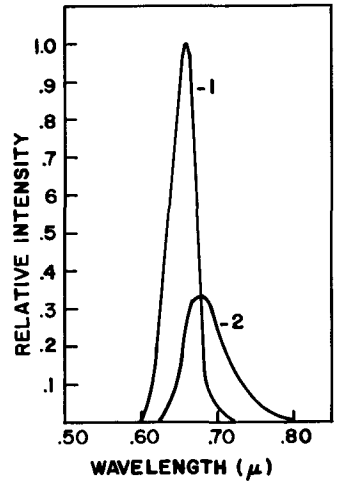

Fig. 2. Comparison of the red emissions of Sylvania 235 phosphor and $Li_2O \cdot 5Al_2O_3$:Fe phosphor. Both phosphors were excited with 254 mμ radiation: 1, Sylvania No. 235 phosphor; 2, $Li_2O \cdot 5Al_2O_3$:Fe phosphor.

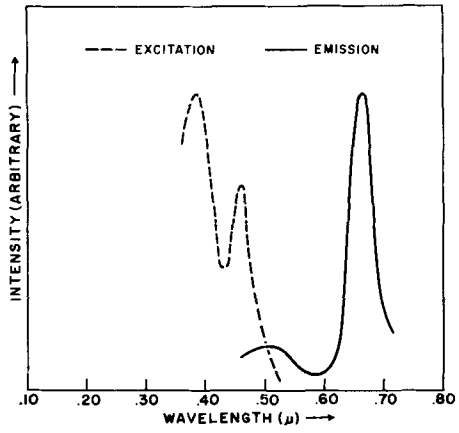

Fig. 3. Emission and excitation spectra for $CaO \cdot 2Al_2O_3$:$MnCl_2$ phosphor. Curves are normalized.

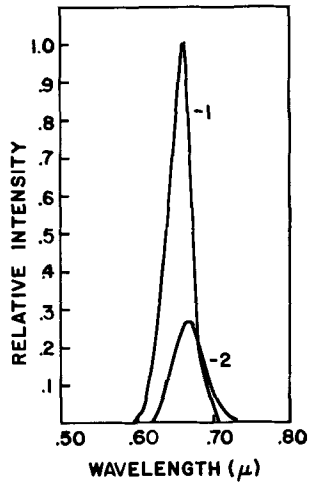

Fig. 4. Comparison of the red emissions of Sylvania 235 phosphor and $CaO \cdot 2Al_2O_3$:$MnCl_2$ phosphor. Both phosphors were excited with 366 mμ radiation: 1, Sylvania No. 235 phosphor; 2, $CaO \cdot 2Al_2O_3$:$MnCl_2$ phosphor.

a Mn-activated magnesium arsenate phosphor. The curves were run under identical conditions and have been corrected for the sensitivity of the photomultiplier tube. The ratio of the integrated intensities under the two curves is 1.8/1.

The temperature dependence of the Al_2O_3 phosphor is excellent. The relative brightness remains essentially constant at least up to a temperature of 320°C. No color shift is observed over this range. The color coordinates[2] (trichromatic coefficients) are $x = 0.729$ and $y = 0.272$.

Another series of red PL phosphors was prepared by slurrying a mixture of Al_2O_3, CaO, and $MnCl_2$ in water and firing at 1450°C. The concentration of CaO can be varied between 4.0 and 17.0% by weight and the concentration of $MnCl_2$ between 0.0048 and 1.0% by weight. The optimum composition appears to be: Al_2O_3—83.0%, CaO—17.0%, $MnCl_2$—0.048%.

X-ray diffraction analysis shows $CaO \cdot 2Al_2O_3$ as the major phase and alpha-Al_2O_3 as a minor phase. The $CaO \cdot 2Al_2O_3$ phase with $MnCl_2$ as the activator gives rise to the PL. It is known that Al_2O_3 emits a red or a green luminescence when activated with Mn (3). However, Al_2O_3 compositions which contained only $MnCl_2$ or only CaO exhibited a very weak red PL. This was also true of those containing $MnCl_2$ and just small concentrations of CaO. As the concentration of CaO increased, the brightness of the phosphor also increased until the optimum was reached.

The spectra are shown in Fig. 3. Again the solid curve shows the emission spectrum and the dotted curve shows the excitation spectrum. There is a strong red emission centered at 665 mμ and a weaker, broad peak at about 500 mμ. The phosphor is excited by both 254 mμ and 366 mμ radiation, but the red emission is most strongly excited by 366 mμ.

Figure 4 gives a direct comparison of the red emission of this type of phosphor with that of the Sylvania No. 235 phosphor. Both were excited with 366 mμ radiation. The integrated intensity of the Sylvania phosphor is about 2.9 times greater than that of the Al_2O_3 phosphor.

Since the blue emission of the first type of phosphor is centered at about 390 mμ, it can be used to activate any other phosphor which is sensitive to this wavelength. This was done with a mixture of the two phosphors described above. Peaks from both phosphors appeared in the spectrum when excited with 254 mμ radiation.

Manuscript received Aug. 19, 1964; revised manuscript received Sept. 24, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

[2] The color coordinates and the temperature dependence were kindly measured by W. A. McAllister of Westinghouse Electric Corporation, Lamp Division.

Silicon Dioxide Films Doped with Phosphorus

Y. Miura, S. Tanaka, Y. Matukura, and H. Osafune

Semiconductor Division, Nippon Electric Co., Ltd., Kawasaki, Japan

There recently has been great interest in the properties of the silicon dioxide film with the development of the oxide coated semiconductor devices such as the planar transistor, MOS transistor, and integrated circuit. It has been reported (1) that the semipermanent changes in the surface potential occur in the oxide coated silicon when an external field is applied at elevated temperature. This instability can be accounted for by the migration of sodium ions (2) and/or oxygen vacancy ions (3) in the silicon dioxide film. It would be very difficult to produce sodium-free or vacancy-free silicon dioxide film in the device production. One method to obtain a stable dioxide film is the doping of phosphorus into the silicon dioxide film, because the phosphosilicate layer is supposed to be an effective mask against the sodium and oxygen vacancy ions (4). The experimental techniques of the phosphorus doping into the silicon dioxide film during the vapor deposition of the silicon dioxide (5) and during the thermal oxidation are discussed in this paper.

Figure 1 (a) shows the schematic diagram of experimental apparatus to obtain the silicon dioxide film doped with phosphorus by vapor growth technique. Through the $SiCl_4$ saturator and $POCl_3$ or PCl_3 satu-

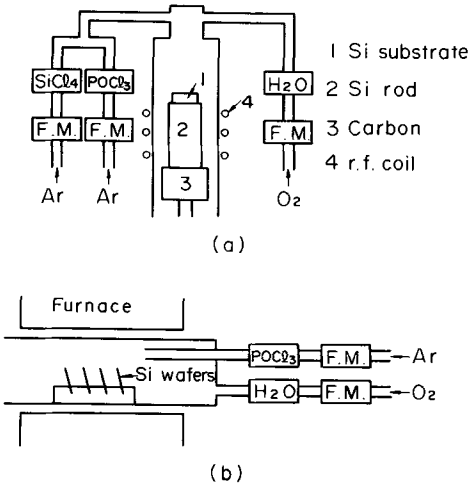

Fig. 1. Apparatus for growth of the silicon dioxide films doped with phosphorus.

rator, argon gas is introduced into the reaction chamber, where the gas is mixed with the oxygen gas saturated with H_2O.

The silicon dioxide doped with phosphorus is grown onto the silicon wafer mounted on the silicon pedestal heated by RF power.

On the incorporation of phosphorus into the silicon dioxide, the following reactions may be written

$$2POCl_3 + 3H_2O \rightarrow P_2O_5 + 6HCl$$

$$SiCl_4 + 2H_2O \rightarrow SiO_2 + 4HCl$$

The upper reaction proceeds only in oxygen atmosphere, and the product P_2O_5 incorporates into the silicon dioxide film. The silicon dioxide free of phosphorus is deposited initially onto the silicon wafer and subsequently phosphorus-doped silicon dioxide.

This procedure prevents the diffusion of phosphorus into the silicon. Deposition of the silicon dioxide is carried out at the temperature above 900°C and the growth rate of the silicon dioxide film is independent of doping with phosphorus.

Figure 1(b) shows another technique to obtain the phosphorus doped silicon dioxide film. Phosphorus is incorporated into the silicon dioxide film during the thermal oxidation process. At first, the wet oxygen is introduced, and then $POCl_3$ is introduced. The oxidation rate in this process is not affected by the addition of $POCl_3$ but is similar to that in the ordinary thermal oxidation.

The presence of phosphorus in the silicon dioxide film is verified by the absorption band at 7.5μ due to phosphorus, although it has not been reported yet that

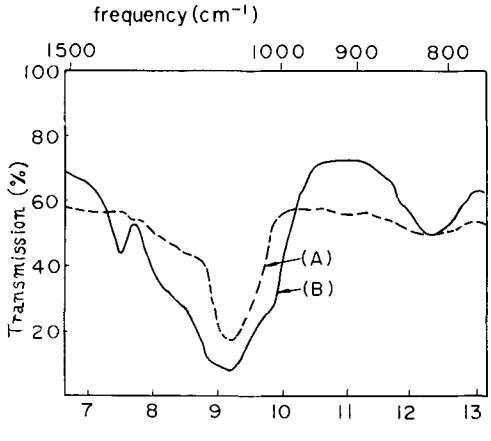

Fig. 2. Effect of phosphorus doped into silicon dioxide layers

Table I. Phosphorus content in the silicon dioxide films
Deposition temperature 900°C

Sample	Mole ratio (P/Si)	P (wt %) in SiO_2
152	0.23	5.6
112	0.49	10.0
117	0.75	15.4
113	1.1	19.6

this absorption band corresponds to phosphorus. Curve A in Fig. 2 shows the absorption curve of the nondoped silicon dioxide film and it does not show the peak at 7.5μ, while curve B for the film doped with phosphorus has the peak at 7.5μ. Phosphorus content is determined by the chemical analysis. The phosphorus content increases linearly with the mole ratio of phosphorus to silicon in gas phase, as shown in Table I.

The etch rate of the silicon dioxide film increases with the increasing phosphorus content. Successive etching of the silicon dioxide film doped with phosphorus shows that phosphorus uniformly distributes along the growth direction of the silicon dioxide. The refractive index slightly increases with the increasing phosphorus content. The dielectric constant is nearly constant, independent of phosphorus content.

MOS diodes are fabricated for studying the stability of the surface potential in the oxide coated silicon under the bias-temperature stress. Silicon substrates are prepared by using an FZ crystal of n-type 15 ohm-cm. No particular caution is taken about the aluminum evaporation. On the experiments of the MOS stability, the shift of the flat-band-voltage, ΔV_{FB}, in capacitance-voltage characteristics of the MOS diode is measured before and after the bias-temperature treatment. Positive sign of ΔV_{FB} means the accumulation of electrons to the silicon surface at the silicon-silicon dioxide interface. The measurements are performed at 1 mc/sec.

Figure 3 shows the relation between ΔV_{FB} and the field strength in the silicon dioxide film during the bias-temperature treatment for 30 min at 300°C. Curve (A) in Fig. 3 corresponds to the diode prepared by using the wafer with the silicon dioxide film doped with 11.4% (BW) phosphorus by the vapor grown technique, and curve (B) corresponds to the diode with 15% (BW) phosphorus doped by the thermal oxidation technique. Positive sign of the field strength shows a bias direction as metal is positive to silicon. For nondoped MOS diode, curve (C), the value of ΔV_{FB} is remarkably large even at a positive low field strength, but for the diodes with phosphorus doped silicon dioxide the value of ΔV_{FB} is small. It is noticeable that ΔV_{FB} at the high negative value of the field strength is negative.

Stable MOS diodes are obtained by doping the silicon dioxide film with phosphorus, as shown in Fig. 3. It

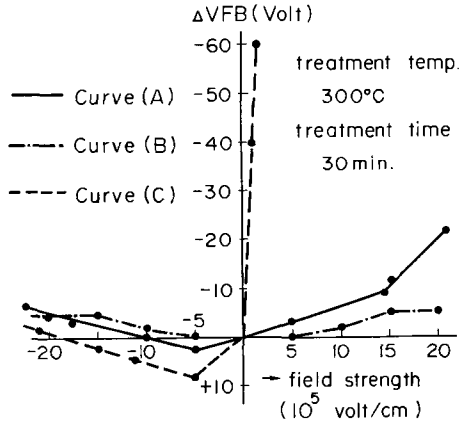

Fig. 3. Relation between the shift of flat-band-voltage ΔV_{FB} and field strength in the silicon dioxide film.

cannot be defined whether or not phosphorus combines with sodium ion or oxygen vacancy ion in the silicon dioxide film. But, it can be concluded that phosphorus doped into the silicon dioxide impedes the movement of such ions and gives stable MOS diodes.

Thermal diffusion of phosphorus into the silicon dioxide film has been put into practice to obtain a stable oxide film (4). But, it has a remarkable gradient of the phosphorus content in the silicon dioxide film. As mentioned above, the etching rate increases with the increasing phosphorus content. In the fabrication of the device, selective etching of the oxide film is an important process, then the uniform distribution of phosphorus in the silicon dioxide film is desirable. The oxide film obtained by the technique, presented in this paper, has a fixed etching rate independent of the position in the oxide film. Thus, these doping techniques are suitable for the fabrication of the planar transistor, MOS transistor, and the integrated circuits.

Preparation of Rare Earth Nitrides by Reactive Arc Melting

R. J. Gambino and J. J. Cuomo

Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

The rare earth nitrides are a group of refractory compounds with the rock salt structure. They are hard, brittle compounds, stable, but extremely sensitive to hydrolysis. Current interest in the magnetic and electrical properties of these compounds has prompted an investigation of improved methods for their preparation.

The nitrides have been prepared in the past by the reaction of rare earth metal filings (1) or hydride powders (2) with nitrogen or with ammonia gas. These methods have not in general yielded stoichiometric products even after long and repeated reaction (1, 2). Elaborate precautions must be taken to prevent the oxidation of powdered rare earth metals and hydrides and the hydrolysis of the nitride product. The product is obtained in the form of a finely divided, highly reactive powder which is unsuitable for many types of physical properties measurements.

The objective of this study was to devise a method for the preparation of high purity, oxygen free, rare earth nitrides in an unreactive, consolidated form. In some initial experiments it was found that the nitrides could be formed by reacting molten rare earth metal, contained in a tantalum crucible, with flowing, high purity nitrogen (3). The reaction did not go to completion, however, because the product formed as an impervious crust on the surface of the melt inhibiting further reaction. The product was very fine grained and sensitive to hydrolysis.

The method ultimately developed was reactive arc melting. This method differs from inert gas arc melting in that the gas phase in which the arc is sustained takes part in the reaction. The rare earth metal is arc melted on a water cooled copper hearth in a high purity nitrogen atmosphere. The steep temperature gradient in the melt, inherent in this configuration, causes the nitride to precipitate at the cooler bottom of the melt. In one operation, the nitride is formed and consolidated into a dense, coarsely grained ingot. The method is rapid and simple and is well suited for the preparation of solid solutions between nitrides as well as doped samples.

Experimental

The apparatus consists of a commercial arc furnace with a water cooled copper hearth and a water cooled tungsten electrode. The chamber was provided with a vacuum port connected to a mechanical pump through a liquid nitrogen trap. The pressure was monitored with a thermocouple gauge and a bellows gauge for pressures above atmospheric. A pressure relief valve, set for 3 psi above atmospheric, was also provided. The input to the chamber was connected to cylinders of argon (ultra high purity 99.999%) and nitrogen (prepurified 99.996%) through appropriate valves and flow meters. A flow of either gas or a mixture of both could be delivered to the chamber.

Metals in both ingot and sponge form were used for this study (analyses of gadolinium are shown in Table I). Most of the samples were prepared from ingot rare earth; in a few cases it was possible to obtain the higher purity distilled sponge. The metal to be nitrided (typically 2 to 5g) was placed in the melting chamber which was then evacuated to about 10μ and backfilled with argon, at least three times. The arc was struck and the sample melted in argon. With the sample still molten, the argon flow was stopped and a flow of nitrogen was initiated. The arc was maintained for 1 min after the nitrogen was introduced. The reaction

was carried out in three or four such melting steps because maintaining the arc for more than 1 min caused overheating of the walls of the chamber. Due to the difficulty of striking the arc in nitrogen, it was necessary to evacuate the chamber and back fill with argon before each melting. The arc current used varied from 180 to 260 amp depending on the melting point of the metal. The nitrogen flow was 10 liters/min. Solid solutions were prepared by alloying the two rare earths, then nitriding the alloy by the same procedure as was used for the pure metals.

Metallographic sections of product ingots were made by conventional techniques with slight modification. The sample was fractured into several pieces in order to obtain a vertical section. The specimen was mounted in glycol phthalate on a metal polishing plug and hand ground on 400, 600, and 0/2 metallographic papers with kerosene as a lubricant and rinse. The sample was then polished with 1μ diamond paste on a vibratory polisher. The polished surface had a blue-black lustrous finish which reacted with air when the kerosene was removed giving interference colors and eventually a white or dull gray surface. The micrographs had to be taken within about 15 min of final polishing to avoid this air corrosion. The initial stages of oxidation were selective with respect to grain orientation and grain boundaries and thus constituted a convenient and effective etch. No other etching procedure was necessary. Analysis of the micrographs was made by the lineal method (4).

Specimens for x-ray diffraction analysis were prepared by pulverizing the nitride to a fine powder in a dry nitrogen (dew point —100°C) filled dry box and sealing the powder in Lindemann glass capillaries (0.3 mm diameter). Powder patterns were made with Fe-Kα radiation in a 90 mm Debye-Scherrer camera.

Results

Most of the rare earth nitrides as well as yttrium nitride have been prepared by this technique. The results of x-ray diffraction and metallographic analyses on some of these samples (prepared from ingot R.E.) are shown in Table II. Samples prepared from gadolinium sponge and gadolinium ingot (see Table I) did not show significant differences in the properties tabulated. From the data in Table II one notes these samples are almost fully dense.

The oxygen concentration in the product nitride and in the as-received rare earth metal sponge was determined by spark source mass spectrographic analysis. In the two samples examined, GdN and ErN, the oxygen level was found to be the same in the nitride as in the metal, both about 1000 atomic ppm. This result suggests that no oxygen contamination occurs during the nitride preparation.

The product ingots usually have a thin layer of unreacted metal on their top and bottom surfaces which can be ground off to isolate the nitride. Occlusions of rare earth metal are observed as a minor second phase [usually <1 v/o (volume per cent)] within the nitride grains. Since the unreacted metal in the nitride portion of the ingot is present in small concentrations and occurs as isolated occlusions rather than at grain boundaries, its effect on the physical properties of the nitride is probably small.

The unreacted metal in the ingots, both at the surface and within the grains, can be eliminated by annealing the ingots in flowing N_2 for 2 hr at 2200°C. This treatment also results in considerable grain growth (see Table II). The samples had to be exposed to air, however, while being transferred from the arc melter to the annealing furnace. The oxide layer, formed on the ingot surface during this air exposure, diffused into the ingot during the anneal and thus was a source of oxygen contamination.

Solid solutions of the type $GdN_{1-x}O_x$ have been prepared by reacting mixtures of Gd metal and Gd_2O_3 with nitrogen. At 2000°C, oxygen can substitute for nitrogen up to an X value of 0.12. The lattice constant of the solid solution decreases with oxygen concentration from 4.99 to 4.96Å at the solubility limit. The paramagnetic Curie temperature, θ_p, decreases from 68°K for GdN to 31°K for the most oxygen rich solid solution. It is apparent from those results that oxygen contamination can have a drastic effect on the magnetic properties of rare earth nitrides.

The lattice constants of the arc melted nitrides are in good agreement with the values reported in the literature (5). The lattice constant of the nitride phase in samples which were intentionally incompletely reacted was the same as that of single phase ingots. This

suggests very limited solid solubility on the metal rich side of the compound. No impurity phase, other than the metal, was observed by x-ray diffraction in any of the samples.

Discussion

In order to elucidate the mechanism of nitride formation, ingots were examined metallographically, in vertical section, after various periods of reaction. A band of nitride several millimeters thick was observed near the bottom of the ingot for 1 min of nitridation. The thickness of the nitride band increased with reaction time until after approximately 3 min it encompassed virtually the entire volume of the sample. A thin (> 1 mm thick) layer of unreacted metal was found on the bottom surface of the ingot in all cases. This surface layer is in contact with the water cooled copper hearth and thus remains solid throughout melting. The last portion of the melt to freeze always contains some unreacted metal and often has the microstructure of a eutectic, suggesting that the nitride is crystallizing from a nitrogen deficient melt. These observations suggest the following mechanism for the reaction:

1. Nitrogen gas dissociates at the surface of the melt and/or in the plasma of the arc and dissolves in the molten metal at temperature T_s (see Fig. 3).
2. The dissolved nitrogen is rapidly distributed throughout the melt by the arc current stirring of the melt until the concentration has the value C_1 (Fig. 3).
3. Initially, the melt-solid interface is at temperature T_I, the melting point of the rare earth metal. Nitride begins to precipitate at the interface when concentration C_1 is achieved.
4. As the concentration of nitrogen in the melt increases, the temperature of the melt-solid interface moves up the liquidus curve. At the same time, the interface moves upward through the melt leaving solid nitride behind it.

A similar mechanism has been proposed for the formation of III-V compounds by the "Solute Buildup" method (6).

Conclusions

Arc melting is particularly well suited for this method of reaction. The melt is in a very steep temperature gradient so that the formation of an impenetrable crust of nitride at the surface is avoided. The dissociation of nitrogen gas in the arc plasma and the rapid stirring of the melt by the arc current probably contribute to the high reaction rate. Rapid reaction makes it practical to use the rare earth metal in bulk form thus eliminating the oxygen contamination associated with the fine powders used in previous methods. The product is in the form of a dense ingot suitable for the fabrication of specimens for physical property measurements and is much more resistant to reaction than the fine powders previously obtained.

Acknowledgment

The authors are happy to acknowledge H. G. Schaefer who assisted with the preparation of the samples, R. Wnuk who assisted with the x-ray diffraction analysis, and J. Kuptsis for the mass spectrographic analysis. We also thank E. A. Giess and J. Gilvey for their advice and encouragement. We are also indebted to T. R. McGuire for permitting us to use previously unpublished data on the magnetic properties of oxygen-doped GdN.

Brief Communication

The Solubility of Oxygen in Molten Carbonates

M. Schenke, G. H. J. Broers, and J. A. A. Ketelaar

Central Technical Institute-TNO, The Hague, The Netherlands

The solubility of gases in molten salts has caused much interest recently with regard to technological problems (1-5). We have determined the solubility of oxygen in molten alkali carbonates with respect to galvanic high-temperature fuel cell research.

Our method is based on an amperometric titration of the dissolved oxygen, by adding stepwise solid Na_2SO_3 as a reducing agent [compare the potentiometric acid-base titrations in molten salts by Shams-El-Din *et al.* (6) and earlier publications]. The oxygen was dissolved by leading an O_2-CO_2 gas mixture of known composition through the melt, and titrations with Na_2-SO_3 were carried out under a cover of a N_2-CO_2 mixture, while the CO_2 partial pressure was kept constant. As indicator a system of two rotating platinum wire electrodes was used; during the experiment a fixed potential difference was maintained between these electrodes potentiostatically, the current being a measure of the amount of dissolved oxygen. The procedure will not be described here extensively; only the results will be given.

We determined the solubility of oxygen in the eutectic mixture of Li_2CO_3, Na_2CO_3, and K_2CO_3 (composition in mole %: 43.5% Li_2CO_3, 31.5% Na_2CO_3, 25.0% K_2CO_3; mp 397°C) and in the eutectic mixture of Li_2CO_3 and Na_2CO_3 (in mole %: 53.3% Li_2CO_3, 46.7% Na_2CO_3; mp 496°C).

Henry's law, $L = Zp$, was found to be obeyed within the limits of accuracy, (p = gas pressure in atm; Z = Henry's coefficient, expressed in mole/cm^3 atm; L = gas solubility in mole/cm^3). In Fig. 1 the decadic logarithm of the Henry coefficient is given as a function of 1/T. The plotted lines were calculated with the method of least squares.

There is a small, but certainly significant dependence of solubility on the composition of the carbonate melt, both with respect to the absolute value and to the temperature coefficient. The solubilities of O_2, as well as the heats of solution are of the same order of magnitude for different melts and comparable with data found for other gases and other melts (1-5). As can be seen, the process of solution is endothermic, the enthalpies of solution, calculated with $\Delta H = -R\,[\partial \ln Z]/[\partial\,(1/T)]$, being + 14.9 kcal/mole for the binary mixture and + 17.7 kcal/mole in the ternary case, respectively. The solubility of H_2 in molten carbonates will be determined in an analogous way.

Solubilities of Mn(II) and Mn(III) Ions in Concentrated Alkaline Solutions

A. Kozawa, T. Kalnoki-Kis, and J. F. Yeager

Research Laboratory, Consumer Products Division, Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

Measurements using a polarographic method of the solubility of Mn(II) in 3-13.5M KOH and 3-19M NaOH at 23°, 50°, and 70°C, as well as solubility of Mn(III) in 5-13.5M KOH at 23°C, are reported. The exponential increase in solubility found with increasing KOH and NaOH concentrations is principally due to the formation of OH^- coordinated-complex ions; $Mn(OH)_2 + nOH^- = [Mn(OH)_{n+2}]^{n-}$. Based on the calculation of the equilibrium constant, a likely predominant species of the Mn(II) complexes is $[Mn(OH)_4]^=$ in 5-12M KOH. Based on measurements for solubility of Mn(II) the heat of dissolution was found to be 6.7 kcal in 9M KOH.

It has been shown previously (1) that the cathodic reduction of electrolytic MnO_2 in 9M KOH took place in two steps, namely, from MnO_2 to Mn_2O_3 (or MnOOH) in the first step and from Mn_2O_3 to $Mn(OH)_2$ in the second step. It was assumed that the first step was a homogeneous phase discharge through a proton and electron transfer in the MnO_2 lattice, and for the second step a new discharge mechanism was proposed (1) based on the presence of dissolved Mn(II) and Mn(III) in 9M KOH. In order to study the details of the second step, solubility values of Mn(II) and Mn(III) oxides or hydroxides in concentrated alkaline solutions were needed. This prompted the present measurements.

Few papers have been published on the solubility of Mn(II) in alkaline solutions. Fox *et al.* (2) in solubility measurements of $Mn(OH)_2$ in neutral solution and up to 4M NaOH solutions found that the solubility increased with increasing NaOH concentration: 7.53×10^{-5}m of Mn(II) in 1.924m NaOH and 29.8×10^{-5}m in 4.14m NaOH. They proposed a reaction, $Mn(OH)_2 + OH^- = HMnO_2^- + H_2O$, to be a main reaction in this NaOH concentration range. Scholder and Kolb (3) measured solubilities of $Mn(OH)_2$ in 6.1-18.7M NaOH solution at boiling temperatures (108°-141.5°C) and found the Mn(II) ion concentration to be 0.211×10^{-2}m-13.34×10^{-2}m in the concentration range of NaOH. They also isolated $Na_2[Mn(OH)_4]$ and Ba_2 (or Sr_2)$[Mn(OH)_6]$ from 50% NaOH (or 19M NaOH) solution saturated with $Mn(OH)_2$.

In the present measurements, by a polarographic method, Mn(II) solubilities in 3-13.5M KOH and in NaOH were obtained at 23°, 50°, and 70°C, and Mn(III) solubility was measured in 5-13.5M KOH at 23°C. The data are discussed to elucidate the equilibrium in the solution and to identify the predominant species of Mn(II) complexes.

A polarographic method was selected in the present measurement because the polarographic diffusion current is not only proportional to the concentration of dissolved Mn(II) or Mn(III), but is usually unaffected by the excess solid material suspended in the solution (except colloidal materials, which will be mentioned later). Therefore, the very difficult separation of the excess manganese hydroxide by filtration from viscous alkaline solutions of high concentration was avoided.

Experimental

General polarographic behavior of Mn(II) *and* Mn(III).—In alkaline solutions, Mn(II) ion gives an oxidation wave and Mn(III) ion gives a reduction wave at a dropping mercury electrode as shown previously in the case of 9M KOH (1). While the half-wave potential of the anodic wave was considerably apart from that of the cathodic wave in lower KOH or NaOH concentrations, with increasing KOH or NaOH concentration the anodic and cathodic polarograms became more reversible and the difference between the two half-wave potentials became smaller. In 19M NaOH (*ca.* 50% NaOH by weight), the anodic and cathodic half-wave potentials were within 5 mv of each other and were equal to —0.467v *vs.* Hg/HgO (19M NaOH). Although the polarograms of Mn(II) and Mn(III) ions were not reversible at lower KOH and NaOH concentrations, a fairly well-defined diffusion limiting current (i_d) was observed in the concentration range studied (3-13.5M KOH and 3-19M NaOH), the i_d values were found to be proportional to the Mn(II) or Mn(III) concentration. Therefore, these polarographic characteristics were utilized to measure the solubilities of Mn(II) and Mn(III) ions in concentrated alkaline solutions.

Solubility measurements for Mn(II).—All the measurements reported here were made in a slightly modified polarographic H-cell with a controlled potential and derivative voltammeter (4) as shown in Fig. 1. The sintered glass disc, which separates the H-cell into two compartments, was placed closer to the test solution arm, so that the viscous solutions of high concentration could be thoroughly stirred by the N_2 gas bubbling. The initial volume of the NaOH or KOH solution in the test arm was 20.0 or 25.0 ml. Both arms were filled with the same solution and the levels were kept equal. In the solubility measurement of Mn(II), $MnSO_4$ solution of known concentration was added step by step. Before the initial addition, dissolved oxygen was thoroughly eliminated by bub-

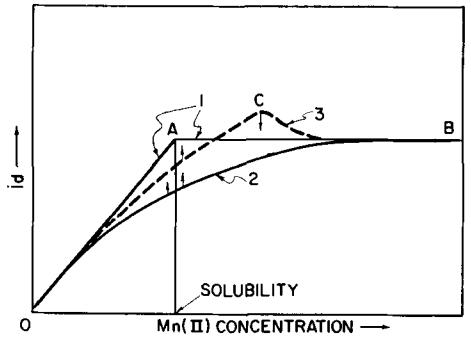

Fig. 2. Schematic i_d-[Mn(II)] curves: curve 1, an ideal curve; curves 2 and 3, experimentally obtained curves. Small arrows on the curves indicate the direction to which the i_d value changed with time.

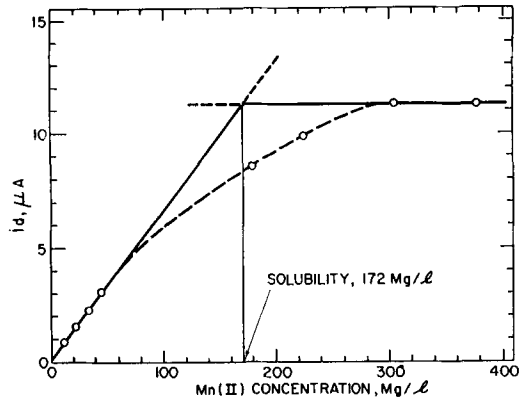

Fig. 4. i_d-[Mn(II)] curve in 11.26M KOH at 70° ± 1°C

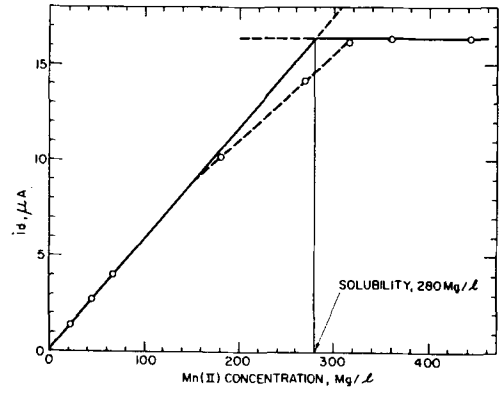

Fig. 3. i_d-[Mn(II)] curve in 13.52M KOH at 70° ± 1°C

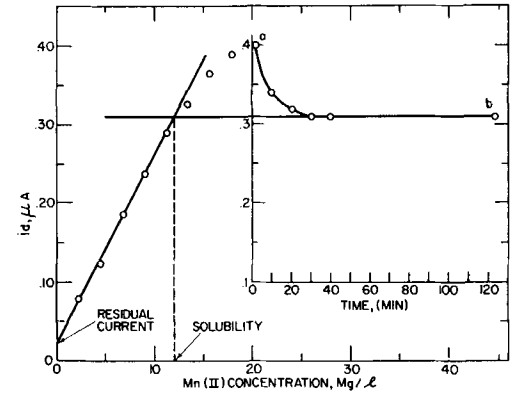

Fig. 5. i_d-[Mn(II)] curve in 5.3M KOH at 23°C

bling pure N_2 gas, because Mn(II) ion is easily oxidized to Mn(III) by dissolved oxygen in alkaline solutions. On each addition of the $MnSO_4$ solution, the solution was thoroughly mixed with pure N_2 gas, and the i_d was measured at —0.130v *vs.* a Hg/HgO reference electrode in the same solution. During the measurements at 50° and 70°C, the polarographic cell was kept in a water bath, but the Hg/HgO reference electrode was held at 23°C. The time required to obtain a constant i_d value, after the addition of $MnSO_4$, varied considerably, depending on the Mn(II) concentration as well as on the temperature. At Mn(II) concentrations far below the saturation value, a constant i_d was obtained usually within 10-15 min after each $MnSO_4$ addition. However, near the saturation value, and particularly at room temperature and low KOH concentrations, in many cases the i_d did not reach a constant value even after 60-100 min. In those cases, the i_d values were taken after 60-100 min even though they are not equilibrium values. At Mn(II) concentrations far greater than the solubility, the i_d reached constancy in a relatively short time, probably because the suspended solid functions as seed for the precipitation and coagulation of the colloid and/or the breaking of the supersaturation may be much easier.

The i_d values thus obtained were plotted against the Mn(II) concentration. The general shape of the i_d-[Mn(II)] curves are shown schematically in Fig. 2 and some measurements are shown in Fig. 3, 4, and 5. Curve 1 in Fig. 2 represents the ideal case where i_d increases linearly with Mn(II) concentration to the saturation value with no further increase after the solubility value. Types of the curves obtained experimentally are shown with curves 2 and 3 in Fig. 2. The reasons for such deviations from the ideal curve may be as follows. When $MnSO_4$ solution was added, even within the solubility value, white precipitate of $Mn(OH)_2$ was formed because of the localized high concentration of Mn(II), and the $Mn(OH)_2$ suspension slowly dissolved or polymerized Mn(II) species slowly decomposed to reach an equilibrium. Curve 2 in Fig. 2 probably represents such a case. In some cases (curve 3 in Fig. 2), the i_d exceeds the value of the solubility concentration. This is probably because of the formation of colloidal $Mn(OH)_2$ and some of the colloidal particles are reacting at the dropping mercury electrode in addition to the dissolved Mn(II) species. At point C on curve 3, the i_d decreases slowly with time to an equilibrium value as such colloidal particles coagulate, as shown in Fig. 5 (curve ab).

At high temperatures and high caustic concentrations, the i_d-[Mn(II)] curve was close to the ideal curve (curve 1 of Fig. 2) as shown in Fig. 3. At low temperatures and low caustic concentrations the i_d-[Mn(II)] curve was of the same type as curve 3 in Fig. 2 and is seen in Fig. 5.

In order to obtain a solubility value, (namely, to find out the intersection A of the lines OA and AB in Fig. 2) enough points to construct a straight line OA and one or two points after the saturation concentration are necessary. Usually three or four points were taken at low Mn(II) concentrations which were far from the saturation value, and one or two points taken beyond the saturation allowing a long time to obtain a true equilibrium.

Solubility of Mn(III).—In order to measure Mn(III) solubility, Mn(II) in KOH or NaOH solution must be oxidized to Mn(III). Two methods for such an oxidation were tested; oxidation by O_2 gas and electrochemical oxidation at a platinum electrode under controlled potential. In the first method, Mn(II) ion was added to the alkaline solution and oxygen gas was bubbled through. The i_d was measured at —1.25v *vs.* Hg/HgO electrode in the same solution, and i_d values were plotted against time; an example of such a curve is given in Fig. 6 in which i_d at —0.13v is also given to show Mn(II) concentration. These curves indicate that Mn(II) is oxidized to Mn(III) with time by

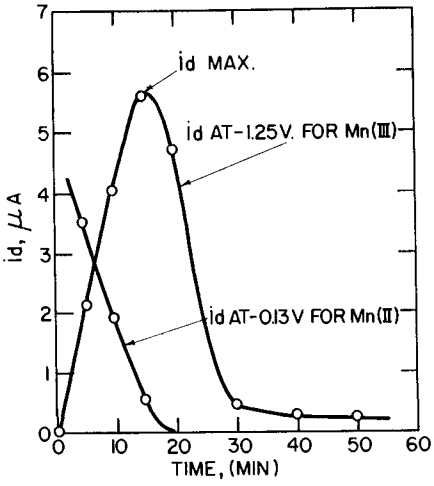

Fig. 6. i_d-Time curves during Mn(II) oxidation in 9M KOH by bubbling O_2 gas.

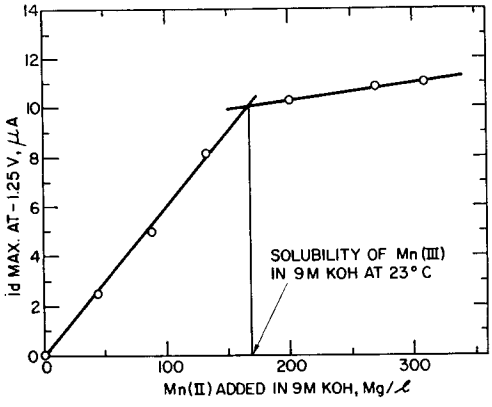

Fig. 7. i_d max-Mn(II) concentration in 9M KOH by the O_2 gas oxidation method (see text).

bubbling oxygen gas, but Mn(III) ion can be further oxidized to MnO_2, because the i_d decreased finally to zero and MnO_2 precipitated. When these i_d-time curves were taken for various initial Mn(II) concentrations and the i_d max (see Fig. 6) was plotted against initial Mn(II) concentration, a curve similar to curve 1 of Fig. 2 was found, and the approximate solubility of Mn(III) was obtained as shown in Fig. 7. The solubility values by this method were close to those obtained by the electrochemical oxidation. However, accuracy of the i_d max measurement was poor, and therefore the results by the electrochemical oxidation will be reported here.

In the electrochemical oxidation, Mn(II) ion in 9M KOH was oxidized at —0.35v *vs.* Hg/HgO (9M KOH). The potential value was found from a current-potential curve (Fig. 8) taken in 9M KOH containing Mn(II) and Mn(III). The current-potential curve may be interpreted as follows, although the details will be discussed in a separate paper. In the potential range from b to c, Mn(III) ion is reduced to Mn(II) ion and from c to f, Mn(II) ion is oxidized to Mn(III) ion, and from f to i, Mn(II) and Mn(III) ions are oxidized to MnO_2 which deposits on the platinum electrode. The potential at d is the approximate standard potential of the Mn(II)-Mn(III) couple in 9M KOH and that at g is of the Mn(III)-MnO_2 couple. The wave j is due to dissolution of the deposited MnO_2, and at k the platinum surface becomes completely bright. The peak potential of k depends on the amount of MnO_2 and is not a constant value.

The potential for the Mn(II) oxidation in other KOH solutions was determined in a similar manner. At various initial Mn(II) concentrations (added as

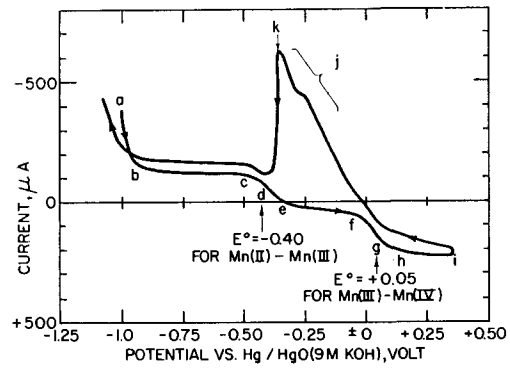

Fig. 8. Current-potential curves at a platinum electrode (apparent area: 9.0 cm^2) in 9.0M KOH containing Mn(II) and Mn(III) at 23°C. The current-potential curve in pure 9M KOH in which no manganese was added was close to the zero current line. The curve was taken with a scanning rate of 250 mv/min along the direction shown by arrows on the curve. Nitrogen gas was bubbled through the solution at a constant rate during the measurement.

$MnSO_4$), i_d values were determined at a dropping mercury electrode at —1.30v after the controlled potential oxidation at —0.35v. Solubilities were obtained from the i_d-[Mn(III)] curve in the same manner as described above for the Mn(II) solubility.

During the measurement, mercury accumulated at the bottom was taken out through the Teflon stopcock.

Accuracy.—All-over accuracy of the solubility data may be ±5% because of various errors associated with volume measurement of $MnSO_4$ solution and i_d measurement in addition to relatively poor temperature control (±0.5°-1.0°C).

In connection with the error of the i_d measurement at the dropping mercury electrode in concentrated KOH or NaOH solutions, stability of the glass capillary or constancy of the drop time must be mentioned, because the tip of the glass capillary may be attacked by alkali solution and may change the characteristics. The i_d is proportional to $m^{2/3}\,t^{1/6}$ (m is flow rate of Hg and t is drop time), of which m is largely determined by the height of the mercury pool and friction in the capillary so that the value may be kept constant even when the tip is attacked, and t may be influenced by the condition of the tip of the capillary. The drop time measurement in 3-19M NaOH was carried out over several hours; the change of the drop time was not appreciable in the period. In the present measurement, the glass capillary was dipped in the solution only during the i_d measurement and, whenever ill behavior started, the tip was renewed by cutting the end approximately a centimeter. For each complete series of measurements of i_d-Mn(II) or Mn(III) curve, the same capillary was used.

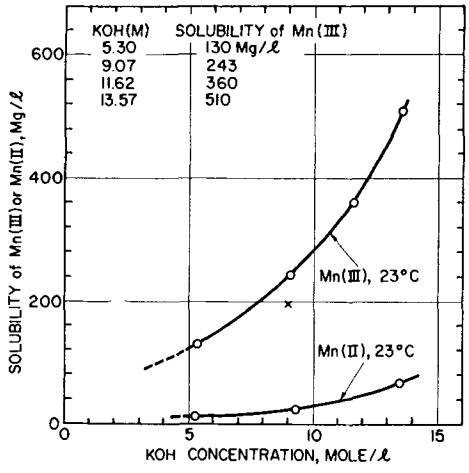

Fig. 11. Solubilities of Mn(III) and Mn(II) in KOH. The point marked with X was measured by oxidizing Mn(II) with O_2 gas (see text).

Results

Solubilities of Mn(II) in KOH and NaOH solutions are shown in Fig. 9 and 10, respectively. In both solutions the solubility increases rapidly with increasing caustic concentration. In Fig. 9 solubility values in KOH solutions are also plotted and show that solubilities in KOH and NaOH are essentially the same when compared at the same caustic concentration (molarity). However, the highest possible concentration was 50% by weight for both KOH and NaOH (13.4M in KOH and 19.0M in NaOH) at room temperature.

The solubility of Mn(III) in KOH is given in Fig. 11 and shows that the solubility of Mn(III) also increases rapidly with increasing KOH concentration. When compared to Mn(II) solubility (lower line in Fig. 11) at the same concentration, Mn(III) solubility is approximately 8-10 times higher than the Mn(II) values. The Mn(III) solubility obtained by O_2 oxidation is a little lower, probably because at the i_d max (Fig. 6) MnO_2 formation has already taken place.

Discussion

Since the main coordination numbers of Mn(II) are four and six (5), a number of Mn(II) complex ions of general formulas $[Mn(OH)_n(H_2O)_{4-n}]^{(n-2)-}$ and $[Mn(OH)_n(H_2O)_{6-n}]^{(n-2)-}$ can coexist in concentrated KOH or NaOH solutions, having an equilibrium among themselves. Of these possible species an equilibrium constant for the $K_2Mn(OH)_4$ formation of Eq. [1] was arbitrarily calculated, because activity coefficients of $K_2Zn(OH)_4$ in KOH solutions are available (7) and can be used in place of those of $K_2Mn(OH)_4$ as a first approximation. Also $[Mn(OH)_4]^=$ may be a predominant form, judging from the work of Scholder and Kolb (3), in which $Na_2[Mn(OH)_4]$ was isolated from the 50% NaOH solution saturated with $Mn(OH)_2$.

In the solubility measurement presented above, $MnSO_4$ solution was added to the KOH solutions. Therefore, there is a question whether the suspended excess solid is $Mn(OH)_2$ or not. In order to check this, Mn(II) solubility was measured by adding excess MnO to 9M KOH. The data were very close to that shown in Fig. 9. This indicates that we can assume $Mn(OH)_2$ as a solid phase.

$$Mn(OH)_2 + 2KOH \rightleftharpoons K_2Mn(OH)_4 \qquad [1]$$

Expression of the equilibrium constant for reaction [1] can be reduced to Eq. [3], assuming $a_{Mn(OH)_2} = 1$.

$$K = \frac{a_{K_2Mn(OH)_4}}{a_{Mn(OH)_2} \cdot a^2_{KOH}} \qquad [2]$$

$$K = \frac{\gamma^2_{K+} \cdot m^2_{K+} \cdot \gamma_{Mn(OH)_4^=} \cdot m_{Mn(OH)_4^=}}{\gamma^2_{K+} \cdot m^2_{K+} \cdot \gamma^2_{OH^-} \cdot m^2_{OH^-}}$$

$$K = \frac{\gamma^3_{\pm K_2Mn(OH)_4} \cdot m_{K_2Mn(OH)_4}}{\gamma^4_{\pm KOH} \cdot m^2_{KOH}} \qquad [3]$$

K's were calculated and are shown in Table I, in which $m_{K_2Mn(OH)_4}$ was calculated from the solubility of Mn(II) at 23°C, $\gamma_{\pm KOH}$ was obtained from the table given by Harned and Owen (6) and the $\gamma_{\pm K_2Zn(OH)_4}$ values (7) in KOH solutions of various concentrations were used in place of $\gamma_{\pm K_2Mn(OH)_4}$. In general, activity coefficients of dissolved salts are largely determined by the dissociation type of the salt, and therefore it is unlikely that the use of $\gamma_{\pm K_2Zn(OH)_4}$ in the same KOH solution of various concentrations introduces serious error in the calculation of K. The K's thus calculated give a fairly good constant in 9-12M KOH, so that a predominant species in this range of KOH concentration is probably $[Mn(OH)_4]^=$.

Another rough way to estimate the number of OH^- ions coordinated to the Mn(II) ion is to plot the logarithm of the Mn(II) solubility against the logarithm of the KOH concentration. The slope of such a plot should give the number of OH^- added to $Mn(OH)_2$. Such a plot is shown in Fig. 12, in which most of the data at 50° and 70°C fall on straight lines of the slope of 2.0. This suggests that the predominant Mn(II) complex ion may be $[Mn(OH)_4]^=$ in 3-12M KOH at 50° and 70°C.

The rough method based on the log [Solubility of Mn(II)] *vs.* log [KOH] plot can be justified as follows. Taking the logarithm of both sides of Eq. [3]

Table I. Calculation of K

KOH M	KOH m	Solubility of Mn^{++}, mg/l	Solubility of Mn^{++}, m	$\gamma_{\pm KOH}$	a_{KOH} $(=\gamma_{\pm KOH} m_{KOH})$	$\gamma_{\pm K_2Zn(OH)_4}$	K
3.07	3.10	5.2	9.75×10^{-6}	1.08	3.41	0.466	7.6×10^{-7}
5.30	5.75	12.0	23.7	2.078	12.4	1.047	3.9
9.31	10.90	25.0	53.8	7.902	87.3	5.39	1.6
10.22	12.30	34.0	74.8	12.44	135.3	8.209	1.8
11.62	14.65	44.0	101.0	18.97	278.4	15.93	1.5
13.52	17.80	68.0	237.0	38.0	676.4	73.77	14.4

Table II. Estimated values of M/m and the activity coefficient ratio of Eq. [3] showing rough constancy

KOH M	M/m for KOH	M/m for Mn(II)	$\gamma^3_{\pm K_2Zn(OH)_4}/\gamma^4_{\pm KOH}$
3.07	0.991	0.973	0.074
5.30	0.922	0.923	0.061
9.31	0.854	0.846	0.042
10.22	0.830	0.829	0.023
11.62	0.794	0.794	0.031
13.52	0.760	0.523	0.194

$$\log m_{K_2Mn(OH)_4} = \log K - \log \frac{\gamma^3_{\pm K_2Mn(OH)_4}}{\gamma^4_{\pm KOH}} + 2 \log m_{KOH}$$

as shown in Table II, M/m for KOH and $K_2Mn(OH)_4$ and log $(\gamma^3_{\pm K_2Mn(OH)_4}/\gamma^4_{\pm KOH})$ are roughly constant in 3-12M KOH. Therefore, we can write

$$\log S = k + 2 \log [KOH]$$

where S is solubility of Mn(II) in mg/l and [KOH] is molarity of KOH. Although molarity values change with temperature and molality values do not, the change in M/m with temperature change from 23° to 70°C is small and can be neglected for the approximate method described above.

Two points on Fig. 12 for Mn(II) in lower KOH concentrations at 23°C deviate from the solid line of the slope 2.0. These points were difficult to measure and may not be accurate because of very low i_d and the possibility of air oxidation of Mn(II) and formation of colloidal $Mn(OH)_2$ as mentioned before. The values measured in NaOH by Fox *et al.* are considerably higher than the present value in KOH, although the present measurements indicate that the solubility of Mn(II) is essentially the same in both KOH and NaOH as shown in Fig. 10. The higher values of Fox *et al.* may be due to the colloidal particles of $Mn(OH)_2$ which passed through their filter and were included in their final colorimetric determination.

Using the equilibrium constant value $K = 1.6 \times 10^{-7}$ (Table I), $\Delta F°$ $(= -RT \ln K)$ was found to be 9.15 kcal for the process of Eq. [1]. The approximate heat of dissolution for the process of Eq. [1] in 9M KOH was calculated from $d \log S/d\ (1/T) = -\Delta H/2.3R$, where S is solubility of Mn(II), by using data for 9M KOH at 23°, 50°, and 70°C; ΔH was found to be 6.7 kcal.

Acknowledgment

The authors wish to thank Dr. G. H. Newman and Dr. G. E. Blomgren for the activity coefficient values of $K_2Zn(OH)_4$ in KOH solution and for their valuable discussion on the calculation of the equilibrium constant.

Manuscript received Dec. 27, 1965. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Ledge Formation on the (111) Surface of Copper

L. D. Hulett, Jr., and F. W. Young, Jr.

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[1]

ABSTRACT

The ledges formed by bunching of atomic steps during dissolution of copper crystals with surfaces vicinal to (111) have been investigated. The conditions for ledge stability were determined in dissolution experiments for which data of step velocities *vs.* step spacings had been determined previously. From these data step interaction functions were generated, and step motion was simulated on a digital computer, making use of the Mullins and Hirth modification of the kinematic theory of dissolution. Ledges could be made to appear or disappear in the computer experiments for conditions corresponding directly to laboratory experiments in which the ledges appeared or disappeared.

On close-packed and vicinal surfaces the preferred sites for atom removal are at monatomic steps, and dissolution processes can be described in terms of the motion of these steps across the surface. The kinematic theory of step motion as developed by Frank and Cabrera (1) deals with average velocity as a function of average step spacing, ignoring microscopic fluctuations. However, there are certain dissolution conditions for which microscopic fluctuations are amplified, causing steps to bunch into multiatomic "ledges." The Frank-Cabrera theory, without modification, cannot treat bunching since it deals only with averages, but recently Mullins and Hirth (2) have considered the velocities of individual steps. A nearest-neighbor interaction model is used, and the velocity of each step is defined as a function of the distances from the step ahead and the step behind, a formulation capable of treating bunching. In previous work (3), the Frank-Cabrera kinematic theory was used to analyze the growth of dislocation etch pits on (111) surfaces of copper. Ignoring ledges, we were able to explain the general dissolution shapes of the pits and determine average step velocities as a function of step spacing. In the present paper we consider the ledges.

The topographic changes associated with dissolution are described in Fig. 1. Figure 1(a) is a photomicrograph of a dislocation pit and ledges formed on a (111) copper surface. Figures 1(b) and 1(c) are schematic profiles of the surface before and after dissolution. Before dissolution is started [see Fig. 1(b)], monatomic steps are present because of slight misorientations from the exact (111) surface. Figure 1(c) shows that as the steps moved across the surface during dissolution they aggregated to form ledges. The sides of the dislocation pit are vicinal surfaces composed of steps nucleated at the point of dislocation-surface intersection.

In this study the step motion illustrated in Fig. 1(b) and 1(c) was simulated on a digital computer, making use of the Mullins-Hirth modification of the kinematic theory. Conditions for stability and instability of ledges were determined by laboratory experiments, and the velocity *vs.* step spacing data were obtained from pits formed under the same conditions. From these data, step interaction functions were generated which were used to simulate laboratory dissolution conditions in the computer experiments. In this paper we shall show correspondence between the laboratory and computer experiments. In addition, there was semiquantitative agreement for the frequency of ledge generation and the slopes of ledge fronts between laboratory and computer experiments.

Laboratory Experiments

In our previous etch pit studies (3) measurements of step flux, J, as a function of step density, ρ, were made for several dissolution conditions. Step flux is defined as $J = \rho V$, where V is the average step velocity and ρ is the reciprocal of step spacing, ϵ. From J *vs.* ρ curves, $\bar{V}$ *vs.* ϵ curves can be calculated. Two such curves are shown in Fig. 2. For the conditions of curve I, step velocity increases monotonically as step spacing increases. For the conditions of curve II the velocity of steps is a maximum for intermediate step spacings. For the conditions of the type I curve there is an effective repulsion between steps for all values of ϵ, while for the conditions of the type II curve there is an effective attraction between steps of large ϵ. The dissolution parameters that determine whether the curve is type I or type II are bromide ion concentration and current density. When these parameters are such that the V-ϵ curve is type II, ledges form and are stable, but under the conditions that cause type I curves, ledges do not form and are not stable. These observations are exemplified in the following

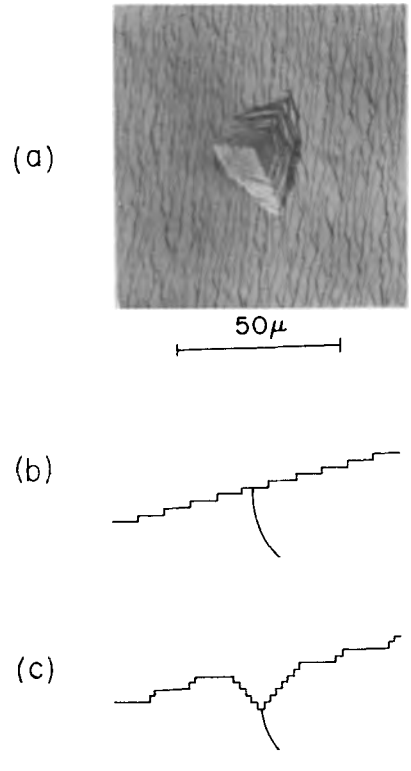

Fig. 1(a). Photomicrograph of dislocation pit and ledges formed by electrolytic etching of a copper surface vicinal to (111). Fig. 1(b). Schematic diagram of dislocation and steps on the vicinal surface in (a) before etching. Fig. 1(c). laboratory experiments. All dissolutions were carried out electrolytically, as previously described (3, 4).

(*A*) Starting with an electropolished surface, ledges are generated if the dissolution is governed by a type II curve and if the average step spacing is less than about 550Å. The ledges in Fig. 1 are the result of such a dissolution. They developed under the same condition as those for which the type II curve of Fig. 2 was measured. The average step spacing was 200Å, corresponding to a misorientation of ½° from the (111) pole. Figure 3 is an electron micrograph of the replica of a ledge formed under similar conditions. From the distortion of the shadow of the ¼ micron polystyrene ball, one can estimate that the height of the ledge and the slope of its front are about 100 atoms and 6°, respectively.

(*B*) Starting with an electropolished surface, ledges are not generated if the dissolution conditions are those of type I curves. The surface in Fig. 4, which has no ledges, was etched under the same conditions as those for which the type I curve of Fig. 2 was measured. The average misorientation and step length of the surface is about the same as that of the surface in Fig. 1.

(*C*) For a given bromide concentration, large changes in current density can cause ledges to disappear. The first frame in Fig. 5 is a photomicrograph of a surface having ledges formed at an average current density of 1.0 ma/cm². The second frame is of the same surface after the current density has been increased to 5 ma/cm². The higher current density caused the $\bar{V}$-ϵ curve to shift from a type II to a type I curve for which ledges are unstable.

Laboratory measurements of average step velocities as functions of average step spacings for conditions under which ledges do not form (curve I) and for conditions under which ledges do form (curve II). Dissolution conditions of curve I: 6M HCl; 0.03M HBr; 5 ma/cm² current density. Dissolution conditions of curve II: 6M HCl; 0.25M HBr; 10 ma/cm² current density.

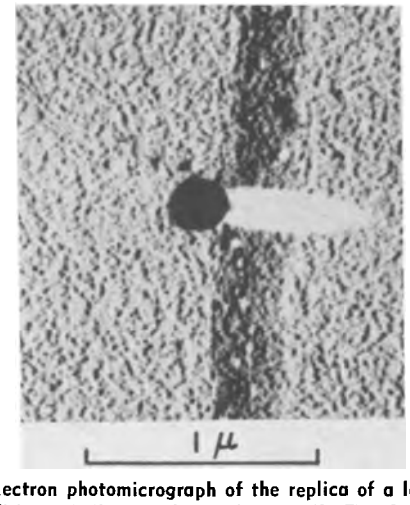

Fig. 3. Electron photomicrograph of the replica of a ledge formed under conditions similar to those of curve II, Fig. 2.

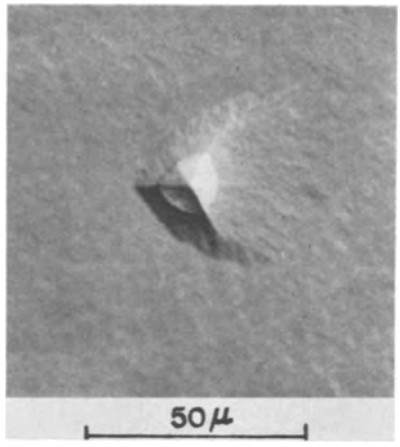

Fig. 4. Photomicrograph of a dislocation pit and vicinal surface having no ledges. Dissolution conditions were the same as those of curve I, Fig. 2.

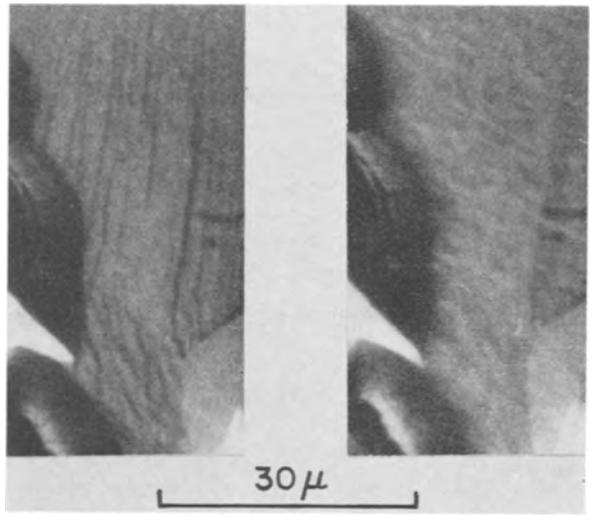

Fig. 5. Ledge disappearance caused by current density increase. Solution composition: 6M HCl, 0.03M HBr. Current density for frame (a) 1 ma/cm²; for frame (b), 5 ma/cm²; time difference between frames is 20 sec.

(*D*) There is a "threshold" step spacing beyond which steps are too widely separated to interact and form ledges, even if the conditions correspond to type II. On (111) surfaces of copper the threshold spacing is 500-700Å. In Fig. 6 the average misorientation[2] of the surface on the right part of the photomicrograph, which has no ledges, is less than ¼° which corresponds to a step spacing of 550Å or larger. The surface having ledges in the left part of the photomicrograph has a step spacing smaller than 550Å. The dissolution conditions were the same as those of experiment (*A*).

The Mullins-Hirth Formulation; Step Interaction Functions

Mullins and Hirth proposed that dissolution processes be described by infinite sets of simultaneous equations, each equation representing the motion of an individual step

$$V_n = f(\epsilon_n) + f(\epsilon_{n-1})$$
$$V_{n+1} = f(\epsilon_{n+1}) + f(\epsilon_n) \qquad [1]$$

[2] Misorientation can be calculated from the asymmetry of etch pits.

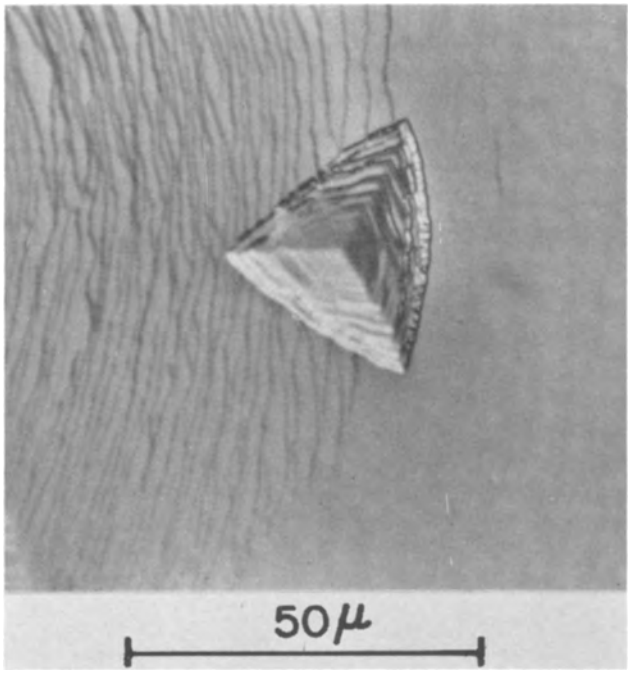

Fig. 6. Illustration of threshold step spacing effect. Average step spacing on left portion of surface, containing ledges, is less than the threshold. Average spacing on right portion of the surface, having no ledges, is greater than the threshold.

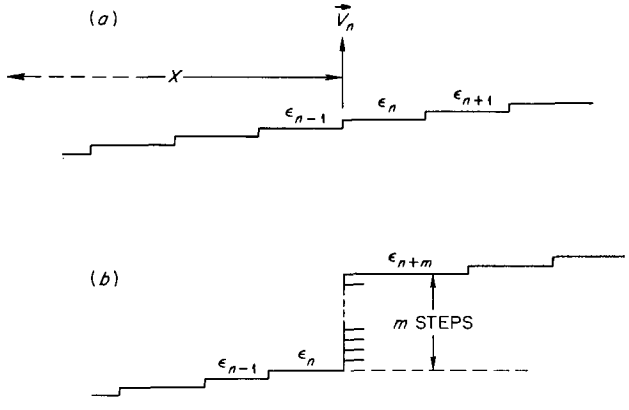

Fig. 7.(a) Schematic diagram of monatomic steps. (b) Schematic diagram of multiatomic step.

The subscript notation is defined in Fig. 7(a); ϵ denotes step spacing, and x denotes the coordinate of the step, measured from an arbitrary reference. The boundaries of the surface are $x = \pm \infty$.

The f-functions are of the same form for the spacings in front and behind a given step. They express the nature of the interaction between steps and are the medium by which conditions of the laboratory experiments are simulated in the computer experiments.

To employ the Frank-Cabrera theory it was necessary to ignore ledges and other surface roughness. Curves I and II, Fig. 2, are therefore measures of average step velocities as functions of average spacing. To extrapolate from these average velocities to f-functions of the Mullins-Hirth formulation it is necessary to assume that a surface with an average step spacing of $\bar{\epsilon}$ is equivalent to a surface with a uniform step spacing of this same $\bar{\epsilon}$. If this assumption is valid, the velocities for trains of steps can be written, according to Eq. [1], as

$$\overline{V} = 2f(\bar{\epsilon}) \qquad [2]$$

The f-functions used in the machine calculations of this paper were determined from curves I and II of Fig. 2 using Eq. [2].

The values of the velocity functions and the f-functions for very small step spacings could not be measured directly and had to be extrapolated. The velocities of steps with average spacings of 0.7Å, which corresponds to the intersection of two (111) surfaces, must be zero since it is assumed that atoms are not removed from close-packed surfaces. Therefore, the $\overline{V}$-functions and the f-functions were extrapolated to zero for 0.7Å spacings.

The values of the $\overline{V}$-functions for very large ϵ's were extrapolated[3] from plots of both V *vs.* ρ and $(\partial J/\partial \rho)$ *vs.* ρ. For spacings larger than the threshold [experiment (D)], the f-functions must behave in such a manner that steps do not bunch; that is, there is no difference in their velocities. This requirement is satisfied if the f-functions are constant for large values of ϵ, a reasonable assumption, since steps spaced from each other beyond a certain distance have negligible interactions and their velocities are constant and equal. Therefore, the type II f-functions were extrapolated to $f(\infty)$ at the spacing of 550Å, which was the experimentally measured threshold spacing. On surfaces etched under type I conditions no threshold spacing could be deduced, but from the V *vs.* ρ plot, V appeared to approach a constant value for spacings larger than 230Å which was used as the threshold spacing.

Calculation Procedure

(*a*) To simulate an infinite surface 100 steps with periodic or cyclic boundary conditions were used. That is, in the course of the calculation the current length of the first step was used as the leading boundary condition (101st step) and that of the 100th step was used as the rear boundary conditions (0th step).

(*b*) The motion of steps was simulated by simultaneous numerical integration of each of the velocity equations (1). For an increment of time, Δt, the coordinate increase of the n^{th} step was calculated as

$$\Delta X_n = [f(\epsilon_n) + f(\epsilon_{n-1})]\,\Delta t$$

This operation was iterated on each of the 100 steps with the cyclic boundary conditions applied to the 1st and 100th steps. At the end of the cycle the ϵ's were recalculated

$$\epsilon_n = X_{n+1} - X_n$$

The cycle was repeated $t/\Delta t$ times, where t was the simulated dissolution time. In all the calculations shown in this paper, Δt was equal to 0.005 sec. Configurations generated by the 0.005-sec calculations were convergent on those generated by calculations using smaller Δt's, thereby justifying the choice of Δt.

(*c*) Steps were permitted to collapse to form multisteps, but negative step spacing, which would correspond to "undercutting," was forbidden; *i.e.*, the machine was programed such that the coordinate of a given step was never allowed to be larger than the coordinate of the step ahead.

(*d*) Mullins and Hirth suggested that the velocity of multisteps such as in Fig. 7b, containing m steps, be defined as follows

$$V = 1/m\,[f(\epsilon_n) + f(\epsilon_{n+m})] \qquad [3]$$

We have used a different treatment. When multisteps were encountered during a calculation cycle, the velocities of all understeps, such as steps $(n + 1)$ and $(n + m - 1)$ in Fig. 4, were set to zero for the instant represented by that cycle. The top steps [step $(n + m)$ in Fig. 7] were allowed to move in a normal manner with their velocities defined by Eq. [1].

[3] $\lim_{\rho \to 0} V(\rho) = \lim_{\rho \to 0} \left(\frac{\partial J}{\partial \rho}\right) = \lim_{\epsilon \to \infty} (\overline{V}(\epsilon))$

Simulation of Experimental Results

To approximate an electropolished surface one must make some assumptions about its nature. Electropolishing makes surfaces very smooth on a macroscopic scale, but there are microscopic fluctuations in step lengths. Very little is known about step configurations on electropolished surfaces, so an empirical choice was made which is illustrated for 100 steps by the uppermost diagram in Fig. 8, and is analytically described as follows

$$\frac{\Delta N(\epsilon)}{\Delta\epsilon} = \epsilon \exp\left(\frac{-\pi r^2}{4}\right)$$

for which $r = \epsilon/\bar{\epsilon}$ and $\Delta N(\epsilon)$ is the number of steps with a spacing between ϵ and $\epsilon + \Delta\epsilon$. The order of the steps is random. All the step diagrams in this paper were plotted by machine, and the step lengths are accurately proportional to those calculated.

(*A*) To simulate laboratory experiment (*A*), the calculation procedure was applied to the electropolished surface configuration using an *f*-function derived from curve II in Fig. 2. The results are illustrated in Fig. 8. The two lower diagrams, representing the surface after 6 and 10 sec of simulated dissolution, show that a step pile-up, corresponding to a ledge, was generated. The use of the type II *f*-function caused the interaction between steps to be such that there was a tendency to aggregate. The periodicity of ledge generation is one ledge per 100 steps, and the slope of the ledge front is about 20°; compare with the 6° slope of Fig. 3.

(*B*) To simulate laboratory experiment (*B*), the calculation was applied to the electropolished surface configuration using an *f*-function derived from curve I, Fig. 2. As shown by the lower diagrams in Fig. 9, no step pile-ups occurred. The surface remained smooth on a macroscopic scale.

(*C*) Ledge disappearance, described in laboratory experiment (*C*), was simulated by applying the calculation procedure, using a type I *f*-function, to an initial distribution of step lengths that contains ledges. As shown in Fig. 10, the ledges were made to disappear after 10 sec of simulated dissolution. The type I *f*-function effects a repulsion between steps in the ledges, causing them to dissociate.

(*D*) In laboratory experiment (*D*) there was no ledge formation because the steps were too widely separated to interact. This observation was simulated by using an initial configuration of steps with an average spacing larger than the threshold spacing (see type II curve, Fig. 2). An average step spacing of 1000Å was used, which is about twice as large as

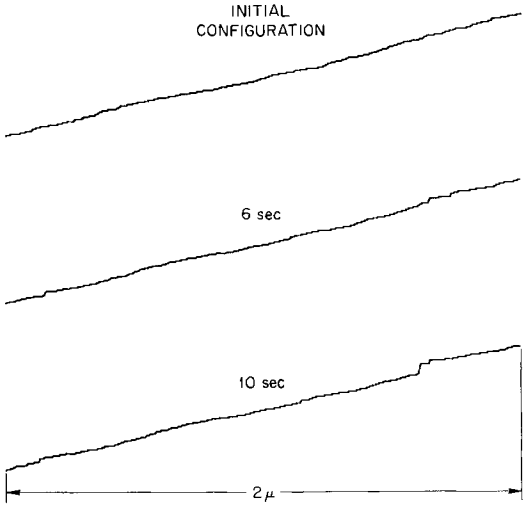

Fig. 8. Step diagrams generated by a simulated dissolution experiment in which the step interaction function was type II.

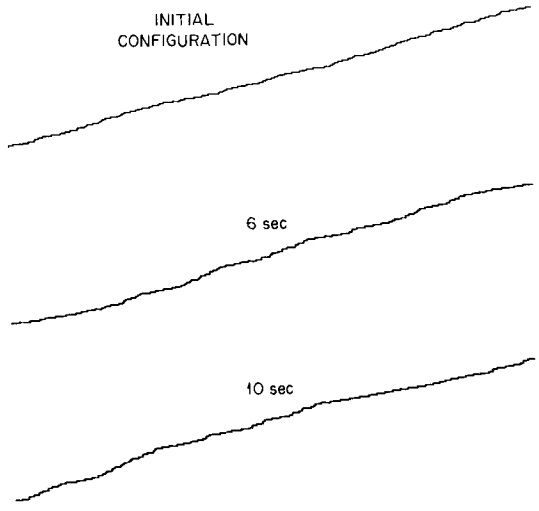

Fig. 9. Step diagrams generated by a simulated dissolution experiment in which the step interaction function was type I.

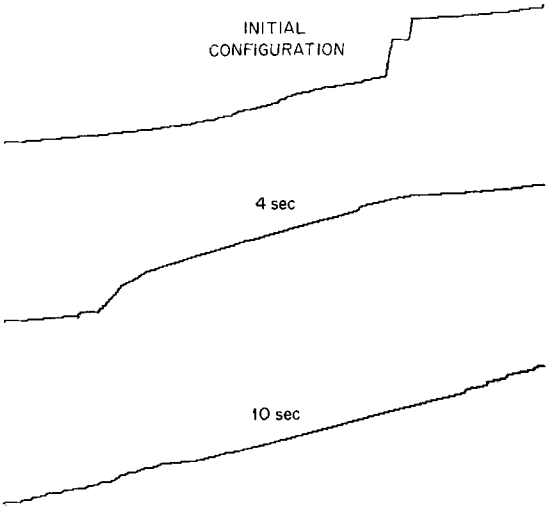

Fig. 10. Ledge disappearance in a simulated dissolution experiment using a type I step interaction function.

the threshold, 550Å. For spacings beyond the threshold, the *f*-function is constant. Fig. 11 shows that after a simulated 10-sec dissolution there were no ledges generated. The simulated surface remained macroscopically smooth, as did the actual surface seen in the laboratory. In the initial configuration used in this calculation, 21 pairs of steps were close enough to interact ($\epsilon < 550$Å). At the end of the calculation this number had decreased to 18.

(*A*-1) The number of ledges generated depends on the initial distribution of steps chosen to simulate the electropolished surface. For the calculation shown in Fig. 12 a random distribution of step lengths was used. It was generated as follows

$$\epsilon_n = \epsilon_{AV}\,(1 \pm R)$$

where ϵ_n is the initial step length of the n^{th} step, ϵ_{AV} is the average step length and R is a random number varying between 0.00 and 0.99. The plus or minus sign was chosen according to whether the second digit of R was odd or even. The calculation procedure was applied to this distribution using the same type II *f*-function as was used in calculation *A*. Because of the different initial distribution of steps, a greater number of ledges were generated. The slopes of the ledge fronts were about the same as that of the ledge generated in experiment *A*. The random distribution of steps used in this calculation represented a more perturbed surface than the Gaussian

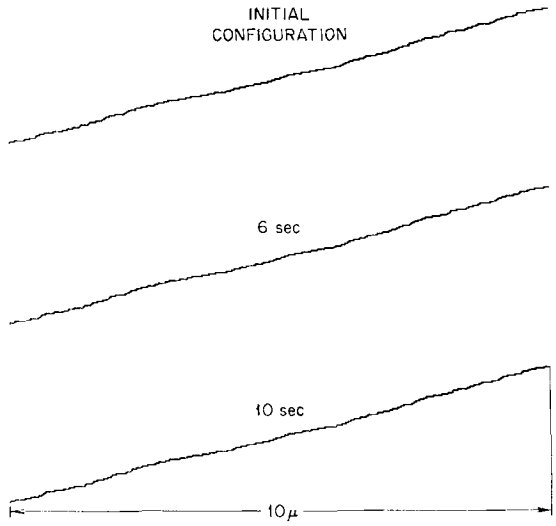

Fig. 11. Simulated dissolution experiment using a type II step interaction function and a surface whose average step spacing is greater than the threshold.

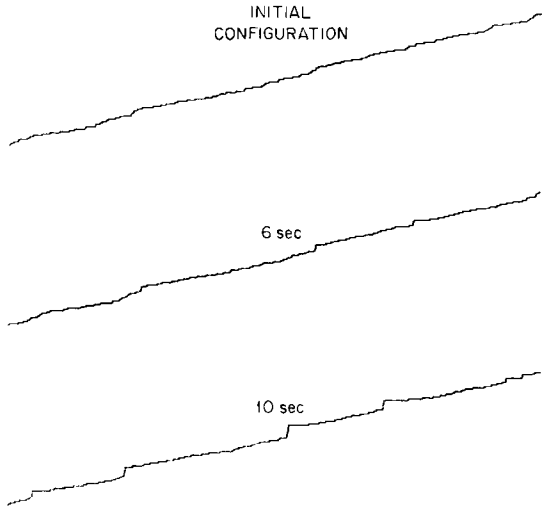

Fig. 12. Simulated dissolution experiment using a random distribution of step lengths to represent the electropolished surface, type II step interaction function.

distribution used in A. That is, the average deviation of the step lengths was greater for the random distribution.

(A-2) If the f-function is given a faster rate of change in the large-ϵ region, more ledges with steeper fronts will be generated. The 10-sec configuration in Fig. 13 was generated from the same initial distribution as was used in A, but the f-function was given a lower value at the threshold spacing. In calculation A, the f-function was extrapolated to a value of 0.04 μ/sec (one-half the extrapolated value of V in Fig. 2) at the threshold spacing. For the present calculation it was extrapolated to a value of 0.02 μ/sec.

Discussion and Conclusions

In these calculations we have modified Mullins and Hirth's treatment of the motion of multiatomic steps. They treat multisteps as units, which once formed cannot dissociate and whose velocity is defined by Eq. [3]. Equation [3] implies that ledge velocity is dependent on height. We have found experimentally that this is not true; ledges may differ in height by large factors, but still move with the same velocity. Also, it seems reasonable that multiatomic steps might dissociate if future conditions permit. For example,

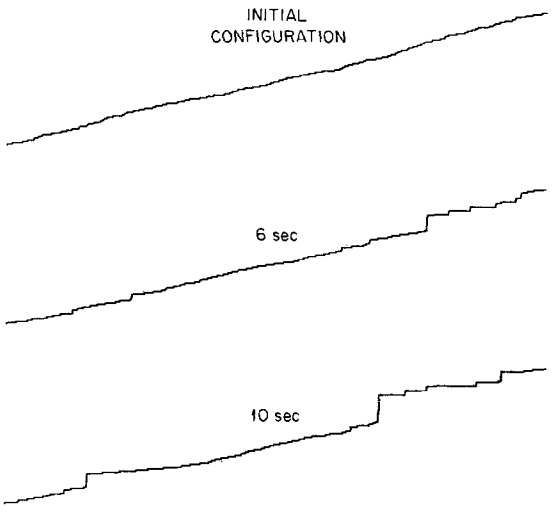

Fig. 13. Simulated dissolution experiment using a type II f-function with a fast rate of change for large step spacings.

the uppermost step in a multiatomic step [step $n + m$ in Fig. 7(b)] can break away from its lower neighbors. Collapsed understeps, of course, should not be able to move since this would result in "undercutting," which amounts to the removal of atoms from close-packed surfaces and is energetically unfavorable. We therefore treated multiatomic steps in the manner described in the calculation procedure. As ϵ attempts to become less than 0.7Å, the f-function should behave in such a manner that strong repulsive terms, which prevent undercutting, arise between the steps. This is accomplished, in effect, by the special instructions in the calculation program which disregard negative values and substitute zero values in their places.

The machine calculations show that this model of step kinematics is capable of explaining the behavior of ledges observed in the laboratory. Experimentally it was found that the conditions for ledge formation and stability can be categorized as those for which the V-ϵ curves are type II, while under the conditions of type I curves, ledges do not form and are unstable. The results of the simulated dissolutions paralleled these observations. This model assumes a nearest-neighbor interaction between steps. The nature of the interaction, "attractive" or "repulsive",[4] is expressed by the f-function. Calculation (A), which simulates laboratory experiment (A), shows that the type II f-function causes the interaction to be attractive, which results in a ledge. For type I f-functions there is a repulsion between steps that tends to dampen large fluctuations in step spacing and prevent ledge formation, and this effect is demonstrated by calculation (B). Type I interactions also tend to annihilate ledges once they are formed. This fact is accounted for by calculation (C). Calculation (D) shows that the theory predicts the fact that ledges do not form when the steps are too far apart to interact. The number of pairs of steps capable of interacting decreased during this calculation which suggests that bunching will never occur, even if the calculation were extended indefinitely.

Admittedly Eq. [2], which illustrates the assumption made in order to be able to evaluate the f-function from experimental data, is an oversimplification. However, it should be a reasonable first approximation and allow at least a semiquantitative estimate of the nature of the interactions. These calculations only purport to describe this system qualitatively or at best semiquantitatively. Whether there is kinematic

[4] Since there are no energy terms involved, it is not proper to consider the interactions as forces in the strict physical sense. Lighthill and Whitham (5) discuss this point. Perhaps a better terminology is "kinematic attraction" and "kinematic repulsion."

attraction or repulsion between steps is the important factor, it is not determined by the exact nature of $f(\epsilon)$, rather by its general form. Therefore, small deviations in $f(\epsilon)$ generally will not alter the type of interaction.

Calculation (*A*) is in semiquantitative agreement with laboratory experiment (*A*) in that the frequency of ledge generation and the slopes of the ledge fronts are approximately the same. In laboratory observations the frequency of ledge generation is approximately 1.2 ledges per 2μ along the surface. The slope of the ledge fronts for the experimental conditions corresponding to this calculation were about 6°. The ledge in calculation (*A*), having a frequency of one ledge per 2μ and a frontal slope of 20°, is a reasonable semblance of these observations. In investigations of some of the factors that determine the frequency of ledge generation and frontal slopes, calculation (*A*-1) shows that the initial step configuration is important in determining the frequency of ledge generation. The random initial distribution, which represents a more perturbed electropolished surface than that used in experiment (A), causes more ledges to be generated. That is, the greater average deviation of step lengths apparently results in a larger number of regions in which the step configurations are such that bunching can occur. Calculation (*A*-2) shows that the *f*-function is also important in determining the frequency of ledge generation. In this calculation the greater rate of change of the *f*-function in the large-ϵ region causes larger differences in step velocities which lead to a higher incidence of steps piling up to form ledges. The slopes of the ledge fronts in calculations (*A*) and (*A*-1) are approximately the same, but those of (*A*-2) are considerably steeper. This observation suggests that the slopes of ledge fronts are dependent on the shape of the *f*-function curve but not on the initial step configuration.

Manuscript received Sept. 27, 1965; revised manuscript received Jan. 25, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Oxidation of Copper Single Crystals in Aqueous Solutions of Inorganic Salts

I. Topography of Oxide Formed in $CuSO_4$ and $Cu(OAc)_2$ Solutions

C. Earl Guthrow, Jr.,[1] and G. Tyler Miller, Jr.[2]

Department of Chemistry, Hampden-Sydney College, Hampden-Sydney, Virginia

ABSTRACT

Electron microscopic examination was made of the topography of Cu_2O formed on the (110), (100), and (111) faces of copper single crystals immersed for varying times in aqueous solutions of $CuSO_4$ and $Cu(OAc)_2$. Considerable differences in the nature of the oxide were observed in the two systems. Polyhedra of Cu_2O were formed on all three faces in solutions of $CuSO_4$, while under the same initial conditions of Cu(II) ion concentration, pH, and temperature in $Cu(OAc)_2$ solutions relatively smooth and continuous films formed on the (110) and (111) faces, while polyhedra were observed on the (100) face. Annealing the copper surfaces in H_2 at 500°C before immersion enhanced the formation of polyhedra in the $CuSO_4$ system and the formation of continuous films in the $Cu(OAc)_2$ system. Epitaxial relationships between the metal and oxide, as shown by reflection electron diffraction, were the same in both the $CuSO_4$ and $Cu(OAc)_2$ systems, and this was the same as found in other studies of Cu_2O formed in gaseous O_2 at high temperatures and in pure water at room temperature.

An understanding of the fundamental processes involved in the oxidation of metals is one of the important, unsolved problems of modern science. The formation of oxide films on metal surfaces exposed to aqueous solutions is quite complex and a great amount of fundamental work needs to be carried out.

This paper reports results obtained in the first of a series of studies designed to obtain a clearer picture of what happens at a surface of copper when it is immersed in an aqueous solution of some inorganic salt. In most corrosion or oxidation studies polycrystalline metal specimens have been used, and as a result the data obtained represented the composite behavior of a number of different crystal faces and grain boundaries. Such measurements are often useful for solving pressing technological problems, but they give only limited information about the mechanism of corrosion reactions. The work of Gwathmey and his associates (1-7) has shown the importance of crystal face and the absolute necessity for careful surface preparation in any fundamental study of metal surfaces.

Since most work with copper single crystals has been concerned with oxidation in the gas phase, there are relatively few studies in aqueous solutions. One notable exception is found in the careful work of Kruger and his associates (8-10) on the oxidation of copper single crystals in pure water. In addition, in-

directly related work on the potentials of copper single crystals in copper sulfate solutions has been reported by Miller (11), Tragert and Robertson (12), Piontelli (13), Jenkins and Stiegler (14), and Jenkins and Bertocci (15).

In an earlier study Miller (11), and Miller and Lawless (16), made an extensive investigation of the oxidation of copper single crystals in $CuSO_4$ solutions. They found that a continuous oxide film did not form, but instead large well-defined polyhedra of cuprous oxide formed at random points on the metal surface. The height, shape, and relative number of these polyhedra varied reproducibly with crystal face. Later, Kassis and Miller (17) carried out exploratory experiments in which copper single crystals were oxidized in solutions of $Cu(NO_3)_2$ and $Cu(OAc)_2$. In the copper (II) nitrate system, polyhedra formed which were similar to those found in the $CuSO_4$ system, while in the $Cu(OAc)_2$ system a relatively smooth and continuous oxide film formed.

Since the continuous film could afford greater corrosion protection than the polyhedra, an extensive study of the variables affecting these two contrasting types of oxide growth was initiated. The present study, which is the first in a series of investigations, is concerned with an electron microscopic and electron diffraction study of the effect of time on the oxidation of the (100), (110), and (111) planes of copper in solutions of copper(II) sulfate and copper(II) acetate. The present study extends the earlier studies (11, 16, 17) to include additional reaction times and additional important variables.

Experimental Procedure

Materials.—Copper single crystal rods of 99.999% purity were grown from the melt by the Bridgman technique and machined into spheres ⅝ in. in diameter and having a cylindrical stem approximately ¼-⅜ in. in diameter x ½ in. in length.[2] Flat surfaces parallel to specific crystallographic planes were cut on the spheres.

In all studies 0.05*N* solutions of either $CuSO_4 \cdot 5H_2O$ or $Cu(OAc)_2 \cdot H_2O$ were made from reagent grade chemicals and water which had been demineralized, distilled through a tin lined still, and stored in a seasoned polyethylene vessel. This water, when cooled to room temperature, was also used to wash all single crystal surfaces. After oxidizing copper crystals in solutions whose concentration varied from 0.001 to 0.40*N*, it was decided to use 0.05*N* as the solution concentration for all experiments rather than the 0.39*N* concentration used in earlier studies (11, 16). This normality could possibly allow the solution to be treated theoretically using Debye-Huckel, Onsager, or other approaches, and at the same time it supported an oxidation reaction with a reasonable rate. Since Shreir and Smith (18) found that $CuSO_4$ solutions were often unstable, fresh $CuSO_4$ solutions were prepared every week.

The polyethylene water reservoir was not used until it had been seasoned for at least two weeks until the reproducible "standard" oxidation pattern shown in Fig. 1 could be obtained on copper single crystal spheres washed with water stored in the reservoir. This pattern, which consisted of a symmetrical and beautiful array of interference colors, was formed by oxidizing the crystal in a cupric acetate solution for 5 min. Experiments on a given day were not run unless this "standard" pattern could be obtained. Since the pattern is sensitive to impurities of the order of a few parts per million and to the slightest change in surface preparation, this practice represented a convenient and extremely sensitive method of checking reproducibility. This approach has been discussed in detail by Young, Cathcart, and Gwathmey (6). These standard patterns will probably vary slightly from one laboratory to another, since they only assure that measurements will be carried out under a constant state of trace contamination.

Preparation of surfaces.—Spheres and flat surfaces were etched in a 1:1 by volume solution of concentrated nitric acid and distilled water, mechanically polished, electrolytically polished, and washed carefully to remove traces of phosphate ions as described by Young, Cathcart, and Gwathmey (6). To be certain that strain and deformation were absent and to insure that each plane remained within 2° of the desired orientation, they were checked with x-ray diffraction using a Laue back-reflection technique after the initial surface preparation and after every 2-4 experiments. In the case of (100) plane the orientation was held within 1°.

Reaction procedure.—After the crystal was washed and polished, it was exposed to the desired electrolyte solution under two sets of conditions. In the first series of experiments the copper specimens were dried in a jet of nitrogen and then annealed in purified dry hydrogen for 1 hr at 500°C in a Pyrex reaction chamber. After the crystal was cooled in a hydrogen atmosphere to 25°C, the desired electrolyte solution was transferred under hydrogen pressure from a solution reservoir to the crystal reaction chamber. In these "annealed" experiments any initial thin film of oxide had to be formed while the crystal was exposed to the electrolyte.

In the second series of experiments, the crystal was not dried after being washed but was immersed immediately for the desired length of time in a glass vessel containing approximately 30 ml of the electrolyte solution and maintained in a water bath at 30° ± 0.05°C. In order to prevent evaporation the reaction vessel was closed for the longer immersion times. In these "unannealed" experiments the oxide formed in the electrolyte solution probably grew on top of a thin 20-30Å oxide film formed in the air. After the desired immersion time the crystal was quickly removed from the solution, immediately washed for 30 sec in distilled water and dried in a jet of N_2.

In both types of experiments no attempt was made to remove dissolved oxygen from the electrolyte solutions. It was estimated that the oxygen concentration was approximately 10^{-4} moles/liter. In all experiments the *p*H of the solution was measured before and after reaction. The *p*H of 0.05*N* $CuSO_4$ was found to be 4.3 ± 0.05. Pourbaix (19) has shown that cuprous oxide is thermodynamically stable at this value but that cupric oxide would not be expected to form. As a result, the initial *p*H of all solutions was set at 4.3 ± 0.05. The value for 0.05*N* $Cu(OAc)_2$, which was normally 5.6, was adjusted to 4.3 by the addition of reagent grade glacial acetic acid.

Surface examination and characterization.—After reaction the surface of the crystal was examined using optical and electron microscopy. In addition, electron and x-ray diffraction techniques were used to identify the reaction products and to determine their epitaxial relationship to the metal substrate. In order to examine the surfaces using electron microscopy, it was necessary to use a replica technique. In most cases the surface was preshadowed with platinum at angles from 5° to 20° and replicated using a carbon evaporation technique. These carbon replicas were stripped successfully from the surface using a sequence of solutions including fresh 5% by volume ethylenediamine, a 3:1 mixture of 10% by volume ammonium persulfate and concentrated ammonium hydroxide, and subsequent washing in 10% by volume nitric acid and distilled water. A modified shadowing and replicating procedure was initiated after it was found that the ethylenediamine dissolved the platinum during the stripping operation. In order to protect the platinum it was sandwiched between two layers of carbon.

[3] The copper single crystal rods used in this study were obtained from the Virginia Institute for Scientific Research, 6300 River Road, Richmond, Virginia.

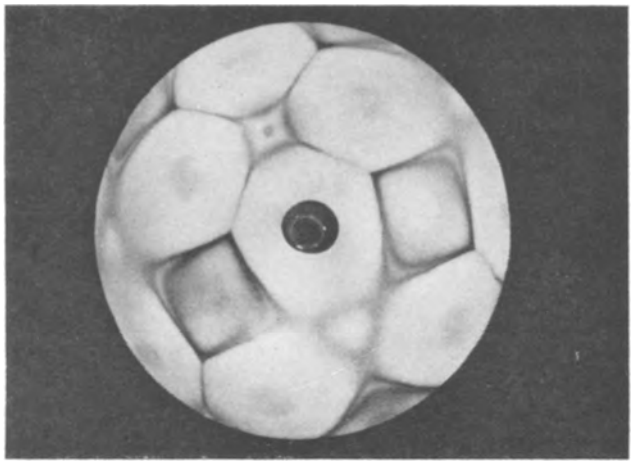

Fig. 1. Oxidation pattern formed on a spherical copper single crystal immersed in 0.39*N* $Cu(OAc)_2$ for 5 min at 30.0°C, *p*H 4.3.

Experimental Results

Oxidation of spheres.—Oxidation of copper single crystal spheres under various conditions gives a symmetrical and beautiful oxidation pattern of interference colors resulting from the different rates of oxidation of the various crystallographic planes. The "standard" oxidation patterns for the oxide formed in dry oxygen gas at 250°C and in $CuSO_4$ solutions at 25°C have been given in the original article of the present study (16). A typical standard pattern formed in $Cu(OAc)_2$ solution at 25°C is shown in Fig. 1. Compared to the pattern formed in $CuSO_4$, this acetate pattern is much sharper and the colors are more brilliant. In general, this indicated the formation of much smoother oxide films in the cupric acetate system. In an earlier article Lawless and Miller (22) suggested that the oxide patterns formed by immersing carefully prepared copper single crystal spheres in a 0.39*N* solution of $CuSO_4$ for times from 1 to 5 min provided a quick and convenient means for identifying particular crystallographic planes for purposes of cutting flat crystal faces or for other purposes. Since the patterns formed after 5 min immersion of the spheres in 0.05*N* or 0.39*N* $Cu(OAc)_2$ are much sharper, they represent an even better method for quickly and accurately locating particular faces on a spherical crystal.

Effect of oxidation time on surface topography.—The (110), (111), and (100) planes of copper were oxided in copper (II) sulfate and copper (II) acetate solutions for times varying from 30 sec to 24 hr. In all experiments reflection electron diffraction showed that the only surface product formed was Cu_2O. The initial *p*H of 4.3 was maintained during the course of oxidation in the copper (II) acetate solutions, while in the copper (II) sulfate solutions it had dropped slightly after 5 min immersion and after immersion for 24 hr it had dropped to values ranging from 3.5 to 3.7 depending on the relative surface area of copper exposed to the solution. The topography of the surfaces after oxidation is shown in Fig. 2-6.

$CuSO_4$ *system.*—In the original study of this series Miller and Lawless (16) showed that large individual oxide polyhedra formed on annealed copper single crystals immersed in 0.39*N* $CuSO_4$ solutions. In the present study these results have been expanded to include additional immersion times, unannealed crystals, and 0.05*N* $CuSO_4$ solutions.

Figure 2 shows the formation of Cu_2O as a function of time on the (110) face. It should be noted that the exposed surface between the polyhedra increased as the polyhedra grew larger. On the (111) plane evidence of oxide polyhedra was observed, although individual polyhedra were very difficult to distinguish, since the surface had the appearance of run-together

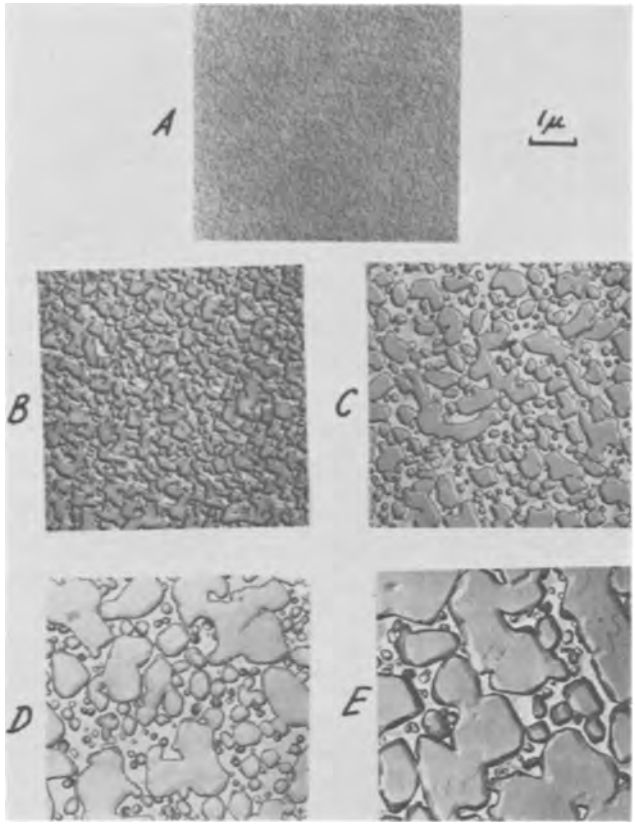

Fig. 2. Growth of oxide polyhedra with time on the (110) face of copper after immersion in 0.05*N* $CuSO_4$ at 30.0°C, initial *p*H 4.3: a, 30 sec; b, 3 min; c, 5 min; d, 15 min; e, 1 hr. Magnification 15000X before reduction for publication.

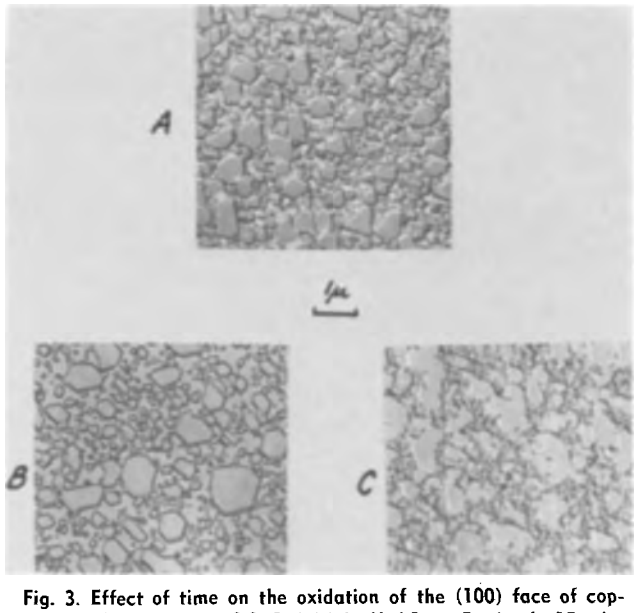

Fig. 3. Effect of time on the oxidation of the (100) face of copper in 0.05*N* $CuSO_4$ at 30.0°C, initial *p*H 4.3: a, 5 min; b, 15 min; c, 1 hr. Magnification 15000X before reduction for publication.

polyhedra after only 5 min. Figure 3 shows that the growth of polyhedra on the (100) face followed the same over-all growth pattern as that on the (110) face.

For immersion times longer than an hour, the polyhedra on the (100) and (110) faces grew together to form a relatively continuous film. As mentioned above, this occurred much earlier on the (111) face. After 24 hr this continuous film on all three faces appeared to be etched, and the *p*H of the solution had dropped from 4.3 to approximately 3.5-3.7, depending on the

particular crystal face. Under these more acidic conditions the rate of dissolution of oxide was probably beginning to become more competitive with the rate of oxidation.

$Cu(OAc)_2$ *system.*—Figure 4 shows that in the acetate system a relatively smooth and continuous oxide film formed instead of polyhedra. Numerous immersion times, other than those shown, were studied and at no time from 30 sec to 48 hr was there any evidence of polyhedra formation on the (110) face. The films formed on the (111) face were also continuous and even smoother than those on the (110) face. On the (100) face the film was relatively smooth and continuous up to oxidation times of about 10 min, as shown by Fig. 5a. However, some very interesting results were observed when the (100) plane was oxidized for times from 10 min to 1 hr. As shown in Fig. 5b and c, well defined polyhedra formed in the acetate system under these conditions. By comparing Fig. 3c and 5c it can be seen that the density of oxide polyhedra after 1 hr in both systems was not significantly different. However, a comparison of Fig. 3a and Fig. 5a shows that there was a significant difference between the two systems after 5 min immersion. At first it was felt that these somewhat unexpected results were obtained because the (100) plane was held within 2° of the desired orientation rather than 1°. A close look at the standard sphere pattern in Fig. 1 revealed that there were more significant changes in oxide thickness in the region around the (100) face than there are in the (111) and (110) regions. After repeating the experiment several times with (100) faces within ½-1° of the proper orientation, polyhedra were still found, although their density and shape differed slightly from those formed on faces greater than 1° off of the (100) orientation. As a result all (100) planes were maintained within 1°.

Effect of annealing.—By comparing Fig. 6a and Fig. 2c, it can be seen that in the $CuSO_4$ system the growth of individual, regularly shaped oxide polyhedra was favored when the crystal was annealed in hydrogen at 500°C. Although the same general tendency to form polyhedra was observed in the case of unannealed crystals, the polyhedra became rounded and ran together to cover a greater fraction of the surface.

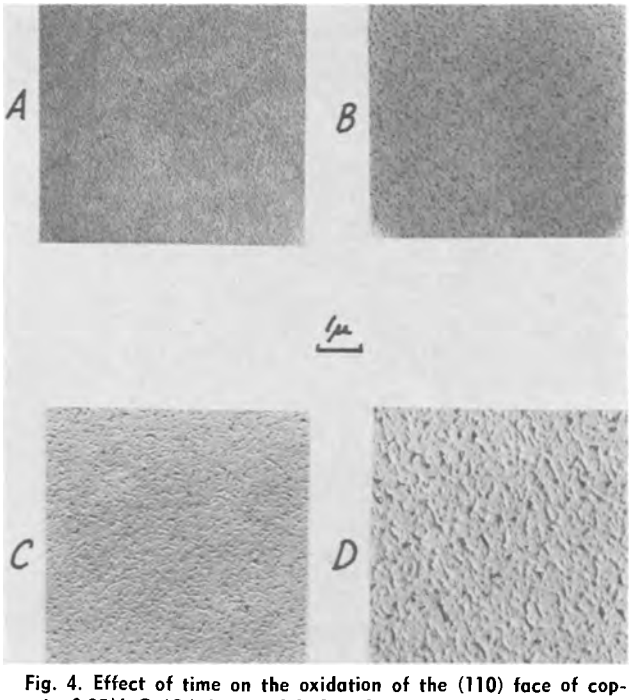

Fig. 4. Effect of time on the oxidation of the (110) face of copper in 0.05*N* $Cu(OAc)_2$ at 30.0°C, *p*H 4.3: a, 30 sec; b, 3 min; c, 5 min; d, 1 hr. Magnification 15000X before reduction for publication.

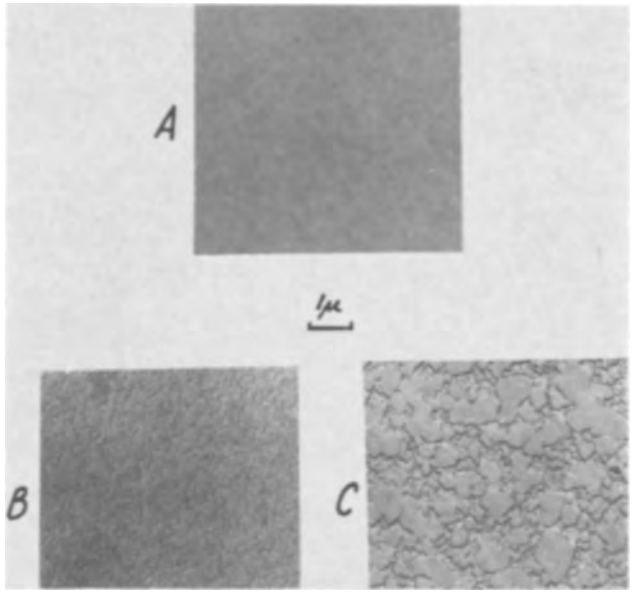

Fig. 5. Effect of time on the oxidation of the (100) face of copper after immersion in 0.05*N* $Cu(OAc)_2$ at 30.0°C, *p*H 4.3: a, 5 min; b, 15 min; c, 1 hr. Magnification 15000X before reduction for publication.

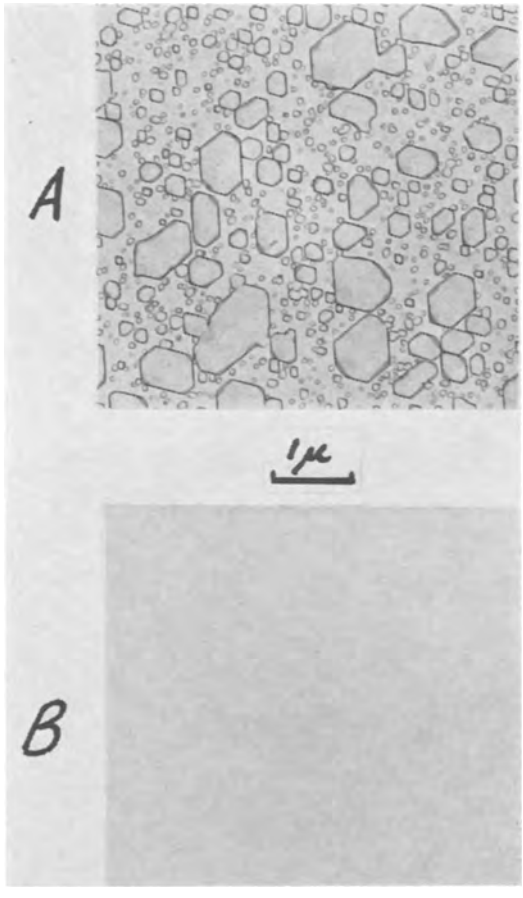

Fig. 6. Oxide formation on annealed (110) faces of copper; a, 5 min in 0.05*N* $CuSO_4$ at 30.0°C, initial *p*H 4.3; b, 5 min immersion in 0.05*N* $Cu(OAc)_2$ at 30°C, *p*H 4.3. Magnification 15000X before reduction for publication.

Figure 6b and Fig. 4c show that in the $Cu(OAc)_2$ system the oxide formed with both annealed and unannealed crystals was relatively smooth and continuous compared to that formed in the $CuSO_4$ system. The smoothness and continuity of the film was greatly enhanced when the crystal was annealed.

Additional experiments were run to determine whether the observed effect of annealing was due to changes in the nature of the metal surface when heated to 500°C or due to the differences in the initial thin oxide films formed on the annealed and unannealed crystals. With annealed surfaces, the initial oxide growth must form in the solution, while in the unannealed system any oxide formed in the solution would be expected to grow on top of a thin (20-30Å) air formed film. In this experiment, a (110) flat face was annealed in hydrogen at 500°C, removed from the annealing apparatus, exposed to the air at room temperature for several minutes, and then immersed in the desired solution. Electron microscopic examination showed that the oxide topography was very similar to that of an unannealed (110) flat exposed to the same solution. Thus, the main effect of annealing appears to lie in the difference between the initial thin films of oxide rather than the effect of heating the metal surface.

Since in both the $CuSO_4$ and the $Cu(OAc)_2$ systems the only apparent effect of annealing was to enhance the over-all type of behavior, *i.e.*, individual polyhedra formation in the sulfate system and smooth continuous films in the acetate system, it was decided to run the majority of experiments under unannealed conditions. Furthermore, since each annealed experiment was long and tedious, it was felt that this would allow a quicker and broader study of the variables affecting the two systems. Annealing experiments thus need only to be run later to check the results at the more important experimental conditions.

Epitaxy.—The epitaxial relationships of cuprous oxide crystals immersed in the $CuSO_4$ solutions have been reported previously by Lawless and Miller (22). In the present investigation electron diffraction studies showed that essentially the same epitaxial relationships were found when the oxide was formed in $Cu(OAc)_2$ solutions. Furthermore, the orientation relationships between the metal and cuprous oxide in the $CuSO_4$ and $Cu(OAc)_2$ systems were in general the same as those previously found for oxidation of copper in pure O_2 at room temperature and at high temperatures by Lawless and Gwathmey (23), and for oxidation of copper in pure water by Kruger (8-10) at room temperature.

Discussion

Since this is the second paper in a long range study of the variables affecting the oxidation of copper single crystals in aqueous salt solutions, it would be premature to engage in a detailed theoretical discussion until additional data have been obtained. It might be helpful, however, to summarize the questions that appear to be important and in some cases to indicate possible explanations.

The present study, as well as the previous study (16), indicated that the following questions must be considered:

1. What factors cause the rate of oxidation in $CuSO_4$ and $Cu(OAc)_2$ solutions to be significantly greater than that in both pure water and in air at room temperature?

2. Why are there differences in the relative thicknesses of the oxide formed on the various crystal faces of copper immersed in $CuSO_4$ and $Cu(OAc)_2$ solutions and what are these differences?

3. What mechanism can account for the formation of oxide polyhedra in the $CuSO_4$ system and the formation of relatively smooth, continuous films in the $Cu(OAc)_2$ system?

4. How can this mechanism also account for the formation of polyhedra on the (100) face in the $Cu(OAc)_2$ system?

5. Why does annealing the crystal in H_2 promote the formation of polyhedra in $CuSO_4$ and the formation of very smooth, continuous films in $Cu(OAc)_2$?

6. Is the anion present in the solution the primary variable controlling the nature of the oxide topography?

7. What is the source of the copper found in the Cu_2O film?

8. What is the source of the oxygen in the Cu_2O film?

9. What are the effects on the oxidation process of variables such as *p*H, dissolved oxygen concentration, temperature, and stirring?

10. What is the significance of the fact that the epitaxial relationships of the metal and oxide were the same for Cu_2O formed in air, pure water, $CuSO_4$, and $Cu(OAc)_2$ at room temperature?

Some discussion of questions 1, 3, and 7 for the $CuSO_4$ system has been given previously by Miller (11) and Miller and Lawless (16). The results of the present study, which included immersion times in $CuSO_4$ between those in the original study, gave a more detailed picture of the growth sequence of polyhedra as shown in Fig. 2. They show that the amount of exposed surface between the polyhedra increased as they grew larger, which suggested that the mechanism of polyhedra growth may involve a dissolution of small polyhedra at certain points. This, in turn, could indicate that changes in *p*H at the reaction surface could be one of the major factors in the formation of polyhedra. This is supported by the fact that the *p*H in $CuSO_4$ solutions decreases with time of oxidation while the *p*H in the $Cu(OAc)_2$ remains essentially constant. This constancy of *p*H would be expected in the $Cu(OAc)_2$ system, since the acetic acid added to adjust the initial *p*H to 4.3 would allow the solution to act as a buffer system. A detailed study of the effect of *p*H on oxidation in both systems is now being carried out in this laboratory. Ives and Rawson (24) have discussed the influence of *p*H on the appearance and dissolution of polyhedra and their ideas will be considered in a future paper devoted exclusively to the effect of *p*H.

A well supported explanation of the formation of smooth films as opposed to polyhedra as posed in question 3 does not appear to be possible at this time. Several factors which could be important are (*i*) localized surface changes in *p*H as mentioned above; (*ii*) formation of complex ions between the Cu (I) or Cu (II) ions and the anions in solution which could result in changes in diffusion rates of copper ions to the reaction surface; (*iii*) selective adsorption of cations, ion pairs, or other species at steps or other spots on the metal or oxide surface; or (*iv*) factors which would change the conductivity of the oxide.

It is very important to obtain the thickness measurements mentioned in question 2, before a meaningful interpretation of the topographical data presented in this paper can be made. It is anticipated that these results will be published in the near future. A comparison of approximate thicknesses of oxide formed on the (110) face of copper in various systems is shown in Table I. It can be seen from the table that oxidation in solutions of copper salts occurs at a much greater rate than that in water or pure oxygen gas at the same temperature. It should be noted that the value of 700-800Å reported for oxide thickness in $CuSO_4$ should be interpreted only as a measurement of total oxide and not of thickness, since Fig. 2c indicates that the surface contains oxide polyhedra

Table I. Relative thickness of Cu_2O formed on the (110) face of copper at room temperature

System	Approximate thickness, Å	Oxidation time	Reference
Pure water	25	5 min	(8), (9)
	80	8-80 min	(8), (9)
Pure, dry oxygen	100	Several months	(20)
0.05*N* $Cu(OAc)_2$	475 ± 50	5 min	(21)
0.05*N* $CuSO_4$	700-900	5 min	(21)

rather than a smooth, continuous film. Indeed, this study again emphasizes the importance of carrying out topographical studies along with rate studies, since it is necessary to assume the formation of a smooth, continuous film in order to get a meaningful rate equation from measurements of oxide thickness as a function of time.

In the earlier study (16) the importance of the reaction $Cu + Cu^{+2} = 2\ Cu^{+}$ was discussed. From a thermodynamic standpoint, it is highly probable that the over-all free energy change of the oxidation of copper metal in Cu(II) ion solutions results from the tendency of the system to approach the equilibrium represented by the above equation. The tendency of the *p*H to decrease towards 3.2 in the unbuffered $CuSO_4$ system along with the tendency of initial corrosion potentials on various crystal faces of copper to approach a limiting value in $CuSO_4$ solution (11, 12) indicate the importance of this reaction, as a possible driving force for the over-all process. The work of Jenkins and Bertocci (15) emphasized that true equilibrium for this reaction exists only in solutions which are free of dissolved oxygen, which have been pre-equilibrated with copper, and which exhibit a *p*H less than about 3.2. Of course, none of these conditions was met in the systems in the present study, since under these conditions oxide would not form on copper.

No explanation for the sudden appearance of polyhedra on the (100) face in the acetate system, as posed in question 4, can be offered at this time. Since oxide on the (100) plane can have four possible orientations while that on the (111) can have two and the (110) only one orientation (11, 22), more grain boundaries could be formed in the oxide on the (100) face. However, since this should affect the acetate and sulfate system in the same manner, this factor may not be the controlling one.

With respect to the effect of annealing, as raised in question 5, it is proposed that this is due primarily to the difference in the nature of the thin base films formed in the two systems. When the unannealed crystal is washed in water and exposed to the air prior to immersion, a thin film of the order of 10Å probably forms immediately. This film then grows fairly rapidly to a thickness of about 30-50Å. In this process the individual crystals in the film possibly have time to obtain a more uniform state of perfection and to patch up any weak spots. On the other hand, with annealed crystals the 30Å initial film forms very rapidly in the electrolyte solution. As a result, the crystals in this film might be expected to vary widely in their degree of perfection. This could promote the growth of individual polyhedra by the mechanism proposed earlier (16). Another explanation of this annealing effect could involve the influence of temperatures on the metal surface. Impurities might diffuse to the metal surface from the interior of the crystal or trace impurities could be left on the surface by reduction when the thin film of cuprous oxide is reduced by hydrogen. These impurities could promote or retard oxide growth at specific reaction sites. The experiments described earlier in this paper indicated that this effect is not the controlling factor.

With respect to question 6, the results of this study certainly indicate that by varying the anion the nature of the oxide can be controlled and perhaps in this way the degree of corrosion protection afforded by the oxide film can be controlled. However, since the *p*H remains constant in one system and varies in the other, this conclusion is not certain. Further study of the effect of anions on oxide topography is being carried out by exposing copper crystals to solutions of copper (II) formate and copper (II) perchlorate. Due to similarities in anions it is hypothesized that the oxide formed in $Cu(OAc)_2$ solution would be similar to that formed in $Cu(CHO_2)_2$ solution, while that formed in $Cu(ClO_4)_2$ would be similar to the oxide formed in $CuSO_4$ solutions.

There appear to be three possible sources for the oxygen in the Cu_2O, as posed in question 7: dissolved O_2 oxygen obtained from the sulfate on acetate radical, or oxygen from the H_2O. Since the reaction is so rapid in copper salt solutions as opposed to pure water, it appears to be improbable that dissolved oxygen is the source. It also seems unlikely that the oxygen would come from the breakdown of the sulfate or acetate radicals, although there is little information available in the literature on this matter. To check this possibility, it was decided to oxidize a sphere in a solution of copper (II) tetrafluoroborate, $Cu(BF_4)_2$, which contains an anion with no available oxygen. Results obtained showed that an oxide pattern did form in the solution of $Cu(BF_4)_2$ and thus it appears that the anion is at least not the primary source of oxygen. The most likely source of oxygen appears to be H_2O. Several equations for possible reactions involving water were given in the previous article (16). Experiments planned for the future include oxidizing a copper crystal respectively in a solution made by dissolving $Cu(OAc)_2$ in O^{18} labelled water and in a solution prepared from normal water and O^{18} labelled $Cu(OAc)_2$. The oxide formed could then be reduced in H_2 in a closed vessel and the water formed could then be analyzed for the presence of O^{18} with a mass spectrograph. In this manner information on the source of oxygen in the oxide could be obtained.

With respect to the variables indicated in question 9, the effect of *p*H is presently under study and the other variables are to be studied in the future.

Finally, the most important observation that can be made about the epitaxial relationships found in this study is that they are the same regardless of whether to Cu_2O is formed in gaseous O_2 at temperatures from 100° to 900°C (23), in pure water at room temperature (8), or in solutions of $CuSO_4$ or $Cu(OAc)_2$ at room temperature. This indicates that one fundamental factor was determining these relationships and that epitaxy may be more fundamental than was thought. These ideas are discussed in greater detail by Lawless and Gwathmey (23) and Lawless and Miller (22).

Summary

1. A more detailed picture of the growth sequence of the formation of Cu_2O polyhedra on the (110), (100), and (111) faces of copper in $CuSO_4$ solution was obtained. The exposed surface between the polyhedra increased as the polyhedra grew larger. This indicated that the mechanism of polyhedra growth may involve dissolution of small polyhedra at certain points.

2. Under the same conditions in $Cu(OAc)_2$ solutions relatively smooth and continuous films of Cu_2O rather than polyhedra were observed on the (110) and (111) faces, while polyhedra were observed on the (100) face.

3. During oxidation the *p*H of the $CuSO_4$ solution dropped from its initial value of 4.3 to 3.5-3.7 for immersion times greater than 1 hr, while the *p*H of the $Cu(OAc)_2$ solutions remained essentially constant throughout the reaction.

4. Annealing of the metal surfaces in H_2 at 500°C prior to immersion into the electrolyte solution enhanced the formation of individual polyhedra in the $CuSO_4$ system and the formation of smooth, continuous films in $Cu(OAc)_2$ solutions. This apparently resulted from the differences in the initial thin oxide films formed on the annealed and unannealed metal surfaces.

5. The epitaxial relationships of the metal and oxide were the same in both the $CuSO_4$ and $Cu(OAc)_2$ systems, and this relationship was the same as that found in other studies of Cu_2O formed on copper in

gaseous O_2 at high temperatures and in pure water at 25°C.

Acknowledgments

The authors are deeply indebted to the late Dr. Allan T. Gwathmey of Cobb Chemical Laboratory, University of Virginia, and to Dr. K. R. Lawless, Department of Materials Science, University of Virginia, for their encouragement and helpful discussions, as well as for the use of the electron microscope and the x-ray and electron diffraction apparatus at the University of Virginia. We would also like to thank Mr. R. W. Topham for his aid in carrying out some of these experiments and Mrs. C. E. Guthrow for her help in preparation of the manuscript. This research was supported in part by grants from the Research Corporation, Sigma Xi, Hampden-Sydney College, the National Science Foundation Undergraduate Science Education Program, and PHS Research Grant DE-01893-01, National Institute of Dental Research, Public Health Service.

Manuscript received Aug. 4, 1965; revised manuscript received Dec. 14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Oxidation of Copper Single Crystals in Aqueous Solutions of Inorganic Salts

II. Topography of Oxide Formed in $Cu(ClO_4)_2$ and $Cu(CHO_2)_2$ Solutions

R. W. Topham[1] and G. Tyler Miller, Jr.[2]

Department of Chemistry, Hampden-Sydney College, Hampden-Sydney, Virginia

ABSTRACT

Electron microscopic examination was made of the topography of Cu_2O formed on the (100), (110), and (111) faces of copper single crystals immersed for varying times in aqueous solutions of $Cu(ClO_4)_2$ and $Cu(CHO_2)_2$. A previous study indicated the importance of the anion on topography in that Cu_2O polyhedra formed on copper oxidized in $CuSO_4$ solutions, while in $Cu(OAc)_2$ solutions relatively smooth, continuous films of Cu_2O formed on the (110) and (111) faces and polyhedra were observed on the (100) face. It was hypothesized that due to similarities in the anions that the oxide formed in copper(II) formate solutions would be similar to that formed in copper(II) acetate solutions and that oxide formed in copper(II) perchlorate solutions would be similar to that formed in copper(II) sulfate solutions. In general, the present study has substantiated this hypothesis.

This is a continuation of a long range study of the growth of oxide on copper single crystal surfaces exposed to aqueous solutions of inorganic salts. The preceding paper (1) indicated that the anion present in solutions containing copper(II) ions could greatly influence the topography formed on copper surfaces. Specifically, it was found that oxide polyhedra formed on copper surfaces exposed to $CuSO_4$ solutions, while relatively smooth and continuous films formed in $Cu(OAc)_2$ solutions on the (110) and (111) faces and polyhedra formed on the (100) face.

Since control of the nature and thickness of the oxide film by varying the anion could significantly vary the degree of corrosion protection afforded by an oxide film, it was desirable to investigate the influence of other anions. If the anion is the primary variable causing the different types of oxide growth, then it was reasoned that because of the similarities in anions, that the topography of the oxide formed in copper(II) formate solutions would be similar to that formed in copper(II) acetate solutions and likewise, that the oxide formed in copper(II) perchlorate solutions would resemble that in copper(II) sulfate

[2] Present address: Department of Chemistry, St. Andrews Presbyterian College, Laurinburg, North Carolina.

solutions. The present study was undertaken to support this hypothesis.

Experimental Procedure

Known crystallographic faces of carefully prepared copper single crystals were exposed to 0.05*N* solutions of $Cu(CHO_2)_2$ and $Cu(ClO_4)_2$ maintained at 30° ± 0.05°C, and at an initial *p*H of 4.30 ± 0.02. With the exceptions given below, all procedures were the same as those used in the previous study (1).

Copper(II) formate was prepared by the reaction of basic copper(II) carbonate and 50% aqueous formic acid. The reaction was carried out at 75°C for ½ hr and the copper(II) formate obtained was doubly recrystallized and dehydrated. The *p*H of copper(II) formate solutions was adjusted to 4.3 by addition of reagent grade formic acid. The copper(II) perchlorate was prepared in a similar manner by reacting basic copper(II) carbonate with 70% aqueous perchloric acid for an hour at 75°C. After allowing the reaction mixture to stand for several days the salt was doubly recrystallized and used in the pentahydrated form.

The washing procedure for the copper crystals after electropolishing was varied slightly from the previous study as follows:

1. Immediately after removal from the electropolishing bath crystals were washed for 1 min in demineralized water with a specific resistivity of at least 1.2 million ohms. This water was obtained from a D-ion Master demineralizer, Model No. 8120.
2. This was followed by washing in a rapidly stirred 10% by volume H_3PO_4 for 1 min.
3. The crystal was then re-washed in the demineralized water for 3 min.
4. Finally, the crystal was washed in distilled water[2] with a resistivity of approximately 1.4 million ohms for 2 min.

Experimental Results

As expected, reflection electron diffraction showed that the oxide formed in the present study was Cu_2O. The initial *p*H of 4.3 was maintained during oxidation in the copper(II) formate solutions but in the copper(II) perchlorate solutions it dropped to approximately 3.5 after immersion for 1 hr. These *p*H effects were essentially the same as those found respectively in the $CuSO_4$ and $Cu(OAc)_2$ solutions.

[2] The distilled water was obtained by using a Consolidated Still, Model CSA-NP-X2.

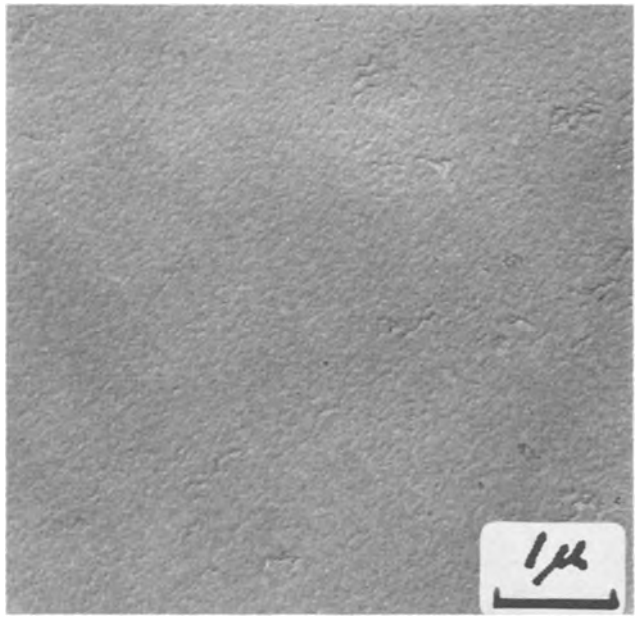

Fig. 2. Oxidation of the (110) face of copper in 0.05*N* $Cu(CHO_2)_2$ at 30.0°C for 5 min. Initial *p*H 4.3. Magnification 15000X before reduction for publication.

Figures 1 and 2 show a general comparison of the topography of the oxide formed on the (110) face in $Cu(ClO_4)_2$ and $Cu(CHO_2)_2$ solutions after 5 min of oxidation. By comparing Fig. 1 and 2, respectively, with Fig. 2c and 4c in ref. (1) it can be seen that polyhedra form in the sulfate and perchlorate systems, while smooth films form in the acetate and formate systems. These pictures along with others taken at immersion times varying from 30 sec to 24 hr show that the film formed in the formate system is normally even smoother than that in the acetate and the polyhedra formed in the perchlorate solutions grow together to a much greater extent than those formed in the sulfate solutions. Results indicated that in $CuSO_4$ solutions the oxide polyhedra require several hours to grow together to cover the entire surface,

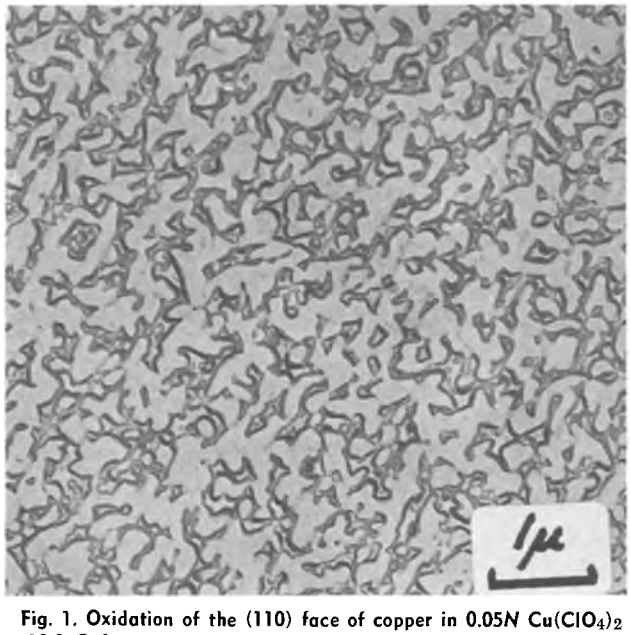

Fig. 1. Oxidation of the (110) face of copper in 0.05*N* $Cu(ClO_4)_2$ at 30.0°C for 5 min. Initial *p*H 4.3. Magnification 15000X before reduction for publication.

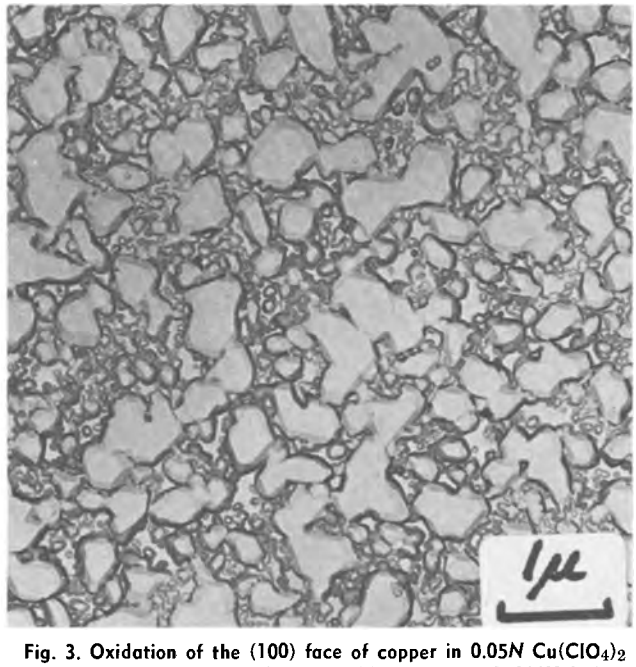

Fig. 3. Oxidation of the (100) face of copper in 0.05*N* $Cu(ClO_4)_2$ at 30.0°C for 10 min. Initial *p*H 4.3. Magnification 15000X before reduction for publication.

while this happens in the $Cu(ClO_4)_2$ system within 1 hr. This indicates that in the $Cu(ClO_4)_2$ solutions the oxide must grow much more rapidly, at least in a lateral direction, so as to cover more of the surface.

The (111) face in both $Cu(ClO_4)_2$ and $Cu(CHO_2)_2$ solutions showed oxide growths similar to those found respectively in the sulfate and acetate systems. A comparison of Fig. 3 with Fig. 3a of ref. (1) shows that the (100) face oxidized in perchlorate showed polyhedra similar to that in the sulfate system. Again the oxide in perchlorate were more run together than those in sulfate solutions. It was shown in the previous study (1) that the oxide formed on the (100) face in acetate solution was continuous up to about 10 min but for immersion times from 10 min to 1 hr polyhedra were observed. A comparison of Fig. 4 in this paper with Fig. 5b in ref. (1) shows that this phenomenon was also observed in the formate system.

Discussion

It would appear that the results of the present study when combined with those in the previous study support the conclusion that the anion can greatly affect the nature of the oxide formed on copper surfaces and that similar anions cause similar oxide growths. However, as mentioned in the earlier paper this conclusion has not necessarily been substantiated. It will be recalled that the bulk *p*H drops in the sulfate and perchlorate systems but remains essentially constant in the buffered acetate and formate systems. It is possible that a major variable or perhaps even the controlling variable could be changes in *p*H at the reaction surface. For example, selective dissolving at weak points in an oxide film could cause the formation of polyhedra of oxide. In order to check this possibility a detailed study of the effect of *p*H is now being carried out in this laboratory.

The present study raises two additional questions.

1. Why is the oxide formed in solutions of copper(II) formate normally smoother than that formed in copper(II) acetate solutions?

2. Why do oxide polyhedra formed in copper(II) perchlorate solutions apparently grow laterally at a faster rate than those formed in copper(II) sulfate solutions?

One possible factor that could influence the formation of continuous films as opposed to polyhedra lies in the nature of the complex species present in the electrolyte solutions. The copper(II) ion in solutions of $CuSO_4$ and $Cu(ClO_4)_2$ would exist predominantly as $Cu(H_2O)_4^{++}$ and the perchlorate and sulfate ions would exist in a noncomplexed form. In concentrated solutions of $Cu(OAc)_2$ and $Cu(CHO_2)_2$ the complex species present are quite different, as shown by Yamada, Nakamura, and Tsuchida (2). In concentrated copper(II) formate solutions there are infinite chains of composition $Cu(CHO_2)_2 \cdot 2H_2O$ joined together by hydrogen bonding through the two water molecules and in concentrated copper(II) acetate solutions there are binuclear complexes of the form $Cu_2(CH_3COO)_4 \cdot 2H_2O$. Of course, these are the monodisperse species only in concentrated solutions; in the relatively dilute solutions used in the present study they would exist in much lower concentrations along with $Cu(H_2O)_4^{++} \cdot C_2H_3O_2^-$, and CHO_2^- ions.

If these formate and acetate complexes with copper were present in sufficient number, they could be more easily adsorbed than the $Cu(H_2O)_4^{++}$ at local charge sites in the thin initial film of Cu_2O. Using Pearson's terms (3) in which "hard" acids are relatively resistant to polarization and "soft" acids are relatively easy to polarize, one would expect the formate and acetate complexes to be fairly "soft" compared to the square planar $Cu(H_2O)_4^{++}$ ion. Thus, these "softer" or more polarizable species could be more readily adsorbed. If they were adsorbed more readily, they would provide a larger number of nucleation sites for further oxide growth than the adsorbed $Cu(H_2O)_4^{++}$ and could thus account for the growth of a fairly smooth, continuous oxide film.

Another explanation could lie in the selective adsorption of the anions as opposed to the metal complex ions. The softer acetate and formate ions could be more easily polarized and adsorbed on the initial thin oxide film. The adsorbed anions could then attract $Cu(H_2O)_4^{++}$. Again, if the acetate and formate ions were more readily adsorbed they would provide a much larger number of reaction sites and could account for continuous films.

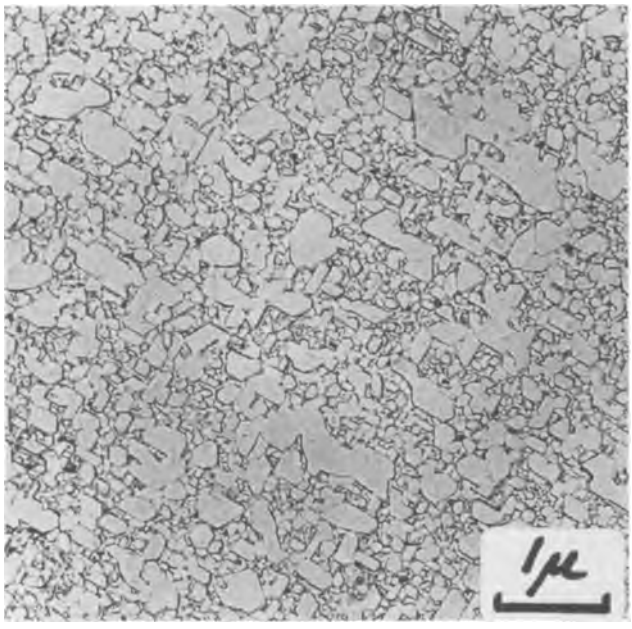

Fig. 4. Oxidation of the (100) face of copper in 0.05*N* $Cu(CHO_2)_2$ at 30.0°C for 10 min. Initial *p*H 4.3. Magnification 15000X before reduction for publication.

Summary

1. Oxide formed in $Cu(ClO_4)_2$ solutions on copper single crystals is generally in the form of polyhedra of Cu_2O.

2. The polyhedra are similar to those found in a previous study using $CuSO_4$ solutions except that they appear to grow together laterally at a faster rate in the $Cu(ClO_4)_2$ solutions.

3. Oxide formed in $Cu(CHO_2)_2$ solutions on the (110) and (111) faces copper single crystals is generally in the form of a smooth continuous film.

4. These continuous films are similar to those found in a previous study using $Cu(OAc)_2$ solutions except that they are even smoother than those formed in $Cu(OAc)_2$ solutions.

5. Oxide polyhedra formed on the (100) face of copper in solutions of $Cu(CHO_2)_2$. This behavior is similar to that found in the previous study for the (100) face exposed to $Cu(OAc)_2$ solutions.

6. During oxidation the *p*H of the $Cu(ClO_4)_2$ solution dropped from its initial value of 4.3 to approximately 3.5 after immersion for 1 hr, while the *p*H of the $Cu(CHO_2)_2$ solutions remained essentially constant throughout the reaction.

Deposition Modes of Cobalt from Sulfate-Chloride Solutions

R. Sard, C. D. Schwartz,[1] and R. Weil

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey

ABSTRACT

The as-plated surfaces of cobalt electrodeposits obtained using various combinations of the common plating variables as well as some thinned foils of these samples were studied. The basal plane was found to be predominantly perpendicular to the substrate leading to $<11\bar{2}0>$ and $<10\bar{1}0>$ fiber axes. Structural features associated with each fiber axis are explained in terms of crystal symmetry and twinning. Using the concepts of free and inhibited outgrowth it was not possible to predict the structure resulting from plating under a given set of variables. The cubic phase of cobalt was observed after deposition at room temperature and low *p*H.

Electrodeposited cobalt has been a topic for research during the past half-century because of its magnetic properties, its similarities to nickel, and its salient crystallographic features. The allotropic transformation in cobalt and the report by Kersten (1) that the high temperature face-centered-cubic phase is present at room temperature under certain conditions of electrodeposition has been of particular interest to investigators. A group at the Institute of Physical Chemistry of Bulgaria (2-4) has been concerned with the effect of certain plating parameters on the occurrence of the cubic phase at room temperature. Their studies consisted of Debye-Scherrer x-ray analyses. From the relative intensities of various diffraction lines they were also able to draw some conclusions about preferred orientation. Other investigators who used x-ray techniques to study growth textures in relation to magnetic properties, were Polukarov (5) and Quinn and Croll (6). Polukarov also studied the surface microstructure of a few samples with replicas. Brenner, Couch, and Williams (7) worked with cobalt deposits from chloride baths and noted the effect of phosphorous content and heat-treatment on the microstructure of optically viewed cross sections and on several other properties.

Finch, Wilman, and Yang (8) studied the orientation of a number of electrodeposited metals, among them cobalt, by electron diffraction. They reported that cobalt has a $<11\bar{2}0>$ fiber axis in the hexagonal form and a $<110>$ orientation in f.c.c. form. Random deposits were also observed. The first attempt to relate orientation to structural type was made by Weil (9). He related the types of surface structures that could be expected under certain plating conditions with the fiber axes as determined by electron diffraction. The structure of cobalt electrodeposited on single-crystal substrates has been the subject of recent work by Cliffe and Farr (10) and also by Goddard and Wright (11).

None of the investigations to date were comprehensive and systematic studies of the effect of the various plating parameters on the structure of cobalt. The present investigation was undertaken to survey the orientation types which can exist in cobalt electrodeposits plated under various combinations of *p*H, current density, temperature, and concentrations of the negative ions of two cobalt salts. This study consisted of a determination of the orientations of various deposits in a way similar to that used by Banerjee and Goswami (12) in their work with nickel, as well as electron-microscopic examinations of replicas of all the surfaces and a number of thin films in order to relate texture and microstructure.

[1] Present address: Central Research Laboratory, Air Reduction Corporation, Murray Hill, New Jersey.

Experimental Procedure

Four plating solutions were prepared from analytically pure chemicals to determine the effects of the important deposition variables, namely *p*H, current density, bath temperature, and composition. The compositions of the solutions, all of which had the same cobaltous ion concentration, 1.25 moles/liter, are given in Table I. The solutions were purified as described by Weil (9).

Initially, the starting cathodes were electropolished copper sheet. Subsequently, some experiments were repeated using cobalt starting cathodes to determine the possible effect of the substrate, to check on reproducibility, and to make it easier to thin the deposits electrolytically for transmission electron microscopy. The starting-cathode sheets were inserted in a plastic frame which exposed an area of 0.4 dm^2 to the plating solution. The cathodes were weighed before and after deposition. The thicknesses of the deposits were calculated from their weights and were about 50μ in all instances. Bagged cobalt anodes were used, and the solutions were not stirred.

Deposition was performed in each of the four plating baths at *p*H values of 2.0, 3.5, and 5.0. The *p*H was adjusted by addition of either H_2SO_4, HCl, or the appropriate mixtures to maintain the existing ratio of sulfate to chloride ions. The plating baths were operated at both room temperature and 60° ± 3°C. At room temperature and at each of the three *p*H values in each of the four baths, deposition took place at current densities of 0.1, 0.5, 2.5, and 5.0 amp/dm^2. The deposits obtained at 0.1 amp/dm^2 and 60°C were not coherent and therefore not studied further. Thus a total of 84 different plating conditions were em-

Table I. Bath compositions*

B	0.625	0.625	1:1
C	1.136	0.114	10:1
D	1.25	0	All sulfate

* All baths also contained 30g/liter H_3BO_3 and 0.15g/liter sodium lauryl sulfate.

ployed. In addition, several samples were deposited in an all-sulfate bath at room temperature with the pH lowered to between 1.0 and 1.5 for the purpose of obtaining deposits with relatively large amounts of face-centered-cubic material.

The crystallographic orientations of the deposits were determined by several methods. The relative intensities of the lines from the various diffracting planes parallel to the surfaces of the deposits were measured by using a diffractometer and Geiger-counter assembly in a G.E. X-Ray Diffraction Unit with cobalt $K\alpha$ radiation. The fiber axes were also determined by glancing a Mo $K\alpha$ incident beam normal to the surface in the manner described by Taylor (13), as well as by reflection electron diffraction.

The microstructures of the as-plated surfaces of all deposits were studied by electron microscopy using carbon replicas. The deposits plated on cobalt substrates were stripped and thinned by covering the deposit with acid-resistant adhesive tape and electropolishing in a stirred solution of 860 cc H_3PO_4, 51 cc H_2SO_4, and 100g CrO_3 at 30-35v and 2-4 amp/cm^2 at about 10°C. The thinned foils were examined by transmission electron microscopy and selected-area diffraction in an Hitachi HU-11 Electron Microscope operated at 100 kv.

Results

The diffraction patterns, which were obtained from the as-plated deposits, could be classified into four types. In all of them the basal plane {0001}, which in the hexagonal system is the most densily packed one, was predominantly perpendicular to the cathode. The most frequently observed pattern also had the most closely packed direction, $<11\bar{2}0>$ as the fiber axis. Occasionally, a $<10\bar{1}0>$ fiber axis occurred. Sometimes a doubly fibered deposit consisting of both $<11\bar{2}0>$ and $<1010>$ textures was observed. A diffraction pattern in which the intensity of each Debye ring had azimuthal symmetry was also observed. In this pattern, however, all reflections from planes of the type {0002}, {0004}, etc. were either absent or quite weak, consequently this type of orientation has been termed pseudo-random. Table II lists the type of fiber axis which was obtained under the various plating conditions. The relative strengths of the fiber axes are also indicated and will be discussed later.

The electron-microscopic examination of the replicas from the as-plated deposit surfaces showed that there were distinct structural features associated with each of the four types of fiber axes. Thus for each set of plating conditions listed in Table II, which produced a given type of orientation, there were certain distinctive features observed. A relatively coarse structure with a layered or faceted morphology represented by Fig. 1a was found to occur in samples plated at 60°C and which had a strong $<11\bar{2}0>$ fiber axis. In some areas the facets were arranged so as to produce pyramidal shapes. The strong $<11\bar{2}0>$ texture in deposits obtained at room temperature, was characterized by smaller, though more readily recognizable pyramids as shown in Fig. 1b. These pyramids generally possessed either four or five sides and usually had fine structure on their faces. The weaker $<11\bar{2}0>$ texture was associated with pyramids with more rounded sides as shown in Fig. 1c. Samples having the $<10\bar{1}0>$ fiber axis and the pseudo-random orientation frequently exhibited acicular or ridge-like shapes on their surfaces. Figure 1d is representative of the $<10\bar{1}0>$ texture. The pseudo-random orientation was observed in deposits that ranged from coarse ridges as seen in Fig. 1e, to the finer structures of Fig. 1f. It can be seen that the ridges were generally symmetric about a plane which was perpendicular to the surface and ran parallel to their long direction. The mixed structure with $<11\bar{2}0>$ and $<10\bar{1}0>$ fiber axes showed both pyramids and ridges. In addition to the aforementioned variation with temperature, it was found that the structural features, in general, became smaller and less distinct with decreasing pH or current density.

In order to elucidate further the structural features associated with the various orientations, transmission electron-microscopic studies of thin foils were conducted. The pyramids were found not to be a single crystal, but to consist of several sections which were in a twin relationship to each other. Figure 2 illustrates this phenomenon for a five-sided pyramid. In each section there are closely spaced parallel lines, which were observed in all deposits and represent the intersection of the basal plane {0001} with the plane of the foil. In Fig. 2, {0001} planes are perpendicular to the surface of the foil in each section. The $<0001>$ directions which therefore lie in the plane of the foil are indicated in Fig. 2. The electron diffraction patterns upon which the crystallographic observations were based, also showed streaking in the $<0001>$ direction, that is perpendicular to the fine

lines indicating that the coherently diffracting regions were quite thin in that direction. When the sample was tilted in the microscope, so that the basal planes were no longer parallel to the electron beam, the finely spaced lines developed into fringes of the kind generally associated with faults in the stacking of closely packed planes. The acicular or ridge-like features had {0001} planes parallel to the long direction which were again perpendicular to the surface. The series of fine lines were again present as seen in Fig. 3, where a <0001> direction is indicated for reference. Figure 3 is a transmission electron micrograph of a sample having the curved-ridge type of surface structure seen in Fig. 1e. The curvature is seen to result from the fact that a ridge was not a single crystal, but again consisted of a series of segments. It is doubtful, however, that these segments bore a twin relationship to one another. On a number of occasions single-crystal needles were also observed.

In the course of the study of the preferred orientations by x-ray diffraction, an extra Debye ring not belonging to the hexagonal system was found in patterns from deposits plated at low *p*H and room temperature in baths containing chloride ions. The samples having the extra line, which was always weak and broadened, are designated by asterisks in Table II. The extra line had an interplanar spacing corresponding to that of {200} planes of the face-centered-cubic lattice. The {200} line is the only cubic line which does not coincide with a hexagonal one.

Deposition in an all-sulfate bath operated at a *p*H of 1.0 to 1.5 resulted in specimens with a very fine grain size and the extra {200} cubic line. Selected-area diffraction of these deposits showed an intense {200} line, superimposed on the hexagonal pattern, but attempts to isolate the cubic material by dark-field microscopy were unsuccessful due to the proximity of this reflection to the neighboring $\{10\bar{1}1\}$ line.

Discussion

Several authors (8, 12, 14) have classified the structures of electrodeposits as lateral and outgrowth. According to Reddy (15) there is lateral growth if preferentially developed planes are parallel to the surface and outgrowth if they are perpendicular. In lateral growth, if the closest packed plane is the preferentially developed one, a condition of free growth is said to exist. In outgrowth, if the densest packed direction is preferentially perpendicular to the surface, it is said to be the freest growth. Thus for cobalt, a <0001> fiber axis corresponds to freest lateral growth and $<11\bar{2}0>$ freest outgrowth. Other fiber axes, therefore, represent conditions of more inhibited growth and are said, according to Reddy (15), to result from variations in the coverage of different atom planes by inhibitors. As in this study the basal plane was in no instance preferentially developed parallel to the surface, only outgrowth can be considered to have occurred. This fact was substantiated by examinations of the cross sections of the samples which showed a columnar type of structure perpendicular to the substrate. From the above, it can be concluded that samples which exhibited a strong $<11\bar{2}0>$ fiber axis therefore had the most free growth and those having other crystal directions perpendicular to the surface represented a more inhibited condition.

An alternate theory of the relationship of preferred orientation to the degree of inhibition has been proposed by Pangarov (16). According to this theory, the work of forming a two-dimensional nucleus for a given lattice plane is a function of the overpotential. The lattice plane for which the work of forming such a nucleus is a minimum is the one parallel to the surface. In the hexagonal system such a calculation leads to the order of fiber axes with increasing inhibition as follows: $<0001>\rightarrow<10\bar{1}1>\rightarrow<11\bar{2}0>\rightarrow<10\bar{1}0>\rightarrow<11\bar{2}0>+<10\bar{1}0>$. As the first two orientations were not observed, according to Pangarov's theory, then $<11\bar{2}0>$ is again the least inhibited growth found in this study. However, it should be pointed out that it is questionable whether two-dimensional nucleation has to occur for growth to continue as screw dislocations (17) can provide continuing sites for atom incorporation. It also was found (18) that there is no definite relationship, in the cobalt baths studied, between overpotential and the type of fiber axis.

The results shown in Table II can now be considered in terms of the effects of the plating variables on the relative freedom of growth as indicated by the degree to which the $<11\bar{2}0>$ fiber axis is developed. The effect of temperature in the two baths with the highest chloride-ion concentration, baths A and B, was opposite from that in baths C and D. In baths A and B, increasing the temperatures resulted in freer growth. Such an effect of temperature was expected because the adsorption of impurities should have been decreased and the metal-ion concentration near the cathode increased due to accelerated diffusion rates. However, at the low chloride-ion concentration or in their absence, increasing temperatures resulted in more inhibited growth except at *p*H 5.0 and 0.5 amp/dm^2 in bath C. It may be postulated that the low anode efficiencies usually associated with low chloride-ion concentration resulted in the formation of other reaction products, which at high temperatures could have diffused rapidly to the cathode thereby inhibiting growth. A diffraction ring, tentatively identified as cobalt hydroxide, was found in deposits plated under these conditions.

The effect of current density as seen from Table II shows a trend toward freer growth with a decrease in the variable at 60°C in all four plating baths and at room temperature in baths A and B. A possible reason for this behavior is less impoverishment of the solution at the cathode at lower current densities. At room temperature in baths C and D, growth became freer with increasing current densities. An explanation is that the chloride ions decreased the adsorption of an inhibitor. As there was a tendency toward freer growth at high *p*H values, the inhibitor could have been hydrogen.

The *p*H value appeared to have had little effect at 60°C when the chloride-ion concentration was relatively high. In bath C, growth became freer with increasing *p*H possibly because the chloride-ion concentration was not sufficient to prevent hydrogen from acting as an inhibitor. In the absence of chloride ions, growth tended to become freer with decreasing *p*H. A possible reason for this behavior may be that the basic substances which tended to form at high *p*H values were the more potent inhibitors when their adsorption was not impeded by chloride ions. At room temperature there was again no significant effect of *p*H on the type of growth.

The chloride-ion concentration exerted the greatest influence at the elevated temperature of any of the variables which were studied. The baths with the higher chloride-ion concentration, baths A and B, behaved alike as far as free growth was concerned and exhibited the greatest number of $<11\bar{2}0>$ orientations. Here, the chloride ion probably prevented inhibition. In bath C there was free growth only at high *p*H. A possible reason for this phenomenon, which has already been stated, is that there were not sufficient chloride ions to prevent inhibition due to hydrogen evolving at low *p*H values. In the absence of chloride ions, in bath D, inhibited growth occurred at high current densities. An explanation for these observations has also already been given. At room temperature, the effect of the negative ions was not definite. Decreasing chloride-ion concentration ap-

peared to favor free growth at low pH and, except at the lowest current density, also at the medium pH value.

Thus, while it is possible to explain the occurrences of inhibited or free growth, the requirements of a satisfactory theory to predict the behavior are not realized. It is clearly necessary to determine experimentally the fiber axis under a given set of plating conditions. However, with a given set of plating conditions, the structures were reproducible, as those samples plated on copper and on cobalt substrates were the same.

The reason why certain structural features were associated with each fiber axis in hexagonal cobalt can be deduced by analogy to Schlötterer's (19) explanation of face-centered-cubic nickel. The closest packed direction in the face-centered-cubic lattice is <110>. When this direction was the fiber axis, multisided pyramids were observed. Schlötterer has shown that these pyramids resulted because there are two sets of twinning planes perpendicular to the substrate. The possibility for the sections of a pyramid to be in a twin relationship to each other permits a higher degree of symmetry. In the hexagonal system when the close-packed direction $<11\bar{2}0>$ is the fiber axis, there are also a number of reported (20) twinning planes of the type $\{10\bar{1}L\}$, where L can be an integer from 1 to 5, perpendicular to the substrate. These planes probably provided the opportunity for forming the type of pyramids shown in Fig. 2.

In nickel when the <211> direction was the fiber axis, Schlötterer (19) found elongated shapes. These shapes were symmetric about a plane parallel to the long direction and perpendicular to the substrate. When there was a <211> fiber axis, there is only one twinning plane perpendicular to the substrate, thus only shapes with a two-fold symmetry can form. The hexagonal direction equivalent to <211> is $<10\bar{1}0>$. When $<10\bar{1}0>$ was the fiber axis in cobalt, the same types of shapes resulted as were observed with <211> in nickel. As the basal plane of the hexagonal lattice is a mirror plane without twinning, shapes having two-fold symmetry can result whenever this plane was perpendicular to the substrate. In the cubic system, as there is no mirror symmetry about the {111} planes, there had to be twinning on these planes in order to produce the types of shapes which Schlötterer observed.

Face-centered-cubic cobalt, unlike "hexagonal" nickel is thermodynamically stable above 420°C. Whereas Schlötterer (19), has shown that the extra line segment observed in diffraction patterns of some nickel deposits and which had been indexed as the $\{10\bar{1}0\}$ of a hexagonal phase can also result from double diffraction, the circumstances for cubic cobalt are probably different. As a complete diffraction ring corresponding to {200} has been observed, it is probable that there actually were crystals or parts thereof which had a face-centered-cubic lattice. Incomplete transformation to the hexagonal phase in wrought cobalt, especially if the grain size is small, is a well-known phenomenon (21, 22). The plated samples in which the cubic diffraction line was observed generally had a very fine grain size. It has been postulated (23) that the excess deposition energy is equivalent to an effective temperature considerably above ambient at the cathode surface. Based on this theory, under the conditions used in this study, the temperature at the growing cathode surface would be one at which the cubic phase is stable. Possibly the fine grain size prevented complete transformation. From Table II it can be noted that the presence of the chloride ion and low pH are also obviously associated with formation of some cubic phase possibly by their effects on the grain size.

Many workers (24-27) have used quantitative x-ray measurements in order to study the nature of lattice faults as well as the effects of particle size and strain on the structure of cobalt powders. The application of these techniques to elucidate the lattice faults and the presence of the cubic phase in electrodeposited cobalt is presently being studied.

Conclusions

1. In all deposits the basal planes were predominantly perpendicular to the substrate which led to the formation of $<11\bar{2}0>$ and $<10\bar{1}0>$ fiber axes.
2. Certain structural features were associated with each fiber axis and could be explained in terms of the crystal symmetry and available twinning planes.
3. Applying the concepts of free or inhibited outgrowth to the various orientations which were found did not permit a prediction of the type of structure which would result under a given set of plating variables.
4. The cubic phase was observed at room temperature and pH 2.0 in the presence of chloride ions, and at pH 1.0-1.5 in an all-sulfate bath.

Manuscript received Oct. 11, 1965; revised manuscript received Feb. 14, 1966. This paper was presented at the Washington Meeting, Oct. 11-15, 1964. This paper is based on theses submitted by two of the authors (R. S. and C. D. S.) in partial fulfillment of the requirements for the MSc degree (Metallurgy) to the faculty of Stevens Institute of Technology.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Effect of Crystal Plane on the Mechanism and the Kinetics of Copper Electrocrystallization

A. Damjanovic, T. H. V. Setty, and J. O'M. Bockris

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

To study the mechanism and the kinetics of electrocrystallization, electrochemical measurements were supplemented with *in situ* microscopic observations of growing copper electrodeposits. The growth was followed on main crystal planes of copper single crystals up to an average thickness of the deposit corresponding to 10 coulomb/cm^2. Highly purified solutions of 0.25M $CuSO_4$ in 0.1M H_2SO_4 were used.

Triangular and hexagonal pyramids form on the (111) plane at low ($\leq$10 ma/cm^2) current densities. Edges in the bases of these pyramids are either parallel to the <112> or to the <011> direction. At higher current densities (>10 ma/cm^2), the pyramids truncate and gradually transform into blocks. On the (110) plane, ridge types of deposit develop. At 2 and 5 ma/cm^2, the ridges are parallel to the [100] direction. At 10 ma/cm^2 and higher current densities, they are parallel to the [110] direction. Details of the types of deposit which are formed are given. Rates of growth of individual growth forms are determined and analyzed.

On all crystal planes, at any given current density the electrode potential changes with the time of deposition. On the (100) plane, the trend is for the potential to increase with deposition time until the average thickness of the deposit corresponds to about 3 coulomb/cm^2. On the (111) plane, however, there is a large decrease in the potential, which reaches a steady value once the average thickness of the deposit corresponds to about 6 coulomb/cm^2. On the (110) plane, the magnitude of the change in the potential with time of deposition is the lowest of the three planes considered.

Current-potential plots, both from the data at the initial stages of deposition, and from those obtained at an average thickness of deposit corresponding to 10 coulomb/cm^2 and the same type of growth, show Tafel slopes close to $2RT/F$. This slope is consistent with a mechanism where the first charge transfer is rate-controlling.

From the current-potential plots for the initial stages of deposition, exchange current densities on different crystal planes are found to be in the order

$$i^o_{111} < i^o_{100} < i^o_{110}$$

The decrease in the potential with time on the (111) plane is accounted for in terms of the formation and growth of new and more active crystal faces over the growing substrate. With this hypothesis, the observed change in the potential on the (100) plane is also explained. The observed exchange current densities at any instant of deposition is an average over all crystal faces of different activities. The dependence of the exchange current density on the crystal plane is discussed.

An inherent difficulty in the study of metal electrocrystallization is the continuous change of the electrode substrate with time of deposition (1). For this reason, the transient technique, or the technique of monolayer deposition, was frequently preferred (2-7) over that of the long time deposition (or electrocrystallization) and has been used successfully in the study of the mechanisms and the kinetics of metal electrodeposition. Most of these short time studies were done on polycrystalline electrodes and thus, because of the effect of grain boundaries and the distribution of various crystal planes, only average values of the kinetic parameters were obtained. This was clearly shown by the work of Bockris and Kita (6) in copper electrodeposition where both the mechanism and, for the same mechanism, the rate of the reaction changed with the electrode pretreatment. To separate the effects of various crystal planes and possibly of the grain boundaries, on the study of short time electrodeposition, single crystals with well defined faces would be preferred over polycrystalline electrodes. This is equally important in the study of the mechanisms and the kinetics of electrocrystallization at longer times. However, in the latter study, new crystal faces with different orientation than the initial substrate may form and grow. Because of this formation of new faces, the mechanism and the kinetics of electrodeposition may change. These latter changes may, in turn, alter the mechanisms of growth and produce new and different crystal faces. For this reason, in the study of the mechanisms of electrocrystallization, the electrochemical data and their changes with time of deposition have to be supplemented by other types of observations, such as optical measurements. These give information concerning the change of the substrate with time and about the formation and growth of new faces.

In the present study of copper electrocrystallization on (111) and (110) planes of copper single crystal, following the work on the (100) plane already published (8, 9), electrochemical techniques were combined with optical ones. The aim was to obtain data, suitable for theoretical treatment, on the dependence of the mechanism and the kinetics of electrocrystallization on the initial crystal plane and on the changes in the plane which arise from the formation and the growth of new faces.

The methods used involve continuous observation and photography at regular intervals of time by means of Nomarski interference contrast microscopy and polarized interferometry together with simultaneous electrochemical measurements. Supplementary analysis by means of electron microscopy was also carried out.

Experimental

Crystals.—Single crystals in the form of cylinders about 10 mm long and 8 mm in diameter were cut so that their bases were closely parallel to (110) or

(111) crystal planes. Each crystal was mounted in the Teflon body of an electrodeposition cell.

Cell.—The all Teflon cell for deposition was described in a previous publication (10). It allows observation of the growing deposit to be made *in situ* with relatively high useful magnification of 600-900X, without the objective of the microscope being immersed in the solution. With this cell it is possible to study deposition from highly purified solutions. The cell with the crystal is assembled and closed to the atmosphere inside a glove-box which is filled with prepurified argon. On the solution outlet tubing (10), a small compartment ($\sim$ 1 cm^3) is located with a copper reference electrode (prepared just immediately before use by electrodeposition from 0.25M $CuSO_4$ + 0.1M H_2SO_4 solution with 10 ma/cm^2 for 30 min). Electrical contact to the cathode is made on the opposite (bottom) side of the crystal (not exposed to the solution).

Solution preparation.—Analytical grade (Baker) copper sulfate was recrystallized twice in a closed system, in an atmosphere of highly purified nitrogen (9), using freshly redistilled conductivity water. Only the copper sulfate which crystallized first was used. The recrystallized copper sulfate was washed quickly three times with freshly redistilled conductivity water, after which it was dissolved in additional freshly redistilled conductivity water. Then the solution was transferred along a closed system of all glass tubing under the pressure of purified N_2 to a pre-electrolysis vessel for further purification by pre-electrolysis. At the same time, 50% H_2SO_4 was pre-electrolyzed in a separate vessel. Details on pre-electrolysis and final solution preparation have been given in a previous publication (8). Just before the experiments with electrocrystallization, the solution was passed through a column of activated charcoal and neutral alumina to remove any residual organic impurities from the solution (8, 11). Before each experiment, charcoal and alumina in the purification column (length $\sim$ 100 cm and diameter $\sim$ 6 cm) were washed with about 4 liters of 1M H_2SO_4, and then, after the H_2SO_4 passed through, three times with freshly redistilled conductivity water, each pass using about 2 liters. The first copper sulfate solution to pass through the column was discarded. The solution from the purification column was collected into a small collector vessel ($\sim$ 2 liter) which was connected to the Teflon cell. This vessel, as all the others, was washed by overnight soaking in a 1:1 mixture of HNO_3 and H_2SO_4, and then thoroughly rinsed with conductivity water. Finally, before the solution from the purification column was collected, the collection vessel was washed *in situ* with freshly redistilled conductivity water.

The solution used was 0.25M in $CuSO_4$ and 0.1M in H_2SO_4. (In a few experiments the concentration of $CuSO_4$ was changed and this has been noted in the text.) In some experiments, n-decylamine was added to the solution after it passed through the activated charcoal and alumina. For this purpose, a small graduated separatory funnel (50 cm^3) was attached to the final collector vessel.

Pre-treatment of the copper substrate.—For each experiment, the copper single crystal together with the main body of the Teflon cell, was mechanically polished first on 4/0 emery paper with ethanol as a lubricant, and then on 0.3μ alumina on a felt. The crystal in the Teflon cell body was washed under running distilled water, then with a mixture of ethanol and ether, and finally with ethanol. At this stage, the crystal and all components of the cell were introduced into the glove box (8).

Further treatment of the electrode surface included electropolishing at a constant potential in 50% H_3PO_4 in the argon atmosphere. After electropolishing, the crystal was washed with 10% H_3PO_4 and with redistilled conductivity water. All components of the cell were washed inside the glove box with water redistilled directly into it. The cell was assembled inside the glove box. The inlet and outlet tubing were attached to the cell at this stage. So assembled, the cell was then transferred to the platform of a microscope, and the connections made to the solution and outlet vessels. Further experimental details are available in ref. (8).

General procedure.—Electrodeposition was carried out at a given constant current density to an average thickness of the deposit corresponding to 10 coulomb/cm^2 (3.6μ). The overpotential (with respect to a polycrystalline copper reference electrode in the same solution) was continuously recorded. A Keithley 600A Electrometer and Moseley Autograf (680) were used. The growing crystal substrate was continuously observed and photographed at regular intervals. Nomarski interference contrast technique was used (12). Occasionally, level differences in the deposit were determined by Nomarski polarized interferometry (12).

Polaroid positive film (3000 ASA) was used. Usually, magnification on the photographs was 600X.

Results

Types of Deposit on (111) Plane

Deposition was carried out at 2, 5, 10 15, 20, and 30 ma/cm^2 from highly purified solutions, at 5 ma/cm^2 from the solution containing n-decylamine in concentrations varying from 10^{-9} to 10^{-4} mole/l, and at 2, 5 and 10 ma/cm^2 with a constant concentration of n-decylamine.

Types of deposits at 2 and 5 ma/cm^2.—At 2 and 5 ma/cm^2, the type of deposit formed from pure solutions may be classified as pyramid formation on either

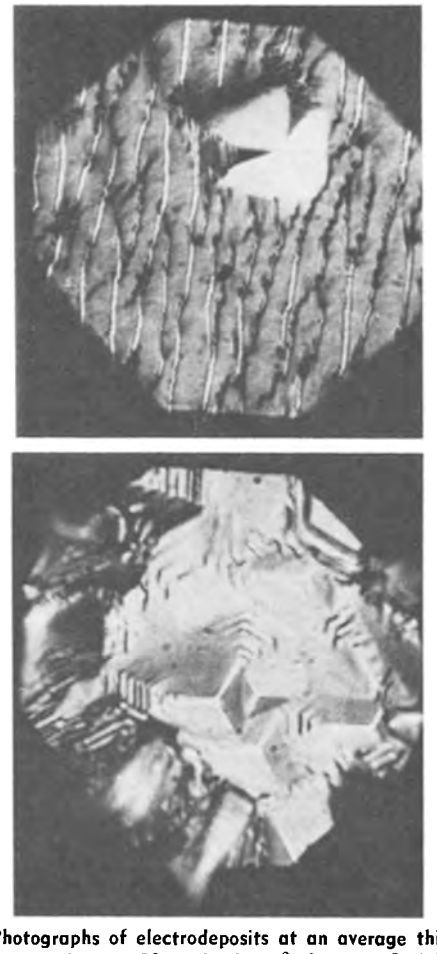

Fig. 1. Photographs of electrodeposits at an average thickness of deposit corresponding to 10 coulomb/cm^2. 2 ma/cm^2. (a) Pyramid on substrate containing macrosteps; (b) high density of pyramidal growth ($1.2 \cdot 10^5$ cm^{-2}). Magnification 600X.

smooth or layered substrate (Fig. 1). Some characteristics of the growth are listed here:

(*i*) Pyramidal growths, which often show a perfect geometrical shape, are of two types, triangular and hexagonal (Fig. 2).

(*ii*) Pyramids, both triangular and hexagonal, may form at any time of deposition.

(*iii*) Pyramidal faces in triangular pyramids are usually smooth. These faces are parallel either to one of <112> or of <110> directions both of which lie in (111) plane. Hence, there are four orientations of these triangular pyramids. These orientations are illustrated in Fig. 3.

(*iv*) As a triangular pyramid grows, it often develops, starting from the base, three extra side faces (Fig. 4, at places a). Edges at the base of these extra faces are parallel either to the <112> or to the <111> direction. As these new faces develop, a triangular pyramid gradually transforms into a hexagonal pyramid.[1] These newly developed pyramidal faces are usually stepped particularly close to the base of the pyramid and often form only close to the base of the pyramids.

(*v*) Triangular pyramids, or hexagonally shaped pyramids originating from the triangular ones, rarely truncate. The apex of some of these pyramids is observed to be a short line (presumably parallel to the base) rather than a point. The line on well developed pyramids can be as long as 1μ.[2]

(*vi*) "Regular hexagonal" pyramids also appear. They form as "hexagonal" in the earliest detectable stage. The occurrence of these pyramids is less frequent than that of the triangular pyramids.

(*vii*) "Hexagonal" pyramids tend to truncate even at an early stage of growth. All side faces, and not only alternate ones, are always stepped (Fig. 2).

(*viii*) Truncated "hexagonal" pyramids grow sidewise and transform eventually to sixfold "blocks" (*e.g.*, Fig. 6 and 7). At the center of a block, a new pyramid may begin growing again (Fig. 2).

(*ix*) When macrosteps are present on the deposit (8), they all propagate in the same direction. Some macrosteps fade out and disappear (8).

Here, some differences between deposits at 2 and 5 ma/cm^2 are given. At both current densities triangular pyramids are more frequent than the "true hexagonal" ones. The ratio of the density of the triangular pyramids to the hexagonal pyramids is less in deposits at 6 than at 2 ma/cm^2. On the average, from a number of experiments, the density of pyramidal growths at 5 ma/cm^2 (5 x 10^5 cm^{-2}) is higher than at 2 ma/cm^2 (about 1 to 2 x 10^5 cm^{-2}). Finally, the tendency for triangular pyramids to acquire additional faces and transform to "hexagonal" pyramids is higher at 5 than at 2 ma/cm^2. At 5 ma/cm^2, hexagonal pyramids truncate more readily than at 2 ma/cm^2.

[1] A pseudo sixfold symmetry is understood.

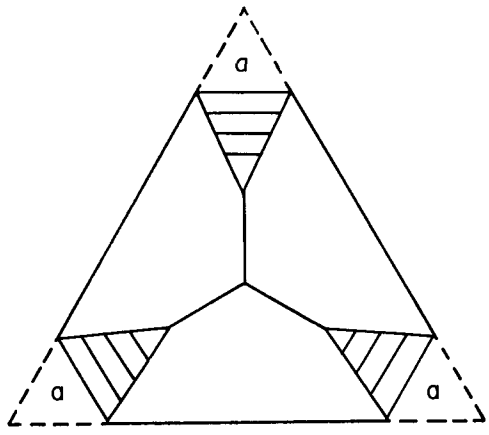

Fig. 4. Schematic representation of a triangular pyramid on which additional (a) faces start forming from the base of the pyramid.

Types of Deposits at 10 ma/cm^2 and Higher Current Densities

Hexagonally shaped pyramids form predominantly at 10 ma/cm^2, whereas triangular pyramids rarely occur at this current density. Almost all "hexagonal" pyramids truncate and transform into blocks and larger hexagonal layers which may eventually disappear by joining with other hexagonal layers (Fig. 5a and 6). Triangular pyramids, if they form, also show a tendency to truncate. Further a new pyramid may begin growing over a truncated pyramid.

At 15 ma/cm^2 and higher C.D., the type of deposit may still be described as pyramidal but truncation is complete. At 30 ma/cm^2 no distinct features in the deposit can be seen. The deposit appears to be polycrystalline.

Effect of addition of n-decylamine.—Addition of n-decylamine to the solution in concentrations below 10^{-5} mole/l has no visible affect on the type of deposit formed. With 10^{-5} mole/l of n-decylamine and at 5 ma/cm^2 truncation occurs readily for hexagonal pyramids and often for triangular pyramids. With 10^{-4} mole/l and at the same current density, hexagonal

[2] Arrow shaped pyramids were previously reported by Economou *et al.* (13).

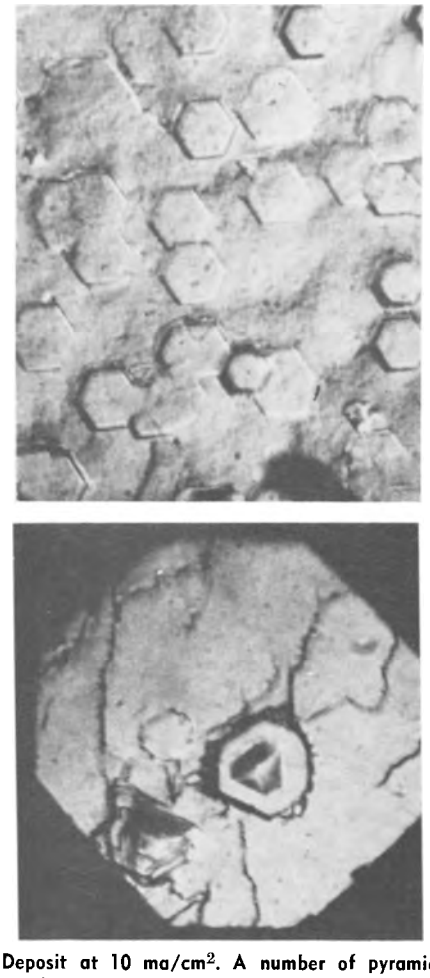

Fig. 5. Deposit at 10 ma/cm^2. A number of pyramidal growth transform to hexagonal blocks (a), and (b) triangular pyramid formed over a block (600X).

pyramids form in preference to triangular, and all pyramids soon truncate. Side faces, even of triangular pyramids, are stepped. Alternate faces of a truncated hexagonal pyramid contain macrosteps which are not parallel to the edge in the base, but are rather normal to it (Fig. 7). Complex shapes of pyramidal growths may also form and are probably due to twinning (Fig. 8).

With 10^{-4} mole/l of n-decylamine and at 2 ma/cm^2, the type of deposit is less affected than that at 5 ma/cm^2. The triangular pyramids remain with smooth faces. With 10^{-4} mole/l of n-decylamine and at 10 ma/cm^2, all pyramids truncate at an early stage of growth.

Fig. 6. Over a block close to its center a "line" parallel to an edge in the base often appears (600X).

Fig. 7. An example of macrosteps on side faces of truncated pyramids. 5 ma/cm^2 in the presence of n-decylamine (600X).

Fig. 8. An example of possible twinning (600X).

In general, n-decylamine affects the structure of the deposit more at high than at low current densities.

Effect of $CuSO_4$ *concentration and of temperature on the deposit.*—Deposition at 5 ma/cm^2 on the (111) plane has been made from solutions containing 0.05 mole/l and 1 mole/l of $CuSO_4$. The concentration of H_2SO_4 was 0.1 mole/l. The types of deposits obtained from these solutions were the same as those obtained from 0.25 mole/l and the same current density.

The morphology of the deposit at 5 ma/cm^2 from 0.25M $CuSO_4$ and 0.1M H_2SO_4 solution at 0°C differed markedly from that at room temperature. No pyramidal growth and only macrosteps were observed.

Types of Deposit on (110) Plane

Deposition was carried out at 2, 5, 10, 15, 25, and 30 ma/cm^2. At all current densities the ridge type of deposit formed. In Fig. 9, these ridges are shown for two current densities. The surface is not necessarily completely covered by ridges and "smooth" areas exist between them. Occasionally over the "smooth" surface macrosteps may have formed. Pyramidal growth rarely formed at 10 ma/cm^2.

At a given current density, ridges are all aligned along a particular direction. This direction is independent of the direction of solution flow. Ridges with two different orientations are observed. At 2 and 5 ma/cm^2, ridges are aligned parallel to the [100] direction. At 10 ma/cm^2 and higher current densities, they are all aligned parallel to the [110] direction.[3] Ridges

[3] This type of ridges was previously observed by Pick *et al.* (14).

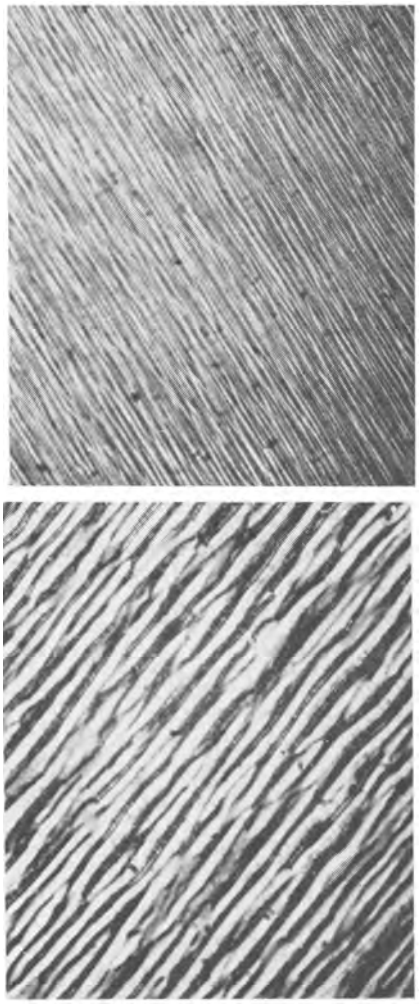

Fig. 9. Ridges developed on the (110) plane. (a) 5 ma/cm^2, (b) 10 ma/cm^2 (600X).

were not observed to advance laterally as, for instance, macrosteps (8).

The effect of n-decylamine was examined at 5 ma/cm^2. No significant change in the type of deposit from that in pure solutions was observed even at 10^{-4} mole/l of n-decylamine.

Rates of Growth

From a series of *in situ* (10) photographs taken at known intervals of deposition times, the rates of growth of pyramids and of macrosteps were measured. In Fig. 10, the normal distance of a macrostep from a reference point (a pyramid) is plotted *vs.* time of deposition. From similar plots rates of growth of pyramids at their bases, and rates of macrostep propagation both on pyramidal faces and on "smooth" substrates were determined. Average rates from a number of measurements are collected in Table I.

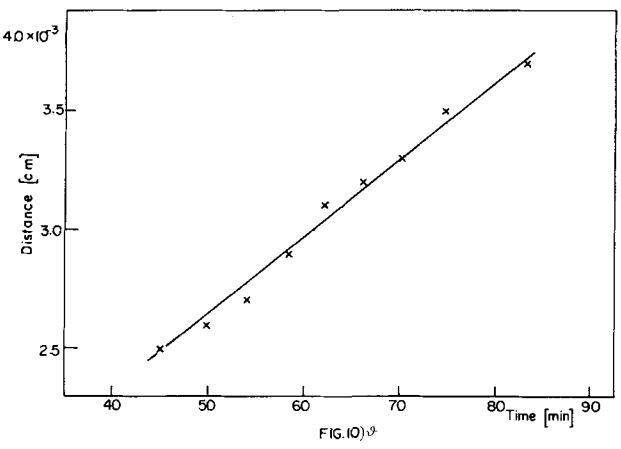

Fig. 10. A plot of distances of a macrostep from a fixed point on the substrate *vs.* time of deposition. 2 ma/cm^2.

In all experiments, it was found that, to a good approximation, the rates of propagation of macrosteps both on "smooth" substrate and on pyramidal faces, and the rates of growth of pyramids in their bases were independent of the deposition time for all the average thicknesses of deposit examined. The rate at which the base of both triangular and hexagonal pyramids, truncated or not, propagate was independent of the current density. The rates of macrostep propagation, both on "smooth" substrate and on pyramidal faces, increased with current density. To a first approximation, these two rates are equal. All these rates are independent of the concentration of $CuSO_4$. Addition of n-decylamine did not significantly affect either of these rates except possibly in the case of macrosteps on pyramidal faces at 2 ma/cm^2 and 10^{-4} mole/l of n-decylamine.

The edge of the upper plateau of truncated pyramids usually propagated faster than the base of the pyramids. In this way truncated pyramids gradually transformed into blocks.

Change of Overpotential with Time

Overpotential at a constant current density usually changed with time of deposition: it either increased or decreased. Often, for the same current density and when on the same crystallographic plane, much the same type of deposit formed. Potential-time dependence may have differed in details from one experiment to another. The general trend and appearance

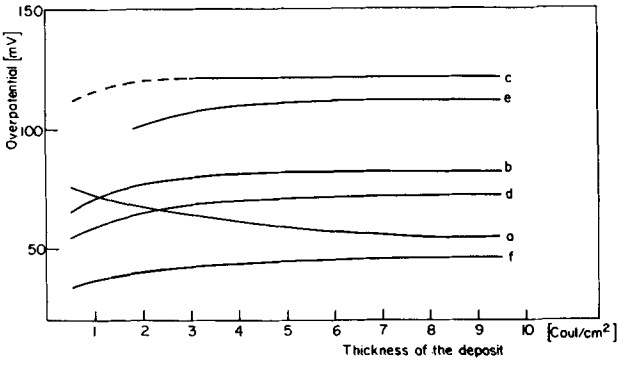

Fig. 12. Overpotential *vs.* the average thickness of the deposit at different current densities. Lines are idealized. The (100) plane. (a) Large layer formation at 5 ma/cm^2; (b) pyramids (and some macrosteps) at 5 ma/cm^2; (c) small layers and pyramids at 10 ma/cm^2; (d) ridges at 5 ma/cm^2 (in the presence of n-decylamine); (e) ridges at 10 ma/cm^2 (in the presence of n-decylamine); (f) smooth substrate (with or without small macrosteps) at 5 ma/cm^2.

of the plot were, however, much the same for both experiments. This is illustrated in Fig. 11, where values of overpotentials for two experiments are plotted *vs.* time of deposition. In both experiments nearly identical deposits were formed [pyramids on the (111) plane at 5 ma/cm^2]. The best fit line is drawn through all the experimental points for each current density. These lines at different current densities are shown in Fig. 12, 13, and 14 for the (100), (111), and (110) planes,[4] respectively. Line d in Fig. 13 corresponds to the experimental points in Fig. 11. In most cases, however, more than two experiments were available for construction of these lines. In these figures, overpotentials are plotted *vs.* average thickness of the deposit in coulomb/cm^2, and not *vs.* time. On this scale overpotentials at different current densities can be compared easily.

The (100) plane.—Some characteristics of the potential-time curves for deposition are:

At all current densities, overpotentials tend to increase with average thickness of the deposit if pyramidal types of growth (8) or if macrosteps on "smooth" substrate develop. The opposite trend, that overpotential decreases with the thickness of the deposit, is observed when a large layer type of deposit forms (8).

Addition of n-decylamine to concentrations less than 10^{-7} mole/l does not affect overpotential-time relation. At higher ($> 10^{-7}$ mole/l) concentrations of n-decylamine, when the ridge type of deposit is formed (8), the potential increases with time, but always stays below that for pyramidal growth.

In all cases overpotential became reasonably constant at the average thickness of the deposit corresponding to about 2-3 coulomb/cm^2 (Fig. 12).

[4] Thanks are due to Mr. M. Paunovic for making data on the (100) plane available.

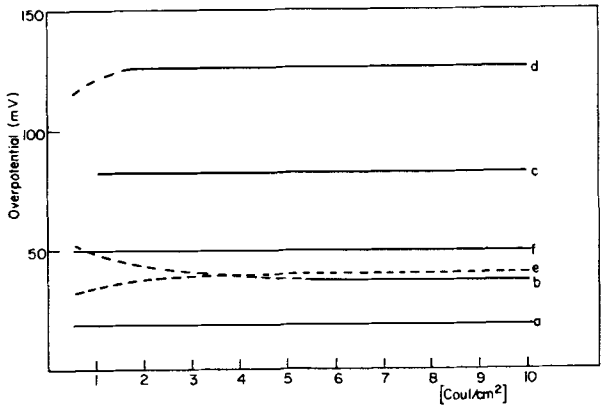

Fig. 14. Overpotential *vs.* the average thickness of the deposit at different current densities. Lines are idealized. The (110) plane. (a) 2 ma/cm^2; (b) 5 ma/cm^2; (c) 10 ma/cm^2; (d) 15 ma/cm^2; (e) 5 ma/cm^2 in the presence of n-decylamine; (f) 5 ma/cm^2 with almost smooth substrate.

The (111) plane.—At any given current density, overpotentials on the (111) plane are higher than on the (100) plane, and, as will be seen later, on the (110) plane.

At all current densities, the overpotential either initially decreases but becomes reasonably constant at about 6 coulomb/cm^2, or it remains reasonably constant from the initial ($\sim$ 0.5 to 1 coulomb/cm^2) time of deposition. In either case, overpotentials for the same current density at the initial time of deposition are approximately equal. When a deposit is smooth, with or without macrosteps (it may contain occasional pyramids, *e.g.*, 10^4 cm^{-2}), the overpotential is fairly constant with time for 2 ma/cm^2, and almost constant for 5 ma/cm^2 (Fig. 13). When large and numerous pyramids form, overpotential at the initial stage of deposition decreases with time rather sharply. In the presence of n-decylamine, overpotentials are usually lower than those in "pure" solutions.

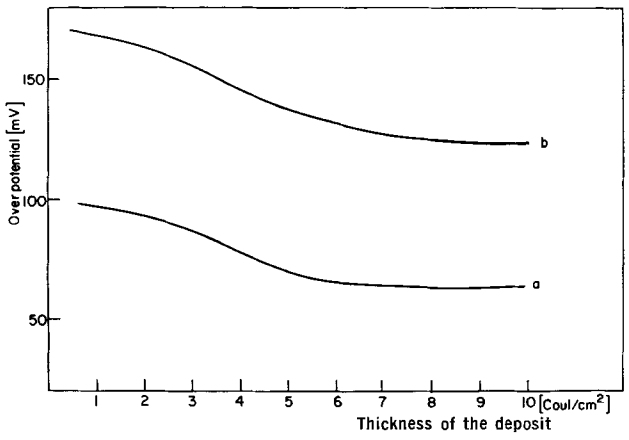

Fig. 15. Overpotential *vs.* average thickness of the deposit at 5 ma/cm². The (111) plane. (a) 1M $CuSO_4$, (b) 0.25M $CuSO_4$.

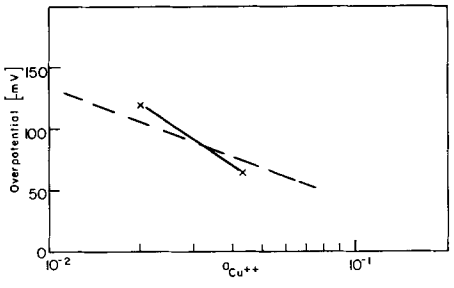

Fig. 16. Overpotential *vs.* activity of Cu^{++}. Broken line represents theoretically expected relationship.

The (110) plane.—For a given current density and any average thickness of the deposit, overpotentials on this plane are lower than on either the (111) or the (100) plane. Except for the initial period of deposition, overpotentials are fairly constant with time (Fig. 14). Contrary to the observation on the (111) plane in the presence of n-decylamine, overpotential at the average thickness of the deposit of 10 coulomb/cm² is higher than that from "pure" solutions.

Effect of Cu^{++} Concentration

Overpotential for electrodeposition onto the (111) plane with 5 ma/cm² from 1M $CuSO_4$ solution decreases with time in much the same way as it does from 0.25M solution. The former overpotential is lower by about 60-70 mv than in the latter case (Fig. 15). In Fig. 16, overpotentials[5] at the average thickness of deposits of 10 coulomb/cm² are plotted *vs.* log a_{Cu++}. The slope through two points is

[5] The activity of Cu^{++} in H_2SO_4 solution was calculated by the equation given by Glueckauf (15).

(x) represents initial values of overpotentials on the (110) plane; (0) represents values at the average thickness of the deposit corresponding to 10 coulomb/cm².

$$\left(\frac{\Delta\eta}{\Delta \log a_{Cu++}}\right)_i \approx 150 \text{ mv}$$

Current-Potential Relationship

In Fig. 17, overpotentials are plotted *vs.* log current density. Overpotentials are taken for the initial stages of deposition as well as at the final stage of deposition corresponding to 10 coulomb/cm². A linear relationship exists between electrode potential and log (current density) over one decade with slopes between 115 and 130 mv. Exchange current densities obtained by extrapolation to zero overpotential[6] differ from one crystal plane to another. In Table II data are summarized on the exchange current densities, and on the slope $dV/d \ln i$. It can be noted that:

(*i*) The exchange current densities, i_o's, obtained from the data at the initial stage of deposition, are in the following order

$$i^o_{110} > i^o_{100} > i^o_{111} \qquad [1]$$

i.e., overpotentials at the same current density are in the reverse order; and (*ii*) overpotential-log *i* line for deposits on (110) planes obtained from the steady state data at 10 coulomb/cm² deviate toward higher overpotentials at current densities above 10 ma/cm². Overpotentials at the initial stages of deposition, however, fall on the same Tafel line (x in Fig. 17).

Discussion

Potential-Time Relationships

The observed changes of overpotentials with time of the deposition can, in principle, be accounted for

[6] It is taken that reversible electrode potentials on different crystal planes are the same (16-18).

Table II. Tafel slopes and exchange current densities for deposition on various crystal planes and types of deposit

by: (*A*) a change in the mechanism of the reaction, (*B*) a change of the "active" surface area, (*C*) the change in the (apparent) exchange current density, and (*D*) blocking of the growth sites (adsorption of impurities on steps).

The observed slope of $2RT/F$ agrees with that found by Mattson and Bockris (4), Bockris and Enyo (5), and Bockris and Kita (6). According to the latter authors, on electrodes of electrodeposited copper, Tafel lines extend to low overpotentials. This is a characteristic of charge transfer as the rate-controlling reaction step, and not of surface diffusion of adions (2, 3, 7, 19-21). In the present experiments, Tafel relationships were observed both at initial ($\sim$ 30 sec) and at final (corresponding to 10 coulomb/cm^2) stages of deposition. Hence, in the considered interval of time, the mechanism of deposition does not change with time, and the explanation under point (*A*) can be discarded.

If the first charge transfer step is rate-controlling (5, 6), then blocking of growth sites, unless it is extensive, is not expected to affect the over-all rate of the reaction; it simply lowers the rate of the succeeding reaction step, which is still "faster" than the first charge transfer step. Furthermore blocking of growth sites, say of monatomic steps which act in the growth process, should tend to increase overpotential for the given current density. On the (111) plane, however, the addition of n-decylamine causes the overpotential to decrease (Fig. 13). Hence, point (*D*) may also be discarded.

Change in the surface area during the deposition.—If the change in the surface area (point *B*) is to explain the change of potential with time of deposition at a constant current density, then for the (111) plane the area has to increase and for the (100) to decrease with time of deposition. The observed increase of overpotential with time on the (100) plane would require an area decrease of 30-40%. Decrease of overpotential on the (111) plane can be accounted for only if the surface area increases by 200-400%.

The largest decrease in overpotentials on the (111) plane occurs when large pyramids form (Fig. 13). This suggests that the observed change in overpotential with time is due to an increase in the surface area arising from the formation of pyramidal faces. This increase can be calculated from the heights of pyramids and their size and density. In all cases examined it was found that $\tan \alpha \leq 0.2$, where α is the angle which a pyramidal face makes with the substrate.[7] Even assuming that pyramids touch each other in a close packing and that $\tan \alpha = 0.2$, the true surface area would increase by only a few per cent. This is calculated on the basis of smooth pyramidal faces. If pyramidal faces are assumed stepped, then the increase in the surface area is about 20%.

Increase in the surface area, therefore, cannot account for the observed change in the overpotential with time on the (111) plane. For the (100) plane, explanation of overpotential behavior in terms of the increased surface area alone is inadmissable, since the overpotential increases with time of deposition.

Change in the "active" surface area may arise from adsorption of "residual impurities." Behavior on the (100) plane could be accounted for by the increased adsorption, but not on the (111) plane. In fact, the following points argue against the explanation in terms of the decrease in the active surface area.

(*i*) Addition of n-decylamine does not significantly change overpotential on the (100) plane, providing that the type of the deposit remains the same.

(*ii*) On the (111) plane, addition of n-decylamine decreases, rather than increases, the overpotential for a given current density at any time of deposition.

Hence, cause (*B*) above must be rejected.

[7] See also Seiter *et al.* (22).

Change of the Activity with Time

The (111) plane.—When pyramids form, the data at the initial stage of deposition indicates a lower exchange current density, i^o_{111}, than at the final stage of the experiment. If, however, "smooth" deposits (with or without occasional pyramids) form, no appreciable change in overpotential with time is observed, and i_o's from the initial and final stages of deposition are nearly equal. It may be postulated that on the close packed (111) plane, the newly formed pyramidal faces correspond to the planes less closely packed (higher indices planes).

Since $i^o_{111} < i^o_{100} < i^o_{110}$, higher over-all activity results. Pyramidal faces close to the apex are parallel to some high index plane. As these pyramidal faces grow, the over-all activity of what was originally a (111) substrate increases and the overpotential for the same "average" current density decreases.

An area of newly formed faces of only a fraction of the total area suffices for the observed changes. Thus, if A is the area of the newly formed faces per unit area of the initial substrate then

$$i = [(1 - A)\, i^o_{111} + A\, i^o_{hkl}] \cdot e^{-\alpha F\eta/RT} \qquad [2]$$

where i^o_{hkl} is the exchange current density for the newly formed high index face. If

$$i^o_{hkl} \geqq 10\, i^o_{111} \qquad [3]$$

then [2] can be written as

$$i \approx [i^o_{111} + A \cdot i^o_{hkl}] \cdot e^{-\alpha F\eta/RT} \qquad [4]$$

Coefficient A in these equations increases with time of deposition. An increase in A to about 0.1 would suffice to explain the observed potential decrease on the (111) plane. Thus, instead of assuming a change in the surface area by 200-400%, the apparent exchange current density

$$(i^o_{Ap})_t = [i^o_{111} + A_t \cdot i^o_{hkl}] \qquad [5]$$

increases by factor 2 or 4. In the last equation suffix t stands for time. In general the apparent exchange current density is the sum over all the planes of the products of the exchange current density for a given plane, i^o_{hkl}, and the corresponding surface area

$$(i^o_{Ap})_t = \sum_{hkl} i^o_{hkl}\, (A_{hkl})_t \qquad [6]$$

For the steady state to be established, no further changes in the area of newly formed faces (planes) is required. This is to be expected under ideal conditions. A further increase in the surface area is prevented when pyramids touch each other. The steady state, however, is established before pyramids cover the entire substrate. This can be accounted for by the fact that the side faces of pyramids close to their bases are stepped (Fig. 1b). Once macrosteps have formed on these pyramidal faces, further growth results in the increase of the surface area of the newly formed more active planes. Inspection of the photographs shows that the surface area of the new faces can easily reach the value $A = 0.1$ even when the stepped portion of the pyramidal faces is excluded. The flat portion of pyramidal faces between macrosteps corresponds most probably to a low index plane, whereas side faces on these macrosteps are not necessarily perpendicular to the substrate and may correspond to a higher index plane, and thus also contribute to the increased activity.

From the foregoing discussion, it is concluded that the change in the apparent activity (point *C* above) can account for the observed change in overpotential with time of deposition on (111) plane. The least active (111) plane is gradually replaced by more active planes and overpotential decreases with time of deposition. It yet remains to explain the potential time behavior on the other two crystal planes.

Overpotential on the (100) plane.—On the (100) plane, in contrast to the (111) plane, overpotentials generally increase with time of deposition. The extent of the increase (Fig. 12) is, however, far less than the decrease on the (111) plane (Fig. 13). This behavior can also be explained in terms of changing the over-all activity of the electrode surface (point C above).

i^o_{100} is larger than i^o_{111} and when new faces are formed their effect would be less than the corresponding effect on the (111) plane. Were the newly formed faces close to, for instance, the (111) plane, it would be expected that the effect should be the opposite one to that for deposits on the (111) plane, namely the overpotential should increase with time of deposition since more active surface is replaced by less active surface. In fact, no large change in overpotential would be expected since the replacement of a small area of active surface by less active surface is far less effective as far as potential change is concerned, than the reverse process (cf. Eq. [2]).

It is possible that initially the electrode surface corresponds to some higher index plane due to local misorientation arising, for instance, from electropolishing. Soon, growth results in a smoothing out of the surfaces which become parallel to the (100) plane. Hence, overpotential initially increases with time and then becomes constant (Fig. 12).

Overpotential on the (110) plane.—The exchange current density is higher for the (110) plane than for the other two crystal planes considered. Time dependence of overpotential on the (110) plane is less than on the other planes.

Even when ridges form at 5 ma/cm^2, the potential does not change with time of deposition to any appreciable extent. This indicates that the side faces of ridges, which are parallel to a [100] direction, are as active as the (110) plane. If these faces were at 45° toward the substrate (toward the (110) plane), they would correspond to {100} planes. Then the over-all activity would not change significantly, particularly since the increase in the surface area arising from the inclination would be compensated by the lower activity at (100) planes. This explanation would clarify the experimental observation that overpotentials at current densities of 2 and 5 ma/cm^2 are virtually independent of the time of deposition. At 15 ma/cm^2 and higher current densities, overpotentials at the initial stage of deposition increase with time of deposition, but soon ($<$ 2 coulomb cm^2) assume a steady value. At these current densities, ridges are parallel to the [110] direction. Side faces of these ridges may correspond to the (111) plane (14). If so, the more active (110) plane is gradually replaced by the less active (111) plane and overpotential increases reaching the value close to that corresponding to the (111) plane. In this way the deviation of η — log i curve for the (110) plane at higher current densities (at 10 coulomb/cm^2) can be explained (Fig. 17).

Ridges at 10 ma/cm^2 are of the same orientation as those at 15 ma/cm^2 and yet no significant increase in η at 10 coulomb/cm^2 was observed (Fig. 14 and 17). This agrees with the observation that at 10 ma/cm^2 not all the surface of the electrode was covered by ridges. Hence, the observed changes of overpotentials with time of deposition on the main three crystal planes of Cu are due to the change in the over-all activity of electrode surface. The latter change arises from the growth of new crystal planes with different orientations and exchange current densities.

Effect of n-decylamine.—Faster decrease of overpotentials with time of deposition on the (111) plane at 2 and 5 ma/cm^2 in the presence of n-decylamine can also be attributed to the formations of new faces of different activity.

In the presence of n-decylamine one would expect "bunching" of monatomic steps which originate at the apex of a pyramid and propagate down their side faces to occur more readily since, in this case, their propagation would be disturbed more than in "pure" solutions. If so, surface area of the newly formed smooth and more active faces close to the apex of pyramids will decrease. Hence, less change in overpotential with time is expected in the presence of n-decylamine than in "pure" solutions. This is contrary to the experimental observation.

In the presence of n-decylamine crystallographically different pyramidal faces form than those in "pure" solutions. This was shown to be the case for copper deposition on the (100) plane. The inclination of pyramidal faces in "pure" solution was found to be larger than in "impure" solution. Even a slight change in the inclination could produce crystal planes with different activities. Side faces of macrosteps, both on the flat substrate and on the pyramidal faces, may also correspond to different crystallographic planes when formed in "pure" solutions or in solutions containing n-decylamine.

The Exchange Current Density

Different values of the exchange current density, i^o, on the main crystal planes (cf. Table II) may, in principle, arise from the change in: (*A*) the mechanism of the reaction, (*B*) the concentration of adions on various crystallographic planes, (*C*) the bond strength between substrate and adions, (*D*) the density of "growth sites" or steps on the surface, and (*E*) the work function. These possibilities are discussed below.

The mechanism of the reaction.—The mechanism of the reaction has been studied in detail by Mattson and Bockris (4), and Bockris and Enyo (5). It is

$$Cu^{++} + e^- \rightarrow Cu^+ \qquad [7]$$

$$Cu^+ + e^- \rightleftharpoons Cu \qquad [8]$$

with the first charge transfer as the rate-controlling step. Bockris and Kita (6) confirmed this mechanism for electrodeposited copper electrodes.

Tafel relationships established in the present experiments are in accordance with the first charge transfer as the rate-controlling step over the range of current densities examined on all the three crystal planes.

Dependence of i^o_{hkl} on adion concentration.—For the first charge transfer rate-controlling, the change in the concentration of adions from one crystal plane to another should not affect the activation energy for the rate-controlling step (6). Adion concentration may, however, affect the rate even under these conditions if the "active" surface area changes with adion coverage. Thus, it is in principle possible that (6)

$$i^o = K[Cu^{++}]\,(1-\theta)\exp(-\beta F V_{REV}/RT)\cdot \exp(-\Delta H^*_1/RT) \qquad [9]$$

where V_{REV} is the reversible electrode potential with respect to a reference electrode, ΔH^*_1 the activation energy for forward reaction, and θ the coverage by adions. There is little (16) or no (18) difference in V_{REV} on different crystal planes of copper. Therefore, the ratio of exchange current densities for the (111) and the (110) planes is given by (6)

$$\frac{i^o_{111}}{i^o_{110}} = \frac{(1-\theta_{111})}{(1-\theta_{100})}\exp[-\beta(H_{111}-H_{110})/RT] \qquad [10]$$

where $\beta(H_{111} - H_{110})$ is the change in the activation energy due to the change in the potential energy of Cu^+ for different crystal planes. If this change is taken as negligible (6), it follows that

$$\frac{i^o_{111}}{i^o_{110}} \approx \frac{(1-\theta_{111})}{(1-\theta_{110})} \qquad [11]$$

From experimental results, i^o_{111}/i^o_{110} is about 0.12, and, consequently, θ_{111} should be greater than θ_{110}.

It is possible to estimate the ratio of coverages on different planes. For the (111) and (110) planes

$$c^{o}_{111}/c^{o}_{110} = [\exp - \Delta F/RT] \quad [12]$$

where $\Delta F = F_{111} - F_{110}$, and F_{111} and F_{110} are the free energies of adsorption of adions on the (111) and (110) planes, respectively. On the (111) plane, an adion has 3 close neighbors in the substrate; on the (100) 4, and on the (110) 5. Energy of the adsorption will depend on the number of bonds formed by an adion. As a first approximation $\Delta F \approx \Delta H$, where ΔH is the heat of adsorption and is estimated from the difference in the number of bonds formed on both planes. It follows that

$$\Delta H = -\frac{L}{6}\cdot 3 + \frac{L}{6}\cdot 5 = \frac{L}{3}\left[\frac{\text{kcal}}{\text{mole}}\right] \quad [13]$$

where L ($\approx$ 84.8 kcal/mole) is the heat of sublimation for copper. Next, hydration energy terms should be considered. In the solution, primary hydration number for Cu^{2+} is approximately 12. The degree of hydration of an adion will depend on the site on the surface. Conway and Bockris (19, 20) calculated the heat of hydration of copper adions at various sites on the surface. Assuming that primary coordination by water molecules is 4 and 3 on the (111) and (110) planes, respectively, the corresponding heats of hydration are found to be —40 and —28 kcal/mole, The difference in the hydration energies is 12 kcal/mole, and $\Delta H \simeq 16$ kcal/mole. This calculation, however approximate, shows that adion concentration on the (110) is expected to be higher than on the (111) plane. Even if the difference in primary coordination of adions were 2, and the difference in the heat of hydration of adion on two planes were —19 kcal/mole [cf. Conway and Bockris (19, 20)], ΔH would be large and positive. Similar reasoning hold if the (111) plane is compared to the (100). It follows that c^{o}_{111} is less than c^{o} on the other two planes, and the change of i^{o} with the crystallographic plane cannot be accounted for by the change in adion concentration.

Dependence of i^{o}'s on energy of adion adsorption and on density of "growth sites."—For the first charge transfer as the rate-controlling step, the energy of adion adsorption should not affect the activation energy of the step, since the reaction product in the rate-controlling step, Cu^{+}, is fully hydrated and not yet attached to the electrode (6).

The density of "growth sites" or steps on the surface changes the rate with which adions can diffuse to and incorporate into the lattice. However, since the first charge transfer is rate-controlling, no affect on the over-all rate of the reaction should occur. Hence, the dependence of i^{o} on crystal plane cannot be explained in terms of adsorption energy or the density of growth steps.

Dependence of exchange current density on work function.—A possible dependence of the exchange current density on work function can be analyzed in the following way.

In a cell with a single crystal test electrode exposing the (*hkl*) plane, the measured potential difference,[8] ΔV, with respect to any reference electrode is given by

$$-\Delta V = -\phi^{In}_{hkl} + \phi^{In}_{S1} - \phi^{In}_{S1} + \phi^{In}_{REF} + V_c \quad [14]$$

Here, ϕ^{In} is the inner potential of the phase considered, (hkl) stands for the given crystal plane, REF for the reference electrode, and S1 for the solution. V_c is the contact potential difference between the two solids of which the electrodes are made, and is equal to (23, 24)

$$V_c = \Phi_{REF} - \Phi_{hkl} \quad [15]$$

where Φ_{REF} and Φ_{hkl} are the work functions for the reference and the test electrode, respectively. With

[8] By potentiometry.

$$\Delta\phi_{hkl} = \phi^{In}_{hkl} - \phi^{In}_{S1} \quad [16]$$

and

$$\Delta\phi_{REF} = \phi^{In}_{REF} - \phi^{In}_{S1} \quad [17]$$

where $\Delta\phi$'s are the corresponding galvani potentials, and with [15], Eq. [14] becomes[9]

$$\Delta\phi_{hkl} = \Delta V + \Delta\phi_{REF} - \Phi_{hkl} + \Phi_{REF} \quad [18]$$

The rate of an activation controlled cathodic reaction, when the rate of anodic reverse reaction is negligible and the ionic strength of the electrolyte sufficient to make the diffuse part of the double layer comparatively small, can be written as

$$i_{hkl} = k\,[Cu^{++}]\exp\left[-\frac{\Delta G^{o\neq}_{hkl} + (\Delta V + \Delta\phi_{REF} - \Phi_{hkl} + \Phi_{REF})\alpha F}{RT}\right] \quad [19]$$

Here, k is the rate constant independent of the work function, and $\Delta G^{o\neq}_{hkl}$ is the activation energy for the rate-determining step and depends on the work function, and thus on the crystal plane considered. When no net current flows across the test electrode, and since for the same reference electrode and the same experimental conditions, $\Delta\phi_{REF} + \Phi_{REF}$ remains constant, [19] transforms to

$$i^{o}_{hkl} = K\exp\left[-\frac{\Delta G^{o\neq}_{hkl}}{RT}\right]\exp\left[\frac{\alpha F\,\Phi_{hkl}}{RT}\right]\exp\left[-\frac{\alpha F\Delta V_{REV}}{RT}\right] \quad [20]$$

where i^{o}_{hkl} is the exchange current density for the (hkl) plane, and ΔV_{REV} is the reversible electrode potential with respect to the reference electrode.[10]

Activation energy $\Delta G^{o\neq}_{hkl}$ is not readily calculated. However, the change in the activation energy arising from the change of the crystal plane, $\Delta G^{o\neq}_{hkl} - \Delta G^{o\neq}_{h'k'l'}$, can numerically be evaluated from the change in the heats of the reaction $Cu^{++}_{aq} + e^{-} \rightarrow Cu^{+}_{aq}$ with the crystal plane considered. Thus, from the cycle

$$\begin{array}{ccc} Cu^{++}_{aq} + e^{-}_{M} & \xrightarrow{\Delta H^{o}_{M}} & Cu^{+}_{aq} \\ \uparrow H_{Solv}\,Cu^{++} & & \downarrow -\Delta H_{Solv,Cu^{+}} \\ Cu^{++} + e^{-} + aq & \xleftarrow{\bar{\mu}\quad I_{Cu^{+}}} & Cu^{+} + aq \end{array} \quad [24]$$

where $\bar{\mu}$ is the electrochemical potential of an electron in the metal, and other symbols have their usual meaning, it follows that

$$\Delta H^{o}_{M} = -\Delta H_{Solv,Cu^{+}} - I_{Cu^{++}} - \bar{\mu} + \Delta H_{Solv,Cu^{++}} \quad [25]$$

The difference in the heat of reaction on two crystal planes is then given by

$$\Delta H^{o}_{hkl} - \Delta H^{o}_{h'k'l'} = (\bar{\mu}_{hkl} + \bar{\mu}_{h'k'l'})F \quad [26]$$

With

$$\bar{\mu} = \mu + e\phi^{In} \quad [27]$$

and since μ is independent of the crystal plane

[9] Identical relationship has been obtained by Bockris and Potter (25).

[10] The absolute reversible electrode potential of an electrode with a single crystal plane exposed to the solution can be written [cf. Kortüm and Bockris (26)] as

$$\Delta\phi_{REV} = K - \Phi_{hkl} \quad [21]$$

where the constant K is independent of the crystal plane. The change in the reversible electrode potential arising from the change in the crystal plane from (hkl) to (h'k'l')

$$\Delta\Delta\phi_{REV} = \Phi_{h'k'l'} - \Phi_{hkl} \quad [22]$$

For the same reference electrode, this change is compensated by the change in the contact potential which arises at the metal-metal junction between the metal of the working electrode and the metal of the reference electrode. This is

$$\Delta\phi_{contact} = \Phi_{hkl} - \Phi_{h'k'l'} \quad [23]$$

$$-\bar{\mu}_{hkl} + \mu_{h'k'l'} = e\,(-\phi^{In}{}_{hkl} + \phi^{In}{}_{h'k'l'}) \quad [28]$$

From [14] and [15] it follows

$$-\phi^{In}{}_{hkl} + \phi^{In}{}_{h'k'l'} = \Phi_{hkl} - \Phi_{h'k'l'} \quad [29]$$

and [26] transforms to

$$\Delta H^{o}{}_{hkl} - \Delta H^{o}{}_{h'k'l'} = e\,(\Phi_{hkl} - \Phi_{h'k'l'}) \quad [30]$$

Assuming now that the entropy terms are nearly the same for the reactions on both crystal planes, then

$$\Delta G^{o\neq}{}_{hkl} - \Delta G^{o\neq}{}_{h'k'l'} = \beta F(\Phi_{hkl} - \Phi_{h'k'l'}) \quad [31]$$

where β is the symmetry factor.

The ratio of the exchange current densities on two different crystal planes is given from [20] as

$$\frac{i^{o}{}_{hkl}}{i^{o}{}_{h'k'l'}} = \exp\left[-\frac{(\beta-\alpha)(\Phi_{hkl} - \Phi_{h'k'l'})F}{RTT}\right] \quad [32]$$

It is apparent, therefore, that, if $\alpha = \beta \approx \frac{1}{2}$, the exchange current density, on the above basis, should not depend on the difference in the work function on the corresponding crystal planes. It is possible however, that $\alpha \neq \beta$ which would result in the dependence of the exchange current density on the crystal plane. In fact, if for the reaction [7] tunneling of electrons were possible [cf. Bockris and Matthews (27)], β would be less than $\frac{1}{2}$. In this case, and with $\alpha \gtrsim \frac{1}{2}$, the ratio of the exchange current densities on the (111) and (110) planes

$$\frac{i^{o}{}_{111}}{i^{o}{}_{100}} = \exp\left[\frac{\gamma(\Phi_{111} - \Phi_{100})F}{RT}\right] \quad [33]$$

where

$$\tfrac{1}{2} > \gamma > 0 \quad [34]$$

can be accounted for only if

$$\Phi_{111} < \Phi_{100} \quad [35]$$

Recently, Blevis and Crowell (28) measured (on a relative scale) work functions on the main crystal planes of copper at various temperatures. Their analysis of the work functions on different planes agreed with the older findings of Underwood (29) that the work function on the (100) plane is positive in respect to the (111) plane by about 0.5v. This value would satisfy the observed ratio $i^{o}{}_{111}/i^{o}{}_{100}$ (< 1) if γ is approximately equal to 0.1, or $\beta \gtrsim 0.4$.

Effect of $CuSO_4$ *Concentration on the Deposition*

Morphology of the deposit does not change with Cu^{++} concentration. The overpotentials at 5 ma/cm² from 1M $CuSO_4$ solution, on average, are by 60-70 mv lower than those from 0.25M solution (Fig. 15) with

$$i^{o} = k\,[Cu^{++}] \cdot e^{-\alpha F V_{REV}/RT} \quad [36]$$

and

$$V_{REV} = V_{REV_0} + RT/2F \ln [Cu^{++}] \quad [37]$$

$$\left\{\frac{\partial\eta}{\partial \ln [Cu^{++}]}\right\}_{i,T} = RT\,(2-\alpha)/2\alpha F \quad [38]$$

or with $\alpha \approx \frac{1}{2}$

$$\left\{\frac{\partial\eta}{\partial \log [Cu^{++}]}\right\}_{i,T} \approx 90 \text{ mv}$$

Data from only two points are available and indicate a slope larger than 90 ($\sim$ 150) mv. Were the second step rate-controlling, $\partial\eta/\partial \log [Cu^{++}]$ would have much lower ($\sim$ 10 mv) slope (4, 6). This confirms that, at both concentrations, the rate-controlling step is the first charge transfer.

The Rate of Growth and the Rate of Deposition

Were the deposit evenly distributed all over the smooth substrate, the calculated rate of growth normal to the substrate, v, would be given by approximately

$$v = 3.75\,i \quad [39]$$

where the current density, i, in ma/cm² gives v in Å/sec. At 2 ma/cm² this rate is 7.5 Å/sec. From Table I, it follows that the rate of macrostep propagation, either on smooth substrate or on pyramidal faces, is about 7 times higher than this calculated rate.

While the rate of propagation of macrosteps, both on pyramidal faces and on smooth substrate, increases with current density, the rate at which pyramidal bases advance laterally was found independent of the current density. The constant rate is not due to local exhaustion of cations which would result in local limiting currents being set up in the neighborhood of the growing pyramids (or steps). Thus, to a first approximation the (local) limiting current should be proportional to the bulk concentration of copper sulfate, c_o, as

$$i_{lim} = K c_o$$

If the rates of growth are limited by diffusion in the solution, they should change with the concentration. When the concentration was changed by factor 20, no change in the rates was observed.

The amount of the deposited metal required for the pyramid formation on the (111) plane can be calculated from the size of pyramids and their density. Thus, in a typical case, the height of pyramids at 10 coulomb/cm² is determined by polarized interferometry at 1.25 x 10⁴Å. The length of a pyramid base was 1.5 x 10⁵Å, and the density of pyramids about 3 x 10⁵ cm^{-2}. The volume of all pyramids at the time of deposition corresponding to 10 coulomb/cm² is then about 2 x 10^{-5} cm³/cm². This volume corresponds to about 6% of the total deposited metal.[11] Thus, to account for all the metal deposited, it has to be assumed that incorporation of Cu-adions occurs also over the flat substrate. This implies that, while a pyramid grows, it is at the same time "buried" by evenly advancing substrate. Consequently, the true rate of growth is not measured (cf. Fig. 18). From Fig. 18, it follows that

$$x = x_o + h \cot \alpha \quad [40]$$

where $h = vt$, and α is the inclination of the pyramidal face toward the substrate. Then, the true rate of growth is given by

$$v_{pyr} = dx/dt = dx_o/dt + v \cot \alpha = v_o + v \cot \alpha \quad [41]$$

where v_o is the observed rate of pyramid propagation. With numerical values for 5 ma/cm² (Table I), v_{pyr} is equal to

$$v_{pyr} = 55 + 18.7 \times 5 = 148.5 \text{ Å/sec}^{-1}$$

This rate is close to the observed rate (135 ± 15 Å/sec) of macrostep propagation on the pyramidal faces. Under ideal conditions therefore the rate at which macrosteps on pyramidal faces propagate is the rate at which the base of the pyramid would propagate were it not for the simultaneous "burying." The latter rates are thus close to the rate with which most of the macrosteps on "smooth" substrate propagate.

At a constant current density, potential changes with time and hence the (relative) rate of deposition and of incorporation of adions[12] into the lattice at the newly formed faces of macrosteps should change with time or thickness of the deposit, contrary to the reported observation of constant (with time) rate of macrostep propagation. The main change in the potential occurs, however, at the initial stage of deposition, while the rate of macrostep propagation was determined for the latter stages of deposition when potential becomes constant.

[11] At initial stages of deposition, the percentage has to be less, as the area of the "flat" substrate is initially larger and decreases with time of deposition. In this particular case, the electrode becomes almost fully covered by pyramids at 10 coulomb/cm².

[12] The effect of the delivery of adions to growth sites by surface diffusion is neglected.

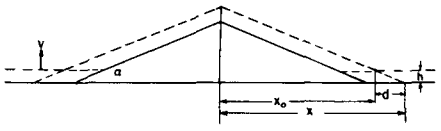

Fig. 18. A model for pyramid growth.

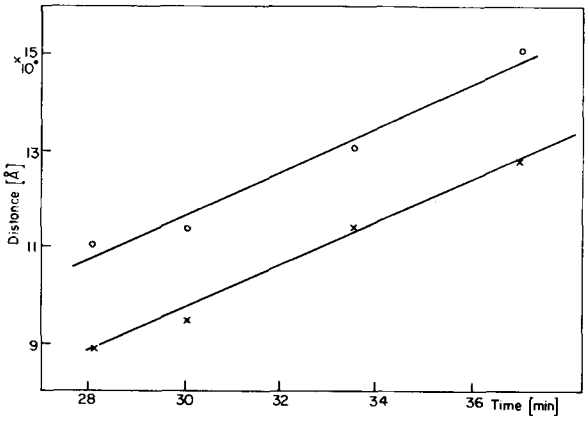

Fig. 19. Position of two macrosteps on a pyramidal face vs. time of deposition, 2 ma/cm^2.

The Mechanism of the Growth of Pyramids

The formation of pyramids on the (111) plane can be accounted for by the screw dislocation mechanism of growth. The appearance of a straight line on the apex of some pyramids instead of "sharp" point favors the mechanism involving a pair of screw dislocations of opposite signs. Macrosteps on side faces of pyramids form by initial bunching of small, ideally monatomic steps which originate at the apex of the pyramid. In support of the bunching mechanism is the fact that close to the apex of pyramids no visible steps appear [cf. ref. (1), (29), and (30)].

Formation of "hexagonal" blocks on the (111) deposits at higher current densities corresponds to the formation of cubic blocks (or layers) on the (100) plane, the mechanism for both of which has already been discussed (1, 8, 11). First, regular pyramids form, the apex of which may become in time blocked by adsorbed impurities. New microsteps then will spread no longer from the apex, and the pyramid truncates. Truncated pyramids gradually transform into blocks.

On the (110) plane, pyramidal growth under the given experimental conditions rarely occurs, and ridges and/or "smooth" deposits form. It is likely that on an ideal (110) plane any site is a growth site. There is no need for surface diffusion of adions and of propagation of microsteps. For pyramidal growth, propagation of microsteps is essential, and consequently no pyramids would be expected to form on the (110) planes. For an understanding of ridge formation, particularly of different current densities, further detailed analysis of the geometry of ridges is required.

Acknowledgments

The authors are indebted to the American Electroplaters' Society for the continued support of this work. They also wish to acknowledge the help they have derived from numerous discussions of results and theory in this field with Mr. E. R. Bowerman, Dr. O. Kardos, Dr. J. Kruger, Dr. J. V. Petrocelli, Dr. D. R. Turner, and Dr. R. Weil.

Thanks are also due to Mr. M. Paunovic for making available some of his experimental data on the (100) plane, and to Mr. G. Razumney for help in some of the measurements, for valuable discussions of some aspects of this work. Thanks are also due to Mr. O. Shannon for machining the cell, and to Mr. T. Dawson for glassblowing.

Manuscript received April 19, 1965; revised manuscript received Jan 29, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Electrodeposited Ni-Fe-As Magnetic Thin Films

W. O. Freitag, G. DiGuilio, and J. S. Mathias

UNIVAC Division, Sperry Rand Corporation, Blue Bell, Pennsylvania

ABSTRACT

Thin films (1000-2000Å) containing 6-20% Fe, 1-15% As, balance Ni were electrodeposited from mixed nickel-ferrous sulfate solutions containing sodium arsenite. Arsenite concentration and ferrous sulfate concentration in the solution were related to the film composition and the magnetic properties. The effects of As in Ni-Fe films was found to be similar to those of P, *i.e.*, H_c and H_k values were lower and switching times were much more rapid in the ternary films than in similarly prepared binary films. Quarternary alloy films of Ni-Fe-As-P are also described.

This work is an outgrowth of earlier studies on the Ni-Fe-P and Ni-Fe-Mo film alloy systems which have already been reported (1,2). Electrodeposited thin films in the alloy system Ni-Fe-As have been investigated and evaluated as magnetic elements for computer memory use, and results are described. A limited amount of work in the quarternary system Ni-Fe-As-P is also discussed.

The objective of the over-all program has been the development of the electrodeposition method for preparation of films having controllable and reproducible magnetic properties.

Experimental

The substrates were 3 by 3 in. microcover sheet, 0.002-0.010 in. thick, coated with vacuum-evaporated layers of chromium and gold. Corning 7059 glass, 1 by 2 by 0.032 in. was also used. The depositions were carried out in rectangular Lucite cells which were fitted with removable cathode holders, permitting accurate alignment of the cathode to the cell. A uniform magnetic field of 30 oe surrounded the cell. Anodes were of nickel sheet. No agitation was used. The current density was normally 6 ma/cm^2 delivered by a constant-current power supply. The films were electrodeposited at room temperature from nickel and ferrous sulfate solutions of the Watts type, containing boric acid, sodium chloride, saccharin, and sodium lauryl sulfate.

The compositions of the electrolytes are shown in Table I. Arsenic was introduced as sodium arsenite. Two series of solutions were made up. In one, the sodium arsenite concentration was varied, and in the other, the ferrous sulfate concentration was varied.

Films were chemically analyzed as follows: A known film area is dissolved in 1:2 HNO_3 and diluted to volume. Arsenic is determined on one aliquot colorimetrically by the molybdenum-blue method after low-temperature evaporation of HNO_3. Spectrophotometric measurements at 820 mμ were made on a Beckman DU. The method was calibrated with standard solutions in the range from 0.006 to 0.3 mg/100 cc. Dissolved film samples 1 by 2 in. in area, containing about 5% As, commonly gave readings in the 0.04 mg/100 cc range. Accuracy in the 5% As range is believed to be ±0.5%.

Nickel and iron are determined on other aliquots colorimetrically as nickel dimethylglyoxime and iron orthophenanthroline. These are also spectrophotometric measurements and are believed to be accurate to within 0.5%. A nickel/iron ratio calculated from these determinations is accurate to within 3%.

The magnetic properties were measured in a 60-cycle BH loop tracer (1) the drive field of which was oriented parallel to the horizontal component of the earth's field. The sample could be placed into the sense coil either parallel to the easy axis for measurement of H_c, or perpendicular for H_k. Relative magnetostriction values were obtained from the change in H_k when tension was applied along the hard axis by flexing the sample into a fixed arc. Magnetic measurements are believed accurate to ±5% or better.

Table I. Composition of plating solutions for the deposition of Ni-Fe-As alloy thin films

Component	Composition of Plating Solutions Concentration, (g/l) Series N solutions	Series P solutions	Preferred
$NiSO_4 \cdot 6H_2O$	218	218	218
$FeSO_4 \cdot 7H_2O$	3.0-8.1	6.0	6.0
$NaAsO_2$	0.4	0.05-1.5	0.4
H_3BO_3	25.0	25.0	25.0

Film Composition as a Function of Electrolyte Composition

Figures 1 through 6 show the effects of variation of the electrolyte composition on the composition of the electrodeposited films. Figure 1 shows the linear increase in arsenic content with increase in sodium arsenite concentration. This was done with the series-P solutions, where the Ni and Fe concentrations were held constant, as was the deposition time. The range studied was from 0.05 to 1.5 g/l arsenite. We did not go higher because the magnetic properties were poor at 1.0 g/l and the deposits appeared streaked and discolored at 1.5 g/l. Figure 2 shows the effect of arsenite concentration on the Ni/Fe ratio in the film. This ratio increases as arsenite concentration increases, although this is not too obvious in view of the scatter of experimental points. The films were plated for 70 sec and had a thickness of 1300Å. Two other sets of films were plated at the same time from these solutions at

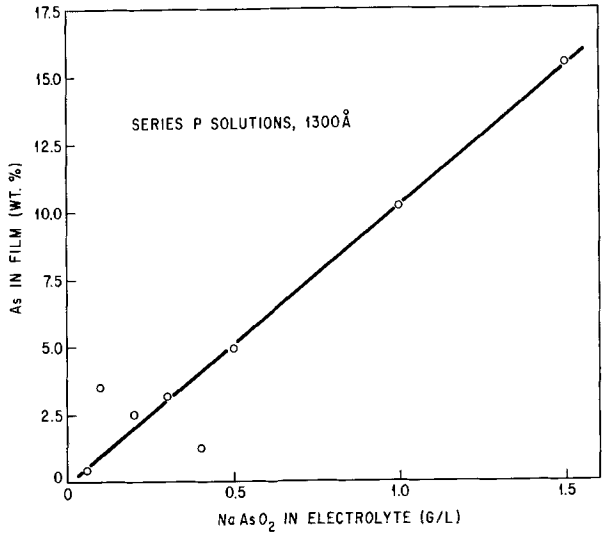

Fig. 1. Arsenic content of 1300Å films as a function of sodium concentration in the electrolyte. Deposition time was 70 sec at 6 ma/cm^2.

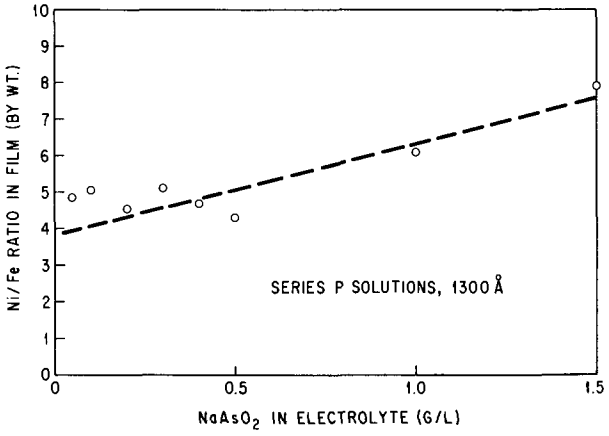

Fig. 2. Nickel and iron content of 1300Å films as a function of sodium arsenite concentration in the electrolyte. The nickel and iron content of the electrolyte was held constant. Deposition time was 70 sec at 6 ma/cm^2.

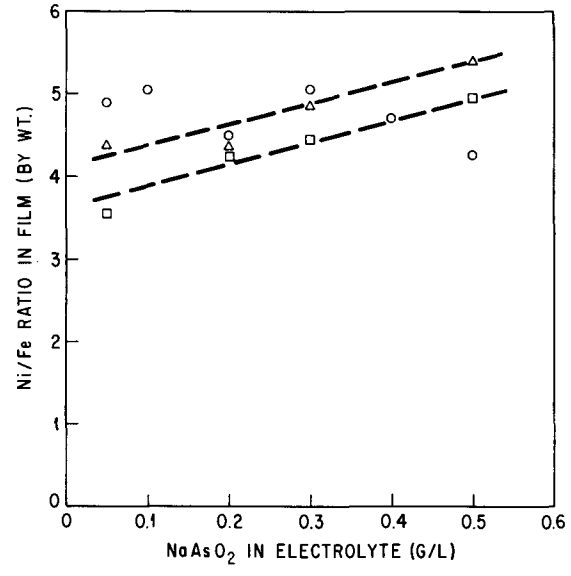

Fig. 3. Nickel and iron content of 1100 and 1500Å films as a function of sodium arsenite concentration in the electrolyte. Plated under the same conditions as in Fig. 4, but for 60 and 80 sec, respectively. Series P solutions: △, 1500Å; ○, 1300Å repeated from Fig. 2; □, 1100Å.

60 and 80 sec, with thicknesses of about 1100 and 1500 Å, respectively. The analyses of these films are shown in Fig. 3, and the upward trend in Ni/Fe ratio is clear. The slope of these lines is about the same as the slope in Fig. 2. Thus the presence of arsenite ion in this system depresses the relative deposition rate of iron, just as hypophosphite ion does in the Ni-Fe-P system (1).

Figure 4 shows the effect of ferrous sulfate concentration on the iron content of the film. These films were deposited for 70 sec at 6 ma/cm^2, from a solution containing a constant 0.4 g/l sodium arsenite. As expected, the iron increases with increasing ferrous ion concentration. The arsenic content of these films is essentially constant; the change in iron concentration, therefore, has no effect on the deposition rate of arsenic.

The compositional variations that occur during the first few seconds of alloy deposition have been studied for nickel-iron by Cockett and Spencer-Timms (3), by Hemstock and Spencer-Timms (4), and by Dahms and Croll (5). The addition of hypophosphite ion reduces but does not eliminate the compositional gradient (1). A similar gradient occurs with Ni-Fe-Mo (2). Figure 5 shows iron content, arsenic content, and

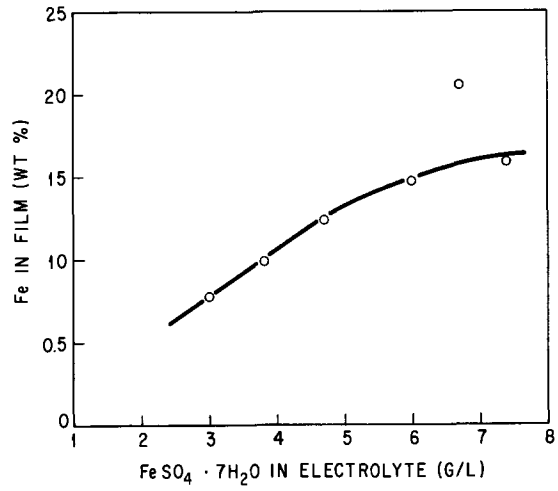

Fig. 4. Iron content in 1300Å films as a function of ferrous ion content in the electrolyte. Arsenite concentration was held constant. Series N solutions: $NaAsO_2$ = 0.4 g/l; plating time 70 sec; c.d. 6 ma/cm^2.

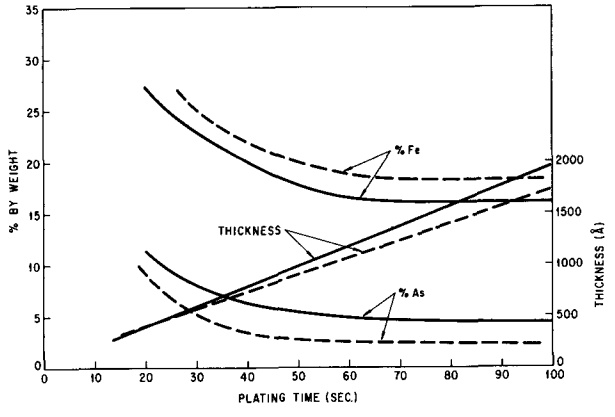

Fig. 5. Effect of plating time on the composition and thickness of Ni-Fe-As films. Series P solutions: c.d. 6.0 ma/cm^2; - - - 0.2 g/l $NaAsO_2$; —— 0.4 g/l $NaAsO_2$.

thickness *vs.* plating time for two levels of sodium arsenite concentration in the Ni-Fe-As system. The decrease in iron as deposition proceeds is apparent. The arsenic content also decreases with plating time. At a higher arsenic concentration the iron content is depressed further. The plating time *vs.* thickness curves have slightly different slopes, with the higher arsenic concentration giving slightly thicker films. This suggests a small increase in current efficiency, with increasing arsenite concentration.

The effect of current density on the film properties is shown in Fig. 6. As current density increases, the relative amount of arsenic occurring in the film decreases. This is what one would expect; since the arsenic is present in low concentrations, arsenic deposition should be diffusion-limited. The Ni/Fe ratio increases as current density increases. This agrees with the current density effects found by Hemstock and Spencer-Timms (4) and by Uehara (6) for Ni-Fe films. The same is true in the Ni-Fe-Mo system (2). The anisotropy of these films passes through a minimum as determined by the Ni/Fe ratio. As we shall see later, there is a minimum in the H_k *vs.* Ni/Fe ratio curve. The variation in H_k with current density can thus be simply explained solely on the basis of compositional changes.

Magnetic Properties as a Function of Electrolyte Composition

Figure 7 shows the effect of the arsenite concentration on the coercivity of films in three thicknesses. The

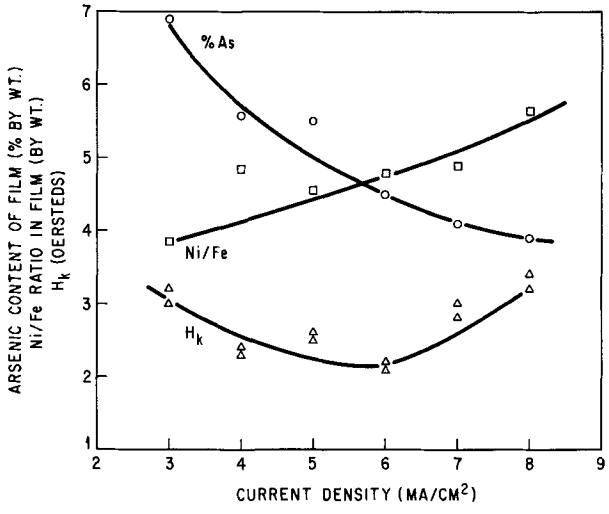

Fig. 6. Effect of current density on the composition and anisotropy field of 1600Å Ni-Fe-As films. Series P solutions: 0.4 g/l $NaAsO_2$.

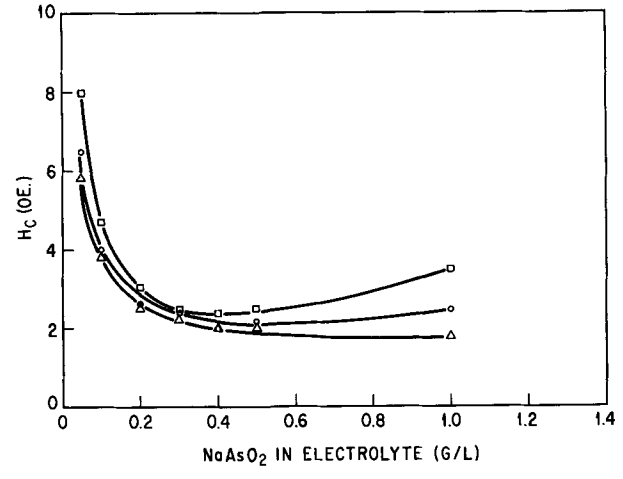

Fig. 7. Coercivity of Ni-Fe-As films deposited from solutions with varying amounts of sodium arsenite. Series P solutions: 6 ma/cm^2; □, 1100Å; ○, 1300Å, △, 1500Å.

addition of arsenic lowers H_c considerably. These films all have Ni/Fe ratios of 4 to 5, and the decrease in H_c brought about by the arsenic is quite clear. It is interesting to note that there appears to be a minimum in H_c which occurs at 0.4 to 0.5 g/l arsenite in the 1300Å films. In Fig. 1, it was shown that at this arsenite level the film contained about 5% As. This corresponds roughly to the solid solubility of As in Ni, which is given by Hansen (7) as 5.5%. Perhaps, at As concentrations above approximately 5%, a second phase appears which begins to raise H_c by interfering with domain wall motion. This is conjecture only, and no attempt at identification of a second phase was made, but the idea is supported by the behavior of the thinner and thicker films. If it is recalled that thinner films from a given solution contain more arsenic (and more iron) than thicker films, it will be expected that the 5% As level will be reached at a slightly lower arsenite concentration, and that the minimum will shift slightly to the left, which indeed it does.

Figure 8 shows the effect of sodium arsenite addition on the anisotropy of the films. Again, H_k values are lower than when As is absent. The Ni/Fe ratio of the deposit increases as sodium arsenite is increased; also, the Ni/Fe ratio increases slightly for increase in thickness, so that As concentration is not the only variable. The same considerations hold for Fig. 9, which shows the change in magnetostriction as As is added.

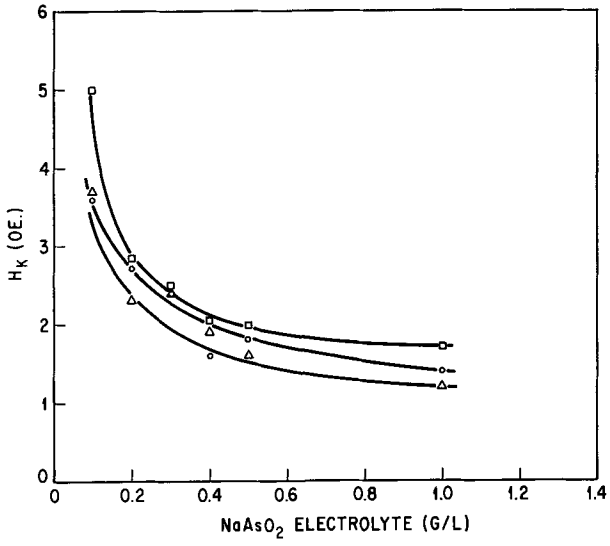

Fig. 8. Anisotropy of Ni-Fe-As films deposited from solutions containing varying amounts of sodium arsenite. Series P solutions: 6 ma/cm^2; □, 1100Å; ○, 1300Å; △, 1500Å.

The magnetostriction units are arbitrary and represent the change in H_k when the sample is placed under tension. These values are positive for nickel-rich composition.

In addition to lowering H_c and H_k of Ni-Fe films, the presence of arsenic also results in greatly improved switching times as shown in Table II which lists switching coefficients for arsenic films. Some further improvements were obtained when the films were subjected to a very mild annealing step. In general,

however, the films were not annealed, and all data reported in this work refer to unannealed films as deposited.

The effect of varying the ferrous sulfate concentration is shown in Fig. 10; H_k passes through a minimum with increasing iron concentration. As film thickness is increased and the relative deposition rate of iron is decreased, it takes more and more Fe in the plating solution to produce the film composition having the minimum H_k value. Higher positive values of ΔH_k indicate nickel-rich compositions. Minimum H_k values do not coincide with the zero magnetostrictive compositions.

In Fig. 11, anisotropy and magnetostriction are plotted as a function of film composition, using the limited amount of analytical data available. Only films that had arsenic contents of 4-5% were selected. A wide range of thicknesses are represented, 500-2000Å, but the majority of the points are in the 1300Å region. The points were differentiated with respect to the two solutions used in their preparation to show the essential reproducibility of this plating system.

A minimum in H_k has been observed in both electroplated and evaporated Ni-Fe films. Wolf (8) reported the minimum at 80-88% Ni in electrodeposited films. The occurrence of this minimum in evaporated films has been attributed to a stress mechanism whereby differences in thermal expansion between film and substrate operate magnetostrictively. These arguments have been discussed by Robinson (9) who studied films evaporated on soda lime glass at 240°C. With respect to films electrodeposited at room temperature, thermal expansion can certainly not be the origin of any stress anisotropy, yet it seems clear that some stress mechanism must be operating. The role of stress relievers has been studied by Wolf (10), who showed the effects of the presence of various stress-relieving agents in the plating bath on H_k of 82% Ni films, but did not study this as a function of alloy composition. It is interesting to note that the addition of Mo to Ni-Fe films sharpens the minimum (2) as well as lowers it.

In Fig. 12, variations in magnetostriction are plotted as a function of plating time and arsenite concentration. In the left-hand side of the figure it is seen that as plating time increases (and the alloy becomes more nickel-rich) higher positive values of ΔH_k are obtained, as expected, at the arsenite concentrations we have been considering up to now. At high arsenite concentrations, the reverse appears to be true. Unfortunately, analyses are not available for these films, so it is not clear whether the Ni-Fe concentration trend is reversed in the high As films, or whether the high arsenic concentration itself is having a dominating effect on magnetostriction. The very high arsenic films were not investigated further, since they were less interesting for our purposes than the 0.4 g/l films.

Effect of Hypophosphite Addition

On the right-hand side of Fig. 12 is a similar set of curves obtained from these same solutions under the same conditions, except that sodium hypophosphite has been added. A well-behaved set of trend lines is obtained, but again the high arsenic films give anomalous results. In general, the effects of adding arsenic to Ni-Fe films are quite similar to the effects of adding phosphorus. Present together, their effects, qualitatively speaking, are additive; that is, H_c and H_k are lowered and rapid switching times are obtained.

The Ni-Fe-As-P composition was not explored in any detail, partly because of analytical difficulties. In

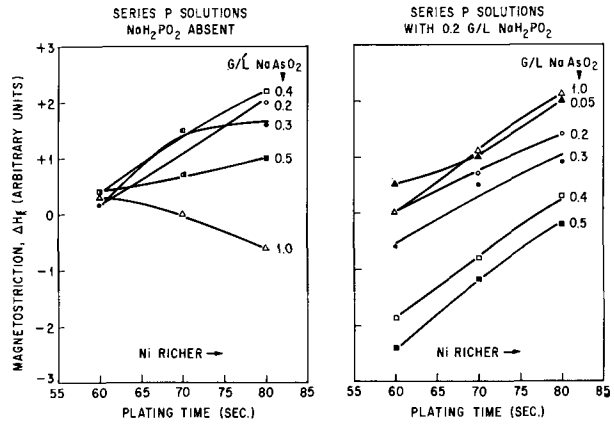

Fig. 12. Left, relative magnetostriction for Ni-Fe-As films as a function of plating time and sodium arsenite concentration. Right, same for Ni-Fe-As-P films obtained from the same solutions after addition of sodium hypophosphite.

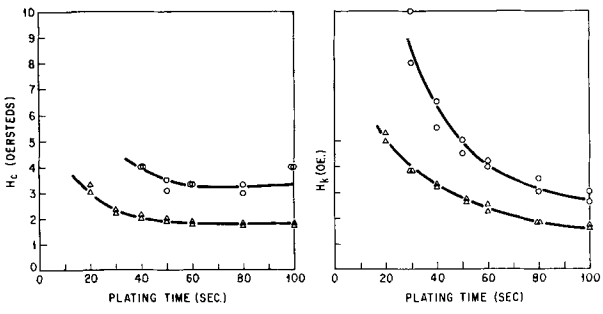

Fig. 13. Effect of substrate surface on coercivity and anisotropy. Series P solutions: 6 ma/cm^2, 0.2 g/l $NaAsO_2$; ○, Cr-Au evaporated on glass; △, electrodeposited Cu on Cr-Au evaporated on glass.

the 5% arsenic films, zero magnetostriction was associated with an anisotropy of about 2.5 oe.

A solution containing 6 g/l ferrous sulfate, 0.4 g/l arsenite, and 0.2 g/l hypophosphite yielded zero, or near zero, magnetostrictive films with H_k of 1.6-1.8 oe and H_c of 1.9-2.5 oe, with a high degree of reproducibility. The composition of these films was about 83% Ni, 13% Fe, 2% As, and 2% P.

Effect of Substrate

In all this work, the substrates were evaporated Cr-Au layers on glass. Substrates must be prepared uniformly with a high degree of quality control, in order for a study of this sort to have meaning. The magnetic properties are, of course, functions of film thickness and composition, and the magnetic properties can be controlled by controlling the deposition parameters which affect composition. But this is practical only if a reproducible substrate is available. This is illustrated in Fig. 13, in which H_c and H_k values are compared for two sets of films, deposited from the same solution under identical conditions, except for the use in one case of Corning 7059 glass with evaporated Cr-Au layers, and in the other case of the same substrates having, in addition to the Cr-Au, an electrodeposited layer of copper. Striking differences in magnetic properties are found, and the copper surface is seen to have an even more reproducible surface than the Cr-Au. The effect of substrate material and substrate preparation procedures on magnetic properties has long been recognized by workers preparing films by vacuum evaporation or sputtering, but this point has not been emphasized in the electrodeposition literature.

Conclusion

It has been shown here that the addition of sodium arsenite to Ni-Fe sulfate solutions of the Watts type leads to the deposition of Ni-Fe-As alloy thin films with magnetic properties superior to those obtained with binary Ni-Fe films; that is, H_c and H_k are lower, and switching times are very fast.

The magnetic properties can be controlled by manipulating the electrolyte composition and plating parameters in a manner analogous to those applied to the Ni-Fe-P system. We have shown that even further improvements may be expected in the quarternary system Ni-Fe-As-P.

Some Aspects of Sensitized Fluorescence in $Ca(PO_3)_2$:Sn:Mn Glass Phosphors

Richard F. Reade

Research and Development Laboratory, Corning Glass Works, Corning, New York

ABSTRACT

Sensitized fluorescence in $Ca(PO_3)_2$:Sn:Mn glass phosphors occurs via a direct transfer of excitation energy from tin to manganese centers. The transfer process is described in terms of its efficiency and the fraction of tin centers which participate. A statistical model for energy transfer is developed on the basis of a random distribution of tin and manganese ions and is shown to be consistent with the experimental data. The effective transfer range of approximately 8.8Å encompasses about 33 cation sites surrounding a tin center.

The phenomenon of sensitized fluorescence in impurity activated crystalline phosphors has been the subject of a considerable body of theoretical and experimental investigation. Klick and Schulman (1) have reviewed this work. Sensitized fluorescence involves two centers or ions, the sensitizer and the activator. The activator ion provides an emission band in a desired spectral region but does not absorb radiation in the excitation range of interest; frequently the 2537Å resonance line of a low-pressure mercury discharge lamp. The sensitizer ion introduces an absorption band in the required excitation range, and if present alone, will fluoresce with its characteristic emission spectrum. When both sensitizer and activator ions are present in a coactivated phosphor, the sensitizer will transfer part of its absorbed energy to the activator causing a fluorescence which is characteristic of the latter. The total fluorescence spectrum of the coactivated phosphor is thus a composite of the emissions of both ions, whose relative intensities are

dependent on the respective ion concentrations.

This paper describes a series of fluorescence intensity measurements designed to clarify the roles of tin and manganese in the energy transfer process leading to sensitized fluorescence in $Ca(PO_3)_2$:Sn:Mn glass phosphors. A statistical model for energy transfer is applied to the data.

Experimental

CaO and P_2O_5 were introduced as reagent grade monobasic calcium phosphate. The fluorescent ions were introduced as reagent grade oxides or carbonates. Reagent grade dextrose was used as a reductant to maintain tin and manganese in their divalent states. The well-mixed batches were melted at 1200°C using a platinum-wound resistance furnace, and annealed at 500°C. A portion of each sample was powdered to pass through a 100 mesh screen.

The fluorescence characteristics of the powdered samples were measured with a powder plaque fluorometer developed in this laboratory. In using this device, a planchet containing the powdered glass was placed under a circular, low pressure mercury discharge lamp. The lamp emission was filtered so that the 2537Å line was predominant. The fluorescence emission from the powdered glass was passed successively through blue, green, and red filters, detected by a photocell and measured by a galvanometer. The galvanometer shunt resistors were adjusted so that the reading obtained with each filter-photocell combination was directly proportional to the fluorescence intensity in the corresponding spectral region. In this manner equal blue, green, and red readings would be obtained for a phosphor which had a uniform spectral distribution of intensity. A magnesium tungstate phosphor was used as a calibration standard.

Fluorescence measurements.—The following quantities were determined experimentally or derived from experimental data.

I_{Sn} = Fluorescence intensity of a singly activated Sn glass.

$I_{Sn:Mn}$ = Total fluorescence intensity of a Sn:Mn coactivated glass.

I'_{Sn} = Tin component of fluorescence intensity in a Sn:Mn coactivated glass.

I'_{Mn} = Manganese component of fluorescence intensity in a Sn:Mn coactivated glass.

I_{Sn} and $I_{Sn:Mn}$ were obtained directly by summing the blue, green, and red readings from the powder fluorometer. I'_{Sn} and I'_{Mn} were obtained by summing the resolved tin and manganese readings for the coactivated glasses.

Resolution was accomplished by assuming that the spectral distribution of either ion, hence its distribution in the blue, green, and red regions of the spectrum was unaffected by the presence of the other ion. This assumption has been found valid for many crystalline phosphors (1, 2). Its validity in the present case was demonstrated by the fact that the ratio of the green to red readings for the resolved manganese intensity component was constant among all the coactivated glasses studied. To confirm the validity of these measurements, comparative fluorescence and excitation spectra were taken on an Aminco-Bowman Spectrofluorometer. Since the spectra were not corrected for instrument parameters, only qualitative results will be given.

It was found that the divalent manganese ion is inefficiently excited by radiation below 320 mμ. The feeble manganese fluorescence caused by 2537Å excitation of $Ca(PO_3)_2$:Mn glasses was too weak to be detected by the powder fluorometer. The manganese excitation spectrum of the coactivated, $Ca(PO_3)_2$:Sn:Mn glasses exhibited an additional, strong excitation band below 320 mμ which was associated with the Sn^{++} ion. The appearance of this band indicated that energy absorbed by the Sn^{++} centers is transferred to Mn^{++} ions causing them to fluoresce. In all other respects, the shape and position of the fluorescence or excitation bands for either ion were the same in both singly and coactivated glasses. Only the relative intensities varied. The presence of the characteristic tin fluorescence in the coactivated glasses showed that not all the tin centers participate in the energy transfer process. The tin excitation spectrum in the coactivated glasses exhibited no bands associated with manganese, indicating that Mn → Sn energy transfer does not occur.

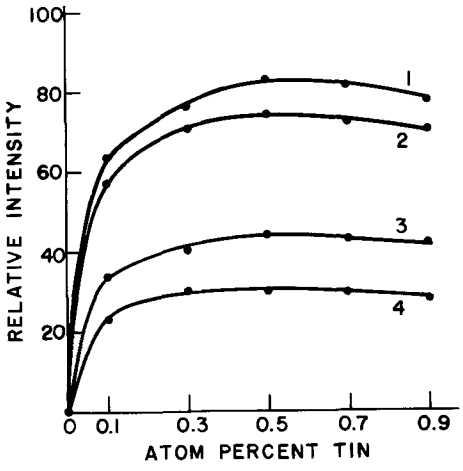

Fig. 1. Fluorescence intensity vs. tin concentration: curve 1, I_{Sn}: total intensity of Sn activated glasses; curve 2, $I_{Sn:Mn}$: total intensity of Sn:Mn coactivated glasses; curve 3, I'_{Mn}: Mn intensity component of Sn:Mn coactivated glasses; curve 4, I'_{Sn}: Sn intensity component of Sn:Mn coactivated glasses.

Results

Coactivated glasses with Mn *constant.*—Plots of fluorescence intensity *vs.* tin concentration for the tin activated glasses and for the Sn:Mn coactivated glasses with manganese held constant at 0.5 a/o (atom per cent) are shown in Fig. 1. The resolved tin and manganese intensity components of the coactivated glasses are also shown. The intensity maximum for the singly activated glasses occurs at a tin concentration of 0.5 a/o. The decrease in fluorescence intensity above this tin level may be caused by concentration quenching in the tin centers. This self-quenching effect has been attributed by Johnson and Williams (3) to the presence of a nonfluorescent center formed by two closely associated fluorescent ions. As the tin concentration increases, the number of these self-quenching, closely associated centers should increase, thereby lowering the fluorescence intensity.

The total intensity of the coactivated Sn:Mn glasses is consistently lower than that for the tin activated glasses, but the intensity maximum also occurs at about 0.5 a/o tin. The correspondence of these maxima indicates that tin self-quenching may be responsible for the intensity decrease in both Sn:Mn and Sn activated glasses.

The lower over-all intensity of the coactivated glasses is not surprising since an absorption and emission process within an isolated Sn^{++} ion is apt to be more efficient than one which involves the transfer of excitation energy between a tin and a manganese center (4). The energy transfer process should increase the probability for nonradiative energy losses accompanied by a decrease in the over-all fluorescence efficiency.

Variations in the tin concentration of the coactivated glasses did not alter the spectral distribution and color (pink) of the composite Sn:Mn fluorescence; only the intensity varied. $I_{Sn:Mn}$, I'_{Sn}, and I'_{Mn} vary similarly with tin concentration denoting a constant I'_{Sn}/I'_{Mn} ratio, and hence a constant fluorescence color. Since the spectral distribution of either ion is independent of the presence of the other, only their relative intensities determine the fluorescence color.

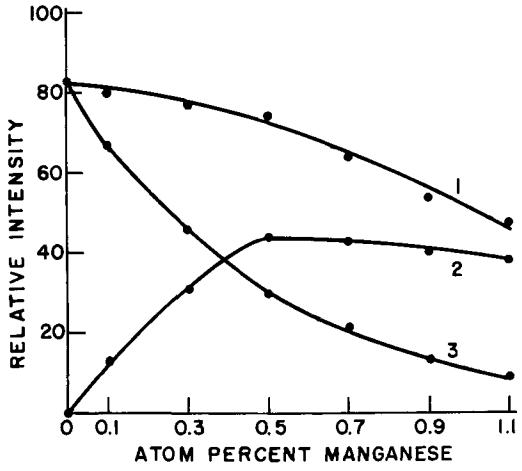

Fig. 2. Fluorescence intensity *vs.* manganese concentration: curve 1, $I_{Sn:Mn}$: total intensity of Sn:Mn coactivated glasses; curve 2, I'_{Mn}: Mn intensity component of Sn:Mn coactivated glasses; curve 3, I'_{Sn}: Sn intensity component of Sn:Mn coactivated glasses.

Coactivated glasses with Sn *constant.*—If tin is held constant while the manganese concentration is varied, a different situation presents itself. Figure 2 shows the variation in $I_{Sn:Mn}$, I'_{Sn}, and I'_{Mn} *vs.* manganese concentration in glasses with tin at 0.5 a/o. An increase in the manganese concentration causes both a decrease in $I_{Sn:Mn}$ and a change in the spectral distribution and color of fluorescence (I'_{Sn}/I'_{Mn} varies). The fluorescence color varied from blue in the manganese-free glass, through white at intermediate manganese levels, to orange in the high manganese glasses. Increasing manganese causes a sharp reduction in I'_{Sn} and an increase in I'_{Mn} up to 0.5 a/o manganese. As the manganese concentration increases, the probability for energy transfer and sensitized manganese fluorescence increases, thereby lowering the intensity of the characteristic tin fluorescence. Although I'_{Sn} continues to decrease above 0.5 a/o manganese, denoting even more concerted energy transfer, I'_{Mn} also decreases. This effect suggests the onset of a significant manganese self-quenching process similar to that previously described for the tin centers. Support for this view was found from the fact that the fluorescence of $Ca(PO_3)_2$:Mn glasses excited by 365 mμ radiation exhibits an intensity maximum at about 0.5 a/o manganese.

The energy transfer process.—The results of the fluorescence intensity measurements indicated that energy transfer in the coactivated Sn:Mn glasses proceeds from tin to manganese centers with some loss of efficiency due to nonradiative processes. The extent to which the energy undergoing transfer is utilized in the sensitization of manganese centers may be estimated from a comparison of the fluorescence intensity of the tin glasses with the resolved intensity components of the coactivated glasses having the same tin concentration. The following quantities will be used to describe the energy transfer process.

$I_{Sn} - I'_{Sn}$ = The decrease in tin fluorescence intensity caused by the presence of manganese where the tin concentration is the same in both singly and coactivated glasses. This decrease is a measure of the energy undergoing transfer between tin and manganese centers.

$\frac{I'_{Mn}}{I_{Sn} - I'_{Sn}} = E$, the efficiency of the energy transfer process. E gives the ratio of the activator (manganese) intensity to the corresponding loss of sensitizer (tin) intensity caused by energy transfer.

$\frac{I_{Sn} - I'_{Sn}}{I_{Sn}} = F_s$, the fraction of available or active tin luminescent centers undergoing energy transfer.

Table I. Energy transfer in $Ca(PO_3)_2$:Sn:Mn glasses

Sn, a/o	Mn, a/o	E, %	F_s, %
0.1	0.5	84	64
0.3	0.5	87	62
0.5	0.5	84	64
0.7	0.5	83	64
0.9	0.5	86	64
0.5	0.1	81	19
0.5	0.3	84	44
0.5	0.5	84	64
0.5	0.7	70	74
0.5	0.9	58	84
0.5	1.1	52	89

The equation for F_s is based on the proportionality between fluorescence intensity and the number of fluorescing centers. The ratio does not account for any tin species which do not normally fluoresce. It is based on the assumption that the total number of tin centers which fluoresce and experience energy transfer in a coactivated glass is equal to the number of tin centers which fluoresce in a singly activated glass having the same tin concentration.

Data are given in Table I. The calculated values of E are somewhat high since the ultraviolet component of the tin fluorescence could not be measured accurately and was not included in the calculations. Comparison with the magnesium tungstate standard indicated that the error in E caused by this omission was small. F_s is not affected.

When manganese is held constant at 0.5 a/o, the percentage of tin luminescent centers undergoing energy transfer and the efficiency of the transfer process are constants from 0.1 to 0.9 a/o tin. The calculated values are 64 and 85%, respectively. Conversely, when tin is held constant at 0.5 a/o, the percentage of tin centers undergoing transfer increases as the manganese concentration increases. The energy transfer efficiency is essentially constant up to 0.5 a/o manganese, but decreases at higher manganese concentrations. This apparent decrease is most probably a result of manganese self-quenching. Any decrease in I'_{Mn} caused by self-quenching would give an erroneously low value for E.

These results suggest that, within the concentration ranges of sensitizer and activator studied, a given tin concentration serves only to provide a certain number of active Sn^{++} centers capable of absorbing and emitting energy. The manganese concentration determines what percentage of these active tin centers will undergo energy transfer and, consequently, what percentage will emit the characteristic tin fluorescence. Although $I_{Sn:Mn}$, I'_{Sn}, and I'_{Mn} decrease uniformly above 0.5 a/o tin, F_s and E remain constant. Only the absolute number of active Sn^{++} centers decreases; in agreement with the idea of tin self-quenching discussed earlier.

The fact that the energy transfer efficiency is constant over the ranges 0.1 to 0.9 a/o tin and 0.1 to 0.5 a/o manganese indicates that a single energy transfer mechanism is operative. The high measured efficiency for this process, about 85%, suggests that a direct Sn → Mn energy transfer is occurring. No evidence was found for the existence of a significant energy transport mechanism involving sensitizer-sensitizer interactions of the type discussed by Botden (5).

Statistical model for sensitized fluorescence.—The experimental results indicate that the over-all efficiency of sensitized fluorescence in the coactivated glasses is a function of (*i*) the intrinsic efficiency, E, of the Sn → Mn energy transfer process itself, and (*ii*) the fraction of tin centers, F_s, that participate in this process. Direct energy transfer from sensitizer, S, to activator, A, should occur if a given S center has at least one A ion within some effective sensitizing distance, r_s. If there is no A within this distance, S will fluoresce with its characteristic emission spec-

trum. An effective sensitizing volume, $V_s = 4/3\ \pi r^3_s$, is associated with r_s. Only active S centers which fluoresce or experience energy transfer are considered; the two alternatives being taken as mutually exclusive. If the S and A centers are randomly distributed throughout the glass, there is a calculable probability that an A will be found in V_s. F_s is taken to be directly proportional to this probability. A standard derivation for the probability of no successes in n mutually exclusive (Bernouilli) trials (6) gives the distribution equation

$$F_s = (1 - F_f) = 1 - (1 - c/\rho)^{V_s\rho} \quad [1]$$

F_s is the fraction of S centers that experience energy transfer, F_f the fraction of S centers that fluoresce, c the manganese concentration, ions/cc, ρ the density of cation sites in the glass, sites/cc, and V_s the effective sensitizing volume, cc.

Stroud (7) utilized this treatment to study positive hole trapping by cerium ions in glass. A similar equation was derived by Shulman *et al.* (8) and used by Botden (5) in studies of energy transfer in crystalline phosphors. In the present investigation $\rho \simeq 10^{22}$ sites/cc, $c < 10^{21}$ ions/cc; therefore $c/\rho < 1/10$ and Eq. [1] may be simplified to give

$$F_s = 1 - \exp(-V_s c) \quad [2]$$

V_s is a constant characteristic of a particular transfer mechanism and of the particular ions involved, but is independent of their concentrations. The energy transfer efficiency was found to be constant over a wide range of sensitizer and activator concentrations, indicating the presence of a single energy transfer mechanism. V_s must likewise be constant over the same concentration ranges to satisfy the imposed condition of randomness on the S and A distributions. The problem of demonstrating that the experimentally determined values of F_s are consistent with the statistical model becomes one of showing that V_s, calculated from Eq. [2], is a constant for all values of F_s and c. The values of V_s and r_s obtained from Eq. [2] are given in Table II along with the experimentally determined values of F_s, F_f, and E.

Equation [2] predicts immediately that V_s will be constant for glasses having the same manganese concentration, regardless of the tin concentration, so long as F_s remains constant. Of greater significance is the fact that V_s remains constant for glasses having the same tin concentration but with varying manganese concentrations. V_s thus fulfills the requirement of invariance imposed by the existence of a single energy transfer mechanism and the condition of randomness placed on the distributions of the tin and manganese ions. Sensitized fluorescence in the coactivated glass phosphors can be rationalized solely on the basis of a random distribution of fluorescent ions; no preferred orientation or pairing of ions need be invoked. In this respect, the $Ca(PO_3)_2$:Sn:Mn glass phosphors are similar to those crystalline phosphors, particularly the phosphates, wherein sensitized fluorescence and energy transfer have been generally explained on the basis of a random distribution of sensitizer and activator ions (2, 5, 8, 9). The use of successive approximations in Eq. [1] indicated that ρ for these glasses is about 1.2 x 10^{22} sites/cc. The number of cation sites around a tin ion which are within the effective sensitizing range of 8.8Å is then about 33, in agreement with values found in the literature for sensitized fluorescence involving the manganese ion (5, 8, 9).

Table II. Application of the statistical model

Concentrations a/o		Concentrations ions/cc × 10^{-20}						
Sn	Mn	Sn	Mn	F_s	F_f	V_s, cc × 10^{21}	r_s, A	E, %
0.1	0.5	0.7	3.6	0.64	0.36	2.8	8.8	84
0.3	0.5	2.2	3.6	0.62	0.38	2.7	8.6	87
0.5	0.5	3.6	3.6	0.64	0.36	2.8	8.8	84
0.7	0.5	5.0	3.6	0.64	0.36	2.8	8.8	83

0.5	0.5	3.6	3.6	0.64	0.36	2.8	8.8	84
0.5	0.7	3.6	5.1	0.74	0.26	2.6	8.5	70
0.5	0.9	3.6	6.5	0.84	0.16	2.8	8.8	58
0.5	1.1	3.6	8.0	0.89	0.11	2.8	8.8	52

The dependence of the normalized tin fluorescence intensity, I'_{Sn}/I_{Sn}, on the manganese concentration, c, is given by the equation

$$I'_{Sn}/I_{Sn} = F_f = \exp(-V_s c) \quad [3]$$

and is shown in Fig. 3. The tin concentration is 0.5 a/o. The agreement of the data with Eq. [3] justifies the earlier statement that the fluorescence intensity is proportional to the number of fluorescing centers. It also demonstrates that the comparison of the tin fluorescence intensity between singly activated and coactivated glasses introduces no difficulties into the application of the statistical model.

Although no experimental evidence was found for the existence of a significant energy transport mechanism involving one or more sensitizer-sensitizer transfers culminating in a sensitizer-activator transfer (5); the possibility exists that such a mechanism may become significant at lower manganese concentrations. In this respect it should be noted that the glass containing 0.5 a/o tin and 0.1 a/o manganese has $V_s = 3.0$ x 10^{-21} cc and $100E = 81\%$. These values are respectively higher and lower than the corresponding values found for the other glasses. Although such discrepancies are within experimental error, they vary from the norms in the manner predicted by the statistical model for a small contribution due to a longer range, less efficient energy transport mechanism.

Effect of quenching in A and S centers on energy transfer.—An examination of F_s, V_s, and E (Table II) for glasses having 0.5 a/o Sn and Mn > 0.5 a/o shows that as the manganese concentration increases above 0.5 a/o, F_s increases, E decreases, but V_s remains constant. It may be assumed that an increase in F_s requires that an increasing number of manganese centers be excited by energy transferred from the tin centers. If the decrease in E were indicative of the presence of some new, less efficient S → A transfer process, then it is likely that V_s would also vary with manganese concentration, since it is difficult to envision two different S-A transfer mechanisms having differing efficiencies but with the same V_s. The fact that V_s remains constant implies that the decrease in E is most likely the result of self-quenching in the manganese centers. As the manganese concentration increases, this quenching effect predominates over the energy transfer process with a resultant net de-

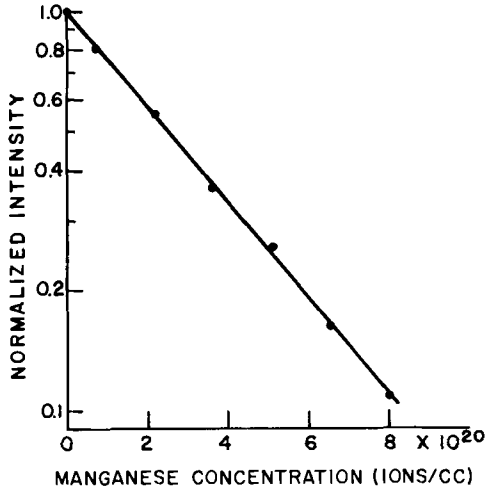

Fig. 3. Normalized tin fluorescence intensity, I'_{Sn}/I_{Sn}, vs. manganese concentration.

crease in the manganese fluorescence intensity, and an erroneously low value of $E = I'_{Mn}/(I_{Sn} - I'_{Sn})$.

The effect of tin self-quenching on the over-all efficiency of sensitized fluorescence can similarly be examined. In Fig. 1 it was shown that both I'_{Sn} and I'_{Mn} pass through a maximum at 0.5 a/o tin and then gradually decrease with increasing tin concentration. The data in Table II show that in the same glasses, F_s, V_s, and E remain constant. Tin self-quenching does not affect the range or efficiency of the S → A energy transfer process, nor does it affect the fractions of tin centers that fluoresce or undergo energy transfer. It does decrease the over-all efficiency of the sensitization process simply by reducing the number of active tin centers that are available for fluorescence or energy transfer.

Independent measurements of concentration quenching among the tin and manganese centers in the host glass would provide useful information on the manner in which S-S, A-A, and S-A interactions compete in coactivated phosphors, since it is unlikely that any one mechanism operates completely independently of the others.

Summary

Sensitized fluorescence in $Ca(PO_3)_2$:Sn:Mn glass phosphors occurs via a direct transfer of excitation energy from an excited tin center to a near-neighbor manganese ion. No other mechanism for energy transport appeared to be significant over the concentration ranges studied. The experimental results were rationalized on the basis of a random distribution of tin and manganese ions in the host glass; no preferred orientation or ion pairing was required to fit the data. The effective sensitization range for Sn → Mn transfer is approximately 8.8Å and encompasses a spherical distribution of about 33 cation sites around an excited tin center. The tin concentration determines the total number of tin centers available for either fluorescence or energy transfer. The manganese concentration determines what fraction of available tin centers will participate in either process. The fluorescence spectrum of either ion does not appear to be affected by the presence of the other. Hence the manganese concentration, by determining the relative fluorescence intensities of the two ions, determines the fluorescence color. The tin concentration places an upper limit on the total intensity which is then decreased somewhat by the efficiency of the transfer process. Concentration quenching in the tin or manganese centers does not appear to affect either the intrinsic efficiency or the sensitization range of the energy transfer process. Both quenching processes affect the over-all fluorescence intensity by decreasing the number of available fluorescent centers.

Emission Spectra of Impurity Activated (Zn,Cd)(S,Se,Te) Phosphors

I. Copper Activated Phosphors

W. Lehmann

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Copper produces two emission bands in all (Zn,Cd)S and all (Zn,Cd)Se phosphors. Both bands shift monotonically to lower or higher quantum energies, if the Zn/Cd ratio is varied, so that their differences to the also varying energy of the band gap remain constant. In contrast, the positions of the emission bands in Zn(S,Se), Zn(Se,Te), and Cd(S,Se) depend relatively little on the S/Se or Se/Te ratio, respectively, except for a pronounced, and as yet not understood, discontinuity near 100% ZnS. Otherwise, the behavior can be understood qualitatively by assuming predominantly ionic crystal bonding, with the Schön-Klasens model of luminescence, and with Fonger's model of term-splitting in all cases where the activator is surrounded by different kinds of anions.

All possible binary compounds between Zn and Cd on the one, and S, Se, and Te on the other hand can be arranged conveniently in the scheme shown in Fig. 1. Each two next neighbors in this scheme are well known to be completely miscible into each other thus forming the ternary compounds (Zn,Cd)S, Zn(S,Se), etc. All these compounds are also luminescent materials which can be activated by the incorporation of

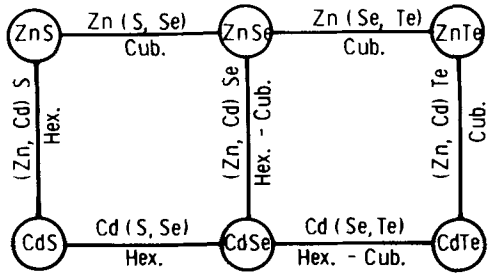

Fig. 1. Binary and ternary (Zn,Cd)(S,Se,Te) compounds

small amounts of certain impurities notably Cu, Ag, and Au. It is the purpose of this study to provide a fairly comprehensive survey over the emission spectra of the binary and ternary (Zn,Cd) (S,Se,Te) phosphors activated by Cu, Ag, or Au, and of corresponding self-activated phosphors, as functions of the composition of the host material. Impurity activated ZnS phosphors (especially ZnS:Cu) are well known, of course, and a fair amount of investigation is reported in the literature also on (Zn,Cd)S phosphors. However, comparatively little, or nothing, is known yet on the emission spectra of all other ternary compounds indicated in Fig. 1. Halsted, Aven, and Coghill attempted to bridge this gap of knowledge by an interpolation between the emission spectra observed in the binary compounds (1), but an actual investigation of the intermediate ternary compounds shows that the matter is not always so simple (2).

The experimental work to be presented here was limited to powder phosphors whose compositions, at the moment at least, are still much better under control than those of single crystals. The investigation was extended over all binary and ternary compounds shown in Fig. 1 with the only exception of compounds containing CdTe which, because of their narrow band gaps, can only give emission rather far in the infrared. Low impurity concentrations were preferred wherever possible in order to minimize complications due to interactions between neighboring impurity atoms. All spectra were measured at 77°K (liquid N_2-temperature) since many emission details do not show up at room temperature.

Experimental

The raw materials used to prepare the phosphors were ZnS, ZnSe, CdS, and CdSe powders of luminescent or electronics grade purity from various suppliers. ZnTe was made by a direct synthesis from metallic Zn and Te (each 99.999% pure) in high-purity argon. The powdered raw materials were dry mixed in the desired ratios. Copper was added as an aqueous solution of $Cu(C_2H_3O_2)_2$, the halogens Cl, Br, I as the Zn or Cd halides, and aluminum, gallium, and indium as nitrates dissolved in water. The resulting slurries were stirred to insure uniformity and dried again. Most samples were fired in amounts of 2% of 1 g-mole, in small capped quartz tubes in argon, H_2S, etc., or in evacuated and sealed quartz tubes in order to insure well-defined compositions even in critical cases.

For measurements, the phosphors were coated in thin layers (in order to minimize influences of possible optical reabsorption on the emission spectra) on small pieces of aluminum metal by means of a nonluminescent binder and placed in a small quartz Dewar with a nonsilvered "window" at one side. The Dewar was filled with liquid N_2 (77°K) so that the phosphors were completely immersed in the coolant. The phosphors were excited to the luminescence, through the window of the Dewar, by the filtered radiation of a small (100w) mercury discharge lamp. The emission spectra were point by point measured with a Beckman DU monochromator and an attached photomultiplier (RCA 1-P-28 for the visible and near ultraviolet, Du Mont K-1430 for the near infrared up to about 1μ). The obtained resolution ($\sim$ 0.01 ev, fairly independent of the spectral position) was sufficient to resolve all details of the generally broad and structureless emission bands of the phosphors. Spectral transparency of the monochromator and spectral sensitivity of the photomultipliers were determined separately by means of a calibrated tungsten ribbon lamp supplied by the National Bureau of Standards.

The measured emission spectra of luminescence are correlated to the quantum energies corresponding to the optical absorption edges of the materials which, in turn, were determined by means of reflection spectra measured on thin layers of the pure (unactivated) binary or ternary compounds. It is estimated from the geometry of the arrangement that the so determined absorption "edge" corresponds to a quantum energy where the intrinsic absorption constant of the material goes through the value of approximately 100 cm^{-1}. This quantum energy is close [but not necessarily identical (3, 4)] to the true band gap of the ideal, defect-free lattice and may be identified with the latter for all practical purposes. The variations of the so determined absorption edges with the compositions of the materials agree closely with data published by other authors in the literature.

Emission spectra presented in the literature are often (not always specified) given as energy distributions, $\epsilon = d(\text{energy})/d\lambda$, as functions of the wavelength, λ. In contrast, the writer prefers to present all spectra in terms of quantum intensity distributions, $q = d(\text{number of quanta})/d(\text{ev})$, as functions of the quantum energy, ev. This is the physically most meaningful way since luminescent processes are quantum processes. The curves in the diagrams are arbitrarily shifted up or down along the logarithmically calibrated ordinates in order to normalize to equal peak heights or to provide clear pictures and to avoid too much crowding of several curves in one area. This means that the shapes and peak positions of the spectra in each diagram can be compared but not their absolute intensities.

Zinc Sulfide

ZnS can be prepared equally well in the cubic (zinc blende) and in the hexagonal (wurtzite) modification. Copper-activated ZnS may well be the most often investigated of all luminescent materials. Its emission spectrum may slightly depend on the modification, cubic or hexagonal, or on the kind of coactivator used to dissolve the copper in the ZnS, but consists generally[1] of two separate, diffuse bands centered in the blue and in the green, respectively. Positions and shapes of both emission bands of any particular sample are almost or completely independent of kind and intensity of excitation, the widths of both bands increase somewhat with increasing temperature, but the peak positions again are little dependent on the temperature at least between room temperature and 77°K or lower. These are well-known facts. However, the following observations made on ZnS:Cu probably are not so well known:

(*A*) The peak positions of both emission bands are slightly uncertain and may vary from sample to sample over a range of approximately 0.03 ev even within phosphors made of identical compositions. This uncertainty was observed already by van Gool and Cleiren (7). A similar uncertainty is observed also in the widths of the emission bands which may vary between about 0.23 and 0.28 ev (measured at half-maximum) at 77°K. Some data are collected in Table I.

(*B*) It is a common belief and is frequently reported in the literature (8-10) that the emission bands of hexagonal (wurtzite) ZnS:Cu phosphors peak at slightly higher quantum energies (*i.e.*, shorter wavelengths) than those of corresponding phosphors of cubic (zinc blende) structure. This is indeed true for

[1] *i.e.*, at copper concentrations in the order of 100 ppm. Higher concentrations produce more complicated effects (5, 6) which are not considered here.

The numbers in ( ) denote the widths of the emission bands at 50% of peak.

both emission bands of phosphors containing halides (Cl, Br, or I) as coactivators, and in the case of the green emission band of phosphors containing group III elements (Al, Ga, In) as coactivators, but not for the blue emission band of ZnS:Cu phosphors containing group III elements where the peak position does not, to an amount exceeding the general uncertainty, depend on whether the phosphor is cubic or hexagonal. Some typical emission spectra are shown in Fig. 2, for more data see Table I.

(C) The position of the blue (but not, or by far not as much of the green) emission band of ZnS:Cu depends on the kind of the added coactivator, in contrast to Kröger and Dikhoff (12) but in agreement with van Gool and Cleiren (7). Halides give peak positions at higher quantum energies than Al, Ga, or In. The effect is less pronounced in cubic but rather strong in hexagonal ZnS.

Hexagonal Zinc-Cadmium Sulfides

Ternary (Zn,Cd)S containing more than a few per cent of CdS crystallizes only in the hexagonal modification under all ordinary preparation conditions. The two main emission bands of hexagonal (Zn,Cd)S:Cu phosphors (blue and green) shift monotonically toward red if zinc is gradually replaced by cadmium (8, 13-17). Some measured spectra are shown in Fig. 3. The blue emission band of hexagonal ZnS:Cu,Cl (peak ~ 2.86 ev at 77°K) corresponds to a band with the peak at ~ 1.53 ev (λ = 810 nm) in CdS:Cu,Cl. Most of this band is located in the infrared, only a small fraction of its high-energy tail extends into the visible red. The green band of hexagonal ZnS:Cu,Cl (peak ~ 2.42 ev) corresponds to a band near 1.16 ev (λ = 1080 nm) in CdS:Cu,Cl. This band is completely in the infrared. The energy difference between both bands scatters around 0.43 ± 0.05 ev and is fairly independent of the ZnS/CdS ratio. Also the widths of both emission bands are (very approximately, at least) independent of the ZnS/CdS ratio if measured in ev.

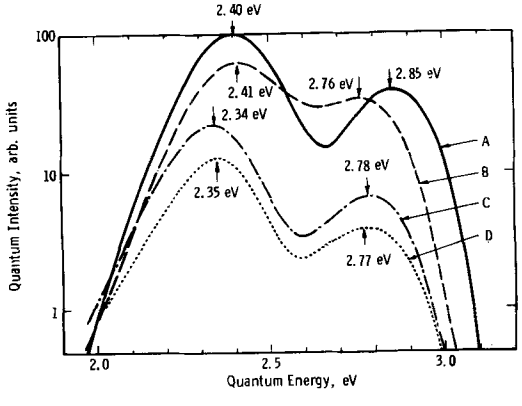

Fig. 2. Emission spectra of four different ZnS:Cu phosphors, all excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K. A, hexagonal ZnS:Cu (0.01%), Cl (0.1%), 1100°C, H_2S; B, hexagonal ZnS:Cu (0.01%), Al (0.03%), 1100°C, H_2S; C, cubic ZnS:Cu (0.01%), Cl (0.1%), 800°C, H_2S; D, cubic ZnS:Cu (0.01%), Al (0.01%), 800°C, H_2S.

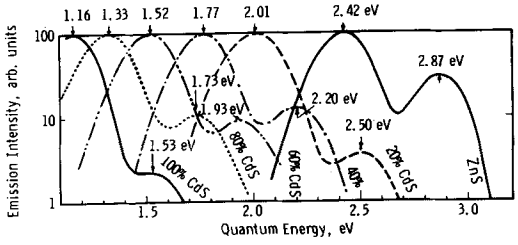

Fig. 3. Emission spectra of hexagonal (Zn,Cd)S:Cu,Cl phosphors excited by band-gap irradiation at 77°K.

II-VI Compounds can be approximately considered to be ionic compounds where the cation belongs to the conduction band and the anion to the valence band. Hence, a variation of the composition from ZnS to CdS means a variation of the conduction band while the edge of the valence band can be represented as a horizontal straight line extending from the ZnS to the CdS in Fig. 4. The generally accepted Schön-Klasens model ascribes the luminescence of ZnS:Cu phosphors to electron transitions from the edge of the conduction band into previously emptied copper acceptor levels. According to this model, the peak energies of the emission bands measured on (Zn,Cd)S:Cu,Cl phosphors (Fig. 3) are plotted downward from the edge

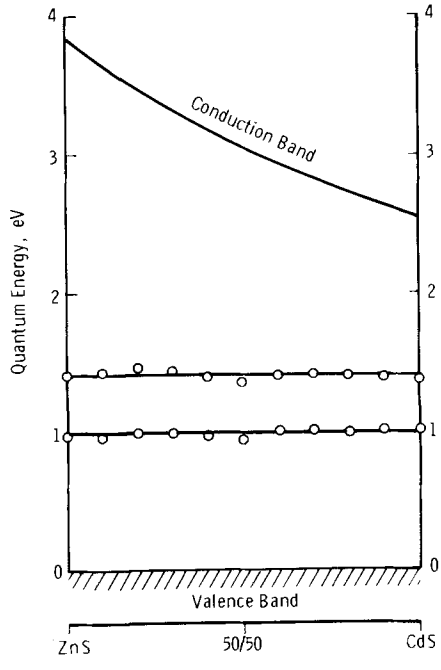

Fig. 4. Recombination term scheme of hexagonal (Zn,Cd)S:Cu,Cl at 77°K.

of the conduction band in Fig. 4. The resulting positions of the two copper terms are remarkably good on two horizontal straight lines extending from the ZnS to the CdS, the one line corresponding to the green, the other to the blue emission band of hexagonal ZnS:Cu,Cl. The distance between the "green" line and the edge of the valence band is approximately 1.40 ev independent of the used coactivator. The distance between the "blue" line and the valence band is approximately 0.98 ev for phosphors containing Cl, Br, or I, and 1.08 ev for phosphors containing Al, Ga, or In as coactivators.

Cubic Zinc Sulfoselenides

Ternary Zn(S,Se) containing more than a few per cent of ZnSe crystallize predominantly in the cubic modification under all ordinary preparation conditions. Emission spectra of Zn(S,Se):Cu phosphors are published by Leverenz (8), by Klasens (18), and by Morehead (19). All varied the S/Se ratio in a few big steps from the ZnS to the ZnSe, and all agree that a gradual replacement of ZnS by ZnSe causes a gradual and steady shift of the green emission band of ZnS:Cu into the red. No corresponding investigation on the blue emission band of ZnS:Cu seems ever to have been made although a steady shift is assumed by Halsted *et al.* (1) also here. This reported, or assumed, behavior is quite in contrast to what is observed in a more detailed investigation.

Some emission spectra of cubic Zn(S,Se):Cu,Cl phosphors are shown in Fig. 5 and 6. The emission peak positions of cubic ZnS:Cu,Cl phosphors at 77°K are, on the average, about 2.35 and 2.79 ev, respectively. Replacement of less than 1% of the ZnS by ZnSe causes a decrease of the intensity of both bands and the appearance of two new bands at about 2.23 and 2.60 ev, respectively. This replacement is essentially completed already at 1% of ZnSe (Fig. 5). Further gradual increase of the ZnSe concentration to 100%

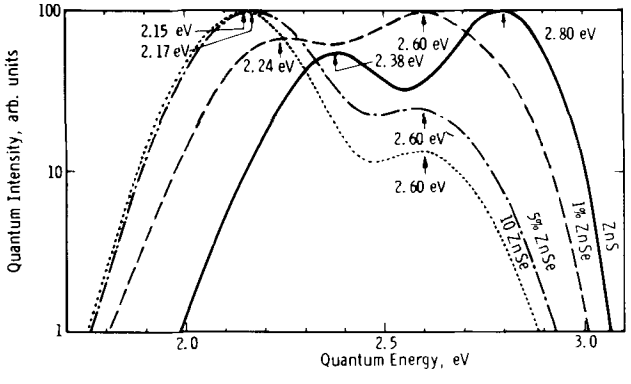

Fig. 5. Emission spectra of cubic Zn(S,Se):Cu (0.01%), Cl phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

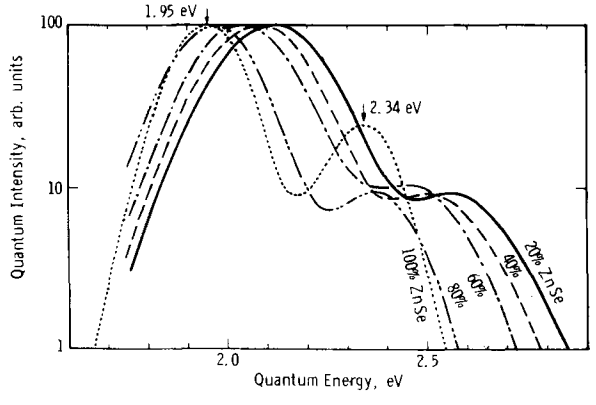

Fig. 6. Emission spectra of cubic Zn(S,Se):Cu (0.01%), Cl phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

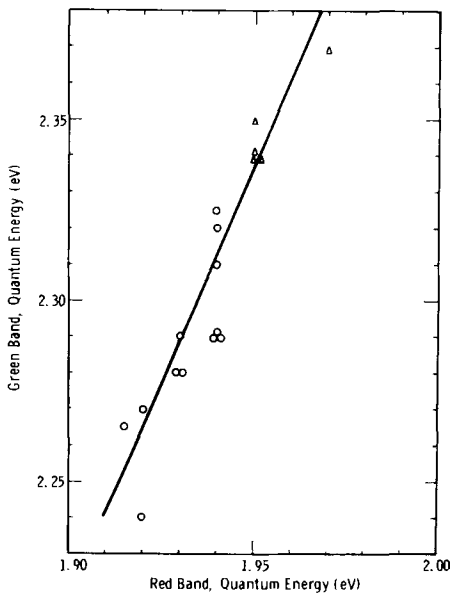

Fig. 7. Correlation between peak positions of the two emission bands of ZnSe:Cu (0.01%) measured at 77°K. △, Cl, Br, I coactivator; ○, Ga or In coactivator.

then causes only a comparatively slow shift of both bands toward red until, in ZnSe:Cu,Cl, they are at about 1.95 ev (red) and 2.34 ev (green), respectively (Fig. 6). Essentially the same behavior is observed also with Zn(S,Se):Cu, Ga phosphors.

Typical width (at half-peak height) of the emission bands at 77°K are 0.26 ev for both bands of ZnS:Cu and 0.19 ev for both bands of ZnSe:Cu. Emission bands of intermediate Zn(S,Se):Cu phosphors are wider; typical widths are about 0.28 to 0.30 ev. This observation strongly supports the assumption that the emission bands of all intermediate Zn(S,Se) phosphors, but not those of the two end members ZnS and ZnSe, actually are close overlaps of two or more sub-bands, as proposed by Fonger (20).

The exact peak positions of the two emission bands of ZnSe:Cu phosphors are even more uncertain than those of cubic ZnS:Cu. Coactivation with Cl, Br, or I generally give both emission bands at slightly higher quantum energies than coactivation with Ga or In. Correlation with details of the preparation conditions, *e.g.*, with the amount of coactivator used, could not be detected. However, there seems to be a linear relationship between the peak positions of the green and of the red band in ZnSe:Cu (Fig. 7). This relationship is not understood at present nor is a similar relationship observed in corresponding ZnS phosphors.

In the ionic picture, a variation of the composition of the host material from ZnS to ZnSe means a variation of the valence band while the conduction band remains constant. Using the Schön-Klasens model of luminescence, the measured peak positions of the emission bands are plotted downward from the edge of the conduction band, and the resulting points connected by two curves (Fig. 8). These curves are not the perfect horizontal straight lines observed in the case of (Zn,Cd)S:Cu phosphors (Fig. 4), but their deviation from the horizontal is much less than that of the edge of the conduction band except only in the neighborhood of ZnS where evidently the introduction of very little ZnSe causes a pronounced unsteadiness. In contrast, no unsteadiness is observed if small amounts of ZnSe are replaced by ZnS.

Cubic Zinc Selenotellurides

ZnSe, ZnTe, and all intermediate Zn(Se,Te) compositions crystallize practically only in the cubic (zinc blende) lattice. The emission band of ZnSe:Cu,Cl is characterized by two separate, diffuse bands in the red

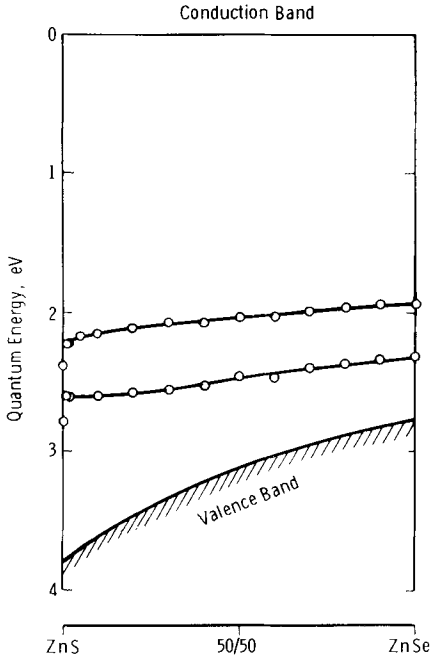

Fig. 8. Recombination term scheme of cubic Zn(S,Se):Cu,Cl at 77°K

(~ 1.95 ev) and in the green (~ 2.35 ev), respectively. Ordinarily the latter can be observed only at low temperature; it is thermally quenched at room temperature. Replacement of a few per cent of Se in ZnSe:Cu,Cl by Te causes the green emission band to decrease in intensity, the red band remains approximately unchanged, and a third emission band builds up in the near infrared at 1.70 to 1.75 ev (Fig. 9). The positions of all bands appear to be independent of the ZnTe concentrations up to the limit to which they could be observed (~ 50% ZnTe). If the observed peak positions are plotted downward from the horizontal edge of the conduction band, one obtains the recombination term scheme of Fig. 10 where, again, all points scatter fairly closely around horizontal straight lines.

The writer was unable to detect any emission in Zn(Se,Te):Cu containing more than about 50% ZnTe which could be ascribed unambiguously to be due to copper. However, Halsted and co-workers report ZnTe:Cu, at 25°K, to emit in two bands at 1.97 and 1.47 ev, respectively (1). Points corresponding to these energies are also indicated in Fig. 10. There is obviously a straight-line connection between the 1.97 ev band of ZnTe:Cu and the red emission band of ZnSe:Cu (~ 1.95 ev), but no such correlation is visible between the reported 1.47 ev of ZnTe:Cu with any emission in ZnSe:Cu.

Zinc-Cadmium Selenides

ZnSe crystallizes practically always in the cubic modification, CdSe always in the hexagonal. The transition point from cubic to hexagonal within intermediate (Zn,Cd)Se powders (fired at 900°C in evacuated and sealed quartz tubes) was determined by x-ray analysis and found to be between 30 and 40% of CdSe. It is obvious, however, that this point may shift either to the ZnSe or to the CdSe side depending on the preparation temperature, on various impurities, etc.

The luminescence of CdSe:Cu phosphors was investigated by Garlick and Dumbleton (21) who report two emission bands at 0.95μ (1.30 ev) and at 1.2μ (1.03 ev), both measured at 90°K, and by Avinor and Meijer (22) who report only one band at 1.20μ (1.03 ev) measured at 77°K. Emission spectra of intermediate (Zn,Cd)Se:Cu phosphors do not seem to be published.

Some emission spectra of (Zn,Cd)Se:Cu, I phosphors are shown in Fig. 11. The two emission bands

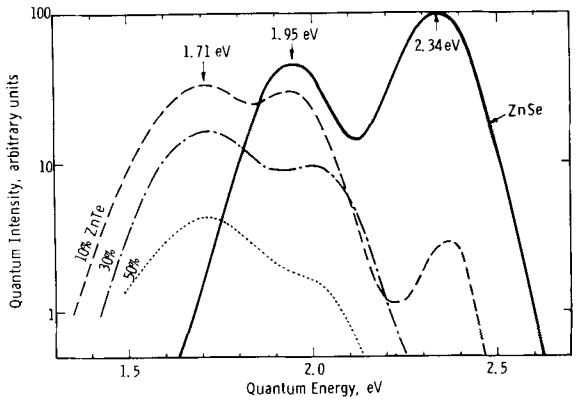

Fig. 9. Emission spectra of cubic Zn(Se,Te):Cu (0.01%), Cl phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

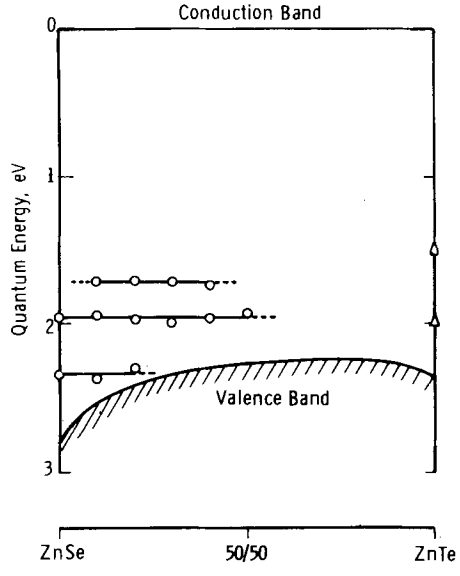

Fig. 10. Recombination term scheme of cubic Zn(Se,Te):Cu,Cl at 77°K. △, data from ref. (1).

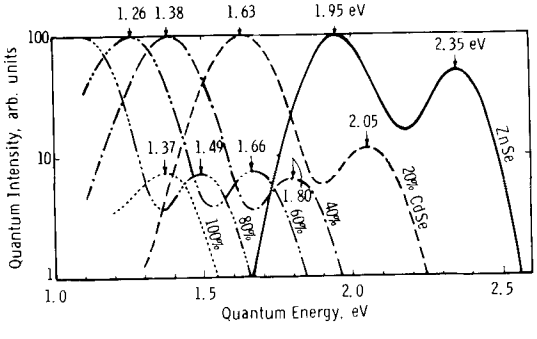

Fig. 11. Emission spectra of (Zn,Cd)Se:Cu (0.02%), I phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

due to copper shift monotonically into the infrared as more and more ZnSe is replaced by CdSe (completely similar to the shift observed in corresponding sulfide phosphors). The green emission band of ZnSe:Cu (~2.35 ev) corresponds to the 1.37 ev band in CdSe:Cu (this is probably identical to the 0.95μ band reported by Garlick and Dumbleton). The emission band of CdSe:Cu corresponding to the red band (~1.95 ev) of ZnSe:Cu could not be measured any more with the used instrumentation, but it is obviously identical the 1.2μ band reported elsewhere (21, 22). If the Schön-Klasens model of luminescence is used here and the quantum energies corresponding to the peaks of the

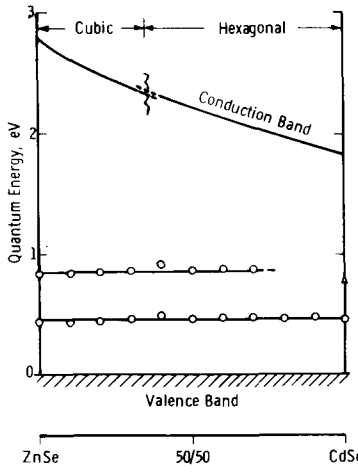

Fig. 12. Recombination term scheme of cubic and hexagonal (Zn,Cd)Se:Cu,I at 77°K. △, from ref. (21).

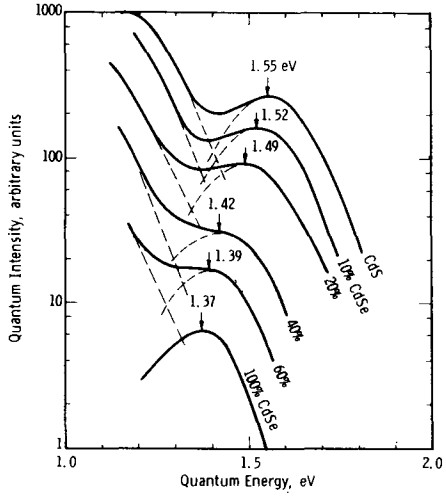

Fig. 13. Emission spectra of hexagonal Cd(S,Se):Cu (0.01%), I phosphors excited by ultraviolet of 3.40 ev (λ = 365 nm) at 77°K.

emission bands are plotted downward from the curved edge of the conduction band, one obtains the diagram of Fig. 12 which may be compared with Fig. 4. Again, all measured points scatter closely around two horizontal straight lines about 0.4 ev apart.

Hexagonal Cadmium Sulfoselenides

CdS, CdSe, and all intermediate Cd(S,Se) crystallize practically only in the hexagonal modification. Emission spectra of copper activated Cd(S,Se) phosphors, except those of the two end members CdS and CdSe, apparently are not reported before. Some spectra measured within this work are given in Fig. 13. All spectra evidently consist of two emission bands although, due to instrumental limitations, only the high-energy band could be measured over the whole composition range. There is some, but very little, shift of the peak position with the CdSe concentration. In contrast to corresponding Zn(S,Se) phosphors (Fig. 5), no discontinuity in the peak position could be observed near the 100% CdS. If the quantum energies corresponding to the peaks of the emission bands are plotted downward from the horizontal edge of the conduction band, one obtains the recombination scheme of Fig. 14. The curve connecting all measured points deviates somewhat from a horizontal straight line, but this deviation is much less than the variation of the band gap, represented by the curved edge of the valence band, over the same range.

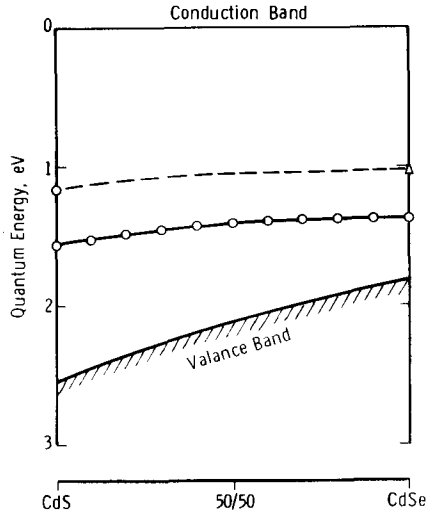

Fig. 14. Recombination term scheme of hexagonal Cd(S,Se):Cu,I at 77°K. △, data from ref. (21).

Discussion

The main observations on the emission spectra due to copper in the II-VI compound phosphors can be summarized as follows.

The emission in the binary compounds ZnS, ZnSe, CdS, and CdSe consists of two diffuse but fairly well separable bands of approximately Gaussian shape whose peaks are about 0.4 ev apart. The exact peak positions depend not only on the host material but also on a number of other parameters some of which are still unknown. Gradual replacement of zinc by cadmium either in the sulfides or in the selenides causes a steady shift of both emission bands toward lower quantum energies so that the differences between the energy of the band gap and the quantum energies of the emission peaks always remain constant. By contrast, gradual replacement of sulfur in ZnS or in CdS by selenium, and gradual replacement of selenium at least in ZnSe by tellurium, causes little or no shift of the emission except for a strong discontinuity near 100% ZnS.

Most of this behavior can be understood qualitatively with the assumption of a predominantly ionic crystal bonding where the conduction band belongs to the cation and the valence band to the anion, and with the familiar Schön-Klasens model of luminescence which ascribes the photon emission to electron transitions from the conduction band into previously emptied electron levels between the activator ion and the four surrounding chalcogenide ions. Any replacement of zinc by cadmium then causes only a variation of the conduction band while the activator electron levels and the valence band remain unchanged. Hence, the energy difference between valence band and activator levels is independent of the Zn/Cd ratio as predicted already by Bube (23). This is expressed by the horizontal straight lines in the term scheme of Fig. 4 and 12. However, if sulfur is gradually replaced by selenium, or selenium by tellurium, the conduction band remains unchanged while the valence band changes and the highly localized electron wave functions of the activator centers split into several levels depending on the four chalcogenide ions surrounding the copper ion. This latter effect is discussed by Fonger (20) for the case of Zn(S,Se) phopshors. It seems that Fonger's assumptions hold essentially also for Zn(Se,Te) and for Cd(S,Se) phosphors although, perhaps, modifications are necessary to explain all observed details.

The discontinuity in Zn(S,Se) observed near 100% ZnS seems peculiar and probably cannot be understood with the above models. Also it does not seem to be related to the discontinuity which Klasens (18)

was looking for in Zn(S,Se):Cu but did not find. Klasens assumed activator centers in ZnS:Cu phosphors to be identical to single sulfur ions disturbed by copper ions as next neighbors and, correspondingly, expected two emission bands to be present in Zn(S,Se) for every one in ZnS, namely, those due to disturbed sulfur and selenium ions. If this assumption (which obviously is in disagreement with Fonger's model) were correct and the reason for the observed discontinuity in Zn(S,Se):Cu near 100% ZnS:Cu, it could hardly be the reason for the completely different behavior observed in Zn(S,Se):Ag near 100% ZnS:Ag (24). Further, similar discontinuities obviously should appear in Zn(Se,Te):Cu near 100% ZnSe:Cu, and in Cd(S,Se):Cu near 100% CdS:Cu, which are not observed in reality. At the moment, the writer is unable to offer any explanation of the discontinuity in Zn(S,Se):Cu near 100% ZnS:Cu.

On the Luminescent Properties of Some $CaMoO_4/LnVO_4$ Systems

L. H. Brixner

Pigments Department, Experimental Station, E. I. du Pont de Nemours & Co., Inc., Wilmington, Delaware

ABSTRACT

The $(LnVO_4)_x(CaMoO_4)_{1-x}$ systems (with Ln = Nd^{+3}, Sm^{+3}, Eu^{+3}, Tb^{+3}, and Dy^{+3}) have been prepared over wide ranges of x and some of their structural, analytical, and optical parameters have been measured. The x-ray phase diagram for the $EuVO_4/CaMoO_4$ system was determined and shows that only very limited solid solubility of the scheelite- and zircon-type constituents exists. Fluorescent emission data are given for the compounds containing the rare earths Sm, Eu, Tb, and Dy, which emit in the visible. The Nd compound emits in the infrared and laser action is reported for a Fabry-Perot resonator machined from a Czochralski-grown single crystal of the composition $Nd_{0.01}V_{0.01}Ca_{0.99}Mo_{0.99}O_4$.

In the series of scheelite-type ABO_4 compounds (where A = Ca, Sr, and Ba, B = Mo, W), $CaMoO_4$ is thermodynamically the least stable and the only one which loses oxygen if pulled as a crystal from melts under normal atmospheric conditions. It is probably for this reason that the thresholds for Nd^{+3} in $CaMoO_4$ as first reported by Johnson (1) were quite high (360 joules at 295°K) and most investigators concentrated on $CaWO_4$ as a laser host crystal. In a previous paper, we (2) demonstrated that the introduction of rare earths into $CaMoO_4$ as their $LnNbO_4$-type niobates not only provides the necessary valence compensation, thereby simplifying the fluorescent emission spectrum, but also stabilizes $CaMoO_4$ so that no oxygen is lost at the melting point. Recently, Duncan (3) observed continuous-wave operation with such crystals, thus showing that Ca-molybdate can be obtained in as high optical perfection as Ca-tungstate. These findings, plus the fact that Ca-molybdate has some inherent advantages over Ca-tungstate (higher refractive index, lower melting point and higher thermal conductivity), generated renewed interest in this composition as a laser host.

Based on the size of the ionic radii as given by Ahrens (4), the V^{+5} ion should provide an even better structural match in substituting for Mo^{+6} than does Nb^{+5}. The V^{+5} ion is only some 5% smaller than Mo^{+6} and since the $LnVO_4$-type vanadates are quite stable (5), it seemed that the $CaMoO_4/LnVO_4$ systems were worth studying, particularly since energy exchange at least for the case of Eu^{+3} had been demonstrated in the $LnVO_4$ (5) system as well as in the $Ca_3(VO_4)_2$ (6) host. Since the $LnTaO_4$-type tantalates did not show any advantages over the corresponding niobates as dopants, the vanadates were the only remaining group VB compositions to be investigated in solid solution with $CaMoO_4$.

Experimental

Since the vanadates crystallize in a structure different from scheelite, the range of solid solubility had to be established first. The techniques used in ob-

1.0	7.253	6.398	I4/amd	336.57

Table II. Fluorescent emission characteristics for some $(CaMoO_4)_{1-x}(LnVO_4)_x$ systems

Ln	x for Maximum fluorescent emission intensity (of underlined wavelength)	Relative intensity of most intense line	Lines at mμ*
Sm	0.02	39	560, 595, 635
Eu	0.20	282	585, 610
Tb	0.02	486	485, 540, 580
Dy	0.01	108	570

* The underlined wavelength was the most intense emission.

taining lattice parameters are essentially those described earlier (2). Some of the data are summarized in Table I and Fig. 1 gives a graphic representation of the phase diagram for $CaMoO_4$-$EuVO_4$.

Between $x > 0.2$ to $x < 0.9$, there was no solid solubility; this makes the two-phase region considerably wider than for the corresponding $CaMoO_4$/$EuNbO_4$ system, a rather surprising result in view of the fact that the closer match of the Mo^{+6} and V^{+5} ion radii should permit even more extended solid solubility. Since there is no change in coordination number for the cationic and the anionic metal constituent in going from either $LnVO_4$ or $LnNbO_4$ to $CaMoO_4$ (8 for A and 6 for B), the $LnNbO_4$ structure is obviously more closely related to the $CaMoO_4$ structure. In view of the fact that Kankov (7) first described $YNbO_4$ as a distorted scheelite this supports this consideration.

Fluorescent emission studies were carried out for the $CaMoO_4$-$LnVO_4$ systems where Ln = Sm, Eu, Tb and Dy. The experimental arrangements for examining fluorescence have been published (2). The data are given in Table II.

Since no corrections were made for photomultiplier response, the intensity data are meant merely to give a qualitative basis for comparison. Obviously, both Tb^{+3} and Eu^{+3} are the most intense emitters in this system.

Typical fluorescent emission spectra of polycrystalline samples are represented in Fig. 2-5. The line sharpening in going from room temperature to liquid nitrogen temperature is particularly prominent for the Dy case, but the complexity of the spectrum and the multitude of still available transitions prevents stimulated emission. Laser experiments with the Dy and Sm compositions in the niobate-molybdate system had failed (2) and were not attempted with these new compounds. The europium spectrum as shown in Fig. 3 is of course substantially simpler, but surprisingly, line narrowing was rather insignificant in this case. The Tb sample as represented in Fig. 4 showed similar behavior, whereas the Sm compound (Fig. 2) gave narrowing almost as pronounced as the Dy composition.

A characteristic plot of intensity of fluorescent emission as a function of activator concentration is given

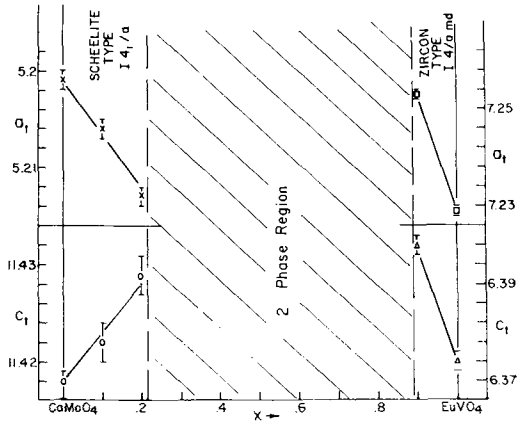

Fig. 1. Structure types as a function of x for the $(EuVO_4)_x(CaMoO_4)_{1-x}$ system.

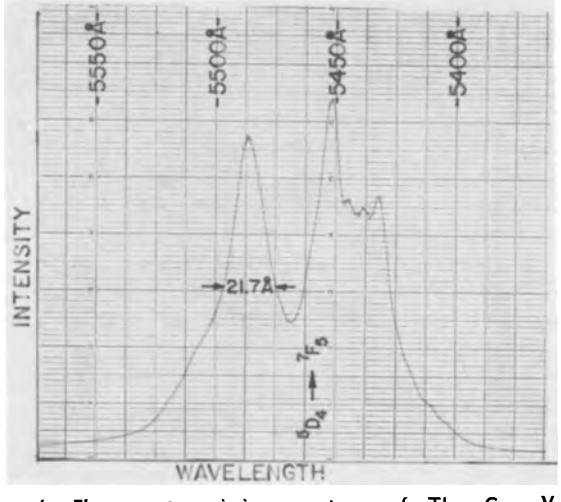

Fig. 4. Fluorescent emission spectrum of $Tb_{0.02}Ca_{0.98}V_{0.02}Mo_{0.98}O_4$ at 300°K.

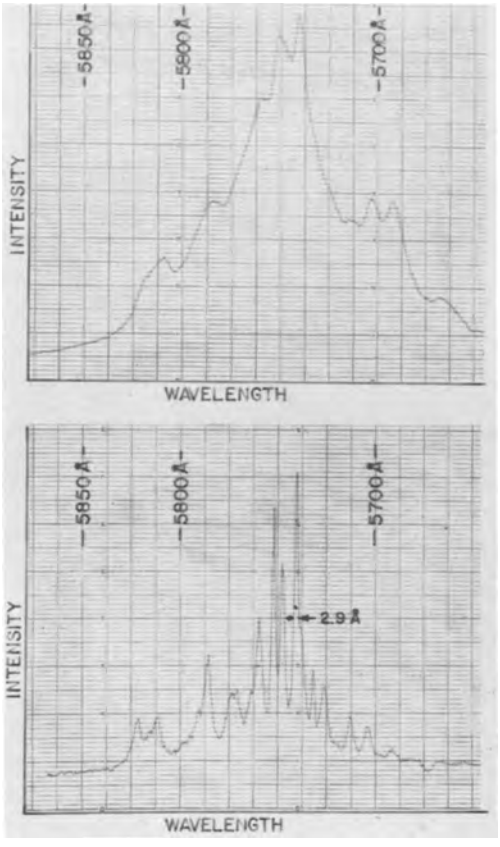

Fig. 5. Fluorescent emission spectrum of $Dy_{0.02}Ca_{0.98}V_{0.02}Mo_{0.98}O_4$ at 300°K (top) and 77°K (bottom).

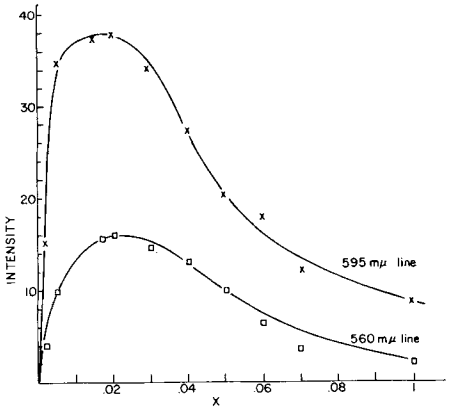

Fig. 6. Intensity of fluorescent emission as a function of x for the $(SmVO_4)_x(CaMoO_4)_{1-x}$ system.

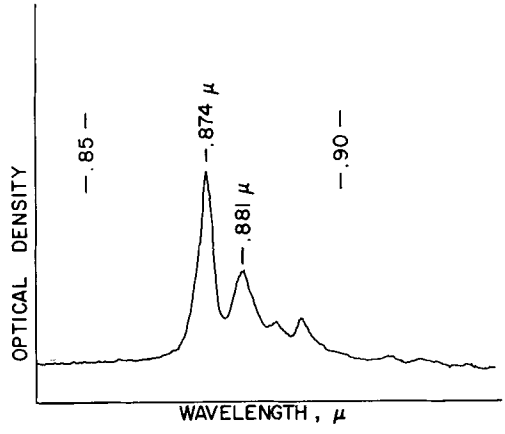

Fig. 7. $4F_{3/2}$ absorption level for $Nd_{0.01}Ca_{0.99}V_{0.01}Mo_{0.99}O_4$

in Fig. 6 for the example of Sm. As can be seen, the shape of the curve is essentially the same for the two different emission lines plotted: a rather steep rise to the optimum at 2 mole % and then gradual decrease of intensity until eventually complete concentration quenching occurs.

Whenever Nd is introduced into a novel host or a new compensation scheme is applied, it is always of interest to observe the absorption characteristics at the $4F_{3/2}$ level, which is the last absorption band before the 1.06μ region of emission for Nd^{+3}. It would be highly desirable to find a host material with an absorption peak at 0.84μ, the emission wavelength of a modified GaAs injection laser. As can be seen from Fig. 7, the shortest peak is still at 0.87μ.

Crystal Growing Experiments

Procedure and equipment have been described earlier (2). The most significant difference from niobate-compensated $CaMoO_4$ was that the oxygen loss in the presence of vanadates was even more severe than for undoped $CaMoO_4$. Contrary to behavior of niobate-compensated crystals, segregation coefficients were below 1 and the melting point was about 10°C lower than that of pure $CaMoO_4$ (1480°C). Despite the use of an automatic voltage control unit to minimize current fluctuations, it was very difficult to control the crystal shape. This was true for crystals grown both in the a- or the c-axis of the scheelite structure. Characteristically, the a-axis crystals were elliptical in cross section, with a considerably higher axial ratio than for Nb-compensated crystals, and the c-axis crystals showed an almost round cross section. Contrary to experience with Na-compensation the vapor pressures posed no problem; no V_2O_5 was lost and materials were charged to the melting crucible in stoichiometric proportions. A detailed examination of the Ln_2O_3:V_2O_5 ratio on top and bottom of a crystal based on the analytical information given in Table III gives the following values:

For Dy: top, Dy_2O_3:V_2O_5 = 1:0.88; bottom, Dy_2O_3:V_2O_5 = 1:0.93 (3.5 in. over-all length representing 42% of weight of original charge).

For Tb: top, Tb_2O_3:V_2O_5 = 1:0.87; bottom, Tb_2O_3:V_2O_5 = 1:0.85 (4.8 in. over-all length representing 51% of weight of original charge).

This indicates that even if ½ of the original charge is grown into a single crystal, there is essentially no

shift in the concentration ratio. Some typical analytical data obtained by x-ray fluorescence analysis are summarized in Table III.

Laser Experiments

Single crystal boules were cut and ground into cylindrical rods ⅛ in. diameter and 1 in. long. The cylindrical surfaces were left rough and the ends polished to form a Fabry-Perot resonator. Silver was evaporated onto the end surfaces; one end was 5% transmissive and the other completely opaque.

Laser characteristics were measured under pulsed illumination in a Lear-Siegler LS-3 laser head with a Kemlite FT100B helical xenon flash lamp. All experiments were run at 295°K. The lamp was flashed by discharging a 5-μf condenser charged to 2000v. Light from the laser rods was detected with a Dumont K1485 photomultiplier through a 3-mm silicon filter. For the purpose of comparison, a niobium-compensated rod of equal size and Nd concentration was also lased. The data for those rods are given in Table IV.

A number of other pertinent parameters have been determined for $Nd_{0.01}Ca_{0.99}V_{0.01}Mo_{0.99}O_4$ and are summarized in Table V.

Based on these data, in conjunction with the laser experiments, it would seem that V^{+5} compensation in $CaMoO_4$:Nd, while quite feasible, does not offer any further improvement over the $CaMoO_4$:$NdNbO_4$ system.

Acknowledgment

The author greatly appreciated the assistance of Mr. F. Walls in growing the crystals and of Dr. P. A. Flournoy in performing the laser experiments.

Pseudobinary InSb-InTe System

A. J. Strauss, M. D. Banus, and M. C. Finn

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The InSb-InTe pseudobinary system has been investigated by thermal, metallographic, x-ray diffraction, and electron microprobe analysis. The results show that there is an unstable phase diagram in addition to the stable diagram. The principal features of the stable diagram are the same as those reported by Deneke and Rabenau, but the temperatures of the thermal arrests are appreciably different. The system contains one ternary compound, with nominal composition In_3SbTe_2, which is a peritectic phase unstable above 556° and below about 420°C. According to the stable diagram, In_3SbTe_2 is the first phase to crystallize during cooling runs on melts containing between 15 mole % InTe (the eutectic composition) and 40 mole % InTe (the liquidus composition at the peritectic temperature), and InTe crystallizes as the primary phase from melts containing more than 40 mole % InTe. When experimental conditions permit sufficient supercooling, however, the ternary compound crystallizes as the primary phase from melts containing between 40 and 75 mole % InTe, since in this region there is an unstable liquidus which lies below the stable liquidus. The unstable liquidus temperature increases monotonically from 556° to 586°C as the InTe content increases from 40 to 75 mole % InTe. For samples of the ternary compound crystallized close to 586°C, the formula In_4SbTe_3 appears to be more appropriate than In_3SbTe_2.

A number of alloy systems involving a III-V compound and an $A_2^{III}B_3^{VI}$ compound containing the same group III element have been investigated (1). The III-V compounds in these systems have the zinc blende structure, and except for In_2Se_3 the $A_2^{III}B_3^{VI}$ compounds have a defect zincblende (or possibly defect antifluorite) structure. Except in the InSb-In_2Te_3 system, the only phases obtained are solid solutions which lie in or close to the pseudobinary section of the two terminal compounds. In several systems, for example InAs-In_2Te_3 (2), the two compounds are soluble in all proportions.

In investigating the InSb-In_2Te_3 system, Goryunova, Radautsan, and Kiosse (3) and Woolley, Gillett, and Evans (4) obtained a phase with rock-salt structure. Goryunova *et al.* (3) showed that this phase was a ternary compound in the InSb-InTe pseudobinary section, rather than in the InSb-In_2Te_3 section. They reported that the ternary compound contained approximately 75 mole % InTe, corresponding to the nominal formula In_4SbTe_3.

[1] Operated with support from the U. S. Air Force.

It was later found in our laboratory (5) and confirmed elsewhere (6) that InTe, whose stable phase at atmospheric pressure has the TlSe tetragonal structure and is not superconducting, is transformed at about 30 kbar into a high pressure phase with rock-salt structure which has a superconducting transition at about 3.5°K. This result suggested the possibility that the ternary In-Sb-Te compound, which also has the rock-salt structure, might be a superconductor. In order to investigate this possibility, attempts were made to obtain the ternary compound by solidifying melts containing 75 mole % InTe. These attempts failed to yield single-phase samples, although the preparation of such samples by the same method had been reported by Goryunova *et al.* (3). To find an explanation for this discrepancy, we undertook a detailed investigation of the InSb-InTe pseudobinary phase diagram by means of thermal, metallographic, x-ray diffraction, and electron microprobe analysis.

This paper reports the results of our investigation and compares them with earlier incomplete data on the InSb-InTe system obtained by Molodyan, Radautsan, and Madan (7) and with the phase diagram recently reported by Deneke and Rabenau (8). The findings of these authors did not come to our attention until our investigation was essentially complete. On the basis of their x-ray diffraction and metallographic data, Deneke and Rabenau (8) report that the ternary compound has the composition In_3SbTe_2. Although our data do not establish the precise homogeneity range of the ternary compound, for samples annealed at 475°C they show that the composition In_3SbTe_2 lies within this range but In_4SbTe_3 does not. Throughout this paper the ternary compound is accordingly designated as In_3SbTe_2, but this should be regarded as a nominal formula. [In our earlier reports (9) of this investigation, the ternary compound was designated as In_4SbTe_3. Evidence will be given that this is probably a more appropriate formula than In_3SbTe_2 for samples of the compound prepared by crystallization under certain conditions.]

Our investigation establishes a stable phase diagram for the InSb-InTe system which is in general agreement with the diagram proposed by Deneke and Rabenau (8). In addition, our results demonstrate the existence of an unstable diagram, for the composition region between 40 and 75 mole % InTe, which explains the observations of Goryunova *et al.* (3) and Molodyan *et al.* (7).

Experimental

With one exception, thermal analysis data were obtained in cooling runs on initially molten samples. Each sample for the cooling runs was prepared by placing appropriate quantities of semiconductor grade In, Sb, and Te (nominal purity 99.999%) totaling 150g in a quartz tube which was then evacuated and sealed. A Pt-(Pt-13% Rh) thermocouple for measuring sample temperatures was inserted into a reentrant tube at the bottom of the sample tube. The thermocouple had been calibrated at the melting point of Sb (630.5°C). Since the difference between the observed and tabulated voltages at this temperature corresponded to less than 0.2°C, no corrections were made in converting the subsequently measured voltages to temperatures. In order to reduce thermal gradients within the sample, the sample tube was placed in a heavy-walled stainless steel cylinder. A reference thermocouple for differential measurements was inserted into a hole in the bottom of this cylinder. The sample and cylinder were heated in a vertical resistance furnace to about 800°C, allowed to equilibrate at that temperature for at least 12 hr, and then cooled at 2°-3°C/min over the range of interest by turning off the furnace power. In order to measure the sample temperature with high precision, most of the thermocouple signal was bucked out with a d-c microvolt potentiometer, and the remaining voltage was amplified with a d-c microvolt amplifier whose output was recorded with a recording potentiometer. The same procedure was followed for the reference thermocouple.

One heating run between about 200° and 700°C was made on an initially solid sample, which was prepared by pulverizing material taken from the first-to-freeze portion of an ingot obtained by the horizontal Bridgman technique from a melt containing 65 mole % InTe. This sample, which weighed about 45g, consisted primarily of In_3SbTe_2 but contained a small amount of InSb as a second phase. A reference specimen of pulverized germanium sealed in an evacuated quartz tube was used. The sample and reference thermocouples were bucked against each other and the difference voltage was amplified and recorded.

Metallographic studies were made with a Leitz MM5 metallograph on a number of the ingots formed during thermal analysis runs on initially molten samples, on ingots prepared by the horizontal Bridgman technique, and on annealed samples prepared in the manner described below. One of the metallographic samples was also examined with a Cameca electron microprobe at Acton Laboratories, Acton, Massachusetts, and others were examined with an electron microprobe at the Department of Metallurgy, Massachusetts Institute of Technology.

Room temperature x-ray diffraction patterns for powdered samples were obtained with a standard 114.6 mm Debye-Scherrer camera. Exposures of 7 hr were made with Cu-Kα radiation. Measurements were made both on as-grown samples (from ingots solidified during thermal analysis runs, prepared by the horizontal Bridgman technique, or quenched from the melt) and on annealed samples. To prepare an annealed sample, a melt of the desired composition was quenched, the resulting ingot was powdered, and about 2g of the powder was pressed into a pellet. The pellet was sealed into an evacuated quartz ampoule and annealed for 2-4 weeks at 475°-500°C. One portion of the pellet was analyzed for In, Sb, and Te by a wet chemical method described elsewhere (10).

X-ray diffraction measurements were also made on 2 samples of In_3SbTe_2 at a number of temperatures up to 540°C with a 90 mm Rigaku-Denki high temperature camera. The period of exposure at each temperature was 12-18 hr. One of the samples had been prepared by annealing in the manner described above. The other was an as-grown sample from an ingot prepared by the horizontal Bridgman technique.

Results and Discussion

Figure 1 shows the pseudobinary InSb-InTe phase diagram, which includes not only the stable diagram (indicated by solid and dotted lines) but also an unstable diagram (indicated by dashed and dot-dashed lines). The data points in Fig. 1 represent the thermal arrests observed in cooling runs on initially molten samples. These arrests are also listed in Table I. For

each run in which InTe was the first phase to crystallize from the melt, all the thermal arrests observed during the run are indicated by closed circles in Fig. 1. Arrests observed during runs in which the primary phase was In_3SbTe_2 or InSb are indicated by open circles and squares, respectively. The compounds InSb, InTe, and In_3SbTe_2 are shown as line phases in Fig. 1 and will generally be referred to as such in the following discussion, since information on their ranges of homogeneity is limited.

Stable phase diagram.—Liquidus, peritectic, and eutectic.—The principal features of the stable phase diagram are the same as those reported by Deneke and Rabenau (8). The ternary compound In_3SbTe_2 is a peritectic phase, unstable below about 420°C, which forms a eutectic with InSb. The eutectic mixture contains 15 mole % InTe. Along the stable liquidus lines, in agreement with Deneke and Rabenau (8), melts containing 15 mole % InTe or less are in equilibrium with InSb, those containing between 15 and 40 mole % InTe are in equilibrium with In_3SbTe_2, and those containing more than 40 mole % InTe are in equilibrium with InTe.

The liquidus temperature for pure stoichiometric InTe was found to be 695°C, in good agreement with the melting point of 696°C recently reported by Grochowski, Mason, Schmitt, and Smith (11) for congruently melting InTe, which according to these authors contains 50.8 a/o (atomic per cent) Te.

According to the stable phase diagram, InTe is the first phase to crystallize from InSb-InTe melts containing more than 40 mole % InTe. Primary crystallization of InTe did occur in all cooling runs on melts containing at least 80 mole % InTe. It also occurred in about half the runs on melts containing 55-75 mole % InTe, while primary crystallization of In_3SbTe_2 according to the unstable phase diagram occurred in the rest of these runs.

When InTe was the primary phase in cooling runs on melts containing up to 80 mole % InTe, thermal arrests were observed at the stable liquidus, peritectic, and eutectic temperatures.[2] Typical thermal analysis

[2] According to the stable diagram, eutectic arrests should not occur in cooling runs on samples containing more than 67 mole % InTe, since these samples should become completely solid at the peritectic temperature. As pointed out by Deneke and Rabenau, however, eutectic arrests can occur for compositions above 67 mole % InTe when the cooling rate is too fast to permit equilibrium to be attained.

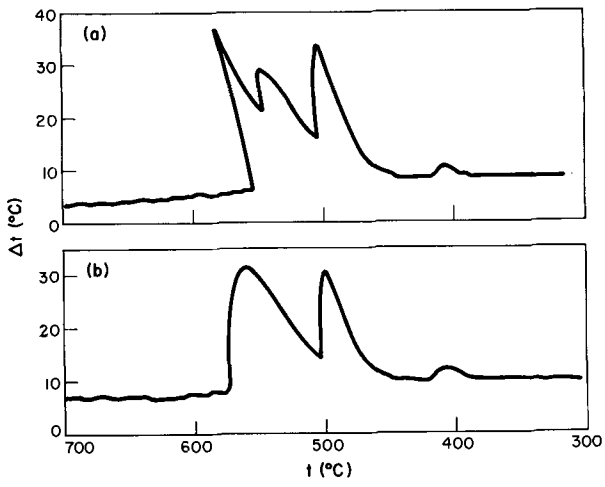

Fig. 2. Differential thermal analysis data obtained in cooling runs on samples containing 57.5 mole % InTe. (a) Sample No. 27, which froze according to the stable diagram. (b) Sample No. 25, which froze according to the unstable diagram.

data showing these three arrests are presented in Fig. 2(a), where the difference between sample and reference temperatures is plotted against sample temperature for a sample (No. 27) containing 57.5 mole % InTe. (The small arrest at 415°C will be discussed below.) When the three arrests were observed, metallographic, x-ray diffraction, and electron microprobe studies showed that InTe, In_3SbTe_2, and InSb were all present in the solidified sample. Figure 3(a) is a photomicrograph of the polished surface of such a sample (No. 7), prepared from a melt containing 55 mole % InTe. The sample consists of dark islands of InTe, each surrounded by a lighter ring of In_3SbTe_2, which is surrounded in turn by a darker matrix of eutectic. (The single-phase appearance of the eutectic will be explained below.) The three phases are present because the cooling rate was too fast either to permit the InTe first crystallized to be removed by the peritectic reaction with InSb-rich liquid or to permit the In_3SbTe_2 to be removed by decomposition below 420°C.

Thermal arrests at the stable liquidus temperatures were not observed in cooling runs on samples containing between 40 and 55 mole % InTe, since these samples froze according to the unstable phase diagram. Therefore, the stable liquidus curve in this composition region, which is represented by a dotted line in Fig. 1, was obtained by extrapolating the portion of the curve above 55 mole % InTe to the peritectic point.

The stable liquidus from pure InSb to the eutectic point at 15 mole % InTe is also represented by a dotted line in Fig. 1, since the solid samples obtained in cooling runs on InSb-InTe melts in this composition range do not lie in the pseudobinary InSb-InTe section. These samples contain two phases: a small quantity of essentially pure In and a solid solution with zincblende structure lying in or close to the InSb-In_2Te_3 section. The In phase was identified by electron microprobe analysis. The nature of the solid solutions was established by x-ray diffraction measurements on samples prepared by quenching InSb-InTe melts containing 1-40 mole % InTe. As shown in Fig. 4, the lattice parameters of the zincblende phase in these quenched samples are in good agreement with those reported by Woolley, Gillett, and Evans (4) for annealed InSb-In_2Te_3 specimens containing the same mole fractions of InSb. For InSb-InTe samples with compositions between 15 and 40 mole % InTe, the lattice parameter of the zincblende phase has a fixed value corresponding to an In_2Te_3 content of about 15 mole %, the same as the maximum solubility of In_2Te_3 in InSb found by Woolley *et al.* (4). As required by

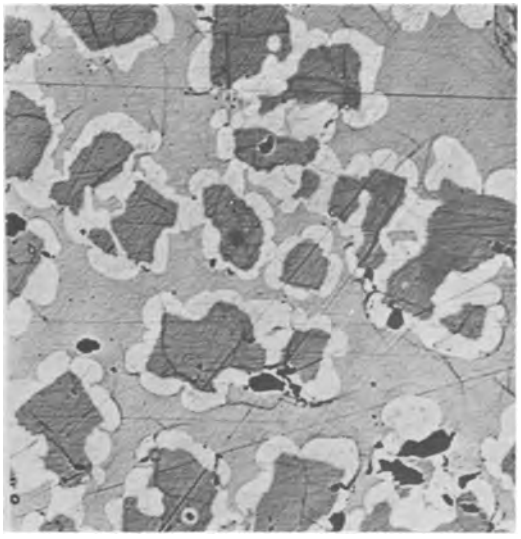

Fig. 3. Photomicrographs of polished specimens from samples prepared by solidification of InSb-InTe melts. (a) Sample No. 7, with over-all composition of 55 mole % InTe, containing InTe (primary phase), In_3SbTe_2, and eutectic.

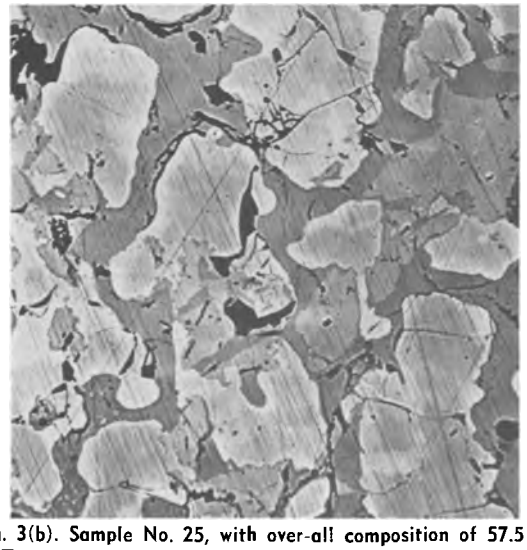

Fig. 3(b). Sample No. 25, with over-all composition of 57.5 mole % InTe, containing In_3SbTe_2 (primary phase) and eutectic.

the stable phase diagram, these samples contain In_3SbTe_2 as well as the zincblende and In phases. The solid obtained by freezing an InSb-InTe melt of eutectic composition (15 mole % InTe) consists almost entirely of a solid solution with approximately 15 mole % In_2Te_3, and therefore this solid contains only small scattered regions of characteristic two-phase eutectic mixture. This explains the single-phase appearance of the eutectic material in Fig. 3.

The mixtures of In and InSb-In_2Te_3 phases in samples obtained by solidifying InSb-InTe melts are unstable, at least at 475°C. When the quenched samples discussed above were powdered, pressed, and annealed at this temperature for 2-3 weeks, the In phase disappeared. A zincblende phase was still present in all samples, and In_3SbTe_2 appeared for compositions between 5 and 15 mole % InTe as well as for those exceeding 15 mole %. As shown in Fig. 4, the lattice parameters of the stable zincblende phase initially decrease somewhat with increasing InTe content but become essentially constant for compositions above about 5 mole % InTe, although there is considerable scatter in the data. We assume that the stable zincblende phase is a solid solution lying in the InSb-InTe section and conclude that the solubility of InTe in InSb is less than 5 mole % at 475°C. It seems reasonable to assume that under equilibrium conditions melts

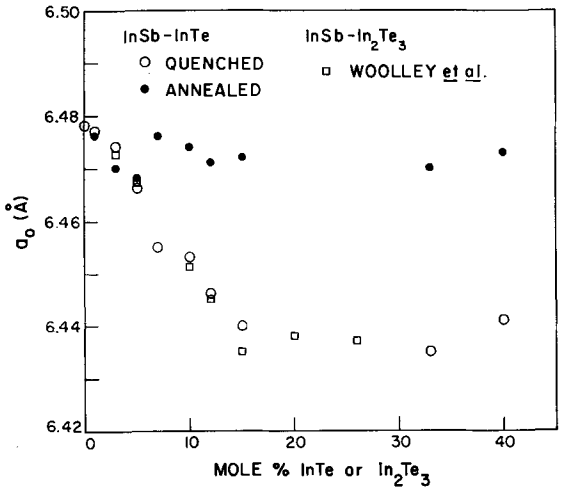

Fig. 4. Lattice parameter of the zincblende phase in InSb-InTe samples quenched from the melt or annealed at 475°C, as a function of over-all sample composition. The data of Woolley, Gillett, and Evans for the zincblende phase in InSb-In_2Te_3 samples annealed at 500°C are also included.

containing up to 15 mole % InTe coexist at the liquidus line with InSb-InTe solid solutions, rather than with the InSb-In_2Te_3 solutions obtained when such melts are solidified during cooling runs or by quenching. No attempt has been made to determine the stable liquidus in this composition region by means of heating runs on annealed samples. However, the stable liquidus probably does not differ much from the dotted line shown in Fig. 1, since the temperature range between the melting point of InSb and InSb-InTe eutectic temperature is only 17°C.

On the basis of the thermal arrests which occurred in cooling runs on initially molten samples, we have adopted 508°C as the eutectic temperature for the InSb-InTe system. In good agreement with this value, a thermal arrest was observed at 507°-509°C in a heating run on a Bridgman-grown sample of In_3SbTe_2.

A peritectic temperature of 553°-554°C for the InSb-InTe system is indicated by the results of our cooling runs on initially molten samples. We have adopted 556°C as the peritectic temperature, however, because the peritectic arrest occurred at 558°C in the heating run on the Bridgman-grown sample of In_3SbTe_2. In good agreement with the latter value, Molodyan, Radautsan, and Madan (7) observed arrests at 558°-560°C, 557°-561°C, and 558°-560°C, respectively, in heating runs on samples solidified from melts containing 50, 75, and 80 mole % InTe. [Molodyan *et al.* (7) did not identify these as peritectic arrests.]

The eutectic and peritectic temperatures reported by Deneke and Rabenau (8) are 512° and 568°C, respectively. Both values are significantly higher than the present ones. The stable liquidus temperatures obtained by Deneke and Rabenau [as read off Fig. 1 of ref. (8)] are also higher than the present values. For a number of compositions the difference is about 15°C, and in some cases it exceeds 20°C. We have not found a satisfactory explanation for these discrepancies. For compositions exceeding 55 mole % InTe, the present stable liquidus temperatures may be lower than the true values because considerable supercooling (15°-40°C) occurred before the initial crystallization of InTe. Although Deneke and Rabenau (8) do not report the amount of supercooling which occurred in their experiments, it was probably less than in the present experiments, since as discussed below they never observed freezing according to the unstable diagram. In the present cooling runs on samples containing 55 mole % InTe or less, the amount of supercooling ranged from 1° to 11°C and was probably insufficient to cause significant errors in the stable liq-

uidus temperatures. It is also unlikely that supercooling caused significant errors in the present peritectic or eutectic temperatures. At the peritectic point, the amount of supercooling was 15°C in one case, 11°C in another, and less than 9°C in all the rest. At the eutectic point, the amount of supercooling was always less than 5°C, and in most cases a constant temperature plateau was observed.

Composition and temperature stability of In_3SbTe_2. —In earlier reports (9) on the InSb-InTe system, we stated that x-ray diffraction data on samples annealed at 475°C established upper and lower limits of 80 and 70 mole % InTe, respectively, for the homogeneity range of the ternary In-Sb-Te compound, although these data did not fix the exact positions of the solidus lines. We therefore accepted the nominal formula In_4SbTe_3, which had been adopted for the compound by Goryunova *et al.* (3) and by Molodyan *et al.* (7) primarily on the basis of data for samples frozen from the melt. We later learned, however, that on the basis of x-ray and metallographic data for samples annealed at 440°-500°C Deneke and Rabenau (8) had reported the formula to be In_3SbTe_2 rather than In_4SbTe_3. We therefore re-examined our x-ray diffraction patterns for annealed samples containing 60-80 mole % InTe and examined these samples metallographically. We also made x-ray and metallographic studies on additional samples in this composition range annealed at 475°C. The results obtained for samples containing between 40 and 90 mole % InTe are shown in Fig. 5, where the room temperature lattice parameter (a_o) of the ternary compound is plotted against sample composition determined by chemical analysis, and the phases detected in each sample are indicated. In agreement with Deneke and Rabenau (8), the data show that at 475°C the ternary compound contains less than 70 mole % InTe and therefore cannot have the formula In_4SbTe_3. (Metallographic examination clearly reveals the presence of InTe as a second phase in samples containing close to 70 mole % InTe, although lines due to InTe cannot be detected in the x-ray diffraction patterns for these samples.) The data are consistent with the nominal formula In_3SbTe_2 given by Deneke and Rabenau (8), since no second phase was detected metallographically in the samples containing 64 and 68 mole % InTe. According to these results, the homogeneity range of In_3SbTe_2 is somewhat wider than reported by Deneke and Rabenau (8), who state that it is less than 2 mole % wide. The values of a_o for In_3SbTe_2 in two-phase mixtures containing InSb and InTe are 6.125 ± 0.001Å and 6.133 ± 0.003Å, respectively. This difference in a_o

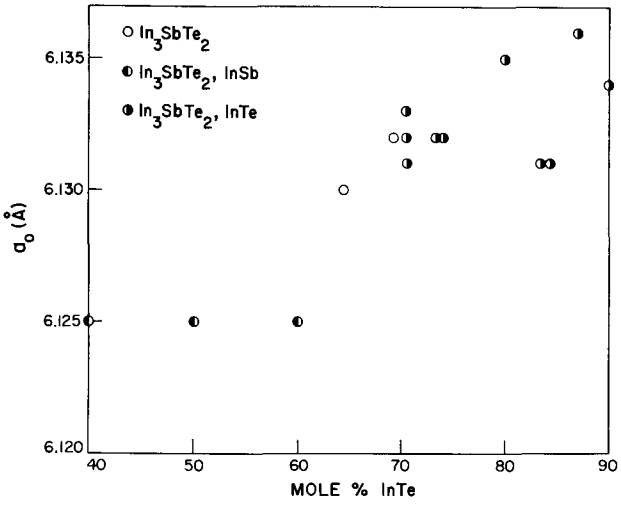

Fig. 5. Lattice parameter of the ternary compound in InSb-InTe samples annealed at 475°C, as a function of over-all sample composition. The phases detected in each sample are also indicated.

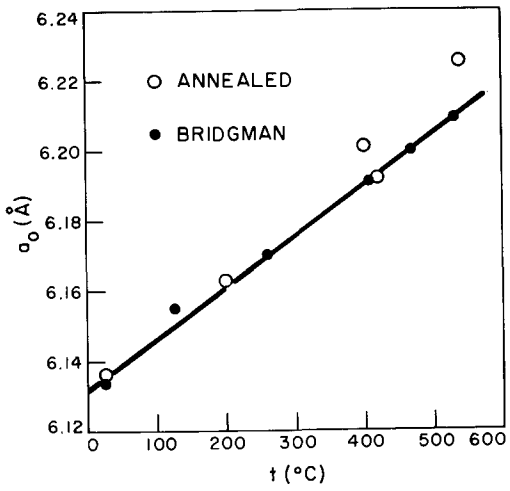

Fig. 6. Lattice parameter for two samples of In_3SbTe_2 as a function of temperature. (Both samples contained a small quantity of InTe as a second phase.)

values is evidence that In_3SbTe_2 has an appreciable homogeneity range at 475°C, although no quantitative estimate of the width of the range can be made from the a_o data. Deneke and Rabenau (8) report a_o = 6.1263 ± 0.0007Å for single-phase In_3SbTe_2. They do not give a_o values for In_3SbTe_2 in two-phase mixtures.

The temperature dependence of a_o between room temperature and 540°C was determined by x-ray diffraction measurements on two samples of In_3SbTe_2, one annealed at 475°C and the other prepared by the horizontal Bridgman technique. The data for these samples, which are plotted in Fig. 6, show that a_o increases linearly with temperature over the whole range. The linear expansion coefficient calculated from these data is 2.4 x 10^{-5} deg^{-1}, in good agreement with the value of 2 x 10^{-5} deg^{-1} obtained by Molodyan *et al.* (7) from lattice parameter data between room temperature and 500°C.

After the present investigation was almost complete, Woolley (12) informed us of his observation that In_3SbTe_2 slowly decomposes into InSb and InTe below about 400°C. Later we learned that Deneke and Rabenau (8) had observed the decomposition of In_3SbTe_2 at 300° and 400°C. We subsequently studied the decomposition of In_3SbTe_2 at 400°C with a high temperature x-ray camera. No lines due to InSb or InTe appeared within the first 24 hr. (This explains why the decomposition of In_3SbTe_2 was not observed in our measurements of a_o as a function of temperature, since each x-ray exposure required only 12-18 hr.) After 2 or 3 days, however, the lines due to In_3SbTe_2 had entirely disappeared, and only lines due to InSb and InTe were present.

In drawing their phase diagram for the InSb-InTe system, Deneke and Rabenau (8) adopted 420°C as the most likely value for the minimum temperature at which In_3SbTe_2 is stable, but they indicated the phase boundary by a broken line, since its exact temperature is unknown. The same procedure has been followed in Fig. 1. The choice of 420°C suggests that partial decomposition of In_3SbTe_2 could be the cause of the small thermal arrest observed close to this temperature in the cooling run on almost every sample containing between 20 and 70 mole % InTe, whether or not it froze according to the stable phase diagram. (Both sets of thermal analysis data in Fig. 2 include arrests of this kind.) This explanation is consistent with the slow rate of decomposition observed at 400°C if it is assumed that the decomposition rate is strongly temperature dependent. In that case, the rate in the immediate vicinity of the phase boundary could be high enough to result in a thermal arrest on cooling, but lowering the temperature only a few degrees

would reduce the rate so much that no further thermal effects could be detected.

Unstable phase diagram.—In addition to the stable phase diagram, Fig. 1 includes the liquidus and solidus of an unstable diagram. This unstable diagram has been constructed in order to explain the results of the cooling runs on about half the InSb-InTe samples containing between 40 and 75 mole % InTe. Typical results for one of these runs are shown in Fig. 2(b), which gives the thermal analysis data obtained for a sample (No. 25) containing 57.5 mole % InTe. Only two principal thermal arrests are observed: one at the unstable liquidus temperature, which lies below the stable liquidus line, and the other at the InSb-In_3SbTe_2 eutectic temperature. There is no arrest at the peritectic temperature. A small arrest is observed at about 420°C, as discussed previously. The pattern of these data is obviously different from the pattern of those in Fig. 2(a), obtained for a sample (No. 27) of the same composition which froze according to the stable diagram. On the other hand, the pattern in Fig. 2(b) is closely similar to the one found for samples containing between 15 and 40 mole % InTe. It was this similarity which first suggested the existence of the unstable liquidus, which is simply an extension to higher InTe compositions of the portion of the stable liquidus between 15 and 40 mole % InTe.

According to the unstable phase diagram, the ternary InSb-InTe compound begins to crystallize as the primary phase at the unstable liquidus temperature, while InTe does not crystallize from the melt at all. This interpretation of the thermal analysis data has been confirmed by the results of metallographic and x-ray studies on solidified thermal analysis samples. These studies show that little if any of an InTe phase is present in samples which did not exhibit a peritectic arrest during cooling. Figure 3(b) is a photomicrograph of the polished surface of such a sample, the same one (No. 25) containing 57.5 mole % InTe for which thermal analysis data are given in Fig. 2(b). As expected, the ternary compound and eutectic phase are present, but not InTe. In contrast, Fig. 3(a) shows that large quantities of InTe are present in a sample containing 55 mole % InTe which froze according to the stable diagram.

In Fig. 1 the unstable liquidus temperature is shown as increasing monotonically to 586°C as the InTe content increases to 75 mole % InTe, the highest value for which primary crystallization of the ternary compound was observed. The shape of the liquidus between 66 and 75 mole % InTe is uncertain, since no data points were obtained between these two compositions. Accordingly, this portion of the liquidus is represented by a dot-dashed line in Fig. 1. It seems almost certain, however, that there is no maximum close to 67 mole % InTe. Such a maximum would be expected if the ternary compound crystallizing along the unstable liquidus had a composition approximating In_3SbTe_2, the formula adopted for samples annealed below the eutectic temperature. Furthermore, in cooling runs on samples which froze according to the unstable diagram, prominent eutectic arrests were observed for 65 and 66 mole % InTe. On the other hand, only a single arrest at 586°C occurred for a sample (No. 40) containing 75 mole % InTe. In addition, the lattice parameter of the ternary compound in sample No. 40 was 6.142 ± 0.003Å, significantly higher than the value of 6.133 ± 0.003Å for the ternary compound in annealed samples containing InTe as a second phase. (Metallographic examination of sample No. 40 revealed traces of both InSb and InTe in addition to the ternary compound.) These observations indicate that the ternary compound contains significantly more than 67 mole % InTe, and probably as much as 75 mole % InTe, when it crystallizes from melts at temperatures sufficiently far above the peritectic temperature. For samples crystallized close to 586°C, therefore, the formula In_4SbTe_3 appears to be more appropriate than In_3SbTe_2. The solidus is shown in Fig. 1 as a dot-dashed line joining the unstable liquidus at 75 mole % InTe with the stable solidus at the peritectic temperature.

In order for an InSb-InTe melt to freeze according to the unstable diagram, it must be supercooled below the stable liquidus by an amount equal to the difference between the stable and unstable liquidus temperatures plus the amount of supercooling required to nucleate crystallization of the ternary compound. In the present investigation, for those runs in which freezing occurred according to the unstable diagram, the amount of supercooling averaged 21°C below the stable liquidus and 7°C below the unstable liquidus. In about half the cooling runs for samples containing between 40 and 75 mole % InTe, the experimental conditions did not permit sufficient supercooling, and the samples froze according to the stable diagram. Apparently, the conditions employed by Deneke and Rabenau (8) were even less favorable for supercooling, since the thermal analysis data of these authors show that freezing according to the unstable diagram did not occur in any of their cooling runs. Consequently they did not discover the existence of this diagram.

Freezing according to the unstable diagram did occur in the experiments of Goryunova, Radautsan, and Kiosse (3), who reported on the basis of x-ray diffraction data that they obtained the ternary compound as a single phase by slow cooling of a melt containing 75 mole % InTe. If this melt had frozen according to the stable diagram, three phases would have been obvious in the solidified sample. These authors had no reason to suspect the existence of an unstable diagram on the basis of their observations. Therefore they assumed that the ternary compound had crystallized as a stable phase, which they identified as In_4SbTe_3.

Freezing according to the unstable diagram also occurred in several experiments performed by Molodyan, Radautsan, and Madan (7), although these authors still failed to realize the existence of this diagram. They too reported that they obtained single-phase samples of the ternary compound by cooling melts containing 75 mole % InTe at a slow rate (15°-20°C/hr). In addition, they report thermal analysis data which show that freezing according to the unstable diagram occurred in cooling runs on melts containing 50 and 75 mole % InTe. For the former composition, arrests occurred at 567° and 503°C, in excellent agreement with the present values of 566° and 505°C, respectively, for a sample (No. 10) with this composition. For the latter composition, a single arrest was observed at 586°C, just as in the present run on sample No. 40. Molodyan *et al.* (7) regarded this observation as confirming the identification of the ternary compound as In_4SbTe_3, and they adopted 586°C as the melting point of the compound.

Molodyan *et al.* (7) also reported thermal analysis and x-ray data which were obviously inconsistent with a simple phase diagram containing In_4SbTe_3 as a congruently melting compound. These data, which they could not interpret satisfactorily, can be explained in detail on the basis of the stable diagram for the InSb-InTe system. For example, they observed three thermal arrests, at 637°, 530°, and 496°C, in a cooling run on a sample containing 80 mole % InTe. These are the characteristic liquidus, peritectic, and eutectic arrests for a sample freezing according to the stable diagram. The liquidus and eutectic temperatures agree satisfactorily with the present values for this composition, but the peritectic temperature is about 20°C lower than the present one. They also observed that InSb, InTe, and the ternary compound were all present in a sample prepared by rapidly cooling a melt containing 75 mole % InTe. In this case, freezing must have occurred according to the stable diagram.

Table II. Electrical properties of samples containing In_3SbTe_2

Sample	Phases	Analysis (Mole % InTe)	T (°K)	ρ (ohm-cm)	R_H (cm^3 $coul^{-1}$)	$n = 1/R_H e$ (cm^{-3})	$R_H\sigma$ (cm^2 v^{-1} sec^{-1})

			77	3.0×10^{-5}	—	—	—

Superconductivity and electrical properties of In_3SbTe_2.—As discussed at the beginning of this paper, we originally wished to prepare In_3SbTe_2 in order to determine whether it was a superconductor, a possibility suggested by its similarity in structure to InTe(II), the superconducting form of InTe prepared under high pressure. Accordingly, a number of annealed samples prepared during the phase diagram investigation, all of which contained one or two minor phases in addition to In_3SbTe_2, were checked for superconductivity by a self-inductance technique (13). None of these samples became superconducting down to 1.3°K, the lowest temperature which could be attained with the apparatus. Subsequently, however, In_3SbTe_2 was found to be a superconductor by Rabenau, Deneke, and van der Meij (14), who were able to make measurements at lower temperatures. These authors, who had independently noted the similarity between In_3SbTe_2 and InTe(II), observed a superconducting transition at 1.06°K.

Table II gives the results of electrical resistivity (ρ) and Hall coefficient (R_H) measurements on four samples containing In_3SbTe_2. The most significant data are those for the single-phase samples 67 and 69, which were cut from annealed ingots with nominal compositions of 67 and 69 mole % InTe, respectively. Sample HA2-1 was also cut from an annealed ingot (nominal composition 75 mole % InTe), and sample H-3 was taken from an ingot prepared by the horizontal Bridgman technique. In each case the values of ρ and R_H are very low, and ρ decreases with decreasing temperature. Thus all four samples exhibit metallic behavior, although it cannot be determined from the data whether In_3SbTe_2 is a metal or a semiconductor with very high carrier concentrations. For samples 67, 69, and H-3, at room temperature ρ is about 5×10^{-5} ohm-cm, more than an order of magnitude lower than the value of 7×10^{-4} ohm-cm reported for In_3SbTe_2 by Deneke, Rabenau, and van der Meij (14).

Table II gives carrier concentrations calculated from the measured R_H values according to the one-carrier expression $n = 1/R_H e$. Although it has not been established that this expression is valid for In_3SbTe_2, it is of interest that the concentrations listed for the single-phase samples 67 and 69 are in good agreement with those expected on the basis of the ionic model proposed by Geller and Hull (15) for high pressure InTe(II) and similar materials. According to this model, such materials exhibit metallic behavior because they contain both In^{+1} and In^{+3} ions, and electrons are easily transferred from one type of In ion to the other. The free electron concentration is equal to twice the concentration of In^{+1} ions. Therefore, the electron concentrations predicted for $InSb_{0.32}Te_{0.68}$ and $InSb_{0.30}Te_{0.70}$ are 1.18×10^{22} and 1.21×10^{22} cm^{-3}, respectively, in comparison with the values of 1.1×10^{22} and 1.3×10^{22} cm^{-3} given in Table II for samples 67 and 69, respectively.

Acknowledgments

It is a pleasure to acknowledge the valuable assistance of R. L. MacLean, who performed almost all the thermal analysis experiments, and of M. Jane Button, J. C. Cornwell, Lynne B. Farrell, Muriel C. Plonko, T. E. Stack, and G. E. Wheatley, who participated in various phases of the experimental work. We are grateful to Professor J. C. Woolley, for communicating his results prior to publication and for a number of helpful discussions, and to Dr. A. Rabenau, for calling our attention to his investigations of the InSb-InTe system.

Manuscript received Oct. 21, 1965; revised manuscript received Jan. 24, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Alloys of InSb with InTe, In_2Te_3 and Tellurium

J. C. Woolley

Department of Physics, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Standard x-ray powder photograph techniques have been used to investigate the phases occurring in the InSb rich regions of the InSb-InTe, InSb-In_2Te_3, and InSb-Te sections of the In-Sb-Te diagram and also in some general ternary alloys of the system. It is found that only the InSb-InTe section is pseudobinary and that in the other two sections three-phase conditions occur. An isothermal section shows that the InSb phase observed is practically identical for all three sections investigated, and that the very narrow InSb single-phase field lies between the InSb-InTe and InSb-In_2Te_3 sections. This accounts for the similarities in the electrical and optical data reported for the InSb-rich regions of the three sections.

It is also confirmed that the sodium chloride type phase which occurs in the diagram is at In_3SbTe_2 and that this phase disappears by a eutectoid reaction in the temperature range 400°-500°C.

Various sections of the In-Sb-Te phase diagram involving InSb have been investigated to some extent (1-5), mainly with reference to the semiconducting properties of the InSb phase. Thus the InSb-rich region of the InSb-Te section is of interest from the point of view of doping of InSb, while the InSb-In_2Te_3 and InSb-InTe sections have received attention from the alloy semiconductor viewpoint. Both the InSb-In_2Te_3 and InSb-InTe sections have usually been treated as pseudobinary in behavior.

The InSb-In_2Te_3 section is of interest in that both InSb and In_2Te_3 have a zincblende structure, that of In_2Te_3 being of the defect type where every third site on the indium sublattice is vacant. (Although the lattice vacancies in In_2Te_3 can be caused to order at temperatures below approximately 600°C, this ordering requires very long annealing or special preparation techniques. For preparations by the quench-anneal method used below, the In_2Te_3 can be assumed to be in the disordered state.) Thus a considerable range of single-phase solid solution might be expected. In the initial work (4) on the InSb-In_2Te_3 section, it was reported that single-phase solid solution occurred out to 15 mole % In_2Te_3 in In_3Sb_3, while at compositions beyond the range of single-phase InSb solid solution a phase with rock-salt structure was observed, but not identified. Later work (1-3) however showed that this phase was in fact a ternary compound in the InSb-InTe section, with a composition of either In_4SbTe_3 (1) or In_3SbTe_2 (2, 3). The occurrence of this phase in the equilibrium alloys of the InSb-In_2Te_3 section shows that this section cannot have pseudobinary properties. This conclusion is reinforced by the semiconducting properties of the InSb rich alloys of the InSb-In_2Te_3 section (6, 7) where the high total electron concentration ($>10^{19}$/cc) indicates the presence of uncompensated ionized tellurium atoms. This can be explained only in terms of the absence of the stoichiometric concentration of lattice vacancies which is equivalent to saying that the equilibrium phase is not represented by a point in the InSb-In_2Te_3 section, and that the apparent single-phase alloys reported previously (4) do in fact contain a small amount of second phase.

From the point of view of the behavior of InSb and its alloys, it is of interest to have more information on this region of the In-Sb-Te diagram. Also, the rock-salt phase has been shown to have superconducting properties (8) so that further information in this part of the diagram also is of interest. The work of Strauss *et al.* (9), carried out at the same time as the present work, considers in detail the vertical section InSb-InTe. It is confirmed that the rock-salt compound has the composition In_3SbTe_2 and that it is stable over only a limited temperature range. In the present work, x-ray methods have been used to obtain data on isothermal sections of the In-Sb-Te diagram, one at a temperature where In_3SbTe_2 is stable and one at a temperature below that at which In_3SbTe_2 undergoes a eutectoid change.

Experimental Procedure

All specimens were prepared from elements of 99.999% purity. In some cases, the alloys were made from the appropriate compounds InSb, InTe, In_2Te_3, while in others they were prepared directly from the elements. No difference in results was observed for the two methods of preparation. The samples were sealed in evacuated quartz tubes, held molten and agitated to give thorough mixing, and then quenched in water. Each sample was then annealed at an appropriate temperature so that equilibrium could be attained, as indicated by x-ray powder photographs. As mentioned below, at temperatures below the eutectoid temperature of the rock-salt compound, considerable difficulty was experienced in bringing samples to equilibrium even though the annealing was carried out for two or three weeks.

Results

The majority of the alloys considered lay on one of the sections InSb-Te, InSb-In_2Te_3, or InSb-InTe, although a few general ternary alloys were also investigated. All alloys investigated are indicated either on Fig. 1 or Fig. 2. The annealing temperatures used were 470°, 430°, 400°, and 350°C.

For all alloys where appropriate, the lattice parameter a_0 of the zincblende phase was determined and the variations of a_0 with composition in the InSb-In_2Te_3 and InSb-Te sections are shown in Fig. 1. This data for the InSb-In_2Te_3 sections [Fig. 1(a)] had been obtained previously (4), and additional points confirmed the apparent pseudobinary form with a

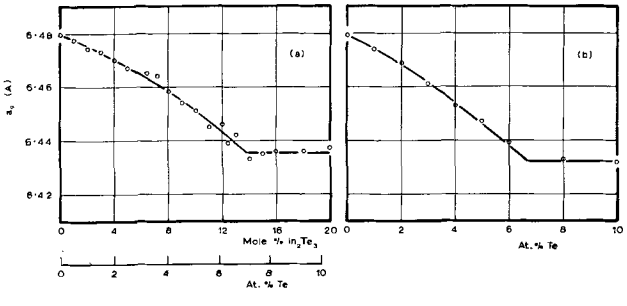

Fig. 1. Variation of lattice parameter a_0 of InSb phase as a function of composition. (a) InSb-In_2Te_3 section. (b) InSb-Te section.

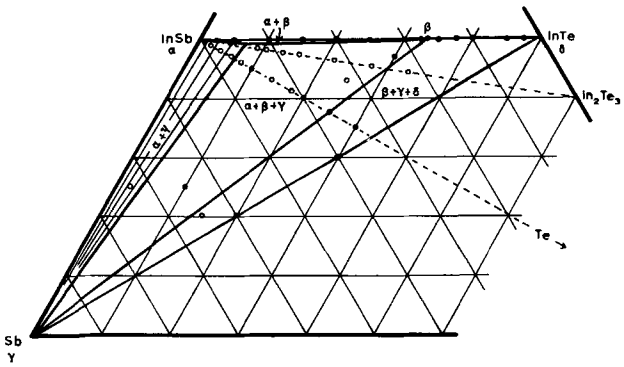

Fig. 2. Diagram showing 470°C isothermal section

range of solid solution of 14 mole % In_2Te_3 in In_3Sb_3, *i.e.*, slightly more than 7 a/o (atomic per cent) Te. The value of a_0 at larger tellurium content was determined for various annealing temperatures, but although the points show some scatter, no systematic variation with temperature could be determined. The results for InSb-Te in Fig. 1(b) are seen to be very similar, giving an apparent range of single-phase solid solution of a little below 7 a/o tellurium.

Study of the x-ray photographs for samples of higher tellurium content on these sections revealed the presence of lines corresponding to antimony, and a photomicrograph of an alloy containing 4 a/o tellurium showed the presence of a second phase, presumably antimony. Investigation of alloys of higher antimony content showed that the isothermal section at 470°C is as given in Fig. 2. The vertical sections InSb-In_2Te_3 and InSb-Te intersect this isothermal section first in a two-phase field InSb(α) + Sb(γ) and then in a three-phase field (α + β + γ) where β is the rock-salt phase. Thus the two parts of the a_0 against composition graphs in Fig. 1 correspond to the zincblende parameters in these two fields. The apparent limits of solid solution in atomic per cent tellurium, quoted above for the two vertical sections, determine the position of the three-phase field boundary and hence indicate the range of the single-phase α field. The exact position of the α field was not determined by x-ray methods, but it is clear from the electrical data on InSb-In_2Te_3 and InSb-InTe alloys (7) that this single-phase region must lie between these two sections as indicated in Fig. 2. From this data it is also seen that the range of single-phase α in the InSb-In_2Te_3 and InSb-Te sections must be very small.

In the InSb-InTe section, the variation in zincblende lattice parameter for the annealed samples was found to be very small, so that an accurate estimate of the limits of solid solution could not be made, but this would appear to be approximately 5 mole % InTe, in agreement with the data of Strauss *et al.* (9). In the two phase region (α + β), the tie lines lie in the plane of the section, this being the limit of a narrow two phase (α + β) field of the isothermal section as shown in Fig. 2. Because of the narrowness in this two-phase field, a very small deficiency in indium would result in a quite different value for the range of solid solution in the zincblende α phase. This could explain the results of Goryunova *et al.* (1), giving a limit of solid solution of 15 mole % InTe in InSb.

Other work (2, 3, 9) has shown that the rock-salt phase β definitely occurs on the InSb-InTe section, and the data obtained here agree with this result. A study of the x-ray photographs showed that two-phase behavior was shown by almost all samples in the range 60-80 mole % InTe, and the β phase appears to be a line phase with a composition close to In_3SbTe_2 and not In_4SbTe_3.

The range of solid solution in InTe was not investigated in detail, but this was observed to be small and less than 5 mole % as indicated by Strauss *et al.* (9). In Fig. 2, the In_3SbTe_2-InTe line forms the limit of a second three-phase field (β + γ + δ) where the δ phase is very close to InTe.

Alloys were annealed at 400° and 350°C in order to determine the equilibrium conditions at temperatures below the range of stability of the rock-salt phase. Difficulties were experienced in obtaining consistent data from the various alloy samples, in that in many cases the x-ray lines corresponding to the rock-salt phase was still observed even after one or two weeks annealing. In most cases however the appearance of InSb or InTe lines (as appropriate) indicated that the rock-salt phase was slowly decomposing into InSb and InTe phases. Although the rock-salt phase was never completely lost, the equilibrium condition at 400° and 350°C could be determined. Thus the two three-phase fields (α + β + γ) and (β + γ + δ) shown in Fig. 2 combine at lower temperatures to give one three-phase (α + γ + δ) field, and the extent of the two-phase (α + γ) and the single-phase α fields are practically unaffected.

Conclusions

The form of equilibrium diagram obtained here explains the similarities in the lattice parameter, electrical and optical data reported for the alloy systems InSb-Te, InSb-In_2Te_3, and InSb-InTe. In the case of InSb-Te and InSb-In_2Te_3 alloys, the zincblende phase observed in the apparent single-phase region is the same for both cases, the difference being only in the amount of antimony second phase present. For concentrations of tellurium of a few atomic per cent, this antimony will have practically no effect on the observed values of energy gap, Hall coefficient, etc. With the single-phase α field being very narrow, as shown in Fig. 2, similar alloys on or close to the InSb-InTe section will consist of the same zincblende phase with a small amount of second phase present and so again will give data similar to that for alloys on the other two sections.

Since alloys on the InSb-Te and InSb-In_2Te_3 sections give the same equilibrium phases, In_2Te_3 can be used for doping InSb. This use of In_2Te_3 can have the advantage that when very heavy doping is required, less second-phase antimony is produced.

Acknowledgments

The author wishes to thank Mr. P. J. Montford-Azmier for assistance in the preparation and x-raying of specimens, and Dr. E. W. Williams for a photomicrograph. He is also grateful to Dr. A. J. Strauss and Dr. M. D. Banus of Lincoln Laboratory, Massachusetts Institute of Technology, for useful discussions.

Vapor Growth of AlP Single Crystals

F. J. Reid, S. E. Miller, and H. L. Goering

Columbus Laboratories, Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Single crystal AlP layers up to 0.1 cm thick and 2 cm in diameter have been grown onto silicon and GaAs substrates by using an open-tube vapor-transport technique. Iodine was found to be more satisfactory than chlorine for transporting aluminum at moderately low temperatures (source at 1100°C; substrate at 900°C). It was essential that the phosphorus vapor be introduced downstream from the aluminum source to prevent the formation of AlP at the source and the eventual retardation of the transport process. The as-grown layers are invariably n-type containing greater than 1 x 10^{18} donors/cm^3. Characteristics of n-p, AlP-Si heterojunctions were obtained and are discussed.

The III-V compound semiconductor aluminum phosphide, AlP, has received very little attention in the past (1), while others of this family, such as GaAs and InSb, have been studied extensively and characterized reasonably well. This situation is understandable when it is considered that AlP is a high-band-gap (2.5-3 ev) semiconductor with a melting point > 2000°C and a dissociation pressure of tens of atmospheres at its melting point. However, since AlP is a compound which is isoelectronic with the most useful of the group IV elemental semiconductors, silicon, studies of its properties would be of value in extending existing knowledge in solid-state science, and the material could prove to be of substantial practical importance. Other III-V compounds, which are isoelectronic to the semiconducting group IV elements, are GaAs and InSb, two compounds which are by far the most interesting and potentially useful of the family in their band-gap ranges.

One of the advantages realized in vapor phase growth of III-V compounds is that crystal growth occurs at temperatures and pressures well below the respective melting point and dissociation pressure of the compound at the melting temperature. The lower growth temperature makes it possible to employ substrates of lower melting compounds or elements, which is also a distinct advantage in the epitaxial growth of AlP. In addition interesting heterojunctions are formed by this technique. An important feature of vapor phase growth, which is sometimes overlooked, is the possibility of growing relatively large volume single crystals that can be removed from a substrate and treated as a bulk crystal. The scope of this paper is directed toward these two points, *i.e.*, the growth of bulk crystals of AlP by a vapor phase growth technique and the growth of semiconductor heterojunctions.

Experimental

The vapor phase process for obtaining AlP involves reacting liquid aluminum with a halogen, preferably iodine, to produce volatile aluminum halides. The various vapors are transported through an open-tube flow system by maintaining a constant flow of hydrogen as a carrier gas. The aluminum halides are carried downstream and mixed with phosphorus vapor in a vapor growth chamber, containing a silicon or a GaAs substrate. In this chamber, free aluminum is released through a disproportionation type of reaction and is available to react with the phosphorus to form AlP as an epitaxial layer on the substrate. An important feature of this technique is that the phosphorus vapor does not contact the liquid aluminum source. If this feature is not provided, a coherent layer of AlP forms over the aluminum, which impedes and eventually stops the reaction of aluminum with the halogen.

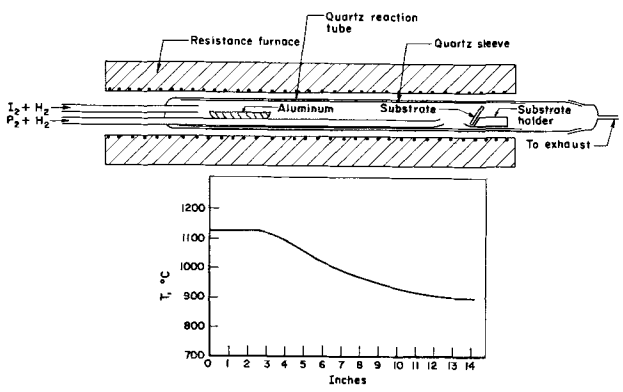

Fig. 1. Vapor growth apparatus

The vapor phase growth apparatus shown in Fig. 1 consists of a quartz tube (40 mm OD, 34 mm ID) about 3 ft long. The aluminum source (5-9's pure) is contained in an alumina boat positioned about midway along the length of the quartz tube. Iodine vapors are admitted to the reaction chamber by directing a stream of hydrogen (passed through palladium) over about 50g of triply sublimed iodine crystals contained in a U-shaped tube attached to the large quartz tube. The quantity of iodine which is carried into the system is determined by the temperature of the iodine and the flow rate of the hydrogen gas. Phosphorus vapors are added in a similar manner, but these vapors are introduced into the quartz tube downstream of the aluminum and immediately upstream of the substrate. Approximately 10g of high-purity white phosphorus makes up the phosphorus source.

The reactions at the aluminum source, which is maintained at about 1130°C, appear to involve at least the two competing reactions

$$Al + 1/2\ I_2 = AlI \qquad [1]$$

and

$$Al + 3/2\ I_2 = AlI_3 \qquad [2]$$

The disproportionation reaction of interest in the vapor growth chamber is therefore,

$$3AlI \rightleftharpoons 2Al + AlI_3 \qquad [3]$$

and finally the free aluminum reacts with phosphorus to form AlP.

During a typical experiment, hydrogen flows through the iodine reservoir at about 1000 cc/min and through the phosphorus reservoir at about 25 cc/min. When the iodine source is maintained at about 45°C, iodine flows into the system at a rate of about 1.3 g/hr. When the phosphorus source is maintained at about 230°C, the phosphorus flows into the system at a rate of about 0.16 g/hr. The aluminum source is maintained at a temperature of about 1130°C, and aluminum is introduced into the vapor stream as aluminum iodide

compounds at a rate of about 0.17 g/hr. It is noted that if the iodine reacts completely with the aluminum source, the rate at which aluminum is transported as AlI is about 0.12 g/hr; the rest of the aluminum (0.05 g/hr) being transported as AlI_3. In addition, it is noted from reaction [3] that the maximum amount of free aluminum which can be produced in the vapor growth chamber by a disproportionation type reaction is 2/3 of the amount of aluminum present as AlI or at a rate of 0.08 g/hr. Therefore under these conditions, the phosphorus is in excess of the amount of free aluminum available in the vapor growth chamber. Hence, as AlP is formed and grown on the chemically polished silicon or GaAs substrate, which is maintained at about 900°C, all the free aluminum can be consumed to form AlP with the excess phosphorus being carried away in the vapor stream.

Results

Preparation.—In the manner described, single crystal layers of AlP as thick as 1000μ have been grown during a 24-hr run. The layers were grown on 2-cm diameter silicon substrates oriented such that a {111} crystallographic plane was exposed. It is noted that silicon is an excellent choice for a seed material since it has the same crystal structure and almost exactly the same atom spacing as AlP. It has also been possible to deposit layers of AlP on GaAs substrates by the procedure given above.

By contrast, if the phosphorus vapor is introduced upstream of the aluminum source, essentially no AlP forms in the vapor growth chamber under similar conditions. Instead the aluminum source is covered with a coherent layer of solid AlP which eventually precludes reaction of the incoming iodine with the aluminum. In a separate experiment, AlP crystals were used in place of the aluminum source and iodine passed over them at 1140°C. No AlP was transported during a 5-hr run. Hence, it is essential to keep phosphorus vapors away from the aluminum source in order to achieve a continuous preparation process at moderate temperatures, which will yield relatively thick layers of AlP epitaxially grown on a substrate. Another advantage in delaying the mixing of the aluminum halides and the phosphorus vapors until they reach the vapor growth chamber is that direct reactions of phosphorus with the aluminum halides are suppressed, thus eliminating an uncontrolled production of AlP over a relatively wide temperature range.

Investigations were made using chlorine, introduced as HCl or $AlCl_3$, instead of iodine as the halogen. The aluminum source was maintained at temperatures as high as 1200°C with no apparent formation of AlP in the vapor growth system. This is not surprising if one considers the thermochemical data available (2) for the aluminum chlorides and the aluminum iodides as shown in Fig. 2. For equal mole fractions of chlorine, reaction [2] is favored over reaction [1] until a temperature in excess of about 1280°C is reached. In the case of the aluminum iodides, reaction [1] is favored at temperatures in excess of about 1080°C. In order to grow AlP using a chlorine transport, aluminum source temperatures in excess of 1300°C would be required. A liner would be necessary to prevent deterioration of the quartz tube by attack from reaction products. This was seen to be a problem even at 1200°C for the chlorine case and, to a lesser extent, at 1130°C for the iodine case. A quartz liner is sufficient to prevent breakage; however, a high-purity alumina liner would be better from the standpoint of eliminating silicon contamination from the quartz.

Figure 3 shows the consumption of aluminum at the source as a function of iodine flow rate. The aluminum source temperature was 1130°C, with a surface area of approximately 10 cm^2. The experimental data lie above the line representing complete reaction of the iodine via reaction [2]. Hence, some of

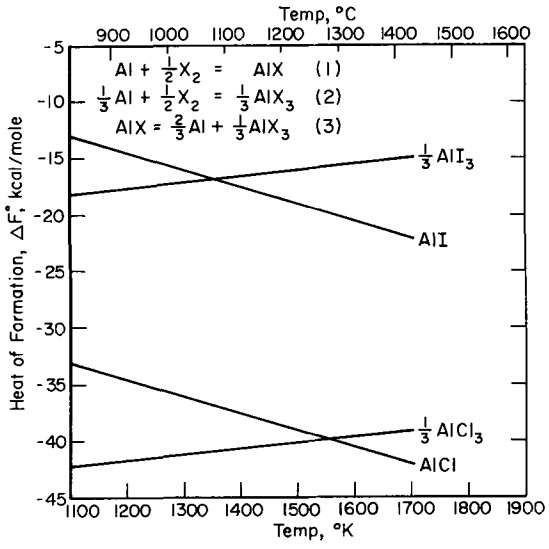

Fig. 2. Heats of formation of aluminum halides as functions of temperature.

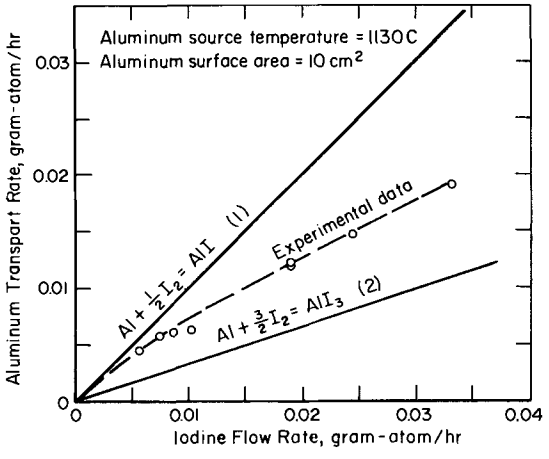

Fig. 3. Consumption of aluminum source as a function of iodine flow rate.

the aluminum must have been transported as an unstable intermediate, such as AlI or AlI_2. Actually the amount of aluminum transported is found to be greater than could be transported solely as AlI_2. On the other hand, the amount of aluminum transported is less than would have been consumed in complete reaction of the iodine via reaction [1], suggesting that the iodine had not completely reacted and/or formation of AlI_3 and possibly AlI_2 occurred at the aluminum source. At the larger iodine flow rates, unreacted iodine was observed experimentally. However, at the smallest iodine flow rate of 5.7 x 10^{-3} gram-atm/hr nearly all the aluminum consumed was transported as AlI, and no evidence of free iodine was observed visually in the exhaust products.

Properties.—The single crystal layers of AlP are easily removed from the silicon or GaAs substrates by lapping away the substrate with a silicon carbide abrasive. It is observed that the rates at which AlP and silicon are abraded are approximately equal, which facilitates the removal of the silicon. After removal of the substrate, the AlP layers are found to be transparent, appearing greenish yellow in color. The surface of the AlP reacts with moist air to form a white film if exposed for any length of time. The AlP surface can be polished mechanically under kerosene and rinsed in a dry organic solvent. The resulting surface appears less susceptible to attack by moist air.

The results of d-c electrical measurements show that the AlP samples prepared to date are n-type,

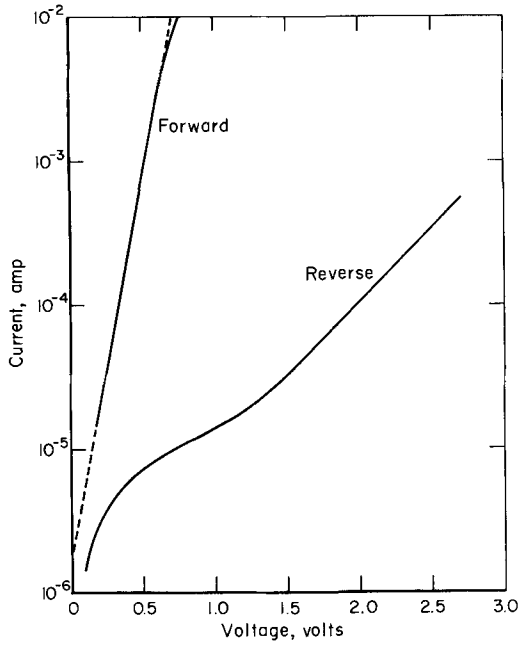

Fig. 4. Room temperature I-V characteristics of n-p, AlP-Si heterojunction.

exhibiting relatively low resistivities and containing relatively large concentrations of free carriers. The free carriers are believed to result from the incorporation of impurities during preparation, and one suspects that the silicon content may be large because the vapor growth was carried out in a quartz tube. However, the effects of carbon and oxygen as substitutional impurities should be considered because these elements may be expected to produce more pronounced effects in AlP than they apparently produce in lower-band-gap III-V compounds. Carrier concentrations obtained from Hall effect measurements have been in the range 5 x 10^{18} to 5 x 10^{19}/cm^3 with the highest electron mobility being about 60 cm^2/volt-sec at 300°K. The Hall coefficient is seen to be constant with temperature and the electron mobility increases with increasing temperature in the range 77°-300°K.

Heterojunctions formed at the AlP-Si interfaces have been examined and I-V characteristics obtained. Figure [4] shows the forward and reverse characteristics of an n-p, AlP-Si heterojunction. One ohm-cm silicon was used; hence both materials are heavily doped. The rectification ratio is about 100 and 1000 at 0.5 and 0.8v, respectively. The log I-V plot is linear for forward bias over an appreciable range, with current varying as exp ($qV/3.2\ kT$). The $\eta = 3.2$ value is too large to be indicative of only Schottky emission ($\eta = 1$). However, if one considers an energy band profile for the n-p AlP-Si structure, it is apparent that a barrier exists. Analysis of forward characteristics in the form

$$J = A^*T^2e^{-\psi/\eta kT}\ (e^{qV/\eta kT-1}) \qquad [4]$$

yields a value of the barrier ψ of about 2 ev, where $A^* = Am^*/m_o$ is the effective Richardson constant (3). When n-n AlP-Si heterojunctions were made with 0.01 ohm-cm n-type Si, no barrier was observed experimentally.

Summary

It has been demonstrated that large single crystals of AlP can be grown by a vapor phase growth technique. Iodine is seen to be superior to chlorine as a transporting agent, primarily from the standpoint of lower source-temperature requirements. Aluminum source temperatures as low as 1100°C have been used for long period continuous growth of AlP. To maintain such growth, it is necessary to prevent the phosphorus vapors from contacting the aluminum source. To make the AlP more attractive for further study of properties and applications, greater attention must be directed to the elimination of impurities.

Autodoping of Silicon Films Grown Epitaxially on Sapphire

D. J. Dumin and P. H. Robinson

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Doping by the substrate of silicon films grown epitaxially on sapphire (Al_2O_3) has been measured. Spectroscopic analysis of the silicon films has shown that aluminum is the major impurity. In films grown with $N_A = 10^{15}$/cc further processing below 1200°C introduces no additional doping from the substrate. The doping of the films by the sapphire becomes significant above 1250°C with the sapphire acting as a source of aluminum. The total number of aluminum atoms entering the silicon films is of the order of $1\text{-}2\cdot10^{15}$ resulting in a concentration of $2\cdot10^{18}$/cc in the silicon film. The mechanism responsible for the liberation of the aluminum from the sapphire has not been determined. A qualitative description of the changes in crystal structure on heat-treatment is given.

Recently silicon has been grown epitaxially on single-crystal sapphire (Al_2O_3) (1), and silicon-on-sapphire has been used in the fabrication of MOS transistors (2). The silicon used in these studies was grown by the pyrolysis of silane (SiH_4) and has been described in detail (3).

All films not purposely doped are p-type, and emission spectrographic analysis of the silicon indicates the major impurity to be aluminum. Substrate doping of silicon grown epitaxially on silicon has been studied (4) and attributed to normal diffusion of impurities from the silicon substrate. A series of ex-

periments has been performed to determine the extent of doping attributable to the sapphire substrate. Measurements of the diffusion constant and concentration of the dopant have been made which indicate that the sapphire acts as a limited source of aluminum. The aluminum is liberated from the sapphire and diffuses into the silicon during the epitaxial growth and during subsequent high temperature heat treatments. This source of aluminum will determine the upper temperature limit for device processing in silicon grown on sapphire.

Experimental Techniques

The silicon films were grown on polished heat-treated sapphire substrates having (0001) and ($1\bar{1}02$) orientations. Other orientations have been tried, and all results reported here appear to be independent of orientation. The silicon grown on sapphire has been single crystal as determined by x-ray Laue back-reflection patterns and electron diffraction patterns. Chemical etches (5) have revealed the dominant crystallographic imperfections to be low angle grain boundaries and stacking faults. The silicon grown from undoped silane is p-type with resistivity between 1 and 100 ohm-cm and Hall mobility between 50 and 250 cm^2/v-sec. The higher resistivity films are produced by growth at lower temperatures and/or by limiting the high temperature hydrogen pre-firing of the sapphire substrate. Typical growth temperatures are between 1100° and 1200°C. N-type silicon films were prepared by adding phosphine to the silane during growth.

The resistivity and mobility of the silicon films as a function of silicon thickness was measured on a six terminal Hall sample delineated by masking and etching. The resistivity and Hall mobility were measured after the silicon was polished to successively thinner sections to a final thickness of 1-2μ. Measurements on thick (40μ) polished and as-grown pieces of silicon showed that the polishing introduced no changes in measured resistivity or mobility. These measurements were performed on as-grown and on heat-treated silicon.

The doping from the substrate was demonstrated by depositing n-type silicon layers and then heat-treating this material in hydrogen. Angle lapping and staining with a copper stain revealed a p-region extending from the substrate into the silicon. This p-region was also revealed using a thermal probe. The thickness of this p-region was studied as a function of time and temperature of heat-treatment.

Before and after the films were heat-treated a four-point probe was used to measure the resistivity of the films utilizing the analysis of Valdes (6) for resistivity measurements of thin layers on a nonconducting plane. The samples were broken into two pieces. One piece was heat-treated in dry hydrogen and the resistivity after heat-treating was compared with the resistivity before heat-treating. The two pieces of the film were polished and Sirtl etched to delineate any changes in crystal structure that might have resulted from the heat-treatment.

Since most of these experiments involved a post-growth heat-treatment, care had to be taken to eliminate contaminants from the gas supply during the heat-treatment step.

The films were heat-treated on a silicon-carbide coated graphite susceptor in an r-f heated furnace with water-cooled quartz walls. Dry hydrogen from a palladium diffuser was used as the ambient gas. When small amounts of H_2O or O_2 were admitted to the gas, etching of the silicon took place; however, no etching was observed in the dry H_2. At temperatures above 1425°C melting of the silicon was observed and pronounced etching of the sapphire by the silicon resulted. The temperature was measured using an optical pyrometer corrected for absorption and emissivity and checked against the melting points of silicon and germanium. Temperatures are estimated to be correct to within ± 10°C.

Heat-treatment of bulk silicon in dry hydrogen at temperatures up to 1400°C resulted in no significant changes in resistivity. During approximately one half of the heat-treatments of silicon-on-sapphire a piece of bulk silicon of resistivity similar to that of the film was included as a control. No significant changes in the resistivity of the bulk silicon were observed. The control pieces were either 10 ohm-cm n-type or 0.1, 3, 5, or 40 ohm-cm p-type silicon.

A further test for doping from the gas supply was performed by heating pieces of bulk silicon in contact with, and out of contact with, pieces of sapphire. Heat-treatment of polished pieces of 5 ohm-cm p-type silicon for 60 min at 1400°C showed no significant changes in resistivity. However, pieces of 5 ohm-cm p-type silicon placed on disks of polished sapphire or sandwiched between disks of polished sapphire dropped in resistivity to about 1 ohm-cm p-type after similar heat-treatment.

Experimental Results

The results of these experiments are presented in the order in which the experiments were described. Typical profiles of doping density *vs.* distance are shown in Fig. 1 for four samples. The doping density has been derived from the resistivity, mobility, and thickness data of each section by using $N_A = 1/\rho e\mu$ where N_A is the acceptor concentration, ρ is the resistivity, e is the electronic charge, and μ is the mobility. Three treatments are described by the data presented in Fig. 1. Two samples are pieces of as-grown silicon and represent the doping due to the substrate during normal growth. These samples were chosen as representative of many samples measured. The third sample was grown using the following growth cycle: 7μ of silicon was grown at 1160°C, heat-treated in hydrogen in the same reaction tube for 30 min at 1325°C, and then 23μ more of silicon was grown at 1160°C. The fourth sample was a 14μ thick film of silicon heat-treated at 1375°C for 30 min after growth. The initial doping of this film was of the order of 10^{17}/cc. The diffusion constant of aluminum in bulk silicon at 1375°C is about $3 \cdot 10^{-10}$ cm^2/sec (7), yielding a diffusion length greater than 15μ. Thus, this film should be uniformly doped. The increase in doping at the

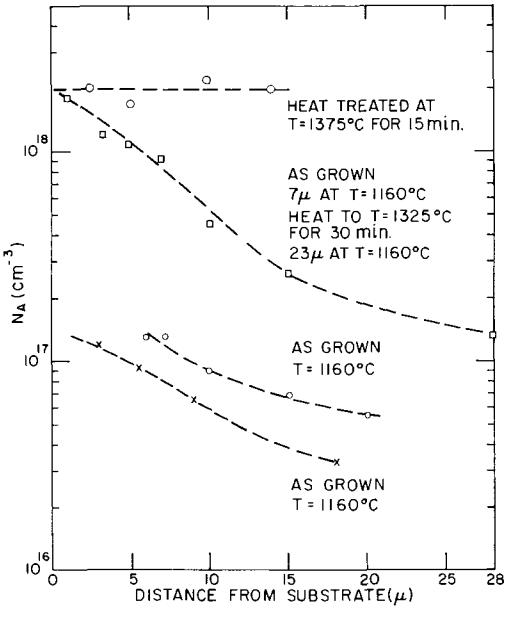

Fig. 1. Carrier concentration vs. distance from the silicon-sapphire interface.

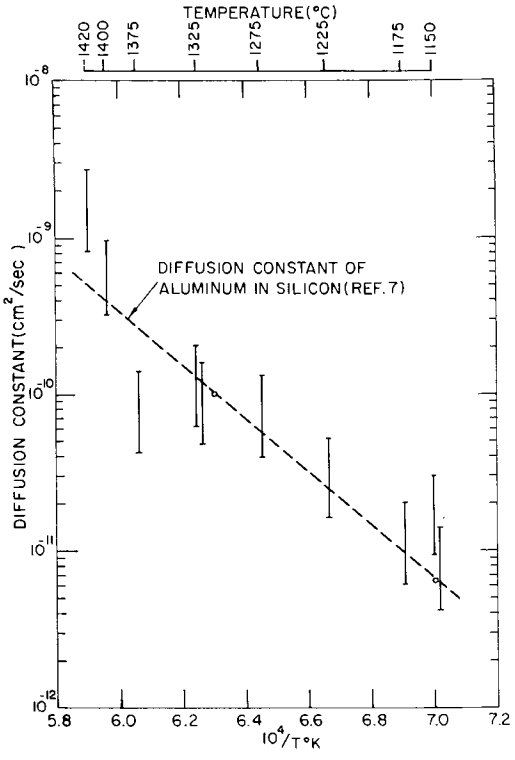

Fig. 2. Diffusion constant vs. temperature for out-diffusion of a p-type dopant from the sapphire into n-type silicon.

silicon-sapphire interface is evident in the as-grown samples and the uniform doping of the heat-treated silicon indicates sufficient diffusion to completely dope the silicon. Measurements of this type have been performed on numerous as-grown films of varying resistivity and all have shown increased acceptor concentrations at the silicon-sapphire interface. Matching of these profiles to an erfc diffusion has resulted in values of D which are 4-10 times that of aluminum in silicon. This is not surprising in light of the fact that this silicon contains large numbers of low angle grain boundaries, and diffusion is enhanced along these grain boundaries (8).

The n-type silicon films were heat-treated at temperatures between 1225° and 1420°C for times ranging from 30 to 5 min. The junctions between the p-region near the substrate and the n-type film were delineated using a copper-stain. From this data the diffusion constant as a function of temperature was determined and is shown in Fig. 2. The data points at 1150° and 1175°C were taken on the as-grown n-type films. The diffusion constant of aluminum in bulk silicon is shown in this figure also. The diffusion constant determined from this experiment agrees well with that of aluminum in silicon. The quality of the silicon films used in the n-type experiments was better than those used in the sectioning experiments which accounts for the difference in the observed diffusion coefficients.

The resistivities of several silicon films 10-20μ thick before and after heat-treatment are shown in Table I. Changes in resistivity were measured when the heat-treatment temperature exceeded 1250°C. Heat-treatments as long as 240 min at temperatures below 1225°C had no significant effect on the film resistivity.

Changes in the crystal structure of the silicon films heated above 1375°C for times greater than 30 min showed a decrease in the density of low angle grain boundaries. Stacking faults were the dominant crystal imperfection in a film heated above 1375°C. In Fig. 3a and b the crystal structure of a film before and after heat-treatment has been delineated by Sirtl etching a polished surface. Diffusion of phosphorus into material that had been heat-treated above 1375°C produced

sharp diffusion fronts of depth similar to diffusion into bulk silicon, while diffusion into as-grown silicon-on-sapphire produced anomalously deep diffusions and irregular diffusion fronts. Diffusions into as-grown and heat-treated films are compared in Fig. 3c and d. As noted, however, the improvement in crystal structure was accompanied by decreases in resistivity.

These results were confirmed by measuring the capacitance of MOS capacitors as a function of distance from the silicon-sapphire interface. The ratio C_{max}/C_{min} for a constant oxide thickness decreases as the doping of the semiconductor increases (9). The normalized MOS capacitance as a function of voltage is plotted in Fig. 4 for different thicknesses of silicon. As the silicon-sapphire interface is approached, the ratio of C_{max}/C_{min} decreases indicative of higher acceptor concentration near the substrate.

Discussion and Conclusions

The following conclusions concerning substrate doping of silicon grown on sapphire have been reached: (I) The sapphire acts as a source of aluminum acceptors. (II) The resistivity of p-type silicon films grown on sapphire substrates can decrease when the films are subsequently heat-treated to sufficiently high temperatures. (III) The amount of aluminum is limited to about $1\text{-}2\cdot10^{15}$ atoms and limits the doping of heat-treated films to a maximum of about $2\cdot10^{18}$/cc. (IV) The doping of the silicon by the substrate during post-growth heat-treatments is not significant below 1200°C but becomes appreciable above 1250°C.

This substrate doping limits the range of temperatures which can be used to anneal defects in the silicon film but does not affect normal device processing which takes place at temperatures below 1200°C. The substrate doping also affects processing of n-type films grown on sapphire. Unwanted p-n junctions can ap-

pear during high temperature processing, and, in fact, conversion to p-type silicon can occur if the temperature is sufficiently high or the processing sufficiently long.

Attempts have been made to determine the mechanism which liberates the aluminum from the sapphire, but no conclusions have yet been drawn. Assuming a temperature independent concentration of aluminum in Al_2O_3 and using the data presented in Table I, the analysis of Paladino and Kingery (10) can be applied to determine the diffusion constant of aluminum in Al_2O_3. The high activation energy of 18 ev resulting from this analysis suggests that the process of liberating the aluminum from the Al_2O_3 is more complicated than a simple diffusion process. The limit in the amount of aluminum that dopes the silicon films may indicate that only the first few atomic layers are involved in the doping process.

Measurement of Epitaxial Film Thickness Using an Infrared Ellipsometer

A. Ray Hilton and Charlie E. Jones

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

The thickness of most epitaxial layers is measured using spectrophotometer scan techniques. The method does not work well for very thin epitaxial layers ($<5\mu$). The principles, underlying the ellipsometric method used to measure thin transparent films in the visible region, apply to the optical interference that occurs between a substrate and an epitaxial layer in the infrared. An ellipsometer and the ellipsometric technique were used to measure the thickness of 40 P on P^+ Ge and 40 N on N^+ Si epitaxial layers. They ranged in thickness from 1 to 10μ. The measured values compared to those obtained by the infrared scan technique agreed within +9.6% for the Ge layers and ±6.7% for the silicon. The reproducibility of the measurements was +2.8% and ±4.1%, respectively. In ultimate form the method should be more accurate and more direct than the infrared scan technique.

Optical interference occurs when infrared light is reflected obliquely from the surface of a semiconductor epitaxial layer grown on a substrate of the same semiconductor material. The interference occurs because of a difference in the optical constants of the layer and substrate brought about by the differences in the infrared absorption of charge carriers in the heavily doped substrate and lightly doped layer. The thickness of the epitaxial layer is commonly measured using an infrared reflectance scan technique which takes advantage of the variation in the reflected intensity as a function of wavelength (1, 2). The method is accurate, fast, and nondestructive. However, the magnitude of the free carrier absorption generating the optical interference increases with the square of the wavelength (3-5). For very thin epitaxial layers ($<5\mu$), the first order of the optical interference occurs in the near infrared where the optical difference between layer and substrate is small. For this reason, the infrared scan method does not work well for very thin epitaxial layers. The ellipsometer technique has been widely used in the visible region of the spectrum to measure films less than one wavelength thick (6, 7). This paper describes the extension of this technique to measure semiconductor epitaxial film thickness.

Calculation of semiconductor optical constants.— Generally, the infrared light obliquely reflected from the semiconductor epitaxial layer is elliptically polar-

ized. In ellipsometry (6, 7), an instrument called an ellipsometer is used to analyze optically the elliptically polarized light. The light is characterized in terms of its azimuth angle ψ and its phase shift angle Δ. The values of ψ and Δ are determined by the optical constants of the film, the optical constants of the surface, the angle of incidence, the wavelength of light used in the measurement, and the thickness of the film. In actual practice, curves in ψ and Δ are constructed from points calculated for films of varying thickness. The measured value of ψ and Δ is compared to the computed curves and the corresponding thickness value determined. The calculation of individual points is very tedious and is usually programmed for electronic computer computation.

The optical constants of the semiconductor epitaxial layer and semiconductor substrate become different in the infrared because of free carrier absorption. Free carrier absorption is the absorption of infrared energy by conduction electrons (or holes) of a semiconductor. The magnitude of the effect depends on the number of free carriers available for absorption and the wavelength of light used in making the measurements. The absorption increases with the square of the wavelength of light (3-5). In epitaxial device specifications, the substrate material is usually more heavily doped than the layer. As the wavelength of light increases, the free carrier absorption in the substrate material increases producing a change in its optical constants. The optical constants of the substrate are then different from the layer so that reflection of light at the layer-substrate interface occurs, producing optical interference.

The substrate material begins to show optical behavior typical of a metal. The refractive index can no longer be represented as a real number. The complex refractive index must be used

$$N = n - ik$$

where n is the real part of the refractive index and k is the imaginary part and is really the extinction coefficient. The extinction coefficient is calculated from the absorption coefficient

$$\alpha = \frac{4\pi k}{\lambda}$$

where α is the absorption coefficient and λ is the wavelength of the light. The contribution to the absorption coefficient by free carrier absorption is given by (3)

$$\alpha_{\text{free carrier}} = \frac{\lambda^2 e^3}{4\pi^2 c^3 n \epsilon_0}\left(\frac{N_n}{M_n^2 \mu_n} + \frac{N_p}{M_p^2 \mu_p}\right) \qquad [1]$$

where e is the electronic charge, c the velocity of light, n the real part of the refractive index, ϵ_0 the permitivity of free space, N_n the number of conduction electrons, M_n the effective mass of the electrons, μ_n the electron mobility, N_p the number of holes, M_p the effective mass of holes, and μ_p the mobility of holes.

The normal case considered is the case of a single carrier semiconductor. In this case the interdependent optical constants n and k can be calculated (8) from

$$n^2 - k^2 - \epsilon = \frac{N_c e^2}{M_c \epsilon_0} \cdot \frac{1}{\omega^2 + g^2} \qquad [2]$$

and

$$2nk\omega = \frac{N_c e^2}{M_c \epsilon_0} \cdot \frac{g}{\omega^2 + g^2} \qquad [3]$$

where ϵ is the optical dielectric constant (no free carrier contribution); ω the angular frequency at wavelength λ, ($\omega = 2\pi/\lambda$); N_c the number of free carriers; M_c the effective mass of the free carriers; and g the reciprocal of the relaxation time τ, ($\tau = \mu_c M_c/e$)

An idea of the magnitude of the free carrier effect can be obtained from examining Fig. 1. The value of α for different resistivities of n-type silicon measured in our laboratory is plotted as a function of the wavelength. The data shows that free carrier absorption in 0.01 ohm-cm n-type silicon is a very large effect even at wavelengths as small as 10μ. Values calculated using Eq. [2] and [3] for 1.0 and 0.013 ohm-cm n-type silicon are shown for comparison values. Also shown are values reported in the literature by Spitzer and Fan (5). Close agreement between the calculated values and experimental values is obtained. The dashed line in Fig. 1 shows the calculated absorption coefficient as a function of wavelength for 0.013 ohm-cm n-type silicon. Silicon with this resistivity was used as substrate material for silicon epitaxial layers measured in this investigation.

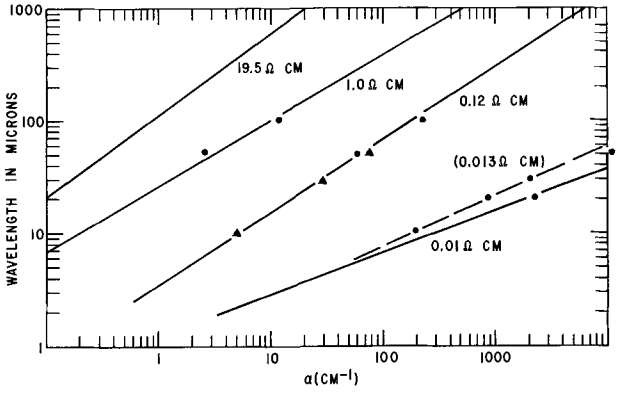

Fig. 1. Magnitude of the absorption coefficient due to free carrier absorption in n-type silicon as a function of wavelength: •, calculated using Lyden method; ▲, Spitzer and Fan.

An Infrared Ellipsometer

The optical constants of the semiconductor layer and substrate at infrared wavelength can be calculated from Eq. [2] and [3] using the appropriate values of resistivity, mobility, and effective mass. All the parameters needed to calculate a set of ellipsometer curves in ψ and Δ for epitaxial layers on a particular substrate are known. All that is needed to measure epitaxial thickness by the ellipsometer technique is an instrument that will operate in the infrared.

General description.—A schematic drawing of an instrument that meets all the basic requirements of a visible ellipsometer but operates in the infrared is shown in Fig. 2. The instrument is built on a Gaertner L118 base. Energy from a globar source passes through an optical chopper, strikes an off-axis front surface parabolic mirror, and forms a globar image

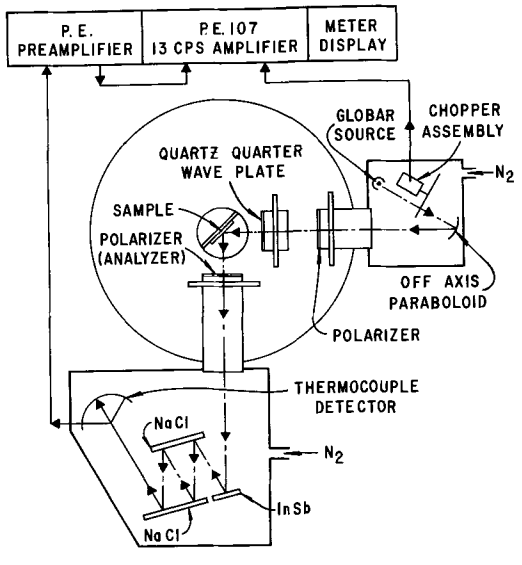

Fig. 2. Schematic drawing of the infrared ellipsometer

at the sample holder. The light striking the sample is not collimated, contrary to the practice followed in visible ellipsometry, because of the use of the parabolic mirror. Such an optical arrangement is required in the infrared because of the necessity of collecting as much energy as possible from the finite globar source. How the use of un-collimated light affects the instrument operation and ultimately, the accuracy of the method will be discussed in a later section.

The light in this path passes through the first infrared polarizer and the infrared quarter wave plate. After striking the sample, the light is reflected down the second arm. It passes through the infrared analyzer polarizer and into the monochromator section. In this section the light is reflected once from a polished InSb surface and four times from polished NaCl plates. The reflection is at near normal incidence. The resultant light strikes an ellipsoid and is focused on a standard thermocouple detector. The signal of the detected energy is amplified by a Perkin-Elmer 13 cps preamplifier and amplifier. The amplified signal is displayed on a high sensitivity voltmeter. Air tight chambers were constructed on each arm so that absorption by atmospheric moisture could be minimized in the optical paths. The chambers are flushed with dry nitrogen. Angles of incidence and polarizer readings are read using the verniers supplied with the instrument. Optical alignment was accomplished using front surface mirrors in place of the NaCl plates so that visible light could be used to determine the optical path. After alignment the mirrors were replaced with the NaCl plates and the detector peaked on the infrared energy. The infrared quarter wave plate, the infrared polarizers, and the monochromator sections warrant further discussion.

Infrared quarter wave plate.—A quarter wave plate is made from optical material that is bi-refractive. The velocity of light traveling through a bi-refractive material is a function of the angle the electric vector of the light makes with the optical axis of the crystal. The velocity (and thus the refractive index) changes from either a maximum or minimum in a direction along the optical axis to a minimum or maximum in a direction perpendicular to the optical axis. If the two refractive indexes are accurately known at a particular wavelength, a bi-refractive crystalline material can be carefully oriented (using an x-ray diffractometer) and a plate cut of sufficient thickness to produce a quarter wave plate. Two light waves of a particular wavelength polarized in and perpendicular to the direction of the optical axis will emerge, after traveling through the plate, separated in phase by 90° ($\lambda/4$).

Selection of the proper optical material was a difficult problem. Most of the optical materials that transmit well in the infrared are not bi-refractive. Of those that are bi-refractive, either the refractive indexes are not accurately known or the materials cannot be obtained in proper sizes. Natural quartz was selected. It can be obtained in large high quality pieces and its optical constants are accurately known (9). The major disadvantage to using quartz is that it is opaque in the normal infrared regions. Quartz does not transmit well from about 3.5 to ~45μ, so that the wavelength selected for the operation of the instrument has to be at least 50μ. The thickness of the quarter wave plate is calculated from the difference in the refractive indexes; the correct thickness for one operating at 55μ is ~10 mils.

The monochromator section.—Any instrument operating in the far infrared is energy limited. The problem encountered in designing the monochromator section was how to produce a source of light of at least 50μ wavelength in a simple manner while conserving as much of the available energy as possible. A unique reflection system was selected which takes advantage of the Reststrahlen reflection bands of ionic crystals for its energy isolation. These bands are the reflectivity maxima that occur in ionic crystals because of the strong absorption of infrared energy by the oscillating constituent atoms or ions.

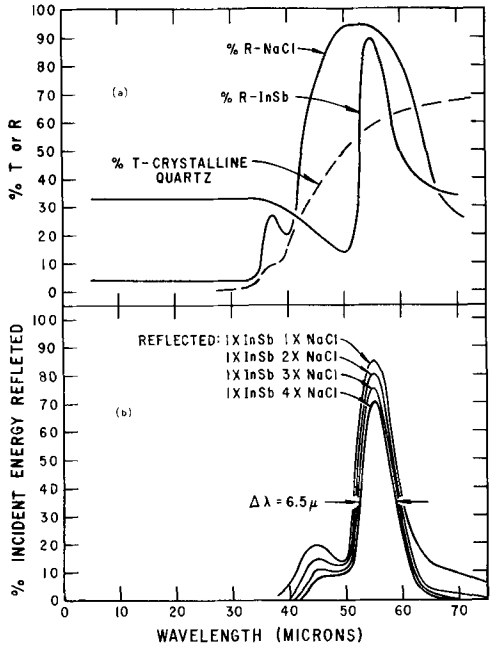

Fig. 3(a) and (b). Monochromator components

The reflectivity of the two materials selected, NaCl and InSb, are shown in Fig. 3a. Notice the reflectivity maxima are 90-95%. The selection of NaCl as a material was based on its reflection maximum (55μ) and its low reflectivity out to 35μ. This low reflectivity allows the elimination of the unwanted radiation on both sides of the 55μ peak. The NaCl reflection peak is too broad to produce a narrow band of radiation. For this reason, InSb was chosen because of its very sharp reflection band which peaks at 54.6μ (10). The transmission of crystalline quartz is included in Fig. 3a to emphasize that a wavelength of at least 50μ is needed if a quartz quarter wave plate is used.

Reflectivity is defined as the ratio of the reflected energy over the incident energy. The method of energy isolation by multiple reflections is based on the fact that the resultant intensity at a particular wavelength after multiple reflections is just the reflectivity of the surface raised to the n^{th} power, where n is the number of reflections. This fact is demonstrated in Fig. 3b. The per cent of incident radiation as a function of wavelength is shown after reflection from one InSb surface and one to four NaCl surfaces. More reflections from NaCl drastically decrease the amount of energy on both sides of the 54.6μ peak while leaving the percentage of energy at the peak quite large. This is because the low reflectivity of NaCl (0.04) on both sides of the peak raised to the fourth power approaches zero. The value of the peak reflectivity (0.95) raised to the fourth power is still quite large (0.81). The small shoulder occurring at ~45μ presents no problem because of the low transmission of the quartz quarter wave plate.

Infrared polarizers.—The best infrared polarizers reported in the literature are transmission wire grid polarizers reported by Bird and Parish (11). They show good transmission, have high polarization, and work well in optical systems where the light is not collimated. The polarizers are produced by shadowing a plastic grating replica with a metal that has high reflectivity in the infrared (Al or Au). The result is a plastic film covered with a set of closely spaced parallel conducting wires. Of course, the plastic film must be transparent at the wavelength of interest. A spacing of $\lambda/3.5$ is required to produce 99% polariza-

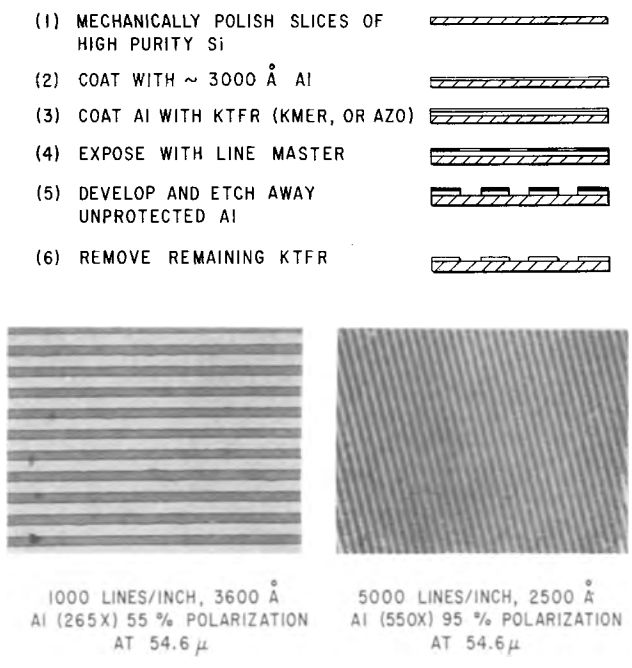

Fig. 4. Preparation of Si-Al grid infrared polarizers

tion (11). For 55μ wavelength, this corresponds to at least 1600 lines/in.

Wire grid polarizers are not commercially available. Attempts in this laboratory to produce polarizers of this type on polyethylene film using Bird and Parish's technique failed. A photomask technique was used instead. High purity silicon was chosen as the optical material to use because of its availability, transparency in the far IR, and because photomask technology is well developed for silicon. A step wise description of the process followed is shown in Fig. 4. Two prints were used, 1000 and 5000 lines/in. Photographs of the finished aluminum lines are shown for both polarizers. The measured polarization for these polarizers at 54.6μ was ~55% for the 1000 lines/in. and 95-98% for the 5000 lines/in. Another advantage of these polarizers is the plane of polarization can be accurately measured.

Two 5000 lines/in. polarizers were used in the instrument operation and worked quite well. At 54.6μ they transmitted about 25-27% of the incident unpolarized light. After operating the instrument for quite sometime, it was decided to try to improve the reading of the nulls by constructing polarizers which would transmit more energy. Polyethylene film polarizers were constructed. These are made by stretching 25-30 films over a holder and allowing the incident radiation to strike the polyethylene films obliquely at the polarization angle ($\phi = \tan^{-1} n$). The transmitted light is then plane polarized. Polarizers constructed in this way did transmit more light (~35% incident radiation) but are not too effective for uncollimated light. The instrument operation did not improve substantially but the polyethylene polarizers are still used because of the slight increase in transmitted energy.

Instrument operations.—The instrument was operated exactly as the visible ellipsometer except that the eye was not used to detect the null. Instead, a sensitive voltmeter was used to display the detected and amplified infrared signal. The system is definitely energy limited in its present form. Nulls are difficult to measure. Readings are taken on both sides of the null to improve accuracy. However, even in its present form the readings are surprisingly reproducible. The present instrument was designed and built to demonstrate the applicability of the ellipsometer technique to epitaxial film thickness. Improvement of the instrument can be readily obtained by using a more sensitive detector or by redesigning the optical system to provide more energy.

A sample that is nonuniform in thickness produces a resultant elliptical polarization which is the average for the entire sample. In visible ellipsometry, for such a sample, total extinction is difficult to obtain because a faint background intensity is still visible at the null. A similar effect is produced by the use of uncollimated light in the infrared ellipsometer. The magnitude of this effect is decreased by careful optical alignment of the instrument symmetric about the center ray. Additionally, a small area of the sample (~¾ in. in diameter) is used as the limiting aperture of the instrument. Considering the size of the source mirror and the image distance, the total possible beam divergence is ±4°. However, a movement of the monochromator arm ±2° from the proper incidence angle reduces the detected signal to half value indicating the rays contributing most heavily to the detected signal travel very close to the center rays. An equal number of rays from the two vertical extremes (<±4°) average out to produce a plane of incidence determined by the center ray. The same averaging process occurs between rays of the two horizontal extremes to produce an average angle of incidence determined by the center ray. Averaging of both vertical and horizontal nonparallel rays occurs when the beam passes through the quarter wave plate to produce an average 90° phase shift for the center ray.

The averaging of the horizontal rays to produce an average plane of incidence does not produce a difference in the measured and calculated ψ and Δ values. The plane of incidence is not involved in the calculation. However, for a particular thickness of film on a particular substrate, the calculated ψ and Δ points may not be linear functions of the angle of incidence. In this case, a small error may result because the effective value of ψ and Δ for all rays does not average out to the same value as that calculated for the center ray. Each particular system must be evaluated for each thickness range. The magnitude of this effect is discussed under the results section for the two systems measured.

Applications

Device specifications usually call for epitaxial materials grown in the N on N^+ or P on P^+ configuration. In this arrangement the resistivity of the layer is at least an order of magnitude higher than the substrate. The two examples chosen for this evaluation, N on N^+ Si and P on P^+ Ge, represent the configuration of the majority of epitaxial slices produced. It was pointed out earlier that the method works best when the layer is nonabsorbing. The nonabsorbing criterion was met by the layer resistivity selected (~1 ohm-cm) at the wavelength of measurement.

N *on* N^+ Si *epitaxial layers.*—About 40 N on N^+ epitaxial layers 1-10μ in thickness were specially prepared for this evaluation. The substrate and layer resistivities were 0.013 ± 0.001 ohm-cm and 2 ± 1 ohm-cm, respectively. The optical constants were calculated for the wavelengths of measurement (54.6μ) using Eq. [2] and [3]. An ellipsometer curve in terms of ψ and Δ for layers 0-10μ thick in 0.1μ increments was calculated using the program described by McCrackin and Colson (12). The results are shown in Fig. 5. The angle of incidence chosen was 50°. In the illustration, every micron increment was designated and the 0.5μ increments marked with an arrow head. The first order of thickness appears on the right hand side of the curve. This would correspond to thickness from 0 to 8.1μ. For thickness greater than 8.1μ, the numbers on the left hand side of the curve are read. This corresponds to epitaxial thickness from 8.2 to 10.4μ on the curve. Thickness greater than 10.4 can be extrapolated from the existing points. Because the film is nonabsorbing the points for films of different thickness fall almost on top of one another (as in the case of

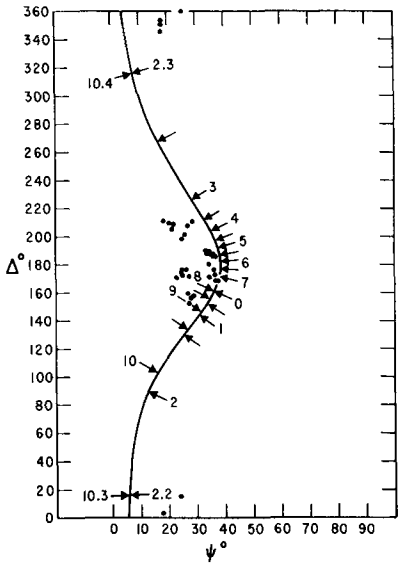

Fig. 5. Ellipsometer curve for silicon epitaxial layers, N on N^+. $\Phi = 50°$, $\lambda = 54.6\mu$.

nonabsorbing oxide films on semiconductors) retracing the curve. For a single set of readings, prior knowledge of the order of thickness of a film is required. The value of Δ goes off scale at the thickness of $\sim 2.2\mu$ (or 10.3) and back on scale $\sim 2.3\mu$ (or 10.4). These points are also marked to avoid confusion.

The measured values of ψ and Δ for 38 samples are indicated in Fig. 5 with small circles. The experimental points follow the general shape of the curve. Considering the fact that the optical constants of the substrate are calculated and that the junction is graded to some variable degree the fit is quite good. The calculation of Δ from the Polarizer reading ($\tan\Delta = \cot 2P$) yields two possible values. Generally this creates no problem because only one value of Δ along with the measured value of ψ make a point which falls on the curve. However, in our case, the experimental error in the measured ψ and Δ may be great enough so that neither point falls on the curve. For this reason, the prior knowledge of the order of thickness is used to select the proper value of Δ.

The thickness values were selected by extrapolating the Δ value to the curve disregarding ψ. The thickness determined for the samples for three separate readings are shown in Table I. The columns headed ellipsometer 1, 2, and 3 show the measured values for each sample. The values determined by the infrared scan technique with a Beckman IR-5A are given in the first column. Portions of some samples were removed from the slice and the epitaxial layer thickness determined by the angle lap and stain technique (L.S.). These results are given in column 2. An interference pattern or a junction stain was not obtained for eight very thin samples. Several of these produced an interference pattern when remeasured at shorter wavelengths using a Perkin-Elmer 337. The calculated thickness are given in Column 3. Average values for the three ellipsometer thickness measurements are given in the sixth column.

In the next column, the error existing between the average ellipsometer and the IR-5A values are given in terms of per cent of the IR-5A measured thickness. No values are given for the eight samples which failed to produce an interference pattern with the IR-5A. The per cent error for the 30 remaining samples ranges from 0 to 14.7% with an average value of $\pm 6.7\%$. The reproducibility of the ellipsometer reading is indicated in the last column. The individual readings for the three thickness determinations are compared to the average value and an average error calculated. For the same 30 samples the average

order on the outside (6.8-13.6μ). Again the film is nonabsorbing and the curve could be used for greater thicknesses.

The measured values of ψ and Δ for 40 samples are shown on the illustration as small circles. They follow the calculated curves much more closely than the silicon points. As pointed out before, prior knowledge of the order of thickness is used in assigning the proper value of Δ from the polarizer reading. The thickness data treated in the same manner as the previous samples in shown in Table II.

Again the values determined by the IR-5A are used for comparison. Poor values were obtained for the eight samples between 1 and 2μ thick. The P-E 337 could be used for the 2μ samples. Large disagreement was obtained between the average ellipsometer readings and four samples about 9μ thick. They were checked using the P-E 337 at shorter wavelength. The indicated values were greater than with the IR-5A, while the IR-5A value was much larger than the one obtained on the ellipsometer at much greater wavelength. The source of this disagreement most probably is a wide graded junction. For the 31 samples for which IR-5A values were available, the average error with the average ellipsometer value was ±9.1%. The reproducibility again was quite good, for the 31 samples, ±2.8%.

Discussion of results.—There are five aspects of the measurements which should be briefly discussed in order to properly evaluate the results: the sample, the instrument, the calculated curves, the angle of incidence, and the wavelength of measurement.

The Samples.—The ellipsometer measures a slightly different thickness than the infrared scan technique. The only way the two methods can agree (within reproducibility of both methods) is for the sample to have a sharp junction. Undoubtedly, the major source of disagreement is the variation in degree of gradation of the substrate layer junction. The calculated curves are based on the optical constants of the substrate. If the junction is very graded, the origin of reflection occurs at some point toward the layer which has a carrier concentration (and thus optical constants) different from the substrate. The measured value of ψ and Δ will fall off the predicted curve and give a slight error in thickness.

The Instrument.—The instrument in its present form is energy limited. Reproducibility nevertheless is better than ±5%. Undoubtedly, some of the error was caused by instrumental troubles, but it was not the major source. Present plans call for an improvement in instrument performance obtained by using a more sensitive detector (a Golay cell) and by the fabrication of infrared polarizers with better transmission (wire grid polarizers on polyethylene film).

The calculated curves.—When the epitaxial samples were prepared, the resistivities of layer and substrate were specified within a certain tolerance range. The normal variation within this tolerance range will produce a variation of optical constants between samples. The effect would be negligible for the essentially nonabsorbing layers. However, the substrate variation could cause ψ and Δ to fall off the curve calculated for the normal or middle value. In order to check the magnitude of this effect, ψ and Δ curves for substrates within the tolerance range were calculated and compared. The curves were only slightly displaced from one another. Variation in substrate resistivity cannot account for all of the observed displacement of ψ and Δ points from the calculated curves. At this time, the main source of displacement is believed to be the junction gradation.

The angle of incidence.—An improvement in accuracy or reproducibility might be expected for another angle of incidence. A set of ψ and Δ curves for the N on N^+ silicon epitaxial layers was calculated for 70° incidence. The curve is shown in Fig. 7. Silicon N on N^+ samples that had been measured at 50° incidence were remeasured at 70°. No improvement in precision or accuracy was obtained.

In the section describing instrument operation it was pointed out that the use of un-collimated light could lead to a thickness error if the calculated ψ and Δ values for a particular system were nonlinear functions of the angle of incidence. The magnitude of this effect is determined by the specific film-substrate combination and each system must be considered separately. For the systems evaluated, curves were calculated for full divergence (±4°). Comparisons were made between the two extreme curves (46° and 54°) at the even micron increments of the 50° curve. The differences in the magnitude of the deviation from the even micron increment were taken as a measure of the nonlinearity. The maximum nonlinearity values

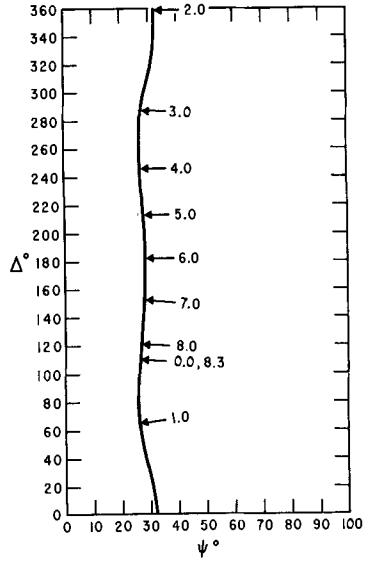

Fig. 7. Ellipsometer curve for silicon epitaxial layers, N on N^+. $\Phi = 70°$, $\lambda = 54.6\mu$.

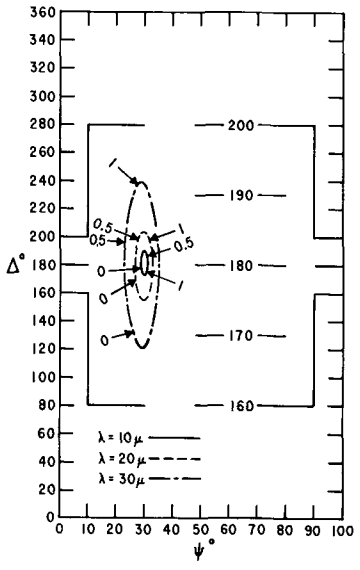

Fig. 8. Ellipsometer curves for silicon epitaxial layers. $\Phi = 50°$, $\lambda = 10\mu$, $\lambda = 20\mu$, $\lambda = 30\mu$.

for the Si system were $\pm 0.1\mu$ and for the Ge system were $\pm 0.2\mu$. For these systems, this effect does not appear to be a major source of error.

The wavelength of measurement.—The amount of energy available at shorter wavelengths from a globar source is many times that available at 54.6μ. If a different $\lambda/4$ plate optical material were available, perhaps an instrument could be constructed which would operate at a shorter wavelength and thus not be so energy limited. To check this possibility, ellipsometer curves were calculated for measurements made on the same N on N^+ silicon epitaxial layers measured before, using the same 50° angle of incidence but changing the wavelength of measurement to 10, 20, and 30μ. The results are shown in Fig. 8. Notice the Δ scale has been expanded by a factor of 5 over the ψ and Δ curves shown previously, in order to show the variation with thickness. The free carrier effect, in this case at least, is so small at the shorter wavelength that a large change in the elliptical polarization of the light is not obtained with thickness. These results indicate 54.6μ is a good choice as a wavelength of measurement.

The results presented here show that on the first try, with no concentrated effort to improve the method or the instrument, the infrared ellipsometer is at least as good and probably better for thin epitaxial layers than the infrared scan. The method should work well on good quality layers $<2\mu$ thick. With improvement in the instrument performance and a better fit of the calculated curves, an accuracy and reproducibility of 1% may be ultimately obtained.

Conclusions

1. The thickness of most epitaxial layers is measured using the infrared spectrophotometer scan technique. The method is not good for very thin epitaxial layers ($< 5\mu$).

2. The ellipsometer is an optical instrument used to accurately measure the thickness of very thin transparent films on highly reflective surfaces in the visible region of the spectrum. The underlying optical principles of the ellipsometric method apply to the optical interference that occurs between an epitaxial layer and its substrate in the infrared region of the spectrum.

3. An ellipsometer was designed and built that operates in the long wavelength infrared region in much the same way as the conventional visible ellipsometer.

4. Using the infrared ellipsometer the thickness of about 40 P on P^+ Ge and 40 N on N^+ Si epitaxial layers was measured. The layers ranged in thickness from 1 to 10μ. The agreement with the values obtained from the infrared scan measurement (when it could be made) was $\pm 9.6\%$ for the Ge layers and $\pm 6.7\%$ for the Si layers. The reproducibility of the measurement was $\pm 2.8\%$ and $\pm 4.1\%$, respectively. All percentages are given in terms of the thickness.

5. The ellipsometer technique ultimately will be a more accurate, more direct method for epitaxial film thickness.

Acknowledgments

The authors are grateful to Phil Kane for his encouragement and support throughout this investigation. Gene Keeney made the successful completion of this program possible by building the instrument and making all the measurements. Special thanks are due to Walt Runyan, Paul Gleim, Murray Bullis, and especially Stacy Watelski of SRDL. These men helped us many times in discussions of the measurement problems and the critical parameters of the materials. Stacy Watelski furnished all the epitaxial samples used in the evaluation.

Manuscript received Nov. 1, 1965; revised manuscript received Feb. 10, 1966. This paper was presented in part at the Denver Meeting of the Society for Applied Spectroscopy, Sept. 3, 1965, and at the Buffalo Meeting of The Electrochemical Society, Oct. 11, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Polarographic Behavior of Some Metal Acetates in Aqueous and Anhydrous Acetic Acid

Harris E. Ulery

Jackson Laboratory, Organic Chemicals Department,
E. I. du Pont de Nemours and Company, Wilmington, Delaware

ABSTRACT

A study of the polarographic behavior of the acetates of Co(II), Ni(II), Zn(II), Pb(II), Cd(II), Bi(III), and Cu(II) at the dropping mercury electrode has been made in the systems: H_2O-HOAc-MOAc and HOAc-MOAc, where MOAc is the supporting electrolyte with M = Li, Na, K, and NH_4. The data are interpreted in terms of the control exerted by solvent on the dissociative equilibria of the reducible metal species and the associative equilibria leading to aggregates involving the inert electrolyte. The half-wave potentials of the reversibly reduced metals (Cd, Pb, and Cu) conform to the qualitative predictions of the equation derived by Schaap (22).

The earliest reported study of acetic acid as a polarographic medium is that of MacGillavry (1), who was unable to obtain sigmoidal curves with the dropping mercury electrode. Later Bachman and Astle (2) and also Hala (3) demonstrated that satisfactory waves could be obtained in this medium provided that caution was exercised to remove all dissolved oxygen and that a suitable correction was made for the sizable iR drop developed across the cell. These workers also showed that the currents obtained in HOAc in the presence of carrier electrolyte, NH_4OAc, although lower than those in aqueous solution, were proportional to the concentration of the reducible species. Since then, proportional currents in glacial HOAc have been obtained with NH_4NO_3 (4) and H_2SO_4 or $HClO_4$ (5) as the inert electrolytes. It has been possible to use this solvent to advantage in the polarographic determination of sulfate ion (6) and of some organic materials (2, 7), particularly the anthraquinones (8).

At this time we would like to report the results of a polarographic study of the behavior of certain metal acetates in anhydrous HOAc as well as in HOAc-H_2O mixtures; included are some comparative results obtained in formic acid.

Experimental Section

Materials.—Anhydrous acetic and formic acids were prepared by the methods of Orton and Bradfield (9) and Garner, Saxon, and Parker (10), respectively.

The anhydrous sodium, potassium, and ammonium acetates were all analytical grade commercial materials and were used without further purification. The anhydrous acetates of lithium, cobalt(II), lead(II), nickel(II), copper(II), cadmium, and zinc were obtained by refluxing the common hydrates for several hours in a 50:50 volume mixture of acetic acid and anhydride, followed by recrystallization from the same solvent; the salts were then dried at 110°C for 1 to 7 days. $Bi(OAc)_3$ was available in these laboratories and was recrystallized in the same fashion. Metal analyses are given in Table I. It is noteworthy that only one solvate was obtained, *viz.*, $Ni(OAc)_2 \cdot HOAc$, while Kolling and Lambert (11) reported obtaining *inter al.* $2Ni(OAc)_2 \cdot HOAc$, $2Co(OAc)_2 \cdot HOAc$, and $Cu(OAc)_2 \cdot HOAc$ by a somewhat similar procedure.

Equipment.—The Sargent Model XXI (S-29303) recording polarograph was employed in conjunction with a Sargent Model A IR Compensator (S-29320) as designed by Arthur (12). The electrolysis vessel, also an Arthur design, was a 100 ml, three electrode assembly (Sargent, S-29322) employing an asbestos fiber bridge. The reference and current electrodes were aqueous saturated calomel (SCE). Transfer of water across the bridge was found to be negligible during the course of a run by Karl-Fischer titration. The d.m.e. had the capillary constants given in Table II. The assembly was thermostated at 25.0° ± 0.5°C.

Method.—All aqueous solutions were prepared volumetrically using deionized water; appropriate concentration values were obtained with the aid of International Critical Tables' density and composition data for the aqueous acids (13). Solutions of the reducible metals were made up fresh from stock solutions of the inert electrolyte; aging the solutions for a few hours appeared to have no significant effect on the data obtained. Routinely, 0.005% Triton X-100 (Rohm and Haas) was used as a maximum suppressor in all the aqueous acid runs, since it was found to have a negligible effect on the measured half-wave potentials. Solutions were thoroughly deoxygenated by sparging with argon.

The polarograms were recorded with the damping switch in the "off" position. The instrument was precalibrated with respect to both recorded voltage and current. Values given for the half-wave potentials, limiting currents, and slopes are the averages of three or more determinations. Half-wave potentials and slopes were obtained by a plot of E *vs.* log $(\bar{i}/\bar{i}_l - \bar{i})$ linearly fitted by a least squares routine programed on an IBM 1410 computer. For uniformity, only $\bar{i}$ values between $E_{1/4}$ and $E_{3/4}$ were utilized; in certain cases where nonsymmetrical polarograms gave rise to nonlinear log plots, the $E_{1/2}$ and slope param-

Table I. Analyses of anhydrous metal acetates

Metal acetate	% M calc'd.	% M found
$Bi(OAc)_3$	54.2	54.8
$Cd(OAc)_2$	48.7	48.8
$Co(OAc)_2$	33.3	33.0

$NH_4HCO_2/HCOOH$	1.444	1.450

[a] $mg^{2/3}$ $sec^{-1/2}$ at h = 50 cm; [b] electrolyte conc. = 0.50 F; [c] values of m were determined with the apparatus described by J. J. Lingaine, *Ind. Eng. Chem., Anal. Ed.*, 15, 588 (1943) and varied over 1.106-1.170 mg/sec.

eters obtained in this manner were slightly higher than values obtained by the usual graphical method.

Mercury heights were corrected by the method outlined by Kolthoff and Lingane (14). Viscosities were obtained by a capillary-flow method at 25.0° ± 0.5°C.

Results and Discussion

Liquid junction potentials.—Nelson and Iwamoto (15) recently suggested a polarographic method for approximating the value of E_j which is based on the measurement of the half-wave potential of the reversible 4,7-dimethyl-1,10-phenanthroline (Fe^{2+}/Fe^{3+}) couple in the desired solvent *vs.* an appropriate reference electrode. The values obtained by them for a number of solvents containing 0.1F lithium perchlorate ranged between 30 and 110 mv *vs.* SCE. We have made some yet unpublished computer studies based on the electrostatic models proposed by Garrick (16) and Born (17), which suggest that these values may be high by a factor of about two. As it happens, it is not possible to use the Nelson-Iwamoto method in acetic or formic acid, since the iron complex is not stable in these media. At any rate, there is no reason to expect that the junction potentials obtained in these solvents would be much different from those found in other nonaqueous solutions, and hence, are probably less than ca. 100 mv.[1] Finally, it can be mentioned that the reversible half-wave potential of cadmium is relatively insensitive at high concentrations to the kind of acetate electrolyte used; this would be expected if the contribution to a junction potential by the carrier acetate was small. This is likely since NH_4OAc is weakly dissociated in HOAc (19).

Half-wave potentials and slopes in aqueous acetic acid.—In Fig. 2 are illustrated the $E_{1/2}$ data obtained from millimolar solutions of the metal acetates in 0.5M NH_4OAc supporting electrolyte. The wave due to Co(II) remained distinguishable over the entire concentration range. At intermediate compositions, however, this wave was so close to the hydrogen wave that the limiting current was ill-defined; this resulted in some scattering of the values for $E_{1/2}$. The wave was irreversible at all times with a slope of 85-100 mv. The rather dramatic change in the half-wave potential at the left end of the scale (*ca.* 80 mv for the first 0.5 mole water added) suggests that selective solvation of some form of Co(II) is occurring to produce a more stable hydrate.[2] Very probably it is the reducible species itself which is being affected, since no appreciable change in the wave slope is noted. The slight maximum at the aqueous end of the scale is due to the influence of *p*H on the concentrations of the various forms of Co(II) in the solution. This was indicated by a pronounced change in the shape of this part of the curve when either a strong base or acid was added.

The curve for Ni(II) (slopes, 80-115 mv) is quite similar to that given by Co(II), displaying analogous,

[1] Failure to find any significant shift in the electrocapillary maximum from the aqueous value (Fig. 1) supports this contention, although a shift due to the development of a junction potential might not be seen if the actual potential of the maximum had undergone a nearly equal change in the opposite sense as a result in the change in solvent (18).

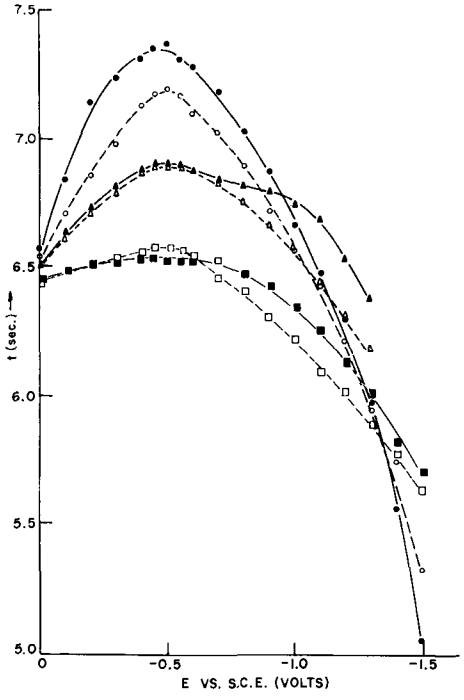

Fig. 1. Comparison of aqueous and nonaqueous electrocapillary curves: •, H_2O; ○, H_2O + 0.005% TX-100; ▲, HCOOH; △, HCOOH + 0.005% TX-100; ■, HOAc; □, HOAc + 0.005% TX-100.

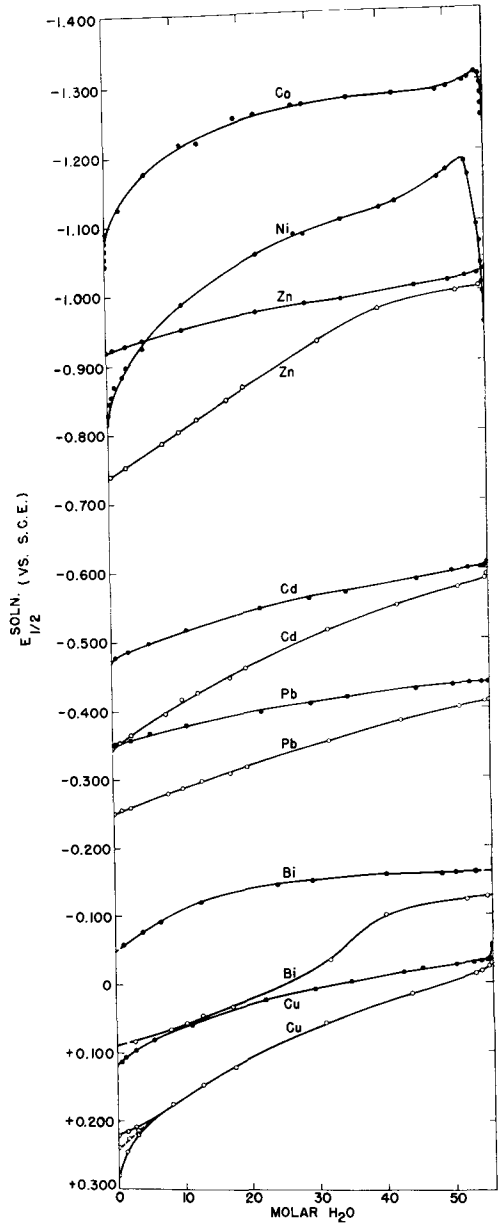

Fig. 2. Effect of composition on half-wave potentials: •, HOAc; ○, HCOOH.

[2] Clearly the peculiar end behavior of the $E_{1/2}$ values of Co(II) and Ni(II) in nearly anhydrous solution cannot be due to a rapid change in either the junction potential or the "effective ionic strength" of the medium, since it is not observed with the other metals investigated.

but exaggerated, features at both ends of the composition scale.

Zinc appears to give a reversible wave with $[H_2O] > 50M$, but the slope of the wave increases as the concentration of the water is reduced, reaching a value of 83 mv in pure HOAc. By contrast, Cd and Pd give waves with reversible slopes for all compositions of the solvent.

Bismuth(III) acetate was not sufficiently soluble in water to obtain a wave, but the solubility improved on adding HOAc. The wave in this medium was nearly reversible with a slope of 23 mv. This parameter increased to a value of 52 mv as the water was reduced to 1.5M. Below this concentration a maximum appeared which could not be suppressed by added Triton X-100. An unsuppressable maximum was also observed with Cu(II) in anhydrous acid, but it disappeared on adding 0.5M water. The development of maxima on the waves of metals which reduce on the positive side of the electrocapillary maximum in HOAc has been studied in some detail by Bachman and Astle (2). The waves obtained with Cu(II) were reversible or nearly so over the rest of the scale.

These results stand in striking contrast to those of Bachman and Astle who found that the half-wave potentials of Pb, Cd, Zn, Co(II), and Ni(II) in 0.25F NH_4OAc were shifted to more negative values by 0.1-0.2v (*vide infra*). Migal and Agas'eva (4), on the other hand, found that the half-wave potentials of Cd, Zn, and Ni(II) were 145, 198, and 162 mv more positive in HOAc containing 0.01M NH_4NO_3 than in water when measured against the SCE.

To facilitate the interpretation of these data, the formic acid-water system was examined similarly, using in this case 0.5M ammonium formate as the supporting electrolyte (Fig. 2). Ni(II) and Co(II) were obscured by the hydrogen wave over most of the range. Zn, Bi(III), and Cu(II)[3] gave waves which displayed dramatic increases in irreversibility as the concentration of acid was raised, while Pb and Cd remained reversible throughout.

In the cases of Cd and Pb which reduce with no detectable overvoltage in both acid media, it is clear that these metals are not as efficiently stabilized in formic acid as they are in acetic. The lower dielectric constant operates to reduce the number of uncomplexed ions in solution, which accounts for the more negative potentials. Also important is the fact that formate is a poorer complexing agent than is acetate as evidenced by the lower pK_a of formic acid in water (3.75 *vs.* 4.76 for HOAc); this can be seen in the slightly more negative half-wave potentials observed in aqueous acetate media as compared to the aqueous formate values (Fig. 3). An additional factor contributing to the destabilization in acid media could stem from the decreased activity of the lyate. It is possible that the activity of the lyate may become so low in poorly ionizing solvents that, despite the correspondingly low value of the dissociation constants for the metal complexes, the degree of dissociation may actually be higher. The observed potential would then reflect a larger contribution from the uncomplexed component. Based on the known dissociation constants of the metal acetates and of ammonium acetate in acetic acid (11, 19) and in water (24), the activity coefficient of acetate ion in acetic acid would have to be very much less than unity to account for such large anodic shifts.

Limiting currents in aqueous acetic acid.—The striking influence of the solvent composition on the limiting currents obtained with various metal acetates is seen in Fig. 3, where the Ilkovic term $\bar{i}_l/nCm^{2/3}t^{1/6}$ is plotted. In each case the curves pass through a generally broad minimum between 5-20M water. Many physicochemical properties of water-acetic acid mixtures display a maximum or minimum at compositions near 13.7M water (mole fraction = 0.5) due to the presumed formation of the monohydrate, $HOAc:H_2O$ (20). In all cases the lower value of the current in acetic acid is anticipated on the basis of the higher viscosity of this solvent. The current data were corrected according to the Ilkovic-Stokes-Einstein equation (Fig. 4); in order not to neglect the effect of the inert electrolyte, the viscosities of 0.5M NH_4OAc solutions were determined (Fig. 5) and employed in this correction.

The corrected curves of Fig. 4 clearly indicated that factors other than viscosity are also responsible for the nonconstancy of the limiting currents. For a dif-

[3] In concentrated solution of HCOOH, Cu(II) presents two irreversible waves (Fig. 2) which merge into one as the water level increases. The dotted line indicates the "midpoint" potential for the wave pair.

fusion controlled process, variations in $\bar{i}_d\eta^{1/2}$ must reflect changes in the nature of the diffusing species. In addition to viscosity effects, there are two ways in which a solvent can be expected to determine the diffusion properties of a solution component. Various solvent properties such as acid-base character, dielectric strength, etc., will operate simultaneously (*a*) to determine the kinds of diffusing species (ionic or nonionic, mono- or polyvalent, simple or complex) present in solution, as well as the positions of the equilibria interrelating these, and (*b*) to determine the extent to which ionic and polar components are solvated, and consequently, the over-all geometry of the diffusing particle and the immediate solvent environment through which it must pass.[4] Similar points can be made concerning currents which are kinetically controlled; in such an instance one is concerned with the effect of the solvent on the transition state of the slow step rather than on the stabilities of longer-lived species, although parallels may exist.

The currents due to Pb(II), Cu(II), and Cd(II) are apparently diffusion controlled over the entire range of solvent composition. As Fig. 4 reveals, the maximum in $\bar{i}_d$ which occurs at the aqueous end of the scale (cf. Fig. 4) is just part of a generally complicated dependence on composition which indicates a wide variation in the bulk structure of the diffusing mass. Each of these metals displays seemingly unique behavior, although the ratio of the corrected currents in water to those in acetic acid are perhaps surprisingly constant (Pb, 1.23; Cu, 1.23; Cd, 1.27). The Zn(II) and Bi(III) currents display increasing chemical control at higher acid concentrations, which is evident in the larger value of this ratio for Zn (1.50); the value for Bi could not be measured. The corresponding ratios for Co(II) and Ni(II) are 1.26 and 0.83; neither metal shows simple diffusion control.

Several general features can be observed in the curves of Fig. 4: (*i*) all pass through a pH sensitive max above 50M; (*ii*) all except Ni show a slight maximum or plateau near 40M; (*iii*) all except Zn and Cd show an exaggerated minimum between 10 and 20M (the value at this point is less than or equal to the value in pure HOAc), followed by a maximum below 10M; the homologues, Zn and Cd, reach a broad plateau in this region; (*iv*) all except Cu and Co have a large positive slope at the nonaqueous extreme. Zn and Cd, whose curves do not possess the minimum described in item (*iii*), do give this feature when the inert electrolyte is 0.01F NH_4NO_3; the same is true for Ni(II) (4). This minimum may be associated with a rather loose solvent shell composed largely of the mono- and dihydrates of acetic acid, to which the composition of the solvent closely corresponds. As the concentration of HOAc is increased the rapid decrease in the dielectric constant would lead to a reduction in the concentration of dissociated ions requiring extensive solvation, and an enhanced mobility of the metal would be expected; the final drop in the current in nearly pure acid might be due to solute aggregation. On the other hand, as the water concentration is increased from about 20M, the more bulky HOAc molecules would be replaced by smaller more efficient solvators, and again, an increase in the mobility of the metal would be the likely result.

Half-wave potentials and slopes in anhydrous acetic acid.—In order to appreciate the effect of the carrier electrolyte on the polarographic behavior of the various metal acetates, the current-potential parameters were measured as a function of the supporting acetate concentration. Figure 6 shows that as the NH_4OAc is decreased from 2 to 0.5M there is a corresponding positive shift in the $E_{1/2}$ of each of the reversible or nearly reversible couples (Cd, Pb, and Cu); the same is true for Zn and Bi, which appear to be irreversibly reduced, although the drawing out of these waves may be due to the presence of two incompletely resolved components. This shift has been predicted by Schaap (22) as a result of ion-pair formation in solvents of low dielectric constants. A much less pronounced negative shift was recorded with Ni and Co, both of which reduce irreversibly. Data on Bi and Cu are incomplete due to the development of unsuppressable maxima at lower carrier levels. The 0.5M points shown in Fig. 6 for this pair of metals were obtained by extrapolation of the $E_{1/2}$ data from the HOAc-H_2O mixtures containing this amount of NH_4OAc.

At concentrations below about 0.5M the polarograms of all the metals became increasingly drawn out; in

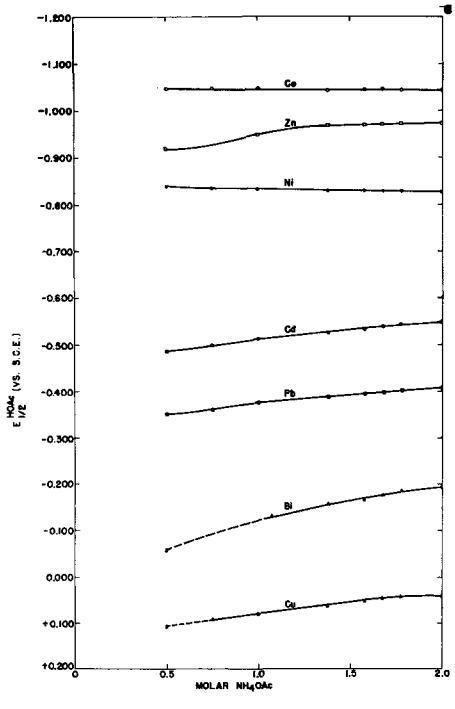

Fig. 6. Effect of NH_4OAc concentration on half-wave potentials of metals in acetic acid.

[4] Fuoss (21) has attempted to accommodate the electrostriction of the solvent shell quantitatively by employing an effective internal viscosity coefficient different from that ordinarily measured.

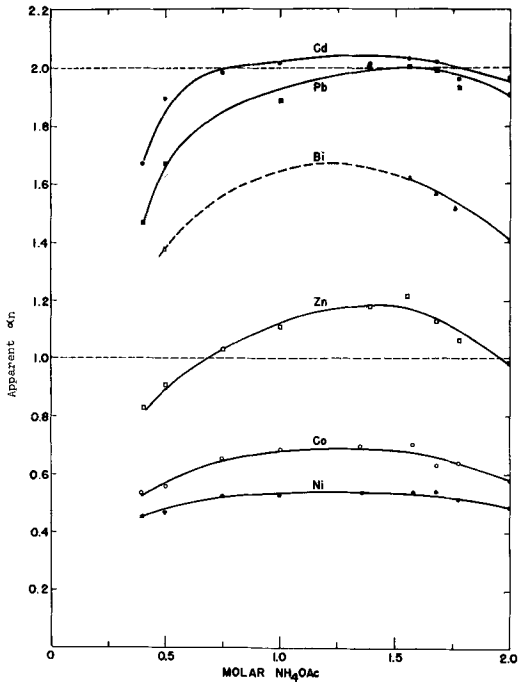

Fig. 7. Effect of NH_4OAc concentration on αn in acetic acid solution.

these instances the current was approximately proportional to the applied voltage. Below 0.1M no diffusion plateau was reached before $E_{applied} = -4$v. The dramatic change in the slope can be seen in Fig. 7 where the apparent "αn" is plotted. The results obtained below 0.3M depended slightly on the position of the microelectrode with respect to the reference. Further, the resistance of the cell at this concentration was of the order of 200,000 ohms, while at 0.5M it was only about 30,000 ohms. It is clear that the three electrode system employed fails to provide adequate iR compensation when the electrolyte concentration is below 0.3-0.5M. This point has been

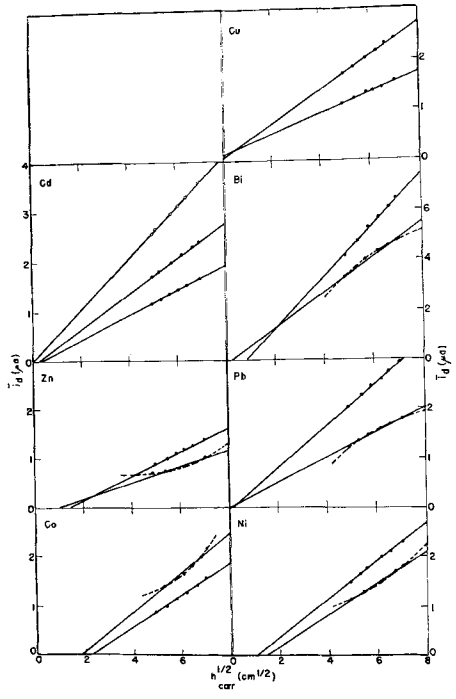

Fig. 8. Effect of mercury pressure on diffusion currents in acetic acid, ○, 0.18M LiOAc; ◓, 0.50M LiOAc; ●, 1.78M LiOAc.

treated in some detail by Schaap and McKinney (23), who obtained very similar results in a solvent system of approximately the same dielectric constant. Although it is possible that, due to the development of kinetic control, an actual change in the reversibility of the electrode process may also be taking place with some metals at lower acetate concentrations, this does not appear to be so in the case of Cd whose reduction is still diffusion controlled in 0.18M LiOAc (cf. Fig. 8).

The effect of the kind of supporting electrolyte on the half-wave potentials was examined. At concentration above 1.0M the observed potentials for Cd (Fig. 9) are essentially independent of the kind of electrolyte. Since an increase in the acetate activity should lead to more negative potentials, one would expect the following order of increasing negative values: LiOAc<NaOAc<KOAc<NH_4OAc. Although some crossing of the curves near 1.0M acetate is evident, the expected order is not attained even for LiOAc and NH_4OAc at 2.0M. This discrepancy may be due to an interfering junction potential or to a lack of sufficient information concerning the relative activities of the alkali acetates at high concentrations.

Below 1.0M the apparent $E_{1/2}$ values for Cd show considerable divergence. This is due to slight differences in wave slopes which have an exaggerated influence on the measured half-wave potentials. The $E_{1/2}$ values in this region are seen to decrease in the order of increasing ionic radius of the electrolyte cation. Since the equivalent conductivities of the alkali acetates increase with the size of the cation (19b), it is probable that the differences in the slopes of the polarograms at low electrolyte concentrations are re-

flections of the uncompensated iR drop existing at low values of the absolute conductivities.

Limiting currents in anhydrous acetic acid.—As can be seen in Fig. 10, the current increases with decreasing concentration of electrolyte, the behavior of Ni, Bi, and Cu deviating from that of the other metals. The viscosities of the electrolyte solutions were determined (Fig. 12), and the data were corrected accordingly as shown in Fig. 11. The near constancy of $\bar{i}_l\eta^{1/2}/nCm^{2/3}t^{1/6}$ at the higher end of the concentration range for Cu, Pb, Cd, and Bi indicates that the current change in this region depends primarily on the change in viscosity of the medium. At the opposite extreme of electrolyte concentration, however, the current is more sensitively and inversely related to the amount of added acetate. Since migration should not be a complication at supporting electrolyte concentrations of 0.01M or greater, even in this weak electrolyte system, the change in $\bar{i}_l$ must be due to an alteration in the structure of the average diffusing species. This is strictly true in the cases of these four

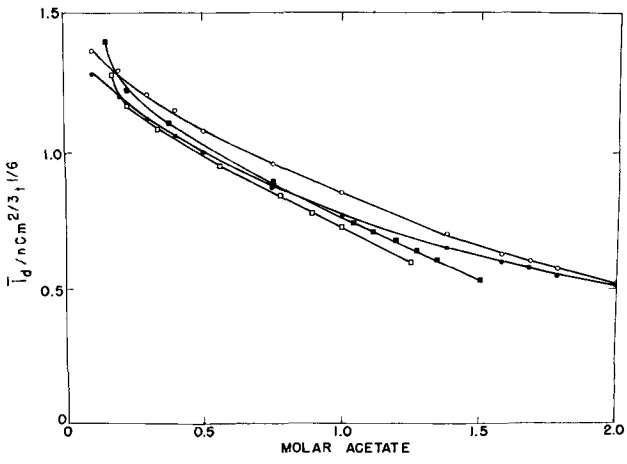

Fig. 13. Effect of concentration of supporting acetate on diffusion current of $Cd(OAc)_2$ in acetic acid. Symbols are the same as those in Fig. 9.

metals for which it can be shown that the limiting-current is diffusion controlled (Fig. 8). The reductions of Zn, Co, and Ni exhibit reaction rate-controlled currents (Fig. 8) which may or may not comply with Walden's rule; the same is true of Bi at low electrolyte levels. The more pronounced change in the currents at low electrolyte concentrations may be a manifestation of aggregation of the reducible metal acetate and one or more supporting electrolyte ion-pairs. The dipole moment of the electrolyte ion-pair will be larger than that of acetic acid with which it is structurally homologous. As the concentration of supporting acetate is increased, this component will compete increasingly more favorably with acetic acid for a position in the solvation sphere of the reducible metal ion, *i.e.*, MeL_n (S) + xMOAc $\rightleftarrows$ MeL_n (MOAc) (S) $\rightleftarrows$ . . . $\rightleftarrows$ $MeL_n(MOAc)_x$ (S). The bulk of the latter will then increase to a point of maximum coordination. Further addition of the electrolyte will lead only to self-aggregation which would not directly effect the diffusion of the reducible metal, except by way of changing the effective viscosity of the medium. This hypothesis is borne out by the observation that the viscosity-corrected limiting currents obtained with Cd in the presence of different supporting acetates were more strongly dependent on the nature of the associated cation than on the concentration of the electrolyte (Fig. 13 and 14). This is just what would be ex-

pected, since the cation would determine not only the size of the "solvating" electrolyte, but also the magnitude of its dipole moment. Figure 14 shows that the initial decrease in the current is relatively small in the case of the larger potassium and ammonium ions and most pronounced with the smaller sodium. The latter ion would be expected to benefit most from aggregation, since it is a much higher energy species; LiOAc is undoubtedly so tightly solvated by acetic acid that its behavior is that of an unusually large species which also has little to gain through aggregation. This rationale does not provide an explanation for the rise is the limiting current at concentration levels above 0.5M. It must not be forgotten, however, that the viscosity corrections employed are not entirely adequate in solvents of low dielectric strength, such that the curves shown may not truly reflect the active mobilities of Cd at the various concentrations (22).

Acknowledgments

The author is particularly grateful to Professor L. B. Rogers for his review and discussion of this manuscript. Thanks also must go to the author's colleague, Dr. D. M. King, who labored many hours with him in helpful discussion.

Manuscript received Aug. 24, 1965; revised manuscript received Jan. 13, 1966. This is Research and Development Division Contribution No. 304, E. I. du Pont.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Raman Spectra of Molten Mixtures of Zinc Halides with Alkali Metal Halides

R. B. Ellis

Southern Research Institute, Birmingham, Alabama

ABSTRACT

Raman spectra of molten compositions in the $ZnCl_2$-MCl (M = Li, K, Rb, or Cs) systems contain strong, polarized bands at 230, 275, 290, and 305 cm^{-1} and weak bands, probably polarized, at ~260 and 345 cm^{-1}. The strong bands have essentially the same frequencies as those appearing in solutions in water and organic solvents. The variations in relative intensity of the bands in the melts with temperature and composition are consistent with assigning them to the same species identified in aqueous solutions, namely, 230 cm^{-1}, a $(ZnCl_2)_n$ polymer; 275 cm^{-1}, $ZnCl_4^{2-}$; 290 cm^{-1}, $ZnCl_3^-$; 305 cm^{-1}, $ZnCl_2$ monomer. The weak 345 cm^{-1} band is tentatively assigned to the $ZnCl^+$ ion. The weak 260 cm^{-1} band is assumed to be associated with an unstable species containing at least one Zn-Cl-Zn bond. In $ZnBr_2$-KBr melts the principal species are $(ZnBr_2)_n$ polymer, $ZnBr_4^{2-}$, and $ZnBr_3^-$. The $ZnBr_2$ and $ZnBr^+$ species are much less stable relative to the corresponding chloride species.

The structure of molten zinc halides is of considerable interest because the physical properties of these salts indicate occurrence of extensive molecular association at temperatures near the melting point. Primarily on the basis of a marked decrease in electrical conductivity and increase in viscosity, Mackenzie and Murphy (1) proposed a network structure of $ZnCl_2$ at the melting point that gradually degrades with rising temperature into Zn^{2+} and $ZnCl_6^{4-}$ ions. They were influenced in their assumption of the hexachlorozincate ion by the C-19 ($CdCl_2$) layer structure assigned to solid $ZnCl_2$ by Bruni and Ferrari (2). In light of the four-coordinate structure for crystalline $ZnCl_2$ recently described by Brehler (3) and their own

Table I. Raman spectra of zinc halide solutions

Assumed species	Observed wave numbers for the symmetrical stretching vibration, cm^{-1}				
	Delwaulle (8)	Kecki (9)	Morris (10)	Irish (11, 12)	Yellin and Plane (13)
$Zn(H_2O)_6^{2+}$				390	
$ZnCl^+$				305	
$ZnCl_2$	305	304	305	305	
$ZnCl_3^-$			286		
$ZnCl_4^{2-}$	282	282	275	278	
$ZnCl_n^{2-n}$				266	
$(ZnCl_2)_n$				230	
$ZnBr^+$					205
$ZnBr_2$	208		206		
$ZnBr_3^-$	184		182		
$ZnBr_4^{2-}$	172		172		172

experimental work on ultrasonic absorption, Gruber and Litovitz (4) suggest that, close to the melting point, the liquid consists of chains of ZnCl tetrahedra sharing corners and that these chains dissociate into Zn^{2+} and $ZnCl_4^{2-}$ ions.

There is evidence from several other lines of investigation for the existence of zinc-halogen complexes, usually assumed to be $ZnCl_3^-$ or $ZnCl_4^{2-}$. Moss (5) calculated the activities of KCl and $ZnCl_2$ in molten mixtures from measurements of vapor pressure and vapor composition, and Lantratov and Alabyshev (6) obtained similar information from electromotive force measurements on galvanic cells. The results of both investigations were consistent with the assumption of $ZnCl_3^-$ or $ZnCl_4^{2-}$, but the identity of the species could not be clearly established. Van Artsdalen (7), using a cryoscopic technique, found that the important species in dilute solutions of $ZnCl_2$ in molten $NaNO_3$ were Zn^{2+}, $ZnCl_2$, and $ZnCl_4^{2-}$.

It is expected that vibrational spectra should be more helpful in identifying the species present than other physicochemical properties. The species present in solutions of zinc chloride and zinc bromide in water and organic solvents, at various levels of total zinc concentration and of zinc-halogen ratio, have been identified and the observed Raman spectra have been correlated with them (8-13). The results are summarized in Table I, indicating excellent agreement among the several investigators. The assignments of the 205 and 186 cm^{-1} bands for zinc bromide species given by Morris, Short, and Waters (10) and by Delwaulle (8) appear preferable to those by Yellin and Plane (13). Especially pertinent to the present problem is Irish and Young's investigation (12) of the transition from highly concentrated aqueous solutions to anhydrous melts, in which two bands, 230 and 266 cm^{-1}, increase in intensity as water is removed from the system. The published data on the Raman and infrared spectra of melts containing $ZnCl_2$ are tabulated in Table II. Bues (14) assigned the 233 cm^{-1} band to a polymeric species, $(ZnCl_2)_n$, the 280 cm^{-1} band to $ZnCl_4^{2-}$, and the 292 cm^{-1} band to $ZnCl_3^-$. Bredig and Van Artsdalen (18) have argued that Bues' data do not justify the assumption of two complex ions and favor the $ZnCl_4^{2-}$ species. It should be noted that the work of Morris, Short, and Waters, that of Irish and Young, and that of Moyer, Evans, and Lo had not been done at that time. In the more recent work of Irish and Young and of Moyer, Evans, and Lo, the species are identified as a polymer, a $ZnCl_2$ monomer, and a $ZnCl_4^{2-}$ ion. On the other hand, Wilmshurst considers his infrared spectra to arise from lattice-type interactions among simple ions rather than from true complexes. This conclusion was based primarily on the variations in wave number and intensity with change in composition.

Table II. Literature data on Raman and infrared spectra* for molten compositions containing zinc halides

Author	Composition	Temperature range, °C	Wave numbers, cm^{-1}
Bues (14)	$ZnCl_2$	350-600	233
	$2ZnCl_2 \cdot KCl$	280	233, 292
	$ZnCl_2 \cdot KCl$	250-500	85, 292
	$ZnCl_2 \cdot 2KCl$	450-550	92, 280
	$ZnCl_2 \cdot 4KCl$	650	92, 280
Salstrom and Harris (15)	$ZnCl_2$	400-500	100, 231, 285
	$ZnBr_2$	440	79, 155
Irish and Young (12)	$ZnCl_2$	340-470	95, 110, 230, 266, 305, 375-400
Moyer (16)	$ZnCl_2$	280-500	75, 226, 250, 305, 360
	$4ZnCl_2 \cdot KCl$		80, 266, 288, 349
	$2ZnCl_2 \cdot KCl$		75, 226, 290, 344

	$ZnCl_2 \cdot 2LiCl$	490	320
	$ZnCl_2 \cdot 3LiCl$	593	330
	$LiCl$	695	350

* The spectra of Wilmshurst are IR, the rest are Raman.

The only data on molten $ZnBr_2$ are the two bands found by Salstrom and Harris (15) at one temperature, which do not agree with those for aqueous solutions.

In order to learn more about the species existing in molten systems containing zinc chloride and alkali metal chlorides and to compare them with corresponding bromide systems, we have made an extensive study of the Raman spectra of these systems.

Experimental

Materials.—Reagent grade $ZnCl_2$, containing about 5% H_2O, was dried by heating under vacuum to the melting point over a period of about 4 hr. Dry HCl gas was then bubbled through the melt for about 4 hr, followed by carefully dried argon for 1 hr or longer. This operation was carried out in a reservoir sealed to the Raman tube with an intervening sintered glass filter of medium porosity. After the drying operation, the melt was transferred through the filter into the Raman tube, which was then sealed off under vacuum. Zinc bromide was treated in the same way, using HBr to counteract hydrolysis. Mixtures were prepared by combining appropriate amounts of the desired zinc halide and alkali metal halide in the oven-dried state and following the same drying procedure.

Apparatus.—The Raman spectra were recorded with a Hilger E612 spectrograph, using the f/5.7 camera and Eastman 103a-J plates. The Hilger-FL1 mercury-lamp source unit was replaced with one of essentially identical design except that the lamps were centered on a 3-in. radius instead of 2 in., in order to have ample space for the sample heater, which was made according to Corbett's (19) design. For estimating depolarization ratios of the Raman lines, a Wollaston prism was inserted into the light path between the source unit and the spectrograph, as suggested by Bender and Lyons (20). The positions of the spectral lines were measured on recording densitometer traces, using the graphical technique of resolving overlapping bands described by Irish and Young (12, 13). Iron and mercury spectra were used for calibration. The 4358Å line of mercury was used as the exciting radiation.

Results

Raman spectra have been obtained on $ZnCl_2$ and its mixtures with LiCl, KCl, RbCl, and CsCl and on $ZnBr_2$ and its mixtures with KBr, in the molten state.

w, weak; m, medium; s, strong; d, depolarized; p, polarized.
[a] Wave numbers are averages of 10 or more observations with a maximum range of ±5 cm^{-1}.
[b] The 290 cm^{-1} band appears only on the anti-Stokes side.

Tables III and IV contain the average wave numbers for chloride and bromide compositions, respectively, along with an indication of the relative intensity and polarization state where determined. No Raman bands were found in molten, pure RbCl. There were no systematic variations in wave number with temperature, although there were some variations in intensity for some of the bands. The reported wave numbers are the averages of values obtained from ten or more recorded spectra for each composition, and each value has a range of ±5 cm^{-1} or less. Since they are close to the parent line, the bands between 50 and 106 cm^{-1} appear as weak shoulders on a steep background curve. In some spectra the background was so dark that these bands were not detected. In others, the presence of a band was recognizable, but the center could not be located accurately. For this reason, the number of bands in the range from 90 to 105 cm^{-1} in the $ZnCl_2$-KCl system cannot be definitely stated. However, the 115 cm^{-1} band in the $ZnCl_2$-RbCl and $ZnCl_2$-CsCl systems is definitely different from the 90-105 cm^{-1} band. In the $ZnBr_2$-KBr system there is clearly a single band at 79-82 cm^{-1}, but the bands in the 50-70 cm^{-1} range cannot be clearly resolved.

In pure $ZnCl_2$, the ratio of the intensities of the 230 cm^{-1} band to that of the 305 cm^{-1} band is about 10:1 at 295° and about 5:2 at 600°. At the $80ZnCl_2$-$20KCl$ composition, the ratio of intensities for these two bands is about 4:1 at 300°, but 1:2 at 625°. At both of these compositions, the intensity of the 260 cm^{-1} band decreases with increasing temperature, while that of the 345 cm^{-1} band increases. The intensity of the 230 cm^{-1} band decreases with increasing percentage of added alkali chloride until it is very weak at 50 mole % $ZnCl_2$ and only traces appear at lower $ZnCl_2$ contents. In the $25ZnCl_2$-$75KCl$ mixture, the 290 cm^{-1} band appears on the anti-Stokes side but not on the Stokes side. In the $50ZnCl_2$-$50LiCl$ mixture the 280 cm^{-1} band appears in some spectra and the 290 cm^{-1} in others, but they have not been observed together.

In the $ZnBr_2$-KBr system, the 150 cm^{-1} band predominates in pure $ZnBr_2$, with its intensity decreasing with increasing temperature and with increasing KBr concentration. The 170 cm^{-1} band is weak in pure $ZnBr_2$ at the lower temperatures. Its intensity increases with addition of KBr. At 50 mole % $ZnBr_2$ it predominates at 270°, but becomes progressively weaker as the temperature increases. However, at 25 mole % $ZnBr_2$ it is strong at 600°. The 180 cm^{-1} band is weak or absent at the lower temperatures at each composition, increases with rising temperature, and

Table IV. Raman spectra of the molten zinc bromide-potassium bromide system

Composition mole % $ZnBr_2$	Temperature, °C	Wave numbers,[a] cm^{-1}

w, weak; m, medium; s, strong; d, depolarized; p, polarized.
[a] Wave numbers are averages of 10 or more observations with a maximum range of ±5 cm^{-1}.
[b] Strong band that cannot be resolved, broad enough to include 150 and 180 cm^{-1}.

becomes predominant at 50 mole % $ZnBr_2$ above 400°. It is weak at 600° at the 25 mole % $ZnBr_2$ composition. The 225 cm^{-1} and 265 cm^{-1} bands are weak at all compositions, having their greatest strength in the range of 50-80 mole % $ZnBr_2$.

Discussion

Zinc chloride systems.—Possible chemical species and the corresponding numbers of fundamental vibrations are summarized as follows:

Fundamental Vibrations

Chemical species	Point group	Total No.	IR active	Raman active	Raman polarized
Zn^{++}	—	—	—	—	—
$ZnCl^+$	$C_{\infty v}$	1	1	1	1
$ZnCl_2$ linear	$D_{\infty h}$	3	2	1	1
$ZnCl_2$ bent	C_{2v}	3	3	3	2
$ZnCl_3^-$ planar	D_{3h}	4	3	3	1
$ZnCl_3^-$ pyramidal	C_{3v}	4	4	4	2
$ZnCl_4^{2-}$ tetrahedral	T_d	4	2	4	1
$ZnCl_6^{4-}$ octahedral	O_h	6	2	3	1

In addition to these mononuclear species, there may conceivably be a variety of polynuclear species. For instance, phase diagrams for the $ZnCl_2$-KCl (21), $ZnCl_2$-TlCl (22), and $ZnCl_2$-NH_4Cl (23) systems show compounds of the type $2ZnCl_2$-MCl, but a binuclear $Zn_2Cl_5^-$ complex has not been proposed as a constituent of aqueous solutions or of melts. However, a polymer made up of $ZnCl_4$ tetrahedra linked by sharing corners has been proposed (4, 12).

The observed Raman bands may be separated into two groups, weak, depolarized bands between 80 and 115 cm^{-1} and polarized bands above 200 cm^{-1}. The first group has wave numbers of a magnitude expected for bending vibrations. Since it was impossible to determine the exact number of bands, they cannot be used as a basis for inferences concerning the species they represent. However, they are consistent with the inferences based on consideration of the other bands. The second group contains polarized bands at approximately 230, 260, 275, 290, and 305 cm^{-1} and one at 345 cm^{-1} for which the state of polarization is in doubt. Since polarized bands arise from totally symmetric vibrations and since stretching vibrations have higher frequencies than bending vibrations, these bands must represent symmetric stretching vibrations. In the above list of fundamental vibrations for the several possible chemical species, there is only one totally symmetric stretching vibration for each species. Therefore, each of the polarized Raman bands must represent a different chemical entity. The almost exact agreement between the wave numbers of the bands appearing in aqueous solutions and those in the melts implies that the same Zn-Cl species exist in both systems.

Brehler (3) has described the structure of crystalline $ZnCl_2$ in terms of $ZnCl_4$ tetrahedra linked by sharing corners. Gruber and Litovitz (4) and Irish and Young (12) have suggested that much of this structure persists in the melt as "polynuclear aggregates" or "polymers." Figure 1 illustrates a portion of this structure. The circles represent chlorine atoms lying in the plane of the paper. Triangles represent zinc atoms, those with apices pointing up lie above the plane of the paper at a distance of +1/3 of *d* and have Cl atoms above them at distance *d* above the plane of the paper. Triangles with apices pointing down lie below the plane of the paper, at —1/3 of *d*, and have Cl atoms below them in the next lower Cl plane. Circles marked with an X lie in the plane of the paper and have Zn atoms above and below them at ±2/3 of *d*. Lines of Cl atoms such as those marked A-A lie in Cl planes tilted 60° to the plane of the paper. Thus, each Zn atom is tetrahedrally coordinated to four Cl atoms and each Cl atom has two Zn neighbors. The array may be formed by fitting together

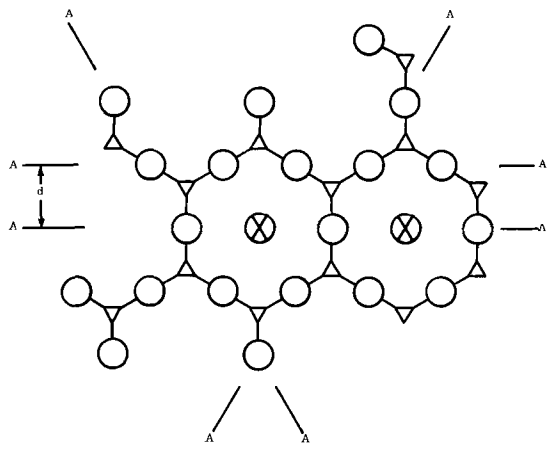

Fig. 1. Structure of crystalline $ZnCl_2$: △ Zn 1/3 of *d* above plane of paper; ▽ Zn 1/3*d* below plane of paper; ○ chlorine.

$ZnCl_2$ molecules, with the four bonds to the Zn atoms becoming equivalent by sp^3 hybridization.

These polynuclear aggregates will have a totally symmetric "breathing" vibration that will give rise to a strong, polarized Raman band. This band has been observed at 230 cm^{-1} in the $ZnCl_2$ crystal, in melts, and in very concentrated aqueous solutions, as given in Table II. There will also be peripheral groups that will vibrate independently of the fully coordinated body of the aggregate. These groups will include $ZnCl_4^{2-}$, $ZnCl_3^-$, and $ZnCl_2$ groups attached through a chlorine. A $ZnCl_4^{2-}$ group will probably be only slightly distorted from the normal tetrahedral symmetry by its attachment, so that the frequency of its symmetrical breathing vibration will not be much different from that of a completely separated $ZnCl_4^{2-}$ ion. Considered as fragments of a tetrahedral structure, a $ZnCl_3^-$ group would be pyramidal and a $ZnCl_2$ would be bent. However, Cl-Cl repulsion would tend to make these structures planar and linear, respectively. In either case, attachment to the aggregate will not change the group frequency greatly.

Just above the melting point, the aggregates will be large, and the number of small groups, both peripheral and free, will be relatively small. Increasing temperature will break the aggregates into smaller units, each of which will still have the characteristic breathing vibration so that the associated Raman band will not change much in intensity until the dissociation is essentially complete. However, the intensities of the bands representing the smaller units should increase. The presence of excess chloride ion from an added alkali metal halide would promote splitting off of peripheral groups and, hence, reduction of the aggregates.

The Raman spectrum of pure molten $ZnCl_2$ is dominated by the strong 230 cm^{-1} band characteristic of the polynuclear aggregate. A band at 305 cm^{-1} is weak at low temperatures and becomes stronger with increasing temperature so that it must be associated with a fragment. Since in aqueous solutions a 305 cm^{-1} band has been assigned to the $ZnCl_2$ molecule and since this unit is one of the most likely peripheral groups or fragments in the melt, it is reasonable to assign the 305 cm^{-1} band to the $ZnCl_2$ molecule in the melt also. There is a still weaker band in the 250-270 cm^{-1} range; Moyer, Evans, and Lo found it at 250 cm^{-1}, Irish and Young at 266 cm^{-1}, and this work at 260-270 cm^{-1}. The intensity of this band decreases with increasing temperature, and so it cannot be associated with a fragment that increases in concentration with temperature, such as $ZnCl_4^{2-}$ or $ZnCl_3^-$. Irish and Young assign it to a fragment that is thermally unstable. If it were associated with the aggregate, it would probably represent an unsymmetric stretching vibration, but our observations indicate that

it is polarized, which means that it arises from a symmetric vibration. The fragment may be a ring of six $ZnCl_4$ tetrahedra or a group containing only one Zn-Cl-Zn linkage. The observation that it is also unstable toward excess Cl^- ion is further evidence against the $ZnCl_4^{2-}$ or $ZnCl_3^-$ groups, but in favor of a species containing at least one Zn-Cl-Zn link. We observed a very weak band at 350 cm^{-1} in pure $ZnCl_2$. Because of its weakness we were unable to establish its state of polarization. However Moyer, Evans, and Lo claim that it is polarized. If the band is polarized, it must belong to a ZnCl vibration of higher energy than that in $ZnCl_2$. The only likely species of this description is the $ZnCl^+$ ion. This assignment is consistent with the behavior on addition of excess Cl^- ion observed by Moyer, Evans, and Lo and by us; namely, that it increased in intensity somewhat in the composition range around 25 mole % added chloride, then decreased until it disappeared at compositions containing more than 50 mole % alkali metal chloride.

At compositions containing 33 mole % alkali metal chloride or more, a band appears at 290 cm^{-1} and, at still higher concentrations of added chloride, another at about 275 cm^{-1}. These bands are definitely different from the 305 cm^{-1} band assigned to $ZnCl_2$ molecules. Since they are associated with successively higher ratios of Cl to Zn, it is assumed that they represent species containing more than two chlorines per zinc, namely, $ZnCl_3^-$ and $ZnCl_4^{2-}$. In Table I, the wave numbers 286 cm^{-1} and 275-280 cm^{-1} are assigned to $ZnCl_3^-$ and $ZnCl_4^{2-}$, respectively, in aqueous solutions. The appearance of the same bands in the aqueous and molten systems implies that the same species are present. However, in aqueous solution, the positions in the coordination sphere of the zinc atom not occupied by chlorine atoms can be filled with water molecules. In the melt the only ligand available is the chloride ion, so that the $ZnCl_3^-$ species, with its incomplete coordination sphere, appears unlikely. Moyer, Evans, and Lo found only one Raman band at 290 cm^{-1}. Bues recorded two bands, 292 cm^{-1} and 280 cm^{-1}, but not at the same composition, and Bredig and Van Artsdalen argue that they were probably the same band. This work confirms Bues' observations of 290 cm^{-1} at the $ZnCl_2$-KCl composition and 280 cm^{-1} at $ZnCl_2 \cdot 3KCl$. The shapes of the bands and the precision of locating their centers indicate the presence of two different bands even though the two have not been observed together in the same spectrum. Therefore, we conclude that both $ZnCl_3^-$ and $ZnCl_4^{2-}$ do exist in melts.

Cation effect.—Two effects of the size of the alkali metal cation might be expected. The presence of the cation might distort the symmetry of the vibrating species and change the frequency somewhat. Janz and James (24) reported this effect on the nitrate ion in melts. We did not find any systematic change in frequency with changing cation for any of the bands. Since we are concerned here with equilibria among several chemical species of different degrees of complexity, a change in cation might affect the equilibria to shift the relative concentrations of the species involved. The high polarizing power of the smaller cations might have a disruptive effect on the more highly complexed species. This effect is observed to a minor extent on the un-ionized species, namely, the $(ZnCl_2)_n$ polymer and $ZnCl_2$ monomer. At the equimolar composition, the relative intensities of the 230 and 305 cm^{-1} bands are somewhat greater for Cs and Rb than for K and Li. No consistent trend is observed for the 280, 290, and 350 cm^{-1} bands.

Zinc bromide system.—The Raman spectra of compositions in the $ZnBr_2$-KBr system show many of the same characteristics of those in the chloride system. There is a group of weak, depolarized bands below 100 cm^{-1} that are presumably related to bending vibrations. There are several strong, polarized bands in the 100-200 cm^{-1} region that are typical of symmetric stretching vibrations and thus represent several chemical species. The spectrum of pure $ZnBr_2$ is dominated by a strong band at 150 cm^{-1}. This band was reported by Salstrom and Harris (15) for a melt, but does not appear in aqueous solutions (of 1M concentration) (10). This band is unstable with respect to increasing temperature and increasing Br^- ion concentration. By analogy with $ZnCl_2$, this band may be assigned to a polymeric complex, $(ZnBr_2)_n$. At higher temperatures and with added Br^- ion, new bands appear at 170 and 180 cm^{-1}, which are identical with the bands assigned to $ZnBr_4^{2-}$ and $ZnBr_3^-$, respectively, in aqueous solutions. Consistent with this assignment, the species associated with the 170 cm^{-1} band increases in stability with increasing Br^-:Zn ratio, but tends to be less stable at higher temperatures than the species represented by the 180 cm^{-1} band. Yellin and Plane (13) assigned the 180 cm^{-1} band in aqueous solution to $ZnBr_2$ instead of $ZnBr_3^-$. In view of the persistence of this band to high concentrations of excess Br^- ion, the $ZnBr_3^-$ assignment seems preferable. A weak 200 cm^{-1} band at 80 $ZnBr_2$-20KBr probably corresponds to the $ZnBr_2$ monomer.

The weak, depolarized bands at 225 and 260 cm^{-1} are assumed to arise from asymmetric stretching vibrations of the $ZnBr_4^{2-}$ and $ZnBr_3^-$ complexes.

Acknowledgment

The experimental work was performed by Mr. A. C. Freeman, Associate Chemist. The very valuable discussions and assistance in interpretation of the spectra of Dr. W. C. Coburn, Jr., is gratefully acknowledged. This work was supported by the U. S. Atomic Energy Commission under Contract No. AT-(40-1)-2073.

Manuscript received Dec. 20, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Adsorption and Electrooxidation of Butane on Platinum Black in H_2SO_4

Joseph A. Shropshire and Hugh H. Horowitz

Process Research Division, Esso Research and Engineering Company, Linden, New Jersey

ABSTRACT

Rates of butane adsorption on platinum black in sulfuric acid have been measured at 95°C using voltammetry in a flow-through electrode system. Initial adsorption rates showed a strong dependence on potential in the range 100-300 mv *vs.* the reversible hydrogen electrode. This effect was shown to arise from blockage of butane adsorption sites by adsorbed hydrogen atoms. The data strongly indicate that butane adsorbs only on Type II (most anodic) H· sites.

Although a significant research effort has been devoted in recent years to the determination of the mechanism of electrooxidation of saturate hydrocarbon fuels, particularly those potentially useful in fuel cell systems, no clear picture of the rate limiting steps involved in such an oxidation is as yet available (1-7). While it is generally conceded that the adsorption or adsorption-cracking of saturate fuels on noble metal catalysts of the type generally used can constitute a significantly slow step in the over-all reaction, and has been suggested as the factor determining limiting current in some cases (5-7), no meaningful measurements of adsorption rates on practical catalysts, free of solubility and diffusion effects, have been made.

Progress has been restricted by the fact that useful fuel cell electrocatalysts are prepared as chemically precipitated high surface powders or highly dispersed on conductive substrates. Catalyst materials of this type may be fabricated into porous electrodes which avoid diffusion limits because they are covered by very thin electrolyte films. However, such electrodes are not well suited to the fast electrochemical transient techniques such as high speed voltammetry and high current chronopotentiometry (8, 9). Smooth microelectrodes, which are suitable for fast techniques, are operated under electrolyte, where they would be subject to diffusion limitations with sparingly soluble hydrocarbon fuels.

Another possible drawback of smooth electrodes is that they may be chemically different from high surface area electrodes, perhaps having different crystal planes exposed and different types of lattice defects. Smooth platinum electrodes consistently appear to oxidize hydrocarbons at more anodic potentials than platinum black. By the same token, adsorption studies from the gas phase on dry catalyst leave open the question of the effect of large quantities of water and other components adsorbable in the aqueous solutions to be used in actual practice and effect of electrode potential on the processes.

This paper describes the results of a study of the adsorption of butane on a commercially available high surface platinum black (Engelhard) in H_2SO_4. In addition to electrochemical measurements of the equilibrium butane adsorption on this catalyst, voltammetric measurements on the catalyst in a rapidly moving stream of butane-saturated electrolyte have been used to determine maximum adsorption rates at low polarization. The flowing electrolyte technique, used previously in studies on highly soluble fuels and oxidants (10), appears to overcome the objections discussed previously and thus sheds considerable light on the over-all question of hydrocarbon adsorption-reaction.

Experimental Technique and Equipment

Two types of electrode were used in this study. In experiments involving measurement of the equilibrium adsorption of butane and its desorption with potential, the (Engelhard) platinum black in 10:1 mixture with Teflon 41BX (du Pont) was pressed on simple platinum flag electrodes.

The apparatus used to obtain measurements on butane adsorption rates in the flowing electrolyte system is shown in Fig. 1. The platinum black powder, generally 10 mg/cm^2 (on a total of 3.8 cm^2) was held at the upper face of an 18 mil porous tantalum sheet (courtesy of Kennametal) by the downward flow of electrolyte. Maximum flow rates obtainable with a 6-in. electrolyte head at 95°C were of the order of 70-80 cc/min (~20 cm/min) with lower values regulated by a stopcock on the exit line at the bottom. The two-liter flask containing 3.7M H_2SO_4 at 95°C was stirred briskly by a stream of Instrument Grade butane. Make-up electrolyte was added as necessary from addition bottle "N" at as near to the equilibrium conditions in the flask as was possible. Electrical connections were made to the tantalum plate via a gold current collector, a platinum auxilliary electrode in the flask, and a saturated calomel electrode with Luggin capillary tip about ¼ in. above the surface of the porous tantalum plate. The Luggin capillary itself was filled with 3.7M H_2SO_4 and changed frequently to prevent chloride contamination of the electrolyte. As a result of the minimum time actually required in measurement and the high butane sparge rates, no effect of the slight amount of hydrogen or oxygen evolved at the counter electrode was ever noticed.

Prior to the individual runs, the piece of porous tantalum plate to be used was abraded lightly on its upper surface with a steel wire brush and cleaned with a once-through application of aqueous HF to remove any oxide film and subsequently rinsed with deionized water at room temperature.

Potentiostatted triangular or sawtooth voltage signals could be applied to the electrode from a modified

Anotrol Model 4100 Research Controller fed by the output of a Servomex LF 51 function generator. Resultant I-V (or t) functions were recorded on a Moseley Model 135 X-Y plotter and coulombic quantities obtained by integration of the desired peaks using a planimeter. For the scan speeds used with these active platinum catalysts all the adsorbed fuel was oxidized from the electrode, and the current equalled the blank values by the time the positive voltage limit of the scan was reached. No remaining fuel was detected in repeat scans on the electrode under quiescent conditions. (Due to the irreversibility of hydrocarbon fuel oxidation, high speed voltammetry and high current chronopotentiometry generally do not fulfill this condition until considerably more positive voltage levels are reached.) Fractional coverages referred to in this paper are derived from measured coulombic values referred to saturation or maximum levels. Thus, for want of precise measurements of true surface area, all coverages refer to the electrochemically active surface.

All solutions were prepared using reagent grade concentrated H_2SO_4 and deionized water of conductivity less than 10^{-6} mho/cm. Previous experiments have shown that further purification of the acid solution by preelectrolysis does not affect the adsorption results. In the measurement times involved trace impurities would not be expected to affect these high area catalysts significantly. Potentials are reported *vs.* the saturated calomel electrode (S.C.E.) the measured voltage of which, as a result of liquid junction and thermal potentials, is 0.138v *vs.* a hydrogen electrode in these acid solutions at 95°C.

Experimental Results and Discussion

Applicability of the flow system concept.—In order to determine the feasibility of determining adsorption rates in a flowing fuel-saturated electrolyte system, a series of screening experiments were carried out to define the response of the system to electrolyte flow rate and catalyst loading changes. For this purpose the quantity of coulombs in the butane oxidation peak during a continuous triangular voltage scan from 0.0 to 1.1v *vs.* S.C.E. at 22 mv/sec was taken as a relative measure of the fuel accumulation rate (6, 11). Measurement of a meaningful adsorption rate requires that the fuel accumulation rate must become independent of the flow rate, *i.e.*, bulk mass transfer, in the region of measurement. Confidence is added to the measurement if the relative rate in the flow independent region is insensitive to catalyst amount.

Results of these initial tests, shown in Fig. 2, for flow rates to 65 cc/min and two catalyst loadings, show that a maximum in fuel accumulation rate, presumed to be an adsorption rate limit, is reached at levels above ~40 cc/min. Excellent agreement in the normalized relative rates for two widely differing catalyst loadings indicates that the method provides a sound basis for further studies. Due to the desire to obtain maximum flow rates in all subsequent experiments of this type, catalyst loading was thereafter maintained at the 10 mg/cm^2 level.

A further confirmation of the limitation of fuel accumulation by adsorption rather than mass transport was obtained from the temperature dependence of fuel accumulation. Thus, in the interval from 80° to 100°C the increase in coulombs accumulated during the fixed scan period indicated an apparent activation energy of 11 kcal/mole. This value, much too high for transport limitation, is in good agreement with that obtained as the temperature dependence of the limiting current for butane electrodes in 3.7M H_2SO_4 at 100°C (6, 11).

Characterization of the platinum substrate.—In order to establish a firm basis for the comparison of further data and subsequent interpretation of effects, voltage scan measurements were carried out to characterize electrochemically the Engelhard platinum black. These measurements were made using the pressed electrodes described previously immersed in argon-sparged 3.7M H_2SO_4 at 80°C. Adsorption-discharge of protons to form H· in the region negative to +0.2v *vs.* S.C.E. was defined as a function of potential, and total coulombs of chemisorbed hydrogen atoms were related to the coulombs for oxide formation and reduction during a fixed scanning procedure. In this way it was possible to relate subsequent measurements to one another, through known relationships.

A summary of this data is contained in Table I and a plot of the hydrogen atom coverage with potential is shown in Fig. 3. The inflection in the coverage curve reflects the existence of two peaks in the anodic volt-

age scan through the hydrogen region on platinum. The presence of two distinct peaks, generally taken to indicate the existence of two "types" of H·, adsorbed under differing energy considerations, is well known and has been the topic of many recent investigations (12-14). Attention is drawn to this point for later reference in the discussion of results.

As a general reference point in this, as well as other previous studies (6), voltage scans on the platinum black electrodes were extended to +1.30v *vs.* S.C.E. Under those conditions, at 0.026 v/sec, Table I indicates that the quantity of coulombs for oxide formation (or reduction) to that potential is, within a few per cent, twice that for the total H· accumulation. Thus, on the usual assumption of one H· per Pt atom, the surface at +1.30v *vs.* S.C.E. is believed to consist essentially of a completed layer of PtO (15).

The value of millicoulombs passed during hydrogen atom chemisorption prior to H_2 evolution was used to calculate a rough value for the electrochemical surface area of the catalyst. Using a value of 210 μcoul/cm^2 as the value for H· deposition on one true square centimeter (8, 14), a total surface area of about 23 m^2/g is calculated. This value is in fairly good agreement with the 28 m^2/g found by the (nitrogen) B.E.T. method.

Technique for measurement of adsorption rates.— Actual voltammetric measurement of adsorption rates was made using a 1.1v single pulse sawtooth potentiostatted signal in conjunction with the flowing electrolyte system described previously. Application of a sawtooth signal enabled the use of the linearly increasing portion of the potential signal (55 mv/sec) for integration and calculation of coulombic quantities of fuel present, while the step function collapse to the preset potential level minimized the time necessary for oxide reduction on the electrode and return to a zero current condition. This return to zero current was accomplished in about 3-5 sec for a total of 38 mg of platinum black in the presence of butane fuel. Using a manual pulse initiating switch, a series of traces was obtained for various adsorption times at a given preset potential in the time interval generally not exceeding 40 sec from the time of return to zero current after the

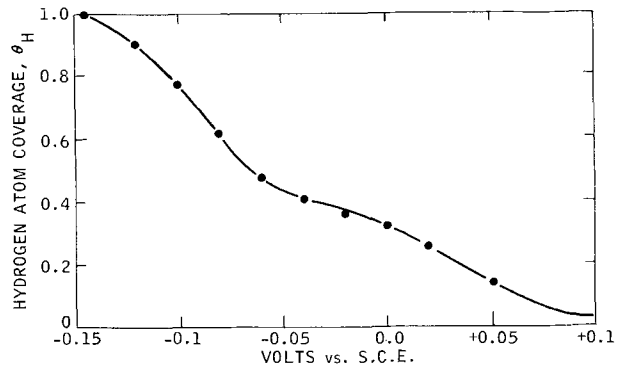

Fig. 3. Relative hydrogen atom coverage *vs.* potential

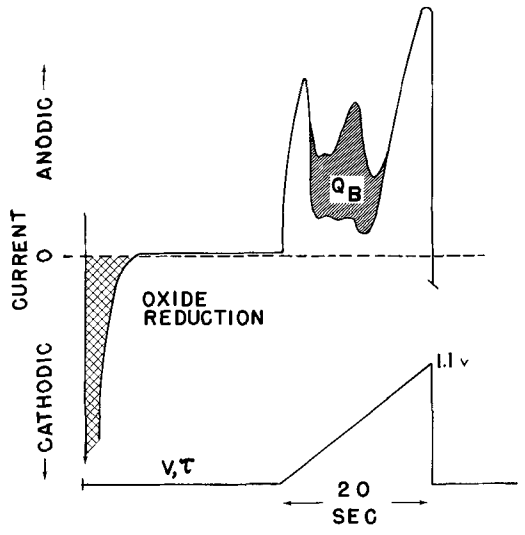

Fig. 4. Diagram of sawtooth scan sequence and typical response

preceding pulse. Normally six to eight scans were enough to clearly define the required coulombs of fuel *vs.* time slope. Accumulation of fuel in this time period represents the initial adsorption rate on the freshly reduced surface and was found to be quite linear up to about 50-60 sec. In the time periods employed maximum butane coverages are less than one third the saturation values. A typical scan sequence is shown in Fig. 4.

Since the oxidation of adsorbed fuel was carried out during a 20 sec scan period, a certain definite quantity of additional fuel was adsorbed and oxidized during the scan period. This fixed contribution, plus any contribution during the few second reduction period was evidenced as an intercept on the Q *vs.* t plot. A typical set of curves obtained at three different potentials is shown in Fig. 5. Constancy of the intercept affirms the fact that the total of these contributions remained essentially constant in the potential range studied.

During the time period while fuel accumulates at the platinum electrode, even in very low polarization regions, these active platinum catalysts do not remain inert. Thus, during the wait period at a given potential, a steady state current of fuel oxidation flows in the circuit. It was necessary, therefore, to measure this current during the wait period for each preset potential and correct the observed slope of the coulombs *vs.* time curve for the appropriate fuel loss. This correction becomes greater as the potential moves positively and soon becomes large enough to render the observed coulombs-time slope unreliable. For this reason adsorption rate measurements were

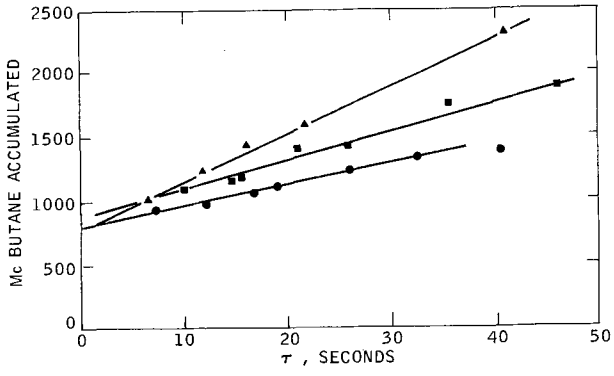

Fig. 5. Typical plot of millicoulombs butane adsorbed *vs.* wait time (from switching); 3.7M H_2SO_4, 95°C, 55 mv/sec sawtooth scan; ■, +0.15v S.C.E.; ▲, 0.05v S.C.E.; ●, 0.0v S.C.E.

restricted to the potential range —0.05 to +0.15 *vs.* S.C.E. Measurements positive to this potential are not considered meaningful since the steady state current becomes excessively large. Argon blanks were obtained for each "preset" potential just prior to commencing the butane adsorption studies.

Rates of Butane adsorption vs. potential and initial hydrogen coverage.—Adsorption rates determined from the coulombs *vs.* time slopes as a function of electrode potential are shown in Fig. 6 for three series of measurements involving separate systems. Corrections applied to compensate for steady state currents are noted in Table II. For reference, Fig. 6 includes a typical curve of butane steady state performance (galvanostatic) on a platinum-Teflon electrode at 95°C in 3.7M H_2SO_4 (11). It is apparent that adsorption rates here are adequately high to easily support the required steady state currents. Although the adsorption for +0.15v *vs.* S.C.E. is subject to the highest probable error, the evidence of a decrease in adsorption rate is believed to be adequately reliable. Thus, adsorption rate is essentially nil at —0.05v and appears to reach a maximum at about +0.10v *vs.* S.C.E. with subsequent decline with more positive potentials, possibly as water or sulfate ions become strongly oriented at the surface and occupy fuel sites.

One further piece of indirect evidence for this decline in rate was obtained from measurement of the maximum butane adsorption on the platinum surface under flow conditions. Thus, the maximum observed (saturation) quantity of butane measured with a 26 mv/sec, 1.3v scan in the flowing fuel-electrolyte system, $Q_B^s/Q_o(1.3) = 1.61$, was about equal to that observed in a stagnant system where fuel accumulation by diffusion is very slow (6). Since, under flow conditions a significant contribution to the observed coulombs is expected as oxidized fuel is replaced during the time of the scan (estimated 10-15% additional total coulombs) this observation suggests that fuel adsorption rates are low in the middle potential region prior to the onset of oxide formation. Details of the estimation of expected fuel adsorption during the scan duration are given in the Appendix.

An explanation of the previous adsorption behavior is obtained from a knowledge of the initial condition of the surface with respect to hydrogen atoms.

Table II. Corrections for butane steady state oxidation during adsorption measurement

Measurement potential, v *vs.* S.C.E.	Current, ma/mg	Measurement potential, v *vs.* S.C.E.	Current, ma/mg

−0.025	0	+0.100	0.58
0.00	0.13	+0.150	0.82

Thus, from the argon blanks obtained prior to each series of butane measurements, it was possible to obtain the initial fractional coverage of the surface with hydrogen atoms for each potential in the absence of butane. This parameter was used to derive the function $(1-\theta_H)$, shown in Fig. 7 plotted against rate of butane adsorption for the three series of experiments. Several features are evident: (*i*) initial rate of butane adsorption is linear with $1-\theta_H$, reaching the observed maximum rate at $\theta_H = 0$ (value for +0.15v *vs.* S.C.E. is not on the plot since θ_H goes to zero just prior to that potential); (*ii*) the intercept of zero rate at $1-\theta_H = 0.5$, coupled with further evidence to be presented next, strongly suggests that the adsorption of this fuel occurs only on the Type II (more anodic) H· sites. Thus, as shown in Fig. 3 the potential of —0.05 *vs.* S.C.E. corresponds closely to the inflection in the curve defining H· coverage and also defines the point in Fig. 6 at essentially zero rate of adsorption. The linearity with $1-\theta_H$ further implies that the initial adsorption rate per exposed site probably does not vary appreciably in the potential region wherein Type II H· is present. As mentioned previously, the observed rate of adsorption beyond about +0.15v *vs.* S.C.E., however, does appear to actually decline.

Additional evidence in support of Type II site adsorption.—With indications that butane adsorption occurred only on that type of site occupied by Type II H·, further evidence was sought in measurement of the equilibrium adsorption of the fuel on platinum. In a previous paper (6) the ratio of coulombs of butane fuel at saturation, Q_B^s, to the coulombs required for reduction of PtO on the electrode, Q_o, from 1.3v *vs.* S.C.E. at 80°C, was established for eight platinum catalysts, including Engelhard platinum black, to be 1.58 ± 0.13. On the basis of the oxide-hydrogen atom coulombic ratios in Table I, this ratio calculated on total H· would be, $Q_B^s/Q_H^s = 3.3$. If, however, adsorption of butane fuel occurs only on Type II H· sites, then saturation of these sites, about 50% of the total H·, would lead to a value of $Q_B^s/Q_{H(II)}^s = 6.6$. This value corresponds closely to the expected 6.5 electrons per site for the complete oxidation of butane to CO_2 (3, 6) if a four-point Pt-C_4H_{10} attachment occurs, and thus adds some strength to the postulated attachment on one type of site.

An additional series of studies was carried out to define the relationship between fuel and H· coverage in potential regions near H_2 evolution. The technique used here was identical to that used previously to obtain equilibrium coverage of butane on platinum (6).

Electrodes were of the pressed platinum-Teflon on platinum flag type described previously and data was obtained in simple butane sparged cells at 80°C in 3.7M H_2SO_4 for comparison with the earlier experiments. Coulombic quantities were determined from triangular voltage scans.

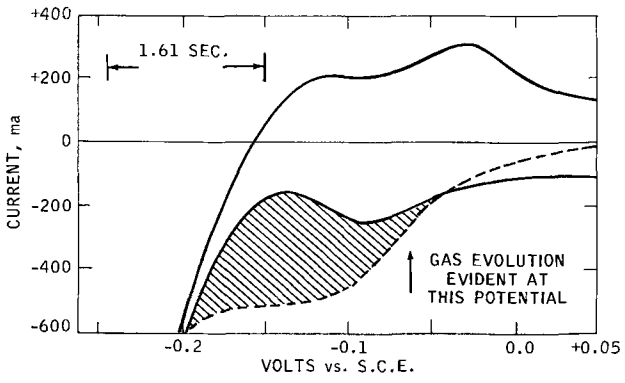

Fig. 8. Typical scan toward H_2 evolution as adsorbed butane desorbs. Dotted line is curve with desorbing butane. Solid line is blank. Integration of hatched area indicates 4 electrons per initial butane molecule.

Saturation of the catalyst surface with butane with the electrode potentiostatted at 0.0v *vs.* S.C.E. gave the expected $Q_B^s/Q_o(1.3v) = 1.6$. Moreover, no trace of Type II hydrogen remained in the anodic scan from 0.0 *vs.* S.C.E. In order to ensure that only Type II sites were involved, however, a similar butane saturated electrode was subjected to a cathodic scan to H_2 evolution potentials. Surprisingly at potentials of —0.02v *vs.* S.C.E., an obvious evolution of gas occurred from the electrode together with a significant increase of scan current in the region of the Type I hydrogen peak as shown in Fig. 8. Integration of the excess coulombs over and above the normal Type I H· coulombs indicated, for two such cases, values equivalent to 3.87 and 3.94 electrons respectively per molecule of butane known to exist on the saturated catalyst. Thus, it is believed that the butane is desorbed rapidly as Type I hydrogen begins to form on the surface and that, subsequent to fuel desorption from the initially saturated Type II sites, the four missing hydrogen atoms are rapidly replaced on the surface with the passage of four electrons per original butane molecule.

Verification that the preponderance of desorbed gas was actually butane was obtained by vapor phase chromatography. A few tenths of a cubic centimeter of desorbed gas trapped in a small sampling apparatus indicated essentially 100% butane with traces of propane, ethane, and methane. Some small amount of cracking of the hydrocarbon fuel apparently takes place as has been reported previously (5, 7).

Desorption of fuel during a cathodic sweep can pose problems for the investigator interested in fuel surface coverages. Although admittedly the cathodic scan here is carried out at a relatively slow speed, 31 mv/sec, it is obvious that the use of the decrease in total H· as a measure of adsorbate coverage, a technique enjoying wide popularity recently, must

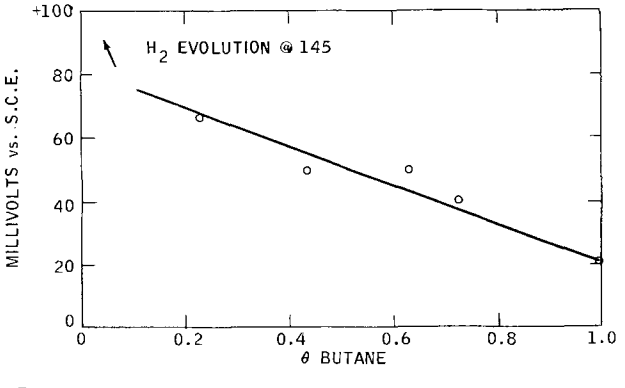

Fig. 9. Potential of initial (desorbing) gas evolution as a function of relative coverage derived from Q_B/Q_B (maximum).

be exercised with caution and with strict attention to scan speed, etc., if misleading effects are to be avoided. If fuel desorption occurs rapidly, surface coverages inferred from adsorbed hydrogen measurements could indicate much lower fuel coverages than actually exist.

A series of experiments was carried out to define roughly the desorption potential as a function of butane coverage, θ, derived from Q_B/Q_B (saturation). For this purpose a visual estimation of the potential of initial observable gas bubble formation was used. A plot of the observed desorption potentials as a function of approximate coverage is shown in Fig. 9. The potential of obvious desorption varies about linearly with coverage over a range from —0.065 *vs.* S.C.E. for the lowest coverage studied, to —0.02 for saturation. Thus, even minimum quantities of butane are desorbed at —0.065, *i.e.*, in the potential range where significant quantities of Type I H· exist. Data on the H· coverage is not sufficiently precise to tell if the anodic end of the range, —0.02v *vs.* S.C.E., is the potential at which first minute quantities of Type I H· are formed. No obvious explanation is at hand to explain this complete incompatibility of adsorbed butane with formation of Type I H·. An answer to this question, however, would undoubtedly require a detailed knowledge of the platinum surface species and the precise nature of the difference in Type I and Type II H· sites.

Discussion and Conclusions

Based on the preceding data, a fairly complete summary of butane adsorption behavior on electroactive Pt can be made. The fuel molecule appears to adsorb only on that type of site normally occupied by Type II (more anodic) H·. The initial observed rate of adsorption is a linear function of the number of such sites empty of H·, although eventually, as saturation fuel coverage is approached all Type II H· is replaced by fuel. Combination of the known coulombs involved in Type II H· deposition with the coulombs obtained from oxidation of an equilibrium (saturated) quantity of butane on the platinum leads to a value of 6.6 electrons/H· site. In view of the 26 electron complete oxidation of the four carbon molecule to CO_2, this value is consistent with a four-site attachment of butane to platinum, *i.e.*, the molecule lying down on the surface. It must be cautioned, however, that this is not a necessary conclusion since an end-on adsorption of the fuel molecule could also result in loss of 4H· if the local energy or space considerations on the surface are significantly affected by the fuel molecule adsorption.

Depending slightly on the surface coverage, adsorbed fuel begins to desorb in the potential range —0.02 to —0.06v *vs.* S.C.E. in this system as the region of Type I H· formation is reached. Traces of lower carbon number saturates indicate some slight cracking of the adsorbed fuel.

Positive to the region of significant Type II H· existence, *i.e.*, positive to ~+0.10v *vs.* S.C.E. in this system, initial rates of fuel adsorption are difficult to measure on the active electrocatalyst since steady state current flow becomes a significant fraction of the adsorption rate. Indications are present, however, that the observed adsorption rate begins to decrease in the region positive to +0.10v *vs.* S.C.E. This might very well be due to loss of fuel adsorption sites again as water begins to strongly orient at the surface. At any rate it seems quite reasonable that the over-all situation is as originally depicted in Fig. 6, with the intersection of the decreasing adsorption rate curve (dotted line) with the $2RT/F$ electron transfer limited Tafel line dictating the limiting current capability of the system.

The knowledge that fuel adsorption can occupy only Type II H· sites in the region from about —0.05 to +0.15v vs. S.C.E. in this system leads to an obvious question as to the occupancy of Type I sites in this

potential range. Since it is probable that Type I sites contain adsorbed water or hydronium ions in this region, is it too bold to suggest that fuel electrooxidation is accomplished by interaction of the fuel molecules adsorbed on Type II sites with water molecules on another, possibly Type I, site? In the absence of a physical picture of the exact nature of these so-called "sites" it is difficult to say. For instance, are the "sites" not really physical but a differentiation in the binding energy for two successive hydrogen atoms? Is one set of hydrogen atoms dissolved in the lattice and the second adsorbed at the external sites? In view of the previous data, the recent suggestion by Will (14) that Type I and II merely represent the H+ discharge-adsorption on two different crystal faces of platinum (the 110 and 100) does not seem too appealing. Thus H· adsorption on one crystal face would not be expected to produce such a significant electronic effect as to cause desorption of butane from an entirely different face on which it is preferentially adsorbed.

The extended implications of the possibility of two-site interaction in the over-all mechanism of hydrocarbon oxidation are too broad, however, to be discussed as a part of this study. Further discussion will be reserved until additional evidence is available to support these preliminary findings. The ramifications of a two-site surface will then be discussed not only with respect to the reaction of saturate hydrocarbons, but also for low molecular weight oxygenated species (CH_3OH, HCHO, etc.) and for olefins.

Acknowledgments

The work reported in this paper was made possible by the support of the Advanced Research Projects Agency under Order No. 247 through the U.S. Army Electronics Laboratories, Contract No. DA 36-039 AMC-03743 (E). Permission to publish is gratefully acknowledged. The authors wish to thank H. E. Frew for carrying out much of the experimental work.

Manuscript received Aug. 10, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

APPENDIX

Estimation of Expected Butane Adsorption During Scan on Initially Saturated Surface

As discussed previously, the saturation adsorption of butane measured under flowing conditions did not differ significantly from that measured under stagnant conditions, during which accumulation of fuel by diffusion is negligible.

If adsorption of butane on free area occurred in the potential region positive to +0.15v *vs.* S.C.E. at the maximum rates observed previously, a significant number of coulombs would be expected to accumulate during the course of the burn-off scan on the previously saturated electrode.

This accumulation in coulombs, ΔQ, would be

$$\Delta Q = \int_{t_1(V_1)}^{t_2(V_2)} R_o(1 - \theta_b)(1 - \theta_{ox})\,dt$$

where θ_b represents the coverage with adsorbed butane at any time (voltage) in the scan, and a term in θ_{ox}, the surface oxide coverage, has been inserted to accommodate the fact that surface oxide formation will undoubtedly interfere with butane adsorption at some voltage level. Two functions for θ_{ox} were considered: (I) A term where $\theta_{ox} = 1$ at one half the total coulombs for total 2 electron oxide formation. This would be the case if PtO formation occurred on a single type of site first. (II) A term with $\theta_{ox} = 1$ at the full oxide level, *i.e.*, when Q_{ox} equalled twice $Q_H{}^s$, the total saturation H· coverage. The θ terms were evaluated over the time interval of the scan by stepwise integration of the respective fuel and oxide formation peaks on the platinum.

Evaluation of the integral for ΔQ indicates that during the course of the scan in the flowing electrolyte system an additional contribution of a minimum of 10-15% would be expected in the observed $Q_B{}^s$ value depending on which θ_{ox} function is assumed. If no $(1 - \theta_{ox})$ diminishing function is applied, this increase would be expected to be about 22%. Thus, it is inferred that the rate of butane adsorption decreases rapidly in the region beyond +0.15v *vs.* S.C.E. and accordingly the rate in this region in Fig. 5 (dotted line) is shown decreasing to intersect the Tafel line.

Faradaic Impedance of Polarized Porous Electrodes

II. Nonlinear Kinetics

R. Darby[1]

LTV Research Center, Ling-Temco-Vought, Inc., Dallas, Texas

ABSTRACT

A previous analysis of the Faradaic impedance of polarized porous gas diffusion electrodes has been extended to include kinetic rate expressions which are other than first order. An approximate analysis reveals impedance characteristics which are qualitatively similar to those for first order kinetics for reaction orders greater than unity and less than ½. However for orders between one and ½, the Argand diagram exhibits two semicircular regions instead of one, as well as the inductive characteristic at sufficiently high frequency. These curves are compared with the data of Brodd on Leclanché cells which exhibit similar characteristics.

The a-c impedance characteristics of electrochemical systems are important as a possible indication of reaction and transport mechanisms [*e.g.*, (1) — (11)], as well as an indication of the response to varying load conditions of such power sources as fuel cells and batteries. Both capacitive and inductive characteristics have been experimentally observed, as discussed by Gutman (12) and have also been predicted for a polarized porous dual-layer gas diffusion electrode for the case in which the electrode kinetics are first order, as shown in a previous paper (13). The object of the present paper is to extend the previous results to include electrode reactions which are not first order, and hence attempt to shed some light upon certain experimentally observed impedance characteristics (7).

In (13), the Faradaic impedance characteristics of a polarized gas diffusion electrode were determined by assuming a small amplitude a-c signal superimposed on a larger polarizing d-c current. The formulation of the problem was in terms of a general electrode reaction, represented by

$$gG + lL + ne^- \rightarrow pP \qquad [1]$$

the kinetics of which was assumed to follow the generalized rate expression

$$I = I_o \left(\frac{G}{G_o}\right)^{g'} \left(\frac{L}{L_o}\right)^{l'} \exp\left(\frac{\alpha n' F}{RT} E\right) \qquad [2]$$

Although [2] is written in terms of a general reaction order, the results given in (13) were for a first order reaction only. The present analysis will be for reaction orders other than unity, including both integral and fractional orders. In this regard, it should be pointed out that [2] is assumed to be simply a rate expression representing the net rate of the overall reaction [1], but not necessarily indicative of the reaction mechanism. Many complicated reactions involving several steps such as the heterogeneous catalytic reaction in a porous medium with which we are concerned can be adequately represented by a nonlinear rate equation such as [2], particularly when adsorption or desorption steps are significant, and where the reaction orders may be nonintegral [see *e.g.* (14)].

The Model

The dual-layer model mechanism was described in detail in (13) and will be reviewed briefly. A schematic of the model, Fig. 1, shows three regions for consideration. Region I is a porous layer containing a gas phase only within the pores (reactant plus inert); region II is a porous layer containing the liquid electrolyte phase (also assumed to consist of a reactant plus inert); and region III is a (narrow) region of the liquid filled layer, adjacent to the interface of the two porous layers, wherein reaction [1] is assumed to take place. The gaseous reactant diffuses through the pores in region I in the presence of the inert component, as does the liquid reactant in region II. At the gas-liquid interface the gaseous reactant dissolves in the liquid phase, the resulting concentration of dissolved gas being determined by Henry's law. As the dissolved gas diffuses through the liquid filled pores in region III, it is simultaneously consumed by reaction at catalytic sites on the pore walls. Region III is assumed to be small compared with region II, so that semi-infinite boundary conditions apply to the dissolved gas reactant. Further, since the concentration of dissolved gas is small compared with the liquid reactant concentration, the latter can be taken as essentially constant over region III (the reaction zone).

The additional assumptions of (13) with regard to the use of a pseudodiffusion coefficient for the porous medium, the influence of migration, and uniform matrix potential apply as before. Also, as concluded in (13), there is no loss in generality for this model by setting the liquid reactant order (l') equal to zero since the effect of liquid reactant concentration on impedance is simply to add an additional term which is similar in form to the contribution from diffusion of the gaseous reactant in region I.

D-C Analysis

The flux of the gaseous reactant, and hence the total electrode current, is governed by the diffusion equation (Fick's second law) in region I, and by this equation including a reaction term, r, in region III

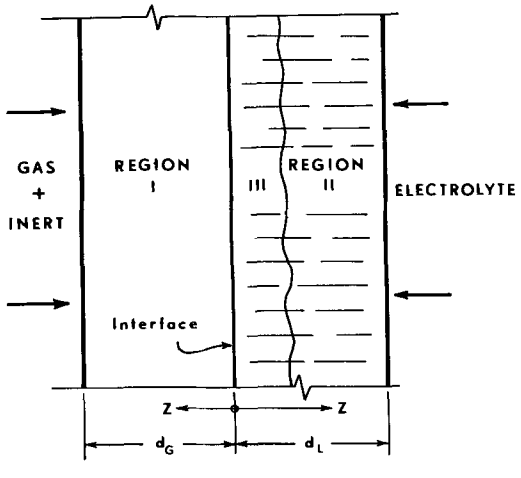

Fig. 1. Schematic diagram of dual-layer model

[1] Present address: Chemical Engineering Department, Texas A & M University, College Station, Texas.

$$\frac{\partial C}{\partial t} = D_{GL}\frac{\partial^2 C}{\partial z^2} - r = D_{GL}\frac{\partial^2 C}{\partial z^2} - I\left(\frac{ag}{nF}\right) \quad [3]$$

Here, Ia represents the local specific current resulting from the electrochemical reaction in region III, in amp/cm^3.

For a steady state, the combination of Eq. [3] and [2] (without the liquid reactant term) for region III results in

$$\frac{d^2C}{dz^2} = KC^{g'} \quad [4]$$

where

$$K = \frac{I_o\, ag}{nF\, D_{GL}\, C_o^{g'}} \exp\left(\frac{\alpha n'F}{RT}E\right) \quad [5]$$

The solution to [4] subject to the following boundary conditions

$$\begin{array}{ll}(a) & C = C_i \text{ at } z = 0\\ (b) & C \to 0 \text{ as } z \to \infty\end{array} \quad [6]$$

is (14, 15)

$$C = C_i\left[(g'-1)\sqrt{\frac{KC_i^{(g'-1)}}{2(g'+1)}}z + 1\right]^{2/(1-g')} \quad [7]$$

The total d-c electrode current is given by

$$I_t = -\frac{nF\, D_{GL}}{g}\left(\frac{dC}{dz}\right)_{z=0} = \frac{nF\, D_{GL}\, C_i}{g}\sqrt{\frac{2KC_i^{(g'-1)}}{g'+1}} \quad [8]$$

from which K can be evaluated in terms of the total current density, I_t, and the concentration of dissolved gaseous reactant at the interface C_i. The latter is determined by the diffusional flux of the gaseous reactant through region I, together with the assumption of equilibrium at the interface as represented by Henry's law. The result, including the effect of the inert component, has been previously derived (13, 15) and is

$$C_i = \frac{cP_o}{H}\left[1 - (1 - G_o/P_o)\exp\left(I_t/A_2\right)\right] \quad [9]$$

where

$$A_2 = (nF\, P_o\, D_{GG})/(g\, RT\, d_G) \quad [10]$$

An inspection of the concentration profile [7] reveals the following characteristics (14). For $g' > 1$, the concentration remains finite for all z, asymptotically approaching zero. However, for $g' > 1$, the concentration falls to zero at a finite value of z equal to $[2(g'+1)/(KC_i^{g'-1})]^{1/2}/(1-g')$.

Equations [5], [7], [8], and [9] define the relation between the steady-state concentration gradient within the reaction zone (region III), the total current density, and the total electrode polarization.

Impedance Analysis

As in (13), the electrode impedance is defined by the ratio of a small amplitude alternating component of polarization (η) to the corresponding alternating component of current (i), which are superimposed upon the steady d-c values.

The assumption of small amplitudes allows linearization of the equations, as follows. Rewriting [2] for region III in terms of total (a-c plus d-c) quantities, gives

$$I + i = I_o\left(\frac{C+\gamma}{C_o}\right)^{g'}\left(\frac{L+\lambda}{L_o}\right)^{l'} \exp\left[\frac{\alpha n'F}{RT}(E+\eta)\right] \quad [11]$$

The small amplitude assumption for the a-c quantities means that

$$\left(\frac{\gamma}{c}, \frac{\lambda}{L}, \frac{n'F}{RT}\eta\right) << 1$$

so that terms of second order in these quantities can be neglected. Thus [11] can be linearized as follows

$$i = I\left[g'\left(\frac{\gamma}{C}\right) + l'\left(\frac{\lambda}{L}\right) + \frac{\alpha n'F}{RT}\eta\right] \quad [12]$$

Combining Eq. [2], [3], and [12] (again omitting the l' term) results in the following equation for γ

$$\frac{\partial \gamma}{\partial t} = D_{GL}\left[\frac{\partial^2 \gamma}{\partial z^2} - KC^{g'}\left(g'\frac{\gamma}{C} + \frac{\alpha n'F}{RT}\eta\right)\right] \quad [13]$$

where C is a function of z, as given by [7].

In order to determine the a-c impedance of the electrode to a sinusoidally varying current, we must solve [13] for the ratio of the LaPlace transforms of the a-c components of polarization and total current, and replace the transform variable s by $j\omega$. The total a-c current density is given by

$$i_t = -\frac{nF\, D_{GL}}{g}\left(\frac{d\gamma}{dz}\right)_{z=0} \quad [14]$$

Combining [13] and [7] and transforming the result gives

$$\frac{d^2\,\bar{\gamma}(s)}{dz^2} - K\bar{\gamma}(s)\left[\frac{s}{KD_{GL}} + \frac{f}{(ez+1)^2}\right] = h\,\bar{\eta}\,(ez+1)^{2g'/(1-g')} \quad [15]$$

where

$$e = (g'-1)\sqrt{\frac{K\,C_i^{(g'-1)}}{2(g'+1)}} \quad [16]$$

$$f = g'\,C_i^{(g'-1)} \quad [17]$$

$$h = (\alpha n'F\, C_i^{g'}\, K)/(RT) \quad [18]$$

The boundary conditions which accompany [15] are

$$\begin{array}{ll}(a) & \bar{\gamma}(s) = \bar{\gamma}_i(s) \text{ at } z = 0\\ (b) & \bar{\gamma}(s) = 0 \text{ at } z = -e \text{ for } g' < 1\\ (b') & \bar{\gamma}(s) \to 0 \text{ as } z \to \infty \text{ for } g' > 1\end{array} \quad [19]$$

Here $\bar{\gamma}_i(s)$ is determined from the diffusion flux (Fick's law) for region I, the total a-c current, and Henry's law in a manner analogous to the derivation of [9]. The result is

$$\bar{\gamma}_i(s) = \bar{i}_t(s)\frac{A_4}{d_G\sqrt{s/D_{GG}}}\left[\frac{1 - \exp\left(d_G\sqrt{s/D_{GG}}\right)}{1 + \exp\left(d_G\sqrt{s/D_{GG}}\right)}\right] = \bar{i}_t\, A_4\, \Gamma(s) \quad [20]$$

where

$$A_4 = (gc\, RTd_G)/(nFHD_{GG}) \quad [21]$$

A general solution to [15] is possible in terms of a finite series or hypergeometric functions, but the resulting expressions are such that boundary conditions [19] cannot be readily applied. However, all that we require from the solution to [15] is an expression for the first derivative of $\bar{\gamma}$ which is valid near $z = 0$, from which $\bar{i}_t$ can be evaluated by means of [14]; hence an approximate solution valid near $z = 0$ should be adequate for this purpose. This is not to imply that the result is valid only for a very narrow reaction zone, as such is not the case, although in practice this zone should be small compared with region II under polarized conditions, as shown previously (13). Thus for sufficiently small z, the following approximations may be made

$$(ez+1)^{-2} \approx 1 - 2\,ez$$

$$(ez+1)^{2g'/(1-g')} \approx 1 + \frac{2g'\,ez}{(1-g')} \quad [22]$$

If we make the additional substitution of $\bar{\gamma}_i(s)z$ for $\bar{\gamma}(s)z$, which is also valid for sufficiently small z. Eq. [15] becomes

$$\frac{d^2\bar{\gamma}(s)}{dz^2} - \bar{\gamma}(s)K\beta_1 = h\bar{\eta}(s)\left[1 + \frac{2g'ez}{(1-g')}\right] + 2eKf\bar{\gamma}_i(s)z \quad [23]$$

where

$$\beta_1 = f + s/(KD_{GL}) \quad [24]$$

The similarity between [23] and Eq. [18] of ref. (13) for first order kinetics is apparent. The appropriate solution for $g' > 1$ is

$$\bar{\gamma}(s) = [\bar{\gamma}_i(s) - h\bar{\eta}(s)/\delta]\exp(-z\sqrt{\delta}) - [h\bar{\eta}(s) + ze\alpha_1]/\delta \quad [25]$$

where

$$\alpha_1 = 2g'h\bar{\eta}(s)/(1-g') - 2fK\bar{\gamma}_i(s) \quad [26]$$

and

$$\delta = K\beta_1 \quad [27]$$

For $g' < 1$, the solution is

$$\bar{\gamma}(s) = \frac{\sinh(z\sqrt{\delta})}{\sinh(\sqrt{\delta}/e)}\left\{[\bar{\gamma}_i(s) + h\bar{\eta}(s)/\delta]\exp(\sqrt{\delta}/e) + \frac{\alpha_1 - h\bar{\eta}(s)}{\delta}\right\} + [\bar{\gamma}_i(s) + h\bar{\eta}(s)/\delta]\exp(-z\sqrt{\delta}) - [h\bar{\eta}(s) + e\alpha_1 z]/\delta \quad [28]$$

Using [25] or [28] to calculate $\bar{i}_t(s)$ (Eq. [14], substituting for $\bar{\gamma}_i(s)$ from [20], and solving the result for $\bar{\eta}(s)/\bar{i}_t(s)$ gives, for $g' > 1$

$$\frac{\bar{\eta}(s)}{i_t(s)} = \frac{(\beta_1 Kg)/(nFD_{GL}) + A_4K\Gamma(2ef - \beta_1\sqrt{\delta})}{h[\sqrt{\delta} + eg'/(1-g')]} \quad [29]$$

and for $g' < 1$

$$\frac{\bar{\eta}(s)}{i_t(s)} = \left\{\sinh(\sqrt{\delta}/e)\left[\frac{g\delta}{nFD_{GL}} - A_4\Gamma(\delta^{3/2} - 2efK)\right] - KA_4\sqrt{\delta}\Gamma[2f - \beta_1\exp(\sqrt{\delta}/e)]\right\} \Big/ \{h\sinh(\sqrt{\delta}/e)[\delta + eg'/(1-g')] - h\sqrt{\delta}[\exp(\sqrt{\delta}/e) - 1/(1-g')]\} \quad [30]$$

The complex impedance, $Z(j\omega)$, is given by [29] or [30] when the transform variable s is replaced by $j\omega$. The result can be separated into frequency dependent real (resistive) and imaginary (reactive) components

$$Z(j\omega) = R(\omega) - jX_c(\omega) \quad [31]$$

or into magnitude and phase angle components. The latter can be represented as the impedance attenuation, $(DB)_z$, and capacitive phase angle, θ, defined as

$$(DB)_z = 20\log(|Z|/|Z_o|) \quad [32]$$

$$\theta = \tan^{-1}(X_c/R) \quad [33]$$

The complex impedance components, attenuation, and phase angle were determined for various values of reaction order g' from 0.25 to 3.0, as a function of the dimensionless frequency parameter ξ,

$$\xi = d_G\sqrt{\omega/2D_{GG}} \quad [34]$$

which enters through Eq. [20]. A family of curves was obtained for each case, each curve corresponding to a given value of ϕ, the ratio of d-c current density to limiting current density

$$\phi = I_t/I_{lim};\ I_{lim} = A_2/(1 - X_o) \quad [35]$$

Results

Impedance characteristics were calculated with the aid of a computer, using representative values of parameters which are listed in Table I. These results fall into three separate groups each showing similar characteristics, depending on the magnitude of g'. These correspond to the following values of g': less than 0.5, 0.5 to 1.0, and greater than 1.0; and are typified by the curves for $g' = 1/3$, $2/3$, and 2.0. Figures 2-7 show the impedance attenuation and phase angle curves for these three reaction orders, and Fig. 8-10 show the corresponding Argand diagrams, or reactance *vs.* resistance components. The curves for g' of 1/3 and 2 appear similar. However, the Argand diagram for $g' = 2$ shows that the diameter of the semicircular region goes through a minimum at a ϕ of about 0.5, then increases with decreasing ϕ, whereas for $g' = 1/3$ this diameter decreases continuously as ϕ decreases. For values of g' between 0.5 and 1.0, two semicircular regions appear on the Argand diagram which appear at least qualitatively to be a combination of the other two cases. That is, the circular region on the left grows as ϕ decreases, whereas the one on the right shrinks and eventually disappears at small values of ϕ.

Figure 9 may be compared with data given by Brodd (7) for the impedance of Leclanché cells at various stages of discharge. Although Leclanché cells do not contain porous gas diffusion electrodes and

Table I. Parameter values used in calculations

Gas phase: $x_o = 0.21$ mole fraction, $P_o = 1$ atm
Henry's law constant: $H = 3.95 \times 10^4$ atm/mole fraction
Porous medium: $\Phi = 0.5$, $\tau = 15$, $d_G = d_L = 0.1$ cm
Diffusivities: $D_{GG} = 0.2$ cm²/sec, $D_{LL} = 2 \times 10^{-5}$ cm²/sec
$D_{GL} = 1 \times 10^{-5}$ cm²/sec
Kinetic parameters: $I_o = 10^{-5}$ amp/cm², $n = n' = 4$, $\alpha = 1/2$
$(aI_o) = 5 \times 10^{-5}$ amp/cm³, $T = 25°C$

would not normally be thought to correspond to the model of Fig. 1, the porous manganese dioxide-carbon black mixture would comprise a region of simultaneous diffusion and reaction analogous to region III of the model. Indeed, it is possible that a similar region might exist adjacent to the zinc electrode after discharge, resulting from the increased surface roughness and/or accumulation of reaction products. Furthermore, although Brodd's data were apparently taken under open-circuit conditions, the various states of discharge of the cells might be considered to correspond to various degrees of polarization. His Argand diagrams are a combination of at least two semicircular regions (he concludes the existence of three from trial and error curve fitting), the relative sizes of which depend on the state of discharge of the cell. His data do not show any region of inductive reactance, although the highest frequency employed was 50 kc and the inductive region would generally be expected to appear at frequencies higher than this. However, in another reference (16), he has indicated the observation of inductive reactances under certain circumstances. Brodd attributes the existence of the several separate semicircular regions to separate electrode rate processes, while the present results show

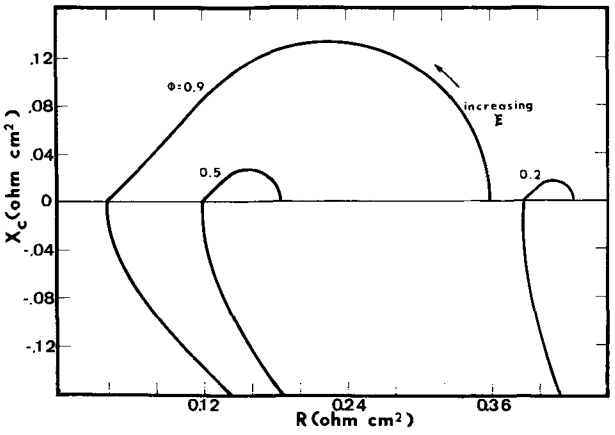

Fig. 10. Argand diagram, reaction order = 1/3

them to result from a single fractional order rate expression. However, these results are not incompatible inasmuch as a fractional order rate expression is most likely to result from a complex heterogeneous catalytic reaction involving several steps, such as that occurring in a porous electrode [*e.g.*, (17), (18)].

As in the previous analysis for first order kinetics (13), the effects of the non-Faradaic ohmic resistance and double layer capacitance have not been included in the calculation of electrode impedance. These effects have been considered by a number of authors, notably Ksenzhek and Stender (19), Winsel (20), deLevie (21), and Feuillade (22). The inclusion of distributed resistive and capacitive circuit elements representing these non-Faradaic effects in a porous electrode is frequently treated in a manner analogous to an R-C transmission line. These contributions can, at least in principle, be separated from impedance data, but while the experimental elimination of ohmic resistance is common practice, the isolation of the combination of distributed resistance and capacitance is not a simple matter. However, these effects would have to be included in a quantitative comparison of data and theory.

Resistance for Flow of Current to a Disk

John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and

Department of Chemical Engineering, University of California, Berkeley, California

In order to obtain the concentration and activation overpotential for a rotating disk electrode it is necessary to subtract from the measured overpotential the ohmic potential drop between the reference electrode probe and the disk. The ohmic drop for a small disk is concentrated in the solution near the disk (Fig. 1). Rather than try to put the probe from a reference electrode very near the surface and thus distort the potential and velocity distributions, one can estimate the ohmic drop from the resistance between a disk imbedded in the surface of an insulator and a counter electrode at infinity. This procedure does not account for deviations from the primary current distribution.

For the purpose of calculating the potential distribution from Laplace's equation, we use rotational elliptic coordinates[1] ξ and η related to cylindrical coördinates by

$$z = a\xi\eta$$
$$r = a\sqrt{(1+\xi^2)(1-\eta^2)} \qquad [1]$$

where a is the radius of the disk, z is the normal distance from the disk, and r is the distance from the axis of symmetry (see Fig. 1, where lines of constant Φ are also lines of constant ξ). In this coördinate system Laplace's equation is

$$\frac{\partial}{\partial\xi}\left[(1+\xi^2)\frac{\partial\Phi}{\partial\xi}\right] + \frac{\partial}{\partial\eta}\left[(1-\eta^2)\frac{\partial\Phi}{\partial\eta}\right] = 0 \qquad [2]$$

and the boundary conditions are

[1] These are related to "oblate spheroidal coördinates" by $\xi = \sinh\mu$ and $\eta = \cos\theta$.

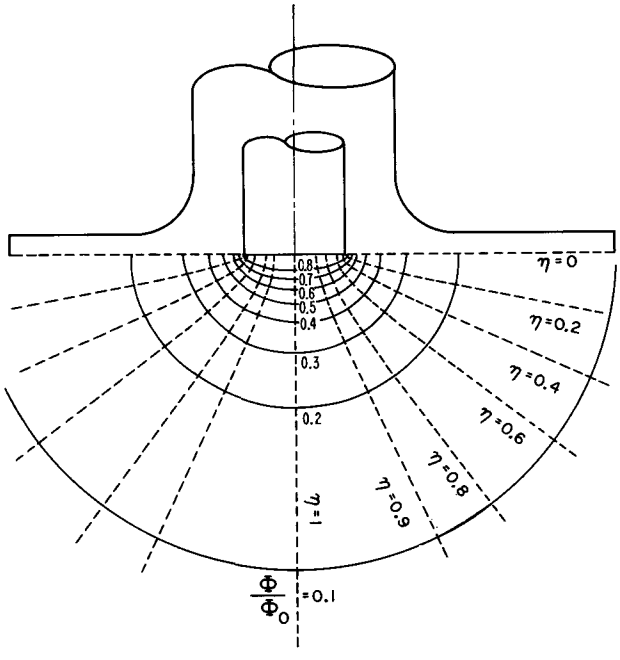

Fig. 1. Current and potential lines for a disk electrode

$$\left.\begin{array}{l}\Phi = \Phi_0 \text{ at } \xi = 0 \text{ (on the disk electrode)}\\ \partial\Phi/\partial\eta = 0 \text{ at } \eta = 0 \text{ (on the insulating annulus)}\\ \Phi = 0 \text{ at } \xi = \infty \text{ (far from the disk)}\\ \Phi \text{ well behaved at } \eta = 1 \text{ (on the axis of the disk)}\end{array}\right\} \qquad [3]$$

To obtain a solution by the method of separation of variables we set

$$\Phi = P(\eta)Q(\xi) \qquad [4]$$

The differential equations for P and Q are

$$\frac{d}{d\eta}\left[(1-\eta^2)\frac{dP}{d\eta}\right] + nP = 0,$$
$$\frac{d}{d\xi}\left[(1+\xi^2)\frac{dQ}{d\xi}\right] - nQ = 0 \qquad [5]$$

where n is the separation constant. The solutions of these equations are Legendre functions. In order to have well behaved solutions, n is restricted to values $n = l(l+1)$ where $l = 0, 1, 2, \ldots$. In order to satisfy the condition on the insulating surface, l must be even. It turns out that the condition $\Phi = \Phi_0$ on the disk can be satisfied simply with the solution for $n = 0$. Integration thus yields

$$\Phi/\Phi_0 = 1 - (2/\pi)\tan^{-1}\xi \qquad [6]$$

Equipotential lines are shown on Fig. 1.

The current density at the disk surface can then be evaluated as follows

$$i = -\kappa\left.\frac{\partial\Phi}{\partial z}\right|_{z=0} = \frac{-\kappa}{a\eta}\left.\frac{\partial\Phi}{\partial\xi}\right|_{\xi=0}$$
$$= \frac{2}{\pi}\frac{\kappa\Phi_0}{a\eta} = \frac{2\kappa\Phi_0}{\pi\sqrt{a^2-r^2}} \qquad [7]$$

Hence the total current to the disk is

$$I = 2\pi\int_0^a i\,r\,dr = 4\kappa a\Phi_0 \qquad [8]$$

and the resistance is

$$R = \Phi_0/I = 1/4\kappa a \qquad [9]$$

This result agrees satisfactorily with that of Gröber (1) for the analogous heat conduction problem. The resistance of a hemisphere of radius a mounted on an insulating plane is easily calculated to be $1/2\pi\kappa a$. Hence the resistance of the disk is greater than that of a hemisphere by a factor of $\pi/2 = 1.5708$.

Table I. Apparent resistance for various probe positions

$a = 0.25$ cm, $\kappa = 0.00872$ (ohm-cm)$^{-1}$

r, cm	z, cm	R, ohm	Probe position
0	0.05	14.48	Below the disk
0	0.1	27.78	Below the disk
0	2.5	107.43	Below the disk
2.5	0	107.39	Beside the disk
2.7	0	107.93	Beside the disk
∞	∞	114.7	At infinity

For a 0.1M copper sulfate solution and a 0.5 cm (diameter) disk the above formula gives $R = 114.7$ ohms since $\kappa = 0.00872$ (ohm-cm)$^{-1}$ for this solution at 25°C (2).

Far from the disk the potential approaches

$$\Phi \rightarrow 2\Phi_0 a/\pi\rho \text{ as } \rho \rightarrow \infty \qquad [10]$$

where ρ is the distance from the center of the disk in spherical coördinates. This formula can be used to estimate the error for the situation where the reference electrode is not at infinity and the potential field is distorted by the walls of the cell.

The ohmic resistance of the solution is tabulated in Table I for several possible locations of the probe from the reference electrode. These show that even with the probe only half a millimeter from the surface, the resistance is by no means negligible. Far from the disk the resistance is not very sensitive to small uncertainties in the location of the probe. These considerations suggest that it is better to put the probe some distance from the disk.

Equation [7] shows that the current density becomes infinite at the edge of the disk, a general characteristic of the primary current distribution where electrode polarization is ignored. This is in marked contrast to the uniform current density predicted by Levich (3) on the basis of mass transfer limitations. At currents below the limiting current both factors, ohmic drop in the solution and mass transfer limitations near the disk, influence the current distribution, which will then finally neither be uniform on the disk nor infinite at the edge of the disk. We have formulated this more general problem and expect to report results for the rotating disk in the near future.

Preliminary Evaluation of Ceria-Lanthana as a Solid Electrolyte for Fuel Cells

David Singman

Power Supply Branch, Harry Diamond Laboratories, Washington, D. C.

Solid electrolytes which are oxygen-ion conducting offer attractive possibilities for the construction of fuel cells capable of electrochemical oxidation of hydrogen and various hydrocarbons. Aqueous electrolyte fuel cells are limited to low current densities by activation polarization. The life of fused salt electrolyte cells is limited by corrosion. A solid electrolyte fuel cell utilizing a mixture of 85 mole % ZrO_2 and 15 mole % CaO was reported by Weissbart and Ruka (1). Although this cell is relatively unaffected by activation polarization, its output is resistance limited to operation near 1000°C because the specific conductance of the solid solution is 0.02 ohm^{-1} cm^{-1} at 1000°C and 0.002 ohm^{-1} cm^{-1} at 800°C (2).

A solid solution of 85 mole % ceria-15 mole % lanthana having higher conductivity has been reported by Croatto and Mayer (3). As is shown in Fig. 1, curves I and II, the conductivity of ceria-lanthana at 800°C is approximately equal to calcia-zirconia's conductivity at 1000°C. Oxygen ion conductance should occur in ceria-lanthana solid solution according to the concepts of Wagner (4) and Kingery (5) because fluorite lattice having anion vacancies exists (6). If the conduction is 95% or more ionic, this electrolyte may be suitable for fuel cell use because as much as 5% electronic conduction may be tolerated (7). Consequently, preliminary investigations were made of this electrolyte to determine its suitability in fuel cells.

Experimental

Initially, 99.9% pure (minimum) cerium oxide and a purified grade of lanthanum nitrate hexahydrate, 98% pure, were used as starting materials. A higher grade of purity of nitrate, 99.997% pure, was later used.

The mixed oxide was prepared by conversion of ceric oxide to an aqueous solution of the nitrate, addition of lanthanum nitrate solution, evaporation to dryness, and ignition of the residue. X-ray intensity measurements indicated that the solid solution had fluorite structure (8). Wafers were molded from the fine powder. After being hydraulically pressed at 10,000 lb/in. and ignited for several hours at 1000°C, the disks had the following dimensions: 2 cm diameter and 0.1 cm thickness. Porous platinum electrodes, 1.4 cm in diameter, were formed on the faces which had been ground smooth and parallel.

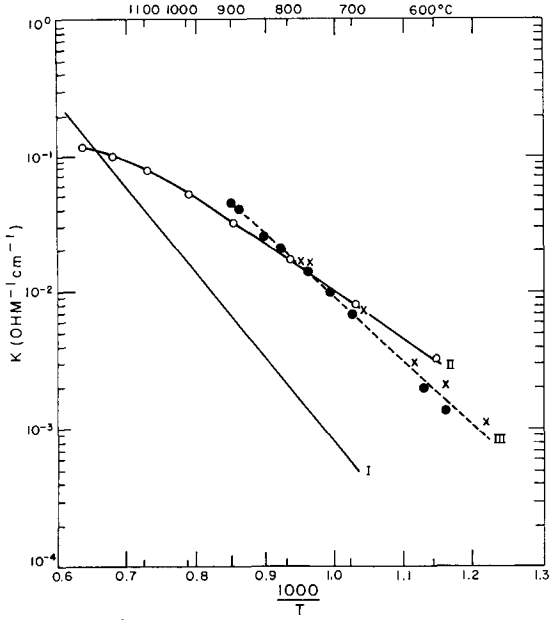

Fig. 1. Comparison of electrical conductivity of calcia-zirconia and ceria-lanthana.

Curves	Electrolyte	Workers
I	Calcia-zirconia	Kingery *et al.* (12)
II	Ceria-lanthana	Croatto and Mayer (3)
III	Ceria-lanthana	This laboratory

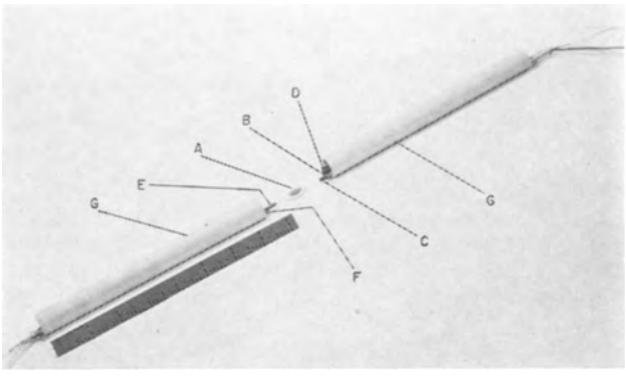

Fig. 2. Experimental cell: A, electrolyte disk; B, thermocouple protection tube; C and E, insulated probe leads; D and F, gas inlet tubes; G, mullite tubes forming half cell compartments.

The experimental cell is shown in Fig. 2. The mullite tubes forming the anode and cathode compartments were held against the electrolyte wafer by spring tension applied by an end plate-bolt assembly external to the furnace. Platinum wire probes encased in thin ceramic tubing were pressed against the platinum coated areas of the disk so as to maintain electrical contact. Thin ceramic tubing was used to feed oxygen into the cathode chamber and 10% hydrogen-90% nitrogen mixture into the anode chamber. Temperatures were measured by a potentiometer and a chromel-alumel thermocouple placed approximately 1 cm from the electrolyte disk. Voltage was determined by use of a potentiometer and current by a milliameter. Electrical resistance was measured by a Wheatstone Bridge at 1000 cycles.

Results and Discussion

The experimental method for evaluating small disks of mixed oxide as electrolyte was tested by the use of commercially available wafers of calcia-zirconia. An open-circuit voltage of 1.05v was obtained at 1010°C for oxygen at the cathode and nitrogen-hydrogen mixture at the anode. The discharge curves obtained at 900° and 1000°C, curves II and III, Fig. 3, are similar to those obtained by Binder *et al.* (9).

Figure 1, curves III and II, compares the experimental results obtained for conductivity as a function of temperature of 85 mole % of ceria and 15 mole % of lanthana with those obtained by Croatto and Mayer (3). The two sets of points in curve III represent separate runs on two samples prepared similarly from the same batch of mixed oxide obtained from the purer grade of lanthanum nitrate hexahydrate. The dependence of conductivity on temperature may be expressed by the equation, $K = Ae^{-Q/RT}$ where K is the electrical conductivity in ohm^{-1} cm^{-1}, A is a constant, Q is the activation energy in calories, and e, R, and T have their usual significance. A value of 21 kcal was calculated for Q. Croatto and Mayer (3) report a value of 14.7 kcal.

The difference in slopes of the conductivity-reciprocal temperature curves, II and III, Fig. 1, was probably caused by differences in purity and porosity of the electrolytes and by contact resistance effects. Croatto and Mayer used nitrates of "special purity" as starting materials. Their electrolyte may have been more porous as their pellets were pressed at a lower pressure, 85 lb/in.^{2}, and were fired at a lower temperature, 1400°C.

Open-circuit voltage obtained with ceria lanthana mixed oxide, prepared from 98% pure lanthanum nitrate hexahydrate, was 0.67v at 800°C and increased only to 0.68v at 850°C. The same open-circuit voltage was observed at 800°C with electrolyte prepared from 99.99% pure lanthanum nitrate hexahydrate thus indicating that the low open-circuit voltage was not caused by impurities contributed by the 98% pure lanthanum nitrate.

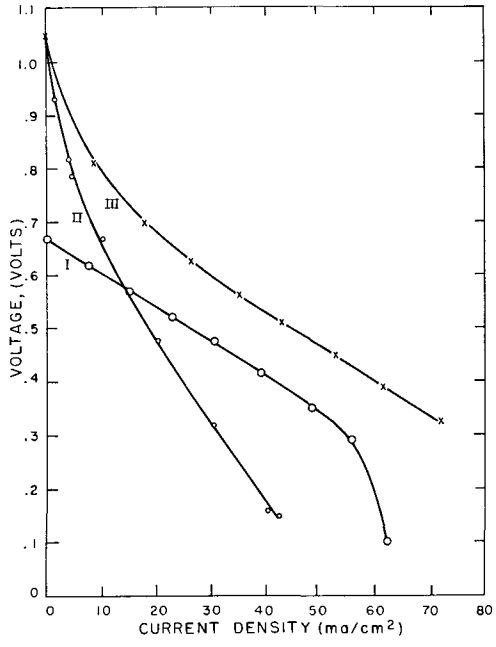

Fig. 3. Comparison of cell voltage-current curves obtained with different electrolytes: curve I for $(CeO_2)_{0.85}$ $(La_2O_3)_{0.15}$ at 800°C; curve II for $(ZrO_2)_{0.85}$ $(CaO)_{0.15}$ at 900°C; curve III for $(ZrO_2)_{0.85}$ $(CaO)_{0.15}$ at 1000°C.

Open-circuit voltages were measured before and immediately after several discharges at constant load. The open-circuit voltage after discharge was 6 to 51 mv lower than before discharge depending on the number of coulombs passing through the disk. Open-circuit voltage obtained with calcia-zirconia electrolyte returned immediately to its initial value when the circuit was opened. The drop in open-circuit voltage observed with ceria-lanthana electrolyte was probably caused by composition changes.

Variation in conductivity with oxygen pressure was observed with electrolyte prepared from both grades of lanthanum nitrate hexahydrate. At 800°C, specific conductivity values of 6.4 x 10^{-2} and 1.1 x 10^{-1} ohm^{-1} cm^{-1} were observed in air and in nitrogen-hydrogen mixture, respectively, for the less pure electrolyte. With electrolyte prepared from the 99.99% pure lanthanum nitrate hexahydrate, lower values were obtained. These values were 2.2 x 10^{-2} and 5.8 x 10^{-2} ohm^{-1} cm^{-1} at 800°C in air and in nitrogen-hydrogen mixture, respectively. In oxygen, 1.4 x 10^{-2} ohm^{-1} cm^{-1} was obtained.

This variance in conductivity with oxygen pressure indicates the presence of electronic conductance (10) which probably contributed to the low open-circuit voltage. Although it was realized that high-purity starting materials were essential to avoid electronic conduction, the finest grade of ceric oxide which was commercially available to this laboratory was 99.9% pure; 0.1% of other rare earths were detected spectrographically (11). Since the further purification of this oxide is especially difficult (11), additional purification was not attempted in this preliminary investigation.

A representative voltage-current curve obtained with electrolyte prepared from the purer grade of lanthanum nitrate hexahydrate is shown by curve I, Fig. 3. The linear portion of the curve from 0 to 50 ma/cm^2 shows that resistance polarization is predominant within this current range. The abrupt change in slope at 50 ma/cm^2 indicates concentration polarization resulting possibly from cation transport.

Conclusion

Change in open-circuit voltage after current is drawn indicates a change in electrolyte composition.

Hence, ceria-lanthana solid solution is probably not suitable for use as solid electrolyte in fuel cells.

Acknowledgments

The author is indebted to C. W. H. Barnett for molding, pressing and igniting the electrolyte disks. Helpful discussions with A. F. Forziati and C. W. H. Barnett and critical review of the manuscript by G. B. Wood are greatly appreciated.

Optical Absorption in Chromium Doped, High Resistivity GaAs in the 0.6 to 1.5 ev Range

Charlie E. Jones, Jr., and A. Ray Hilton

Central Analytical Chemistry Facility, Texas Instruments Incorporated, Dallas, Texas

Optical absorptions, in high resistivity gallium arsenide, on the long wavelength side of the main absorption edge have been previously reported (1, 2, 3). Sturge (1) reported thresholds of 0.70, 0.49, and 0.27 ev, from the main absorption edge, for some unknown impurities. Bube (2) recorded three unidentified impurity absorptions at about 0.5, 0.6, and 0.7 ev below the conduction band. Holeman and Hilsum (3), studying photoconductivity in high resistivity GaAs, observed a deep lying level with a threshold energy of 0.63 ev. The electrical properties of doped, high resistivity, GaAs are still not thoroughly understood. Investigators are not in agreement as to whether a deep donor or a deep acceptor is responsible for the high resistivity. These difficulties are discussed by Cronin and Haisty (4) and by Sturge (1). We have noted an energy level common to all chromium doped samples. The accurate location of this level and its behavior at reduced temperature adds to the present knowledge of high resistivity GaAs.

Experimental

The measurements were made using a Perkin-Elmer Model 350 spectrophotometer. The 350 is a double beam recording instrument covering the range 0.46-7.1 ev. The energy passes through the monochromator prior to entering the sample chamber. The instrument scans from low energy to high with a resolution at 1.5 ev of better than 0.002 ev. The output is a linear plot of transmittance or absorbance against wavelength.

The measurements were performed with the sample located in a Dewar capable of maintaining the specimen at the temperature of the inner chamber. The sample holder is a large mass of copper attached directly to the bottom of the Dewar. Samples are attached to this holder with Dow Corning silicone vacuum grease. Measurements using a gold-cobalt *vs.* copper thermocouple, as described by Powell *et al.* (5), show that samples properly mounted on this sample holder reach a temperature of about 80°K when the inner chamber contains liquid nitrogen. Samples reach an equilibrium temperature about 1 hr after the 1-liter Dewar is filled and hold constant for about 3 hr. All measurements, carried out at reduced temperature, were performed at this stable temperature. Quartz windows were used and the base of the system was designed to fit directly into the raceways of the sampling compartment.

Material

The slices studied were sawed from a high resistivity (10^8 ohm-cm) crystal of GaAs. The crystal was pulled from an alumina boat on the (111) direction from a melt compounded in the crystal puller. The technique used was previously described (4). The crystal was doped with radiotracer Cr^{51}. The chromium was added to the gallium metal. Chromium content of each slice was accurately known from a knowledge of the activity of the slice.

The slices were mechanically polished, to a mirror finish, with 0.05μ alumina and then briefly etched in a $H_2SO_4 \cdot H_2O_2 \cdot H_2O$ etchant. We have previously shown (6) that a GaAs surface treated in this manner has the optical properties of the bulk.

Results and Conclusions

Five samples were measured in this investigation. The chromium content of each sample was as follows:

Sample	Cr atoms/cc
A	5.9×10^{15}
B	1.9×10^{16}
C	2.1×10^{16}
D	2.5×10^{16}
E	3.2×10^{16}

Each sample was scanned through the 0.6 to 1.5 ev range at 295° and 80°K. A common absorption which increased as the chromium content increased, was noted. Figure 1 shows a spectrophotometer trace of one of the samples at each temperature. An absorption is evident at a wavelength slightly larger than the band edge. As the temperature decreases to 80°K the absorption is stronger and the absorption edge moves to shorter wavelength. The absorption coefficients for each sample were calculated from the simplified expression

$$T = (1 - R)^2 e^{-\alpha x}$$

where T = transmission, R = reflectivity (0.296 for GaAs), x = sample thickness (cm), and α = absorption coefficient. Since there is a theoretical relationship between the absorption coefficient and energy squared (1) and in order to define the threshold energy more carefully, the square root of the absorption coefficient

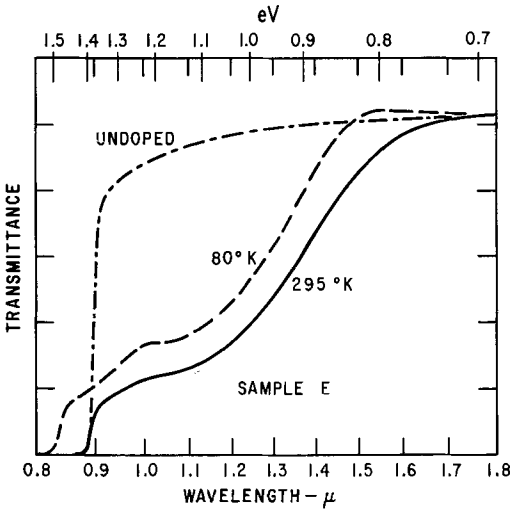

Fig. 1. Transmittance of chromium doped GaAs

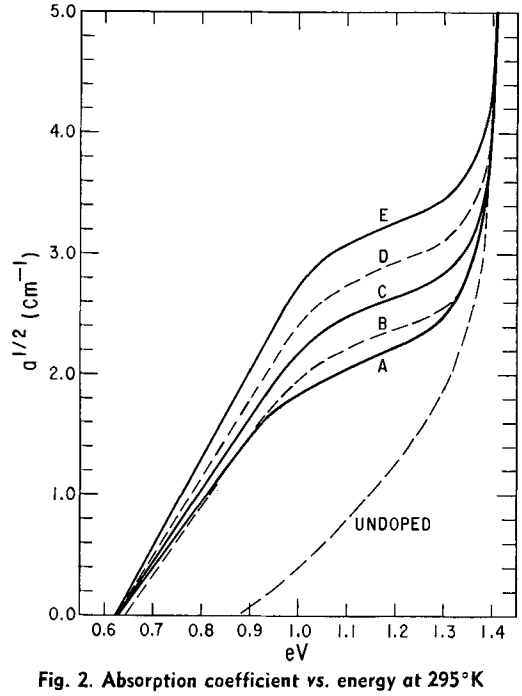

Fig. 2. Absorption coefficient vs. energy at 295°K

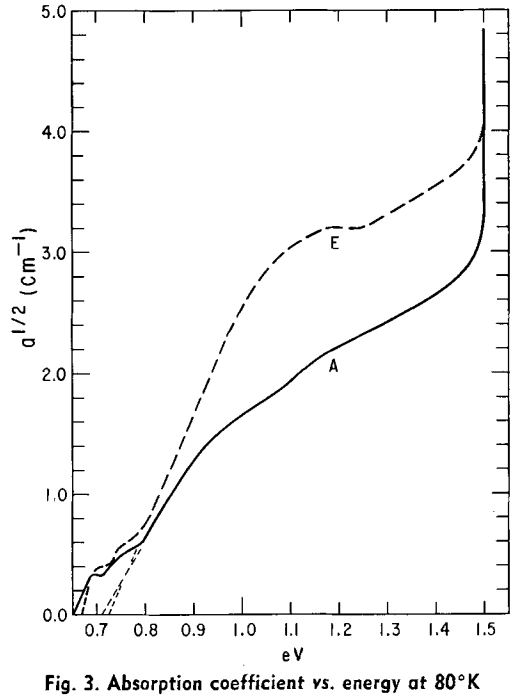

Fig. 3. Absorption coefficient vs. energy at 80°K

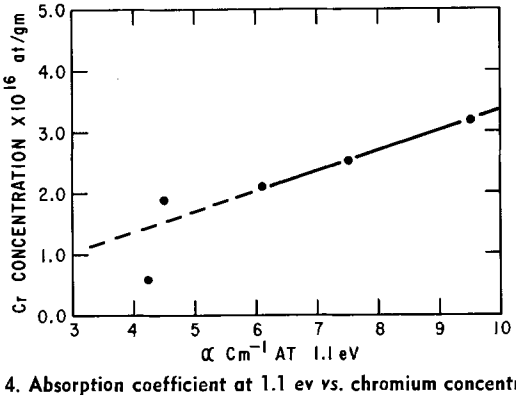

Fig. 4. Absorption coefficient at 1.1 ev vs. chromium concentration

was plotted against energy. This plot, for the 295°K measurements, is shown in Fig. 2. The threshold was determined by extrapolating the linear part of the absorption curves to zero absorption. The extrapolated energy values for all samples are the same within the experimental errors of the measurements. The threshold is at 0.63 ± 0.02 ev. Following Sturge's connotations and band gap value (1.43 ev) this level is 0.80 ev from the main absorption edge. Similar data for two samples from the 80°K measurements are shown in Fig. 3. The level at 80°K is 0.79 ev from the absorption edge. Apparently, the energy level is attached to either the valence or conduction bands and does not change its position relative to the appropriate band as the temperature is lowered. Other levels also begin to appear at the lower temperature. This is consistent with Sturge's (1) work. Figure 4 is a plot of the absorption coefficient (295°K) at 1.1 ev, the approximate maximum, *vs.* the chromium concentration. There is a linear relationship between absorption and chromium content for all except sample A, the lightest doped sample. The nonlinearity of the curve in the lowest doping region could be due to difficulties in the measurement technique or partial compensation in the sample with a small chromium content. An optical absorption was found to occur at the same wavelength, in more than 15 different samples, grown in our laboratory, of chromium doped high resistivity GaAs. This absorption measurement alone is insufficient evidence to determine whether the level is a deep acceptor state. The energy level observed does agree with the value found by Cronin and Haisty (4) by plotting the $RT^{3/2}$ *vs.* $1/T$ and the photoluminescence peak of Turner *et al.* (7) if the transition observed is from the valence band to the chromium state.

Acknowledgments

The authors wish to thank G. Larrabee for supplying the samples used in this study and G. R. Cronin, R. W. Haisty, and R. Conrad for helpful discussions. Jim Parker made the transmission measurements.

Vapor-Deposited Microcrystalline Silicon

E. Sirtl and H. Seiter

Forschungslaboratorium, Siemens & Halske AG, München, Deutschland

For some years thin films of semiconductors have been of growing interest for device technology. On the one hand there are papers on polycrystalline films of II-VI compounds (1), III-V compounds (2), and silicon (3); on the other hand some authors obtained an oriented growth of thin silicon layers on an insulating substrate (4-6). Since only a few single crystal substances are suitable for this purpose, we therefore have examined, along with our own work on oriented silicon layers (7), the growth and the properties of polycrystalline silicon films.

In the material normally resulting from uncontrolled growth the crystal shapes and sizes widely differ and depend on the nature of the substrate. A silicon film of uniform and small grain size requires a sufficient number of nuclei for its growth; this is attainable by simultaneous deposition of a second phase which favors nucleation. In this paper we discuss the growth and properties of shiny microcrystalline layers of silicon formed during the thermal decomposition of organosilicon compounds. It was found that in this case simultaneously deposited silicon carbide caused the continuous formation of nuclei of arbitrarily oriented silicon crystallites of uniform grain size.

Preparation and Structure of Silicon Layers

If organosilicon compounds, such as CH_3SiCl_3, CH_3SiHCl_2, or $(CH_3)_2SiCl_2$, are decomposed below 1300°C, the reaction results primarily in deposits of silicon, in contrast to investigations at higher temperatures (8). The same phenomenon can be observed when mixtures of chlorosilanes and simple hydrocarbon derivatives, such as CH_2Cl_2, near the stoichiometric ratio required for the formation of SiC are thermally decomposed in the presence of hydrogen or an inert gas. Most of our experiments were carried out under the following conditions: temperature (uncorrected), 1100°C; molar ratio CH_3SiHCl_2: $SiHCl_3$: H_2, 1:2:60; gas flow rate in the reaction zone, 3 cm/sec; deposition rate, 10μ /min.

The layers in this study were produced in a quartz reactor, the schematic layout of which is shown by Fig. 1. The samples were placed on a gas-tight graphite heater which is brought to the desired temperature by passing a current directly through it. The pyrometrically measured temperatures are given without corrections. All gas reactions took place in a flowing system (approximately 1-2 l/min).

If a material of this type is deposited on smooth surfaces, shiny layers will be obtained at certain temperatures and concentrations. If the layers are made thicker, even rough substrate surfaces will yield the same result. The grain size of this microcrystalline deposit is often below the resolution limit of light microscopes. Figure 2 shows the fracture of such a layer, the plane of the fracture being perpendicular to the surface of a silicon monocrystal disk which was used as the substrate in this case. This picture already shows the uniform structure and the low degree of roughness on the surface of the relatively thick growth layer. Figure 3 enables comparison of the photos taken of a typical surface structure through a light microscope and through an interference mi-

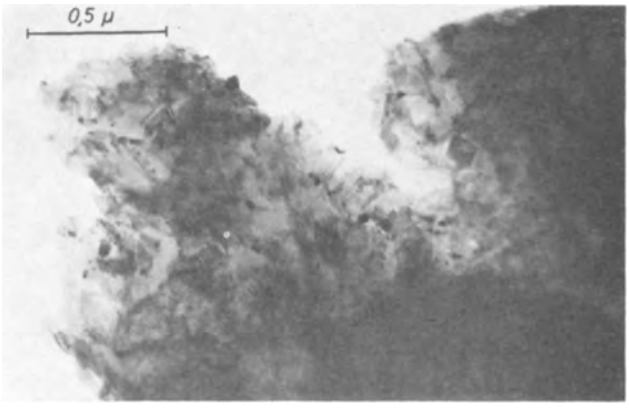

Fig. 5. Edge of microcrystalline silicon layer deposited at 1200°C (uncorr.). Transmission electron micrograph.

croscope. A deflection of the interference lines by an amount corresponding to the distance between two lines would indicate a difference in thickness of 0.27μ.

Electron micrographs of thin etched layers showed the high degree of dependence of the grain size on the deposition temperature. Thus the dimensions of the crystallites discernible in Fig. 4 are very near the limit of the resolution power of the electron microscope (1050°C), while Fig. 5 already shows larger uniform areas (1200°C).

X-ray and electron diffraction patterns confirmed that silicon carbide in measurable quantities is present in such layers. The presence of carbon was also proved by chemical and spectrometric methods. A quantitative determination of the total carbon content was made possible by burning the silicon samples in an oxygen current and coulometric determination of the CO_2 produced in this way.[1] However, there could be made only semiquantitative comparisons between the chemical total carbon values and the x-ray or electron diffraction data. Surprisingly, analytical values of samples deposited at temperatures between 1000° and 1150°C did not display any significant differences. In all cases the carbon content amounted to about 2 g-a/o. This result might be explained by the fact that both the tendency to form SiC precipitates and the silicon yield increased considerably in this temperature range. The better crystallinity of SiC at higher temperatures would then result in a coarsening of the grain structure of the silicon because of the reduced rate of nucleus formation.

Chemical Behavior

Since the grain size of microcrystalline silicon depends practically only on the conditions prevailing during the gas reaction, it is possible to get shiny layers on a wide variety of substrates. Such production is dependent on good adherence of the films to the substrates, an inert behavior of the substrate under deposition conditions, and a minimum difference between the thermal expansion coefficients of the two substances.

The following substances have been found suitable for use as substrate material: silicon(with and without oxide layer), porcelain, sintered corundum, molybdenum, and graphite (roughened). Only thin layers (10-30μ) can be deposited if there is a noticeable difference in the expansion behavior of the substances, since otherwise the layers would tend to crack and chip. A certain extent of p-type doping (by diffusion of aluminum from the interface) will be found in most cases where porcelain or sintered corundum is used for the substrate.

The carbon content of microcrystalline silicon apparently does not affect the latter's behavior during oxidation. The oxidation rates agree with those measured in the case of monocrystalline samples. The same applies to the porosity of the oxide layers. No grain growth could be observed during any of the oxidation or annealing processes.

Depending on the carbon (carbide) content, etching of the surfaces is rendered more or less difficult. At higher carbon concentration, an oxidizing fused salt bath (*e.g.*, KOH-KNO_3-KF mixture at 400°C) proved helpful.

Table I.

	n cm^{-3}	ρ ohm-cm	μ cm^2/vsec
as grown	$4.5 \cdot 10^{15}$	60	23
4 hr in O_2 1200°	$2.1 \cdot 10^{16}$	8.6	34
8 hr in O_2 1200°	$7.4 \cdot 10^{16}$	5.8	15

Electrical Properties

Doping of the growing silicon by adding volatile arsenic or boron compounds to the reaction gas does not yet result in reproducible electrical properties. Thus the carrier concentration of otherwise unprocessed samples is much lower than that measured in monocrystalline growth layers with a comparable history. Definite p-type doping by the vapor phase seems to be altogether impossible.

However, if such layers are subsequently annealed in nitrogen or oxygen, the carrier concentration calculated from Hall measurements will correspond approximately to that originally expected. This means that the doping agents which are concentrated primarily in the grain boundaries will be homogeneously distributed by a diffusion process. The carrier mobility measured in subsequently annealed layers was between 10 and 50 cm^2 volt^{-1} sec^{-1}. Typical results are shown in Table I. The layers had a thickness of 150μ and were gas doped by a molar ratio of PCl_3 : Si-compounds = 10^{-5}.

In the growth direction, the electrical properties varied greatly since different zones had formed, probably as a result of heater temperature fluctuations. It was possible to make these zones visible by etching the surface of oblique cuts. The diffusion rate of boron (B_2O_3-SiO_2 source, "box method") is greatly reduced in samples with a higher SiC content. The diffusion front is wavy, and the corresponding p-n junctions display almost no barrier effect, mostly because of the very high series resistances, the magnitude of which depends on geometric factors and on the carbon content.

Discussion

It is not yet known if it is possible to increase the mobility in the system silicon-silicon carbide. Irrespective of the electrical properties, the silicon "modification" here described should be suitable wherever components technology calls for polycrystalline material with maximum uniformity in grain size. A typical field for its appliance could be the method of "dielectric isolation" (9, 10). This method of growing microcrystalline silicon layers may be transferred to other systems; this means that one may insert any other additional phase of low solubility instead of SiC into silicon or other semiconductors.

Acknowledgments

The authors wish to express their gratitude to Mr. G. Prätzel for the great care with which he prepared the silicon layers, Mrs. Ch. Raetzel for the performance of the electrical measurements, and Dr. E. Fuchs for the electron-microscope photographs. The authors gratefully acknowledge the support of this work by the Federal Ministry of Defense.

Manuscript received Nov. 1, 1965; revised manuscript received Jan. 31, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

A Point Contact Method of Evaluating Epitaxial Layer Resistivity

C. C. Allen, L. H. Clevenger, and D. C. Gupta[1]

Semiconductor Research and Development Laboratory, Texas Instruments Incorporated, Dallas, Texas

Various methods (1-5) have been devised for measuring the resistivity of epitaxial layers of silicon or germanium on substrates of the same conductivity type and lower resistivity. The point contact breakdown voltage method gives a nondestructive and a quick measurement. The purpose of this report is to present a semiautomatic pulsed current technique which (*a*) reduces the error in determining when breakdown has occurred, and thus allow better reproducibility, and (*b*) reduces power dissipation in the sample during measurement.

Pulse Technique and Apparatus

The apparatus uses a current regulated square wave pulse which increases until breakdown is reached. Figure 1 shows a block diagram of the set. A square wave of 500 μsec pulse duration and repetition rate of 80 pulses/sec is generated by the blocking oscillator. Risetime of the pulse varies between 20 and 200 μsec, depending on the load. The pulse is fed to a ramp generator which, on command, produces a series of progressively increasing voltage pulses. These voltage pulses are used to control the current output from a constant current generator. The current generator has a maximum capability of about 600v, with a current of 0 to 125 ma.

The voltage probe is connected through a voltage divider to a high input impedance amplifier. A diode detector is used to charge a capacitor to the peak voltage. The breakdown point is detected by means of a slope detector. This detector turns the ramp generator off when the rate of change of voltage becomes zero or negative. Reset and timing are handled by means of a monostable flip flop with a 10-sec time constant. The breakdown voltage is read on a peak reading voltmeter which has a risetime of 150 μsec.

Osmium-tipped probe having a tip radius of 2.5 mils is used. The weight on the probe is adjusted to 20g in normal use.

[1] Present address: General Electric Company, SPD Electronics Park, Syracuse, New York.

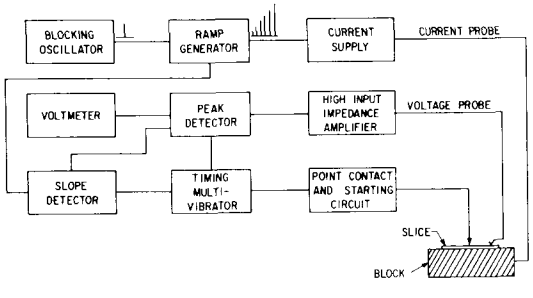

Fig. 1. Block diagram of the semiautomatic measuring circuit

Experimental Techniques

Since the point contact method of measuring epitaxial layer resistivity is empirical, a calibration curve for point contact breakdown voltage *vs.* resistivity was developed as follows. Slices of 30 mils thickness or more were cut from melt grown bulk material. The resistivity of these slices was measured on a four-point probe resistivity meter (6) and the avalanche breakdown voltage was measured on point contact resistivity set several times. Impurity concentrations were determined from the measured resistivity and Irvin's curve (7). The avalanche breakdown voltage is plotted as a function of impurity concentration in Fig. 2.

Whenever the layer thickness is greater than or equal to the depletion layer thickness, the breakdown voltage can be represented as a function of concentration only. However, for smaller layer thickness, the breakdown is limited by the width of the epitaxial layer as well as its impurity concentration. Total breakdown voltage for this epitaxial layer can be calculated by assuming the relationship of ionization rate per unit path length as a function of electric field (8) and is given by (see Appendix)

$$V_T = \left(\frac{2qK}{3\epsilon\epsilon_0} N^{p+1}\right)^{1/2} \cdot t - \frac{q}{6\epsilon\epsilon_0} N t^2 \qquad (0 \leq t \leq t_{\min}) \qquad [1]$$

$$V_T = V_{B^\infty} \quad (t \geq t_{\min}) \qquad [2]$$

where t is the epitaxial layer thickness, N is the impurity concentration in the layer, $t_{\min}$ is the minimum

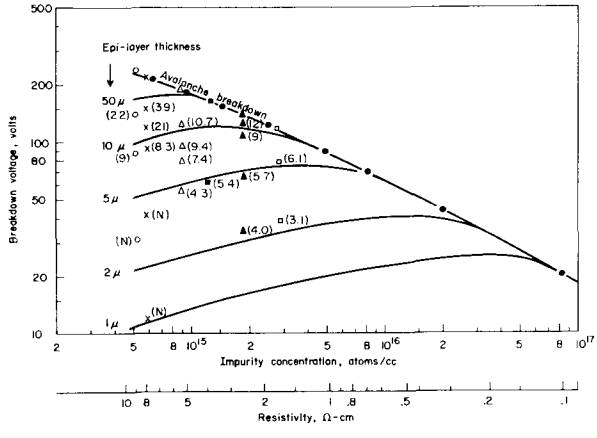

Fig. 2. Point contact breakdown voltage for n-type silicon. •, melt grown bulk material; other symbols, epitaxial wafers etched successively several times; ( ), thickness of the epitaxial layer in microns; (N), epitaxial layer thickness not available.

thickness required to obtain avalanche breakdown V_{Boo} and K and p are constants given in Table II.

The breakdown voltage is calculated using Eq. [1] in the region where it is limited by the width of the layer as well as its impurity concentration and is plotted in Fig. 2 for epitaxial layer thicknesses of 1, 2, 5, 10, and 50μ.

To verify the theoretical curves for epitaxial layer width limited samples experimentally, n-type silicon epitaxial slices sufficiently thick to provide avalanche breakdown were taken and were etched several times. The breakdown voltage was measured on the point contact breakdown set and the epitaxial layer thickness was measured on a Beckman IR-5A Spectrophotometer each time. Results are plotted in Fig. 2. A fair correlation exists between the experimental results and the theoretical calibration.

Effects of Duty Cycle, Probe Pressure, and Surface Quality

Figure 3 shows the breakdown voltage obtained for samples of n-type silicon when 60 cps half-wave rectified current and a 500 μsec current pulse are used. Due to a reduction of power dissipation heating, pulse technique yields a higher breakdown voltage for the same resistivity sample. However, for a given per cent error in a voltage measurement the range of corresponding resistivities is equal for both methods.

The point contact breakdown voltage is dependent on the probe pressure. An increase in weight on the probe decreases the avalanche breakdown voltage as shown in Fig. 4. The effect of pressure has been noted to be generally less on low resistivity material than on high resistivity material. Data published by Gardner and Schumann (5) on pressure effects on n-type bulk silicon have been compared (Fig. 4) by calculating V_{BO} by $V_{BO} = V_B/0.955$ where V_B = 45v taken from Fig. 2 for 0.33 ohm-cm. It was observed that the effect of probe pressure is different on avalanche and punch through voltages above 25g on the probe, however, below this value, both voltages were affected in the same manner by the probe pressure. Weights below 10g were not sufficient to provide desired repeatability in the measurements. Therefore, a weight of 20g was used on the probe in normal use. Figure 5 shows the change in avalanche breakdown voltage

with respect to resistivity of p-type silicon for different weights on the probe.

To determine the effects of surface quality on breakdown voltage, three silicon slices of different resistivities having a mechanical polish on one side and a lapped surface on the other side were measured. The slices were then chemically polished, and the breakdown voltage was measured on the lapped side several times as the etching progressed. Figure 6 shows the results. It is seen that the breakdown voltage increases as the chemical etching progresses, finally approaching a limiting value as the material damaged by the lapping operation is removed.

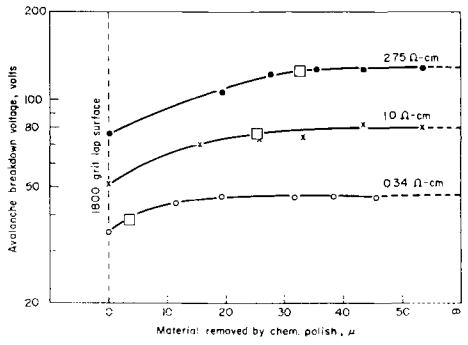

Fig. 6. Effect of surface quality on avalanche breakdown voltage of n-type silicon. □ Represents mechanically polished mirrorlike surface.

Accuracy

To compare the accuracy of the pilot slice method (3) and the point contact method, the resistivities of ten p/p^+ epitaxial slices were determined by the pilot slice method and by the point contact method. Diodes were then constructed from these slices, and the resistivity of the epitaxial layer was found by the diode voltage capacitance technique. Results are shown in Table I. Using the resistivity as determined by the diode voltage capacitance technique as the actual resistivity of the epitaxial layer, only 10% of the resistivities as found by the pilot slice method agreed to within 20% of the value as found by the diode V-C technique, whereas 70% of the values found by the point contact method agreed to within 20% of the resistivity as found by the diode V-C technique.

Conclusion

In conclusion, the point contact breakdown voltage method for measuring resistivity has been shown to be more accurate than the pilot slice method by comparing the two with the diode voltage capacitance technique. An automatic test set using the pulsed current supply gives a fast read out and eliminates the operator judgment. A method for obtaining the calibration for epitaxial layers of thickness greater than or less than the depletion layer thickness has been discussed. This calibration, however, is dependent on the probe pressure. A weight of 20g on the probe was found to be most suitable. To obtain a consistent breakdown voltage, a damage-free chemically polished surface should be used.

Acknowledgment

The authors wish to acknowledge help from several colleagues in the Materials Branch of the Semiconductor Research and Development Laboratory, in particular to W. R. Runyan and S. B. Watelski for their encouragement and suggestions.

APPENDIX

The differential equation describing the growth of current density for spherical geometry can be written as

$$\frac{dj_n}{dr} = J\alpha(E) \qquad [3]$$

where, $J = j_n + j_p$ and $\alpha(E)$ is the ionization rate of electrons and holes. Integrating Eq. [3] and assuming, multiplication factor, M to be much greater than one (9) and $\alpha(E) = CE^n$ where C and n are constants (8), one can write for avalanche breakdown, *i.e.*, where the depletion layer is confined to a single resistivity region.

$$E_{B\infty} = \left(\frac{q}{3\epsilon\epsilon_0} \cdot \frac{n+1}{C} \cdot N\right)^{1/n+1} \qquad [4]$$

Using Poisson's equation, the breakdown field, $E_{B\infty}$ can be calculated in terms of the breakdown voltage $V_{B\infty}$ as

$$E_{B\infty} = \left(\frac{2q}{3\epsilon\epsilon_0} NV_{B\infty}\right)^{1/2} \qquad [5]$$

From the curve of avalanche breakdown, Fig. 2, one can write

$$V_{B\infty} = KN^p \qquad [6]$$

The values of constants K and p are given in Table II. Equations [4], [5], and [6] give the values of n and C in terms of K and p.

As the voltage across the thin epitaxial layer is increased above the punch-through voltage, V_p, the space charge region extends to a region of the different resistivity material, *i.e.*, substrate. If E_{add} is the additional field after punch-through necessary to cause breakdown, the condition for breakdown is written as

$$\int_{E_{add}}^{E_p+E_{add}} \alpha(E)\,dE = \frac{qN}{3\epsilon\epsilon_0} \qquad [7]$$

Integrating Eq. [7] and assuming

$$E_p + E_{add} >> E_{add} \qquad [8]$$

the expression for total breakdown voltage $V_T = V_p + V_{add}$ is given by Eq. [1] for $0 \leq t \leq t_{min}$ where t_{min} is the minimum thickness required to obtain avalanche breakdown $V_{B\infty}$ and is given by

$$t_{min} = \left(\frac{6K\epsilon\epsilon_0}{q} N^{p-1}\right)^{1/2} \qquad [9]$$

for $t \geq t_{min}$

$$V_T = V_{B\infty} \qquad [10]$$

The Preparation of Ultrahigh-Purity Nickel Single Crystals

V. J. Albano and R. R. Soden

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Ultrahigh-purity nickel single crystals are required for experimental studies of their intrinsic electrical properties. The presence of certain impurities, even in the extremely low ppm range, may completely obscure such phenomena as magnetoresistance and cyclotron resonance which are used to explore electronic structure. The suitability of a metal for these studies is conveniently judged by its resistance ratio ($R_{273°K}/R_{4.2°K}$). The room temperature resistance ($R_{273°K}$) is mainly a measure of the thermal contribution to the resistance, and the liquid helium temperature resistance ($R_{4.2°K}$) is dominated by the contribution of chemical impurities in solid solution. This ratio is a relative measure of the impurity content. In general purer materials will have higher resistance ratios. Values for nickel up to 1000 have been reported heretofore (1). Reed and Fawcett of these laboratories (2) in their studies of the Fermi surface of nickel by means of magnetoresistance measurements used single crystal nickel obtained in the early stages of the present work which had a ratio of 2200. Nickel having a resistance ratio of 3500 has been produced by the present technique.

Electrochemical deposition from rigorously purified nickel chloride was used as the primary means of winning the metal. This method produces the nickel directly in massive form and avoids high-temperature reduction operations which could be serious sources of contamination. Further refinement of the plated nickel and consolidation into single crystal form was accomplished by zone melting individual bars of the material after a surface oxidation treatment.

Purification of $NiCl_2$ *solution.*—The nickel chloride used as the starting material was Baker and Adamson's special reagent grade which is low in cobalt. A spectrographic analysis of one lot of this material is given in Table I. Its purification was accomplished principally by the ion exchange technique. Extensive studies by Kraus and Nelson (3) showed that strong-base anion exchange resins of the type Dowex I are capable of removing the anionic chlorocomplexes of about 30 elements from solutions of HCl of appropriate concentrations, but will not remove nickel since it does not form a chlorocomplex. Our studies showed that the use of HCl is unnecessary when purifying $NiCl_2$ since the salt itself provides the high concentration of chloride ions needed to form anionic chlorocomplexes. A high-purity analytical grade Dowex I anion exchange resin designated AGI-XIO, 50-100 mesh, chloride form was used in these studies. It is obtainable from Bio-Rad Laboratories of Richmond, California.

The efficacy of the anion exchange method for removing iron and cobalt, two elements which may have a particularly adverse effect on the resistance ratio of nickel, was tested by radioisotope tracer techniques. A 10*N* $NiCl_2$ solution was treated with H_2O_2 to convert iron to the ferric state and was then passed once through a 12 in. column of clean anion exchange resin. By this treatment the iron is decreased by a factor of better than 1/500 and the cobalt by a factor of 1/1000. After two passes through the resin, both the iron and the cobalt are unmeasurable.

Other possible impurities in nickel chloride that are of considerable concern in this work and which are removable by ion exchange treatment of the 10*N* chloride solution are copper, zinc, and all the platinum metals except rhodium. Lead, silver, and rhodium, which also may be contaminants, are not removed from the 10*N* solution by ion exchange, but can be removed from a solution in which the chloride concentration is 2.5*N*. The ion exchange technique will not eliminate aluminum or silicon which may be present in the nickel chloride solution. These may be removed by precipitation as $Al(OH)_3$ and silica by using a specially prepared slurry of $Ni(OH)_2$ in dilute $NiCl_2$ as the precipitant.

The anion exchange treatment does introduce into the nickel chloride solution traces of organic material which apparently manifests itself as carbon impurity in the finished nickel. The AGl-XlO resin used in this work was chosen because it contributed less organic contamination than other resins which were explored. It was possible to effect an appreciable lowering of the organic content of the treated nickel chloride solution by prolonged degradative oxidation with H_2O_2 at 80°C.

The sequence of operations and the quantitative details for the preparation of about four liters of plating solution are shown in the flow sheet in Fig. 1. This chart also outlines the plating and zone refining steps.

Plating operations.—The plating procedure used for winning the nickel is essentially that reported by Wesley (4) in 1956. The plating bath contains nominally 300 g/l of the purified $NiCl_2 \cdot 6H_2O$ and 17 g/l of a special high-purity B_2O_3 for *p*H buffering pur-

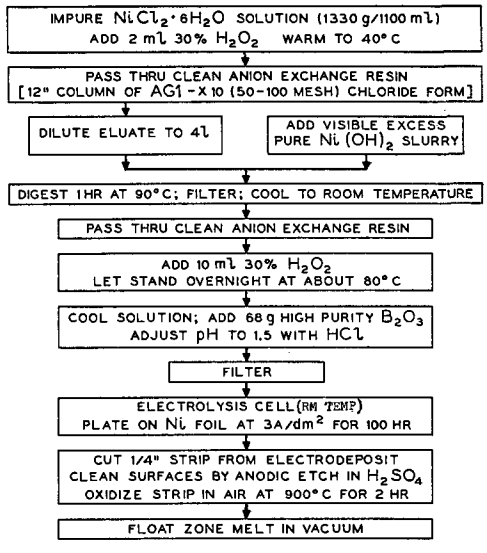

Fig. 1. Flow sheet for production of ultrahigh-purity nickel

poses. The bath is adjusted to a *p*H of about 1.5 by a small addition of HCl and is filtered through an 0.8μ "Micropore" filter to remove any particulate matter which may be present. Plating was carried out initially from 3 liters of solution contained in a 4-liter Pyrex beaker. The volume of plating solution increases progressively during a plating run as appropriate additions of concentrated pure $NiCl_2$ and HCl are made periodically to compensate for nickel depletion and to maintain the *p*H at about 1.5. The cathode on which the nickel was plated is an etched foil 1 mil x 2.5 cm x 13 cm prepared from highest purity nickel available. Twin anodes of 10% iridium-platinum were used to plate both sides of the foil. The purest nickel thus obtained was plated at room temperature, without agitation, at a cathode current density of about 3 amp/dm^2. Plating must be carried out in a fume hood since chlorine is evolved during the operation.

The nickel thus deposited was satiny in appearance. It was nominally flat over the area corresponding to the original foil, but extending beyond this it was roughly cylindrical at the sides and bottom and nodular at the corners. The spectrographic analysis of a section of a flat portion is given in Table I.

Zone melting.—The electrodeposited nickel is polycrystalline and, although very pure in terms of metallic impurities, it does contain occluded nickel chloride and traces of organic matter which are probably adsorbed on the crystal faces of the nickel. Zone melting will remove the nickel chloride by volatilization and will convert the metal to single crystal form. At the same time the organic matter will be degraded to carbon which dissolves in the nickel and is not removed by zoning. Simple float-zone-melting of the plated nickel results in a product containing about 20 ppm of carbon and having a resistance ratio of the order of 2000.

The lowering of the carbon content is accomplished by first oxidizing a strip of the nickel in air at 900°C for 2 hr. This results in a thin green coating of NiO on its surface. The sample is then suspended in the vacuum floatzone melting apparatus (6) and given 4 to 6 passes at 0.001 ips. Apparently the carbon in the nickel reacts in the molten zone with the oxygen from the NiO to form CO and/or CO_2 which are then removed by volatilization along with excess oxygen. Typical vacuums run between 2×10^{-5} to 5×10^{-7} mm of mercury during zone melting. The removal of total oxygen to less than 2 ppm can be observed by noting when the surface of the rod becomes smooth. At this point zone melting should be stopped since carbon recontamination can occur from back-streaming of vapors from the oil used in the diffusion pumps of the zone melting apparatus even though extensive liquid nitrogen traps are present. Nickel having a resistance ratio of 3500 has been obtained by this treatment.

Discussion

The absolute chemical purity of nickel made by this process is very difficult to assess since the usual analytical techniques are not precise enough for determining impurities in the very low or fractional ppm range. Emission spectrographic analysis using specially refined techniques was used as the principal means of evaluation because of its broad capabilities. Experience has shown that no significant change in the metal impurity content of the plated nickel occurs after it has been zone melted. Consequently the spectrographic analysis given in Table I is applicable to the oxidized and zone melted nickel having a resistance ratio of 3500. Mass spectrographic analysis of a sample of Ni-XVI which had been float-zone melted without prior oxidation agreed in essence with the emission spectrographic findings and indicated that other metallic impurities, if present at all, were there in fractional ppm. Very slight traces of cobalt cannot be determined by either of these methods, but in view of the fact that it was so thoroughly removed from the $NiCl_2$ by the ion exchange treatment, its presence in the nickel is highly improbable.

Table II. Analysis for H, N, O, and C

Element	Ni-XVI, Before zone melting	Ni-XVI, After zone melting
H	0.5	0.2
N	2.0	2.0
O	4.6	2.0
C	29	<5*

* Estimated.

Reliable values for its carbon content are not available since the precision of the analytical method is low at carbon levels as low as they are in this nickel. The purification technique used for removing carbon is basically the same as the combustion method used for its analytical determination, and since this method is only sensitive to about 5 ppm, the probable carbon content of the nickel is less than 5 ppm. The H,N,O contents of this Ni-XVI before and after zone melting were determined by the vacuum fusion method and are reported in Table II.

Efforts are being directed at lowering the impurity levels still further by prepurification of the materials and reagents used in the procedures and, in general, by more diligent attention to cleanliness to avoid contamination during processing. Lowering the impurity levels should result in nickel having resistance ratios higher than the 3500 which has been achieved to date. It is not possible to predict what the ultimate ratio should be since the exact contribution of each impurity to the resistivity of Ni at liquid helium temperature is not known and may be vastly different for each element (5). Work in progress indicates that iron and carbon have very serious effects on the resistivity of nickel at 4.2°K (6). Other impurities which are not being detected by the present analytical methods possibly may have even more adverse effects on the resistance ratio than the iron or carbon. If all the impurities were removed, the resistance ratio would probably approach some high but limiting value since structural defects in the crystal lattice would then be the controlling factor. It is evident that an urgent need exists for more sensitive methods of analysis in order to recognize and evaluate the effects of these ultra trace impurities so that appropriate procedures can be developed to improve the nickel further by removing the remaining significant contaminants.

Electrolytic Reduction of Amides

II. p-Aminobenzanilide and Anisamide

Sherlock Swann, Jr., J. C. Bresee,[1] and R. A. Strehlow[1]

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

This communication is the final part of a study of the influence of the cathode material on the electrolytic reduction of amides in sulfuric acid solution. In the first part (1) the compounds studied were N-substituted aliphatic amides, N-dimethylvaleramide and acetanilide. An attempt was made later (2) to reduce N, N-dimethylvaleramide at a carbon cathode. The present study is on aromatic amides. The amino substituted benzanilide was chosen in preference to the unsubstituted compound on account of its greater solubility in the electrolyte and anisamide because it is less easily hydrolyzed than benzamide itself.

There appears to have been no previous study of the electrolytic reduction of p-amino or any benzanilide in an aqueous or aqueous alcoholic catholyte.

The reduction of anisamide to p-methoxybenzylamine has been carried out by Kindler (3) at a lead cathode, but the reduction at a carbon cathode was unsuccessful (2).

Apparatus and Procedure

The apparatus and general procedure was the same as that in the first part of the investigation (1, 5).

Reduction of p-Aminobenzanilide.—The procedure for recovery of the products of the reduction of p-aminobenzanilide used in most of the runs was as follows: The catholyte was diluted with water and neutralized with sodium carbonate. Any p-aminobenzylaniline should float to the surface yellow oil (4). It was found that large amounts of the starting material appeared as a white crystalline solid as soon as the catholyte was diluted. After some runs, therefore, the crystals were filtered off before neutralization. In no case was any oil found; there was, at best, a small amount of semi-solid after some runs with a lead cathode.

p-Methoxybenzylamine.— The procedure for the recovery of the products of the reduction of anisamide has already been described (2). In the last part of the work sodium hydroxide was used for the neutralization. Any amine formed was extracted with ether. The extract was dried with solid sodium hydroxide, the ether removed by distillation, and the remaining amine heated in a small distillation flask until the temperature of the thermometer reached 200°C. The residue was then weighed.

Discussion of Results

Electrolytic reduction of p-aminobenzanilide.— Anode, lead cylinder; anolyte, 10% sulfuric acid; catholyte, 10g of p-aminobenzanilide in 90-110 cc of a solution of 50 cc of water, 110 cc of ethyl alcohol, and 60g of sulfuric acid; cathode area, 100 cm²; amp 5; current density 0.05 amp/cm²; temperature about 30°C; duration of run, 1 hr (theoretical for reduction to p-aminobenzylaniline).

The following cathodes were used: copper, zinc, cadmium, mercury, aluminum, lead, tin, bismuth, iron, cobalt, and nickel. Only traces of product were found even with a lead cathode after double the theoretical amount of current had been allowed to pass. Between 5 and 8½g of starting material remained after each run.

Electrolytic reduction of anisamide.—Anode, lead cylinder; anolyte, 10% sulfuric acid; catholyte, 20g of anisamide in 90-100 cc of a solution of 50 cc of water, 110 cc of ethyl alcohol, and 60g of sulfuric acid; amp, 5; area of cathode, 100 cm²; current density, 0.05 amp/cm²; temp, about 30°-37°C; duration of run, 2 hr and 50 min (theoretical for reduction to p-methoxybenzylamine).

Other cathodes tried were: iron sheets, copper rods, nickel sheets, electroplated cobalt, electroplated bismuth, aluminum, tin, and mercury. Before use they were prepared in the usual manner (5). The only active cathodes were zinc, cadmium, and lead. Other methods of treament before reduction led in all cases to lower yields than those obtained when the cathode was etched.

The product was converted to the hydrochloride, which was recrystallized from n-butyl alcohol after the solution had been decolorized by activated charcoal. The mp of the hydrochloride was 235°-238°C (unc.). The mp of the pure hydrochloride is 240°C.

Optimum temperature, and current density were not studied with the lead cathodes shown in Table I but other studies showed 0.05 amp/cm² to be the limiting current density. Poor results were obtained at room temperature.

[1] Present address: Oak Ridge National Laboratory, Oak Ridge, Tennessee.

Table I

Cathode material	Grams of p-methoxybenzylamine	% Yield of p-methoxybenzylamine	Treatment of cathode
Zinc RT	7.6	47	Etched in 1:4 HCl 5 min at 10°-15°C
Same	7.4	40	
Cadmium RT	7.6	40	Etched in 1:6 HNO_3
Same	5.6	30	3 min at 10°-20°C
Lead RT	11.1	59	Etched in conc. HNO_3
Same	11.3	61	at 60°C

RT, Cast in a mold at room temperature.

Conclusions

Attempts to carry out the electrolytic reduction of p-aminobenzanilide were unsuccessful.

Anisamide was found to be reduced to p-methoxybenzylamine only at cathodes of zinc, cadmium, and lead. The best results were obtained at lead. Etched cathodes were far more active than those which had been anodized, as had been found in certain previous studies.

Anodic Tafel Slopes for N-Type Germanium

C. Gordon Peattie

Texas Instruments Incorporated, Dallas, Texas

As a preliminary part of another study, reproducibility of the Tafel slope of the n-type germanium anode and its sensitivity to electrolyte type and temperature have been measured.

Experimental Procedure

The cylindrical, single-crystal germanium anode used throughout these measurements was n-type, with a resistivity of 12-18 ohm-cm. The crystal had been grown by pulling along the (111) axis. Ohmic contact to the germanium was made by doping one surface with a 99% Au-1% Sb alloy in a dry helium atmosphere at 570°C for 2 hr and then by soldering a lead to that surface. The lead and the area where it joined the germanium were then covered with Apiezon W wax.

A schematic diagram of the experimental system is shown in Fig. 1. Current measurements were made with a Model 425A Hewlett-Packard DC microvolt ammeter and voltage measurements with a Model 801B John Fluke potentiometric-type voltmeter. Current adjustments were made with a series combination of four Model AR Beckman Helipots (100K, 200K, 300K, and 400K ohms), two Model IN-11 Heathkit decade resistance boxes, and four coarse rheostats that had a total resistance of 7 megohms. Temperature for any one run was held constant to ±0.5°C or better by a water bath and an E. H. Sargent "Thermonitor." Four 45v dry cell batteries in parallel were used as the current source.

Two different electrolytes were used: (*i*) 0.2M KCl, buffered at *p*H 5.0 with potassium hydroxide and potassium acid phthalate and (*ii*) 0.1*N* H_2SO_4 containing 0.1M K_2SO_4. The nominal electrolyte volume used was one liter. Finely ground semiconductor grade germanium was added to the electrolyte. Measurements in 0.2M KCl were made in the range 20.2°-20.6°C and 50°-55°C; in 0.1M K_2SO_4-0.1*N* H_2SO_4, at 0°C and in the 50°-55°C range.

The following etch technique was used: CP-4A for 20 sec, deionized water rinse, 48% HF for 30 sec, deionized water rinse. The sample was then moved quickly into the electrolyte and an anodic voltage applied to it.

The germanium electrode was held in the electrolyte with the (111) face (5.1 cm^2) completely immersed. The sides of the cylindrical electrode were also wet with electrolyte to a height varying between 1/16 and 1/8 in. Considering the area wet on the sides by the electrolyte to lie between 1.3 and 2.6 mm and disregarding any surface roughness factor, the total geometrical anodization area lay somewhere between 6.4 and 7.7 cm^2. The end of the agar bridge that led to the reference electrode, a saturated calomel electrode held at room temperature, was positioned about 1/8 in. from the center of the immersed germanium face. The cathode was a platinum cylinder having an effective area of 56 cm^2. The electrolyte was deaerated by cylinder CO_2 that had been first passed sequentially through an Engelhard Deoxo Model D purifier, Linde molecular sieves, and "Drierite," and then bubbled through water before passing into the electrolyte. The electrolyte was deaerated for at least an hour before starting a run. Deaeration was continued throughout the experiment.

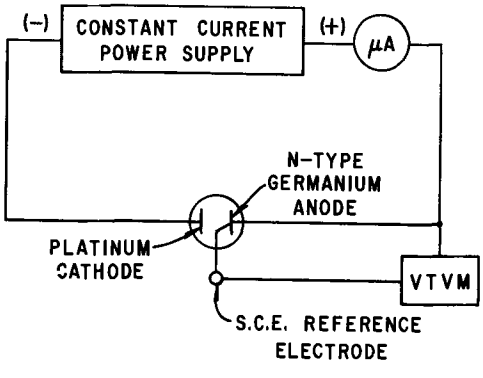

Fig. 1. Schematic diagram of experimental system

Anodic Tafel data were obtained under two conditions:

1. The current-voltage curve was begun within a minute of etching of the sample;
2. The current-voltage curve was preceded by anodization at 100 μa for a measured period of time, equal to or greater than 30 min.

After each current change, at least one minute was allowed to elapse before the voltage was measured. Over the anodic current range studied, 2.3-3000 μa, no correction of voltage was made for IR drop.

Experimental Results

The average value of the Tafel slopes in 24 sets of current-voltage curves, made by starting the measurements within a minute of etching the sample and without any pre-anodization, was 0.087 ±0.004 (std. devn.). Twenty of these curves were measured in 0.2M KCl, buffered to *p*H 5.0. Of these 20 runs, 16 were at 20.2°-20.6°C and four at 50°-55°C. The four remaining curves were measured in 0.1M K_2SO_4-0.1*N* H_2SO_4 electrolyte. Three of these were run at 0°C, the fourth, at 51.6°C. This last curve is shown by curve A in Fig. 2. Curves obtained in the *p*H 5-buffered 0.2M KCl electrolyte were parallel to curve A but displaced from it along the voltage axis because of the difference in *p*H of the two electrolytes.

The average value of the Tafel slopes in 12 sets of current-voltage curves, each preceded by a pre-anodization of at least 100 μa for 0.5 hr, was 0.106 ±0.010 (std. devn.). Five of these runs were made in the temperature range, 19.3°-21.1°C, seven in the 50°-55°C range. A Tafel curve obtained under these conditions at 51.8°C is shown by curve B in Fig. 2.

Analysis of variance (F-test) showed that with 99% confidence these two average Tafel slopes, 0.087 ±0.004 and 0.106 ±0.010, were significantly different.

Discussion

Relation of Tafel slope to pre-anodization.—The slope of 0.087, obtained without pre-anodization, agrees with the value, 0.08, reported by Lovrecek and Moslavac (1) for n-type germanium, etched with CP-4 and anodized in 0.5*N* NaOH to 1.6 ma/cm^2. Gerischer (2) reported slopes in the range 0.073-0.082 for p-type germanium, dissolved anodically in 0.01*N* NaOH/0.9*N* $NaClO_4$ and 0.1*N* NaOH/0.9*N* $NaClO_4$ over the current density range, 10-1000 μa/cm^2, presumably without pre-anodization following a CP-4 etch.

Without pre-anodization, there was some voltage instability in the current range, 1-10 μa. Brattain and Boddy (3) have commented on this voltage instability, presumably etch-derived. To counteract it, they applied pre-anodization currents of 100-200 μa/cm^2 for around 5 min, together with illumination of the n-type germanium electrodes, before taking current-voltage data. The slope of the Tafel curve for 25.5 ohm-cm,

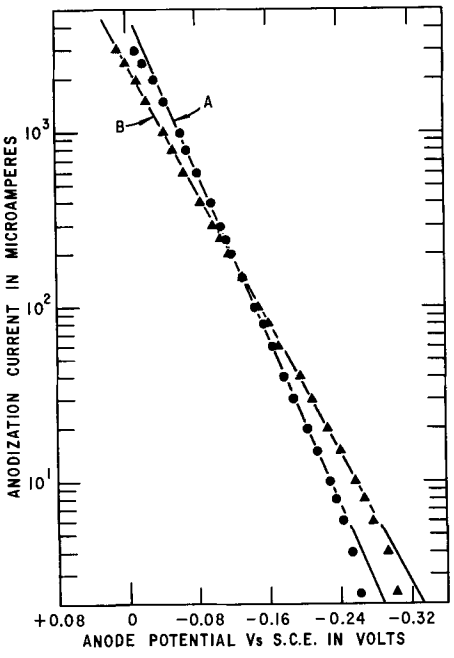

Fig. 2. Tafel curves for 6-18 ohm-cm, n-type germanium electrode, run with and without pre-anodization following etch. Electrolyte, 0.1M K_2SO_4-0.1*N* H_2SO_4; curve A (51.6°C), no pre-anodization; curve B (51.8°C), with pre-anodization.

p-type germanium, shown in Fig. 5 of their paper, is 0.11. Turner (4) cites 0.12 as the approximate Tafel slope obtained with either n-type or p-type germanium anodes in either 0.1*N* H_2SO_4 or 0.1*N* NaOH, but he does not state whether or not pre-anodization was used. Anodic dissolution data in the 1-100 $\mu a/cm^2$ range, reported by Boddy (5) for 38.65 ohm-cm, p-type germanium, polished in CP-4 and then pre-anodized at the (111) face in *p*H 7-buffered 0.1M K_2SO_4 electrolyte, show Tafel slopes of 0.10-0.11. Boddy stated that the dissolution curves for n-type electrodes were very similar.

It is felt that the two significantly different Tafel slopes measured in this work reflect two different compositions of the germanium anode surface. The surface of germanium, freshly etched with CP-4 or CP-4A, is probably covered with adsorbed HF molecules (6). Pre-anodization presumably brings about replacement of these with hydroxyl groups. The hydroxyl-saturated germanium surface is the one assumed in mechanisms proposed to explain the anodic dissolution (4, 7).

The relatively significant role of the initial surface composition in determining the anodic Tafel slope is interesting. Over the current range, 2.3-1000 μa, and under the measurement conditions used, no change of slope was observed during the course of a single run to denote a shifting of the surface composition from that characteristic of the freshly etched surface to that typical of the pre-anodized surface. This apparent retention of initial surface condition may be similar to the effect of specific anion adsorption on the kinetics of chemical (not anodic) dissolution of germanium observed by Harvey and Gatos (6). However, either prolonged anodization at relatively low currents (100 μa for 30 min) or short anodization at relatively high currents (1000-3000 μa) will suffice to change the Tafel slope from the 0.087 ±0.004 range to the 0.106 ±0.010 region. For example, the effect of the higher currents was shown by the fact that, on repeating a series of Tafel measurements without removing the sample from the electrolyte, the slope of the second curve would be that characteristic of the pre-anodized electrode.

Lack of effect of electrolyte type on anodic Tafel slope.—The Tafel slopes obtained without pre-anodization were measured in two different electrolytes, 0.2M KCl, buffered to *p*H 5.0, and 0.1M K_2SO_4-0.1*N* H_2SO_4. No measurable effect of electrolyte on slope was observed, nor did the widely differing *p*H values of the two electrolytes change the Tafel slope. This lack of effect of *p*H on slope agrees with the constant slopes reported by Beck and Gerischer (7) for electrolytes with different hydroxyl ion concentrations.

Lack of effect of temperature on anodic Tafel slope.—All Tafel slopes measured in this work were free from any observable temperature effect at the three nominal temperatures 0°, 20°, and 55°C. Young (8) has discussed the expected temperature dependence of the anodic Tafel slope. The value, $dE/d \log i$, where E is the measured anode potential and i is the anodic current should increase directly with absolute temperature. With such a temperature dependence, there should be a 20% increase in the slope of the anodic Tafel curve for germanium on going from 0°C (273°K) to 55°C (328°K). Such a change in slope would have been seen in measurements made at 0° and 55°C without pre-anodization because the standard deviation for such measurements was ±4.6%. In the case of measurements made with pre-anodization, the standard deviation of ±9.4% would still not have obscured the change in slope on going from 0° to 55°C.

Temperature independence of anodic Tafel slopes has been reported by other investigators for several metals. Vermilyea (9) has reported that the anodic Tafel slope of tantalum showed no temperature dependence at 0.5°, 19°, 40.5°, 60.5°, and 79°C. His observations were confirmed by Young (10) at 20° and 60°C and by Bray, Jacobs, and Young (11), working from 0° to 100°C. Young (12) observed a similar independence of anodic Tafel slope from 0° to 100°C for niobium. He (13) also reported that measurements by Adams, van Rysselberghe, and Willis on zirconium from 6° to 55°C gave indications of the same temperature independence of anodic Tafel slope. Dewald (14) proposed that this temperature-independent Tafel slope results from cancellation, under appropriate conditions, of the temperature effect which theory predicts by space charge in the oxide film.

However, Adams and Koo (15), working at intervals of 10°C over the temperature range —10° to 70°C, found that the measured temperature dependence of the Tafel slope for very thin anodic oxide films on niobium agreed with that predicted by the single-barrier theory of Mott and Cabrera, which assumed that no space charge is established in very thin films (<100Å). Adams and Koo pointed out that Vermilyea (9) and Young (10), who had observed no temperature dependence, had worked with oxide films ranging in thickness from several hundreds to several thousands of angstroms and that, under these conditions, it was probable that a space charge was established in the steady state.

In the work reported here, the temperature independence of the anodic Tafel slope over the temperature range 0° to 55°C indicates an oxide film thick enough for the existence of one or more factors, presumably space-charge-derived, that act to cancel the direct variation of the anodic Tafel slope with temperature. On the other hand, the solubility of the GeO_2 would tend to limit this film thickness. For example, Zwerdling and Sheff (16), who formed anodic oxide films 730-1240Å in thickness on germanium in 0.25*N* sodium acetate dissolved in glacial acetic acid, had initially failed to grow satisfactory oxide films on germanium in aqueous electrolytes because of the appreciable water solubility of the formed GeO_2.

The total charge passing through the germanium anode in a typical Tafel measurement like that shown in Fig. 2 would nominally be 784,500 μcoulomb. Assuming a 100% current efficiency, this would correspond to 850 μg GeO_2. Using a density of 4.703g GeO_2/cm^3 GeO_2 and an anodization area of 6.4-7.7 cm^2, the corresponding oxide thickness would be 2400-2800Å.

However, the solubility of GeO_2 in water at 20°C is 0.405g per 100g H_2O. Its solubility in either of the two electrolytes used in this work is not known. Judging from the experience of Zwerdling and Sheff (16) mentioned above, this solubility should be relatively high. However, it is apparently not high enough to result in the existence of a space charge-free oxide film.

The Effects of Gravity on the Electromotive Force of Thermogalvanic Cells

Minas Ensanian

Physical Chemistry Group, Bell Aerosystems Company, Buffalo, New York

What may be termed a "zero gravity effect" has been discovered on the potential of a partially frozen thermogalvanic cell under conditions approaching nearly free fall. In a series of drops in air from a 17-ft tower, iron, copper, and aluminum thermocells all exhibited an oscillation in potential of 0.4 sec maximum duration, followed by a sharp decrease in potential and a subsequent recovery prior to impact. The results indicate a possible cross-phenomenon or coupling between a gravitational field and chemical reaction of interest in the theory of coupled transport processes.

Des Coudres (1) and Tolman (2), respectively, have studied the effects of gravity and centrifugal force on the emf of galvanic cells. Des Coudres, *e.g.*, simply connected two reversible calomel electrodes by means of a rubber tube filled with 2.71*M* KCl and by variations in their respective heights obtained a value of 0.510×10^{-8} v/cm for the (potential/height) ratio.

Tolman, whose apparatus attained speeds of 80 rps, found that the cell emf varied directly with the square of the number of revolutions per second. MacInnes (3) has given a theoretical discussion of these effects.

To the author's best knowledge the literature with respect to the effects of reduced gravity on the operation of a thermogalvanic cell is nonexistent, and the general question of a "gravitational effect" on the rate of a chemical reaction, although academic, would in its most profound philosophical aspects entail Einstein's famous "clock paradox" (4-6) especially if a terrestrial observer were following the kinetics of an electrochemical process in an orbiting satellite.

Generales (7) has defined zero-gravity as that particular point, never fixed, at which two or more gravitational fields become neutralized so that we have a physical situation, mathematically supported, where there is no gravitational attraction of an object, however big or small, that would cause it to accelerate beyond the momentum originally imparted to it within the confines of the universe.

The principal effect of zero-gravity is the absence of body forces, *i.e.*, a body in zero-gravity retains its mass but does not exert any weight on its environment. The behavior of liquids in free fall has given considerable insight into the behavior of liquids in space and is now established on a theoretical and experimental basis (8-10). The problem of heat transfer in boiling liquids in a zero-gravity environment has been considered by Zuber and Kutateladze-Borishanskii (11).

In practice, a thermogalvanic cell or thermocell is the simplest battery that can be made, consisting merely of a glass tube filled with a solution of a metal salt at whose opposite ends are electrodes of the same metal but at different temperatures. In the present work, and as previously reported by the author (12), iron, copper, and aluminum thermogalvanic cells in which the electrolyte surrounding one of the electrodes was frozen by means of dry ice while the other remained at ambient temperature, were dropped in air (without the use of guide wire) from a 17-ft tower. The cells were made from 10 mm ID Pyrex tubing, 33 cm long and mounted in a vertical position in the drop capsule. The total weight of the test capsule was 5 lb and consisted of a 15 in. by 4 in. ID plastic pipe with a steel weight attached. For practical reasons no attempts were made to measure the respective electrode temperatures.

To reduce induction effects resulting from the 26-ft lead wires crossing the earth's magnetic field, the wires were given about 5 twists per inch to reduce surface area. Variations in the output potentials, which could vary between 0-500 mv, with the cells operating under equilibrium (temperature of the cold electrode constant) or nonequilibrium conditions during the free fall period (1 sec), were observed in different experiments by means of recorders, VTVM, microammeters, and potentiometers. With minor modifications a millivolt recorder with a balancing speed of 1 sec was found satisfactory.

Figure 1 represents a typical (time/potential) curve from data obtained from over 80 drops with the thermocells mentioned. There is an initial oscillation in potential lasting up to a maximum of 0.4 sec, then

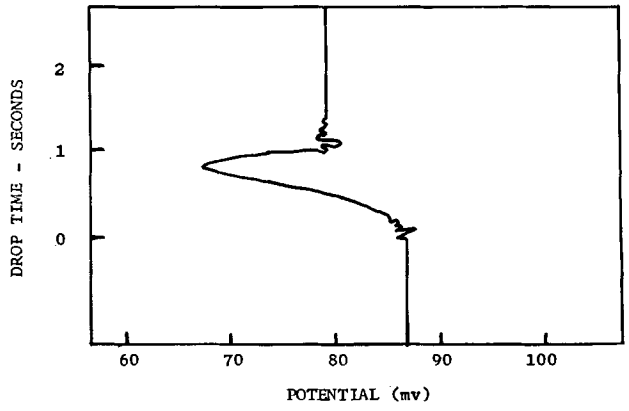

Fig. 1. A typical (time/potential) curve for a partially frozen aluminum thermogalvanic cell (0.1M sulfate solution) representative of the type of curves observed in this study. The electrodes (coiled wire 4 cm in length) were mounted in a vertical glass tube and 21 cm apart, and the upper electrode was frozen. Although these same cells frozen and dropped in a horizontal position exhibited the same general type of curve, the initial perturbations at the beginning of the postdrop period were more erratic and voltage stabilization took longer. The recorder chart speed was 24 in./min.

a sharp decrease followed by a buildup just prior to impact, whereupon voltage is soon stabilized and generally at a lower value, provided the system was not damaged.

Each experiment may be considered as having three phases, *viz.*, a predrop, drop, and postdrop period. The iron copper, and aluminum thermogalvanic cells were studied when their predrop potentials varied between their maximum and minimum value, the only criterion being, however, that the cell be hermetically sealed as a result of the frozen upper electrode, thus eliminating any possibility of spillage or bubbles.

On the average a predrop potential below 10 mv (during the freezing cycle) would diminish by 20-50% during the dropphase; however if it were above 10 mv, the decrease would range from 10-20%.

Below a 5 mv predrop potential there was no observable recovery prior to impact. In the initial phases of this work two cell geometries were considered, *viz.*, a U-tube and a straight tube (mounted in a vertical position); because of its general stability with regard to handling, the straight tube was preferred. The latter were often mounted, frozen, and tested in the horizontal position.

Although the electrolyte concentration was generally 0.1M, some tests were made with 1 and 0.01M sulfate solutions; however, the data were insufficient and comparison difficult, although there is a semblance of a more pronounced effect at the higher concentration where the predrop potentials permit a reasonable comparison.

It is a characteristic of newly constructed thermogalvanic cells to exhibit a high output potential (short lived) when no temperature differential exists between the electrodes. These may arise from differences in the elastic strain energy between the supposed identical electrodes or from local effects associated with microscopic bubbles. For nonfrozen systems when negligible current is drawn, the total voltage produced by a thermocell is approximately the product of the thermogalvanic coefficient (dE/dT) and ($T_2 - T_1$).

There are two possible explanations for the observed potential recovery just prior to impact, *viz.*, that the nearly free fall condition does not exist near the end of the drop due to air resistance, or the inability to resolve the exact impact time, since in the attempt to eliminate all electromagnetic effects which could in any way interfere with the measurements, the test capsule was released manually by means of a mechanical device. However, after numerous calibration drops in which this factor was studied, it appears that the effect is genuine.

Preliminary tests were made with hermetically sealed standard Weston cells and, although perturbations were noted during the drop phase, instrumentation difficulties do not permit any conclusions to be made at this time.

It is of interest to note (13) that a silver-cadmium cell aboard the Explorer XIV satellite for a period of 10 months, during which the g-level decreased from 5×10^{-2} to about 10^{-7}g, showed no adverse effects in the low g environment; however, this may have been due to the particular construction which limited discontinuities in the liquid phase. However, there may have been an influence on the separation of the evolved gases at the electrodes.

In the present work, in order to substantiate and isolate this observed gravity effect, numerous tests were made to ascertain role and magnitude of the following factors, *viz.*, induction effects due to the earth's magnetic field, effects due to the twisting of lead wires as well as frictional effects due to slip between metal wire and plastic insulation, effects due to stray electromagnetic radiation, effects of handling, shaking, vibration and rotation of the weighted test capsule, the role of entrapped microscopic gas bubbles and metallic thermocouple effects.

In addition to these considerations, iron, copper, and aluminum wire and plate were used to short-circuit the cell leads; with and without controlled current running through them, the drop phases were studied, and it became evident that it was possible under the experimental conditions of the reported work to resolve the effect.

It is of interest to consider the nature of the observed effect in terms of the phenomenological theory of irreversible thermodynamic processes (14) particularly with respect to cross-phenomena between the scalar gravitational potential and scalar chemical reaction.

For example, with respect to cross phenomena, ordinary stress corrosion not only reflects the principle of Le Chatelier (15), but also the coupling between two scalar transport processes, *viz.*, relaxation and chemical reaction. In a more complicated situation involving coupling between physical and chemical scalar transport processes reported by Croatto (16) where stress corrosion proceeds in the presence of a magnetic field, it was shown that the reaction rate depends jointly on the stress and the intensity of the magnetic field.

Coupling phenomenon are governed by Curie's theorem, which forbids the coupling of transport processes of different tensor rank, *i.e.*, a vectorial flow cannot be combined with a scalar force nor a scalar flow with a vectorial force. Although the flow of a scalar quantity constitutes a vector flux, nevertheless the theorem is still valid under special circumstances with respect to coupling between scalar chemical reaction and vector heat flow, provided the chemical reaction is spatially variable, *i.e.*, proceeding at different rates in different regions of space.

In a thermogalvanic cell the imposed thermal gradient gives rise to a concentration gradient (Soret effect); in a similar manner an electrical potential gradient may produce a concentration gradient and may be expressed in terms of the so-called diffusion potential (17).

In electrochemical phenomena, since mass and electric charge are carried together as a result of ion movement, the two forces may be coupled and thus may be represented by a single function, *viz.*, the electrochemical potential difference. In this same vein deBethune (18) has considered the total entropy transferred during the operation of a galvanic cell in terms of two quantities, *viz.*, the entropy of electrochemical transport and entropy associated with electrolytic migration.

The well-known Nernst and Ettinghausen effects reflect crossflow between a magnetic field and a spatially variable thermal field.

Finally, with respect to the nature of the potential decrease, several explanations may be possible since the physical system (cell) is experiencing a reduction in the force of gravity, *viz.*, a certain amount of unmixing either at the electrode/electrolyte interface or in the bulk of the solution in the absence of convective forces. One can never rule out the possibility of gas films although controlled experiments with small bubbles present in the solution displayed (time/potential) curves of a different character than that shown in Fig. 1.

If the weak assumption is made that the nearly free fall state does not give rise to changes in the thermal and concentration gradients, then the remote possibility exists that the reduction of the gravitational field has somehow reduced the collision frequency of the reactants perhaps via viscosity changes as a result of changes in liquid order in the immediate vicinity of the reacting species since there is no evidence for a remaining possibility, *i.e.*, a gravitational field effect on electron transport in the solid state.

In conclusion, aside from the necessity for additional experimental facts, a theoretical treatment of possible crossflow between a gravitational field and thermogalvanic phenomena might be resolved within the present framework of the theory of nonequilibrium thermodynamic processes.

Acknowledgment

The author wishes to thank the Engineering Laboratories and the members of the Chemistry Section for their generous cooperation and B. N. Ensanian and A. O. Ensanian for the tedious task of constructing numerous cells. He also thanks Dr. W. G. Amey and W. McAdam of the Leeds & Northrup Company for their interest and comments as well as for the loan of a recorder, and James W. Useller and D. A. Petrash of NASA-Lewis for a helpful discussion.

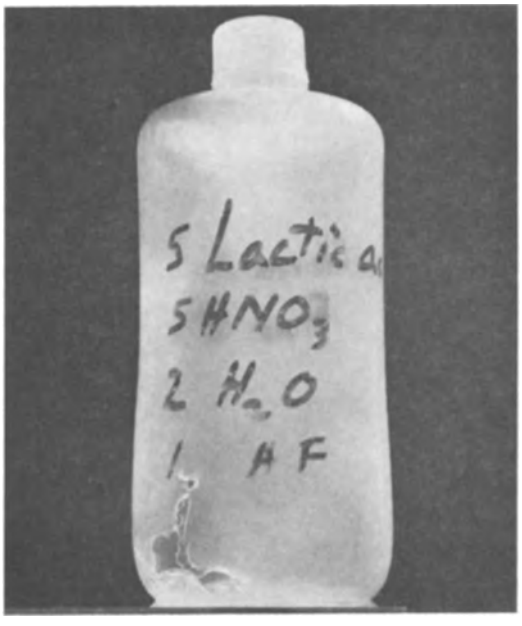
Brief Communication

Explosion of a Chemical Polishing Solution

S. F. Bubar and D. A. Vermilyea

General Electric Company, Research and Development Center, Schenectady, New York



Caution should be exercised in the use of the chemical polishing solution described by Banter in his article "Determination of the Refractive Index and Thickness of Oxide Films on Anodized Zirconium From Transmission Interference Measurements" (1). The solution in question consists of (by volume) 5 parts lactic acid, 5 parts nitric acid, 2 parts water, and 1 part hydrofluoric acid. This solution is unstable and should not be stored after mixing.

Lactic acid and nitric acid react autocatalytically, so that while there is no apparent reaction for the first few hours, there is a very rapid rise in temperature (to ~90°C) and extremely vigorous gas evolution approximately 12 hr after mixing.

In our experience, this gas evolution was sufficient to rupture the plastic container we had used because of the HF content of the solution. Fortunately in our case, the solution was stored in a fume hood and no one was standing nearby when the explosion occurred. It may be worth noting that if a sealed glass bottle had been used, a much higher pressure would have been present at rupture, possibly sufficient to blow a few more bottles of various concentrated acids off the shelf. The enclosed photo shows the container used. A similar incident was recently reported by Green (1). Other dangerous etching and polishing solutions have been mentioned (3).

Manuscript received Feb. 9, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

A Stable High-Valency Nickel Oxide

P. Bro and D. Cogley

Laboratory for Physical Science, P. R. Mallory & Co., Inc., Burlington, Massachusetts

ABSTRACT

A high-valency amorphous nickel oxide prepared by the hypochlorite oxidation of nickel nitrate exhibited a mixture of oxidation states characterized by a mean nickel valency of approximately 3.5. The high-valency amorphous oxide was stable in strongly alkaline solutions, but it decomposed rapidly below pH 9. The oxide discharged efficiently when used as a cathode in an alkaline primary cell.

The existence of high-valency amorphous nickel oxides is well established (1), but there has been some discussion regarding the nature of the excess nickel valency in such oxides. The high valency has been attributed to the presence of a tetravalent nickel ion (2) and to superficial oxygen (3). The recent magnetic studies of Labat (4) provide convincing evidence for the existence of a tetravalent nickel.

Data in the literature (5, 6) indicate that high-valency nickel oxides decompose readily, but recent work of Tuomi (7) shows that it is not necessarily so. The data given by Tuomi imply a reasonable stability of tetravalent nickel prepared electrochemically under suitable conditions.

We were interested in exploring the use of a high-valency amorphous nickel oxide as a cathode material for primary cells, but before such use could be considered, it would be necessary to establish whether the high valence state could be stabilized and whether it could be exploited faradaically. Both of these questions can be answered affirmatively, and we report here the work which led to these conclusions.

Experimental Techniques

A laboratory evaluation was conducted of the various methods for preparing high-valency nickel oxide. First among them was the anodic oxidation of mixtures of divalent nickel hydroxide and carbon with a CMC binder in concentrated base at room temperature on a nickel screen. The electrochemical method was unsatisfactory because of the poor adhesion of the oxide to the conductor and because of analytical complications due to the oxides of carbon and the presence of nickel. These considerations notwithstanding, Tuomi (7) obtained satisfactory results with the electrochemical method. Among the chemical methods, the hypochlorite oxidation was found to be most convenient and we used it. It is interesting to note that, although this method has been known for many years (8), it apparently was not recognized that it could yield a stable high-valency oxide.

Preparative procedures.—All the reagents, except the technical grade hypochlorite, were analytical grade chemicals, and the specific preparative conditions were varied as shown in Table I. The sequence of the operations was the same in all cases. The solution of nickel nitrate was added dropwise to the solution of the alkaline hypochlorite during approximately ½ hr. When the nickel oxide precipitate had settled the supernatant liquid was removed by siphoning, and the precipitate was washed twice with fresh base. The oxide was stored under base in a polyethylene container at 25.0°C.

No interferences would be expected by the nitrate shuttle discussed by Casey *et al.* (9), since no reducing agents were present. The anion effects would have to be considered in assembled cells.

The possibility was considered that the oxidative capacity of the nickel oxide might be caused, at least in part, by hypochlorite inclusions in the precipitate. Analyses of the dissolved precipitate for chloride ions showed any such inclusions to be negligible.

In order to evaluate the variability of the entire sequence of the preparative operations and the analyses, a set of three oxides were prepared separately under identical conditions similar to those used in run 4 with the results shown below:

Preparation	Oxidation state
a	3.49
b	3.50
c	3.48

It may be seen that the oxides could be prepared reproducibly with a variability of ±0.01 in the average nickel valency.

The results shown in Table I indicated that the oxidation state of the nickel did not change markedly with the preparative conditions. The values were all within the range of 3.33-3.61. Attempts to prepare higher valency oxides with an oxidation state approaching four were successful in a restricted sense. In the presence of an excess oxidant, under conditions similar to those of run 4, oxidation states between 3.95 and 4.00 were obtained. However, these high valency oxides decomposed rapidly to the lower valency compounds (*ca.* 3.5 oxidation state) as the hypochlorite concentration decreased. The hypochlorite concentration decreased due to the decomposition of hypochlorite in the presence of high-valency nickel oxide. The decomposition of the oxide and the hypo-

chlorite was accompanied by a noticeable gas evolution. The decomposition reaction between the valence states of approximately 4.0 and 3.5 was not investigated beyond these summary observations.

Chemical analyses.—The oxidation state of the nickel was obtained by iodometric titrations and concurrent polarographic analyses for nickel (Metrohm, Polarecord Model E261). Since the procedures deviated from conventional practice, they will be given in some detail. Two to ten milliliters of slurried nickel oxide in base were added to 35 ml 20% KI with stirring. The *p*H of the solution was adjusted by the slow addition of 2M H_2SO_4 to bring the solution to *p*H 3 and to hold it there for *ca.* 3 min. Then, more H_2SO_4 was added to give a solution of *p*H 1.5, and within 1 min 25 or 50 ml of the solution was transferred to a beaker containing 15 ml H_2O, 5 ml 2M H_2SO_4, and thyodene indicator. The free iodine was titrated with 0.1*N* $Na_2S_2O_3$ to a colorless end point.

The preceding steps were selected from several alternate schemes which were evaluated. The nickel oxide had to be added to an alkaline KI solution, contrary to standard iodometric practice, to avoid losses due to the escape of oxygen which occurs in acid solutions. Calibration tests showed that the results were unaffected by the initial alkalinity provided the titrations were conducted in acid solutions under conditions which prevented air oxidation of iodide. At *p*H values above 2, the nickel oxide was incompletely reduced, and at *p*H values less than 1, air oxidation became noticeable. Therefore, the titrations were done at *p*H 1.5. The iodometric calibration runs agreed with one another within 0.3%.

The nickel content of the oxide was determined by analyzing 1-5 ml of the *p*H 1.5 solution polarographically in 20 ml 1M NH_4Cl, 1M NH_4OH at 40°C. A 0.008% solution of CMC was found to be a satisfactory suppressor. The use of the elevated temperature was dictated by the suppressor requirements. The polarographic method was calibrated against a standard nickel solution prepared from the pure metal, and the calibration runs were reproducible within 0.5%. All of the analytical results reported in this paper represent average values obtained from four determinations for each set of conditions, except for the values given in Fig. 1 where single determinations were made.

Stability of the Oxide

The preparative work had established that a high-valency nickel oxide could be prepared reproducibly. Accordingly, a series of experiments was initiated to investigate the relative stability of the oxide under various conditions.

Sample No. 1, Table I, which had been prepared and stored at —5°C in 1M KOH was analyzed periodically. No change was observed in the oxidation state of the nickel; it remained at a value of 3.54 during the period of observation, 105 days. Thus, the high-valency oxide was stable at —5°C in 1M KOH. Sample No. 7, prepared at 25°C, showed no decomposition during the two days it was examined at 25°C, and sample No. 8, prepared at 40°C, showed no decomposition during the three days it was tested at 40°C. These and similar tests on the other specimens indicated that the high-valency oxides were stable at room temperature in 1M or more concentrated, strong base.

A large batch of high valency oxide, run 12, Table I, was prepared to provide a single source of specimens for a study of the effect of solution *p*H on the stability of the oxide. The oxide was prepared at 25°C and stored at the same temperature under 10^{-3}M KOH. Small portions of nickel oxide suspensions were introduced with stirring into large volumes of buffers with *p*H values down to *p*H 6.0 at 25°C, and samples were withdrawn after a period of three days for analyses. Results are shown in Fig. 1. It may be seen that the oxide had decomposed appreciably in the solutions with a *p*H less than *p*H 9 and that it was relatively stable in the high *p*H solutions. Some decomposition had occurred in the high *p*H solutions, since the nickel valency had decreased from 3.46 for the freshly prepared oxide to a value of 3.34 for the three day old sample in dilute base.

Decomposition of the Oxide

The existence of a *p*H range in which the high-valency oxide decomposed at an appreciable rate allowed measurements to be made of the influence of temperature and *p*H on the rate of the decomposition reaction. The rate measurements were made, using the procedures already described, and the time intervals between the *p*H adjustment of the suspensions and the addition of the suspensions to the iodide solutions were taken to be the reaction intervals. The nickel oxide suspensions were taken from the same master batch to insure an identical starting material for comparison purposes.

The decomposition rates of the high-valency oxide in a *p*H 6.0, 2M phosphate buffer are shown in Fig. 2 for three different temperatures between —1° and 55°C. The results are again expressed in terms of the mean oxidation state of the nickel. It may be seen that the decomposition curves exhibited an induction period at —1° and 15°C, but not at 55°C. Furthermore, the reaction rates increased markedly with the temperature.

The influence of the *p*H of the solutions on the rate of the decomposition reaction was investigated at 25°C in MacIlvaine buffers between *p*H 4.0 and *p*H 6.0. Results are shown in Fig. 3. The rate of the reaction increased markedly as the acidity of the solutions increased, and the reactions proceeded practically to the divalent nickel state. The *p*H effect was studied on a fresh batch of high-valency oxide, and the data indicated that the fresh oxide was more reactive than the aged oxide. In the *p*H 6 phosphate

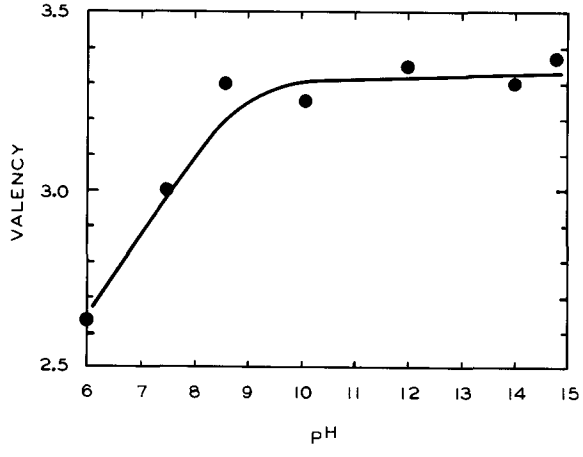

Fig. 1. The *p*H effect on the stability of high-valency nickel oxide

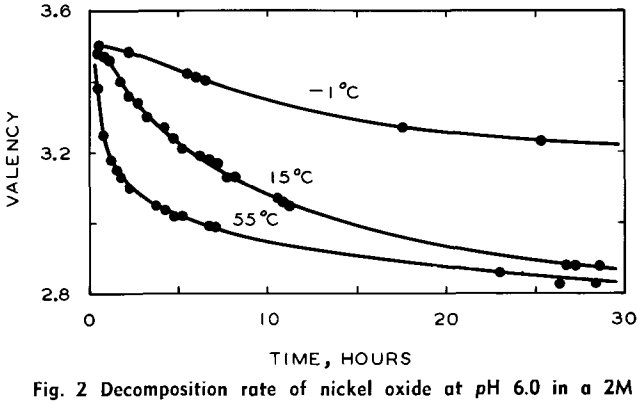

Fig. 2 Decomposition rate of nickel oxide at *p*H 6.0 in a 2M phosphate buffer, aged oxide.

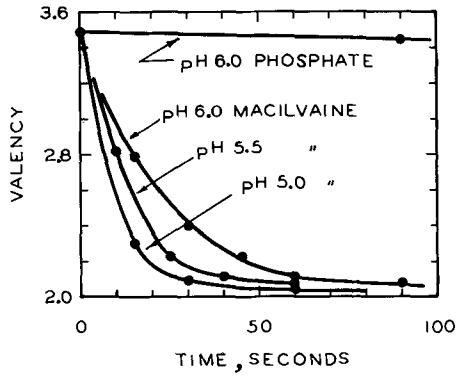

Fig. 3. Influence of pH and buffer type on the decomposition rate of nickel oxide, fresh oxide.

buffer, the valency of the fresh oxide changed by 0.78 units at 25°C during the first 3.9 hr of reaction time, whereas the valency of the aged oxide changed by only 0.53 units at 55°C during the same period, the higher temperature of the latter notwithstanding. A comparison of the pH 6 phosphate and pH 6 MacIlvaine data in Fig. 3 shows the decomposition reaction to be much faster in the MacIlvaine buffer, which indicates a specific buffer effect.

Cathodic Utilization of the Oxide

Some of the electrochemical characteristics of the high-valency oxide were evaluated by discharging the oxide in conventional primary cell configurations *vs.* zinc anodes in 40% KOH containing 6% ZnO. The desiccated oxide was blended with 5 w/o graphite and pressed into circular pellets approximately 0.25 cm thick with a diameter of 1.3 cm under a pressure of 30,000 psi. The discharge curve of such a cell is shown in Fig. 4. It had an open-circuit voltage of 1.75v, and it exhibited a fairly flat discharge curve. The cell voltage remained at an average value of 1.5v for drain rates in the range of 5-7 ma/cm^2. Polarization characteristics of the cell are shown in Fig. 5 for various discharge levels. It polarized severely at deep discharge levels for current densities in excess of 10 ma/cm^2. However, the cell was not optimized to give a good discharge behavior.

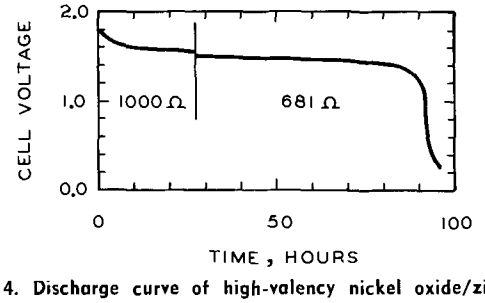

Fig. 4. Discharge curve of high-valency nickel oxide/zinc cell, two load conditions.

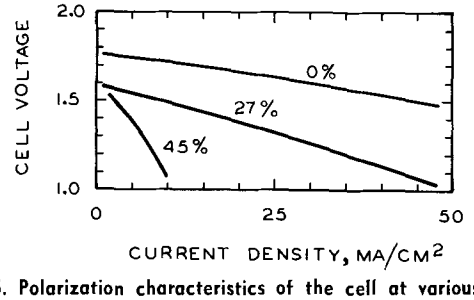

Fig. 5. Polarization characteristics of the cell at various depths of discharge.

An analysis of the discharged cathode showed that the nickel had been reduced to an oxidation state of 2.41. The failure of the cathode to discharge to a valence state of 2.0 may be attributed to an excessive polarization under the conditions of the experiment. The charge withdrawn from the cell was equivalent to a valence change of 0.91, which corresponded to an initial oxidation state of 3.32. The nickel in the wet starting material had a valency of 3.49, but experiments had shown that drying of the high-valency oxide tended to decrease its oxidation state. The dried, charged cathodes had not been analyzed.

Discussion of the Results

The high-valency nickel oxide has been described in terms of the mean oxidation state of the nickel. In an attempt to define the chemical species more precisely, we examined the x-ray diffraction patterns of the oxides in various valence states between 2.2 and 3.5 (Norelco X-Ray Diffraction Unit). In no case did we observe any lines except those due to the cellophane tape used to mount the sample, which prevented a comparison on a structural basis of our material with that of other investigators. Electron microscopic observations (Hitachi HU-11) of the oxide after it had been washed in water and ethanol failed to disclose any discrete crystals at a magnification of 30,000X. The alcohol rinse was used to prevent the introduction of any water into the electron microscope, and it was accompanied by the decomposition of the oxide to the divalent state. Distinct electron diffraction patterns were obtained of the decomposed oxide, which showed it to be a crystalline material. There is a possibility that the material may be composed of very thin crystalline flakes, less than 30Å thick and as large as 1000Å in diameter, which would be transparent to the electron beam except when viewed on edge. It would appear, therefore, that no definitive statements can be made on the basis of our data regarding the exact chemical nature and physical structure of the reaction products resulting from either the oxidation or the reduction reactions.

The highest mean oxidation state obtained in reproducible experiments was 3.6 (except as noted below), and there is a question whether or not this state represented an equilibrium composition of the oxide. It is conceivable that the solid phase contained tri- and tetravalent nickel in equilibrium proportions. However, large surface area states do not normally represent equilibrium states. They may be expected to undergo morphological changes to reduce their surface free energy. Thus, we are led to consider the oxidation product as a metastable entity, and there are no apparent reasons why a mean nickel valency of 3.6 should represent the highest attainable oxidation state for the oxide. We did obtain specimens with mean oxidation states between 3.95 and 4.00, but they could not be maintained in these high valence states unless an excess of the oxidant was present. There are reasons for believing, therefore, that higher valency oxides may be synthesized and stabilized.

No stable tri- or tetravalent nickel ions have been reported in aqueous media; the only stable aqueous nickel ion being divalent (10). It would seem, therefore, that the oxidation reaction must be a heterogeneous reaction, and two requirements must be met for the successful synthesis of very high-valency oxides: (*i*) an adequate concentration of the oxidant must be maintained at the reaction site, and (*ii*) the oxidized surface must be protected from reaction with water by the further precipitation and concomitant oxidation of nickel hydroxide on top of previously oxidized nickel. Thus, there would seem to be a need for detailed investigations of the precipitation kinetics and the morphology of nickel oxides to provide a basis for the selection of the best conditions for the synthesis of high valency nickel oxides. The observations of Okada *et al.* (11) on the

formation of amorphous divalent nickel hydroxide provide a useful basis for further studies.

The observed stability of the high-valency oxide in strongly alkaline solutions agreed with the results obtained by Tuomi (7) who found that the high-valency alpha nickel oxide could be formed readily in concentrated KOH or NaOH but not in dilute alkali solutions and with the results of Conway and Bourgault (12) on a series of oxides having a lower valency than the oxides studied by us.

An analysis of the kinetic form of our rate data was precluded by the inadequacy of the available information. In addition to the absence of an identification of the reaction species, the surface area of the oxides and the concentration of the nickelous ions in solution in the electrolyte occluded in the amorphous precipitate were unknown. The two latter quantities are experimentally inaccessible. Surface areas measured by gas adsorption techniques would be invalid because area changes take place during the dehydration of the specimens. The use of solution adsorption isotherms (13) may prove useful for these materials in the future. Insofar as the analysis of the residual valence state of the oxide is concerned, there is no chemical method available for distinguishing between the nickel in solution in the occluded electrolyte and the nickel in the solid oxide which is sufficiently rapid to be used for kinetic measurements. To the extent that it is possible to determine the true composition of the solid phase and the adjacent solution, it should be possible to obtain mechanistically meaningful data on the decomposition reaction. A detailed analysis of the reaction mechanism using the methodology of Conway and Bourgault (14) would be valuable.

The coincidence of the *p*H range of oxide instability with the *p*H range of solubility of divalent nickel in equilibrium with solid $Ni(OH)_2$ (10) suggested that the decomposition reaction proceeded *via* a dissolution step. Supporting evidence for such a conjecture comes from the observation that the MacIlvaine buffer enhanced the decomposition rate significantly. This buffer contains citrate ions, which are known to complex with divalent nickel (15). Therefore, the solubility of $Ni(OH)_2$ would be greater in citrate buffers than in pure phosphate buffers, and an enhanced decomposition rate would be expected in the citrate buffer, if the mechanism involved the reaction between a high-valency surface ion and a solution species to give a low-valency surface oxide. The transport of reagents and/or products through the divalent surface oxide would control the rate of the reaction, and the removal of the divalent oxide by means of complexation would lead to an increase in the decomposition rate.

The explanation for the differences observed in the reaction rates of fresh (fast) and aged (slow) oxides under comparable conditions must remain conjectural in the absence of a defined morphology of the oxide. An assumption which appears reasonable is that the aged oxide had rearranged to provide a smaller exposed surface area, or that the oxide had rearranged on aging to a configuration with an increased activation energy for one of the solid-state reaction steps involved in the decomposition process. It is also possible that the aged oxide had acquired a thicker surface layer of divalent oxide. However, if this were the case, an accompanying substantial decrease should have been observed in the mean nickel valency, which was not the case.

The rate curves obtained on the aged oxide in the *p*H 6 phosphate buffer at the low temperatures exhibited an initial induction period, an intermediate fast reaction period, and a final slow reaction period. This behavior is consistent with the conjecture that the oxides had acquired an inhibiting surface film. While still present, the film would prevent the decomposition reaction from proceeding very rapidly. Its dissolution would lead to an acceleration in the rate of the reaction because of the increase in the reactive surface area. As the reaction products would accumulate in the interior of the porous structures, the rates would decrease and become mass transfer controlled. The differences in the reaction rates during the intermediate reaction period at the various temperatures would, therefore, be due to the influence of the temperature on the rate of dissolution of low-valency surface oxide. The mass transfer controlled rates would be expected to be relatively insensitive to temperature, as observed. The fresh oxides did not exhibit any induction periods probably because of their larger surface areas, or because of the absence of an effective low-valency surface layer.

The cathodic behavior of the high-valency oxide showed that the high oxidation state of the chemically prepared material was available for electrochemical reduction. This agrees with observations on nickel-cadmium cells where some excess capacity can be obtained by discharging the cells immediately after charging. In the case of secondary cells, however, the excess capacity disappears in a few hours.

The open-circuit potential of the high-valency oxide-zinc primary cell corresponded to that expected for the system in concentrated KOH on the basis of the values given by Latimer (16). Since the high-valency oxide did discharge and since no significant potential arrests were observed above the trivalent nickel potential, it would appear that the high valence state did have a potential close to that of trivalent nickel. However, the assignment of an exact and a thermodynamically meaningful potential to the high-valency material must await the required definitive studies.

If the closeness of the discharge potentials of the trivalent and the higher valency oxides holds for their reversible half-cell potentials as well, the equilibrium constants of the reactions leading to the formation of trivalent and tetravalent nickel would be correspondingly close. Therefore, since the formation of trivalent oxide is thermodynamically favored, so would be the formation of tetravalent nickel. The observed, apparent limitations in the value of the mean valence state of nickel suggest that the reaction of tetravalent nickel with water is kinetically favored over that of trivalent nickel. This is in agreement with our conjecture that the synthesis of the high-valency oxide is limited by kinetic rather than thermodynamic factors. Therefore, it is to be expected that nickel oxides with valencies above 3.6 may be prepared provided the proper oxidation conditions can be established based on detailed information on the kinetics of the precipitation and decomposition reactions of the nickel oxides.

Conclusions

Investigations of the high-valency amorphous nickel oxides showed that they could be prepared reproducibly at room temperature with a mean oxidation state of 3.6 for the nickel. The oxides were stable at room temperature and at lower temperatures in strongly alkaline solutions but decomposed at *p*H values below *p*H 14. Between *p*H 9 and *p*H 14 the decomposition reaction was very slow; below *p*H 9 it became very fast.

The results indicated that the degree of oxidation of the nickel was kinetically as well as thermodynamically controlled, and it is believed that it may be possible to prepare nickel oxides with mean valencies in excess of 3.6.

Primary cell cathodes prepared from the high-valency material exhibited a good utilization of the high oxidation state of nickel.

Equilibrium Pressures of Oxygen over Oxides of Lead at Various Temperatures

Earl M. Otto

National Bureau of Standards, Washington, D. C.

ABSTRACT

PbO_2 apparently requires four stages of decomposition to reach PbO. Based on thermogravimetric studies the intermediate products appear to be $5PbO_2 \cdot 4PbO$, $4PbO_2 \cdot 5PbO$, and Pb_3O_4. Although the first three stages seem irreversible, they too come to a steady state in decomposition, but no recombination takes place. $\Delta H°$ and $\Delta S°$ values have been calculated for the four stages.

Thermal decomposition of lead dioxide has been studied by a number of investigators with the emphasis being placed on the composition and the crystal structure of the dioxide and the lower oxides that were formed. Earliest work indicated that an intermediate product of Pb_2O_3 is formed (1) (1878). Later, Moles and Vitoria (2) (1929), Renker (3) (1936), and Baroni (4) (1938) agreed that no other substance than Pb_2O_3 is formed before Pb_3O_4 appears. When the mathematical error of Baroni was corrected showing the formula of the oxide to be $PbO_{1.6}$, more investigation and speculation began. Clark and Rowan (5) (1941) refer to the oxide as Pb_5O_8. Holtermann and Laffitte (6) (1937) ascribed the formula Pb_7O_{11}. However, LeBlanc and Eberius (7) (1932) had stated that the structure of PbO_2 persists to $PbO_{1.66}$ and had ascribed the formula Pb_3O_5 to an intermediate product. They also reasoned that Pb_2O_3 is formed. A few years later Bystrom (8) (1945) and Katz (9) (1950) showed that two intermediate oxides were indicated and these were termed $\alpha\ PbO_x$ and $\beta\ PbO_y$, the former having a monoclinic crystal structure of nonstoichiometric composition where x is somewhat more than 1.5 and the latter having an orthorhombic crystal structure of nonstoichiometric composition where y is less than 1.5 and approximating 1.4. Recently Butler and Copp (10) (1956), and Anderson and Sterns (11) (1959) have confirmed the existence of two intermediate oxides, the latter authors proposing the formulas $Pb_{12}O_{19}$ and $Pb_{12}O_{17}$.

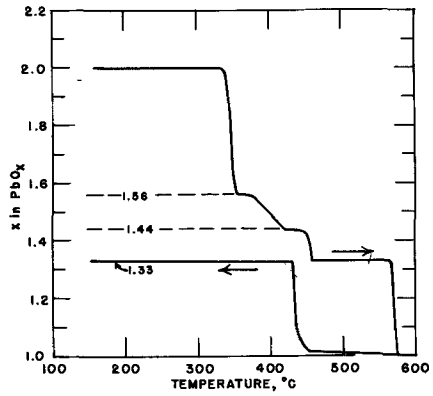

Fig. 1. Thermal balance study of the dissociation of PbO_2 to PbO and reoxidation to Pb_3O_4. Influence of temperature on the value of x in PbO_x, calculated from weight loss.

Very little study has been made of the equilibrium pressures of oxygen over the various oxides of lead. LeChatelier (12) (1897) Reinders and Hamburger (13) (1914) separately determined oxygen pressures over $PbO\text{-}Pb_3O_4$; the two sets of data did not show much agreement.

In view of the lack of pO_2-oxide temperature equilibrium data for the oxides of lead it was thought desirable to conduct the present investigation.

Experimental

Preliminary to the study of oxygen pressures over the PbO_2 and the lower oxides a thermal balance was constructed and used to get indications as to the approximate temperatures at which decompositions in air could be expected. Figure 1 shows that weight loss began before a temperature of 330° was reached and that at about 360° the weight became constant and the formula of the oxide was calculated to be approximately $PbO_{1.56}$. At 420° another level was reached, and calculations indicated the oxide to be approximately $PbO_{1.44}$. At 450° further decomposition began and continued to 460°, at which stage the oxide was $PbO_{1.33}$. (This material is the well-known "red lead," Pb_3O_4.) The final decomposition was reached at 570°, and the product was $PbO_{1.00}$. On cooling the PbO slowly in air, oxygen was consumed starting at about 450° and forming $PbO_{1.33}$. No further reoxidation was observed. The time of decomposition, from PbO_2 to PbO was seven days. This whole experiment was repeated twice, and the results were essentially the

same. Anderson and Sterns suggested that the formation of lower oxides is a result of nucleation and growth. The above mentioned values of x in PbO_x appear to indicate that nine molecules of PbO_2 are involved in the formation of each unit. Thus the products formed are postulated to be $5PbO_2 \cdot 4PbO$, $4PbO_2 \cdot 5PbO$, and $3PbO_2 \cdot 6PbO$. (The last substance may break down forming $PbO_2 \cdot 2PbO$, which is the same as Pb_3O_4.) Further evidence of a nine molecule unit is supplied by Anderson and Sterns for they say that acid leaching of one intermediate oxide gave $PbO_{1.886} \cdot 0.16H_2O$. The product in this case could be represented by $8PbO_2 \cdot PbO$.

The apparatus used for the pressure studies was similar to that previously employed by the author (14, 15) in studies of the Mn_2O_3-Mn_3O_4 and MnO_2-Mn_2O_3 equilibria. Both Fisher, and Baker and Adamson analytical grades of PbO_2 were used in the investigations. Five furnaces, four sets of manometers, and one 300-psi gauge were involved. Each furnace had its own constant temperature cabinet. Essentially the procedure consisted in heating *in vacuo* a sample of PbO_2 in a bulb contained in a crucible furnace until the evolved oxygen, having passed through the silica gel desiccant, began to change the mercury levels in the manometers. The temperature was stabilized and the pO_2 was allowed to become steady. Time for reaching a steady pressure sometimes was hundreds of hours and sometimes less than 5 hr, depending on the stage of dissociation. In one instance in the last stage the build-up in pO_2 from near vacuum to one third equilibrium pressure required less than 2 min. After a steady state was established the temperature or pressure or both were altered and a new steady state sought. After the first stage of dissociation was satisfactorily studied the investigation was extended to the second and third stages. Only one sample of PbO_2 was carried to the fourth stage because the equilibria of the last stage were so quickly attained and because commercially produced (analytical reagent grade) Pb_3O_4 could be used.

Except for the last stage of decomposition no recombination was ever observed when a somewhat higher than steady-state pressure of oxygen was provided to the partially dissociated oxides. The Pb_3O_4-PbO-O_2 reaction was readily reversible and equilibrium attainable in either direction.

The data obtained are shown in Table I and Fig. 2 to 5. The only available data from the literature are included in Fig. 4. The present data on Pb_3O_4-PbO are in good agreement with those of Reinders and Hamburger.

* Minimum time to steady state was not observed. These were the periods that were convenient to the investigator.

Treatment of Data

The straight lines shown in Fig. 2, 3, and 4, drawn for the new experimental data, form the basis for determining values for the thermodynamic functions ΔH° and ΔS°, on the assumption that steady pressures were true equilibrium pressures. The equations for the straight lines, fitted to the experimental point by sight, were put in the form of

$$\Delta H^\circ/T - \Delta S^\circ = \Delta G^\circ/T = -4.5756 \log pO_2$$

The resolved values for the four stages of dissociation are, precisely applicable only for the mean temperatures, as follows:[1]

Proposed equation	Temperature range, °C	ΔH° kcal mol^{-1} O_2	ΔS° cal deg^{-1} mol^{-1} O_2
$9/2PbO_2 \rightarrow 1/2(5PbO_2 \cdot 4PbO) + O_2$	270 ± 30	66.4	121.0
$2(5PbO_2 \cdot 4PbO) \rightarrow 2(4PbO_2 \cdot 5PbO) + O_2$	345 ± 25	44.2	70.9
$2(4PbO_2 \cdot 5PbO) \rightarrow 6Pb_3O_4 + O_2$	367 ± 17	39.9	61.4
$2Pb_3O_4 \rightarrow 6PbO$ (yellow) $+ O_2$	560 ± 80	37.5	43.2

Excepting for the Pb_3O_4-PbO stage these values cannot be converted from the experimental temperatures to 298°K, since heat capacities, heat contents, and entropy changes are unknown for the intermediate oxides and are estimated or partially known for PbO_2 and Pb_3O_4. Considering the first three stages as one, the equation becomes $3PbO_2 \rightarrow Pb_3O_4 + O_2$. Using the

[1] One thermochemical calorie = 4.1840 joules.

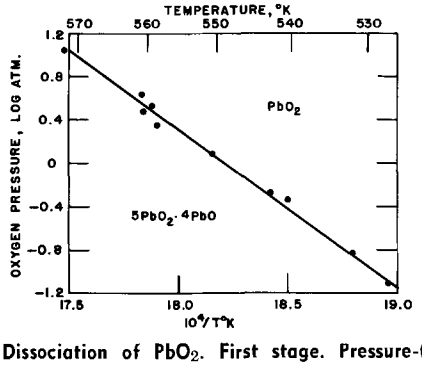

Fig. 2. Dissociation of PbO_2. First stage. Pressure-temperature relationship at steady state.

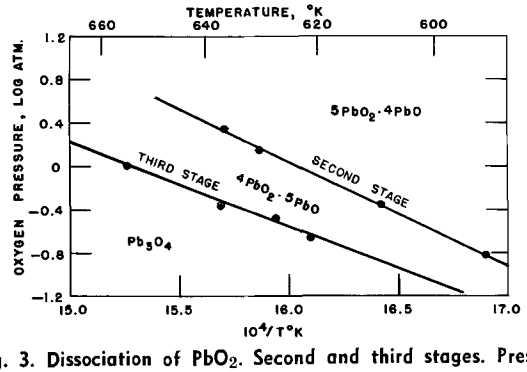

Fig. 3. Dissociation of PbO_2. Second and third stages. Pressure-temperature relationship at steady state.

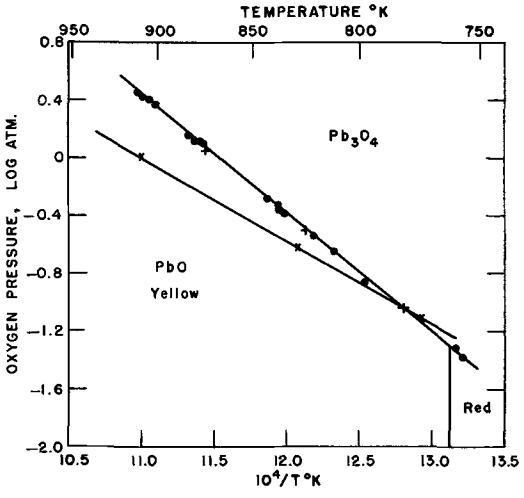

Fig. 4. Dissociation of PbO_2. Fourth stage. (Identical with first stage of dissociation of Pb_3O_4.) Half of the equilibrium points obtained in forward direction and half in the reverse. ● Present work; × LeChatelier; + Reinders and Hamburger.

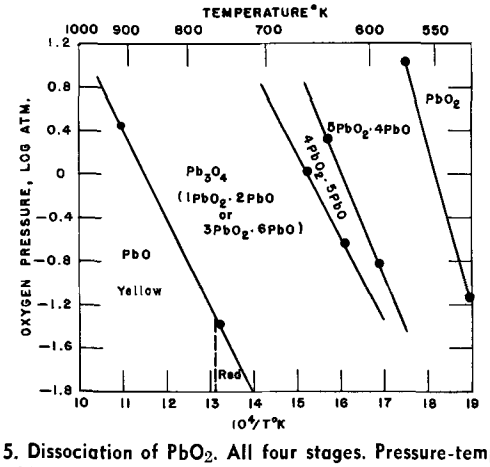

Fig. 5. Dissociation of PbO_2. All four stages. Pressure-temperature relationship at equilibrium. Dots mark the limits of experimental investigation.

Cp values given by Kelley (16) the $\Delta(H_T-H_{298})$ and $\Delta(S_T-S_{298})$ were obtained, where T = 585°K (a rough average of the temperatures of the first three reactions). These are −1.7 kcal/mol O_2 and −2.7 cal/deg, respectively. When these are added to the ΔH° and ΔS° values for the sum of the three reactions, one obtains ΔH°_{298} = 56.6 kcal and ΔS°_{298} = 100 cal/deg. From these ΔG° is calculated to be +26.8 kcal. Taking ΔG°_f of PbO_2 to be −52.0 kcal the ΔG°_f of Pb_3O_4 becomes −129.2 kcal.

The Pb_3O_4-PbO-O_2 system was readily brought to equilibrium and the Cp equation for PbO is well established. It does have to be assumed that the Cp value for Pb_3O_4 at 298°K is usable up to 1000°K. For the reaction $2Pb_3O_4 \rightarrow 6PbO + O_2$ at the mean temperature of 833°K ΔH°_{833} = 37.5 kcal/mol O_2 and ΔS°_{833} = 43.2 cal/deg.

From the Cp equations the calculated value of $\Delta(H_{833}-H_{298})$ becomes +7.1 and $\Delta(S_{833}-S_{298})$ becomes +21.1, thus making ΔH°_{298} = 44.6 kcal/mol and ΔS°_{298} = 64.3 cal/deg. From these two figures ΔG°_{298} is found to be 25.4 kcal. On the selection of ΔG°_f of PbO as −45.2 kcal ΔG°_f of Pb_3O_4 then becomes −148.3 kcal.

The resulting values for Pb_3O_4 may now be compared with those from the literature.

	$\Delta G^\circ_f Pb_3O_4$ kcal
From cell data for $Pb_3O_4 + 2HgO = 3PbO_2 + 2Hg$	
Chartier (17)	−148.4
Andrews and Brown (18)	−146.0
From cell data for $3PbO + HgO = Pb_3O_4 + Hg$	
Andrews and Brown (18)	−142.5
From present work $3PbO_2 = Pb_3O_4 + O_2$	−129.2
From present work $2Pb_3O_4 = 6PbO + O_2$	−148.3

Note: In the above considerations selected values were

$$\Delta G^\circ_f PbO_2 = -52.0 \text{ kcal and } \Delta G^\circ_f PbO = -45.2 \text{ kcal}$$

The results are surprisingly good, considering the lack of precise thermodynamic data for some of the oxides of lead and considering the fact that steady-state pressures were obtained in only one direction for the first three stages of dissociation.

Manuscript received Nov. 9, 1965; revised manuscript received Feb. 11, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Oxidation of Copper Single Crystals in Aqueous Solutions of Inorganic Salts

III. Kinetics of Oxidation in $Cu(OAc)_2$ Solution

W. W. Porterfield and G. T. Miller, Jr.[1]

Department of Chemistry, Hampden-Sydney College, Hampden-Sydney, Virginia

ABSTRACT

The kinetics of formation of Cu_2O on the three principal (low-index) faces of Cu metal monocrystals are reported and correlated with the surface microtopography. A novel technique is described for the determination of surface areas of small metal samples. Over extended periods of time the relative rates of oxide formation are found to be: (100)>(111)>(110); the forms of the rate curves, however, differ markedly. The specific forms of the rate curves on the three faces are accounted for by a proposed mechanism in which the rate-controlling step is the drift velocity of positive holes through the Cu_2O film. This mechanism also correctly indicates the microtopography on the basis of the previously observed epitaxial relationships.

This is the third in a series of papers describing the oxidation of copper metal in solutions of copper(II) salts. The first two papers (1, 2) dealt with the topography of the copper(I) oxide film formed in such oxidations and are indispensable to an understanding of the data reported here. The present work attempts to describe the kinetics of the oxide growth and to begin, at least, the inference of a mechanism for the oxidation process.

Benard (3) has an excellent summary, with critical comments, of experimental techniques for the determination of oxide film thickness on metal surfaces. Of the methods he describes, the coulometric was chosen because of its experimental simplicity. This method is well established (4-8) but requires some comment in two respects. First, even though the electropolishing technique enables the worker to assume that the metal surface area is equal to the gross area of the specimen, the measurement of area continues to be a problem with this method; in this case, the problem was accentuated by the small areas available when using monocrystalline specimens. A procedure was devised, which is described below, that enabled the measurement of surface areas within an error of 1%; in this work the error was on the order of 0.1 mm^2. It is felt that this may be of use to other workers using coulometric techniques on small specimens. Second, as Evans (9) has made clear, the phenomenon of metal corrosion is, to a substantial extent, inherently irreproducible. It is therefore necessary to indicate clearly the extent to which irreproducibility affects conclusions to be drawn from irreproducible data. Unfortunately, many previous workers have not made such an indication. It should be noted, then, that the error bars shown in Fig. 2, 3, and 4 represent 2σ, the standard deviation for measurements displaying Gaussian scatter about an unknown true value.

The previous studies, in parts I and II of this series, of the topography of oxide films as a function of the anion and as a function of time show clearly that in this system, as in others, there is a marked difference in the behavior of the three principal crystal faces. It seemed likely, then, that the coulometric study of oxide formation, performed on individual crystal faces and interpreted in conjunction with the known variations of topography with time, would yield important evidence bearing on the mechanism of the oxide growth. This appears to be true, although much further experimentation will be required to conclusively demonstrate a detailed mechanism.

Experimental

99.999% copper monocrystals were used throughout this series of experiments (Virginia Institute for Scientific Research, Richmond, Virginia). Flats were cut on these crystals to expose the (100), (110), and (111) faces individually. The orientation of these faces was maintained within 2° [1° for the (100) face] by Laue back-reflection x-ray photography after every fourth mechanical polishing [every second mechanical polishing for the (100) face]. The crystals were mechanically polished through 4/0 Buehler paper, then electropolished in an unstirred phosphoric acid bath and washed, finally, in water of approximately 1.2 x 10^6 ohms resistivity. The flats were dried in a stream of Seaford grade nitrogen (Southern Oxygen Company, Washington, D.C.; maximum impurity limits 30 ppm total) before immersion in the corroding solution. The only solutions used in this study were 0.0500*N* $Cu(C_2H_3O_2)_2$, made up from Fisher copper(II) acetate dihydrate, used as received from lot number 731759. Oxidation patterns from this lot were found to remain unchanged upon repeated recrystallization, whereas other lot numbers gave patterns which only approached that from this lot after two or three recrystallizations. Solutions were adjusted to a *pH* of 4.300 ± 0.005 before each oxidation. All solutions were thermostatted at 30.0°C before and during the corrosion process, since a study of the effect of temperature on the corrosion process, to be undertaken shortly, is expected to reveal marked temperature dependence. After oxidation for stipulated times, each crystal was dried and the spherical sides of the crystal, together with the edges of the flat face, were masked by painting with the electrically insulating lacquer Miccrostop (Michigan Chrome and Chemical Company, Detroit, Michigan). Coulometric measurement of the oxide on the area remaining was made in the apparatus shown in Fig. 1, after appropriate deaeration. The electrical potential of the crystal against an Ag/AgCl electrode was recorded on a Bausch and Lomb VOM-5 recorder. The exposed area of the flat was calculated by stripping the masking lacquer from the crystal, photographing the flat by using a Polaroid film pack at 6X on a Reichert metallurgical microscope, and measuring the photographed area with a planimeter. Equivalent copper(I) oxide film thickness could then be calculated on the assumptions that: (*i*) film density was equal to that of the bulk oxide; (*ii*) current efficiency was 1.000; and (*iii*) the oxide formed a film of uniform thickness. A discussion of the influence of departures from these assumptions upon reproducibility follows below; here it might be noted that the error bars in Fig. 2, 3, and 4 are roughly between 5 and 10% of the indicated mean.

With respect to the first assumption, lattice parameter measurements for films on the major faces of copper [(10) and references therein] indicate a linear expansion of 1-2% normal to the surface, but an offsetting compression in the surface plane. The unit cell volume is that of the bulk oxide, and the density

[1] Present address: Department of Chemistry, St. Andrews Presbyterian College, Laurinburg, North Carolina.

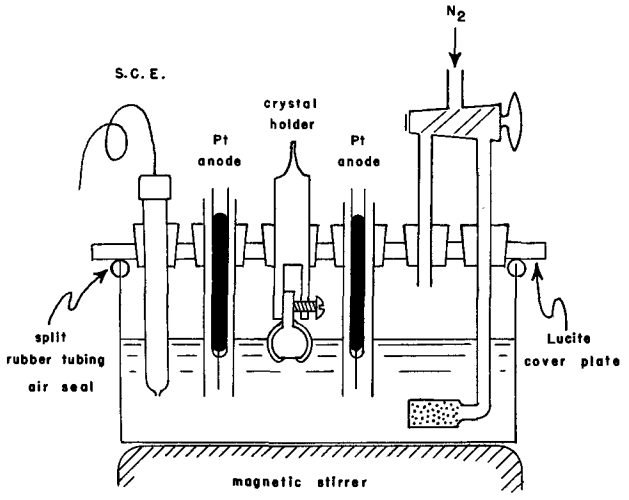

Fig. 1. Apparatus for coulometric oxide determination. Crystal holder is shown with a masked crystal in place.

will thus be unaffected. The validity of the second assumption is more difficult to establish. Studies comparing oxygen uptake (in gaseous oxidation) with coulometric values suggest an efficiency of at least 0.90 (11), and studies of current efficiency as a function of current density (micro-amperes/cm^2) for the Fe-Fe_3O_4-Fe_2O_3 system (7) suggest the same approximate figure under our experimental conditions. Of course, this is not a comparable system, but the order of magnitude of current density is perhaps suggestive. In any event, only the absolute determination of deposited oxide mass would suffer from this type of error; the rate curves would retain their general form and relative magnitudes. However, substantial scatter could arise from this source. Finally, the assumption of a uniform oxide film requires severe qualification. The rather rugged microtopography revealed in the electron micrographs (1, 2) indicates that interpretation of the coulometric data as thicknesses of oxide films is illusory. Clearly, the only appropriate interpretation is that of a gross average, that is, deposited oxide mass per unit area. This figure is used in each case.

Results and Discussion

Figures 2, 3, and 4 show the oxide growth rates on the three low-index faces of copper metal crystals, as determined in this study. Figure 5 indicates the marked differences between the faces. In Fig. 2, 3, and 4 the notation is as follows: (*i*) The error bars, as previously stated, are 2σ long. (*ii*) The arithmetic mean of all determinations is indicated by a crossbar. It must be remembered, however, that the arithmetic mean is the most probable value only for a Gaussian error distribution. It is not certain that this is the true distribution in corrosion measurements. (*iii*) The mode

is indicated by a heavy dot. Evans (9) has suggested that, given the irreproducible nature of the measurements, the mode may be the most significant quantity. (*iv*) The number of measurements at a given time of immersion is indicated over the error bar. (*v*) To provide a more meaningful interpretation, the right-hand scale in these figures is given as deposited copper(I) oxide mass per unit area (micrograms per square centimeter). However, the convenient comparison of this work with other film-thickness studies requires that the data also be presented as equivalent average thickness in Angstrom units. It must be remembered that these thicknesses are rather fictional; that both vertical and lateral growth are occurring, and to different extents on different crystal faces of the metal.

It was anticipated from preliminary experiments that the oxide growth would be quite rapid; Fig. 2, 3, and 4 confirm this. Indeed, the growth on all three faces is so fast that it does not seem possible for the

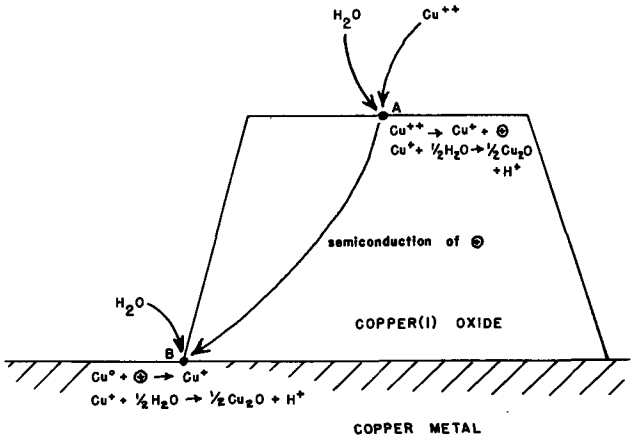

Fig. 6. Schematic representation of proposed mechanism

rate-determining step to be the diffusion of copper atoms through the oxide film, which is almost immeasurably slow at 30°C, the temperature of the reaction. Thus it seems likely that a significant amount of Cu(I) in the oxide film must originate from the Cu(II) in solution. Furthermore, if atomic (or ionic) diffusion is ruled out, any Cu(I) in the oxide originating from the metal must be obtained from a location where the oxide is either quite thin or nonexistent.

Figure 6 diagrammatically indicates a mechanism which appears to satisfy these requirements. Copper(II) ions from solution are adsorbed onto existing copper(I) oxide nuclei which are in contact with bulk copper metal. This adsorption may be assumed to occur preferentially on the close-packed faces of the oxide (not necessarily on the close-packed faces of the metal). After adsorption each ion donates a positive charge to the copper(I) oxide, becoming a Cu(I) ion. This ion may react immediately with the solution's oxygen-supplying species (at point A) or may migrate some distance across the surface of the Cu_2O polyhedron before reacting to form additional Cu_2O. The mean migration distance will be governed by the ratio of the migration velocity to the rate of reaction with the oxygen-supplying species in solution. The copper(I) oxide, functioning as a p-type semiconductor, conducts the positive hole to a point at which the three phases Cu_2O, Cu°, and solution are all present (such as point B in Fig. 6). Here a copper atom acquires the positive charge, becoming a copper(I) ion, and reacts with the solution to form more Cu_2O. The same migration considerations apply at point B as at point A. The mechanism may be summarized as follows:

(*i*) diffusion of Cu(II) species and adsorption on the oxide surface

(*ii*) $Cu^{2+} \rightarrow Cu^+ + \oplus$ (cathodic reaction at A)
(*iii*) $Cu^+ + \frac{1}{2}H_2O \rightarrow \frac{1}{2}\underline{Cu_2O} + H^+$
(*iv*) movement of $\oplus$ from A to B
(*v*) $\oplus + Cu^\circ \rightarrow Cu^+$ (anodic reaction at B)
(*vi*) $Cu^+ + \frac{1}{2}H_2O \rightarrow \frac{1}{2}\underline{Cu_2O} + H^+$

The net cathodic and anodic processes are, respectively the sum of (*ii*), (*iii*) and (*v*), (*vi*):

$$Cu^{2+} + \tfrac{1}{2}H_2O \rightarrow \tfrac{1}{2}\underline{Cu_2O} + H^+ + \oplus \qquad (E_c)$$

$$Cu^\circ + \tfrac{1}{2}H_2O + \oplus \rightarrow \tfrac{1}{2}\underline{Cu_2O} + H^+ \qquad (E_a)$$

$$Cu^{2+} + Cu^\circ + H_2O \rightarrow \underline{Cu_2O} + 2H^+ \qquad (E_{net})$$

It must be noted that steps (*v*) and (*vi*) of such a mechanism require that the oxidizing solution be in contact with the oxide-metal interface for growth to occur, since the solution must provide the oxygen for the lattice, otherwise the oxide cannot continue to remove positive holes from its surface. The crevices visible in the earlier electron micrographs (1) would appear to provide just such a solution contact. Possible sources of oxygen would be free H_2O, the aquo complex of Cu(II), CH_3COO^-, or dissolved O_2. (H_2O is used as an example in the equations above.) Exploratory experiments using BF_4^- anion and dissolved O_2 removal indicate that probably neither the anion nor dissolved O_2 provides the oxygen.

In examining the rate curves it will be shown below that the adequacy of the proposed mechanism depends on the assumption that adsorption of the copper(II) species on the Cu_2O surface occurs preferentially on the most closely packed surface of the oxide. This is intuitively reasonable but by no means necessary. It may be that another mechanism could be devised which would not require this feature, but its nature is not immediately obvious.

The forms of the three rate curves (Fig. 2, 3, and 4) must be examined separately with respect to the proposed mechanism because of their strikingly different natures (Fig. 5).

Oxide growth on the (100) face occurs by an apparently uniform mechanism over an extended period of time (Fig. 2). It might be noted in passing that on the logarithmic scale employed here the age of the universe would not fill a double-page spread of this Journal! The mathematical form of the growth law, as determined from the inverse slope of the log-log plot, is very roughly parabolic (exponent 1.86). The parabolic law might be expected if the positive hole draft velocity were the rate-determining step: $d(Th)/dt = K\mu$, where Th represents oxide thickness and μ the drift velocity. Drift velocity is proportional to electric field strength, which in this case is decreasing with increasing thickness, so that

$$\mu = K'/Th$$

Then

$$d(Th)/dt = KK'/Th, \text{ and } (Th)^2 = K''t$$

The steady growth is also consistent with the topography of the oxide on the (100) face (polyhedra), since the crevices between the polyhedra would permit the necessary uninterrupted solution contact with the metal-oxide interface.

The (110) face is quite different. Oxide grows on it somewhat faster than on the (100) face initially (exponent 1.57), but only for the first three or four minutes. Growth then stops almost completely. Some justification for this may be found in the electron micrographs of the (110) face, which reveal an unusually smooth oxide film (1). Apparently lateral growth fills the crevices between oxide nuclei in this orientation, thereby preventing solution contact with the oxide-metal interface and providing effective protection for the metal. The very slow growth which continues to occur may be due to a few unfilled crevices or to positive hole conduction to exposed oxide-metal interfaces on adjacent faces of different orientation. It is interesting to observe that the initial growth on this face is faster than that on the (100) face; one would not expect this either from metal-atom packing considerations or by analogy with the high-temperature dry oxidation of copper (12).

Upon consideration of the probable modes of deposition of the copper(II) ions, however, the relative rates may be rationalized. The epitaxial relationships displayed in this system are as follows (13): the (100) copper face requires the growth of the (111) Cu_2O face parallel to it; the (110) metal face, the (110) oxide face; the (111) metal face, the (111) oxide face. Then, following the assumption of preferential adsorption on the close-packed face, the (100) and (111) metal faces will both tend to adsorb copper(II) ions on the top of the nuclei, thereby producing the vertical growth governed by the parabolic law; but the (110) metal face, having the thermodynamically more stable (close-packed) (111) faces on the slant sides of the nuclei, will tend to adsorb on the sides. In this case the growth will be predominantly lateral, with

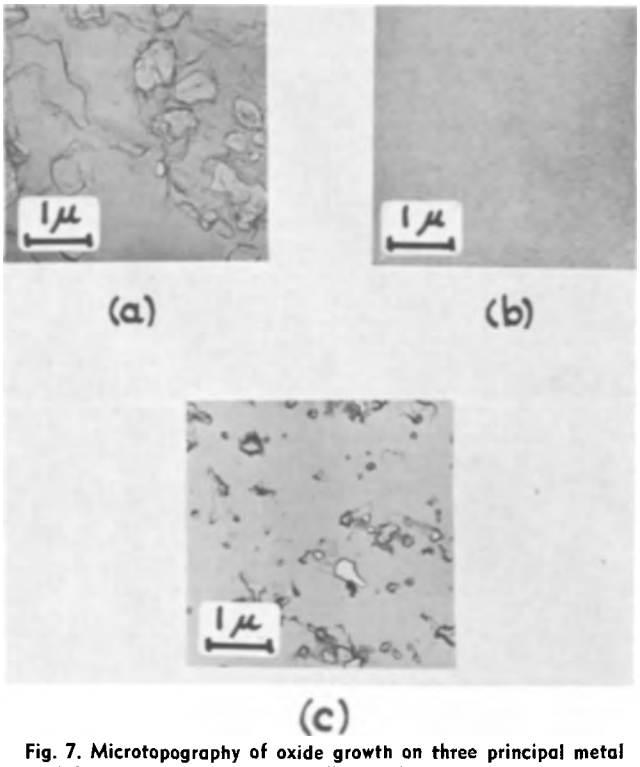

Fig. 7. Microtopography of oxide growth on three principal metal crystal faces after 72 hr (2.6 x 10^5 sec). (a) (100); (b) (110); (c) (111).

the vertical thickness changing only rather slowly. The drift velocity, μ, will be essentially constant, and the oxide growth will occur by a linear law. To the extent, then, that lateral growth predominates over vertical growth, the exponent in the growth law will be reduced from 2 toward 1. The faster growth on the (110) face, characterized by the lower exponent, is thus consistent with the orientation of close-packed faces produced by epitaxy, as is the almost complete cessation of growth after complete coverage has been achieved. The slight lowering of the exponent for the (100) face (from the hypothetical 2.00 to the observed 1.86) is perhaps also due to appreciable lateral growth.

Growth of oxide on the (111) face is also, initially, approximately parabolic (exponent 1.99). After five to ten minutes, however, a slackening of rate occurs like that on the (110) face. The electron micrographs at this time (1) corroborate this, since the surface appears to be reasonably uniformly covered, with few crevices to allow solution access to the positive hole sink. The rate soon increases again to approximately the parabolic value, and after quite a long time increases to nearly a linear rate (exponent 1.0). The increase appears to be due to etching of the oxide film, which would provide renewed solution access to the metal.

Etching is indicated by the electron micrographs shown in Fig. 7 for the three faces after 72 hr. These electron micrographs were obtained as part of the series described in part I (1). The conditions of polishing, washing, and microscopy are described therein. Note that the etching appears to be more pronounced on the (100) and (111) faces than on the more or less permanently protected (110) face. Photomicrographs (a) and (c) of Fig. 7 indicate that etching probably occurs to roughly the same extent for the oxide on the 100 and 111 metal faces. However, the patterns of etching are not at all similar and it is difficult to compare the two faces' kinetic behavior on this basis. Close examination of Fig. 2 suggests that there may be a slackening of oxidation rate (around 10^4 sec) like that seen clearly in Fig. 4, but the reproducibility of the data is simply inadequate to allow a confident interpretation in this way. After a crevice had opened by etching it would presumably remain open, since further nucleation on the bare metal could not occur due to the surface tension differential between a new nucleus and the large polyhedra.

A consideration of etching brings up the question of the importance of the effect of *p*H on the growth process proposed in the mechanism outlined above, which produces H^+ at localized sites. Although the bulk *p*H remained essentially constant during each experiment, local *p*H changes could profoundly affect the topography. Careful observations of the *p*H changes during the reaction and its *p*H dependence are presently being made and will be reported on in a subsequent part of this series.

The present measurements provide only a possible interpretation of the growth laws and topography of the principal faces; the proposed mechanism assumes existing nuclei and does not suggest any features of the nucleation process. Preliminary results from the *p*H study which is underway indicate that the nucleation is quite sensitive to small *p*H changes. Other studies are contemplated which might yield more information on nucleation and confirm or reject the proposed growth mechanism. It must also be pointed out that this study does not account for the persistence of well-defined oxide polyhedra on the (100) face and their merging on the other two faces (1). It is felt that this is a feature more of the nucleation process than of the growth process, and may be due to the symmetry mismatching in epitaxy.

Acknowledgments

The authors are deeply indebted to Dr. K. R. Lawless of the Department of Materials Science of the University of Virginia for the generous use of specialized equipment, and to Dr. Lawless and Dr. J. W. Mitchell of the Department of Physics of the University of Virginia for helpful discussions. Effect of Plastic Deformation on the Anodic Dissolution of Iron in Acids

Z. A. Foroulis

Esso Research and Engineering Company, Florham Park, New Jersey

ABSTRACT

The effect of plastic deformation, introduced by cold-rolling, on the anodic dissolution of iron was investigated using short-time galvanostatic transients in deaerated HCl, H_2SO_4, and $HClO_4$ at 25°C. Cold-rolling was found to have no effect on the anodic Tafel polarization parameters of iron. Anodic Tafel lines in 1*N* HCl have slopes of about 60 mv; the slope is reduced at higher polarizing potentials. For 1*N* H_2SO_4 and 1*N* $HClO_4$ the slopes were about 40 mv and 35 mv, respectively. The results indicate that the dissolution kinetics of iron is controlled by charge transfer, and any effect on the kinetics of iron dissolution, due to surface topography, is not observed. The variation of the anodic Tafel polarization parameters with the nature of the acid anion is explained by specific adsorption of anions on the iron surface in competition with OH^-. The decrease in polarization of iron in HCl solutions at higher polarizing currents ($i > 10^{-2}$ amp cm^{-2}) indicates that adsorbed Cl^- may directly participate in the dissolution process depending on the potential region of polarization.

The published work relating to the influence of mechanical stress on the electrode behavior of metals in aqueous media is contradictory. It is well established that stresses within the elastic range change the potential reversibly by less than 1 mv (1, 2). It is in the range of plastic deformation and its effect on the anodic polarization and corrosion that many investigators have reported conflicting results and interpretations (3-10). It is clear, then, that this problem should be reexamined. This paper reports the results of a laboratory study on the effect of cold-rolling on the anodic polarization behavior of iron in acidic environments, using short-time galvanostatic transients.

Experimental

The cell used for electrochemical measurements consists basically of three compartments; the inner two compartments each approximately 100 ml in volume are removable and fitted through ground glass joints to the center compartment; these compartments contain one auxiliary platinum electrode each and could be deaerated in the same manner as the large center compartment. Electrical communication is achieved by means of fine glass fritted discs. The test electrode was introduced through the center compartment by means of two eccentric joints so that the distance between the test electrode and the top of the Luggin capillary could be adjusted. The tip of the Luggin capillary, about 1 mm OD, was placed about 1 to 2 mm from the electrode, so that screening effects and IR corrections were negligible (11). Additional features of the cell include a capillary stopcock for withdrawing known quantities of solution for analysis, a hydrogen bypass arrangement, and a salt bridge with a Luggin capillary filled with same solution as the cell. Greaseless ground glass joints were used to avoid possible contamination from lubricant.

The electrodes about 2-3 cm^2 total exposed area were cut from remelted (in a helium atmosphere) electrolytic iron castings. The analysis of the iron was 0.009%C, 0.003% N, < 0.003% S, < 0.004% O, < 0.001% Cu, < 0.001% Ni. The castings were cold-rolled in the direction of the long axis by successive passes to a final reduction in thicknesses 20, 40, 50, 60, and 70%. After cold-rolling the specimens were aged at R.T. for about two years. Before cold-rolling, the castings were homogenized in a purified helium atmosphere at 1050°C for about 48 hr. All the reported results were obtained with electrodes made from the above remelted electrolytic iron. The electrode assembly was similar to the one described earlier (12). Surfaces were abraded through 4-0 emery paper, pickled in same solution as the test solution to remove effects of abrading, rinsed thoroughly in double distilled water, and immediately placed in the solution.

Solutions were prepared using reagent grade acids and double distilled water, one distillation of the latter being carried out in dilute alkaline potassium permanganate. The following test solutions were used, 1*N* HCl, 1*N* H_2SO_4, and 1*N* $HClO_4$. Solutions were deaerated by bubbling prepurified hydrogen through the solution for at least 24 hr prior to a run and over the solution during the run. Additional purification of the high-purity commercial hydrogen was done by passing it successively through copper turnings heated at 500°C, ruthenium catalyst at 350°C, and palladium catalyst at R. T. The solutions were preelectrolyzed between platinum electrodes for about 24 hr at about 1.5 ma. Preelectrolyses were carried out at a potential below that corresponding to appreciable evolution of H_2 to avoid significant change of *p*H in the solution. Potentials were measured against a SCE using a vacuum tube millivoltmeter (high impedance). Constant current was obtained through an appropriate assembly of decay resistance units from a high d-c voltage source ($R_{ext} >> R_{cell}$). Figure 1 shows

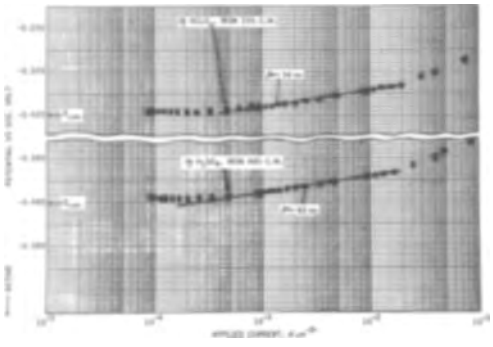

Fig. 2. Anodic polarization of iron in acids (H_2 sat'd), 25°C

the experimental arrangement which is similar to the one reported earlier (13).

In making a run, each electrode was immersed in solution and after a stable corrosion potential was measured, solution samples were withdrawn for Fe^{++} analysis, and immediately after that anodic polarizations were conducted by applying short-time galvanostatic transients. The electrode was subjected to a series of short-time anodic pulses (from 10 to 15 sec in duration) at various increasing current densities. In a few instances, the potential/time transients were recorded photographically on the oscilloscope screen and enlarged several times. The polarization curves were established by plotting the steady-state potential *vs.* the applied current density. Similar polarization curves were established at various decreasing current densities.

Results

The time of sweep for the anodic galvanostatic transients was determined by the time necessary to reach steady-state and was about 10-15 sec. The analysis of galvanostatic transients and their advantages for polarization studies were discussed earlier in the literature (13-15). The applied current density range was about 5×10^{-5} to 1×10^{-1} amp cm^{-2}.

In H_2SO_4 and $HClO_4$ solutions after each pulse the electrode potential returned to the steady-state corrosion potential usually within a few seconds so that further pulses were applied almost continuously ("continuous" polarization). The polarization curves traced with increasing and decreasing current density coincide (Fig. 2). In this figure are shown anodic polarization curves for iron in deaerated sulfuric and perchloric acids. The upper curve is for iron (cold-rolled to 20% reduction in thickness) in 1*N* $HClO_4$. The lower curve is for iron (cold-rolled to 40% reduction in thickness) in 1*N* H_2SO_4.

In the HCl solutions a much longer time of recovery was necessary after each pulse before the electrode potential returned to the steady-state corrosion potential so that further pulses were applied only after sufficient time had elapsed for the electrode potential to return to the steady-state corrosion potential ("interrupted" polarization). When "continuous" polarization was applied in HCl solutions, hysteresis was observed between the ascending and the descending polarization curves (lower curve in Fig. 3). In Fig. 3 are shown anodic polarization curves of iron (cold-rolled to 20% reduction in thickness) in 1*N* HCl. The upper curve was determined by interrupted polarization. The lower curve was determined by continuous polarization, and a hysteresis was observed between the ascending and descending polarization curves.

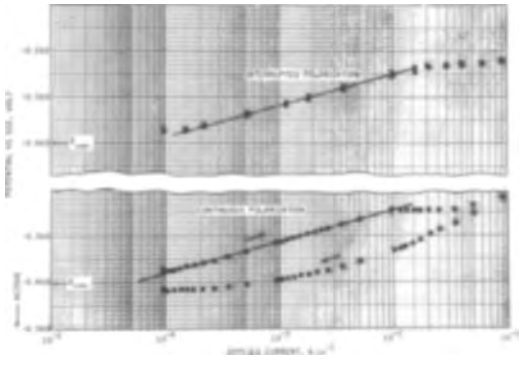

Fig. 3. Anodic polarization of iron, 20% C.W., in 1*N* HCl (H_2 sat'd), 25°C.

Cold-rolling was found to have no effect on the anodic Tafel polarization parameters of iron. The anodic Tafel lines in 1*N* HCl have slopes β_{Fe} of about 60 ± 8 mv at c.d. 10^{-4} to 10^{-2} amp cm^{-2}, and are the same for both the annealed and cold-rolled iron as shown in Fig. 4. Tafel slopes in HCl solutions were determined from the ascending polarization curves established by continuous polarization. Interrupted polarization gave identical Tafel slopes.

Figure 5 shows the dependence of the anodic Tafel slopes at c.d. 6×10^{-4} to 2×10^{-2} amp cm^{-2} for iron dissolution on the degree of cold-rolling for H_2SO_4, $HClO_4$ acids. A slope of about 40 ± 10 mv was found for 1*N* H_2SO_4 and about 35 ± 8 mv for 1*N* $HClO_4$. In both acids the slopes were the same for the annealed as well as the cold-rolled specimens.

At current densities higher than 10^{-2} amp cm^{-2}, the Tafel slope in HCl is reduced to about 40 mv or lower, but the reproducibility of the slope in this region of polarization was poor and in many runs a slope of zero was observed. As can be seen from Fig. 3 in HCl, iron does not polarize significantly at anodic current higher than 10^{-2} amp cm^{-2}. In $HClO_4$ and H_2SO_4, at c.d. 2×10^{-2} to 10^{-1} amp cm^{-2} or higher, polarization of iron deviates from the Tafel line and increases appreciably. This deviation is probably due to IR contribution and in particular to concentration polarization due to diffusion limited mass transport

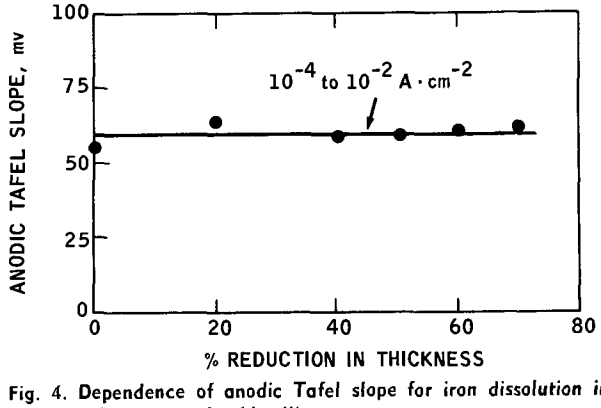

Fig. 4. Dependence of anodic Tafel slope for iron dissolution in 1*N* HCl on the degree of cold-rolling.

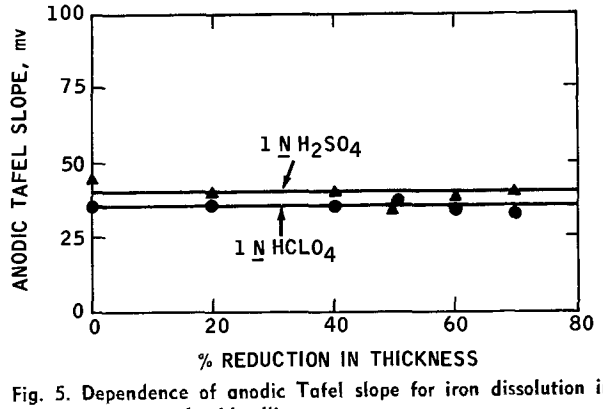

Fig. 5. Dependence of anodic Tafel slope for iron dissolution in acids on the degree of cold-rolling.

of OH^- at the iron surface sites. It is, therefore, rather apparent that the significant decrease in polarizability of iron in HCl at c.d. higher than 10^{-2} amp cm^{-2} is associated with chloride ions which directly participate in the dissolution process by adsorption and eventual complex formation with the iron surface atoms.

Exchange current densities for the anodic dissolution of iron ($i_{o,Fe}$) were determined by extrapolation of the Tafel lines to the reversible potential of iron in each solution tested. The concentration of Fe^{++} in each solution was determined by colorimetric analysis prior to each polarization using the orthophenanthroline colorimetric method (16). Reversible potentials were calculated using the Nernst equation and the activity of Fe^{++} in solution. Activity coefficients were calculated from the Debye-Hückel theory using equation (17)

$$\log f = -\frac{0.358\, Z^2\, \Gamma^{1/2}}{1 + 10^8\, \alpha\, 0.2325\, \Gamma^{1/2}} \qquad [1]$$

where f is the rational activity coefficient for Fe^{2+}, α is the effective diameter of the hydrated Fe^{2+} ($\alpha = 6 \times 10^{-8}$ cm), Z is the charge on each Fe^{2+} in solution, and $\Gamma = 2\, I(m)$ where $I(m) = \sum_i m_i Z^2_i$ is the ionic strength of the solution taking into consideration all the ionic components of the solution. The activity coefficients were calculated because of the lack of experimental data on activity coefficients of Fe^{2+} in HCl solutions. The error in $i_{o,Fe}$ introduced by calculating the activity coefficients by use of Eq. [1] is small in comparison with that produced by small errors in the experimentally determined Tafel slopes.

As can be seen from Table I, for any particular acid solution the $i_{o,Fe}$ was found to be independent of the degree of cold-rolling. However, it varied substantially with the nature of the acid anion and was of the order of 10^{-11} amp cm^{-2} for 1*N* HCl, 10^{-13} for 1*N* H_2SO_4, and 10^{-16} for 1*N* $HClO_4$. The experimental analyses for Fe^{2+} in solution for a typical set of runs, together with the calculated activities and reversible potentials ($E_{Fe,Fe2+}$) are given in Table I.

Anodic polarization ($E_{meas'd} - E_{corr}$) at 10 ma cm^{-2} determined for iron in various solutions from the polarization curves as a function of per cent reduction in thickness by cold-rolling is given in Fig. 6. Figure 6 shows that the anodic polarization at 10 ma cm^{-2} is the same for the annealed iron as well as iron cold-rolled down to 70% reduction in thickness. However, the anodic polarization depends on the acid anion and is about 145 mv in 1*N* HCl, about 65 mv in 1*N* H_2SO_4, and about 52 mv in 1*N* $HClO_4$. Similar independence of the anodic polarization on the degree of cold-rolling was observed at an applied current of 2 ma cm^{-2}.

Discussion

It is well known that an equilibrium metal surface is characterized by a distribution of steps each having a large population of kinks. The nonequilibrium metal surface has, in addition, a large distribution of steps arising from dislocations having a component of the Burger's vector normal to the surface and numerous other steps arising from the mechanism of growth of that particular surface.

An annealed polycrystalline iron specimen is bounded by numerous such surfaces of various crystallographic orientations, which are separated by ordinary high angle grain boundaries of rather high surface energy. Cold-rolling such an iron specimen introduces numerous dislocation loops which are arrayed in their slip planes. They are prevented from retreating into their sources when the deforming force is no longer applied by formation of jogs as a result of intersection with other dislocations, by becoming "locked" by interaction with other dislocations, because their source may have moved out of the slip plane in which the loops have originated, or because parts of the loops may have emerged at a free surface or into a grain boundary. During severe deformation, arrays of dislocations are produced on several intersecting sets of slip planes, so that numerous parts of dislocation loops are emerging at a free surface. Severe cold-working is known to increase the density of dislocations from perhaps 10^8 for annealed iron to 10^{12} dislocations/cm² (18).

Another major effect of deformation is on the orientations of the grains. It is known that the deformation of a randomly oriented polycrystalline specimen results in material with a preferred orientation, the grains tending to approximate progressively to one or more well-defined orientations. Cold-rolling of iron produces a preferred orientation of the (001) crystal face parallel to the rolling plane (19). In addition to a high content of dislocations, cold-rolling produces a considerable excess of vacancies as a result of the movement of jogs in directions that do not correspond to slip. However, it is expected the excess vacancies anneal during the long R.T. aging of our specimens after cold-rolling.

Let us now consider the dissolution of a specimen bounded by such surfaces in contact with an electrolyte. At temperatures below the critical temperature of surface roughening (20) such surfaces are expected to be characterized by large numbers of equilibrium and nonequilibrium steps and kinks. Consequently, such surfaces have been considered (7) to be able to dissolve at least initially by the lateral motion of such steps in accordance with the crystal growth and dissolution theories (21-23). Jenkins (24) found that under certain conditions the dislocations played a role in the dissolution process of the (100) copper surface at low current densities in deaerated

solutions of acidified $CuSO_4$. He showed that at current densities of about 2 $\mu a/cm^2$ dissolution occurred only from the steps on the surface that result because of the difficulty of preparing a perfect crystal face. At current densities of about 10 $\mu a/cm^2$, pitting attack was observed at dislocations until finally the pits grew in size and a faceted surface resulted. The above experiments were carried out under low overpotential, to which crystal growth and dissolution theories might be applicable. However, during anodic dissolution of iron in acid solutions, the anodic overpotential is much higher, and it probably plays a dominant role in determining the kinetically slow step in the over-all reaction path of anodic iron dissolution.

It is more likely that at the high overpotentials (large driving free energy) necessary to establish the anodic polarization curve for iron homogeneous dissolution occurs anywhere on the surface, and any effect due to surface topography is lost. This is in accord with the present data indicating that, in the three acid solutions used, cold-rolling was found to have no effect on the Tafel parameters ($i_{o,Fe}$, β_{Fe}) for anodic dissolution of iron (Fig. 4 and 5 and Table I), or the anodic polarization (Fig. 6).

In sulfuric acid solution the observed Tafel slope of 40 mv/decade, *i.e.*, $2/3(2.303RT/F)$ in the region of current density 6×10^{-4} to 1.5×10^{-2} amp cm^{-2} is in agreement with results obtained by Bockris *et al.* (13) and more recently by Kelly (25) for iron in acidic sulfate solutions. For the anodic dissolution of iron in sulfuric acid solutions, the mechanism proposed by Bockris *et al.* (13) can be expressed in terms of the following equations.

$$Fe + OH^- \rightleftarrows Fe(OH)_{ads} + e^- \quad [2]$$

$$Fe(OH)_{ads} \rightarrow (FeOH)^+ + e^- \text{ (rate determining)} \quad [3]$$

$$(FeOH)^+ = Fe^{++} + OH^- \quad [4]$$

in which the surface species $Fe(OH)_{ads}$ act as a reaction intermediate.

In 1*N* HCl solution the observed Tafel slope of 60 mv/decade, *i.e.*, $(2.303RT/F)$ during interrupted polarization experiments or during continuous polarization from the ascending curve, in the region of current density 10^{-4} to 10^{-2} amp cm^{-2} is consistent with the following mechanism

$$Fe + OH^- \rightarrow Fe(OH)_{ads} + e^- \text{ (rate-determining)} \quad [5]$$

$$Fe(OH)_{ads} \rightarrow Fe(OH)^+ + e^- \text{ (rate-determining)} \quad [6]$$

$$Fe(OH)^+ \rightleftarrows Fe^{++} + OH^- \quad [7]$$

in which the OH^- competes with the Cl^- for the metal surface sites.

Tafel slopes of 54 mv/decade in chloride solutions were reported by Makrides *et al.* (26), 68 mv/decade by Stern and Roth (27), and 30 mv/decade in HCl (pH > 1.5) by Lorenz *et al.* (28). The difference in Tafel slopes obtained by the various investigators can be attributed to the various chloride anion concentrations and the experimental techniques used. Recently, it has been recognized (29) that short-time galvanostatic transients offer many advantages over conventional polarization techniques which often give rise to complex results difficult to interpret.

In 1*N* $HClO_4$ solution the observed Tafel slope of 35 mv/decade, *i.e.*, $(2.303RT/2F)$ is consistent with the following mechanism:

$$Fe + OH^- \rightleftarrows Fe(OH)_{ads} + e \quad [8]$$

$$Fe(OH)_{ads} \rightarrow Fe^{++} + OH^- + e \text{ (rate-determining)} \quad [9]$$

The observed Tafel slope is in agreement with the results of Bonhoeffer and Heusler (30) who found for iron in perchlorate solutions at 20°C a slope of 30 mv/decade.

The observed hysteresis in the anodic polarization of iron in HCl during continuous polarization (Fig. 3)

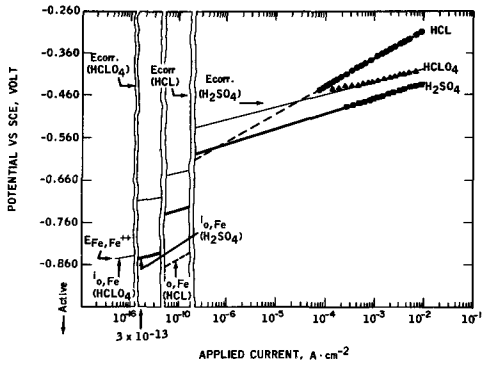

Fig. 7. Anodic polarization curves for iron illustrating the influence of the Tafel slope, β, and the ferrous ions activity in solution, a_{Fe++}, on the exchange current, $i_{o,Fe}$, in three acids.

is probably due to adsorption of Cl^- and the eventual complex formation with the iron surface atoms at higher polarizing potentials. This phenomenon will be discussed in more detail in another paper (31). Participation of anions such as Cl^-, Br^-, I^- in the dissolution of cadmium and indium amalgams was proposed by Kolotyrkin (32). Heusler and Cartledge (33) also suggested that the iodide ion participates in the anodic reaction of iron dissolution.

The large variation of the exchange currents for anodic dissolution of iron ($i_{o,Fe}$) with the nature of the acid anion shown in Table I can be realized if one considers the difference in the Tafel slopes for the various acids and the low activity of Fe^{++} in solution, necessitating extrapolation of the Tafel slopes to the fairly active potential of the reversible iron electrode in these solutions ($E_{Fe,Fe++}$) in order to establish the $i_{o,Fe}$. This is shown in Fig. 7. It is also obvious that a small error in the experimentally determined Tafel slopes produces a large error in $i_{o,Fe}$. This explains the large scatter in $i_{o,Fe}$ values observed (Table I) for the same acid.

In determining the reversible electrode potential $E_{Fe,Fe++}$ using the Nernst equation, the same value of the standard electrode potential $E^o_{Fe,Fe++} = -0.440$v *vs.* SHE was used for both cold-rolled and annealed iron electrodes. This is justified because of the lack of precise data on the effect of cold-rolling on the reversible standard electrode potential of iron, which in any case is very small.[1]

The lack of any effect of cold-rolling on the Tafel polarization parameters of iron dissolution in acids and also the acid anion dependence of this reaction suggest that at high polarizing potentials necessary to establish the anodic polarization curves (large driving free energy) homogeneous dissolution takes place directly from the surface and it is independent of the number of kink sites on the iron surface. The rate of anodic dissolution is kinetically controlled by the charge transfer step. The nature of the rate-determining charge transfer step depends on the nature of the acid anion as can be seen from Eq. [3], [5], [6], and [9].

Recently, Greene and Saltzman (8) reported an increase, with plastic deformation, of the exchange current density for anodic dissolution of iron and steel in 1*N* H_2SO_4. They interpreted their results to indicate that iron dissolves during anodic polarization, preferentially from dislocation sites because of the lower bonding energy of iron atoms at such sites. This explanation, however, is not compatible with the small increase in residual energy (approximately 5 cal/g) of severely cold-worked iron (34), and in

[1] For iron the increase in internal energy by severe cold-working was measured calorimetrically to be about 5 cal/g (34). Neglecting entropy effects, this value of enthalpy change corresponds to a change of potential of about 6 mv (35). However, as shown by Titchener and Bever (34) the change in entropy by cold-working a metal is positive and thus the change of potential due to cold-working, corrected for entropy effects, should be less than 6 mv.

particular with the high overpotentials involved during anodic polarization of iron in 1*N* H_2SO_4. Our own work, on the other hand, has not shown an effect of plastic deformation on the anodic Tafel polarization parameters. The increase noted by Greene and Saltzman must, therefore, have another explanation. The above authors reported that the specimens (wires) after torsional deformation, by twisting them a number of times, were degreased in benzene, rinsed in water, and dried before testing without additional polishing of the twisted wire surface. It is possible, therefore, that the torsional straining produced an increase of true surface area with accompanying higher exchange current densities.

It remains our conclusion, therefore, that at high overpotentials the anodic iron dissolution is kinetically controlled by the charge transfer step, and it is independent of the number of kink sites introduced by cold work on the iron surface.

Details on the kinetics of anodic dissolution of iron in various acidic environments are not given in the present paper since the purpose of this report is to discuss the effect of cold-rolling on the anodic polarization behavior of iron. However, the kinetics of anodic dissolution of iron will be discussed in detail in another report.

Acknowledgment

The author is grateful to Esso Research and Engineering Company for permission to publish the work. He also acknowledges the skillful assistance of Mr. A. W. Putnoky who conducted the experimental measurements.

Manuscript received Nov. 17, 1965; revised manuscript received March 10, 1966. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Role of the Anion in the Anodic Dissolution of Magnesium

P. F. King[1]

Metallurgical Laboratory, The Dow Metal Products Company, Division of The Dow Chemical Company, Midland, Michigan

ABSTRACT

In a number of aqueous environments the increase in the corrosion rate (i_c) of magnesium with an increase in impressed anodic current (i) is expressed by

$$\frac{d\,i_c}{di} = \tau_a$$

where τ_a is the transport number of the anions of the electrolyte. This adds confirmation to the viewpoint that film damage by anions rather than metal spalling or the production of monovalent magnesium ions is the chief contributor to the current inefficiency observed with magnesium anodes. The same equation holds for the decrease in corrosion rate of magnesium with applied cathodic current in acids, indicating that anion supply to the metal surface is controlling that process, also.

Because of its low equivalent weight and its active potential under load, magnesium has become important as an anode for cathodic protection and in primary cells. However, the full benefit of magnesium's low equivalent weight is not realized. Instead, the anode consumption is substantially greater than that

[1] Present address: Parker Rust Proof Division, Hooker Chemical Corporation, Detroit, Michigan.

calculated from Faraday's law and the formation of divalent magnesium ions as the sole electrode process. This excess metal loss results in an increase in the amount of hydrogen at the anode above that evolved on open circuit in contrast to the decrease observed on other, less active metals. Since the decrease has been known historically as the difference effect (1), the increase as observed with magnesium has long been known as the negative difference effect.

The causes for the coulombic inefficiency of the magnesium anode have been the basis for much research and conjecture. Explanations that have been offered for the inefficiency include: (*a*) the formation of metastable, monovalent magnesium ions as well as the divalent ions (2-5); (*b*) the loss of metal by spalling (6-8); and (*c*) corrosion that is accelerated through damage to the protective film by the impressed current (9, 10).

In an earlier publication, Robinson and King (10) expressed the view that the film damage explanation offered a reasonable and sufficient description of the excess consumption, the steady-state potential, and the transient potential behavior of the magnesium anode. According to this view, the consumption of the anode (i_t) can be represented as the sum of the applied and local action currents (i and i_c^o, respectively) and the excess weight loss caused by the applied current [$f(i)$]

$$i_t = i + f(i) + i_c^o \qquad [1]$$

In many environments, as discussed previously (10), $f(i)$ has been shown to be directly proportional to i, so that for these environments Eq. [1] can be rewritten

$$i_t = i + ki + i_c^o \qquad [2]$$

If we define the excess corrosion rate i_c as

$$i_c = i_t - i \qquad [3]$$

from Eq. [2] we have

$$i_c = ki + i_c^o \qquad [4]$$

and differentiation gives

$$\frac{di_c}{di} = k \qquad [5]$$

We suggested previously that this is true because the number of anions transported to the anode and, therefore, the amount of film damaging soluble magnesium salts at the anode increases linearly with current. Thus, a logical extension of the above reasoning is that k in Eq. [2], [4], and [5] and the anion transport number τ_a should be simply related. Indeed since both are dimensionless numbers, they might be equal. The work to be described here was planned to test this hypothesis.

Experimental Details

The experiments were carried out in the following manner. Primary magnesium was chosen for study because of its relative purity (98.5%), availability, and the unlikelihood, as deduced from the work reported by Robinson and George (11), that impurities have much effect on the efficiency of the magnesium anode at high enough current densities. A 2.5 × 0.5 cm cylindrical primary magnesium anode was mounted in a glass holder as previously described (10) and immersed in a round bottom flask containing additional openings for platinum working electrodes and a capillary reference probe. The latter was used only to insure that the anode had not become passive during the measurements.

The experiments were run at room temperature (20° ± 2°C) in stagnant solutions made from chemically pure salts and distilled water. The experiments in acidic environments were usually of 5-min duration. In salt solutions under anodic drain, times were adjusted to give weight losses of the order of 50 mg. Where currents greater than 100 ma/cm² were required, the anode area was reduced by the use of electroplater's tape. Before use, the specimens were pickled for 1 min in the so-called acetic-nitrate pickle (5% $NaNO_3$, 40% acetic acid, remainder distilled water), thoroughly rinsed and dried before weighing. At the conclusion of electrolysis they were rinsed with distilled water, cleaned until cleaning action stopped at 90°C in 20% chromic acid containing a pinch of $AgNO_3$, rinsed, and once again dried thoroughly before weighing. Where electroplater's tape was used, this final drying took considerable time.

Results and Discussion

In order to test the hypothesis that the constant k in Eq. [2], [4], and [5] is equivalent to the transport number of the anion of the electrolyte under study, the anodic dissolution rate of magnesium was tested at a number of current densities in six electrolytes selected for wide variation in transport properties. The results of these tests are shown in Fig. 1-5. In Fig. 6 results are summarized with the anion transport numbers from the literature (12) compared with the constant k as calculated from Eq. [2]; it should be pointed out that in some cases the literature transport numbers are extrapolated ones. The agreement, while not perfect, is good enough and covers a wide enough range of values to suggest that Eq. [5] may be rewritten

$$\frac{di_c}{di} = \tau_a \qquad [6]$$

a strikingly simple expression, and one which adds additional credence to the theory developed in the earlier publication.

It now becomes apparent why the observed anode efficiency of magnesium almost always lies between 50 and 100% if measurements are made at high enough current densities that the open-circuit corrosion is a trivial portion of the total anode consumption. The efficiency under these conditions is defined as

$$\% \text{ eff} = \frac{i}{i + i_c} \times 100 \qquad [7]$$

or, substituting τ_a for k in Eq. [4] and then combining Eq. [4] and [7] (continuing to neglect i_c^o)

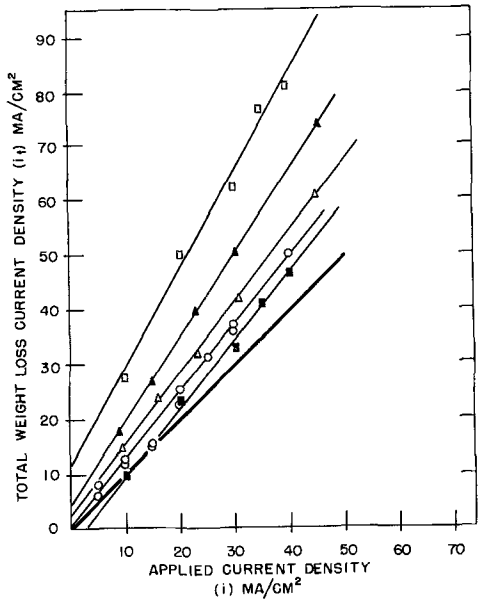

Fig. 1. Weight loss current density as a function of applied anodic current density for primary magnesium in 1*N* potassium malonate (○); 0.1*N* LiCl (□); 0.1*N* $KC_2H_3O_2$ (■); 1*N* $KCHO_2$ (△); and 2*N* $MgCl_2$ (▲). The heavy line represents Faraday's law.

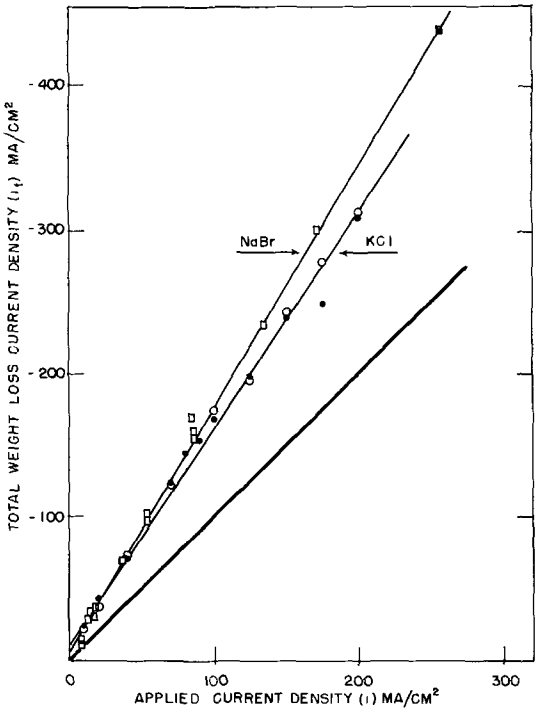

Fig. 2. Weight loss current density as a function of applied anodic current density for primary magnesium in 1*N* NaBr (□); 1*N* KCl (○); and 0.1*N* KCl (●). The heavy line represents Faraday's law.

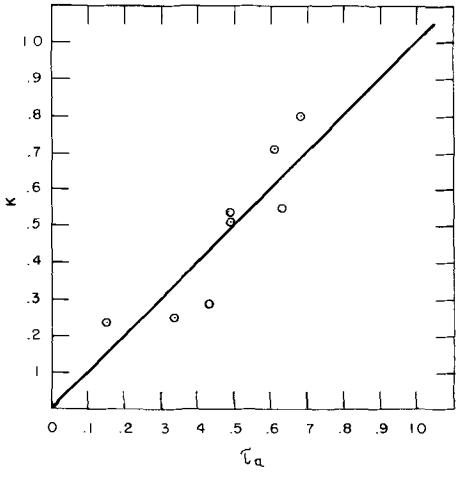

Fig. 3. Comparison of the constant *k* from Eq. [5] with literature τ_a values. The line is theoretical; that is, it assumes $k = \tau_a$.

$$\% \text{ eff} = \frac{i}{i + \tau_a i} \times 100 = \frac{100}{1 + \tau_a} \qquad [8]$$

and since τ_a is bounded by 0 and 1, the efficiency must be bounded by 100 and 50%.

Table I shows a test of Eq. [8] as a method for predicting the limiting efficiencies. The agreement between the measured and the predicted efficiencies suggests that Eq. [8] will be of practical value in the selection of electrolytes.

The results suggest that each anion equivalent which reaches the magnesium surface removes, in some manner, an equivalent of magnesium over and above that which is put into solution by the external anodic current. The exact mechanism by which this occurs is still unclear. However, since the limiting anodic efficiency of magnesium thus appears to bear a quantitative relationship to the electrochemical properties of

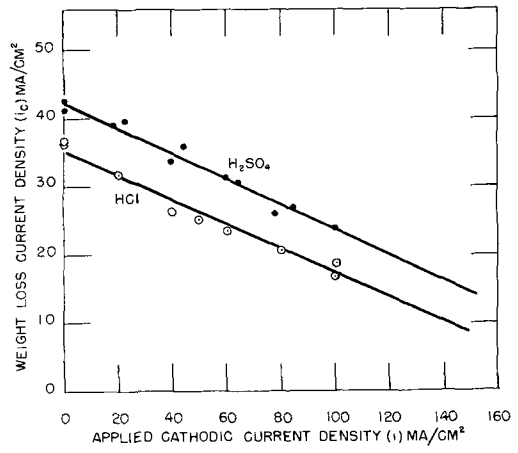

Fig. 4. Weight loss current density as a function of applied cathodic current density for primary magnesium in H_2SO_4 at pH 1.1 and in HCl at pH 1.1. The lines are drawn with slopes corresponding to τ_a in $H_2SO_4 = 0.18$; τ_a in HCl = 0.17.

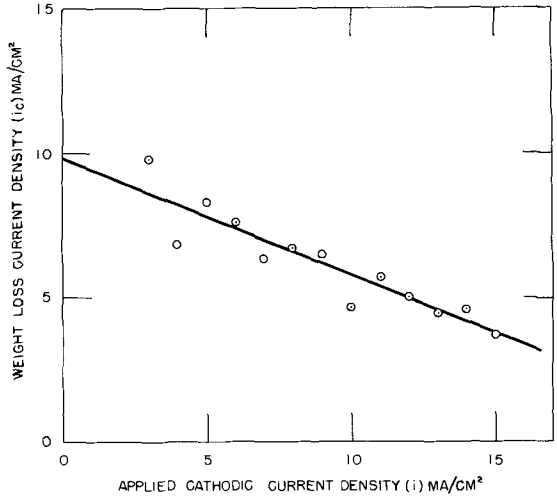

Fig. 5. Weight loss current density as a function of applied cathodic current density for primary magnesium in 1*N* $NaC_2H_3O_2$ containing 0.1*N* $HC_2H_3O_2$.

the environment, it seems unlikely that Mg^+ formation and metal spalling can be an important part of the process. It should be pointed out that there is no doubt that some magnesium spalling does occur. One can sometimes see metal in the anodic corrosion products. If one tries to liberate hydrogen from this corrosion product with acid in these cases, however, one can account for at most only a few per cent of the wasteful corrosion. In addition, only a few per cent of the corrosion product appears to be solid metal by x-ray diffraction examination.

It also appears that τ_a is the appropriate coefficient for the linear reduction of the corrosion rate of magnesium in acids with applied cathodic current which was observed by Coates (13) and Roald and Beck (14). These authors did not attempt to explain this linearity beyond Roald and Beck's comment that

Table I. Comparison of experimental and theoretical efficiency values

Salt	Efficiency calculated from: Concentration, *N*	Literature transport numbers, %	Experimental efficiency, %
$MgCl_2$	2	61	65
$KCHO_2$	1	70	78
$KC_2H_3O_2$	0.1	75	80
LiCl	0.1	60	56
Potassium malonate	2	87	81
NaBr	1	62	59
KCl	1	67	66
KCl	0.1	67	65

transport within the diffusion layer might be responsible. In contrast to the anodic case where the detailed mechanism remains obscure to the author, a reasonable physical picture of this situation can be proposed.

It is generally agreed (13-16) that on open circuit the dissolution of magnesium is controlled by the diffusion of acid to its surface. The over-all reaction is

$$Mg + 2HA \rightarrow H_2\uparrow + MgA_2$$

where A stands for the anion of a magnesium salt which must be soluble to prevent film growth with concomitant stifling of the reaction. Because preservation of charge requires that both protons and anions diffuse to the surface at the same rate, protons to provide the cathodic reaction and anions to sustain the solubility of magnesium are equally available to sustain dissolution.

If now magnesium reacting with pure aqueous acid is made a cathode, the current carried by protons reaching the magnesium surface will be increased by $\tau_{H^+} i$. However, since the applied cathodic current must liberate hydrogen at the cathode at a rate equal to i, it follows that

$$i_c = i_c^o + \tau_{H^+} i - i = i_c^o - (1 - \tau_{H^+}) i \qquad [9]$$

Because $(1 - \tau_{H^+}) = \tau_a$ for the pure acid, Eq. [9] can be restated as

$$i_c = i_c^o - \tau_a i \qquad [10]$$

which is the same equation one would deduce if anion supply, being reduced by transport away from the surface by cathodic current, were controlling the dissolution rate. That these equations do apply to the present case is shown by Fig. 4, which compares the reduction of i_c by impressed cathodic current for magnesium in dilute H_2SO_4 and dilute HCl at pH 1.1 with lines having slopes of —0.18 and —0.17 corresponding to the respective τ_a values for each acid.

It appears that distinction can be made between the relative importance of proton transport and anion transport by using a buffer wherein the dissociation of the acid is greatly suppressed. Figure 5 shows the results for the dissolution of a magnesium cathode in 0.1*N* HOAc plus 1*N* NaOAc. In this system τ_{H^+} should be trivial. Thus, τ_a should be approximately 0.42, which is the transport number for acetate ions in 1*N* NaOAc, while $(1 - \tau_{H^+})$ should be very close to unity. The line in Fig. 5 has a slope of —0.41. Therefore, it appears that under impressed cathodic current

$$i_c = i_c^o - \tau_a i > i_c^o - (1 - \tau_{H^+}) i \qquad [11]$$

This suggests that the rate of supply of anions rather than the rate of supply of protons controls the rate of dissolution of magnesium in acids. A simple rationale for this result is that so long as film growth is thwarted by the formation of soluble reaction products, the reduction of water is able to sustain the rate.

Summary

The excess corrosion of the magnesium anode at currents high with respect to open-circuit corrosion currents appears to be related quantitatively to the rate of arrival of the anions of the electrolyte at the anode surface. That is, the excess corrosion is equal to $\tau_a i$, where τ_a is the transport number of the anion involved and i is the applied anodic current. Thus, the increase in the wasteful corrosion rate with increasing anodic current, di_c/di is simply τ_a.

Correspondingly, in acids the corrosion of magnesium is decreased by cathodic current since anions are thereby transported away from the magnesium surface. The proportionality constant between the applied current and the decrease in corrosion rate again is τ_a.

These observations support the view that anion promoted film-damage and a resultant more or less direct reaction of the underlying magnesium with water is responsible for the nonfaradaic corrosion of the magnesium anode in aqueous environments.

Correction

In the paper "Concentration Gradients at Horizontal Electrodes" by R. N. O'Brien which appeared in the April 1966 issue of the *Journal*, pp. 389-392, the principal formula was printed incorrectly. It should be

$$AC_{(x,t)} = \frac{2\sqrt{Dt/l^2}\, Ilt^-}{nFD} \text{ierfc} \frac{1 - x/l}{2\sqrt{Dt/l^2}}$$

The Oxidation of GaP and GaAs

M. Rubenstein

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Thermal oxidation of GaP and GaAs by oxygen has been studied. GaP on oxidation undergoes a violent exothermic reaction at 1130° ± 20°C. The products of the oxidation of GaP are the christobalite form of $GaPO_4$ as a primary product and β-Ga_2O_3 as a secondary product (about 5 w/o). GaAs on oxidation undergoes a mild exothermic reaction at 840° ± 10°C. The products of this reaction are β-Ga_2O_3 as a primary product and the low quartz form of $GaAsO_4$ as a secondary product (about 10 w/o). The $GaAsO_4$ at temperatures higher than 1000°C decomposes to As_2O_5 + β-Ga_2O_3. The above statements are made on the basis of x-ray diffraction data, change in weight data, and wet chemical analyses. On the basis of this data, it is concluded that thermal oxide masking should be readily applicable to GaP and that thermal oxide masking should not be applicable to GaAs.

GaP and GaAs are usually considered very stable compounds, especially with respect to their reactivity toward oxygen. At temperatures less than 800°C this is more or less true. A film might form on the surface at temperatures less than 800°C, but the bulk of the material would not change with respect to weight, crystal structure, or other physical parameters. The thermal oxide masking of GaAs was investigated (1) but was found to be not readily applicable.

Experimental

Oxygen was passed over the sample to be oxidized at a flow rate of about 200 cc/min. A Pt-Pt 10% Rh thermocouple was tied to the quartz boat containing the sample, using a platinum wire insulated from the thermocouple. A hinged split furnace with a 1¼ in. bore accommodated the quartz tube. A variable autotransformer and a Wheelco Capacitrol Model 402 were used to control the temperature. The oxygen was dried using a P_2O_5 packed vertical tower and a CO_2-acetone cold trap.

Weight change determinations were made to the nearest tenth of a milligram. Sample sizes were usually about half a gram. Wet chemical analyses were made on some of the oxidized GaP and GaAs samples. Phosphorus was determined by the precipitation of magnesium ammonium phosphate in the presence of citric acid. This precipitate was ignited, thermally decomposed, and weighed as $Mg_2P_2O_7$. Arsenic was extracted from a 2*N* HCl solution with diethyl-ammonium diethyldithiocarbamate in chloroform. The extracted arsenic was oxidized and determined by the photometric molybdenum blue method.

X-ray diffraction studies were made using a 57.32 mm radius Straumanis-type camera with nickel filtered copper radiation.

Results

GaAs.—If GaAs, on being oxidized by oxygen, produced only β-Ga_2O_3, the weight loss would be 35.20%. If $GaAsO_4$ were the product, there would be a weight gain of 44.25%. When GaAs was heated above 700°C, a weight loss was observed which increased with temperature (see Fig. 1). In the range of temperature between 830°-850°C, an exothermic reaction took place. Between 850° and 965°C the weight loss was 30-32%. At a temperature of 1000°C and higher, there was a total weight loss of about 35.4%.[1] Samples heated for longer periods of time, at temperatures under 830°C, showed larger decreases in weight than samples heated for shorter periods of time, at the same temperature (see Fig. 1, samples heated at 760°C).

X-ray diffraction studies showed that the products of the oxidation of GaAs between 850° and 965°C were

[1] $2GaAsO_4 \rightarrow \beta$-$Ga_2O_3$ + As_2O_5 at 1000°C and at higher temperatures (2).

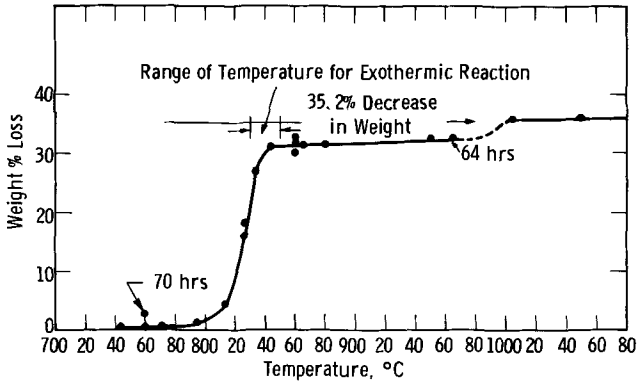

Fig. 1. Oxidation of GaAs in oxygen. Per cent weight loss vs. temperature. All points on this curve are for samples fired for 20 ± 2 hr, except 2 labeled points.

primarily β-Ga_2O_3 (3) with a minor constituent of the low quartz form of $GaAsO_4$ (2) (about 10%). Samples heated at temperatures of 1000°C and above showed only β-Ga_2O_3 as a product.

Wet chemical analyses of several samples of oxidized GaAs were performed and the total weight per cent arsenic in the samples was obtained. Assuming that the samples analyzed contained only $GaAsO_4$ and Ga_2O_3, weight per cent values for these two products were calculated from wet analysis data and from weight loss data. These values are presented in Table I-GaAs. The weight percentages of $GaAsO_4$ and Ga_2O_3 obtained from these two independent measurements agree quite well. The total weight loss of sample S14S (Table I) is 35.6%. The theoretical weight loss if all the GaAs were oxidized to β-Ga_2O_3 is 35.2%. Possibly some of the Ga_2O_3 and/or GaAs was vaporized during the oxidizing reaction.

Figure 2 shows photographs of the progressive oxidation with temperature of slices of GaAs. Figure 3 shows how the oxidation proceeds from the surface of a sample. The samples in Fig. 3 were cracked perpendicular to the plane of the plate, and lapped and polished on this cracked edge to give these cross-sectional views.

When a sample of GaAs was oxidized with oxygen to 965°C, there was a loss of volume of 0.66% and the bulk density is 3.58 g/cc. Since the density of GaAs is 5.3216 g/cc (4), the density of the low quartz form of $GaAsO_4$ is 4.20 g/cc (2), and the density of β-Ga_2O_3 is 5.88 g/cc (2), the product of the oxidation of GaAs showed a porosity of 35.6%.

GaP.—If GaP, on being oxidized by oxygen produced only β-Ga_2O_3, there would be a weight loss of

Table I

GaAs

Sample designation	Temperature, °C	Hr at temperature	Weight % loss	Weight per cent $GaAsO_4$ From weight loss	Weight per cent $GaAsO_4$ From wet analysis	Weight per cent Ga_2O_3 From weight loss	Weight per cent Ga_2O_3 From wet analysis

6.92%. If $GaPO_4$ were the only product, then there would be a weight gain of 63.6%. When GaP was heated above 1000°C, a weight increase was observed, increasing slowly with temperature (see Fig. 4) until a range of 1110°-1150°C. In this range a very energetic exothermic reaction took place. The product of the reaction melted.[2] At the beginning of this exothermic reaction, the furnace was opened (for several experiments), and measurements as high as 1700°C were made with an optical pyrometer. It was noted at that time that a small amount of white powder was evolved during this reaction. This powder deposited on the quartz wall nearby which had a temperature in excess of 1100°C. Samples which had undergone the exothermic reaction experienced a weight gain of 62-63%. Heating at higher temperatures (as high as 1250°C) did not cause any further weight change. Samples heated for longer periods of time, at temperatures under 1110°C, showed larger increases in weight than samples heated for shorter periods of time, at the same temperatures (see Fig. 4, samples heated at 1100°C). Figure 5 photographically shows the progressive oxidation with temperature of slices of GaP. The 1120°C sample had gone through the exothermic reaction and the melted product is shown in its quartz boat. Figure 6 is a cross section of the "1100°C, 70 hour" sample of Fig. 5. This sample was cracked perpendicular to the plane of the plate and lapped and polished on this cracked edge to give a cross-section view.

X-ray diffraction studies showed that the products of the oxidation of GaP over the entire range of temperatures were the christobalite form of $GaPO_4$ (2) as a major phase and as a minor phase, β-Ga_2O_3 [5-10 w/o (weight per cent)].

Wet chemical analyses of several samples of oxidized GaP were performed and total weight per cent phosphate in the samples was obtained. Assuming that the samples analyzed contained only $GaPO_4$ and Ga_2O_3, weight per cent values for these two products were calculated from the wet analysis data and the weight gain data, and these values are given in Table I-GaP.

[2] The melting points of β-Ga_2O_3 and the christobalite form of $GaPO_4$ are 1715° ± 15°C (3) and 1670° ± 10°C (2), respectively.

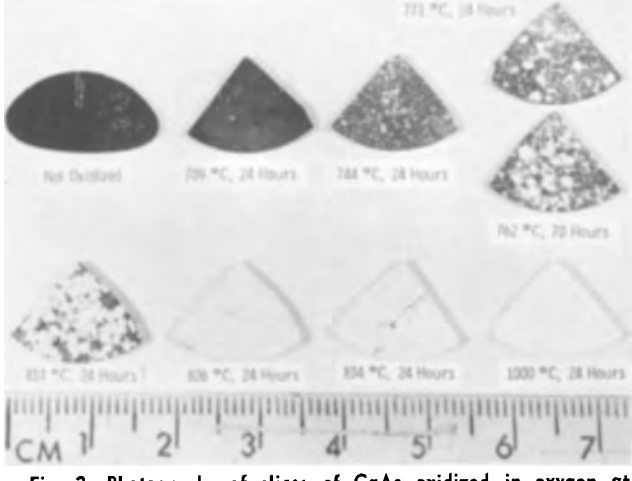

Fig. 2. Photographs of slices of GaAs oxidized in oxygen at various temperatures. Samples oxidized at 834° and 1000°C had undergone the exothermic reaction.

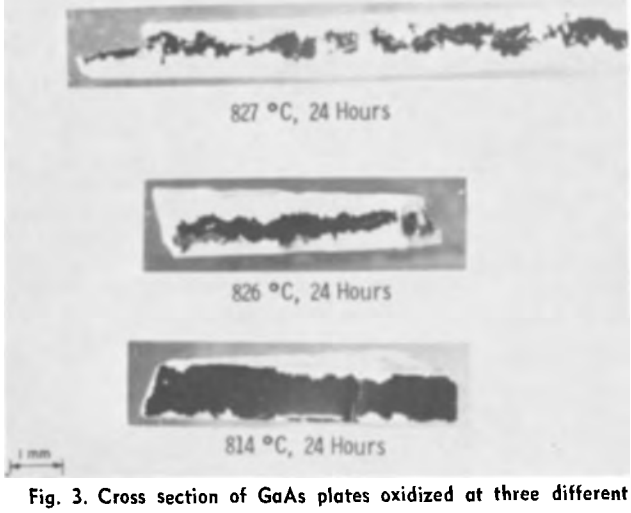

Fig. 3. Cross section of GaAs plates oxidized at three different temperatures.

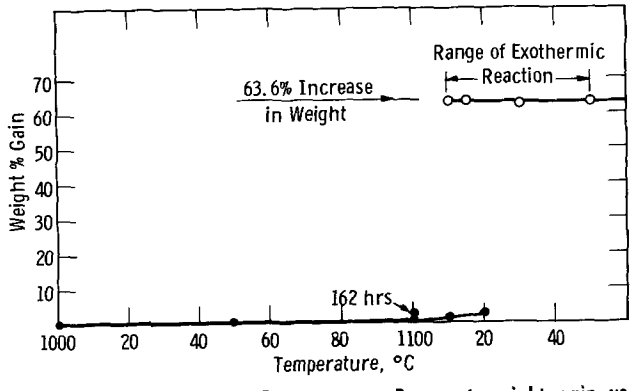

Fig. 4. Oxidation of GaP in oxygen. Per cent weight gain vs. temperature. All points on this curve are for samples fired for 22 ± 2 hr, except the labeled points.

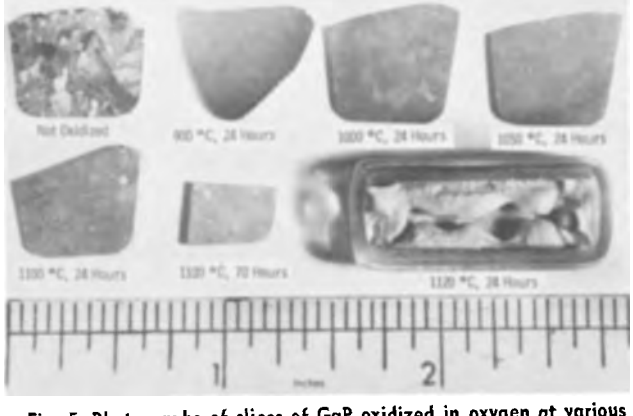

Fig. 5. Photographs of slices of GaP oxidized in oxygen at various temperatures. Sample fired at 1120°C for 24 hr had undergone the violent exothermic reaction.

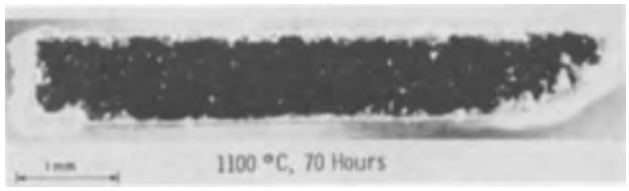

Fig. 6. Cross section of GaP plate oxidized in oxygen. Some sample as 1100°C, 70 hr in Fig. 6.

The values obtained for the weight per cent of $GaPO_4$ and Ga_2O_3 from wet analysis and weight gain data differ markedly. Since β-Ga_2O_3 was observed on the x-ray film for these samples, one can be sure that β-Ga_2O_3 was present in concentrations of at least a few per cent. It is felt that the weight gain measurements are all on the high side. Some of the powder deposited during the reaction was scraped off the wall of the quartz tube and examined by x-ray diffraction. Christobalite $GaPO_4$ with a small amount of β-Ga_2O_3 was identified. Therefore, the weight per cent $GaPO_4$ and β-Ga_2O_3 obtained by wet chemical analysis are considered quite reliable, and the quantitative data for Ga_2O_3 obtained from weight gain data are to be considered too low.

The densities of the christobalite form of $GaPO_4$, GaP, and β-Ga_2O_3 are 3.29 g/cc (2), 4.1304 g/cc (4), and 5.88 g/cc (3). The density of the oxidation product is certainly less than either GaP or β-Ga_2O_3.

Conclusion

The thermal oxidation of GaAs with oxygen produces β-Ga_2O_3 as a primary product and the low quartz form of $GaAsO_4$ as a secondary product. This was demonstrated by x-ray diffraction and quantitatively proved by weight loss determinations and wet chemical analysis. Minden observed that an oxide masking film was not formed when GaAs was thermally oxidized with oxygen. This paper has tried to prove that a low bulk density product composed primarily of β-Ga_2O_3 is formed, but the product is porous (about 35%), and As_2O_3 is driven from the area of the reaction.

The thermal oxidation of GaP with oxygen produced the christobalite form of $GaPO_4$ as a primary product with a secondary product of β-Ga_2O_3. This was demonstrated by x-ray diffraction, indicated by weight loss determinations, and proved by wet chemical analysis. When GaP is thermally oxidized by oxygen, the resulting product is primarily $GaPO_4$. Since this is a lower density material than GaP it spreads over the surface of the GaP and tends to cover the entire surface in much the same manner that an SiO_2 film covers a silicon surface. Only a small amount of a volatile product (P_2O_5) may be produced in this reaction since some β-Ga_2O_3 is formed.

Since this oxidation of GaP takes place slowly at temperatures below 1100°C the thickness of the oxide film can easily be controlled. This paper would like to suggest that thermal oxide masking may be applicable to GaP.

Properties of Anodic Films Formed on Reactively Sputtered Tantalum

D. Gerstenberg

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The technique of reactive sputtering has been used for producing tantalum films with various concentrations of interstitial additives like oxygen, carbon, nitrogen, and hydrogen. A number of compounds between tantalum and these nonmetallic elements also have been deposited. The dielectric properties of anodic films on the tantalum formed in an aqueous solution of citric acid have been related to the composition of the tantalum. It was found that the capacitance density of 130v anodic films remains unaffected by the presence of oxygen and hydrogen, while it decreases as the atomic concentration of nitrogen and carbon in the tantalum increases. The dielectric constant, ϵ, of anodic films on Ta_2N is approximately 50% of the value of anodic Ta_2O_5 formed on pure tantalum.

The properties of sputtered refractory metal films like tantalum, niobium, and titanium are influenced greatly by deliberate addition of reactive gases to an argon sputtering atmosphere (1-4). Nonmetallic additives like oxygen, nitrogen, or carbon are incorporated in these films during the deposition process. At low concentrations, this incorporation takes the form of interstitial solution, and the solubility limits for all three additives appear to be much higher in tantalum and niobium films than in the bulk metals. At higher concentrations a number of compounds like oxides, nitrides, and carbides are formed. The resistivity and the temperature coefficient of resistivity of reactively sputtered refractory metal films depend strongly on the type of gas and the partial pressure at which the films are sputtered.

Reactively sputtered tantalum nitrides and carbides have a much higher resistivity than tantalum, a very low temperature coefficient, and a high thermal stability when deposited on heated substrates. In particular, tantalum nitride films have proven their usefulness as resistive components for integrated circuitry (5) and as individual components (6).

Preliminary results also indicated interesting dielectric properties of anodically formed films on tantalum sputtered with deliberately added nitrogen (7). These results were obtained on anodic films formed on tantalum which, initially, without deliberate addition of

nitrogen consisted of β-tantalum (8). As the atomic concentration of nitrogen is increased in the tantalum films the resulting anodic film has lower capacitance, but equivalent dielectric loss and leakage compared to anodic films formed on pure tantalum films (9). It was also demonstrated that the decrease in capacitance was caused by a change in dielectric constant due to the formation of a tantalum oxynitride. Associated with the decrease in capacitance is a large increase in the cathodic breakdown voltage. The purpose of the present investigation was to study the influence of other nonmetallic elements on the dielectric properties of anodic films formed on reactively sputtered tantalum films. The reactive gases used in this study include oxygen, methane, hydrogen, and nitrogen. Nitrogen has been added to this list because it was desirable to reinvestigate the properties of thin film capacitors fabricated from nitrogen containing tantalum sputtered under conditions which allow deposition of bcc α-tantalum reproducibly.

Experimental

As in the previous investigation (1) the tantalum films were sputtered from a high purity tantalum cathode through a mask on clean 2.5x7.5 cm barium alumina borosilicate glass substrates to a thickness of 4500Å. The distance between cathode and anode was 6.5 cm and the deposition rate about 130 Å/min for tantalum at 0.25 ma/cm^2, 4 kv and an argon pressure of $25\text{x}10^{-3}$ Torr. A removable shield between substrate and cathode allowed equilibrium to be reached in the sputtering atmosphere before starting deposition on the substrate. For outgassing, the mask and the substrate were maintained at 400°C during the presputtering and the subsequent sputtering run. The resistivity of the tantalum films was determined by a four point probe technique immediately after deposition.

The tantalum films were anodized at room temperature in an aqueous solution of 0.01% citric acid at a current density of $5\text{x}10^{-3}$ amp/cm^2. After reaching the desired voltage the anodization was continued for another 30 min allowing the current to decrease to $5\text{x}10^{-6}$ amp/cm^2 which is in the order of the electronic leakage current. The majority of the films were anodized to 130v resulting in oxide films on pure tantalum about 2000Å thick (10). In most cases, the anodization was interrupted to etch the tantalum films electrochemically at weak spots in the oxide in an aluminum chloride in methanol solution, which has proven beneficial in reducing anodic leakage or shorts (11). A number of films were anodized to voltages ranging from 75 to 250v for determining the amount of charge passed during anodization, and the dependence of the capacitance density on the forming voltage. The last step in the capacitor fabrication was the evaporation of the counter electrode structures from a tungsten filament at pressures of $1\text{x}10^{-4}$-$1\text{x}10^{-5}$ Torr. Gold counter electrodes, about 2000Å thick, were evaporated through mechanical masks yielding from 8 to 10 capacitors per substrate with an area of 0.35 cm^2 per capacitor. A General Radio Type 1620A Measuring Assembly was used for the determination of the capacitance and tan δ at 1 kc, and in a number of cases at frequencies ranging from 0.1 to 10 kc.

The structure of the tantalum films sputtered at different reactive gas pressures has been determined by x-ray diffraction analysis of processed slides after the capacitor properties had been evaluated. Since the anodic oxide is x-ray amorphous it does not generate a pattern interfering with the x-ray diffraction pattern obtained from the underlying tantalum film.

Experimental Results and Discussion

Resistivity.—Figure 1 shows how the resistivity of reactively sputtered tantalum films is affected by the type and the partial pressure of the reactive gases added to the argon atmosphere. The tantalum films

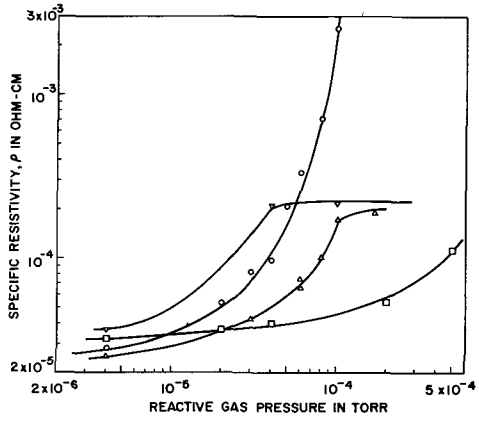

Fig. 1. Specific resistivity of 4500Å tantalum films as a function of the type and reactive gas pressure (measured by four-point probe). Sputtered films: ▽ N_2; △ CH_4; ○ O_2; □ H_2.

which were sputtered without deliberate addition of a reactive gas ($p = 3\text{x}10^{-6}$ Torr) have resistivities, ρ, ranging from 25 to 35 μohm-cm. These values are between 2 and $3\cdot\rho_B$, where ρ_B is the resistivity of pure bulk tantalum, indicating an impurity concentration of less than 3 a/o (atomic per cent) of interstitials like oxygen or nitrogen (1). The deliberate addition of reactive gases increases the resistivity until in the case of nitrogen and methane the curve reaches a plateau region at about 200-250 μohm-cm. These values agree very well with those reported for 1200Å films (1). The curve for tantalum sputtered in a partial oxygen atmosphere shows a sharp rise in resistivity above $6\text{x}10^{-5}$ Torr. The formation of insulating Ta_2O_5 occurs at partial pressures of oxygen of $1.7\text{x}10^{-4}$ Torr and above. The presence of hydrogen in the sputtering atmosphere does not seem to influence the resistivity of the tantalum films very much below 10^{-4} Torr, while in the 10^{-4} Torr range the values increase by about an order of magnitude.

Structure and composition.—The structure of the tantalum films sputtered with various additions of nitrogen, methane, oxygen, and hydrogen is indicated on the upper half of Fig. 2. The tantalum films deposited in a partial nitrogen atmosphere have the same phases Ta_2N and TaN which have been reported before (1). Sputtering of tantalum in a partial methane atmosphere results in the formation of Ta_2C and TaC (12). The phase Ta_2C had not been observed for reactively sputtered tantalum films before (1) either due to the small concentration range of this phase or due

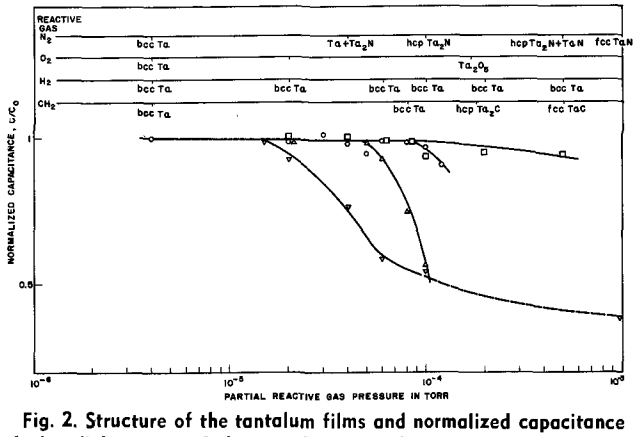

Fig. 2. Structure of the tantalum films and normalized capacitance of the dielectric at 1 kc vs. the type of gas and gas pressure. Capacitors were fabricated by anodization in 0.01% citric acid to 130v and have an area of 0.35 cm^2. C_0 is the capacitance of Ta_2O_5 on pure bcc tantalum films. C_0 = 0.031 uF. Sputtered films: same symbols as in Fig. 1.

Table I. Data on tantalum films sputtered in a partial oxygen atmosphere prior to anodization

Partial oxygen pressure P_{O_2} 10^5 Torr	Resistivity $\rho \times 10^6$ ohm-cm	Lattice constant a_o, in Å	Average crystallite diameter in Å*	Concentration** of oxygen in at. %

2	52	3.360	64	3.6
4	97	3.405	52	11.4
6	340	3.430	17	—
8	720	3.46	16	29.5
10	2500	3.50	14	46

* The true average size of the crystallite is probably somewhat larger because of the x-ray line broadening on which this calculation was based might also be caused by strain in the tantalum films.
** Determined by anodization of films using Faraday's law.

to a higher solubility limit for carbon in tantalum at small film thicknesses. The films for the structural determination in the previous study by electron diffraction were only 300Å as compared to about 4000Å for the present films. Only preliminary data with respect to the composition of nitrogen and methane sputtered films are available. It has been established, however, that for both types of films (13, 14) the solubility limits are in the order of 10 to 15 a/o before the x-ray diffraction pattern of a second phase, Ta_2C or Ta_2N, can be observed.

The addition of oxygen to the sputtering atmosphere results in a drastic decrease of the crystallite size while the lattice constant increases as shown in Table I. The drop in crystallite size becomes particularly noticeable between $4x10^{-5}$ and $6x10^{-5}$ Torr probably indicating the formation of small Ta_2O_5 particles. These particles, however, are not large enough to contribute to the x-ray diffraction pattern. The tantalum films sputtered in a partial hydrogen atmosphere do not show a change in structure. This is reasonable in view of the fact the substrate temperature during deposition was about 400°C, too high a temperature for the formation of stable tantalum hydrides (15). It is likely, however, that there is interstitial solution of hydrogen which might occur during deposition or during the cooling period after sputtering.

Capacitance.—The lower half of Fig. 2 shows how the normalized capacitance of 130v anodic films on the reactively sputtered tantalum measured at 1 kc changes with increasing reactive gas pressure. The concentration of the gases in the tantalum is not known for all films, but the preliminary analytical results mentioned in the previous section indicate that the atomic concentration of the reactive gases is directly proportional to the reactive gas pressure in the sputtering atmosphere. The normalized capacitance of the dielectric on tantalum films sputtered with additions of oxygen and hydrogen appears to be affected the least. This result is to be expected for the anodic film formed on tantalum films sputtered in a partial oxygen atmosphere. The drop in capacitance for these films at $1x10^{-4}$ Torr is probably due to the presence of oxide particles prior to anodization resulting in an increased effective thickness for the anodic film. Films sputtered at this pressure contain about 45 a/o of oxygen. Anodic films formed on tantalum containing such high oxygen concentrations also tend to crystallize during anodization.

The incorporation of nitrogen and carbon in the tantalum films results in fairly large decreases in capacitance which are accompanied by a slow change of the interference color of the 130v anodic film. It will be shown in the next section that the lower capacitance for the capacitors formed on nitrogen sputtered films is not due to a variation in oxide thickness but rather due to a decrease in the dielectric constant with increasing nitrogen concentration in the films. The anodization of Ta_2N does not present difficulties; the voltage increases at a constant rate with time during the constant current period, and after reaching voltage the anodization current drops inversely with time (16). The films consisting solely of TaN exhibit gas evolution during the anodization process. They can be anodized to at least 130v but the resulting anodic film has a rather dull appearance. The finished capacitors also have low anodic and cathodic breakdown characteristics. In the case of the carbon containing tantalum, anodization of films sputtered at $1x10^{-4}$ Torr of methane consisting of a mixture of tantalum with a small amount of Ta_2C results in discoloration and low breakdown characteristics for the dielectric. For Ta_2C and TaC films citric and nitric acid act as etchants when a positive voltage is applied to these films.

Coulometric and other measurements.—A number of "pure"[1] tantalum films, and films sputtered at various reactive gas pressures were used for measuring the charge transfer during anodization. The theoretical values for the charge transfer per volt during the conversion of tantalum metal to Ta_2O_5 has been calculated on the basis of a reduction in thickness of the metallic film which is $k_3(Ta) = 6.63$ Å/v (10, 17). This value and the one obtained for converting metallic Ta_2N to the dielectric by anodization, $k_3(Ta_2N) = 4.8$ Å/v, (17, 18), had been determined previously from the increase in resistance of samples due to the reduction of the conducting film thickness by anodization. The number of electronic charges per volt of anodization and per square centimeter of film area, q_{th}, is then according to Faraday's law

for Ta:

$$q_{th} = n \cdot k_3(Ta) \cdot N_{Ta} \cdot e \quad [1]$$

and for Ta_2N:

$$q_{th} = n \cdot k_3(Ta_2N) \cdot N_{Ta_2N} \cdot e \quad [2]$$

where n is the number of charges per tantalum atom, N is the number of tantalum atoms per cubic centimeter of the original film of tantalum or Ta_2N which is equal to the inverse of the volume of the unit cell times the number of tantalum atoms per unit cell, and e is the electronic charge. The resulting q values for tantalum and Ta_2N are, respectively, $q_{th} = 0.287 \cdot 10^{-2}$ coulomb/v cm^2 [2] and $q_{th} = 0.194 \cdot 10^{-2}$ coulomb/v cm^2 for $n = 5$, assuming no changes in valency for the nitrogen atoms during anodization.

The experimental values for q were determined graphically from the plot of the anodizing current as a function of time. A comparison of the theoretical value with the experimental value for tantalum films sputtered without addition of a reactive gas which were anodized to 130 and 250v shows satisfactory agreement (see Table II) indicating about 100% efficiency for the anodization process. The oxygen containing tantalum films show the expected decrease in the q values. In Fig. 3 the resistivity of these films has been plotted as a function of the atomic concentration of oxygen calculated from the q values. Also shown are the resistivity values of 1200Å films *vs.* oxygen concentration de-

[1] Pure films are those sputtered without deliberate addition of a reactive gas.

[2] In a more refined treatment the change in cell parameter due to the presence of interstitial oxygen, etc. would have to be taken into consideration for the calculation of q_{th} of tantalum.

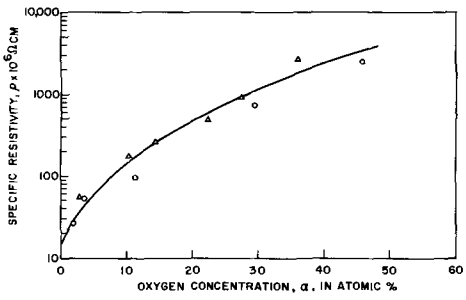

Fig. 3. Resistivity as a function of the atomic concentration of oxygen in reactively sputtered tantalum films: ○ based on the coulometric measurements, 4000Å; △ analyzed by inert gas fusion analysis, 1200Å.

Table II. Results of coulometry experiments on reactively sputtered tantalum films

Gas pressure $p \times 10^{-5}$ Torr	Reactive gas	No. of samples	Anodization voltage, V_A in V	Charge transfer $q \times 10^3$ coulomb/v-cm^2	Structure of the original film

10×10^{-5}		2	130	0.118	bcc Ta + O
10×10^{-5}	N_2	4	100, 150, 200, 250	0.192 ± 0.014	Ta_2N
8×10^{-5}	CH_4	4	100, 150, 200, 250	0.293 ± 0.008	bcc Ta + C
35×10^{-6}	H_2	2	130	0.289	bcc Ta + H

termined by inert gas fusion analysis (1). Both sets of values agree very well suggesting that the coulometric experiments are a convenient method for oxygen analysis of tantalum films if the oxygen is uniformly distributed throughout the tantalum.

The experimentally determined value for the charge transfer during formation of the dielectric on Ta_2N, listed in Table II, is approximately equal to the theoretical value. The calculation of q_{th} for Ta_2N was based on the assumption that the tantalum atoms reacting with oxygen during anodization have five charges. The good agreement between the theoretical and the experimental value, therefore, seems to indicate five oxygen atoms react with each Ta_2N molecule during the formation of the anodic film. This has been confirmed by the gravimetric determination of the mass of the dielectric on Ta_2N formed during anodization. The conversion factor k_3 has not been determined for methane and hydrogen sputtered films. But if we assume that it is close to that of pure bcc tantalum which still is the structure of these reactively sputtered films it can be concluded from the q values that carbon and hydrogen do not participate in the charge transfer during anodization.

The results of capacitance measurements, plotted in Fig. 4 as a function of the anodization voltage, reveal that the inverse capacitance is not a linear function of the voltage which would be expected for a uniform composition of the dielectric. Especially the inverse capacitance of the dielectric film formed on Ta_2N films shows a large deviation from linearity at higher voltages. But the values for the dielectric formed on methane sputtered tantalum films also reveal a nonlinear dependence on voltage. Such a nonlinearity could be attributed to either a nonlinear dependence of the thickness of the dielectric with increasing voltage or a nonuniform distribution of the additives in the original film. Both possibilities have been investigated for the Ta_2N films and the results indicate that these two factors cannot be responsible for the nonlinearity of the inverse capacitance.

For all the Ta_2N films, anodized from 70 to 200v, the step height of the dielectric above the surface of the original Ta_2N film has been measured by Talysurf[3] and it was found to be a linear function of the anodization voltage. The factor for the increase in thickness was found to be $k_2(Ta_2N) = 11.9$ Å/v.

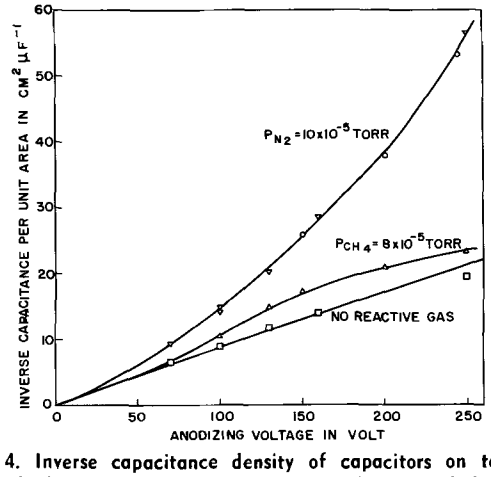

Fig. 4. Inverse capacitance density of capacitors on tantalum films with three different compositions as a function of the formation voltage.

Thus the total thickness of the dielectric formed on Ta_2N films per volt is then $k_3(Ta_2N) + k_2(Ta_2N) = k_1 = 16.7$ Å/v. Similar measurements for pure tantalum films yielded a value of $k_3(Ta) + k_2(Ta) = k_1 = 16.5$ Å/v. These values were used to determine the dielectric constant, ϵ, which is listed in Table III. The table also contains the film thickness of the original films before anodization. Since the anodic films formed on Ta_2N showed a systematic decrease in dielectric constant with increasing anodization voltage which might be due to a nonuniform composition of the Ta_2N, films with only half the original thickness have been anodized to intermediate voltages. The values of the dielectric constant of the anodic films formed on 2200Å Ta_2N films correspond closely with those found for the anodic films on thicker Ta_2N films. These results suggest that the decrease of the dielectric constant for the dielectric on Ta_2N films cannot be explained by a nonuniform distribution of nitrogen in the original film. It might be speculated, however, that the potential applied during anodization might cause migration of nitrogen ions. Such a migration might then result in a nonuniform distribution of the nitrogen in the dielectric.

It is not clear at present whether the increase of the dielectric constant with anodizing voltage obtained for anodic films on pure tantalum (Table III) is systematic and what its causes are. In addition, the average of the dielectric constant, 21.7, is considerably lower than the value reported by Young (19) which is widely used in the literature, but very close to the value recently obtained by Klerer (10).

Finally, the values for the decrease in thickness below the surface of the metallic film, k_2V_A, and the total thickness of the oxide, $(k_2 + k_3)V_A$, have been used for determining the density of the anodic films formed on pure tantalum and Ta_2N films. The density was calculated by combining Eq. [3] and [4]

$$\rho_{Ta_2O_5} = \frac{M_{Ta_2O_5}}{A \cdot (k_2 + k_3) \cdot V_A} \quad [3]$$

$$\rho_{Ta} = \frac{M_{Ta}}{A \cdot k_2 V_A} \quad [4]$$

to Eq. [5]

$$\rho_{Ta_2O_5} = \frac{M_{Ta_2O_5} \cdot k_2}{M_{Ta} \cdot (k_2 + k_3)} \cdot \rho_{Ta} \qquad [5]$$

where ρ is the density, M is the mass (which can be replaced by the molecular weight in Eq. [5], V_A is the anodizing voltage, and A is the area of the anodized film which both can be eliminated. The resulting value of 8.12 g/cm³ for the density of the Ta_2O_5 formed on pure tantalum is in good agreement with those found by Young (19) and Klerer (10).

For the calculation of the density of the dielectric on Ta_2N films it has been assumed that the dielectric has the stoichiometric composition Ta_2O_5N yielding a density of 5.30 g/cm³. But even if the anodic film contains a nitrogen concentration which is larger or smaller, it would have only a small effect on the molecular weight and, therefore, would change the density of the dielectric very little. Thus the presence of nitrogen in the dielectric formed on Ta_2N appears to result in a structure considerably less dense than that of Ta_2O_5 formed on pure tantalum.

Frequency and temperature characteristics.—The capacitance and the dissipation factor of a number of typical capacitors have been measured at frequencies between 0.1 and 10 kc. The results are summarized in Fig. 5. Since tantalum oxide belongs to a category of dielectrics which show only a small dependence of the dielectric loss on frequency up to very high frequencies, the dissipation factor of the dielectric itself and the loss due to the series resistance of the tantalum film can be separated according to the following equation (20)

$$\tan \delta = \tan \delta' + \omega C R_2 \qquad [6]$$

Where tan δ' is the frequency independent dissipation factor of the dielectric, ω is the angular frequency, C is the capacitance, and R_2 is the series resistance of the tantalum film and the counter electrode.

If the dissipation factor, tan δ, obeys this equation, then when tan δ is plotted against frequency as shown in Fig. 5, tan δ' should predominate at low frequencies and tan δ will vary little with frequency. At higher frequencies ωCR_2 will predominate and the curve will approach a 45° slope. The capacitors made from pure tantalum films appear to fulfill this expectation. There is little change in tan δ from 0.1 to 1 kc, and above 5 kc the curve approaches a 45° slope indicating predomination of ωCR_2. With increasing oxygen concentration, this term predominates at lower and lower frequencies suggesting a steady increase of the R_2 values. An analysis of the data shows that R_2 increases from 8.5 to 810 ohms while tan δ' decreases from 0.0051 to 0.0030 as the partial oxygen pressure used in sputtering is increased to $1x10^{-4}$ Torr. The capacitors made from nitrogen sputtered tantalum films have the lowest tan δ' values.

The R_2 values of the methane sputtered film are even lower than the value of the pure tantalum film although its specific resistivity is six times higher, and the film thickness is the same. The low R_2 value and the initial decrease of tan δ (Fig. 5) probably indicate that tan δ' is dependent on frequency and that the present model is too simple for describing the frequency dependence of tan δ for these films. The capacitors made from carbon containing tantalum films are the only ones showing such a behavior.

The changes in capacitance in the frequency range are between 0.59 and 1.19%, except for the capacitors formed upon oxygen containing tantalum films. They reveal a larger decrease in capacitance at higher frequencies, especially those on films sputtered at $8x10^{-5}$ and $10x10^{-5}$ Torr of oxygen.

Figures 6 and 7 show how the reduced capacitance and dissipation factor of a number of capacitors change with temperature. The measurements were carried out in a dry atmosphere in order to eliminate the influence of moisture on these properties (11). For control purposes the measurements were made while increasing the temperature as well as while decreasing it.

The capacitors fabricated on pure tantalum films (sputtered without deliberate addition of a reactive gas) show the largest changes (Fig. 6). The temperature coefficient of capacitance for these capacitors in

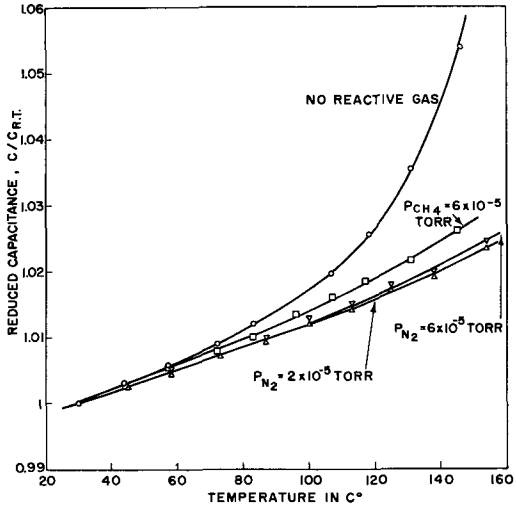

Fig. 6. Capacitance ratio as a function of temperature for capacitors formed on reactively sputtered tantalum.

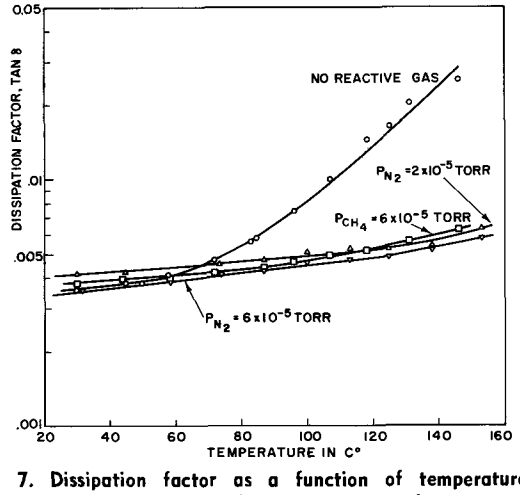

Fig. 7. Dissipation factor as a function of temperature for capacitors formed on reactively sputtered tantalum.

the range of a linear dependence of the capacitance on temperature, up to 60°C, is 220×10^{-6}/°C, below the value reported for tantalum thin film capacitors (8). Between 100° and 150°C these capacitors display a more rapid change with temperature. The capacitors made from reactively sputtered films (containing nitrogen and carbon) have smaller temperature coefficients, between 170×10^{-6} and 190×10^{-6}/°C, and the linear dependence of the capacitance on temperature holds up to higher temperatures. The capacitors made from pure tantalum films also show the largest change in the dissipation factor with temperature which is about an order of magnitude for the temperature range (Fig. 7). The temperature dependence of tan δ is much smaller for the capacitors made on reactively sputtered films.

Conclusions

One of the important results of the present investigation is the observation that the presence of interstitial oxygen, nitrogen, carbon, and hydrogen atoms does not interfere with the formation of anodic films on tantalum when it is deposited by reactive sputtering. The presence of Ta_2C in the tantalum film, however, results in a varied oxide growth so that the anodic film does not show a uniform interference color but rather displays a spectrum of interference colors. The dielectric strength of these anodic films is an order of magnitude lower. Further increase in carbon concentration, when the structure of the films is that of Ta_2C or TaC, inhibits the formation of anodic films in 0.01% citric or 0.01% nitric acid. In the case of the nitrogen containing tantalum the anodic films formed on Ta_2N still show uniform and bright interference colors and the dielectric strength remains high. It does not begin to decrease until the Ta_2N films become mixed with a considerable amount of TaN. There is an anodic reaction in citric acid even for TaN films but the resulting anodic film on TaN has very low dielectric strength. The capacitance density of the anodic films on carbon and nitrogen containing tantalum films decreases with increasing atomic concentration of these additives in the tantalum to less than 50% compared to that of anodic films on pure tantalum. The cause for this decrease in capacitance for nitrogen containing tantalum films could be attributed to a lower dielectric constant of the anodic film. The dielectric on tantalum nitride films also shows a much lower density than that of Ta_2O_5 and its stoichiometric composition can probably be best described as $Ta_2O_5N_x$ where the upper limit for x remains to be determined by analytical techniques. More experimental data are also required for the determination of the dielectric constant and the density of anodic films formed on carbon containing tantalum.

Acknowledgment

The x-ray diffraction analysis of the tantalum films by Mrs. M. H. Read and the Talysurf measurements of film thicknesses by R. Brown are greatly appreciated.

The Effect of the Concentration of Hypophosphite Ion on the Magnetic Properties of Chemically Deposited Co-P Films

J. S. Judge, J. R. Morrison, and D. E. Speliotis

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Samples of electroless cobalt phosphorus films of various thickness in the region less than 3000Å were prepared from solutions containing different concentrations of hypophosphite ion. These samples were analyzed by x-ray fluorescence and their magnetic characteristics were studied. The per cent phosphorus in the films was found to increase approximately logarithmically as the concentration of hypophosphite was increased. The plating rate increased concomitantly. The saturation magnetic moment and the coercivity were found to depend strongly on the phosphorus content of the films. The coercivities of these films also have a strong dependence on thickness. To a large extent the interaction of these two physical properties of the film determine the magnetic properties observed.

The magnetic properties of films of chemically deposited cobalt-phosphorus have been investigated several times in the past. Fisher and Chilton (1) have reported the preparation of high coercivity deposits as possible media for magnetic recording. The present authors have shown that somewhat thinner deposits exhibit superior recording performance and have reported on their magnetic properties (2, 3). Ransom

$(NH_4)_2$ SO_4	0.307M

pH = 8.3 (at 85°C)—adjusted with NH_4OH
Temperature = 85°C

and Zentner (4) have shown that low coercivity uniaxial deposits of electroless cobalt can be prepared under somewhat different conditions of deposition. In short, the magnetic properties of chemically deposited cobalt-phosphorus films are critically dependent on the conditions of preparation. The magnetic properties of these deposits are a complicated function of the phosphorus content, crystallite size, and orientation of the deposits which in turn are controlled by the deposition variables, primarily solution composition, pH, and temperature. In this investigation we have restricted ourselves to a study in some detail of the effects of one of the more important variables in solution composition, the concentration of hypophosphite ion.

Preparation

The films were deposited on Mylar[1] substrates which were presensitized with the usual $SnCl_2$-$PdCl_2$ treatments (5). Prior to this, the Mylar substrates had been rendered hydrophilic by immersion into a hot chromic-sulfuric acid solution and then a hot sodium hydroxide solution (6). The composition and condition of the solution used for the deposition are shown in Table I. This solution is similar in composition to that used by Ransom and Zentner for the deposition of low coercivity uniaxial films, except that it is operated at a significantly higher pH. The agitation during deposition was kept at a minimum, merely sufficient to assure temperature and concentration uniformity.

The weight of cobalt and phosphorus deposited was determined by x-ray fluorescence analysis. The amount of phosphorus codeposited was found to be independent of deposit weight, as shown in Fig. 1. However,

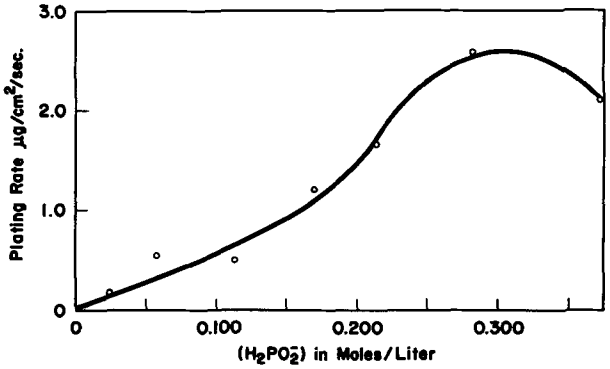

Fig. 3. Plating rate vs. $(H_2PO_2^-)$

above deposit weights of ~ 200 μg/cm², or approximately 2500Å in thickness, there was a tendency for the phosphorus content to decrease with increasing thickness. Since such deposits would tend to exhibit a trend in composition with thickness, these were not included in this study. Consequently only deposits of less than ~ 2500Å were considered. Fortunately it is in this thickness region that the most interesting magnetic behavior is exhibited.

The average phosphorus content for the deposits at each concentration of hypophosphite ion was determined from the slope of such plots as shown in Fig. 1. The dependence of the per cent phosphorus on the hypophosphite content of the solution is shown in Fig. 2. It is apparent that the phosphorus content of the deposits increases as the hypophosphite content of the solution increases. Moreover, there is apparently an approximately logarithmic relationship between the two. Figure 3 shows the dependence of the plating rate on the hypophosphite content of the solution. The rate increases monotonically to ~ 0.3M in hypophosphite and then exhibits a slight decrease as the hypophosphite concentration is further increased. This effect is similar to electroless nickel deposition where an optimum ratio of metal ion to hypophosphite ion exists for maximum deposition rate.

Crystallographic Properties

X-ray diffraction indicated that all deposits were predominantly hexagonal cobalt. The crystallite size of the deposits was estimated from x-ray line broadening. Such estimates gave values in the range 200-1000Å. However, the crystallite sizes so obtained showed no correlation with thickness, phosphorus content, or magnetic properties. In order to obtain significant peaks for x-ray diffraction, it was necessary to use several samples stacked together. This would be expected to produce additional line broadening. In addition, deposit stresses and stacking faults will contribute to the line broadening. Consequently these estimates of crystallite size are in reality the lower limit of the crystallite size in these deposits. All deposits exhibited a preferred orientation of the C-axis in the

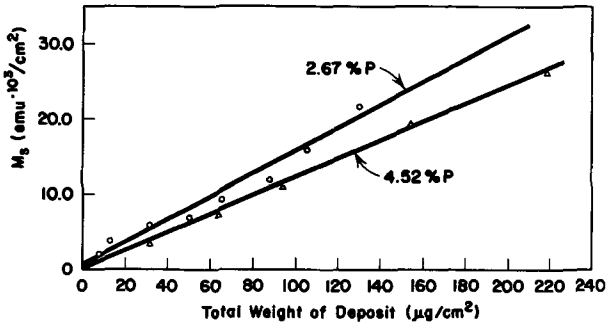

Fig. 4. Dependence of the saturation magnetic moment on deposit weight.

Table II. Values for various phosphorous contents

% P	σ_s emu/gram
2.67	156.0
2.62	147.5
3.45	114.0
3.81	118.0
4.06	120.5
4.22	127.5
4.52	122.5

plane of the substrate. However, a higher degree of orientation was exhibited by the higher phosphorus deposits. Unfortunately it was impossible to obtain an estimate of orientation on deposits of less than ~ 500Å in thickness.

Magnetic Properties

The saturation magnetic moment of the deposits was measured by a Faraday type magnetic balance in a field of 6000 oe. The moments so obtained were found to be independent of deposit thickness. This fact is illustrated by Fig. 4 which is a plot of the magnetic moment *vs.* deposit weight for the two extremes of phosphorus content. The saturation magnetic moment per gram (σ_s) of the material was calculated from the slopes of such plots. Table II illustrates the values so obtained for the various phosphorus contents. At the lowest per cent P the highest values of σ_s are observed. A decrease as the per cent P is increased would be expected whether the phosphorus merely acted at a dilutant or entered in chemical combination with some of the cobalt. However, the observed decrease is not monotonic with increasing per cent P, but exhibits a minimum at ~ 3.5% P.

Measurement of the hysteretic properties of the deposits were made in a vibrating sample magnetometer with a maximum field of approximately 10,000 oe. The squareness (*i.e.*, the ratio of the remanent magnetic moment to the saturation magnetic moment) showed no clear trends with thickness, but the average value decreased from 0.83 to 0.70 as the phosphorus was increased from 2.6 to 4.5%.

For the two lowest phosphorus contents the dependence of the coercivity of the deposits on deposit weight or thickness is shown in Fig. 5. Both of these series had very near the same per cent P, 2.62 and 2.67%. In both cases the coercivity drops as the weight increases from ~ 1100 oe at a deposit weight of ~ 15 $\mu g/cm^2$ approaching a constant value of ~ 300 oe for large deposit weight. Figure 6 is a similar plot for the remaining series of higher per cent P. At 3.45% P a slight maximum begins to appear in the coercivity at ~30 $\mu g/cm^2$. As the per cent P is increased beyond this, the maximum begins to shift out in thickness until at 4.5% P the coercivity appears to increase with increasing weight over the entire weight range. The heights of these maxima, however, are decreasing with increasing per cent P. These points are clarified in Fig. 7 where the value of H_c at the peak and the weight of deposit at which the peak in H_c occurs has been plotted against the per cent P. The value of (H_c) peak drops from ~ 1200 oe at 3.5% P to 650 oe at 4.5% P. Meanwhile, the deposit weight at which the maximum occurs increases from < 20 $\mu g/cm^2$ for the low P deposits to > 200 $\mu g/cm^2$ for the 4.5% P deposits. Since the deposits with the least phosphorus did not exhibit a maximum in H_c for even the thinnest deposits measured, the actual (H_c) peak and weight at the peak would probably be higher and lower respectively than those points entered which merely represent the highest H_c observed.

Figure 8 summarizes the effect of phosphorus content on H_c for constant deposit thickness. The thicknesses have been calculated assuming a density of 8.9 g/cm^3. For a given thickness the coercivity increases to a maximum and then falls as the % P increases. At a deposit thickness of 560Å a maximum coercivity of 1200 oe is reached at ~3.5% P whereas at 2250Å a maximum H_c of ~ 800 oe is reached at 4.2% P. The

intermediate thickness deposits of 1120Å reach an intermediate maximum of 1050 oe at an intermediate phosphorus content of 3.8%.

Discussion

The high coercivities observed for many of the samples of chemically deposited cobalt-phosphorus necessitate a single domain model to explain their magnetic properties. Assuming the phosphorus exists as the weakly magnetic Co_2P, 4% by weight of P would correspond to ~25% by volume of Co_2P. At any rate a significant proportion of the volume of these films consists of a nonmagnetic dilutant. A semi-particulate model is therefore reasonable for these films. The high magnetocrystalline anisotropy of cobalt, moreover, demands that these particles exhibit a strong uniaxial character. Consequently these films can be characterized qualitatively as a random (in the plane) assembly of interacting uniaxial particles. It has been shown by Reimer (7) that such a model leads to squarenesses higher than 0.64 (which would be expected for no interactions).

The energy loss in rotational hysteresis as a function of applied field was measured on a number of samples by means of a torque balance. Figure 9 is a plot of this energy, W_{Rot}, normalized for differences in magnetic moment *vs.* the reciprocal of the applied field. The values on the Y axis can be interpreted as the energy per magnetization jump times the number of particles involved. It is apparent that the low thickness low phosphorus sample shows a very narrow distribution of high field rotational processes consistent with its high coercivity. However, the low thickness, high phosphorus sample exhibits a large proportion of low field processes, again consistent with its low coercivity. Figure 10 shows the same results for much thicker films of low and high per cent P. With reference to the high phosphorus film, the distribution is now much sharper and apparently as the film has grown those particles exhibiting low field switching characteristics have disappeared. The low phosphorus film, on the other hand, now has its distribution shifted to much lower fields, indicating the appearance of low field processes as the film has grown.

Table III. Values for sample of three different per cent P

% P	Deposit wt (μg/cm²)	H_c (oe)	R	H_{pk} (oe)

	219	637	1.72	690

The value of the area under these curves has been shown to be characteristic of the mode of magnetization reversal. The theoretical values for the area (8) are (*a*) single-domain model, coherent rotation, 0.4; (*b*) single-domain model, incoherent rotation, 0.4 to 4.0; (*c*) domain wall, 4.0. In Table III the values of R, the area under the curve, are tabulated for samples of three different per cent P values. All values lie in the range 1.2-2.2 and exhibit no trends with thickness or per cent P. These values are consistent with a single domain model involving incoherent reversal, probably a magnetization buckling in the plane of the film. The value of the applied field at which the peak of the rotational hysteresis was observed is also tabulated in Table III. It can be seen that the value of this peak field decreases with increasing thickness in all cases. Figure 11 is a plot of the peak field *vs.* thickness for these samples. The peak field drops much more sharply as the thickness is increased for the low per cent P film than for those of higher phosphorus. Thus in the low per cent P films both the rapid decrease in peak field and especially the significant build up of low field processes as the thickness increases indicate a growth of particles out of the single domain size to particles large enough to support domain walls.

For the high per cent P films the peak field decreases and approaches the value of the coercivity as the thickness builds up and the low field processes disappear. This suggests that the thinner films have a significant portion of very small particles which exhibit a semi-superparamagnetic behavior. The particles grow as the film becomes thicker and enter the single domain size region. The greater the per cent P of the film, the greater is the thickness which must be reached before the contribution of these very small particles disappears. However, at the same time, because of the initial wide distribution of particle size in the higher per cent P films, some particles grow and enter the multidomain region causing a lowering of the maximum coercivity observed as the % P increases.

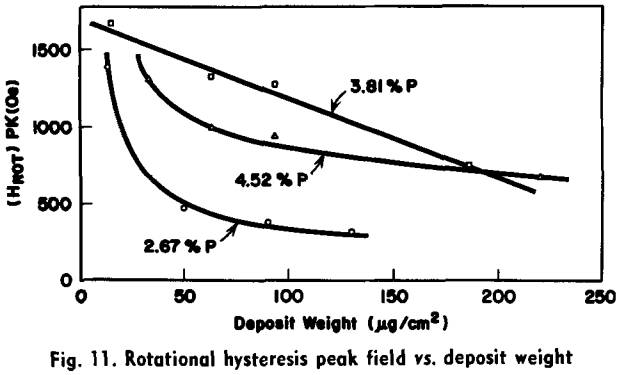

Fig. 11. Rotational hysteresis peak field *vs.* deposit weight

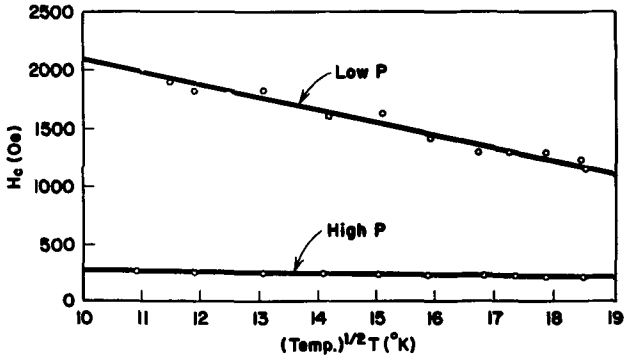

Fig. 12. Dependence of H_c on temperature for two thin deposits of different per cent P.

The temperature dependence of the coercivity of a selected number of these films was measured and the results for two of them are shown in Fig. 12. These particular samples are the thinnest samples of the low and high phosphorus films. The presence of near superparamagnetic particles should contribute a temperature dependence to the coercivity, such that H_c would be proportional to $-T^{1/2}$ if the anisotropy constants for the particles involved were independent of temperature (9). As shown in Fig. 12 the coercivity of these films is approximately proportional to $-T^{1/2}$. However, the low per cent P film shows by far the greatest temperature dependence.

Summary

Table IV summarizes the previous results for a selected number of samples. The temperature dependence of H_c is seen to be greatest for the low per cent P films. This appears to be in conflict with the postulate of less superparamagnetic behavior in these films. However, the uniaxial anisotropy constant for cobalt does increase ~50% in going to 77°K and this alone may be sufficient to account for the observed temperature dependence. All of the samples exhibit an orientation of the C-axis of cobalt in the plane of the film. The degree of orientation, however, is apparently greater for the higher per cent P films. In thin films in which the magnetization may be constrained, due to shape effects, to stay in the plane of the film, this orientation would lead to higher coercivity. However, the difference in orientations indicated here do not seem to play a large role.

Table IV. Summary of results for a selected number of samples

	Low P (2.6%)	Med P (3.8%)	High P (4.5%)
~t(Å)	150Å	180Å	350Å
$\frac{I(002)}{I(100)} \cdot N$	—	—	—
H_c	1000 oe	450 oe	200 oe
% increase of H_c at 77°K	70%	18%	22%
t(Å)	980Å	1070Å	1060Å
$\frac{I(002)}{I(100)} \cdot N$	0.54	0.23	~0
H_c	400 oe	1100 oe	400 oe
% increase of H_c at 77°K	53%	4%	14%
t(Å)	1460Å	2100Å	2460Å
$\frac{I(002)}{I(100)} \cdot N$	0.46	0.09	0.08
H_c	300 oe	700 oe	600 oe
% increase of H_c at 77°K	54%	24%	31%

In conclusion, we have shown that variation of the hypophosphite concentration of this plating solution causes concomitant variations in the plating rate and the per cent P of the resulting films. Below a thickness of ~2500Å the composition and magnetic moment density are independent of thickness. The hysteretic properties are a function of both thickness and per cent P. The study of the magnetic properties indicate that the high per cent P films have smaller particles at higher thicknesses than do the low per cent P films.

Gold Plating Directly on Molybdenum

R. M. Finne and W. R. Bracht

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A technique has been developed to electrodeposit gold directly on a molybdenum substrate without prior deposition of other metals. The electrodeposited gold films are adherent and protective against highly corrosive ambients. The process involves the formation of a porous oxide on the molybdenum substrate, deposition of gold into this oxide, and hydrogen reduction of the oxide. During the reduction of the oxide, the gold is mechanically trapped and the substrate in the vicinity of the molybdenum surface is converted to a two-component gold-molybdenum layer. This layer provides a suitable surface for further deposition.

Prior to the development of the technique described in this paper, it had not been possible to electrodeposit gold on molybdenum or molybdenum-manganese substrates to produce an adherent and highly protective coating. Previous techniques have generally depended on the deposition of a more active metal such as copper, nickel, or chromium prior to deposition of gold (1). For many applications, particularly in the semiconductor field, such predepositions are undesirable since they may subsequently diffuse into the gold and degrade its alloying characteristics, or may diffuse into a semiconductor and perturb its electronic

properties. Alternatively, techniques have been proposed which involve the deposition of thin layers of gold followed by heat-treatment in non oxidizing ambients to form alloyed surface regions (2). Attempts to deposit gold directly on molybdenum by employing such standard electroplating techniques together with heat treating have not, in general, yielded acceptable results. This is because of the critical nature of certain preparatory steps in the process. By insuring the formation of a porous oxide on the molybdenum surface, depositing gold into this oxide and reducing the oxide to trap the gold, it has been possible to gold plate directly onto the molybdenum sample.

Apparatus and Materials

The electrodeposition apparatus and materials used were essentially standard in nature, and both still and barrel plating proved suitable. A typical bath construction was as follows: polypropylene tank, quartz immersion heaters, and gold anodes in an anode to cathode area ratio in excess of four to one. The acid citrate gold bath was prepared by mixing 20 ± 1g of sodium gold cyanide (71% gold) and 100 ± 1g of diammonium citrate and water to make one liter of solution. This was then boiled in a hood for 30 min to convert the cyanide gold complex to the citrate complex with the accompanying evolution of HCN. The bath was operated at a current density of 49 ma/in.^{2} at 60°C, and deposited 0.93 mg/cm^2/min. Both acid citrate and alkali cyanide solutions were used successfully.

Substrates used in the initial work were both machined molybdenum studs and molybdenum-manganese films which were silk-screened onto ceramic surfaces. Subsequent work has been done with a great variety of sample shapes and sizes.

Method

Figure 1 shows a schematic flow diagram for the plating method. The following is a description of the optimum procedure developed for our samples.

1. Initial degreasing of the substrates in trichloroethylene.
2. Fire in dry hydrogen (< 2 ppm H_2O) at 1000°C for approximately 10 min. (In no case were the samples passed through the flame curtain on the oven.)
3. Immerse in a solution of four parts NH_4OH (28%) to one part H_2O_2 (30%) for approximately 8 sec at room temperature.
4. Wash in deionized water.
5. Gold strike to deposit 0.15-0.62 mg/cm^2.
6. Wash in deionized water.
7. Fire in dry hydrogen (< 2 ppm H_2O) at 900°C for approximately 10 min.
8. Electrodeposit gold to the final desired thickness (~ 15 mg/cm^2).

Evaluation

The electrodeposited gold was tested for substrate protection against gaseous and liquid ambients, and for adherence to the substrate.

Protection against gaseous ambients was evaluated by exposure of the sample to wet hydrogen at 600°C for 1 hr. Protection against liquid ambients was evaluated by immersion of the sample in a 5 part HNO_3 (70%) —1 part HF (48%) solution at room temperature. The presence of blistering, peeling, or cracking on the sample when viewed under ten power magnification was considered evidence of unsatisfactory plating.

Nonadherence of an electrodeposited gold film would, in all probability, be made evident by a blistering of the coating during the testing described above. However, to test adherence further, a silicon wafer 30 mils in diameter was alloyed to the plated sample and the alloyed wafer was subjected to a shearing force of 9500 psi. If the wafer pulled gold from the substrate, the plate was considered unsatisfactory.

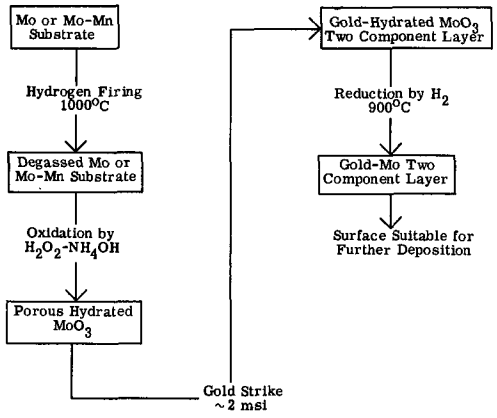

Fig. 1. Flow chart of the optimum processing steps

Discussion

Initial attempts to gold plate directly on molybdenum surfaces resulted in either nonadherent plates or plates which would not survive exposure to corrosive ambients. The substrates were carefully cleaned so that it was not a case of failure caused by surface contamination. These molybdenum samples (20 mils thick) were degassed at 1200°C for 1 hr in a vacuum of 10^{-6} Torr, but were unsatisfactory after plating. We therefore concluded that gassing was not the main problem. Since it is well known that molybdenum forms oxides such as MoO_3 which are stable at low temperatures, we postulated that such oxides were forming a barrier between the gold plate and the molybdenum surface.

Since gold and molybdenum form no alloys, and the solubility of each in the other is negligible (3), it is not possible to form a two-component phase by heating a gold plated molybdenum sample below its melting point. Since gold does not react with molybdenum oxide, chemical bonding cannot occur at the gold plate-substrate interface. Such mechanisms may be instrumental in the formation of satisfactory electrodepositions with metals such as copper, nickel, and chromium.

Instead of attempting to remove the nonporous oxide immediately prior to plating, the technique which was evolved makes use of a porous oxide which is generated on the molybdenum surface by aqueous oxidation. Plating solutions can permeate this type of molybdenum oxide and are deposited in the oxide during the strike. Reduction by hydrogen follows, which converts the molybdenum oxides to molybdenum, physically trapping the gold in a molybdenum matrix. This two-component layer is then suitable for further plating.

The postulated roles played by the significant processing steps are as follows:

1. The firing of dry hydrogen prior to plating serves two purposes: first, it reduces surface oxides; second, it degasses the surface. The temperature of this firing exceeds that of any subsequent processing step.
2. The treatment with ammoniacal peroxide solution forms a porous oxide on the substrate. The major reaction proceeds as in Eq. [1].

$$Mo + 3H_2O_2 \rightarrow MoO_3 \cdot xH_2O + (3-x)\ H_2O \qquad x = 1, 2 \qquad [1]$$

This oxide dissolves in the ammonium hydroxide forming ammonium molybdate as in Eq. [2].

$$MoO_3 \cdot xH_2O + 2NH_4OH \rightarrow (NH_4)_2MoO_4 + (x+1)H_2O \qquad x = 1, 2 \qquad [2]$$

This etching action forms a fresh surface which reacts to form a porous, hydrated oxide.

3. The gold strike solution permeates the oxide structure.

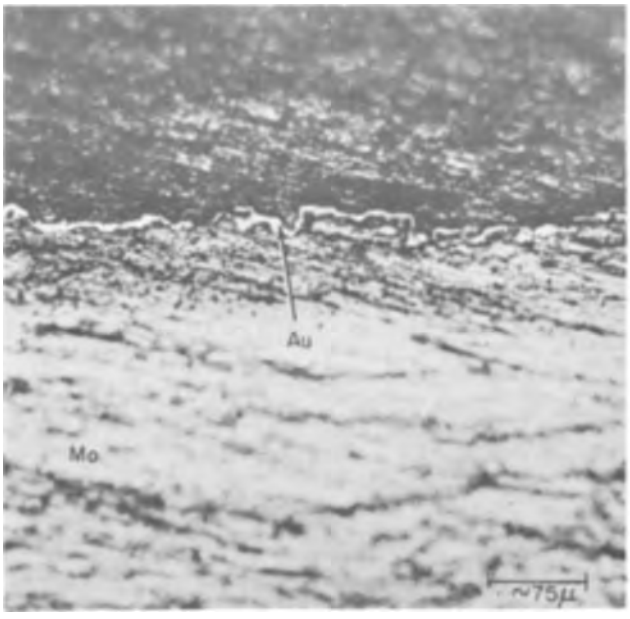

Fig. 2A. Thermally oxidized sample, angle lapped. Magnification *ca.* 170X.

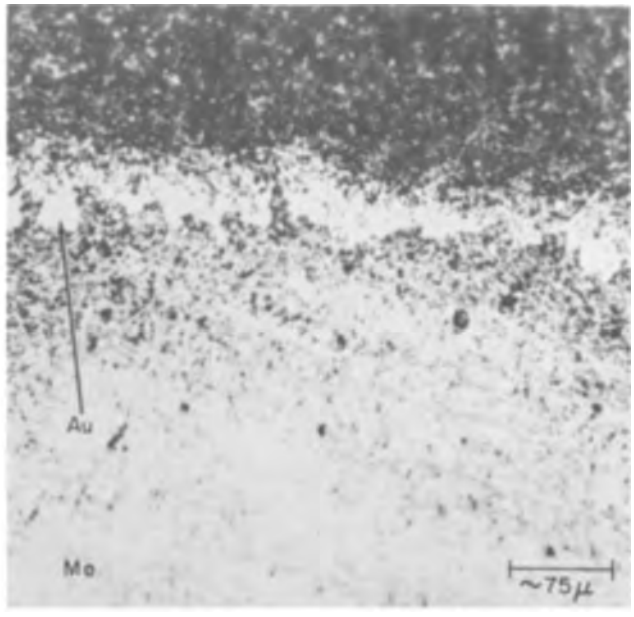

Fig. 3A. Chemically oxidized sample, angle lapped. Magnification *ca.* 170X.

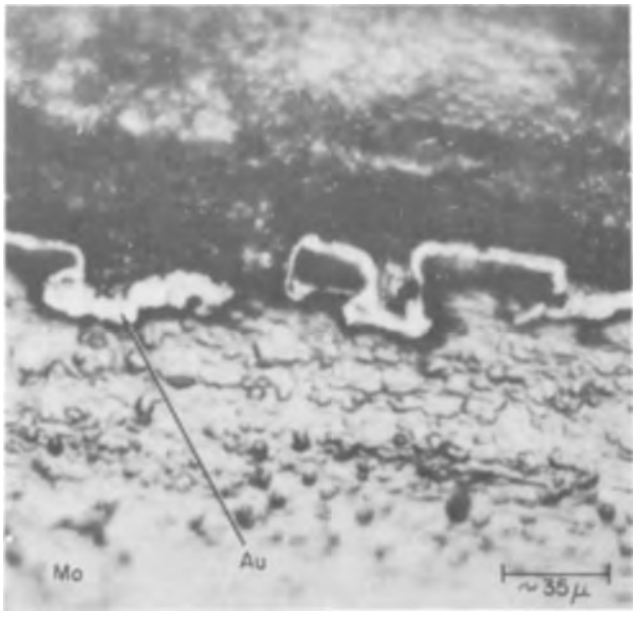

Fig. 2B. Thermally oxidized sample, angle lapped. Magnification *ca.* 670X.

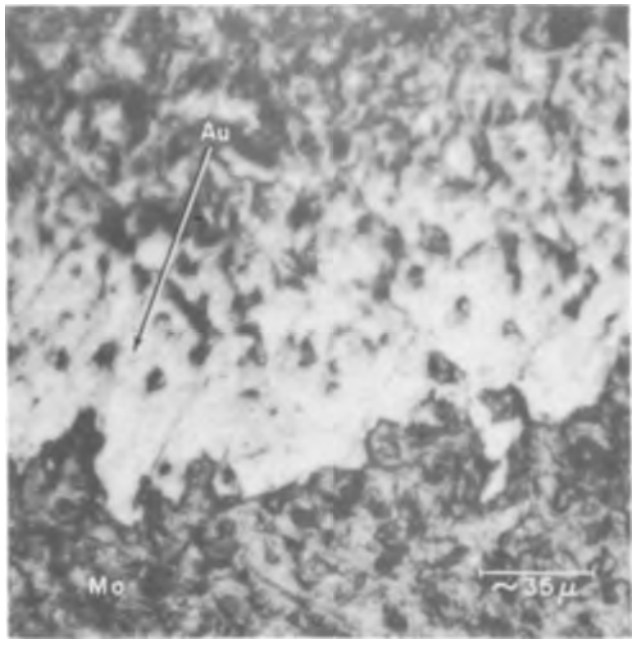

Fig. 3B. Chemically oxidized sample, angle lapped. Magnification *ca.* 670X.

4. The firing in dry hydrogen subsequent to the gold strike reduces the molybdenum oxide to molybdenum as in Eq. [3].

$$MoO_3 \cdot xH_2O + 3H_2 \rightarrow Mo + (3 + x)H_2O \qquad [3]$$
$$x = 1, 2$$

This creates a two-component region at the surface of the substrate which is suitable for further plating by routine techniques.

In order to verify the critical postulated roles, several experiments were performed.

Firing.—The initial hydrogen firing of step two was eliminated from the processing. The resulting samples blistered on heating, predominantly at the corners and edges. This is often characteristic of gassing. From this we may infer that step two is instrumental in degassing the substrate.

In addition, argon was substituted for hydrogen and the final results were satisfactory. This implies that the process is a thermal one and does not depend on the chemical nature of the heating ambient.

Oxidation.—A thermal oxidation was substituted for the ammoniacal peroxide treatment. All plated parts failed the tests. The results of metallographic sectioning and angle lapping are shown in Fig. 2 and 3. In the case of the thermal oxide, the electrodeposited gold appears to rest on the surface of a thin oxide layer. In the case of the chemically produced oxide, the electrodeposited gold appears to have penetrated into the oxide.

In addition, electron micrographs were taken of the oxide surfaces. Figures 4 and 5 show the results for the two types of oxide described. The chemical oxide appears to have a cellular, porous structure while the thermally grown oxide appears to be smooth and continuous.

Strike.—The gold strike was increased in thickness which resulted in an increased porosity of the electrodeposited film. This may be due to the formation of a relatively continuous layer of gold over the gold-permeated oxide. Such a continuous layer might inhibit the reduction of the oxide which takes place in

the following step. It appears desirable, therefore, not to provide complete surface coverage by the strike.

Reduction.—The hydrogen reduction after the strike was eliminated from the process. This resulted in non-adherent electrodepositions. Also, a lowering of the firing temperature produced an increase in the porosity of the gold plate. This step is essential to the process.

Variations in the processing are possible. For example, molybdenum samples which had a large surface to volume ratio and which appeared to be without surface oxide on delivery were processed successfully without the use of the hydrogen firing prior to the gold strike.

Fig. 4. Chemical oxide, electron micrograph, replica. Magnification *ca.* 23,330X.

Fig. 5. Thermal oxide, electron micrograph replica. Magnification *ca.* 23,330X.

Fig. 6. Oxide formed with NH_4OH, electron micrograph. Magnification *ca.* 6700X.

Fig. 7. Oxide formed with H_2O_2, electron micrograph. Magnification *ca.* 6700X.

Fig. 8. Oxide formed with H_2O, electron micrograph. Magnification *ca.* 6700X.

This same type of sample was also successfully processed with the substitution of water for the ammoniacal peroxide solution in step three. However, this can only be done with samples which do not require the removal of surface layers for cleaning. Attempts to use only NH_4OH (28%) were successful, but attempts to use H_2O_2 (30%) only were not. Figures 6, 7, and 8 show electron micrographs of the oxide surfaces of samples processed in NH_4OH (28%), H_2O_2 (28%), and water. It can be seen that the cellular structures formed by water, ammonium hydroxide, and the ammoniacal peroxide solution are similar whereas the hydrogen peroxide solution appears to attack the surface more vigorously and produces an extremely rough oxide. This rough surface is apparently not satisfactory for further plating.

This process has also been used on molybdenum-manganese films deposited on ceramics. In this case, the time of the oxide formation step is critical since excessive removal of the thin metal film is undesirable.

Conclusion

The process described can be used to electrodeposit gold on molybdenum and molybdenum-manganese substrates without the use of preplates of other metals. Essential steps in the process are:

1. Formation of a porous molybdenum oxide.
2. Permeation of the oxide with gold, without forming a continuous gold layer over the oxide surface.
3. Reduction of the oxide, which traps the gold in the molybdenum lattice and forms a two-component layer on the surface.

The electrodeposited gold films produced by this process are adherent and protective, and have been plated to thicknesses of over one mil using both still and barrel plating.

Protection of Steel from Hydrogen Cracking by Thin Metallic Coatings

I. Matsushima and H. H. Uhlig

Corrosion Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Cold rolled and stress relieved 0.5% carbon steel specimens electroplated with Ni, 0.50-2.5μ thick and bent to the test span after plating are especially resistant to hydrogen cracking when polarized cathodically in dilute sulfuric acid saturated with As_2O_3. Arsenic or an As compound deposits cathodically on the Ni coating which supplements protection by Ni alone. The dual coating is also effective in the presence of additives to H_2SO_4, such as thiourea, which normally accelerate occlusion of hydrogen by steel. The critical hardness value of steel below which some degree of protection is achieved by Ni + As coatings is about Rockwell C 35. Ni coatings alone are protective against sulfide cracking when cathodically protected in 6% NaCl-0.5% acetic acid, saturated with H_2S. The mechanism of protection is apparently one of altering the kinetics of H^+ discharge, resulting in less occlusion of hydrogen by steel. Accordingly, such coatings to be protective need not be continuous.

Limited data have been reported previously on the protective quality of metallic coatings on steel exposed to environments which generate hydrogen by a corrosion reaction, thereby leading to hydrogen cracking (1,2). Still less information is available on the relative effect of such coatings under conditions of continuous polarization which provides cathodic protection to the coating and avoids damage to it by corrosive attack. This situation deserves study both because it leads to a better understanding of the mechanism of protection by coatings and also because it suggests practical means of protecting susceptible steels against damage. This is the subject of the present paper. The problem has become much more important in recent times be-

cause of increased use of high-strength steels which are exposed to many different environments, some of which induce hydrogen cracking.

Probably the most significant data bearing on this problem were presented by Freiman and Titov (3). They measured diffusion rates of hydrogen through Armco iron sheets 0.17 mm thick, cathodically polarized in H_2SO_4 to which $NaAsO_2$ was added. A thin coating of Cu, Sn, Pb, or Ni applied to one side of the sheet effectively slowed down entrance of hydrogen into the iron when H^+ discharged on the coating. Nickel coatings only 0.1-2.5μ (0.004-0.1 mil) thick were especially effective whereas Pb coatings to be similarly effective had to be 10μ (0.4 mil) thick. There was little or no difference in diffusion rates for any of the coatings when H^+ discharged on the iron surface and occluded hydrogen diffused subsequently through the metallic coating.

Tardif and Marquis (4) cathodically charged 0.06% C steel sheet 0.38 mm thick in 2% NaOH at 40°C. They measured diffusion rates of hydrogen through the coated steel and also measured the fracture tendency of the steel after it had been polarized, employing a special deformation test. All coatings, *e.g.*, Cr, Au, Au-Ni, Ni, Cu, Pb, Cd, and Al, except for Zn and Mg, were beneficial to some extent in retarding entry of hydrogen into the steel.

Experimental

The base steel on which coatings were applied was a commercial 1055 steel (0.52% C, 0.81% Mn, 0.01% P, 0.01% S) cold reduced 50% and stress relieved in a salt bath at 400°C for 3 hr. The rolling direction was parallel to the longest dimension. Stress relief heat-treatment was chosen to prolong normal cracking time and thereby improve reproducibility of the present tests from an average of 6 min for the cold-rolled steel to 42 min for the stress-relieved steel. For some experiments, the steel specimens were quenched from 925°C and tempered at various temperatures up to 500°C in a salt bath for 1 hr. Above 500°C specimens were sealed in evacuated Vycor capsules and heated in a furnace for 1 hr. Specimens, as sheared to size, measured 1¾ x 3/16 x 0.041 in. (4.5 x 0.48 x 0.10 cm). After shearing they were abraded to a final No. 0 emery paper which removed approximately 1 mil of all 6 surfaces. They were then degreased in boiling benzene, pickled in 5 v/o HNO_3, 95°C for 1 min, washed, immersed in acetone, and dried in a warm air blast. Specimens were subsequently plated and then bent to the proper span for testing.

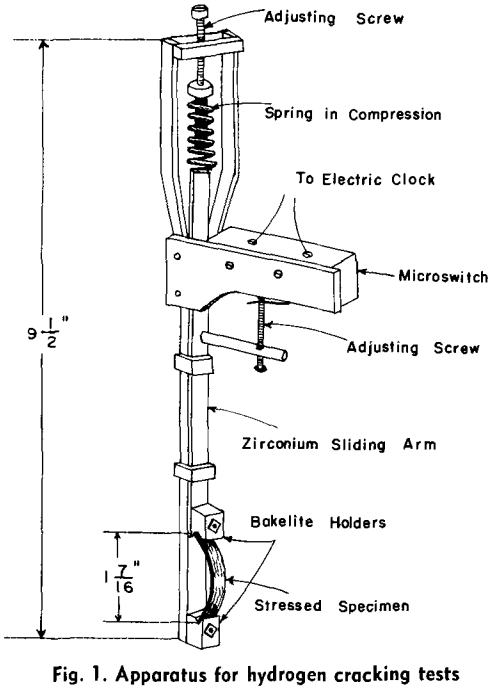

Fig. 1. Apparatus for hydrogen cracking tests

The test apparatus depicted in Fig. 1 was arranged so that specimens under constant spring load were polarized cathodically at 24 ma/cm^2 in 5% H_2SO_4 saturated in most cases with As_2O_3 at room temperature. Failure by cracking tripped a switch connected to an electric clock. That portion of the test apparatus in contact with the electrolyte was constructed of commercial Zr[1] to avoid corrosion. The insulated specimen itself was cathodically protected by the prevailing cathodic current. Specimens were bent beyond the elastic limit to an initial span of 1⅝ in. (4.1 cm), then transferred by means of a metal holder to the notched Bakelite insulators of the test apparatus. A compression spring was adjusted until the final span of the specimen was 1-7/16 in. (3.65 cm), carefully avoiding springback. A nickel wire, previously spot welded to one end of the test specimen, was attached to the negative terminal of a rectifier; the positive terminal was connected to an auxiliary Pt electrode immersed in the electrolyte contained in a 250-ml beaker. Tests were carried out a maximum of 200 hr, lack of failure within this time representing appreciable resistance to hydrogen cracking. Susceptible specimens commonly cracked within a fraction of an hour. For long runs, distilled water and As_2O_3 were added to the electrolyte every 24 hr.

Some tests were carried out in 6% NaCl-0.5% acetic acid saturated with H_2S at room temperature. For those tests, specimens were bent to the usual span and mounted in simple holders of Bakelite. They were placed in a 5-liter glass desiccator vessel and totally immersed in the test solution. Specimens were examined visually for cracks without removing them from the container.

Coatings, when applied, were electrodeposited to a thickness of 0.01-0.5 mil (0.25-12.7μ) as determined by weight gain. Nickel electrodeposits employed a $NiSO_4$-NH_4Cl-boric acid bath, lead coatings a fluoride-boric acid bath, copper coatings a cyanide bath, iron coatings a ferrous sulfate bath, cobalt coatings a cobalt sulfate-boric acid bath, and arsenic coatings a sodium cyanide-As_2O_3 bath. A few specimens were coated with electroless Ni (5).

Results

Cracking times of coated steel specimens are summarized in Table I. Lead coatings were relatively effective if the thickness was at least 0.1 mil, and copper coatings were similarly effective at 0.5 mil. Nickel coatings of 0.5 mil thickness, on the other hand, cracked when the specimen was bent preparatory to testing; such specimens subsequently failed in the H_2-cracking tests. Surprisingly, however, thinner Ni coatings which did not visibly crack afforded protection for a thickness of only 0.02 mil. This thickness seems also to coincide with marked reduction in porosity of the coating as shown by data of Fig. 2. A measure of

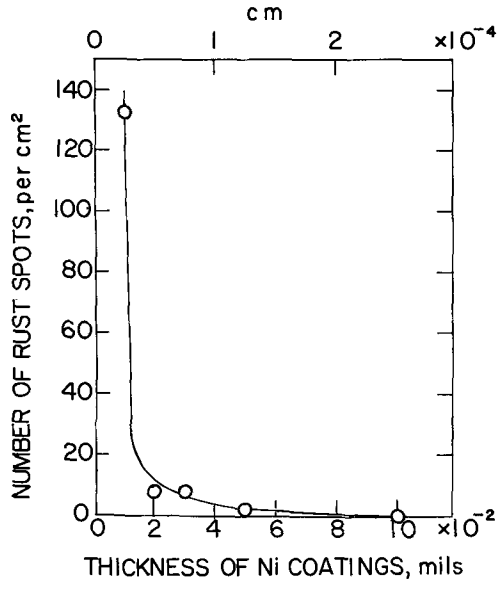

Fig. 2. Porosity of nickel coatings as a function of thickness

porosity was obtained by counting under the microscope the number of rust spots per unit area after immersing specimens horizontally for 10 min in 3% NaCl + 1.5% by volume of 30% H_2O_2. It is unlikely that any of the Ni coatings were truly pore free, so that the protective mechanism of thin Ni coatings probably depends on a critical area ratio of Ni to exposed Fe at pores. This unusual protective quality of Ni coatings prompted a more detailed study of their properties.

The next attempt was to protect a quenched martensitic 1055 steel (Rockwell hardness = C 64), which, compared to the stress relieved cold-rolled material (C 31), is much more sensitive to hydrogen cracking. Uncoated quenched specimens cracked prematurely on bending; tempered at 300°C for 1 hr (C 51) they could be bent but, subsequent to bending, they suffered H_2 cracking within 1/3 min. Data for various tempering temperatures are summarized in Fig. 3. Here it is noted that the quenched steel, tempered subsequently at 300° or 400°C, cracked in very short time whether or not a thin coating of nickel covered the surface. However, at higher tempering temperatures, beginning at 450°C (Rockwell hardness = C 35), the nickel-coated specimens were appreciably more resistant than the uncoated specimens. Since hardness of the steel decreases with increasing tempering temperatures accompanied by decrease in susceptibility to hydrogen

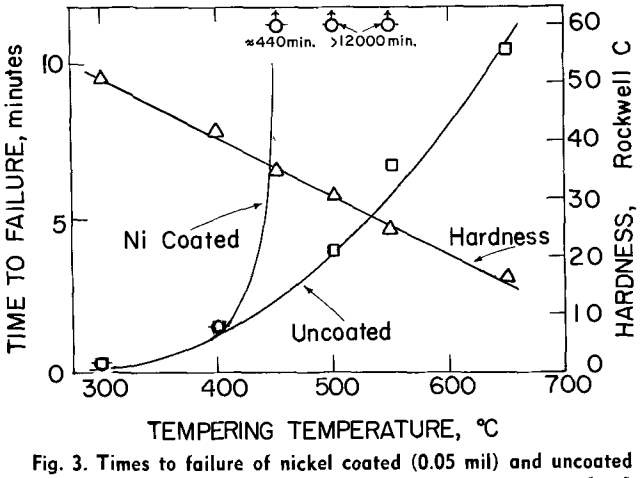

Fig. 3. Times to failure of nickel coated (0.05 mil) and uncoated quenched AISI 1055 steel tempered at various temperatures for 1 hr, 5% H_2SO_4 + As_2O_3 (saturated), 24 ma/cm², room temperature.

Table II. Effect of various catalyst poisons in 5% H_2SO_4 on H_2 cracking of 1055 steel, cold rolled 50%, annealed 400°C, 3 hr, coated with Ni, cathodically polarized 24 ma/cm²

Poison	Avg cracking time
0.05 mil Electrodeposited Ni	
As_2O_3 (sat'd)	>200 hr (3 spec.)
Sb_2O_3 (1.6 g/l)	163 hr (3 spec.)
Thiourea (0.2 g/l)	26 hr (7 spec.)
H_2SeO_3 (0.3 g/l)	14 hr (4 spec.)
0.1 mil Electroless Ni	
As_2O_3 (sat'd)	>200 hr (2 spec.)
Thiourea (0.2 g/l)	2 hr, 169 hr

cracking, it is presumably only below a critical susceptibility (Rockwell hardness <C 35) that the thin Ni coating provides an advantage. It is possible, of course, that Ni coatings would extend their range of effectiveness for more susceptible specimens under less severe conditions of H_2 charging.

Of interest to the mechanism were experiments carried out on Ni-coated specimens using catalyst poisons in H_2SO_4 solution other than As_2O_3. Data are summarized in Table II. Results are also included for 2.5μ (0.1 mil) electroless Ni coatings which were found to behave in much the same manner as electrodeposited coatings. Electroless Ni coatings 3.8μ (0.15 mil) thick were similar in behavior to the thinner coatings. It is obvious that thin Ni coatings are effective in presence of As_2O_3, but less so in presence of other poisons.

Experiments were next carried out to determine whether Ni-coated specimens prepolarized in 5% H_2SO_4 + As_2O_3 afford subsequent protection when cathodically polarized in 5% H_2SO_4 containing other type poisons, *e.g.*, thiourea. The thought behind this experiment was to learn whether protection was supplemented by arsenic deposited on a Ni surface. Also, if arsenic is effective, would it be similarly effective if predeposited from a cyanide bath, or if codeposited along with nickel by adding As_2O_3 to a nickel plating bath. Results are summarized in Table III. Prepolarization in H_2SO_4 + As_2O_3 for 15 hr is effective, the time for which can be shortened by prepolarizing at the boiling temperature of the H_2SO_4 electrolyte. None of the other pretreatments comparatively was as effective. This is a preliminary conclusion which should be substantiated by further tests accompanied by analyses of the electrodeposits. Probably the main reason for lack of protection is that specimens were bent for testing after deposition of As or As + Ni coatings, thereby producing cracks in the coating which allowed hydrogen penetration to the base steel. Ni-plated specimens

Table III. Effect of arsenic plus Ni coatings on H_2 cracking of 1055 steel, cold rolled 50%, annealed 400°C, 3 hr, cathodically polarized in 5% H_2SO_4 + 0.2 g/l thiourea, 24 ma/cm², room temperature

NC = no cracking in >8 days.

of Table III prepolarized in H_2SO_4 + As_2O_3 were already stressed to the test span during pretreatment and were then transferred to the H_2SO_4 + thiourea electrolyte without changing the span.

The next series of experiments was conducted to determine to what extent Ni plus As coatings are effective in total immersion tests in 6% NaCl-0.5% acetic acid periodically saturated with H_2S. This test is commonly employed to determine susceptibility of stressed steels to hydrogen cracking or sensitivity to so-called sulfide cracking. The base steel was again 1055 steel, cold rolled and annealed at 400°C, with the thickness of nickel coating being either 0.05 or 0.1 mil. Data are summarized in Table IV. Since all specimens failed within 2 days whether coated with Ni or with Ni plus As, additional tests were carried out with continuous cathodic polarization of the specimens in the same test medium. At 0.05 ma/cm², failure times for some specimens coated with Ni + As were extended, but all specimens failed nevertheless. At a higher current density of 0.5 ma/cm², Ni-coated specimens, except one, survived the maximum test period of 8 days. Protection was obtained whether or not the specimens were prepolarized in the H_2SO_4-As_2O_3 electrolyte. In other words, thin Ni coatings are effective in diminishing H_2 cracking of steel for H_2S-type exposures, but only if the coated steel is cathodically protected. Unlike the polarization experiments in H_2SO_4 previously reported, presence of As on the nickel surface does not seem to be essential, although results at 0.05 ma/cm² suggest that some small advantage results.

Discussion

Although metal coatings conceivably protect against hydrogen penetration into steel by acting as a diffusion barrier, it is not likely that this particular mechanism operates for the thin films now under study. Instead, the coatings apparently act mainly to alter kinetics of hydrogen ion discharge, resulting in less occlusion of hydrogen by the metal electrode. The specific surface properties of the metal are more important, in other words, than its diffusivity for hydrogen. This was demonstrated by results of Freiman and Titov (3) who also proposed that the surface electrochemical factor in their experiments accounted largely for the protective effect of thin metal coatings on diffusion of hydrogen into steel.

The important effect of the electrode surface is also apparent from the large effect on cracking produced by small additions of catalyst poisons, *e.g.*, arsenic compounds, thiourea, sulfur ions, etc., to the electrolyte. In absence of $NaAsO_2$ in their sulfuric acid electrolyte, Freiman and Titov (3) found no hydrogen to diffuse through uncoated steel after cathodic polarization for 2 hr, whereas in the presence of $NaAsO_2$ hydrogen appeared after 1 or 1½ min. Schuetz and Robertson (6) found that CS_2 additions to H_2SO_4 electrolyte increased hydrogen absorption of a cathodically polarized 10% Ni-Fe alloy by a factor of 15. It is known, moreover, that often a highly stressed steel exposed to an acid environment will not hydrogen crack except in presence of compounds like H_2S or As_2O_3.

The present results are the more surprising in view of the beneficial effect of thin Ni coatings associated with As where the latter element instead of increasing hydrogen occlusion by the underlying steel, decreases it. The arsenic retains its beneficial influence even in presence of other poisons such as thiourea (Table III). One exception is in the acetic acid-H_2S test (Table IV) where Ni coatings alone are effective, and As is not required to supplement protection against failure. Addition of As_2O_3 to H_2SO_4 leads to visible cathodic deposition of elemental As or an As compound on the cathode surface, and, as Freiman and Titov (3) showed, if the film is not too thick, occlusion of hydrogen by uncoated steel is increased by its presence. Elemental As has a high value of hydrogen overvoltage apparently leading to increased thermodynamic activity of adsorbed atomic hydrogen on the steel surface and hence to a greater tendency for hydrogen to enter the metal lattice.

Accordingly, the beneficial effect of As associated with a Ni coating can be ascribed to the possibly low hydrogen overvoltage of a chemical compound formed between As and Ni. This hypothesis is supported by the reduced time necessary to achieve protection by the duplex coating when the electrolyte is heated during As deposition which probably favors compound formation (Table III). Raub *et al.* (7) found that when As is codeposited with Ni on an electrode at which H^+ discharges simultaneously, the potential becomes more noble, corresponding to a decrease in hydrogen overvoltage. This shift of potential is in the right direction to explain the effect of the present Ni-As coatings. The Ni coatings containing As by codeposition, on the other hand, were not found to be especially effective, but, as described earlier, this is probably because of the brittle nature of coatings containing arsenic, allowing formation of cracks during bending through which hydrogen can enter the steel. Preliminary potential measurements on the present protective Ni-As coatings confirmed that a lower hydrogen overvoltage results when As is deposited on Ni. The observed difference of 40 mv at 24 ma/cm² (changing with time), was not large, however; hence there is the possibility that factors enter in addition to overvoltage effects. Even for metals like Pb with high H_2 overvoltage, there is apparently little tendency for cathodic hydrogen either to enter the Pb lattice or to transfer occluded H to the underlying steel.

Assuming that a compound is formed between Ni and As, the next step was to identify it by x-ray. The thin black surface layers of several Ni-As coated electrodes were carefully removed and examined in a Debye-Scherrer camera, but only lines of Ni appeared. Patterns were repeated several times with the same results. A black residue which collected on the bottom of the H_2SO_4-As_2O_3 electrolyte after a long period of electrolysis, and which is presumably elemental arsenic, gave an amorphous pattern. Hence it is concluded that if a surface compound of Ni and As forms, it is either amorphous or the layer is too thin for x-ray diffraction. The inability of the Ni-As coatings to protect quenched 1055 steel suggests that the amount of hydrogen necessary to cause failure of the martensitic steel is so small that the present thicknesses of coatings are not sufficiently protective. For tempered martensite, or for cold rolled steel, on the other hand, the apparent required amount of hydrogen is greater, and for this situation the coatings adequately reduce occlusion of hydrogen by steel to a value below that required for failure. The present investigation demonstrates that metal coatings need not be continuous in order to protect steel against hydrogen cracking and that their porosity need only fall below a critical value.

Impurity Segregation in Binary Compounds

M. R. Lorenz and S. E. Blum

Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

The effect of the pressure of the constituents of a binary compound on the segregation coefficient (k_o) of a substitutional impurity is considered. The theory concerning the incorporation of an impurity is briefly reviewed, and the dependence of k_o on P_M is given for various combinations of electrical character of an impurity and the site the impurity occupies. The impurities In and Sb were studied in CdTe. k_o(In) is inversely proportional to P_{Cd} and k_o(Sb) directly proportional to P_{Cd}. The results are in quantitative agreement with the theoretical prediction if it is assumed that native defects play a negligible role as a source of free carriers or charge compensation. The donor Te, the acceptor Zn, and the amphoteric impurity Sn were studied in InAs by pulling crystals by the Czochralski method at various arsenic pressures. The k_o's follow the predicted behavior. The practical significance of the dependence of k_o on the pressure of compound constituents in relation to materials preparation is discussed briefly.

Research on semiconductor systems has brought about a good understanding of segregation processes and of the factors governing distribution coefficients in binary systems (1). The knowledge acquired in such two-component systems has also been applied to the more complex ternary systems. There have been a number of investigations concerned with various aspects of the segregation of an impurity in a binary compound. Most of this work was done on III-V compounds and much of it has been recently reviewed (2). In many of these studies the segregation coefficients were determined by assuming a pseudobinary system, *i.e.*, an impurity (one component) and a binary compound (the second component). In general the investigations were concerned with segregation in liquid-solid phase equilibria. More recently Chang and Pearson (3) studied solubilities and distribution coefficients of Zn in GaAs and GaP from vapor-solid equilibria while McCaldin (4) studied the Zn-GaAs system as a true three-component system. The behavior of Ge in GaAs was investigated in liquid-solid phase equilibria (5). Segregation of Zn between solid InSb and In-Sb melts of various compositions has also been investigated (6). The solubility of group II, IV, and VI elements in GaP was studied by Trumbore *et al.* (7, 8).

The major aim of this study was to examine the dependence of the distribution coefficient on the site the impurity occupies, the effects of the electrical characteristics of the impurity, and the role of the chemical potential of the component that normally occupies the site. For our experimental investigation we chose the In-As system as a representative of the III-V compounds and the Cd-Te system as a representative of the II-VI compound family. Both compounds are low melting and therefore presented the least difficulty experimentally. Three impurities were studied in InAs, and two impurities were investigated in CdTe.

Theory

We wish to review briefly the theory concerning the incorporation of an impurity atom X in the compound MN. We will use the mass action approach of Kroeger and Vink (9) and follow approaches similar to those used by Thomas (10), McCaldin (4), and Kroeger (11). We confine our attention to impurities which sit on normally occupied lattice sites. Let us assume first that X is a donor which resides on an M site (X_M^D). The equilibrium of X in the solid MN and some external phase (X_l) can be illustrated by the reaction.

$$V_M + X_l = X_{MD}^+ + e^- \qquad (I)$$

where V_M is a neutral M vacancy, X_{MD}^+ is the ionized donor, and e^- is a free electron. Making the usual assumption of ideal solution behavior, we write the equation which governs reaction (I) as follows

$$\frac{[X_{MD}^+]\, n}{[V_M][X_l]} = K_1(T) \qquad [1]$$

where $K_1(T)$ is the temperature dependent equilibrium constant. Since all K's are temperature dependent, the bracketed T will hereafter be dropped for simplicity. In general, we are concerned with impurity states which lie close to their respective bands. For such states we can assume that at or near the melting temperature of the compound they are sufficiently ionized that the concentration of the ionized impurity is equal to the total concentration of that impurity, *i.e.*, $[X_M^D] = [X_{MD}^+] + [X_{MD}^0] \cong [X_{MD}^+]$. With this assumption we may write the equilibrium segregation coefficient for a donor impurity substituted on an M site, $k_o(X_M^D)$

$$k_o(X_M^D) \simeq k_o(X_{MD}^+) = \frac{[X_{MD}^+]}{[X_l]} = \frac{V_M K_1}{n} \qquad [2]$$

where k_o describes the solid-liquid equilibrium. Since $[V_M]$ is inversely proportional to the pressure of M. as $P_{M_y}^{1/y}$ where y is the number of atoms in the given vapor specie, we can write Eq. [2] as

$$k_o(X_M^D) = \frac{K_3}{n\, P_{M_y}^{1/y}} \qquad [3]$$

Table I. Dependence of the impurity segregation coefficient, k_o, on lattice sites, P_M, and carrier type and concentration
The K's are temperature dependent constants with subscripts omitted for simplicity. For the definition of k_o see Eq. [2]

Impurity character site	X_M^D	X_N^D	X_M^A	X_N^A	$X_{M,N}^{A,D}$
Segregation coefficient	$\frac{K}{n P_{M_y}^{1/y}}$	$\frac{K P_{M_y}^{1/y}}{n}$	$\frac{K}{p P_{M_y}^{1/y}}$	$\frac{K P_{M_y}^{1/y}}{p}$	$\frac{K}{n P_{M_y}^{1/y}} + \frac{K' P_{M_y}^{1/y}}{p}$

Inherent in the above and subsequent treatment are the assumptions that solid MN has a narrow homogeneity range, the impurity concentration is small, the system is nondegenerate, and that Schottky disorder prevails.

If we now consider the same case but let X occupy N sites, we find that

$$k_o(X_N^D) = \frac{K_4}{n P_{N_y}^{1/y}} = \frac{P_{M_y}^{1/y} K_5}{n} \quad [4]$$

From Eq. [3] and [4] we note that the segregation coefficient for an impurity is either directly or inversely proportional to the pressure of M in the system. Similar equations govern the segregation coefficients of acceptors at substitutional sites. There are also a limited number of impurities which can occupy either site readily. If a mass action law is valid for the impurity on each type of site, then

$$k_o(X_{M,N}^{A,D}) = \frac{[X_M^A] + [X_N^D]}{[X_i]} = \frac{K_6}{p P_{M_y}^{1/y}} + \frac{P_{M_y}^{1/y} K_5}{n} \quad [5]$$

where p is the hole concentration. A summary of the dependencies of segregation coefficients on the site the impurities occupy and on the electrical characteristics they have is given in Table I.

Experimental

Cadmium telluride.—The CdTe ingots used in these studies were prepared from high-purity, 6-9's, elements in vacuum-sealed quartz tubes by the Bridgman Drop procedure. Ingots weighed typically about 80g and occupied about 60% of the tube volume. The dopant, In or Sb, was added directly to the Bridgman tube. The cadmium pressure in the system was initially controlled by the excess Cd used. However, it is apparent that the P_{Cd} in the system is changing throughout the freezing period because the composition of the melt is changing. We analyzed only the first 15% of the ingot to freeze and assumed a P_{Cd} corresponding to the initial condition (12-14). This leads to an uncertainty of about 10% in P_{Cd}. The distribution coefficients of indium and antimony were determined at cadmium pressures of 5.3 and 0.08 atm.

Indium arsenide.—The indium arsenide crystals used in these studies were prepared from high purity, 6-9's, elements. The sealed magnetic Czochralski crystal puller used was previously described (15). InAs was synthesized *in situ* and grown in the <111> direction. The solid-liquid interface was always flat and perpendicular to the pull direction. The rotation rate was in all cases 8 rpm. Hall measurements taken on wafers cut perpendicular to the growth axis showed no appreciable variation in carrier concentration within a wafer. Therefore inhomogeneous segregation of the impurities due to faceting effects (26, 27) was assumed to be negligible. The dopants were added directly to the indium charge. The arsenic pressure in the system was maintained at the desired value by the temperature control of condensed arsenic at the coldest portion of the puller tube. Crystal growth was obtained in the usual way. To study the influence of arsenic pressure, the pulling was interrupted and the arsenic reservoir temperature was increased. After arsenic pressure equilibrium was established, the pull was resumed.

Tellurium and tin in InAs were treated as nonvolatile dopants. The initial dopant composition of the melt was therefore known. The dopant concentration in the melt after the pressure change was calculated from the InAs phase diagram (16). The quantity of Te already incorporated in the pulled crystal was taken into account. Our justification for treating Te as a nonvolatile dopant is based on the fact that for our experimental temperature conditions Te is a noncondensable impurity and the gas volume is sufficiently small to make the quantity of Te in the gas phase negligible compared to the total Te in the system.

As in the above case, the dopant zinc was added directly to the melt. However, the zinc concentration in the melt must be calculated differently from the Te or Sn case. When the InAs-zinc melt is in equilibrium with arsenic at a vapor pressure of 0.17 atm, the zinc concentration in the melt is dependent on the vapor pressure of condensed Zn_3As_2 at the arsenic reservoir temperature where solid Zn_3As_2 coexists with solid As. Using Silvestri's data (17), the zinc pressure in the system was calculated. The corresponding concentration of Zn in the melt was calculated from Raoult's law and the vapor pressure of pure Zn at the melt temperature (18). When the minimum temperature in the system was increased to 623°C (P_{As_4}= 1.45 atm), condensed Zn_3As_2 still controlled the Zn vapor pressure and condensed arsenic controlled the arsenic pressure. The Zn concentration in the melt was recalculated as above.

Measurements.—The cadmium telluride crystals were analyzed for the dopants by emission spectrochemical analysis. The indium arsenide crystals used were similarly analyzed for the dopants Te and Sn. In addition, the InAs crystals were investigated by measurements of their Hall coefficients. When possible we used Hall bridges; otherwise Van der Pauw samples had to suffice.

Results and Analysis

CdTe.—The results of segregation of In and Sb in CdTe under high and low P_{Cd} are shown in Table II. The first column gives the initial composition and the second column the cadmium pressure associated with the initial composition (12-14). The third column gives the corresponding liquidus temperatures (T_l) (12, 14). C_l is the initial solute concentration in the liquid and C_s is the measured impurity concentration in the solid. The segregation coefficients are shown in the last column. We note that the k_o's for In differ for the two P_{Cd}'s by about a factor of 6. Similarly for Sb the k_o's show a variation by a factor of about 17. The dependence of k_o on P_{Cd} is significant.

Because the k_o's above were not determined at the same temperature, we must rule out the possibility that the variation in k_o is due to the temperature difference. It has been shown empirically for a number of impurities in Si and Ge with k_o's much less than unity that the temperature dependence of the distribution coefficient can be approximated by the expression (19)

$$k = (k_m)^{T_m/T} \quad [6]$$

Here k_m is the segregation coefficient of the solute at infinite dilution; this occurs at the maximum melting point (T_m) of the solvent; k is the segregation coefficient at any temperature, T. Trumbore *et al.* (20)

Table II. Segregation coefficient of In and Sb in CdTe
The k_o for each impurity is given for each of two initial melt compositions. The calculated P_{Cd}, melting point, impurity concentration in the melt C_l, and in the solid C_s are listed.

Atom fraction Cd	Cd pressure atm	T, °K	Solute	C_l *	C_s * ‡	C_s** at./cm³	$k_o = \frac{C_s}{C_l}$
0.555	5.3	1308	In	4.45×10^{-4}	3.8×10^{-5}	1.18×10^{18}	8.5×10^{-2}
0.445	0.081	1328	In	4.45×10^{-4}	2.2×10^{-4}	6.84×10^{18}	49×10^{-2}

0.445	0.081	1328	Sb	4.45×10^{-4}	5.2×10^{-6}	1.62×10^{17}	1.2×10^{-2}

* In units of gram atoms solute per gram atoms of solvent (Cd plus Te).
‡ Three separate determinations were made in the first 15% of the solid that froze. The average is shown.
** The intrinsic electron concentration at the above temperatures are, respectively, $n_i(1308°K) = 3.9 \times 10^{17}/cm^3$; $n_i(1328°K) = 4.3 \times 10^{17}/cm^3$.

have shown that Eq. [6] is not applicable over large temperature ranges. For the relatively small temperature differences near the maximum melting point in question here Eq. [6] may serve as a useful estimate. Applying this equation to CdTe (treating the system as a pseudobinary for determining the "pure" temperature dependence), we calculate a change in k_o of about 5% for the 20°K difference shown in Table II. This is a negligible change compared to the experimental observation.

Let us now consider the influence of P_{Cd} and n on the segregation coefficient for the shallow donor In in CdTe (14, 21). We assume substitutional occupation of Cd sites. According to Eq. [3]

$$k_o(In_{Cd}) = \frac{K}{n P_{Cd}}$$

We need to determine the carrier concentration n at the high temperature equilibrium condition. If we assume that the deviation from stoichiometry contributes a negligible number of carriers and that self compensation itself is negligible, then the charge neutrality equation becomes $n - p = [In_{Cd}{}^{D+}]$. Furthermore, the carrier concentration due to the intrinsic process is governed by the relation

$$np = K_i = N_c N_v \exp(E_v - E_c)/kT \qquad [7]$$

where N_c and N_v are the density of states in the conduction and valence band, respectively, E_v and E_c the relative energies of the valence and conduction band edges, k is the Boltzman constant, and T the absolute temperature. Combining Eq. [7] with the charge neutrality equation leads to

$$n^2 - n[In_{Cd}{}^{D+}] = K_i \qquad [8]$$

We evaluate K_i as follows. For the density of states, we have used an effective electron mass (21) of 0.1 m_o and a hole mass of 0.6 m_o (22, 23). The term $E_v - E_c$ is equal to the negative of the band gap energy E_g, which has also been reported as a function of temperature (14). The calculated K_i for 1308°K is 1.52×10^{35} ($E_g = 0.96$ ev) and 1.85×10^{35} ($E_g = 0.95$ ev) at 1328°K. The intrinsic carrier concentrations corresponding to these values are shown at the bottom of Table II. The value of n at 1328°K deduced from Eq. [8] is equal to $[In_{Cd}{}^{D+}] = C_s$. The same holds for n at 1308°K. Therefore

$$k_o(In_{Cd}{}^{D}) = \frac{K}{C_s P_{Cd}}$$

Using the experimental results for $P_{Cd} = 0.081$ atm, we find the temperature dependent constant K_{In} (1328°K) $= 2.7 \times 10^{17}$ atoms atm cm^{-3}. We can now compute the segregation coefficient for $P_{Cd} = 5.3$ atm utilizing the experimentally determined $C_s = 1.2 \times 10^{18}$. The calculated value for k_o is 4.3×10^{-2} which is to be compared with the experimental value of 8.5×10^{-2}. The agreement is good for measurements and analyses of this type. This also gives some justification for our assumption of negligible self-compensation. If appreciable self-compensation occurred, then our results would be in variance with the predicted behavior.

A similar analysis can be made for the impurity Sb which acts as an acceptor and is assumed to be a substitutional impurity residing on the Te site. Again we compute the temperature dependent constant using the data, $P_{Cd} = 5.3$ atm, $p = C_s = 2.7 \times 10^{18}$ and $k_o(Sb_{Te}{}^{A}) = 20 \times 10^{-2}$, and obtain for $K_{Sb}(1308°K)$ a value of 1.02×10^{17}. In calculating the segregation coefficient for $P_{Cd} = 0.081$ atm, we determine p from the neutrality condition and note that $p = 5.2 \times 10^{17} \neq C_s$. The calculated value for $k_o(Sb_{Te}{}^{A}) = 1.6 \times 10^{-2}$ which compares very well with the experimental value of 1.2×10^{-2}. We note that segregation coefficients can change significantly with a change of component pressure. Moreover the analysis shows that there is a near quantitative agreement between experiment and theoretical prediction.

InAs-Te.—The impurity segregation in the InAs system was investigated at constant chemical potentials of the constituents, *i.e.*, crystals of InAs were pulled from the melt at constant As pressure. The ingot was characterized along the growth axis by measuring the carrier concentration (Hall measurements) and by spectrochemical analysis. For Hall measurements, the constant r in the relation $n = r(R_H ec)^{-1}$ was taken as unity. We found that n from electrical measurements was consistently higher than the corresponding [Te] deduced from chemical analysis. This was observed only for Te. We have arbitrarily made the two sets of data coincident by applying a constant multiplying factor of 1.45 to the chemical data (the accuracy of the chemical analysis for Te was ±20% and therefore does not explain the observed difference). The results are shown in Fig. 1.

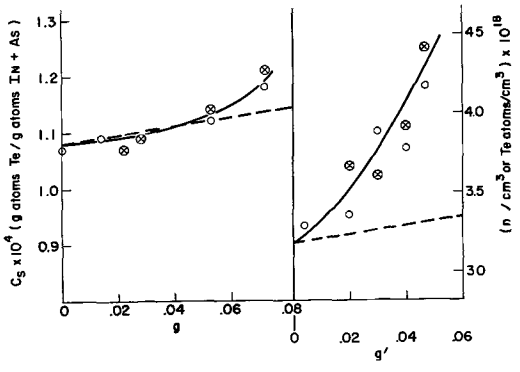

Fig. 1. Tellurium concentration in InAs as a function of the fraction of the melt grown. The data for $P_{As4} = 0.53$ atm and for 1.1 atm are shown. The dotted lines represent the theoretical curves for normal freeze of the off-stoichiometric melts for $k_o = 0.311$ and $C_o = 3.48 \times 10^{-4}$ for the g curve ($T_M = 942°C$) and for $k_o = 0.290$ and $C_o = 3.11 \times 10^{-4}$ for the g' curve ($T_M = 931°C$). ○ represents electrical data and circle with x chemical data. The chemical data was multiplied by a constant factor of 1.45 to bring it into coincidence with the electrical data.

The concentration profile of Te in the solid phase is given by the solid lines. The curve is extrapolated to obtain C_s at $g = 0$ where g is the fraction of melt solidified. Since the initial Te concentration (C_o) in the liquid is known, we can compute the segregation coefficient for the initial P_{As}. After the As pressure change, C_o' was recalculated as described previously, C_s' at $g' = 0$ is obtained as before and k_o' is calculated. All the pertinent data are given in Fig. 1. It is to be noted that the dotted lines correspond to the theoretically predicted modified normal freeze curves which take into account the off-stoichiometry in the liquid phase (24). A strong positive deviation of the experimental data at the higher P_{As} is noted. This is believed to be caused by a too rapid rate of growth. We used the same pulling speed of 12 mm/hr for both arsenic pressures. Although the rate was sufficiently slow for the lower P_{As} which corresponded to a near stoichiometric melt, it was too rapid for the higher P_{As}. For the latter case slower rates are necessary to allow for the diffusion of the excess component As away from the growing interface. It is also suspected that the extrapolation of C_s' to $g' = 0$ leads to a value which is higher than the equilibrium value.

The effect of changing the As pressure during crystal growth is well demonstrated in Fig. 1. The discontinuity at the point of ΔP_{As} is clear. The change in the amount of Te incorporated in the solid is due to two effects. First there is a dilution effect which occurs when additional As is transferred from the reservoir to the melt as a result of increasing P_{As} (24). The second effect, of course, is the one we are mainly concerned with in this investigation. We have sufficient knowledge of the InAs phase equilibria (16) to take into account the dilution effect. Therefore, using $k_o = 0.311$ for $P_{As4} = 0.53$ atm as a standard we can calculate k_o' for $P_{As4}' = 1.1$ atm from the relation

$$k_o' = k_o \frac{n}{n'} \left[\frac{P_{As4}}{P_{As4}'} \right]^{1/4}$$

We assume that the temperature dependence of k is negligible for the small difference in liquidus temperatures, *i.e.*, 942°C *vs.* 931°C. Again, as in the case of CdTe, we assume the simple charge neutrality condition: $n - p = Te_{As}^{D+}$. We have calculated K_i for InAs at 930°C using the following data: $E_G = 0.415$ ev at 2°K (25), $dE_G/dT \simeq 3 \times 10^{-4}$ ev/deg., $m_h = 0.3\ m_o$ (25), and $m_e = 0.03\ m_o$ (25). The assumptions include a constant temperature dependence of E_G and that only the conduction and valence band near $k = 0$ are involved in the intrinsic ionization process. The intrinsic electron concentration was found to be 4.5×10^{18} cm^{-3} which makes $K_i = 2.0 \times 10^{37}$. We calculate the appropriate n's from an equation similar to Eq. [8] and determine $k_o' = 0.28$. This compares favorably with the observed value of 0.29.

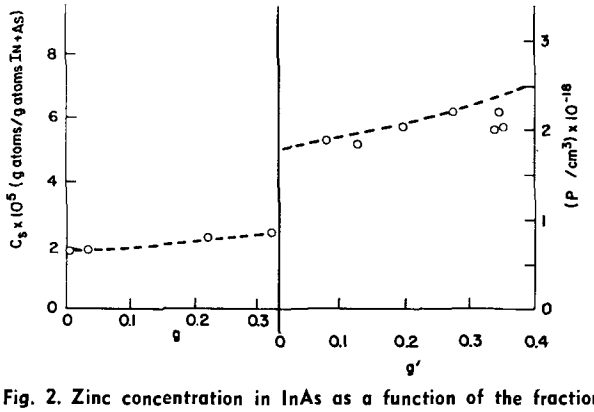

Fig. 2. Zinc concentration in InAs as a function of the fraction of the melt grown. The data are for $P_{As4} = 0.165$ atm and 1.45 atm. The data were obtained from electrical measurements. The dotted lines represent theoretical curves for normal freeze of the off-stoichiometric melts for $k_o = 0.324$ and $C_o = 5.65 \times 10^{-5}$ and for $k_o = 0.421$ and $C_o = 1.2 \times 10^{-4}$ for g ($T_M = 937°$) and g' ($T_M = 920$°C), respectively.

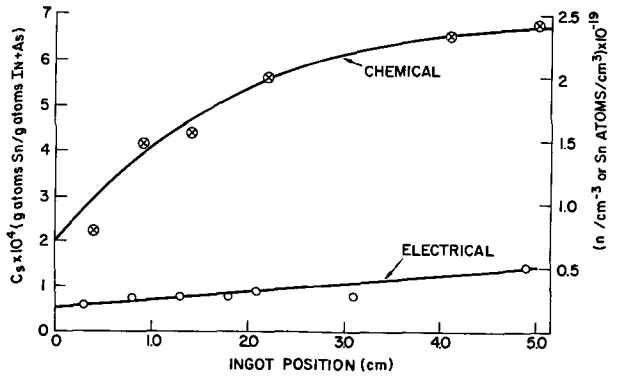

Fig. 3. Concentration of tin and free charge carriers in InAs as a function of length and ingot grown for $P_{As4} = 0.17$ atm; $C_o = 1.226 \times 10^{-3}$; $T_M = 937$°C; $k_o = 1.63 \times 10^{-1}$.

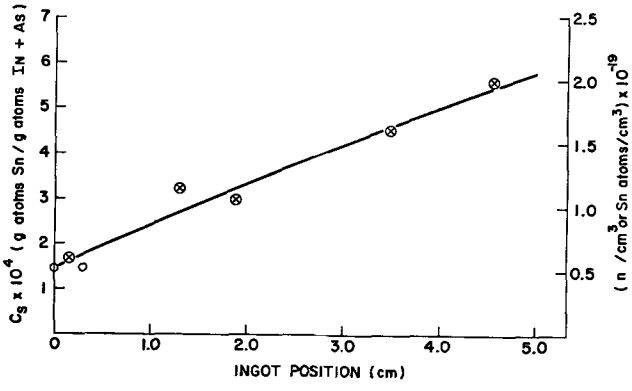

Fig. 4. Concentration of tin and free charge carriers in InAs as a function of length of ingot grown for $C_o = 2.75 \times 10^{-3}$; $T_M = 885$°C; $k_o = 5.34 \times 10^{-2}$; $P_{As4} = 3.5$ atm; ○ electrical data; circle with x chemical data.

InAs-Zn.—The impurity Zn in InAs occupies In sites and is an acceptor. Essentially the InAs-Zn system was treated like the InAs-Te one. The zinc concentration in the melt, however, was calculated as described in the experimental section.

In characterizing the pulled ingot only electrical measurements were used. The results of this study are shown in Fig. 2. Again, one notes the discontinuity at the point where P_{As} was increased. The theoretical normal freeze curves (24) are much more closely approximated by the data. This is undoubtedly due to the reduction of the pulling rate to 6 mm/hr.

We have analyzed our results along the same line as before. We assume that [Zn] = p, where the latter is the measured hole concentration. We again calculate p at the high-temperature equilibrium from our neutrality condition and K_i. If we use $k_o = 0.32$ for $P_{As4} = 0.165$ atm as a standard, then we would predict k_o for $P_{As4} = 1.45$ atm to be 0.49. This compares favorably with the measured value of 0.42.

InAs-Sn.—Impurities of group IV A of the periodic table have been observed to act both as donors and acceptors in III-V compounds depending on the site they occupy. Tin is this type of amphoteric impurity in InAs. We have grown two ingots of InAs doped with Sn at two different As pressures. The impurity and carrier concentration profiles of the ingots were obtained from chemical analysis, and electrical measurements and are shown in Fig. 3 and 4. The chemical analyses (emission spectroscopy) are precise to ± 20% at the 90% confidence level. The crystal pulled

at 0.17 atm As pressure was mainly single, and electrical measurements were made along most of the ingot. It should be noted in Fig. 3 that the chemical analyses indicate considerably larger concentrations of Sn than found by electrical measurements. We interpret these results as follows. Sn is basically a donor in InAs and therefore at low Sn concentration it prefers the In sites. However, at low P_{As_4} as the total Sn concentration increases, the probability of occupation tends to the same value for both sites. Therefore. the free electron concentration stays essentially constant for high concentrations of Sn as is shown in Fig. 3.

At P_{As_4} of 3.5 atm it was quite difficult to pull single crystals. Even at the slowest pull speeds attainable with our equipment (3 mm/hr) the ingot was polycrystalline except for the first few mm near the seed, which was single and free of gross defects. After the first centimeter of ingot, void inclusions were observed. These were characteristic of trapped arsenic gas bubbles. It was therefore possible to make electrical measurements only in the first few millimeters of the ingot. The rest of the ingot was characterized by chemical analysis. Results are shown in Fig. 4. We note that for this case the carrier concentration is equal to the concentration of Sn in the initial part of the ingot. We cannot say whether this holds true for the higher concentration of Sn, *i.e.*, for every part of the ingot. Nevertheless, the results indicate that under the higher As pressure the Sn atoms favor the In sites. The results follow the prediction that as the As pressure increases the occupation of As sites by Sn decreases relative to similar occupation of In sites. Along with the decrease of Sn solubility on As sites, there is a decrease in the total distribution coefficient. This is not unexpected. A more quantitative analysis and comparison of the Sn segregation coefficient is unfortunately not possible.

Discussion

We have reviewed the theoretical aspects of impurity incorporation in binary compounds. The primary variables affecting k_o are the temperature, the pressure of the compound constituents, the concentration of the impurity, and the free carrier concentration. Of these variables we have been concerned mainly with the pressure of the compound constituents and how the variation of P_M or P_N affects the segregation coefficient of various impurities. Of primary importance are the sites the impurities occupy. The theoretical predictions were tested experimentally for several impurities in CdTe and InAs. In no cases were the experimental observations in conflict with the theory; moreover, in most cases there was good quantitative agreement. One assumption inherent throughout is that the impurity activity in the liquid phase is not strongly dependent on the composition of the liquid phase. The agreement between theory and experiment indicates that our assumption was justified. It should be noted, however, that the impurity concentration was always dilute. When the liquid phase is appreciably off stoichiometry, *i.e.*, when $M >> N$ or $M << N$ then the assumption of composition independence may no longer be valid.

The dependence of k_o on the chemical potential of the constituents is of practical importance. k_o is a parameter that is useful in either minimizing or maximizing the incorporation of impurities into the host crystal. In addition there is another aspect that is of particular importance with high vapor pressure compounds, *e.g.*, GaAs, InP, etc., where one must maintain good control of P_M usually by temperature control of a reservoir. A fluctuation of P_M may induce temperature fluctuations in the melt, due to the solution or evaporation of the reservoir component. These fluctuations result in variations of k_o, and this may yield inhomogeneities in the growing crystal.

Special consideration must be given to the phase diagram of the binary compound under investigation. In the II-VI systems, either constituent can be used to control the composition of the vapor phase and hence the other phases. Large variations in the component pressure lead to only small variations in the liquid composition as seen in Table II. The III-V compounds on the other hand are generally controlled by the pressure of the group V elements only. In the III-V system the liquidus curves near the binary compound composition are quite flat, and therefore a variation in the component pressure is reflected more strongly in a variation of the liquid composition. The determination of the most suitable conditions must thus take into account the phase diagram of the system.

Acknowledgments

The authors wish to express their appreciation to R. C. Chicotka for growing the InAs crystals, to J. A. Kucza for growing the CdTe crystals, and to W. Reuter for performing the chemical analyses.

Anomalous Behavior of Copper during Acceptor Diffusions into Gallium Arsenide

G. B. Larrabee and J. F. Osborne

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

A radioactive tracer study of the behavior of copper during acceptor diffusions into gallium arsenide has clearly shown anomalous copper concentration profiles. A pronounced minimum in the copper diffusion profile was found in the vicinity of the electrical p-n junction. The shape and position of this minimum was dependent only on those diffusion conditions (time and temperature) which affected the indiffusing acceptor. Crystal origin, crystal orientation, and annealing had no effect on the copper diffusion profile. It is felt that the minimum or dip in the profile is caused by the large built-in field of the p-n junction which sweeps out the singly charged copper interstitials in the vicinity of the junction.

The diffusion, solubility, and electrical activity of copper in gallium arsenide have been carefully studied (1-3) and with the excellent work of Hall and Racette (4) is now better understood. The behavior of copper in all semiconductors is considerably complicated by the existence of the two copper species, interstitial Cu_i, and substitutional Cu_s. These two species exist together in gallium arsenide and their ratio (Cu_s to Cu_i) is controlled by several factors including the doping of the gallium arsenide. In intrinsic gallium arsenide, this ratio was found to be around 30 (4). This ratio is upset if the material is doped greater than the intrinsic carrier content of the copper content. If the semiconductor is n-type, the ratio is shifted in favor of the substitutional species. Similarly, p-type material shifts the ratio to favor interstitial species. The properties of these two copper species are radically different both during and after diffusion.

Interstitial copper (Cu_i) diffuses very rapidly into gallium arsenide (effective $D \sim 10^{-6}$ cm^2-sec^{-1} at 800°C). Electrically, interstitial copper is a singly charged donor. However, in the crystal the interstitial species reacts with vacancies to produce copper in substitutional sites

$$Cu_i + V = Cu_s$$

Substitutional copper is relatively immobile and appears to be a double acceptor in gallium arsenide (4). Furukawa *et al.* (6, 7) observed only the 0.145 ev copper level but their work did not preclude the presence of the deep level at 0.47 ev. Fuller *et al.* (5) and Allison *et al.* (13) carefully investigated the behavior of copper diffused into n-type gallium arsenide and demonstrated the double acceptor behavior of copper.

The effective diffusion coefficient for copper is a function of the relative abundance of the two copper species which in turn is determined by the dopant. In the formation of a p-n junction, by diffusing an acceptor into n-type material, it is not at all clear how copper will behave. Hall (4) showed that the diffusion coefficient for interstitial copper was independent of the acceptor concentration. However, diffusion into extrinsic n-type gallium arsenide material is complicated by the fact that the copper interstitial solubility is greatly reduced.

This work was initiated to determine the behavior of copper during acceptor diffusions into n-type gallium arsenide.

Experimental Procedure

Each gallium arsenide sample was sawed to a thickness of 30 mils and then lapped and polished until optically flat. The sample was etched in 8:1:1 etch (8 parts H_2SO_4, 1 part 30% H_2O_2, and 1 part H_2O), and rinsed in running deionized water. The radiocopper-64[1] was introduced onto the crystal wafer by equilibrating the crystal in a 1*N* nitric acid solution containing 4 to 5 ppm copper ion (labeled with copper-64) for 30 min. The copper was thereby electrochemically deposited on the gallium arsenide (8). The wafer was then carefully rinsed in deionized water and allowed to dry. The slice was sealed into a 10 cm^3 volume quartz tube[2] with other acceptor diffusants at a pressure of less than 1μ. Unless otherwise stated, all diffusions were carried out at 815°C for 6 hr in a furnace with a 10-in. zone that was flat to ± 1°C. After diffusion, the quartz diffusion ampoules were air quenched, and the diffused gallium arsenide slice was removed. The edges were lapped with a coarse grit on a lapping plate to a depth of at least 500μ. The face of the diffused slice was then incrementally lapped and each lapping was gamma counted using a sodium iodide scintillation detector. Both gamma-ray spectroscopy and half-life studies showed only the presence of copper-64 activity.

Experimental Results

The initial acceptor diffusion studied was manganese into a copper-64 labeled wafer as described in the Experimental Procedure. Figure 1 shows the copper concentration profile as a function of depth into the crystal. As can be seen, a pronounced dip or minimum was obtained that looked much like that reported by Cun-

[1] Copper-64 was obtained and assayed from Oak Ridge National Laboratories, Oak Ridge, Tennessee. An average specific activity of 60,000 to 80,000 mc/g was used.

[2] All quartz used was G.E. 204.

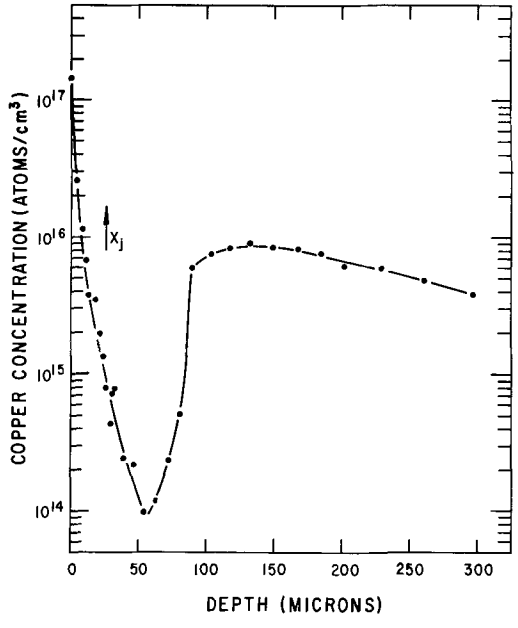

Fig. 1. Typical distribution of copper in n-type gallium arsenide when diffused with manganese at 815°C for 6 hr.

nell and Gooch (9). The surface concentrations of manganese, observed using radiomanganese-54, were of the order of 10^{19} atoms/cc. The diffusion conditions were repeated several times and shown to reproducibly yield this anomaly. It was decided to vary carefully only one experimental parameter at a time in an effort to understand this phenomenon.

Material origin and crystallography.—Several different Texas Instruments n-type pulled gallium arsenide crystals (lightly doped tin and tellurium and undoped, but not intrinsic) as well as some undoped, but not intrinsic Bell and Howell horizontal Bridgeman material were shown to behave in the same manner. This dip in the copper diffusion profile was not peculiar to any one melt grown n-type gallium arsenide crystal. The gallium arsenide material used in the acceptor diffusion reported in this work was tin doped to 4 to 6 x 10^{16} at./cm^3. Heavily doped material as discussed by Schockley and Moll (14) was not investigated as n-type substrates in this study.

Similarly, efforts to show a dependence on crystallographic orientations was not successful. Manganese diffusions into <311>, <111>, and <115> material all yielded copper profiles with a pronounced dip or minimum.

Since most of the diffusion work in this study was carried out on <111> oriented crystals, the effect of the gallium rich (A) face *vs.* the arsenic rich (B) face was investigated. No differences in the copper diffusion profiles were observed. This was not unexpected since <311> and <115> oriented wafers have only very slight A and B face characteristics.

The one material or slice parameter that had the most pronounced effect on the over-all shape of the dip in the copper profile was positioning in the diffusion tube. That is, the face laying up in the diffusion tube consistently showed more pronounced or sharper dips in the profiles than the down face. This observation has added significance when it is coupled with some radiomanganese-54 and -56 work (10) which clearly shows the upper diffusion face to have higher manganese surface concentrations and deeper p-n junction depths. This would imply that the anomalous dip in the copper profile was intimately connected with the indiffusing acceptor and is not dependent on the host crystal.

Diffusion conditions.—On the premise that the dip in the copper profile was caused by the manganese; several diffusion conditions were studied.

Diffusion time.—A manganese diffusion into a copper-64 labeled wafer was carried out as described in the Experimental Procedure except the diffusion time was reduced from 6 to 0.6 hr. The copper diffusion profile is shown in Fig. 2. The depth of the minimum (12μ) is significantly less than in comparable 6 hr diffusions

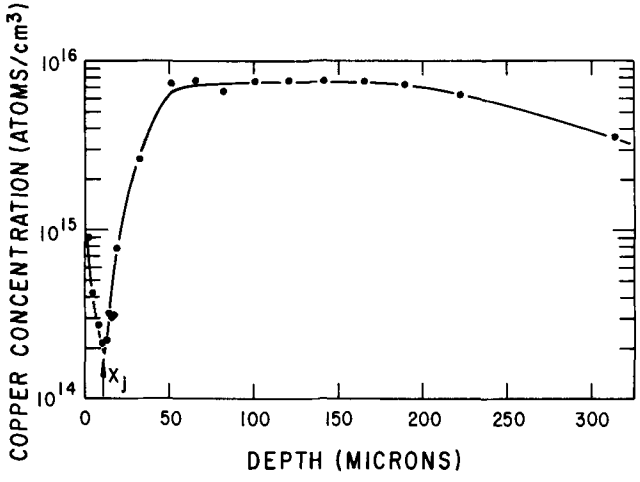

Fig. 2. Effect of diffusion time on the copper distribution during manganese diffusion into n-type gallium arsenide. Diffusion carried out at 815°C for 0.6 hr.

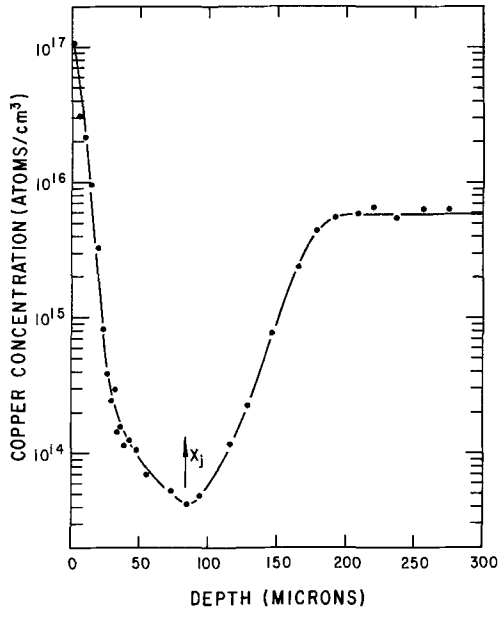

Fig. 3. Effect of increased temperature on the copper concentration profile during the diffusion of manganese into n-type gallium arsenide. Diffusion carried out at 915°C for 6 hr.

which average around 55μ. Since the acceptor diffusion depth would vary with the square root of the diffusion time, one would expect the minimum to be about 1/3 the depth of a comparable 6-hr diffusion. An average of two 0.6-hr diffusions was 15μ which is in good agreement with the time dependent diffusion laws.

Temperature.—A manganese diffusion was carried out as described in the Experimental Procedure but increasing the diffusion temperature to 915°C. As can be seen in Fig. 3, the dip in the copper profile was much wider and the minimum was deeper into the crystal (87μ) than the 815°C diffusions. A diffusion at 1000°C produced a much broader dip with a minimum around 150μ. This change in the shape of dip in the copper profile along with the change in the position of the minimum again strongly suggest a dependence on acceptor behavior and movement.

Annealing.—Two diffusions were carried out under the standard diffusion conditions described earlier. At the end of the 6-hr diffusion one tube was removed and water quenched while the other tube was removed inside a larger Inconel block which took approximately 3 hr to reach room temperature. There was no difference in the shape of the copper diffusion profiles. The anomalous dips occurred at the same depth in the crystal. It appears that the effects of annealing after diffusion are very small.

Other Acceptor diffusants—zinc.—All of the copper-acceptor diffusions reported in this work were carried out using manganese with the exception of two zinc diffusions. In these zinc diffusions all diffusion conditions were as described earlier except that the amount of zinc was chosen to yield a p-n junction at a depth of 20 to 30μ. The copper profile is shown in Fig. 4, and it is apparent that an extremely sharp dip is obtained using zinc.

Here again, the anomalous distribution of copper appears to be closely related to the indiffusing acceptor. It should be noted that the width of the minimum is considerably more narrow than in comparable manganese diffusions.

Absence of acceptor.—To gain some insight into the mechanism of the interaction between the copper and the indiffusing acceptor, a series of diffusions was carried out with copper-64 labeled wafers in the absence of an acceptor. The gallium arsenide used was horizontal Bridgeman grown, undoped, but not intrinsic, with a carrier concentration of 1.2 x 10^{16} electrons/cm^3. The first series of diffusions was run with

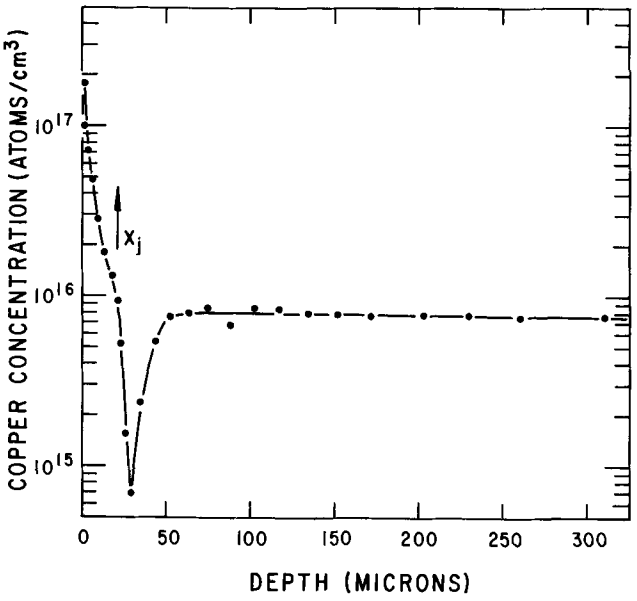

Fig. 4. Copper distribution oberved during zinc diffusion into n-type gallium arsenide at 815°C for 6 hr.

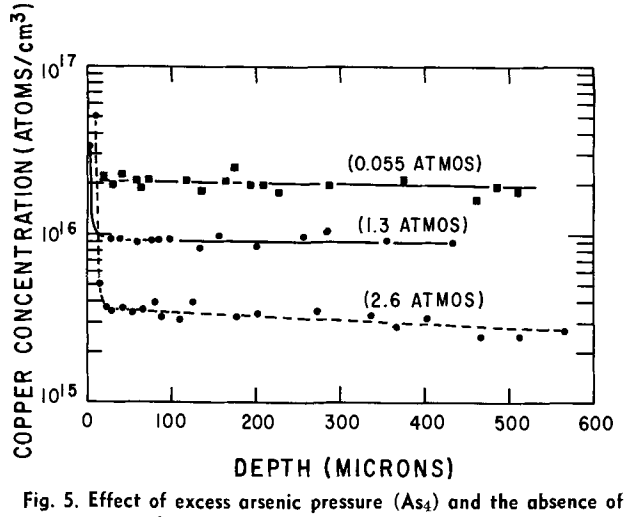

Fig. 5. Effect of excess arsenic pressure (As_4) and the absence of an acceptor on the copper distribution during a 6-hr diffusion into n-type gallium arsenide at 815°C.

varying amounts of excess arsenic in the diffusion ampoule. The excess arsenic would prevent dissociation of the gallium arsenide and would generate gallium vacancies in the crystal near the surface.

The results of three diffusions with varying amounts of excess arsenic in the diffusion tube are shown in Fig. 5. The apparent inhibition of the copper diffusion by the excess arsenic suggests interaction of the copper with gallium vacancies to form immobile substitutional copper. Hall and Racette (4) report reduced solubility of copper in n-type (5×10^{15} electrons/cm^3) gallium arsenide and suggest that this reduced solubility is due to the presence of an arsenic-rich phase at the surface. This suggestion of precipitation of copper arsenide at the surface does not seem to fit the experimental data since in all three cases the amount of arsenic added to the diffusion tube was far in excess of that necessary to react with the small amount of copper on the surface.

Furukawa and Thurmond (6) report a similar decrease in copper solubility with increasing arsenic pressure and explain the dependence by assuming that copper on arsenic sites is singly ionized Cu_{As}^-. It should be noted that the larger dips or minima observed in the copper diffusion profiles during acceptor diffusions were not obtained here.

Discussion

A simple straight forward explanation of the behavior of copper during acceptor diffusions does not appear possible. From the experimental data it is apparent that the minimum or dip in the copper diffusion profile is closely associated with the acceptor and, by implication, the formation of a p-n junction. Any changes made in the diffusion parameters which affect the acceptor impurity are reflected in the copper diffusion concentration profile by changes in the position and shape of the dip.

Kendall (11) has reported a similar phenomenon when indium was diffused into gallium arsenide in the presence of cadmium. Kendall attributes the "uphill" branch to an interaction between interstitial indium (In^{3+}) and gallium vacancies with the vacancies diffusing out of the interior toward the acceptor diffusion zone. The "downhill" side of the dip in the indium profile was attributed to a retardation of the incoming interstitials by the built in field of the acceptors.

Cunnell and Gooch (9) reported a similar anomaly in their investigation of the diffusion of cadmium into gallium arsenide using cadmium-115. Kendall (11) feels that the anomaly observed was due to the rapidly diffusing interstitial indium-115 daughter. Kendall was able to duplicate their results using indium-114 diffusing simultaneously with nonradioactive cadmium.

The electrical p-n junction in all the manganese and zinc-copper diffusions in this work were found to occur just at the minimum or slightly to the left of the minimum. In no case was the junction found to the right or deeper than the minimum of the dip in the copper diffusion profile.

In any explanation or interpretation of the behavior of copper during acceptor diffusions, the solubility data of Hall and Racette (4) must be carefully examined. Hall and Racette clearly showed that copper had high solubility in extrinsic p-type gallium arsenide because of enhanced interstitial solubility. This enhanced solubility of an impurity as a function of doping in a semiconductor is the same as that explained by Riess, Fuller, and Morin (15) using chemical interactions in silicon and germanium. Shockley and Moll (14) explained this same enhanced solubility of a charged impurity in a semiconductor using band theory by using the Fermi level as a measure of the dopant concentration. None of these workers predict the depressed solubility for copper in the vicinity of the pn junction that was observed in this work. At the temperatures used in these diffusions (815°C) and the low copper concentrations used, there is no question of solubility limitations. At 815°C the n-type substrates used in this work are intrinsic (E_F near mid gap) and Hall (4) observed no distinguishable difference between the copper solubility in semi-insulating (E_F mid gap) and extrinsic n-type material. On the basis of these solubility considerations, one would expect enhanced copper solubility in the p-region and a flat distribution in the n-region. But there should be no pronounced minimum or anomaly in the copper diffusion profile. For the Shockley-Moll model (14) to explain the concentration difference observed in Fig. 3, for example, it would be necessary for $e^{\Delta E_F/kT} = 3 \times 10^2$ on the n side of the p-n junction. That is the Fermi level would have to move about 0.57 ev which is not reasonable because at 815°C the band gap has decreased to around 1.0 ev ($\beta_G = -4.9 \times 10^{-4}$ ev/°K). The Fermi level for 1×10^{19} Mn/cm^3 in 1×10^{16} electrons/cm^3 material is 0.24 ev above the valence band edge and the n-type substrate Fermi level is mid gap ($E_F \sim 0.5$ ev) at 815°C.

Copper is known to diffuse by the dissociative mechanism (1) and has an effective D of approximately 5×10^{-6} cm^2/sec (1) at 815°C. The time required for the interstitial copper to saturate the 30 mil wafers used in this work would be in the order of 10 min which is small compared to the total 6-hr diffusion time used. We feel that the copper rapidly diffuses

throughout the wafer during the first 10 min of the 360-min diffusion cycle and then redistributes as the slower acceptor diffusion proceeds. This is supported by our experimental data on the 0.6-hr diffusion where the copper was profiled for 350μ (half-way through 30 mil wafer) (Fig. 2) into the crystal and found to be more or less uniformly distributed past the usual minimum.

Hall and Racette (4) showed that the mobile copper interstitial species was a singly charged donor by using drift measurements in an electric field. The drift field used was small (2 v/cm) compared to the built in field caused by acceptor gradients and p-n junctions ($\sim$ 600 v/cm) (12). It would be reasonable to expect this large built-in field to sweep the singly charged copper interstitials out of the region of the p-n junction. The enhanced interstitial solubility in the p-type region would not adversely affect this movement and would lead to the formation of a sharp minimum in the copper diffusion profile because of the solubility minimum observed by Hall (4) in slightly extrinsic p-type material. The copper concentration after the junction would then rise to an equilibrium level and be flat in the n-type bulk region of the crystal.

Acknowledgment

The authors wish to thank R. W. Haisty and P. Hoyt for their helpful discussions and for supplying some of the gallium arsenide samples used in this work. Their grateful acknowledgment is due to R. A. Reynolds for his discussions.

Compositional X-Ray Topography

J. K. Howard[1] and R. D. Dobrott

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

The advent of new semiconductor materials frequently demands new methods of investigating and defining those growth flaws which can degrade device performance. A new x-ray topographic method and concept were developed to study the defect structures in the heteroepitaxial systems. Compositional x-ray topography is an extension of the scanning-reflection method, which permits a nondestructive evaluation of the perfection in the substrate, deposit, and heterojunction. The theory and limitations of this method are discussed. Compositional x-ray topography was applied to the study of homogeneity and perfection in various heteroepitaxial systems, *i.e.*, GaAs-GaP, GaAs-InAs.

Heteroepitaxial systems have become the focus of many new device concepts (1, 2). Epitaxial deposition of pseudobinary alloys such as Ga(As, P) onto GaAs substrates has received considerable attention in the semiconductor industry (3-9). Layers of (Ga, In)As have also been deposited on single crystal GaAs substrates yielding material from which light-emitting diodes, mixer diodes, and varactor diodes can be fabricated (2). The crystalline perfection and homogeneity of these deposits is of importance in fabricating devices from this material. Since imperfections reflect the growth process, a knowledge of their concentration and type will permit a better understanding of the deposition parameters and clarify their effect on the deposit quality. Previous investigators have utilized back-reflection Laue methods and powder diffraction techniques to ascertain information on the structural quality and homogeneity of their deposits (4, 6). These methods are time consuming and yield results which may not be characteristic of the bulk deposit.

X-ray topography is a nondestructive method of evaluating the defect structure of many monocrystalline materials (10-18). The extinction contrast transmission method was developed by Lang (10) and modified by Schwuttke (13-15) for the study of semiconductor grade silicon. Defects in GaAs have been investigated by the anomalous transmission topographic method (16). The scanning-reflection x-ray topographic method (17) was developed to map imperfections over large area crystal surfaces (18). Compositional x-ray topography introduces a new concept to the field of x-ray topography. This method is capable of nondestructively examining the defects created at the heterojunction and "tracking" them through the deposit.

[1] Present address: IBM Systems Development Division, Fishkill, New York.

Scanning-Reflection X-Ray Topography (SRT)

Using the transmission arrangement, Schwuttke (15) was able to study dislocation arrays in silicon epitaxial deposits. The dislocation density of the silicon substrates was nearly zero in most cases; the superposition of the substrate flaws on the topographic image did not prevent the imperfections in the deposit from being discerned. The dislocation density of GaAs is usually $> 5 \times 10^3$ cm^{-2} which prevents exact identification of deposit flaws in the transmission topographs. Since the total thickness of the GaAs deposit and substrate produced a value of $\mu t >> 1$, anomalous transmission must be used if a nondestructive analysis is required (16).

The scanning-reflection method was designed to inspect the active growth surface of the GaAs substrate for mechanically induced damage and grown-in de-

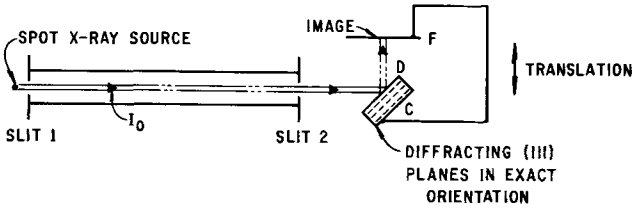

Fig. 1. Experimental arrangement for scanning-reflection x-ray topography.

fects. After deposition, another topograph revealed only the defect array in the GaAs deposit (17, 18); an attempt was made to relate the deposit flaws to either the substrate preparation and/or perfection, or the deposition parameter.

The experimental arrangement is depicted in Fig. 1. The substrate crystal (C) in diffracting position is coupled to a film holder (F) mounted perpendicular to the diffracted beam (D). The incident beam (I_0) is restricted by slits (S_1) and (S_2); slit (S_2) is adjusted until only the $K\alpha_1$ component of the characteristic radiation can diffract. The ribbon-shaped incident beam (25 x 0.05 mm) impinges on the crystal at the proper angle, and a projected image of the flaws in the irradiated material is formed on the photographic plate. An image of the entire slice is obtained by translating the coupled film-sample unit perpendicular to the incident beam or parallel to the slice surface. The sequence of examination (substrate topograph-deposition-deposit topograph) is tedious and can introduce a contamination and/or strain problem because of handling. A more desirable method of inspection would permit *in situ* examination of the substrate and epitaxial film perfection after deposition.

Principle of Compositional X-ray Topography

Compositional x-ray topography is an application of the scanning-reflection x-ray topographic method. The perfection, homogeneity, and single crystallinity of many heteroepitaxial systems can be investigated with this method. The diffraction angle depends on the lattice parameter (which can be calculated or experimentally determined); the substrate and film can be examined separately by the employment of the proper diffraction angle. Only that volume element in the irradiated material which has the desired lattice parameter will diffract to form the topographic image. This method of examination is effective to the depth of penetration of the incident x-ray beam. The maximum penetration depth, D (microns), can be expressed by the relation

$$D = -\ln A \cdot 10^4 / \left(\frac{\mu}{\rho} \cdot \rho \left[\csc(\theta - \psi) + \csc(\theta + \psi) \right] \right) \quad [1]$$

μ/ρ (cm^2/g) is the mass absorption coefficient, ρ (g/cm^3) is the density, θ the diffraction angle, ψ the angle between the slice surface and the diffracting planes, and A is the fractional attenuation of the incident beam.

A plot of the penetration depth as a function of $\theta - \psi$ (angle between the incident beam and the slice surface) is shown in Fig. 2. For a given radiation, crystal growth axis, and reflecting plane, the $\theta - \psi$ value can be calculated and the penetration depth determined. The graph depicts D in GaAs for various wavelengths of radiation ($A = 0.1$); this plot is a good approximation for Ga(As, P).[2]

[2] Experimental verification of $\theta - \psi = 45°$ (copper radiation) consists of determining the Ga(As, P) thickness which completely attenuates the (333) reflection of the substrate. The composition measurement developed by Miller (19) and employed by Dobrott (20) indicated that a 25μ Ga(As, P) deposit eliminated the (333) GaAs reflection ($\theta - \psi = 45°$) as compared to 21.8μ calculated from Eq. [1].

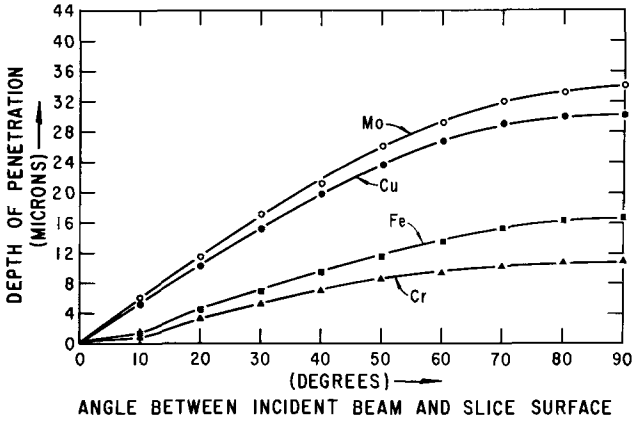

Fig. 2. X-ray penetration depth in GaAs

The principles of compositional x-ray topography are only satisfied under certain conditions: (*a*) the total film thickness is less than the penetration depth of the incident x-ray beam; (*b*) the diffraction angles of the film and substrate are sufficiently separated to insure exact angular selection; (*c*) the absorption coefficient is constant for each compositional layer. These restrictions, however, can be utilized to gauge the quality of the deposit.

Compositional x-ray topography applied to the GaAs-GaP *and* GaAs-InAs *heteroepitaxial systems.*— The variation of lattice parameter and composition has been shown to be linear in the GaAs-GaP and GaAs-InAs alloy systems (5, 21). Since the difference between the diffraction angles for GaAs and GaP (or GaAs and InAs) is small compared to θ, then θ_x (where x is the mole fraction of GaP) has been shown to vary directly with composition (20). A plot of these variables is depicted in Fig. 3 for the case of a Ga(As, P) film deposited on a (111) GaAs substrate. The Δ 2θ value changes from the (333) reflection of GaAs to the (333) reflection of GaP (copper Kα radiation). Because of this linearity, the mole fraction of GaP, x, can be related to the diffraction angle by the expression

$$2\theta\,[GaAs_{1-x}P_x] = x \cdot 2\theta\,[GaP] + (1-x) \cdot 2\theta\,[GaAs] \quad [2]$$

Similar relationships exist for other reflections, *i.e.*, the {440} reflections of GaAs and GaP. The composi-

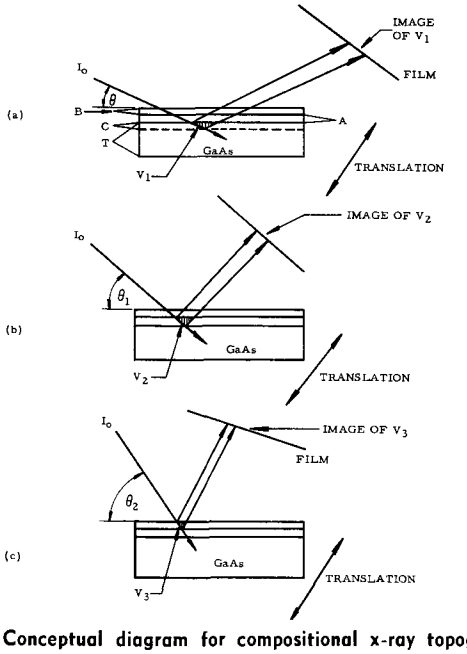

Fig. 4. Conceptual diagram for compositional x-ray topography. Each layer can be diffracted separately by utilizing the diffraction angle which corresponds to the lattice parameter (composition) of that layer.

tion of the alloy deposit determines the diffraction angle.

Figure 4 depicts an idealized case of the GaAs-GaP heteroepitaxial system. Epitaxial layers A and B have been sequentially deposited on a GaAs substrate. Assume that the A layer has a composition $GaAs_{1-x_1}P_{x_1}$ and diffraction occurs when the incident beam impinges at an angle θ_1 with respect to the diffracting planes which are parallel to the slice plane. The B layer has a GaP concentration x_2, $GaAs_{1-x_2}P_{x_2}$, where $x_1 << x_2$. This layer is in diffraction position when the incident beam impinges at an angle θ_2 where θ (GaAs) $< \theta_1 < \theta_2$. In Fig. 4(*a*) the incident beam I_0 strikes the crystal at the angle θ, and only the GaAs substrate is properly oriented. The beam penetrates to a depth C below the substrate surface; a volume element, V_1, diffracts coherently to form the topographic image. The image of the defects in V_1 is registered on the film plate placed perpendicular to the diffracted beam. As the crystal-film unit is translated perpendicular to the incident beam, the diffracting volume V_1 is "swept" parallel to the diffracting planes. This total image displays the perfection of the substrate in the C layer. If the crystal is rotated about an axis perpendicular to the plane of Fig. 4, the incident beam now impinges at an angle θ_1. The A layer is now in diffracting position [Fig. 4(b)]. The volume element V_2 bounded by the incident and diffracted beams diffracts to form an image of the flaws in V_2. Subsequent translation permits the A layer to be examined independent of the B layer and the substrate. The perfection of the B layer can be determined in a similar manner [Fig. 4(c)]. If Fig. 4 represents a cleaved {110} surface perpendicular to the plane of the slice, then (SRT) topographs of this surface would reveal compositional changes in the growth direction.

Experimental

Materials.—Single crystals of GaAs were grown using the Czochralski method; the growth axis was parallel to either the [111] or [100]. In the case of the crystals grown on the (111) plane, slices were cut 5° off (111) toward <100>. The slice thickness after sawing with an ID saw was approximately 0.030 in. The slices were then chemically polished on the (111)-B [or the (100)] face with a solution of NaOCl: H_2O (22). These slices were employed as substrate material following a brief etch ($8H_2SO_4$:H_2O:H_2O_2).

An open-tube vapor transport system was used to deposit epitaxially the Ga(As, P) or (Ga, In)As alloy on the GaAs substrate (1-3).

Composition measurement and x-ray procedure.—The sample (film/substrate) was clip-mounted on a goniometer head which was at the end of a shaft. The shaft was inserted into a standard Norelco diffractometer. Characteristic copper radiation was employed in the measurement; the diffracted radiation was rendered monochromatic with a focusing monochromator. The substrate was then aligned to diffract the (333) reflection in the case of a (111) sample. The (400) reflection was utilized if the substrate was (100). However, asymmetric reflections have been employed for specific applications. The sample was scanned between the angular limits of the alloy, *i.e.*, 2θ [GaAs] to 2θ [GaP]. The Ga(As, P) reflection occurs between these angles. Since the diffraction angle of the GaAs substrate was known, the substrate reflection acts as an internal standard. Since Vegard's laws hold in the GaAs-GaP alloy system and the interplanar spacing, d, can be determined from the alloy peak position, then the mole fraction of GaP can be calculated from the expression

$$x = (d\,\mathrm{Ga(As,P)} - d\,\mathrm{GaAs}) / (d\,\mathrm{GaP} - d\,\mathrm{GaAs}) \quad [3]$$

x can also be calculated from Eq. [2] as θ_x is linear with d in the alloy range.

The composition measurement uniquely determined the diffraction angles of the compositional layers in the deposit. These angles are used to align each layer for (SRT) topographs. An open-tube detector was used to establish the diffraction peaks; receiving slits were employed to culminate the alignment. Previous investigators have employed the standard powder diffraction methods to determine composition; this method is destructive and time consuming (4, 6).

The sample was mounted on a standard goniometer head in the (SRT) camera. The GaAs substrate was oriented with a scintillation detector-ratemeter circuit. The diffraction angles of the deposit are found by rotating the sample about the ω axis. The topographs were obtained with copper radiation. The effective size of the focus was 100μ (Jarrell-Ash microfocus generator). Nickel foil (0.002 in.) was placed over the film holder to filter the radiation diffracted from the sample. Kodak type A plates were utilized; the average exposure time was 1½ hr.

Results and Discussion

Inhomogeneity.—A composition measurement performed on a (100) deposit of (Ga,In)As yielded the (400) diffraction angle of 64.2°; the GaAs reflection was registered at 66.2° (Fig. 5). This angular separa-

tion corresponds to a 50% InAs alloy. The (400) topograph of the alloy layer reveals an image which exhibits nonuniform darkening (Fig. 6a). The central region of the image is of lower contrast than the periphery. The relative contrast was reversed by the employment of the GaAs diffraction angle to form the topographic image (Fig. 6b). The GaAs layer is coherently incorporated into the alloy matrix. This layer acts as an absorber, which attenuates the intensity diffracted from this region. These topographs map the spatial position of the compositional variations in the deposit.

A (111)-B (Ga, In)As deposit was also evaluated for composition (Fig. 7). The (333) alloy peak was displaced 2.5° from the (333) GaAs reflection. The (333) topograph of the 35% InAs layer revealed large areas of null contrast in the matrix (Fig. 8). The inhomogeneous region was shown to be GaAs rich in the same manner as Fig. 6a and Fig. 6b.

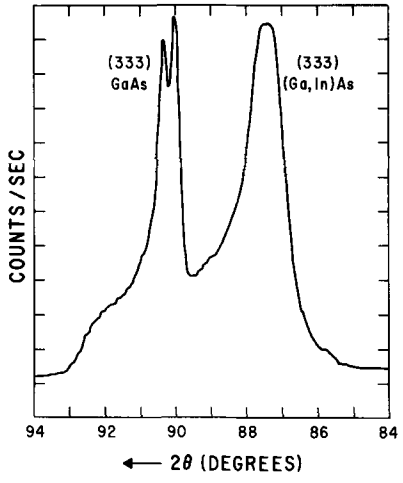

Fig. 7. Diffraction scan of an inhomogeneous (111) deposit of (Ga,In)As. The alloy composition was 35% InAs.

The scanning-reflection x-ray topographic method was employed to investigate planar variations in composition over large area deposits of (Ga, In)As. This type of analysis has certain advantages in the detection of gross inhomogeneity in the alloy deposits: (*a*) the scanning and /or counting time which would be involved in an electron microprobe analysis of these large area deposits would be impractical; (*b*) the shape of the alloy peak (composition measurement) has been shown to be sensitive to inhomogeneity, but no inference can be made to the spatial distribution of the inhomogeneous regions; (c) the reflectivity method (20) could not detect small variations in composition across the surface. X-ray topography clearly differentiated two regions in a Ga(As,P) deposit which differed by only 3% GaP (18). The topographic method is a fast, semiquantitative, and nondestructive technique to evaluate homogeneity.

Reflectivity measurements have been employed to determine axial changes in composition of Ga(As,P) epitaxial deposits (20). Homogeneity can be evaluated by incrementally etching the deposit, in conjunction with compositional determinations by reflectivity; the reflectivity measurements determine the composition at the surface only. This measurement can be quantitative (x-ray standards), but is a destructive process which involves a long evaluation time.

Compositional x-ray topography can also be applied to the evaluation of axial changes in composition. The method is simple, nondestructive, and yields a very sensitive qualitative display of the compositional changes encountered during epitaxial growth. A (111)-B Ga(As,P) deposit (0.002 in. thickness) was

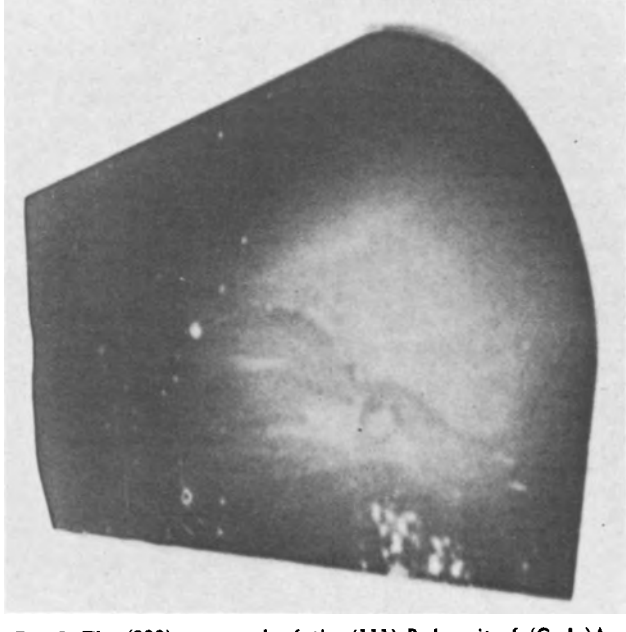

Fig. 8. The (333) topograph of the (111)-B deposit of (Ga,In)As which reveals a compositional gradient across the slice.

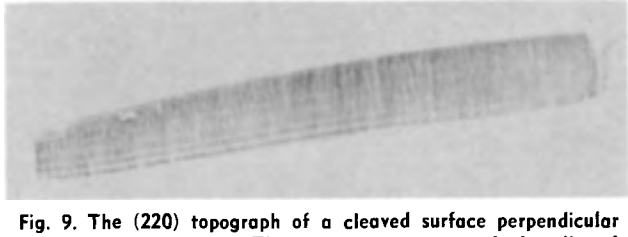

Fig. 9. The (220) topograph of a cleaved surface perpendicular to the (111) slice plane. The deposit image reveals lamella of different composition.

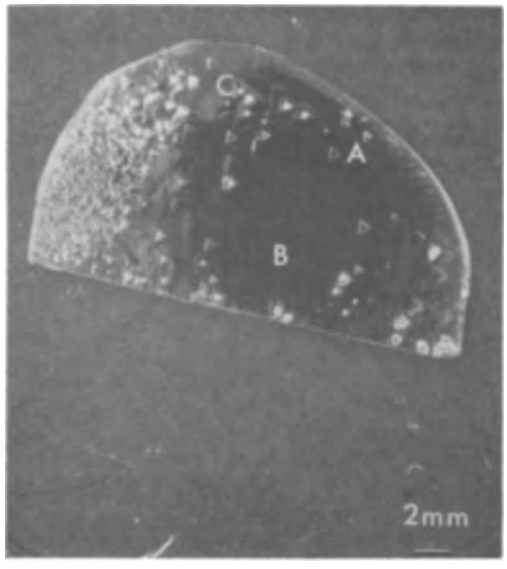

Fig. 10. Numerous hillocks on a (111)-B Ga(As,P) epitaxial film

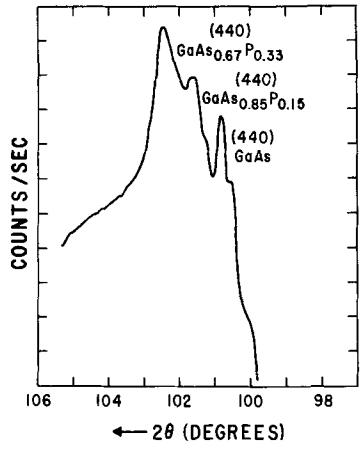

Fig. 11. Composition scan of Ga(As,P) deposit with hillocks

cleaved to expose a {110} cleavage plane normal to the plane of the slice. This is a standard technique to determine film thickness by interferiometric methods. A $(2\bar{2}0)$ topograph of the cleaved surface is shown in Fig. 9. The image consists of a series of alternating light and dark lines.

Since the sample was aligned to diffract Ga(As,P), the substrate image was not observed. The deposit image revealed dark lines traversing the width of the film. These lines correspond to regions of fixed composition, whereas the light lines (no contrast) represent lamella of different composition. The spacing between the lines decreases during growth which indicates that the deposit was approaching a constant composition. This effect has been observed in many alloy deposits and could degrade the efficiency of light-emitters fabricated from this material (23).

Hillocks.—Hillocks (localized surface protrusions) have been observed on epitaxial deposits of silicon (24-26), germanium (27-28), and GaAs (29). More recently, these (or similar) defects were detected in epitaxial deposits of Ga(As,P) and (Ga,In)As. Compositional x-ray topography was used to study the morphology of these flaws in Ga(As,P).

Numerous hillocks were obtained in a (111)-B deposit of Ga(As,P) (Fig. 10). The thickness of the film was determined to be 14μ. A composition measurement was obtained by the employment of the asymmetric (440) reflection. The diffraction scan is shown in Fig. 11. The (440) GaAs reflection was registered at 100.8°; the (440) $GaAs_{0.85}P_{0.15}$ layer and the (440) $GaAs_{0.67}P_{0.33}$ layer yielded diffraction angles of 101.6° and 102.5°, respectively. The relative peak heights indicate that the 15% GaP layer was the initial deposit, *i.e.*, this reflection was attenuated by absorption more than the 33% GaP layer. The diffraction angles were then used to align each layer for (SRT) topographs.

The (440) topograph of the GaAs substrate (Fig. 12a) reveals the hillocks as triangular regions of null contrast. The image shapes are either sharp (arrow A), diffuse (arrow B), or diffuse with a definite triangular center (C). The lack of contrast observed in the hillock images indicated that they are misoriented with respect to the substrate which corresponds, in this case, to a difference in composition. The (440) topograph of the $GaAs_{0.67}P_{0.33}$ layer also displayed the hillocks as regions of reduced contrast (Fig. 12b). The intense darkening in this image was the result of local cracks in the deposit which indicates the effect that hillock formation can have on the deposit quality. The sample was then oriented to diffract the $GaAs_{0.85}P_{0.15}$ layer; the (440) topograph exhibits only the hillock images (Fig. 12c). The matrix was misoriented for diffraction.

The hillocks are probably generated at the substrate interface since their composition corresponds to the 15% GaP layer. The final compositional layer (33% GaP) forms around the hillocks and frequently overgrows these defects. A diffuse image was observed in Fig. 12a (arrow B), and no image was registered in

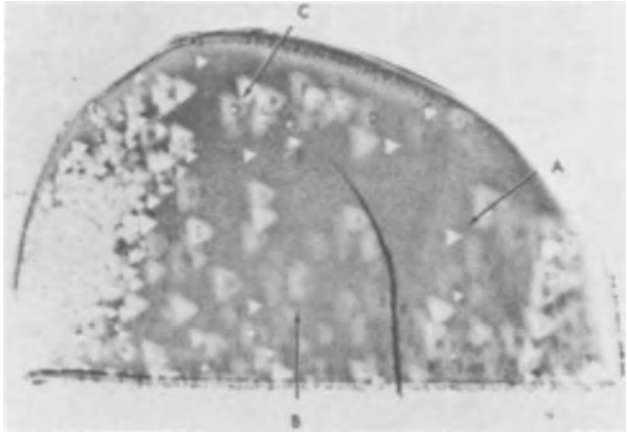

Fig. 12(a). The (440) topograph of the GaAs substrate which reveals the hillocks as triangular regions of null contrast. The dark line traversing the image is a spurious reflection.

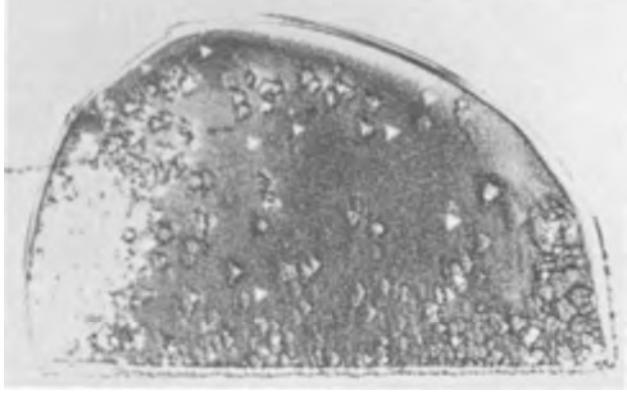

Fig. 12(b). The (440) topograph of the $GaAs_{0.67}P_{0.33}$ layer; the dark contrast results from local cracks in the deposit.

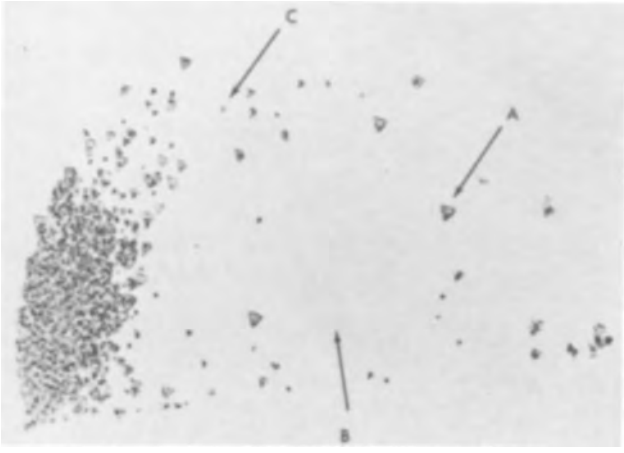

Fig. 12(c). The (440) topograph of the $GaAs_{0.85}P_{0.15}$ layer, only the hillocks are in diffracting position.

Fig. 12c. However, other hillocks protrude through the top layer (arrow A). The hillocks which protruded through the surface layer are revealed as triangles in Fig. 12c (arrow A). The partially overgrown hillocks (C) produce the diffuse images with null contrast centers (Fig. 12a, arrow C); only the triangular center can be seen in Fig. 12c.

The sample was angle-lapped and stained (Fe-HNO_3) on a 5° bevel to reveal the cross section of a hillock (Fig. 13). The dark irregular line, A, is the substrate and $GaAs_{0.85}P_{0.15}$ layer interface. The line at B is the junction between the $GaAs_{0.85}P_{0.15}$ and $GaAs_{0.67}P_{0.33}$ layers. The hillock, C, has the same stain as the $GaAs_{0.85}P_{0.15}$ layer which confirms the x-ray results. This hillock was determined to be 7μ above the $GaAs_{0.85}P_{0.15}$ layer.

Summary and Conclusions

The joint application of x-ray topography (SRT) and a diffractometer method to determine composition (compositional x-ray topography) has been shown to be an effective method to study the structural perfection and homogeneity of epitaxial Ga(As,P) and (Ga, In)As. Some results of this investigation are: (*a*) a planar compositional gradient was observed in (Ga,In)As deposits; the inhomogeneous regions were spatially located, and their composition was shown to be GaAs rich; (*b*) axial changes in composition were detected in a Ga(As,P) deposit (presumed to be constant composition); (*c*) the composition of hillocks generated at the substrate-$GaAs_{0.85}P_{0.15}$ layer interface was determined to be 15% GaP; (*d*) the hillocks (15% GaP) were frequently overgrown by a 33% GaP layer, and local cracking of this layer appeared to be related to the existence of hillocks.

Although this investigation was restricted to the GaAs-GaP and GaAs-InAs heteroepitaxial systems, this method has been successfully used to study stress relief mechanisms in deposits of germanium on silicon substrates (30). Another application concerns the perfection of (Ga, In)As which was deposited in holes that were cut (etched) into heavily dislocated monocrystals of GaAs (31). The dislocation density at the GaAs-(Ga,In)As heterojunction has also been compared to the dislocation density characteristic of the deposit (32). This type of examination is of interest in the determination of structural flaws created by lattice mismatch.

Potential of a Platinum Electrode at Low Partial Pressures of Hydrogen and Oxygen

II. An Improved Gas-Tight System with a Negligible Oxygen Leak

Sigmund Schuldiner, Bernard J. Piersma,[1] and Theodore B. Warner

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

A tight electrochemical system was constructed in which the P_{O_2} above the cell solution was $<10^{-9}$ atm. Comparing potentials with data from a previous paper (1) showed that very small amounts of O_2 leaking into a closed system can have marked effects on potential behavior at low P_{H_2}. Reduction of the oxygen leak to negligible proportions showed that: (*a*) the Nernst equilibrium relation for the H^+/H_2 couple holds only for P_{H_2} in excess of 10^{-6} atm; (*b*) at low P_{H_2}, trace amounts of O_2, even in the presence of several orders of magnitude more hydrogen, acted as an electrode poison causing a positive deviation from the theoretical Nernst behavior; (*c*) in O_2-free solution, at P_{H_2} below 10^{-6} atm, the potential remained at 0.18v positive to NHE and was independent of P_{H_2}. The potential-determining reaction in this region may be an exchange of H^+ in solution with H atoms dermasorbed in the Pt. The potential *vs.* oxygen partial pressure relation was essentially the same as found in previous work from this laboratory. Residual hydrogen associated with Pt at potentials from 0.18 to 0.2v did not react with oxygen.

In the first paper of this series, Warner and Schuldiner (1) determined open-circuit rest potentials on bright platinum as a function of oxygen or hydrogen partial pressures from 10^{-2} to 10^{-7} atm. The oxygen leakage (from air) into the cell was estimated to give a partial pressure of about 10^{-7} atm. The Nernst equilibrium relation for the H^+/H_2 couple held only at hydrogen partial pressures in excess of 1×10^{-4} atm. At hydrogen pressures smaller than this value the measured potentials were positive to the theoretical Nernst values. No satisfactory explanation could be given for this deviation, but it was felt that the trace of oxygen leaking into the system might be the cause. Even though a correction for the oxygen leak, assuming complete reaction with hydrogen at the Pt surface, was made, trace amounts of oxygen could possibly have remained on the surface when the hydrogen partial pressure was below 10^{-4} atm. This oxygen might then act as a poison for the H^+/H_2 exchange (even though the hydrogen partial pressure was several orders of magnitude higher) and give potentials positive to the theoretical equilibrium values. To determine if such traces of oxygen could affect the potential at low hydrogen pressures it was necessary to improve our gas-tight system to reduce further the leakage of oxygen into the cell. This was done in three ways: (*a*) improved purification of the helium carrier gas (Fig. 1) using two Meyer-Ronge (2) columns instead of one; (*b*) construction of a more compact gas purification and cell system; (*c*) installation of the critical part of the gas purification system, the gas generator, and the cell in a controlled environment box under an atmosphere of nitrogen (Fig. 2). Thus the outside of the system was exposed to nitrogen rather than air. The partial pressure of O_2 in the environment box was maintained at $5 \pm 2 \times 10^{-4}$ atm. This meant that at the outside of the system the O_2 pressure was reduced by 1/400 of the value in air.

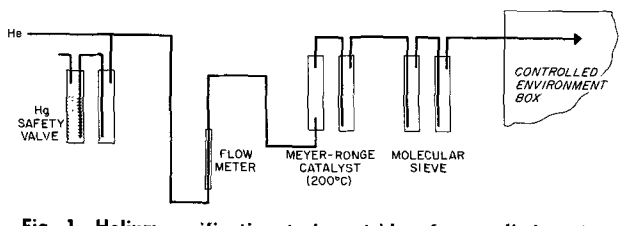

Fig. 1. Helium purification train outside of controlled environment box.

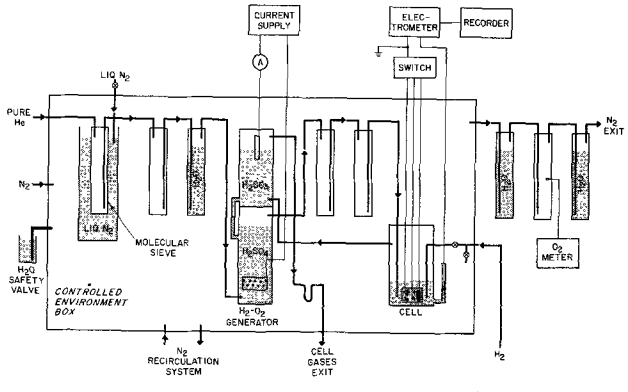

Fig. 2. Electrochemical system inside of controlled environment box and associated equipment.

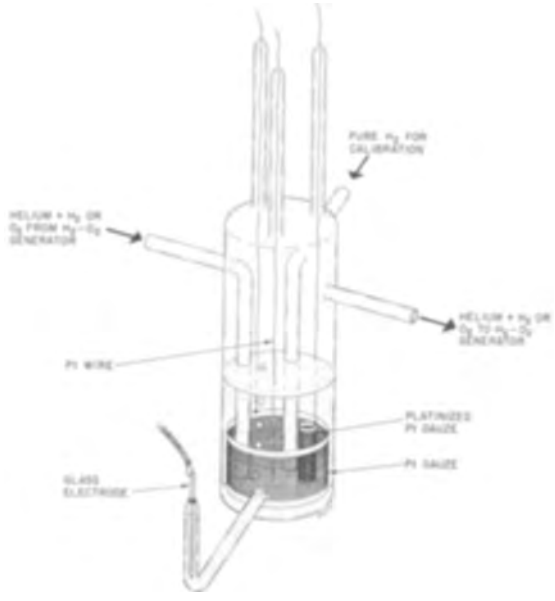

Fig. 3. Schematic of electrolytic cell. Glass pipe connections were actually used for electrode and gas connections and to connect upper and lower section of cell compartment. [See Fig. 1, p. 1143 of ref. (3) for illustration showing construction of cell.]

This improved gas-tight system reduced the oxygen leak into the cell to immeasurable proportions and, as the data will show, strongly affected the hydrogen pressure *vs.* potential relation.

Experimental

Apparatus.—The electrochemical cell (3) (Fig. 3) contained a miniature glass electrode, a Pt wire electrode 5 cm long with a 0.064 cm diameter, a large Pt gauze electrode (~100 cm^2), and a large tightly rolled cylinder of Pt gauze platinized in lead-free platinic acid (total geometric area about 30 cm^2). The electrolyte was 1M H_2SO_4 maintained at 25° ± 2°C. The helium purification train, electrolytic H_2 or O_2 generator (1), cell, and controlled environment system are shown in Fig. 1 and 2. The two stopcocks leading to the cell (Fig. 2) were Kern high-vacuum greaseless stopcocks with Viton A diaphragms. The controlled environment box was manufactured by Vacuum/Atmospheres Corporation and was 45 in. long by 30 in. deep by 33 in. high. The liquid nitrogen cold trap consisted of a molecular sieve (Linde 5A) column in a Linde LD 10 liter Dewar. This Dewar flask was filled *via* an insulated copper pipe which led outside the box where it was shut off with a valve. Copper tubing connected the helium tank to the flow meter. From this point the system was glass with one Viton A O-ring connection between the two Meyer-Ronge catalyst columns. At the end of the second molecular sieve column a gold-plated (to prevent diffusion of hydrogen in from the room atmosphere) copper tube was connected with a second Viton A O-ring. This gold-plated copper tube conducted the purified helium into the environment box to the cold trap. Therefore, even though two Viton A seals were used outside the box, one seal was between the two Meyer-Ronge columns so any trace of O_2 which diffused through it was removed by the second Meyer-Ronge column. The second seal outside the box was in front of the molecular sieve-liquid N_2 cold trap so that any O_2 which diffused through this O-ring would be frozen out. Since the liquid N_2 cold trap was inside the environment box, diffusion of O_2 through any of the other seals was minimized. The manufacturer of the Viton-A O-rings claims a seal good to 10^{-6} Torr, and previous work (1) indicated an oxygen leak in the entire system equivalent to about 10^{-7} atm, so with the new system used we feel that the oxygen leak within the cell should not exceed 10^{-9} atm. In any case, attempts to determine the amount of oxygen leaking into the cell from the atmosphere were fruitless because of its extremely low concentration.

An N_2 atmosphere inside the environment box was obtained by passing tank N_2 into the box for several days until O_2 partial pressure inside the box dropped to about 10^{-3} atm. The flow of N_2 was then reduced, and the gas inside the box was recirculated through a bed of copper turnings at 450°C to remove oxygen. Recirculation was *via* a high-speed gas pump with a flow of about 1.5 l/min. It was soon discovered that the evaporation of liquid N_2 maintained a sufficient gas flow through the environment box and the tank N_2 was eliminated. Once the O_2 pressure dropped to 5 x 10^{-4} atm, as determined on the outlet side with a Beckman, Model E2 oxygen analyzer, recirculating N_2 was no longer helpful in reducing the O_2 partial pressure. From that point on the only sources of N_2 needed were from the evaporation of liquid N_2 and from the tank N_2 used to pump liquid N_2 into the Dewar. It was necessary to fill the Dewar every two weeks. This operation resulted in a large influx of N_2 into the box so that a large outlet valve from the box had to be kept open to keep the internal pressure below 5 in. of water in excess of atmospheric pressure. In addition a water-filled safety valve was attached to the box. This valve would release N_2 when the pressure inside of the box exceeded 5 in. of water above normal atmospheric pressure.

Electrical connections were made as shown in Fig. 2. A system of rotary switches was used to alternate every 5 min from one Pt electrode in the cell to another. The potential between each Pt electrode and the glass reference electrode was measured with a Keithley 610A electrometer and displayed alternately on a Varian recorder.

Procedure.—Glassware was cleaned with boiling nitric acid and rinsed 12 to 15 times with triply distilled water (one stage of distillation from alkaline permanganate solution, another from water containing fumed phosphoric acid, the final two stages being from a quartz still). The sulfuric acid solution was preelectrolyzed for three days at 50 ma. This was followed by calibration of the glass electrode against the platinum electrodes in H_2 saturated solution at 1 atm pressure. Hydrogen flow was then replaced with a flow of pure helium always maintained at 40 std ml/min. Pressure within the cell was about 10 Torr above atmospheric. The hydrogen line was disconnected, flushed, and filled with helium. The environment box was then sealed and air was replaced with N_2 by the procedure described above. Either hydrogen or oxygen was introduced into the helium carrier gas by the special electrolytic H_2 or O_2 generator (1) designed at this laboratory. Gas generation rates were calculated from constant electrolysis currents. The partial pressures were calculated from the rate of flow of helium (known to 5%) and the rates of H_2 or O_2 generation (known to 1%).

The rate of attainment of steady-state potentials was very dependent on electrode area, especially at partial pressures below 10^{-6} atm. The platinized Pt electrode area was so large that at low partial pressures this electrode lagged far behind the other two Pt electrodes. All three electrodes would come to the same potential given sufficient time, but the platinized Pt electrode required such a long time (months) at very low partial pressures that in most measurements only enough time was allowed for the Pt wire and gauze to come to the same steady-state values. The experiments which gave the data recorded in this paper took about 11 months. Several runs up and down the pressure scale were taken.

When pure helium or helium mixtures with low hydrogen partial pressures flowed through the cell, the addition of liquid N_2 to the cold trap caused the Pt

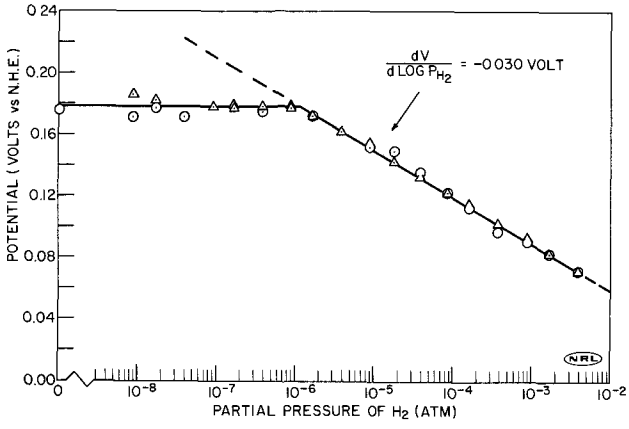

Fig. 4. Relation between hydrogen partial pressure and rest potentials. Dashed line shows normal Nernst potential relation for H^+/H_2 exchange; ○ decreasing H_2 pressure; △ increasing H_2 pressure.

wire and gauze electrode potentials to deviate in a positive direction. Several hours were required for these electrodes to recover their original potentials. We attribute this effect to a trace of O_2 which was introduced during the cooling of the environment box (its temperature usually decreased to about 17°C during the filling of the Dewar). This cooling caused a decrease in pressure in two arms of the cell, and the space above the solution in these compartments decreased as the cell solution rose slightly in them. This may have caused a trace of oxygen trapped in these side arms or in the counter electrode side of the gas generator to go into solution and/or caused a further removal of traces of oxygen associated with the interior walls of the glass system. The rise of solution in these side arms showed that leaks did not exist. In any case liquid N_2 was added only once every 14 days so that this effect was minimized.

Results and Discussion

Experimental results.—The experimental results are shown in Fig. 4 for the hydrogen electrode and in Fig. 5 for the oxygen electrode. Values were obtained with both increasing and decreasing gas partial pressures and were taken only after steady-state potentials were reached. For hydrogen partial pressures below 10^{-5} atm, steady-state meant no significant change in potential (values constant within ± 3 mv, and no monotonic trend within this uncertainty) on the Pt wire and gauze for at least several days. Their potentials generally agreed to 2 mv, with occasional differences of 5-7 mv. For the platinized platinum gauze at the lowest partial pressures, the electrode continually changed in the expected direction, but at such a slow rate that we did not normally wait for this electrode to reach the steady-state value of the other two electrodes.

For oxygen partial pressures, the rate of attainment of steady-state potentials for decreasing oxygen pressures was very slow, even for the Pt wire. Here also the potentials shown in Fig. 5 represent values that were unchanged for at least several days, but because of extreme system sluggishness, agreement between electrodes was poorer (5-30 mv) and random variations with time larger. Experiments were conducted also in which the gas flow was changed from helium containing first hydrogen and then oxygen and *vice versa*. This made no difference in the final rest potential providing one waited long enough for the rest potential to be attained.

In one experiment, after the electrodes were exposed to oxygen-containing helium for over two months, the oxygen flow was cut off. The rest potential on the Pt wire was reached in about one week (0.2v). Then, to test the purity of the solution, the cleanliness of the electrodes, and the tightness of the entire system, a single constant current pulse was applied to the Pt wire in the helium-saturated solution. This test took place six months after cleaning and closing the system. An anodic charging curve of the first applied current pulse gave an oscilloscopic trace which showed a small hydrogen region from 0.2 to 0.4v followed by double layer and linear oxygen regions. The shape of the charging curve met our published (4) requirements for a clean Pt surface free of detectable amounts of either oxidizable or unoxidizable organic contaminants or of electrode poisons. The fact that hydrogen was still associated with the Pt surface after such a long exposure to oxygen was unexpected, but it does account for the relatively low positive potentials of Pt observed in helium-saturated solution.

Effect of oxygen leak.—In order to estimate the maximum possible amount of oxygen which leaked into the cell, the following experiment was carried out. After passing pure helium through the cell for five days, the average potential of the three Pt electrodes was 0.175v. The sequence of changing the partial pressure of either oxygen or hydrogen in the cell to the values shown in Fig. 6 was then carried out. At the end of each time noted for the given partial pressure shown in Fig. 6 the potential of the Pt wire, the electrode with the fastest response, is shown. It should be noted that these are not the final rest potentials at these partial pressures. These results are for the purpose of demonstrating the effects of small alternate additions of oxygen and hydrogen on the potential. As the data show, potentials are sensitive to oxygen partial pressures as low as 4.4×10^{-9} atm and hydrogen partial pressures as low as 8.7×10^{-9} atm. From this we can conclude that the oxygen leak into the system cannot be, at most, more than enough to give a partial pressure of 10^{-9} atm. In fact, from the relatively fast response times shown in Fig. 6, one can conclude

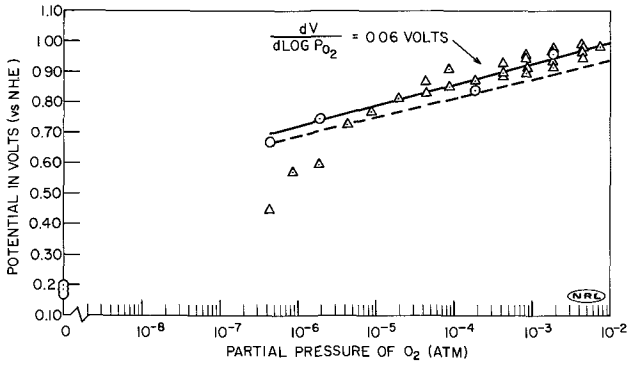

Fig. 5. Relation between oxygen partial pressure and rest potentials. Dashed line indicates average values previously obtained at this laboratory (1, 3); ○ decreasing O_2 pressure; △, increasing O_2 pressure.

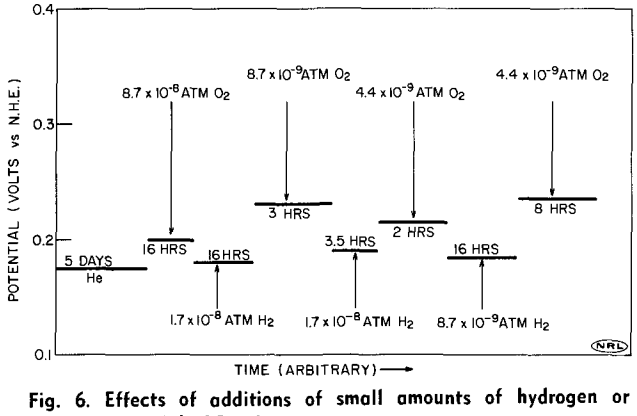

Fig. 6. Effects of additions of small amounts of hydrogen or oxygen on potential of Pt wire.

that the oxygen leak, expressed in terms of resulting partial pressure, was likely under 10^{-10} atm.

Platinum rest potentials vs. P_{H_2} or P_{O_2}.—The data in Fig. 4 demonstrate that a normal Nernst equilibrium relation between potential and log P_{H_2} exists down to 1 x 10^{-6} atm of hydrogen. At lower hydrogen pressures the potential is independent of P_{H_2}, this implies that the exchange current density of the H^+/H_2 exchange at P_{H_2} below 10^{-6} atm is so low [$\approx$1.4 x 10^{-9} amp/cm^2 (5)] that another potential-determining reaction takes over. Such a reaction could be

$$Pt\text{-}H \rightleftarrows Pt + H^+ + e$$

where Pt-H either represents hydrogen atoms dermasorbed in the Pt skin or an alloy of Pt and H atoms. Schuldiner, Castellan, and Hoare (6) concluded that a similar potential-determining reaction took place on α Pd-H alloys.

Luk'yanycheva and Bagotskii (7) determined the initial open-circuit potentials of carefully degassed platinum in 1*N* H_2SO_4 degassed under vacuum. These potentials were 0.210 and 0.215v. They observed that these rest potentials are close to the point of zero charge of platinum.

Our measurements in helium-saturated solution gave rest potentials 15-50 mv more negative than those of Luk'yanycheva and Bagotskii. In addition, the fact that we were able to find a small amount of hydrogen associated with the electrode after prolonged exposure to oxygen showed that the rest potentials we found in helium-saturated solutions and the plateau at 0.178v shown in Fig. 4 are influenced by hydrogen.

Since the potential plateau in Fig. 4 is below the theoretical Nernst line, oxygen is not a factor as it was in the first paper of this series (1). The stability of Pt-H in this region is demonstrated by the rest potential in pure helium-saturated solution. The experiments which showed that after an electrode has been in oxygen-rich helium the rest potential in pure helium is about the same indicate that this residual hydrogen does not react with oxygen. In addition, it shows that sorbed oxygen is in equilibrium with O_2 gas because when the O_2 pressure drops to zero the oxygen coverage of the surface appears to drop to zero. The stability of this residual hydrogen indicates that it is irreversibly sorbed with respect to H_2 and supports the repeatedly stated view from this laboratory that this hydrogen is dermasorbed in the Pt skin and may be alloyed with Pt. The hydrogen content of the Pt electrode apparently did not change with H_2 partial pressures below 10^{-6} atm, as indicated by the unchanging electrode potential in this region. This may be contrasted with the dependence of hydrogen content of α Pd-H on H_2 partial pressure as shown by Moon (8). However, much smaller amounts of H are involved than in the case of α Pd-H alloys.

One may argue that the plateau shown in Fig. 4 is due to an organic or other trace material in solution. However, the cleanliness test made after the system was used for six months shows that this possibility is unlikely. In addition, finding hydrogen associated with the platinum after long exposure to oxygen indicates that hydrogen determines the potential. Another experiment to show the effects of hydrogen on potential was made by determining the rest potential in pure helium followed by addition of oxygen to give a more positive rest potential followed by the addition of less than 10^{-6} atm H_2 which then gave the same rest potentials shown in Fig. 4. Furthermore, the total area of Pt in solution was so large that impurity levels, which were below the detectable limit of our cleanliness test (4), would be so minute that even the traces of oxygen or hydrogen used would overcome their effects (as was demonstrated by the reported tests).

The possibility must also be considered that the 0.2v open-circuit potentials under pure helium could be due to leakage of hydrogen into the gas stream from the Pd-tube counter electrode in the electrolytic gas generator. The design of the gas generator made this improbable. Additional evidence that this did not occur came from the following experiment: after the electrodes were exposed to a He + O_2 mixture, pure helium was substituted. While the potentials were changing to less positive values the electrolyte contact with the Pd counter electrode in the gas generator was broken. The rate of potential change on the Pt electrodes in the cell did not change significantly, and final rest potentials were the same as previously found.

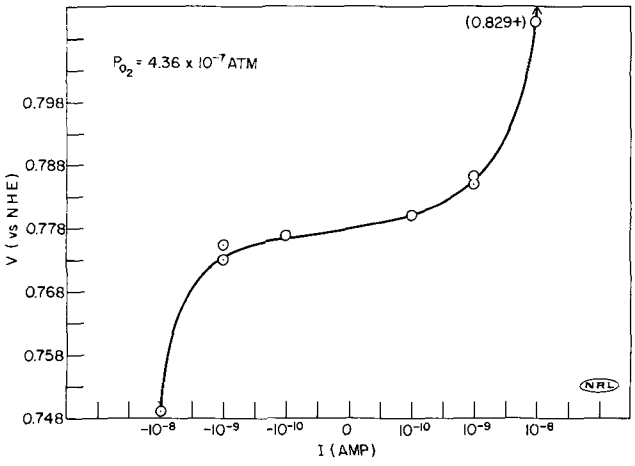

Fig. 7. Anodic and cathodic polarization of Pt wire electrode

The rest potentials shown in Fig. 5 give essentially the same dependence of potential on oxygen partial pressure as was previously determined (1, 3). There was, however, a significant difference. The broken line in Fig. 5 represents the average data previously found (1, 3) and as can be seen the data from this investigation indicated the same slope but an upward displacement of the average curve by about 40 mv. The reason for this difference is unknown. Stirring effects, effect of platinized Pt, effects of light, etc., were all checked and none seemed to be important. It also should be noted that the low potential values found at increasing very low oxygen partial pressures is most likely due to the very long times required to attain steady state. Decreasing values of oxygen partial pressures fell on the straight line shown in Fig. 5. A current-voltage relation was determined at P_{O_2} = 4.36 x 10^{-7} atm and is shown in Fig. 7. The open-circuit potential was a little above the rest potential later found. The data in this curve indicate that the potential is determined by a reversible reaction involving oxygen.

In previous work (1, 3) it was suggested that the potential was determined by an O_2/HO_2 exchange. The results found in this work confirm this.

Conclusions

1. True steady-state open-circuit potentials can be obtained and maintained when sufficient steps are taken to insure solution and gas purity and electrode cleanliness.

2. Considerable periods of time (up to a month or more) are required to establish steady-state potentials with low partial pressures (below 10^{-4} atm) of H_2 or O_2. Response times are faster with hydrogen.

3. At low partial pressures, the surface area becomes dominating in the time for establishment of steady-state potentials. At higher partial pressures, the surface/volume ratio of the electrode is the determining factor.

4. The oxygen background in this improved system is less than 10^{-9} atm.

5. The deviation from Nernst behavior previously reported (1) for the hydrogen electrode was due to the effects of small amounts of oxygen poisoning the hydrogen equilibrium.

6. Below hydrogen partial pressures of 10^{-6} atm, the steady-state potential is independent of P_{H_2}, *i.e.*, the Nernst potential relation for the H^+/H_2 equilibrium is not valid below 10^{-6} atm.

7. The potential plateau observed at 0.18v for hydrogen partial pressures below 10^{-6} atm is not due to an organic impurity.

8. The 0.18v potential is believed to be established by an equilibrium involving hydrogen ions in solution and hydrogen atoms dermasorbed in the electrode (or alloyed with the Pt). This reaction has an exchange current density on the order of 10^{-9} amp/cm^2.

9. The residual hydrogen associated with Pt at potentials from 0.18 to 0.2v did not react with oxygen.

10. The potential-oxygen partial pressure relation found had the same slope as previously reported (1, 3) although potentials at the same partial pressures ran about 40 mv higher.

Electrochemical Measurement of the Available Surface Area of Carbon-Supported Platinum

J. F. Connolly, R. J. Flannery, and G. Aronowitz

Research and Development Department, American Oil Company, Whiting, Indiana

ABSTRACT

The measurement of charge consumed in the galvanostatic stripping of adsorbed oxygen or hydrogen from carbon-supported platinum surfaces gave a measure of the area of platinum in contact with solution. A combination of the two methods proved superior to either used alone. The combination compensated for the charge consumed on the carbon with sufficient accuracy to permit measurements down to the region where the platinum area is 1/100 of the support area. Comparison with x-ray diffraction measurements suggests that, with high platinum concentrations on low area carbons, standard platinum deposition techniques yield electrodes in which much of the platinum surface is not in contact with solution.

When platinized porous-carbon electrodes are used in fuel cells, some of the platinum may be unavailable because it is physically inaccessible to the solution or because of adsorbed material on its surface. Knowledge of the available area of the platinum is useful for optimizing cell performance. X-ray diffraction does not exclude unavailable platinum area and may miss very small crystallites. However, electrochemical methods can be expected to measure only platinum which is in contact with solution, and there should be no lower limit on the size of platinum crystallites which can be detected.

The areas of unsupported metals can, in principle, be measured by four electrochemical techniques: measurements of capacitance (1), measurement of exchange currents (2), stripping or deposition of oxygen (3), and stripping or deposition of hydrogen (4). The first technique has been applied to a number of unsupported metals (1), while the other three would be useful only in special cases.

For platinum supported by a porous-carbon electrode, capacitance measurement may be ruled out because the capacitance of the platinum will not differ enough from that of the support, and because pore resistance makes capacitance difficult to measure. Likewise, measurements of exchange currents will in general be thwarted by mass transfer limitations in a porous electrode and where this is not the case, as in hydrogen evolution, by excessive pore resistance.

However, the oxygen and hydrogen stripping methods are probably unaffected by mass transfer in a porous electrode although nonuniform current distribution due to pore resistance has some effect on the form of the "arrest" (a region of minimal slope in the potential *vs.* charge curve). Therefore, these two methods were investigated, singly and in combination, with a series of platinized porous-carbon electrodes having a broad range of surface areas and platinum loadings. The major difficulty encountered was in correcting for the charge consumed on the carbon support, the area of which was many times the platinum area. This problem was solved to the extent that cases in which the platinum area is as small as 1/100 of the support area can be handled.

Experimental

The measurements were carried out in an H-cell, connected to a mercurous sulfate-mercury reference electrode through a Luggin capillary. Carbon-supported platinum electrodes were held between tantalum screens mounted in a tantalum holder. Potential was controlled by a Wenking potentiostat, and mercury wetted relays were used for switching to a galvanostat which consisted of resistors and a 90v battery. Voltage variations were followed on a Tektronix oscilloscope and recorded with a Polaroid camera.

The arms of the H-cell were separated by a medium glass frit and could be flushed with helium to remove oxygen. Preelectrolyzed 1M H_2SO_4, prepared from permanganate-distilled conductivity water, was the electrolyte in the cell, in the bridge to the reference electrode, and in the reference electrode compartment. For comparison with the mercurous sulfate-mercury reference electrode, the working compartment was frequently converted to a hydrogen reference electrode. This was done by inserting a platinized platinum electrode into the compartment and changing the flushing gas from helium to hydrogen. All voltages are given with reference to this "hydrogen electrode in the same solution." Ohmic voltage drops not

eliminated by the Luggin capillary were corrected for by noting the gap in the oscilloscope trace at the beginning of a galvanostatic pulse.

The carbons, in block form, were platinized by impregnating with a solution containing chloroplatinic and oxalic acids, and then heating to 160°-180°C in an inert atmosphere for 8 hr. The reduction was completed by adding hydrazine and excess reagents were leached out in distilled water. In a few cases hydrogen of hydrazine alone was used as the reducing agent. Because these procedures did not give uniform platinum loadings, the platinized carbons were powdered before samples were taken for platinum analysis, x-ray diffraction, and electrochemical area measurements.

Carbon supports were obtained from National Carbon (NC), Pure Carbon (FC), Stackpole (PC), and American Cyanamid (AC). The manufacturer's designations and areas of the block form are listed in Table I. When powdered, the carbons having low surface areas all increased in area, as indicated by apparent integral capacitance in the 0.05-0.30v range. This is reflected in the large carbon charge consumptions listed in the last two columns of Table I. The surface areas of the high-area carbons were relatively little affected by powdering.

To form the electrodes, platinized-carbon powders were mixed with Teflon suspension, dried at room temperature, and pressed at 50,000 psi. The finished electrodes contained 3% Teflon and were strong enough to hold together in solution as long as they were supported between tantalum screens. Because the Teflon bonding procedure often made platinized carbons electrochemically inactive the electrodes were anodized at 1.2-1.4v for 10 to 30 min. However, care had to be used to obtain the mildest possible activating conditions in each case because anodizing roughens the carbons.

The affect of grinding and Teflon bonding on the platinum area measurements was ascertained as follows: Electrochemical measurements were made on several chips of solid platinized carbon. The chips were then processed into Teflon-bonded electrodes and the electrochemical measurements were repeated. The results showed that apparent losses in platinum area caused by the electrode-forming procedure were less than 10% as long as the Teflon-bonded electrodes were sufficiently anodized.

Immediately prior to oxygen stripping, the electrodes were pretreated by holding at 1.4v for 1 min. Before hydrogen stripping they were held at 1.2-1.4v for 1 min and then at 0.05v for 1 min. After

[1] This behavior and the comparison with x-rays to be made later indicate that the surface migration of hydrogen from platinum to carbon observed for gas-solid systems at high temperatures (5) is not a problem in the present case.

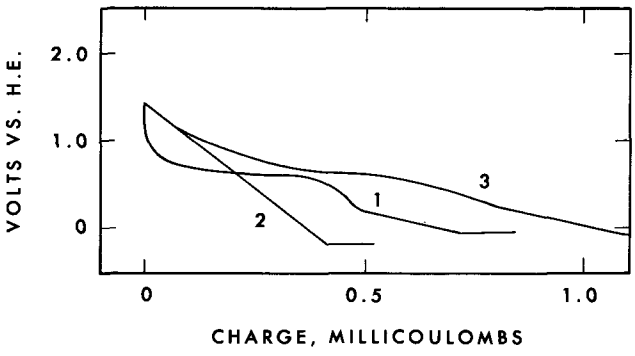

Fig. 1. Oxygen reduction: curve 1, 1 cm^2 Pt; curve 2, 15 cm^2 carbon; curve 3, Pt on carbon.

the first 30 sec there was very little change of arrest length with time at 0.05v,[1] unless the solution contained oxidizable impurities. These treatments were in addition to any necessary to cure poisoning of the Teflon-bonded electrodes.

The current densities during the galvanostatic strippings were adjusted to give an over-all voltage change rate of about 0.05v/sec. This required current densities of 0.5 to 1.0 $\mu a/cm^2$ of true area for the blank carbon electrodes, and higher values for the platinum loaded electrodes. Under these conditions 5-10 mg electrodes required total currents ranging from 0.1 to 25 ma. For any particular blank carbon sample the charge consumption in the 1.1 to 0.35 or 0.05 to 0.30 voltage intervals usually decreased or increased by about 10% for a fivefold increase or decrease in current density. The platinum loaded carbons were less affected by changes in current density. The current necessary for holding a sample at a particular voltage before switching to the galvanostat was less than 5% of the stripping current.

Oxygen Arrest

The arrest formed when adsorbed oxygen is stripped galvanostatically from a pure platinum electrode is illustrated by curve 1 in Fig. 1. The arrest starts near 1.1v and is complete at 0.35v. A potential *vs.* charge curve for a blank carbon electrode of moderate area is nearly linear as shown by curve 2. The effects of using carbon-supported platinum, rather than solid platinum, are to lengthen the oxygen arrest and to make its end points less distinct. These effects are illustrated in Fig. 1 by curve 3, in which 40% of the charge is being consumed on the carbon support. Because of the lack of distinctness in the arrest end points, measurements were made by using the end points which were consistently observed for those cases where the end points were distinct, *i.e.*, 1.1 and 0.35v.

For electrodes which have all been anodized in the same way, the charge consumed on platinum in the oxygen arrest is proportional to the platinum area, *i.e.*

$$A_{Pt} = Q_{Pt,O}/k_O = (Q_{T,O} - Q_{C,O})/k_O \qquad [1]$$

where A_{Pt} is the available platinum area, $Q_{Pt,O}$ is the charge consumed on the platinum in the oxygen arrest, k_O is a proportionality constant, $Q_{T,O}$ is the total charge consumed in the electrode in the oxygen arrest, and $Q_{C,O}$ is the charge consumed on the carbon support.

Because we did not have a platinum sample of known roughness, the results of Laitinen and Enke (3), corrected for the difference between H_2SO_4 and $HClO_4$ electrolytes (6), were used to estimate the proportionality constant k_O. This procedure gave 0.45 mc/cm^2 of true platinum area, for the charge consumed between 1.1 and 0.35v after pretreatment at 1.4v for 1 min.

$Q_{C,O}$, the charge consumed on the support, can be assigned in part to double layer capacitance and probably even in greater measure to oxygen adsorbed on

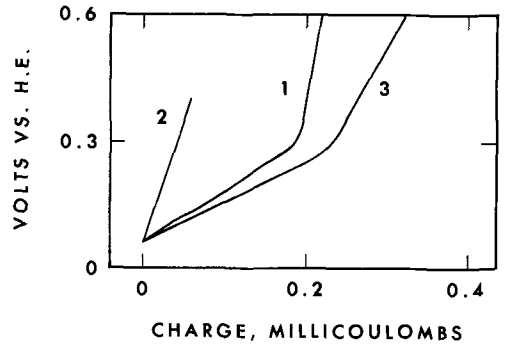

Fig. 2. Hydrogen oxidation: curve 1, 1 cm² Pt; curve 2, 15 cm² carbon; curve 3, Pt on carbon.

the carbon. This effect was small per unit area (an apparent integral capacitance of about 20 μf/cm² over the interval 1.1 to 0.35v) but, because the carbon area ranged up to 100 times that of the platinum, a major correction was necessary in most cases. It was evaluated by making a separate stripping measurement on an electrode formed from a nonplatinized sample of the same support. This procedure involved considerable uncertainty because of possible differences between the carbon supports of the platinized and nonplatinized electrodes. These differences could be expected to occur because of: nonuniform carbons, differences in grinding during the electrode preparation procedure, effect on the carbon of the chemicals used for platinizing, blockage of pores by platinum, and small differences in the stripping measurements.

Hydrogen Arrest

The arrest formed when adsorbed hydrogen is stripped galvanostatically from a pure platinum electrode is illustrated by curve 1 of Fig. 2. In the illustration the arrest commences at 0.05v and is complete near 0.30v. The hydrogen arrest for carbon-supported platinum differs from that of solid platinum in three aspects. It is longer, the faint fine structure is lost, and the change in slope near 0.30v is less sharp. These effects are illustrated by curve 3 in Fig. 3 in which 20% of the charge is being consumed on the carbon support.

The hydrogen arrest is analogous to the oxygen arrest in that the platinum areas of electrodes which have had like pretreatment will be proportional to the charge consumed on the platinum, *i.e.*

$$A_{Pt} = Q_{Pt,H}/k_H = (Q_{T,H} - Q_{C,H})/k_H \qquad [2]$$

where $Q_{Pt,H}$ is the charge consumed on the platinum in the hydrogen arrest, k_H is a proportionality constant, $Q_{T,H}$ is the total charge consumed in the electrode in the hydrogen arrest, and $Q_{C,H}$ is the charge consumed on the carbon support.

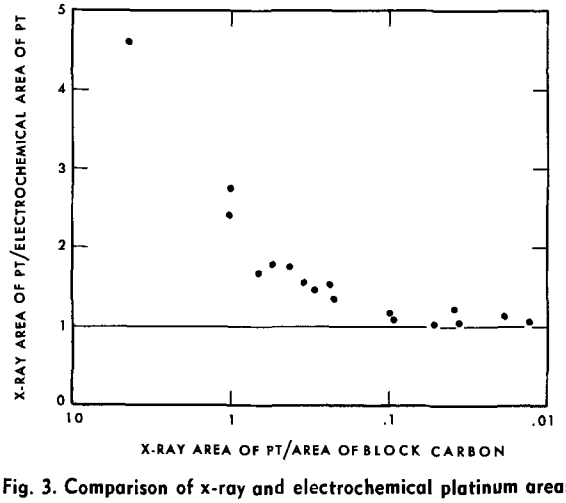

Fig. 3. Comparison of x-ray and electrochemical platinum areas

The proportionality constant k_H was determined by using pure platinum electrodes whose areas had been determined from the length of the oxygen arrest. This gave 0.19 mc/cm² of platinum for the charge consumed between 0.05 and 0.30v on bright platinum and platinized platinum electrodes which had been exposed to the atmosphere for several days. Freshly prepared electrodes gave a value 20% higher. The lower value was adopted because the aged electrodes should be a better approximation to the situation encountered with carbon-supported platinum. The carbon charge consumptions $Q_{C,H}$ were measured on nonplatinized carbon electrodes and are subject to the uncertainties listed in the oxygen arrest section.

Because $Q_{C,H} < Q_{C,O}$, the accuracies of the hydrogen arrest and oxygen arrest methods differ. To evaluate the relative uncertainty we will assume that the main error in an area measurement is due to the uncertainty in determining the charge consumed on the support. If this charge consumption is uncertain by some value e in per cent, then the percentage errors in the area determination by the oxygen and hydrogen arrest methods are

$$\Delta_O = eQ_{C,O}/Q_{Pt,O} \qquad [3]$$

and

$$\Delta_H = eQ_{C,H}/Q_{Pt,H} \qquad [4]$$

Now $Q_{Pt,H}/Q_{Pt,O} = k_H/k_O = 0.19/0.45$ and, as shown in Table I, $Q_{C,O}/Q_{C,H}$ is about 6.5. Thus, measurements of carbon-supported platinum areas, made using the oxygen arrest, should contain an error 2.7 times larger than those made using the hydrogen arrest.

Therefore, where the ratio of platinum area to support area is low, the hydrogen arrest method should give the better result. However, when this ratio is large, greater ease of activation (leading to earlier achievement of a reproducible state) and insensitivity to solution impurities (which do not adsorb as readily in the surface oxide formation region) favor using the oxygen arrest.

Oxygen and Hydrogen Arrests Used in Combination

As the platinum to carbon area ratio approaches 0.01 the fraction of the charge consumed in the carbon in the oxygen arrest reaches 75% and the fraction consumed in the hydrogen arrest reaches 50%. Thus, unless the carbon charge consumption is accurately known these methods become useless.

For reasons discussed in the oxygen arrest section, a separate measurement on the nonplatinized carbon does not give an accurate value for the charge consumption of the carbon in a platinized carbon. To get reasonable accuracy a method which uses direct measurements on the platinized carbon, with minimal dependence on blank carbon measurements, is desirable. Such a method is obtained by combining the oxygen-arrest and hydrogen-arrest charge consumptions as measured on the platinized-carbon electrode, with the ratio of the charges consumed by the support in the same regions as measured on a blank-carbon electrode, *i.e.*, from Eq. [1], [2], and

$$r = Q_{C,O}/Q_{C,H} \qquad [5]$$

we obtain

$$A_{Pt} = (rQ_{T,H} - Q_{T,O})/(rk_H - k_O) \qquad [6]$$

Thus the measured area of platinum becomes dependent on a ratio of carbon charge consumptions rather than on their absolute values.

The superiority of this combination method lies in its minimizing of dependence on blank carbon electrode measurements. Thus r should, as measured on the blank carbon electrode, apply to the platinized electrode with much greater accuracy than similarly measured absolute values of carbon charge consumption; *e.g.*, the plugging of carbon pores by platinum

of the platinized-carbon electrodes causes major reductions in the absolute values of the carbon charge consumptions in the oxygen and hydrogen arrests. However, their ratio, r, should not be appreciably affected.

Results

The platinum areas of carbon-supported platinum electrodes were measured for a variety of carbon supports and platinum loadings. Table II compares the results for carbons having areas from 0.4 to 700 m^2/g and for platinum loadings from 1 to 28%. The reproducibility of these measurements was about 10% for the oxygen-arrest method and the hydrogen-arrest method, as long as the charge consumption on the carbon supports did not exceed 25% of the total charge consumed in the arrest. The combination method (Eq. [6]) gave a reproducibility of 10% or better for all of the electrodes.

If numerator and denominator of Eq. [3] are each divided by $Q_{T,O}$, the total charge in the oxygen arrest, we see that the uncertainty in the platinum area increases in proportion to $P/(100\text{-}P)$, where $P = 100Q_{C,O}/Q_{T,O}$ is taken from Table I. Thus when the percentage of the charge consumed on the support is 75%, the error is three times as large as when this consumption is 50%.

Expressions for the charge consumed on the supports in carbon-supported platinum electrodes can be derived from Eq. [1], [2], and [5], *i.e.*

$$\frac{Q_{C,O}}{Q_{T,O}} = r\left(1 - \frac{k_O}{k_H}\frac{Q_{T,H}}{Q_{T,O}}\ r - \frac{k_O}{k_H}\right)$$

$$\frac{Q_{C,H}}{Q_{T,H}} = \left(\frac{Q_{T,O}}{Q_{T,H}} - \frac{k_O}{k_H}\ r - \frac{k_O}{k_H}\right)$$

Calculated fractions of total charge consumption due to carbon are listed in Table I.

The platinum areas in the last column of Table II were obtained from crystallite sizes measured by x-ray diffraction. The average crystallite sizes derived from x-ray spectra depend on the calculation method because assumptions about particle size distribution differ. The two areas listed are from crystallite sizes calculated by the method of Jones (7) and Warren's method (7), respectively. The model for calculating platinum areas from crystallite sizes was that of cubes with one face obscured by contact with the support surface.

Figure 3 compares the electrochemical platinum area values, obtained by combining the oxygen and hydrogen arrests (Eq. [6]), with the averaged x-ray results. The agreement between the electrochemical and x-ray surface areas gets progressively better, as evidenced by the x-ray to electrochemical area ratio approaching 1, as the platinum to carbon area ratio decreases. After the latter ratio reaches 0.10 the agreement stays within experimental error.[2] This behavior suggests that the crystallites are crowded at high platinum to carbon area ratios (at least in the case of the preparation methods used here) and hence much of the platinum surface does not contact the solution. Thus, while the x-ray method sometimes gives areas which are "truer" they are not always "available."

Conclusion

Carbon-supported platinum surface area measurements, using a combination of the arrests due to adsorbed oxygen reduction and adsorbed hydrogen oxidation, are feasible at least down to a platinum to carbon area ratio of 0.01, and are much more accurate than values obtained from either method alone. When the charge consumption on the carbon support is very small, one method is sufficient, adsorbed oxygen reduction probably being more reliable.

Comparison of the electrochemical method with x-rays shows good agreement for high area carbons, but when platinum is crowded onto a low area support agreement with x-rays is poor; probably because much of the platinum area is inaccessible to wetting. In the latter case, the electrochemical area measurement is to be preferred for predicting the performance of fuel cell electrodes.

[2] In view of the arbitrary assumptions made in obtaining crystallite sizes and then in choosing a model to calculate areas, the consistency deserves more note than the absolute agreement.

The Electrochemical Reduction of Oxygen on Electrodes Partially Immersed in Phosphoric Acid

R. J. Roethlein and H. J. R. Maget

Direct Energy Conversion Operation, General Electric Company, Lynn, Massachusetts

ABSTRACT

Diffusion-controlled currents for the reduction of oxygen in phosphoric acid for partially immersed electrode structures which have an intrinsic meniscus and thin film extending over their surface can be predicted from a general rate equation. For platinum black electrodes, and temperatures ranging from 25° to 170°C, the limiting current varies linearly with the square root of electrolyte conductivity, electrode polarization, and oxygen partial pressure. The increased current obtained on partially immersed electrodes has been shown to be associated with a very narrow region starting approximately 0.28 cm (the height of the meniscus) above the bulk of the electrolyte solution. Approximate calculations of the activation energy of diffusion using parameters from the rate equation give values which are close to those expected for a diffusional process. Good agreement is obtained between theoretical and experimentally determined values of the limiting current at 25°C. Equations have been derived to describe the interfacial liquid-gas geometry of the intrinsic meniscus and film formed by contact of the electrolyte with the electrode.

The purpose of this work was the development of an analytical model needed to interpret the behavior of oxygen (air) electrodes operating at high temperatures (less than about 170°C), in concentrated phosphoric acid [greater than 85 w/o (weight per cent)]. Since practical electrode structures frequently display rather complex interfacial geometries and geometric characteristics, investigations of transport phenomena were carried out on a simplified model of an oxygen cathode, *i.e.*, a single pore.

The reported experimental work was conducted to determine the rate-controlling reactions associated with the electrochemical reduction of oxygen. Earlier work conducted in presence of sulfuric acid (1) had shown the importance of the liquid electrolyte film and electrode surface roughness on local and total currents observed on simulated single macropores. This paper presents some results obtained at higher temperatures.

Experimental

Apparatus.—The experiments were carried out in a Pyrex cell consisting of a large central compartment and two smaller sections separated from the main section by fine pore fritted glass disks. The middle compartment which served as the test electrode section also contained a thermometer well and a gas bubbler which was capable of keeping a steady gaseous flow over the electrolyte solution. One of the side compartments contained a platinum black mesh electrode which served as the counter electrode. The other section served as a reference cell and had a Luggin capillary extending into the main compartment. The reference consisted of two platinum black electrodes with a constant current of 1.0 ma flowing between them. The electrode which evolved hydrogen gas came to a steady overpotential within a few minutes; this then served as the reference potential.

The test electrode consisted of a cylindrical piece of platinum tubing (99.99%) pure, 1.0 cm long, 1.5 cm in diameter, and 0.2 cm in wall thickness. The electrode assembly was essentially the same as that described in a previous paper (1) except that only one cylindrical section was employed as the test electrode. A modified 10/30 Teflon gland provided a closed system and still enabled the electrode structure to be raised or lowered into solution without allowing the system to be open to the atmosphere. Measurements of electrode height above the solution were made by means of a specially modified L. S. Starret Vernier height gauge with an accuracy of $\pm$ 1.2 x 10^{-3} cm.

The height and shape of meniscus and film were determined by electrical methods. The resistance measurements were obtained by means of a semicircular platinum foil 1.0 cm in diameter and 1.27 x 10^{-2} cm thick, sealed between two cylindrical glass tubes and finely polished to form a continuous smooth surface. Electrical contact was made by spot-welding a platinum wire to the foil inside the glass cylinder. The Starret Vernier height gauge could raise or lower the glass tube into the electrolyte. Resistance measurements were obtained by means of an a-c resistance bridge operating at 1000 cps.

The electrode surface was pretreated by electrodeposition of platinum from a 3 w/o chloroplatinic acid solution (with traces of lead acetate) at 10 ma/cm^2 for 12, 60, and 240 sec.

Procedure.—Polarization measurements were made with a "fast rise" Wenking potentiostat (Model 61 TR) which has an operating potential source of $\pm$ 2v, a current measurement accuracy of 1.5% full scale, and a zero point stability of 5 mv/day. All gases used in these experiments were of a high grade prepurified quality. A silicone oil constant temperature bath maintained the desired study temperature within $\pm$ 1°C.

All reactant gases were preheated and humidified by passing through a gas bubbler which contained electrolyte at the same temperatures and concentration as that in the test cell.

The various phosphoric acid concentrations used in these experiments were prepared from C.P. Reagent Grade stock solution using doubly distilled water containing less than 0.4 ppm impurities.

Experimental Results and Discussion

Interfacial liquid-gas geometry.—Resistance measurements can be used to determine the liquid-gas interfacial geometry at the meniscus-film boundary. Figure 1 presents a plot of ohmic resistance divided by the electrolyte resistivity *vs.* x/h, the relative position in the meniscus (h = total intrinsic meniscus height, x = variable distance above the electrolyte level). Only a gradual resistance increase with height is observed in the meniscus region. However, on entering the thin film region, the resistance increases rapidly. The slope of this linear increase can be used to calculate the electrolyte film thickness.

The interfacial liquid-gas geometry of the intrinsic meniscus and film can be approximated by the expression

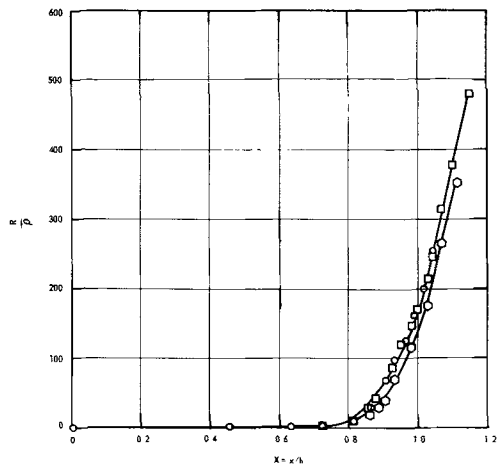

Fig. 1. Normalized ohmic resistance vs. relative position in the meniscus. R, measured resistance; ρ, electrolyte resistance; x, height above electrolyte level; h, height of meniscus, 0.28 cm; □, ○, 95.8 w/o H_3PO_4, 130°C; ○, 96.5 w/o H_3PO_4, 140°C.

$$\delta = \delta_h + A(1-X)^2 \text{ for } X \leq 1 \qquad [1]$$

where δ = meniscus thickness, cm; δ_h = film thickness, cm; $X = x/h$ represents the relative position in the meniscus; A can be theoretically evaluated from properties of the electrolyte, as presented by Landau and Lifshitz (2). However, since the surface tension of phosphoric acid at these temperatures is not known, it is better to evaluate A from resistance measurements.

It can be shown (1) that, near the meniscus-film interface, the ionic resistance is expressed by

$$R(x) = \frac{\rho h}{2b\pi} \frac{1}{(A\,\delta_h)^{1/2}} \left\{ \frac{\pi}{2} - \tan^{-1}\left(\frac{A}{\delta_h}\right)^{1/2}(1-X) \right\} \qquad [2]$$

where ρ = electrolyte resistivity, ohm-cm and b = electrode radius, cm. The film thickness δ_h can be determined from the slope of the linear section of the resistance plot

$$\left(\frac{dR}{dX}\right)_f = \frac{\rho h}{2\pi b\,\delta_h} \qquad [3]$$

The constant (A) can be evaluated from the total meniscus resistance, R_m at $X = 1$, for which

$$R_m = \frac{\rho h}{4b\,(A\,\delta_h)^{1/2}} \qquad [4]$$

For the experimental results presented in Fig. 1, the film thickness is calculated to be 0.5μ. The resistance can be represented by

$$R = 253\left\{ \frac{\pi}{2} - \tan^{-1} 16\,(1-X) \right\} \qquad [5]$$

and the meniscus-film geometry by

$$\delta = [0.5 + 130\,(1-X)^2]\,10^{-4} \qquad [6]$$

for values of $X \geq 0.9$, *i.e.*, at a level in the meniscus and film where the largest contribution to the total current is observed.

Current-potential behavior.—Current voltage curves taken on platinum black electrodes at elevated temperatures for the reduction of oxygen in phosphoric acid are similar to those obtained at lower temperatures in sulfuric acid (1). Raising the electrode out of solution causes an increase in current up to a maximum value obtained when the full meniscus and film are formed on the electrode surface. This behavior is represented in Fig. 2. For overvoltages greater than

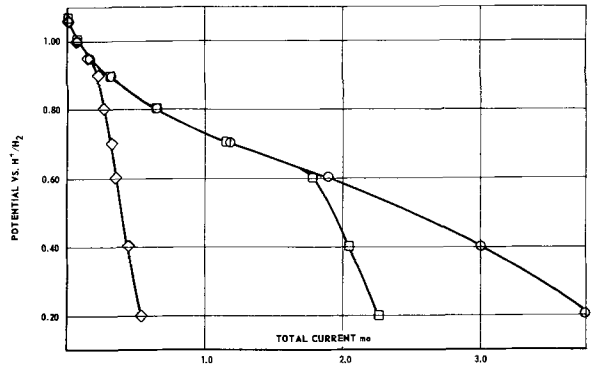

Fig. 2. Current-potential behavior as a function of electrode position. 97.8 w/o H_3PO_4, 150°C, pure O_2. Electrode position: ○, full meniscus and film; □, partial meniscus; ◇, submerged.

about 0.25v (*vs.* electrode rest potential) *i.e.*, at potentials outside the region of activation overvoltage, the current follows a square-root relationship with overvoltage. This experimental result is presented in Fig. 3 for various electrolyte concentrations, temperatures, and surface roughnesses.

The variation of the current with position, above the electrolyte level, obtained at constant potential is also similar to that observed in sulfuric acid. The electrode current rises sharply in a narrow region which coincides with the boundary between upper meniscus and thin film which are formed on the electrode surface above the level of the bulk electrolyte. Figure 4 represents a typical variation of the current

* All data obtained for binary mixtures O_2-N_2.

with electrode position; the height of the meniscus is approximately 0.28 cm (identical to the value observed in 1*N* and 10*N* H_2SO_4). Further withdrawal of the electrode from the electrolyte does not produce additional variations in current once the full meniscus and film have been formed.

On a partially immersed platinum black electrode the limiting current shows a linear variation with the square-root of the oxygen partial pressure. This relationship is valid for varying concentrations of H_3PO_4 (5-100 w/o) and over the complete temperature range of this study, *i.e.*, 25°-170°C. Characteristic values are reported in Table I.

Relationship between limiting current and conductivity.—Extensive studies were conducted to determine the current on partially immersed platinum black electrodes in the high phosphoric acid concentration range, from 80 to 100 w/o. It was found that the currents obtained at a constant potential of 0.400v *vs.* H^+/H_2 varied in a monotonic manner with the square root of the conductivity, Fig. 5. Two slopes were obtained: one in the low conductivity region which extrapolates to zero, as expected, and another in the higher conductivity range where the linear dependence is mantained over a large conductivity range from 0.36 to 0.64 (ohm-cm)$^{-1}$. Since the conductivity varies nearly linearly with temperature (3), it is not possible to explain the monotonic variation of the current, as presented in Fig. 5, on the basis of abrupt variations in conductivity in the temperature range between 110° and 170°C. (The measured currents were divided by the square root of the oxygen partial pressure to correct for water vapor pressure above the electrolyte since under experimental conditions the vapor pressure of water could be as high as 410 mm Hg.) Experimental results are presented in Fig. 5 as a function of the square root of electrolyte conductivity, since the correlation of the result was based on the assumption that currents on partially immersed electrodes can be predicted from the following general equation (4, 5) derived for hydrogen oxidation

$$i_L = \pi D\ (n\mathbf{F}C\mathcal{D}\mathcal{H}\eta)^{1/2} \qquad [7]$$

where D = diameter of the cylinder, 1.5 cm; n = number of electrons; $\mathbf{F}$ = Faraday's constant; $\mathcal{H}$ = electrolyte conductivity (ohm-cm)$^{-1}$; C = concentration of oxygen in phosphoric acid, mole/cm^3; $\mathcal{D}$ = diffusion coefficient, cm^2/sec.; η = polarization from open circuit, volts. Verification of the above equation will be shown for a region where limited values for solubilities and diffusion coefficients are either available or can be reasonably estimated.

A possible explanation for the increased slope at higher electrolyte conductivities and temperatures may be based on the change of oxygen solubility and diffusion coefficient in phosphoric acid at elevated temperatures. The combination of these parameters plays an important role in determining the limiting current.

The dependence of current on conductivity was further verified by adding $NaH_2PO_4 \cdot H_2O$ to a H_3PO_4 solution in order to decrease the electrolyte conductivity. [400g of $NaH_2PO_4 \cdot H_2O$ added to a liter of 85% H_3PO_4 yielded a conductivity of 0.33 (ohm-cm)$^{-1}$ at 130°C as compared to 0.49 (ohm-cm)$^{-1}$ for a salt-free identical acid concentration.] The current obtained from the lowered conductivity fell within the predicted value for the current at this conductivity (see Fig. 5).

Variation of electrode surface roughness did show some effect on current behavior. Platinum black was electrodeposited on the cylindrical electrode for 12, 60, and 240 sec at 10 ma/cm^2. Several concentrations were investigated for each roughness, and the currents were observed to increase with increasing surface roughness. Variations, however, were not large, *i.e.*, a current increase of 30% was observed for the highest as compared to the lowest surface roughness.

Current-temperature relationship.—Temperature effects on the currents, measured at 0.4v *vs.* H^+/H_2, are appreciable, as can be observed from Fig. 6 for various electrolyte concentrations, once corrected for oxygen partial pressure and electrolyte conductivity.

Since the conductivity does not vary appreciably with temperature for concentrated solutions (3), the slopes of $i_L/(\mathcal{H}P_{O_2})^{1/2}$ *vs.* $1/T$, at constant potential, represent the contribution of solubility and diffusivity to an activation energy. Solubility measurements reported in the literature (6, 8) for high concentrations

of H_3PO_4 between 25° and 170°C allow one to estimate a heat of dissolution of 1 kcal/mole. The slopes of Fig. 6, once corrected for this heat of dissolution, yield activation energies of 4.1 and 4.3 kcal/mole, which are within the range of values expected for diffusion-controlled processes.

Variation of limiting current with phosphoric acid concentration.—Currents for the reduction of oxygen on a partially immersed platinum black electrode were obtained potentiostatically at an applied potential of 0.400v *vs.* H^+/H_2 as a function of phosphoric acid concentration at 25°C. Results plotted in Fig. 7 show good agreement with the theoretical values calculated from the general equation assuming a mass transport-controlled process on a partially immersed electrode displaying a full meniscus and thin film on its extended surface, Eq. [7]. Data for the electrolyte conductivity and oxygen solubility is available in the literature (3, 6, 8). Since no data are available for the diffusion coefficient of oxygen in phosphoric acid at 25°C values were estimated from the equation of Wilke and Chang (7). Table II presents the values for the conductivity, oxygen solubility, and diffusivity in phosphoric acid at 25°C as a function of acid concentration, used to calculate the current reported in Fig. 7.

Lack of data concerning the diffusivity of oxygen in concentrated phosphoric acid does not allow to prove the application of Eq. [7] to currents measured at higher temperatures. However, on the assumption that Eq. [7] is applicable, it is possible from available data on oxygen solubility, electrolyte conductivity, and measured limiting currents to estimate diffusion coefficients. From the computed values presented in Fig. 8 for the temperature range from 25° to 170°C good agreement is obtained between the calculated values and two experimental results measured in 85.5 w/o H_3PO_4 (8). These results suggest that this method may be used to determine rapidly the product of solubility and diffusivity.

Conclusions

The electrochemical reduction of oxygen on partially immersed platinum black electrodes in phosphoric acid, from room temperature to 170°C, occurs mainly

in the upper meniscus and thin film region of the electrode surface. This was shown by the increased current associated with the gradual withdrawal of a submerged electrode, potentiostatically polarized, into a condition of partial immersion. The height of the meniscus in phosphoric acid even at elevated temperatures is the same as that found for sulfuric acid at room temperature, *i.e.*, approximately 0.28 cm.

Using a general equation which describes diffusion-controlled limiting currents for an electrode having a meniscus and film, good agreement has been obtained between the observed currents and those predicted from the equation over the entire concentration range of phosphoric acid at 25°C. For higher temperatures, results obtained show that the limiting currents also depend on the square root of electrolyte conductivity, polarization, and oxygen partial pressure. In addition, diffusion coefficients obtained by the use of this equation show good agreement with experimentally measured values of this parameter. This suggests that this general equation is also applicable to temperatures up to 170°C.

Further proof of the validity of this equation is exemplified by the approximate values obtained for the activation energy of diffusion for two different acid concentrations. The values obtained are in the approximate range of energies associated with diffusional processes. This same equation may be able to predict currents at other temperatures once sufficient data are obtained for oxygen solubility and diffusivity in phosphoric acid.

From the resistance measurements, equations have been derived to describe the interfacial liquid-gas geometry of the intrinsic meniscus and film formed by contact of the electrolyte with the electrode. These measurements have also provided an approximate value of the film thickness immediately above the intrinsic meniscus, 0.5μ.

Manuscript received Aug. 2, 1965; revised manuscript received Feb. 21, 1966. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Electrochemical Oxidation of Ethylene

Comparison of Results by the Potential Sweep and Steady-State Methods

University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The electrochemical oxidation of ethylene on platinum electrodes in 1*N* sulfuric acid at 80°C was studied by the potential sweep method over a wide range of sweep rates (10^{-5} — 2 v/sec). The results were compared with those obtained previously under steady-state conditions. Over three decades of sweep rate (2×10^{-3} — 2 v/sec) an apparent Tafel slope of approximately $2.3 \times 3\ RT/\mathbf{F}$ was observed. This was shown to be consistent with the behavior for a totally irreversible diffusion-controlled reaction. In the same region the peak potential V_M was found to shift 65 mv/decade increase in sweep rate and the peak current i_M was proportional to the square root of the sweep rate with a proportionality constant in agreement with the calculated value.

It is shown that the application of the potential sweep may change the mechanism of the process taking place (in the present case the change is from activation control in steady state to diffusion control during potential sweep). During potential sweep a totally irreversible, diffusion-controlled reaction will give rise to a linear Tafel plot with a slope about 35% higher than the mechanistically significant slope of $2.3\ RT/\alpha\mathbf{F}$. Further, an apparent passivation region can be observed, due to depletion of the solution near the electrolyte from reactant molecules and quite independent of the nature of the electrode surface. During potential sweep measurements the partial coverages θ by various species on the surface cannot reach their steady-state value. The kinetic parameters derived from such measurement, therefore, cannot be used to represent the results under steady-state conditions, unless the sweep rate is made sufficiently slow to correspond in practice to steady state.

The anodic oxidation of ethylene on platinum electrodes in 1*N* H_2SO_4 at 80°C has been studied recently (1). From the kinetic parameters obtained under steady-state condition a mechanism has been suggested, with water discharge as the rate-determining step, preceded by equilibrium adsorption of ethylene (1). This mechanism was further confirmed by a comparative study of the electrochemical oxidation of a number of unsaturated hydrocarbons under identical conditions (2) and by recent tracer studies (3). Independent electrosorption measurements for ethylene (4) and benzene (5) in the same system by a radiotracer technique yielded further support for the above mechanism. Thus, for the rate-determining step

$$H_2O \rightarrow OH_{ads} + H^+ + e \qquad [1]$$

the rate equation was given as

$$i = i_o\,(1 - \theta)\exp(\beta V\mathbf{F}/RT) \qquad [2]$$

where θ represent the total surface coverage which in the linear Tafel region (0.4 — 0.8v RHE) is essentially equal to the coverage by unreacted adsorbed organic molecules. Under the conditions studied [*i.e.*, with ethylene bubbled through the solution or with liquid benzene at equilibrium with the solution (1, 2)] the surface coverage by organic is in the saturation region (4, 5), and hence θ may be considered independent of potential, giving rise to

$$b = \left(\frac{\partial V}{\partial \log i}\right)_{T,C_i} = \frac{2.3\ RT}{\beta\mathbf{F}} \sim 2.3 \times (2RT/\mathbf{F}) \qquad [3]$$

The negative reaction order observed is also consistent with the adsorption data for this mechanism since, while θ remains essentially constant in the saturation region, the term $(1 - \theta)$ can vary substantially and give rise to a decreased reaction rate with increasing bulk concentration of the organic.

Most recent studies of electrochemical oxidation of potential fuels have relied on nonsteady-state techniques, in particular the potential sweep method (6, 7) and cyclic voltametry (8). The results of such measurements have not usually been interpreted in terms of a molecular mechanism.

In the present work the electrochemical oxidation of ethylene on bright and platinized platinum electrodes in 1*N* H_2SO_4 at 80°C was studied as a function of sweep rate over a wide range (1×10^{-5} — 2v/sec). The results obtained in this manner are compared with previous results of steady-state measurements in the same system, and the limitations of the application of potential sweep techniques for the study of the kinetics of complex electrode reactions are brought out. The potential sweep technique has been applied previously to the oxidation of ethylene on rotating disk platinum electrodes (9), but the effect of sweep rate has not been considered.

Experimental

Cell, electrodes, and solution.—A standard three-compartment all-glass cell was employed with glass frits separating the compartments. A bright platinum wire of 1 cm^2 served as working electrode and was treated anodically and cathodically as described pre-

[1] Present address: Chemistry Department, Tel-Aviv University, Tel-Aviv, Israel.

viously (1). For lower sweep rates a 50 cm^2 planar bright platinum electrode was used, and for comparison a small 1 cm^2 planar platinized Pt electrode was employed. A Hg/Hg_2SO_4 reference electrode in the same solution was used and a large platinized platinum gauze served as the counter electrode.

Solutions were made up from Baker Analyzed sulfuric acid in distilled water. C. P. grade ethylene (99.5% purity) and prepurified nitrogen (99.996% purity) were employed.

Electrical circuit.—The potential between the working and reference electrode was controlled by a Wenking potentiostat, and the current between the working and counter electrode was recorded on a Moseley "Autograph" recorder model 680 in parallel with a variable shunt resistance. For slow potental sweeps the reference potential fed into the potentiostat was varied with motor drive potentiometers connected to a battery. For faster sweep rates a transistorized triangular sweep generator constructed in this laboratory was employed (10), which could supply a symmetrical triangular wave form with sweep rates in the range of 10^{-3} — 10^3 v/sec. During measurements at higher sweep rates the current was recorded as a function of potential on a Tektronix model 564 memory oscilloscope used as an X — Y recorder (with the time base replaced by a differential amplifier type 2A63 plug-in unit). The oscillographic traces were photographed with a model C-12 oscilloscope poloroid camera.

Procedure.—Electrodes prepared in the manner described elsewhere (1) were introduced into the sulfuric acid solution, and prepurified nitrogen was bubbled through until the rest potential of approximately 0.25v NHE was reached. Ethylene was then introduced into the cell, and sufficient time was allowed for adsorption equilibrium at this potential to be reached (15-30 min). All data reported here refer to a single anodic sweep. Good reproducibility between different runs in the same solution and runs on different days in different solutions was obtained.

Results

Current-potential relationship.—The current-potential relationships obtained at three sweep rates are represented in Fig. 1 as a plot of current density *vs.* potential. The same results are shown in semilogarithmic form in Fig. 2 as V *vs.* log i. The variation of b, the apparent Tafel slope observed experimentally with sweep rate, is shown in Fig. 3. A constant value of $b = 2.3 \times (3\ RT/F)$ is observed for sweep rates of 2×10^{-3} up to 2 v/sec. The steady-state value of $b = 2.3 \times (2\ RT/F)$ is approached only at very slow sweep rates of the order of 10^{-5} v/sec.

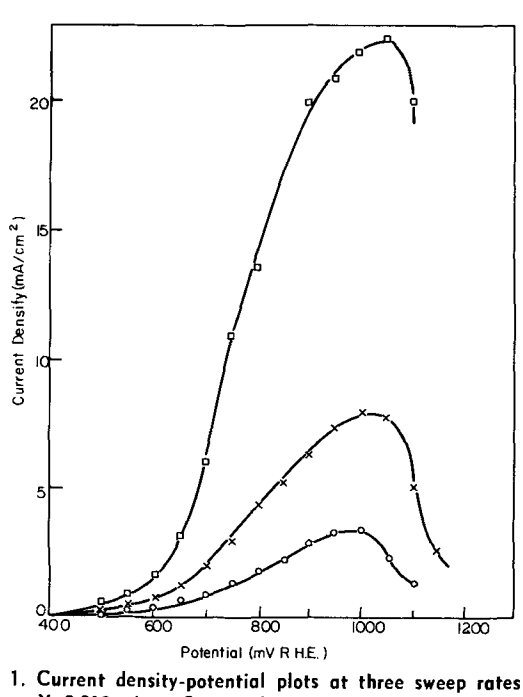

Fig. 1. Current density-potential plots at three sweep rates: □, 0.1 v/sec; X, 0.013 v/sec; ○, 0.0022 v/sec.

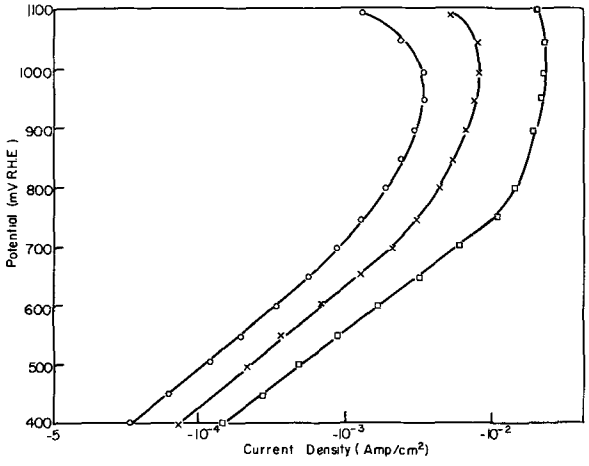

Fig. 2. Results of Fig. 1 plotted on a semilogarithmic scale

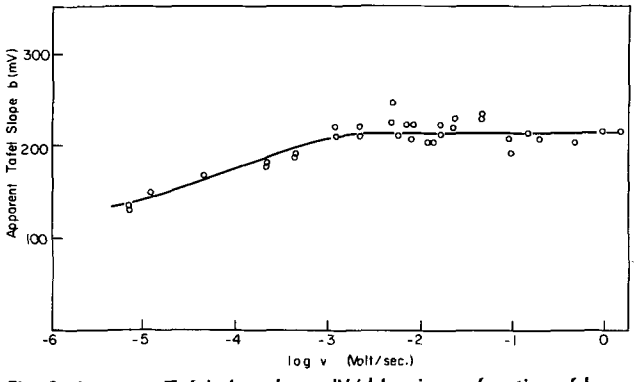

Fig. 3. Apparent Tafel slope $b = dV/d \log i$ as a function of log v

Peak current and potential.—Figure 4 shows a plot of the peak current i_M as a function of the sweep rate v on a log-log scale. A linear plot results for sweep rates above a few mv/sec, with a slope of approximately 0.5. At lower sweep rates the peak currents are much smaller and depend only to a very small extent on sweep rate. Results obtained for a platinized Pt electrode are shown for comparison.

The potential V_M at which the current reaches a maximum is plotted in Fig. 5 as a function of log v. A

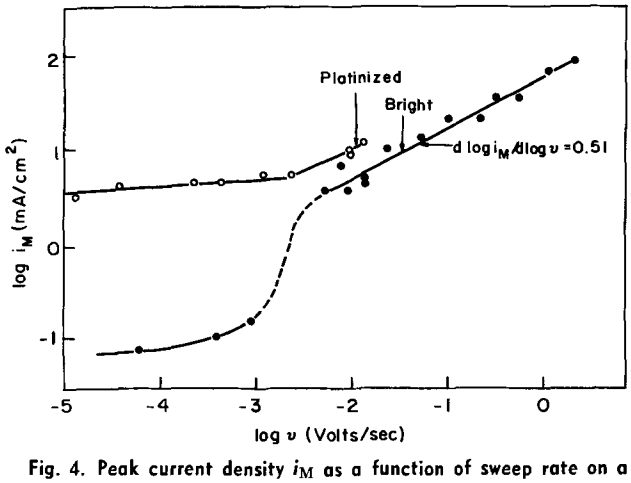

Fig. 4. Peak current density i_M as a function of sweep rate on a log-log scale; ○, platinized Pt; •, bright Pt.

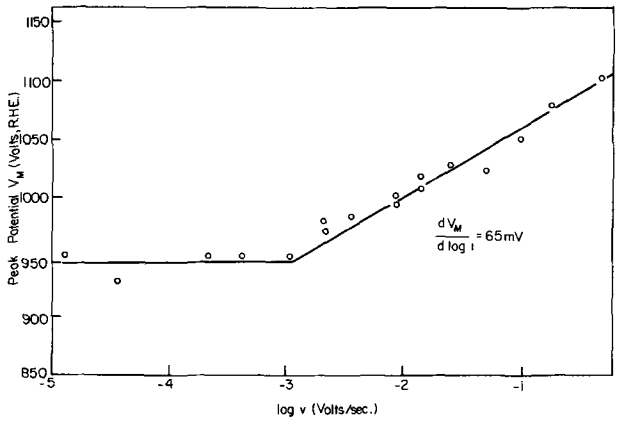

Fig. 5. Peak potential V_M as a function of log v

slope of $dV_M/d \log v \sim 2.3 \times (RT/\mathbf{F})$ is obtained for sweep rates higher than a few mv/sec. At lower sweep rates V_M is essentially independent of sweep rate and the same for bright and platinized electrodes. It should be noted that the break in the lines in Fig. 3, 4, and 5 occur at the same sweep rate, within experimental error.

Discussion

The peak current.—For a totally irreversible, diffusion-controlled reaction the current density during potential sweep has been shown (11, 12) to be given by an equation of the following form

$$i = \pi^{1/2} n\mathbf{F}\beta^{1/2} D^{1/2} C^o \chi(\beta t) \quad [4]$$

where (utilizing for this equation Delahay's symbol)

$$\beta = \frac{\alpha n_a \mathbf{F}}{RT} v \quad [5]$$

n and n_a are the number of electrons transferred in the over-all reaction and in the rate-determining step, respectively; α is the transfer coefficient, D the diffusion constant, C^o the bulk concentration of reactant, and $\chi(\beta t)$ is a complex function of (βt) which has been given numerically as a function of (βt). It is noted that during a linear potential sweep

$$V = V_i + vt \quad [6]$$

where V_i is the initial value of the potential at the $t = 0$. Hence from Eq. [5] and [6]

$$\beta t = \frac{\alpha n_a \mathbf{F}}{RT} (V - V_i) \quad [7]$$

and the function $\chi(\beta t)$ may be regarded as dependent on potential. The variation of $\chi(\beta t)$ with (βt) has been calculated by Delahay (11). In view of relationships [4] and [7] this also reflects the variation of the current density with potential.

At the peak potential $\chi(\beta t)$ has a value of 0.282. With $D = 1.7 \times 10^{-5}$ cm²/sec (9), $C^o = 2.2 \times 10^{-6}$ mole/cm³ (9), $n_a\alpha = 0.5$ and $n = 12$, Eq. [4] yields

$$i_M = 23v^{1/2} \text{ ma/cm}^2 \text{ (real area)} \quad [8]$$

The experimental relationship obtained from Fig. 4 is

$$i_M = 60\, v^{1/2} \text{ ma/cm}^2 \text{ (apparent area)} \quad [8a]$$

The discrepancy between calculated and observed results may be due in part to the uncertainty in the values of D and C^o used, and in part to departure from semi-infinite linear diffusion in the experimental set-up. Below a sweep rate of a few millivolts per second the peak current on bright platinum drops drastically to lower values corresponding to the activation-controlled process taking place at steady state with a much smaller dependence on sweep rate, which can probably be associated with the slow "time effects" observed in steady-state measurements. A comparison of results on bright and platinized Pt lends further support for the diffusion-controlled behavior postulated here for the higher sweep rate region. At low sweep rates the current density on platinized Pt is found to be about 40-50 times higher than on bright Pt. Taking a roughness factor of 2 for the bright surface this gives rise to a reasonable value of 80-100 for the roughness factor on the platinized surface. At higher sweep rates the line for platinized Pt parallels that for bright Pt, but the ratio of current densities is only approximately 2.0. For a diffusion-controlled process the current is determined largely by the apparent surface area. The slightly larger current densities observed on platinized Pt are probably due to surface irregularities of dimensions similar to or larger than the diffusion layer thickness.

Variation of peak potential with sweep rate.—The relationship between peak potential and sweep rate has been given by Delahay (11, 12) as

$$V_M = V_i + \frac{RT}{\alpha n_a \mathbf{F}}\left[0.77 - \ln(k/D^{1/2}) + \tfrac{1}{2} \ln\left(\frac{\alpha n_a \mathbf{F}}{RT} v\right)\right] \quad [9]$$

where k is the (potential dependent) specific rate constant at the potential V_i. Thus

$$\frac{\partial V_M}{\partial \log v} = \frac{2.3\, RT}{2\alpha n_a \mathbf{F}} = 2.3 \times (RT/\mathbf{F}) \text{ for } \alpha n_a = 0.5 \quad [10]$$

In Fig. 5 a slope of $\partial V_M/\partial \log v = 65$ mv is obtained, in agreement with Eq. [10] ($2.3 \times RT/\mathbf{F} = 70$ mv at 80°C).

It is important to note the fact that a peak in the $i - V$ relationship is obtained here for a diffusion-controlled reaction, independent of the state of the electrode surface. This may account for some of the apparent passivation regions which have been reported in studies of the anodic oxidation of organic fuels by the potential sweep method. The position of the peak depends, among other things, on the specific rate constant of the reaction studied, but not on the bulk concentration of reactant (cf. Eq. [9]). When stable intermediates are formed in the reaction sequence in concentrations not negligible with respect to the concentration of the reactants several "diffusion peaks" of this kind could be observed on the polarogram. This has already been pointed out by Delahay (12), but has apparently been disregarded in subsequent work.

Observed Tafel slope.—Figure 3 shows the variation of Tafel slope with sweep rate. The steady-state value of $2.3 \times 2\ RT/\mathbf{F}$ is only approached at very low sweep rates $V < 10^{-5}$ v/sec in this system. As the sweep rate is increased above 10^{-5} v/sec, the observed Tafel slope increases steadily toward a value of $2.3 \times 3\ RT/\mathbf{F}$. Above approximately 2×10^{-3} v/sec the Tafel slope remains constant independent of sweep rate over three decades of sweep rate up to $v = 2$ v/sec. The region of constant Tafel slope of $2.3 \times 3\ RT/\mathbf{F}$ coincides with the upper regions of Fig. 4 and 5 where $d \log i_M/d \log v = 0.5$ and $dV_M/d \log v = 2.3\ RT/\mathbf{F}$, respectively, corresponding to diffusion-controlled kinetics.

The existence of a linear Tafel region for a diffusion-controlled reaction is only due to the particular method of measurement (*i.e.*, the potential sweep method), and the observed slope of $2.3 \times 3\ RT/\mathbf{F}$ (which is not normally encountered in kinetic studies of activation controlled reactions) can be shown to be consistent with the water discharge mechanism postulated earlier as the rate-determining step under steady-state conditions.

Figure 6 gives a plot of (βt) *vs.* $\log \chi(\beta t)$ which was constructed from the plot of $\chi(\beta t)$ *vs.* (βt) given by Delahay (11, 12). From this plot one finds numerically

$$\partial(\beta t)/\partial \log \chi(\beta t) = 3.1 \quad [11]$$

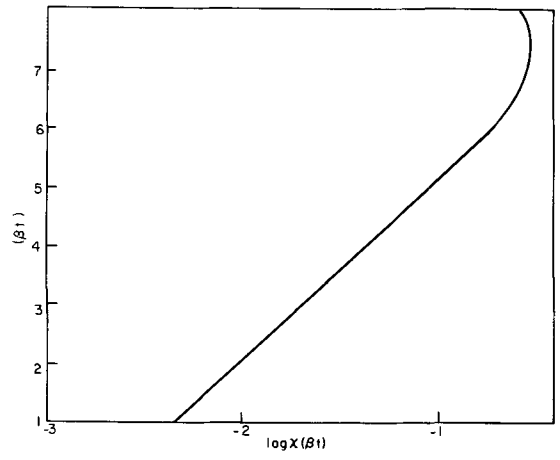

Fig. 6. (βt) plotted vs. the function log $\chi(\beta t)$

and

$$\frac{\partial V}{\partial \log i} = \frac{\partial V}{\partial \log \chi(\beta t)} \times \frac{\partial \log \chi(\beta t)}{\partial \log i} \quad [12]$$

From Eq. [4]

$$\partial \log \chi(\beta t)/\partial \log i = 1 \quad [13]$$

and from Eq. [7]

$$\partial V = \frac{RT}{\alpha n_a \mathbf{F}} \partial(\beta t) \quad [14]$$

Combining Eq. [12]-[14] one has

$$\frac{\partial V}{\partial \log i} = \frac{RT}{\alpha n_a \mathbf{F}} \frac{\partial(\beta t)}{\partial \log \chi(\beta t)} = \frac{3.1\,RT}{\alpha n_a \mathbf{F}} = \left(\frac{3.1}{2.3}\right) \times \frac{2.3\,RT}{\alpha n_a \mathbf{F}} \quad [15]$$

Thus a linear Tafel relation with a slope 35% higher than the mechanistically significant slope of 2.3 $RT/\alpha n_a \mathbf{F}$ can result due to diffusion control during the potential sweep. In the case studied here, the observed Tafel slope of b = 210 mv is consistent (at 80°C) with the above interpretation if αn_a = 0.45. This is in agreement with the steady-state value of α = 0.46-0.50 reported for this system.

Limitations of the potential sweep method.—The mechanism of the anodic oxidation of ethylene on Pt electrodes has been established previously on the basis of kinetic parameters obtained under steady-state conditions (1), as discussed in the introduction. The critical question to be answered here is what type of mechanistic information could have been derived from the potential sweep data presented in this paper alone. The answer to this question will then bear relevance to the limited applicability of the slow potential sweep technique for the study of mechanisms of anodic oxidation of organic fuels. Typical sweep rates used by various authors for mechanistic studies are in the range of 10-100 mv/sec (*e.g.*, Griffith and Rhodes (9) used v = 26 mv/sec, Breiter (6) used v = 35 mv/sec), and thus the behavior observed here in the upper sweep rate region (2 x 10^{-3} — 2 v/sec) will be discussed below.

As has been shown above, the relationship between peak current, peak potential, and sweep rate satisfies Eq. [4] and [9] which have been derived (11, 12) for a totally irreversible diffusion-controlled reaction. This should be contrasted with the activation-controlled kinetics established at steady state. Further, a positive pressure effect is observed during the sweep measurement while at steady-state negative reaction orders were observed for ethylene (1) and several other unsaturated hydrocarbons (2). Thus, the results of potential sweep measurements would indicate that the reaction is diffusion controlled. This, however, will have little effect on the operation of a fuel cell, the characteristics of which will be determined by the steady-state activation-controlled kinetics.

The transition from activation control at steady state to diffusion control during the transient is unusual and arises due to the time dependence of the partial coverage θ during the transient. It will be remembered that the steady-state current is proportional to the term $(1 - \theta)$ (Eq. [2]). Also direct adsorption measurements show (4) that θ must be very high and $(1 - \theta)$ is probably of the order of 10^{-2} or less. During the potential sweep transient the reactant at and near the electrode is used up and θ decreases. Under these conditions the water discharge step can occur a hundred times or more faster and, it is no longer rate limiting for the over-all process.

The observed Tafel slope can be discussed next. If measurements at a single sweep rate were performed, any slope between 2.3 x 2 $RT/\mathbf{F}$ and 2.3 x 3 $RT/\mathbf{F}$ could be obtained, depending on the sweep rate chosen. The observation that the Tafel slope is independent of sweep rate over a wide range is no indication that it is also equal to the value which would be obtained at steady state, as shown above. If it is established that the system is a totally irreversible, diffusion-controlled reaction (as is the case in the present study), the mechanistically significant Tafel line can be calculated from the observed value (Eq. [15]). This again will only be relevant, however, to the kinetic behavior during the transient which may be entirely different from that observed at steady state.

In conclusion, the potential sweep technique is not generally applicable to kinetic studies because the system is altered by the measurement. In a proper study, when correction for sweep rate and diffusion effects are made, the kinetic behavior of the system during the sweep may be evaluated. This, however, may be quite different from the steady-state behavior which is the only one relevant for the continuous operation of electrochemical energy converters.

Conclusions

The kinetic parameters calculated from measurements employing the potential sweep or cyclic voltametry technique cannot be used directly as diagnostic criteria for mechanistic determinations. In general three regions of potential sweep rate may be expected to occur. At sufficiently low sweep rates (region A) the steady state of the system is not significantly disturbed by the sweep, and the kinetic parameters observed are independent of sweep rate. At intermediate sweep rates (region B) the reaction can be diffusion controlled. This region is characterized by a linear dependence of peak current i_M on the square root of the sweep rate and (for totally irreversible reactions) a linear dependence of the peak potential V_M or log v, with a slope of $\partial V_M/\partial \log v$ = 2.3 $RT/2\alpha n_a \mathbf{F}$ (11, 12). In this region a linear Tafel behavior can also be observed with a slope which is about 35% higher than the mechanistically significant slope of 2.3 $RT/\alpha n_a \mathbf{F}$. Finally, at very high sweep rates (region C) most of the Faradaic current is associated with oxidation of reactants which have been adsorbed on the surface before application of the sweep; or with adsorption or desorption of intermediates formed in the reaction sequence. Region C is characterized by a linear dependence of the current on sweep rate [the current may be regarded as pseudocapacitative in this region in that it obeys the simple relationship $i = Cv$ where C is the effective pseudocapacity of the system under a given set of conditions (13)]. A linear plot of V_M *vs.* log v will result in this region. The slope, however, will be 2.3 $RT/\alpha \mathbf{F}$, *i.e.*, twice that observed in the diffusion controlled region (14).

The sweep rate corresponding to the three regions discussed above will depend on the specific rate con-

stants of the reactions studied, the concentration of reactants in the bulk of the solution and other factors. In the case of ethylene oxidation on platinum electrodes at 80°C studied here, region A corresponds to $v < 10^{-5}$ v/sec. Region B spreads from $v = 2 \times 10^{-3}$ up to 2 v/sec, and region C probably starts at $v > 100$ v/sec. In certain cases these regions may tend to overlap, and in particular diffusion controlled conditions may not be observed experimentally at high reactant concentration and for systems where steady state can be reached rapidly.

The peak current and subsequent decrease in current with increasing potential (quasi-passivation region) observed in steady-state and slow sweep measurements (region A) have been associated with formation of oxide layers on the surface. In contrast, the apparent passivation in regions B and C are due to a depletion of the electrolyte near the electrode from reactant molecules and to a decrease of the combustible adsorbed reactant on the surface, respectively, and are independent of the state of the electrode surface. Several such peaks may occur in region B if stable intermediates are formed in substantial amounts in the reaction sequence, or due to impurities in the fuel or in the electrolyte.

Current Distribution at a Gas-Electrode-Electrolyte Interface

I. Experimental Observations

Douglas N. Bennion[1] and Charles W. Tobias

Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The variation of current density along a cylindrical, partially immersed electrode relative to the position of the apparent or intrinsic meniscus has been measured as a function of total applied current. Measurements of current distribution are reported for the cathodic reduction of O_2 gas in aqueous KOH electrolyte on sectioned Ni and Ag electrodes. A thin film of electrolyte was observed to exist above the intrinsic meniscus. It was found that the charge transfer which takes place at the electrode-electrolyte surface occurs almost totally above the bottom of the intrinsic meniscus, and that a large portion of this charge transfer occurs in the thin film as high as 1-5 mm above the top of the intrinsic meniscus. However, as the total current is increased, the charge transfer reaction is gradually crowded closer to the top of the intrinsic meniscus, and a smaller fraction of current passes up into the film. On nickel the current is more uniformly distributed in the upper areas of the thin film than on silver.

Many of the possible fuels and oxidants proposed for use in fuel cells are gases. To gain an understanding of the dynamic behavior of electrodes involving gaseous reactants, analysis of transport phenomena at gas electrode-electrolyte interfaces is necessary. Various studies of porous media involving only electrode-electrolyte interfaces have been presented recently (1-4). The presence of a gas phase provides additional problems which are to be considered here.

Porous electrodes are used to increase the reaction area per unit volume and, in the case of gaseous reactants, to provide separation between gas and electrolyte. In such electrodes, many simultaneous and consecutive processes occur, and the nature and extent of the actual reaction area within the pores is not well defined or understood. A plane electrode partially immersed in an electrolytic solution offers a simpler system for studying the behavior of gas electrode-electrolyte interfaces.

[1] Present address: Department of Engineering, University of California, Los Angeles, California.

In 1957 Wagner (5) postulated that a thin film of electrolyte exists above the visible meniscus on the surface of a partially immersed electrode and that the electrode surface in contact with this thin film should contribute appreciably to the charge transfer reaction.

In their study of current density distribution of oxygen reduction on copper, Weber, Meissner, and Sama (6) did not consider the possibility of the existence of a thin electrolyte film above the intrinsic or readily visible meniscus. Will (7, 8), in experiments involving oxidation of hydrogen in sulfuric acid on platinum, observed the variation of the total current with the length of platinum extending above the liquid level of the electrolytic solution at a constant applied overpotential. Will concluded that a thin film did exist above the intrinsic meniscus and that most of the charge transfer reaction occurred in a narrow region adjacent to the upper edge of the meniscus. He also showed that surface migration of hydrogen along the platinum was not a significant mode of mass transfer.

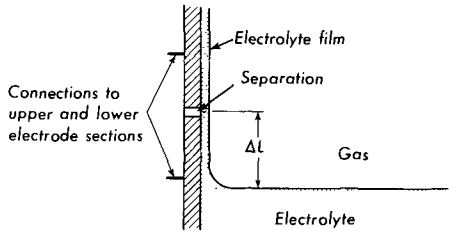

Fig. 1. Schematic representation of gas electrolyte interface showing the insulating separator. ΔL could be changed by raising or lowering the electrolyte level.

Diffusion of hydrogen through the film was determined to be the rate-controlling step. This was the first really definitive experiment to show the role of thin electrolyte films. However, as the platinum electrode was extended further and further out of the electrolyte, new area on which an electrolyte film could exist was produced. Thus, the film geometry and resulting current distribution changed during the course of an experiment.

The present work was undertaken to investigate the role of the thin film during oxygen reduction, and to obtain a quantitative description of the transport processes involved. For experimental work, oxygen gas, aqueous 3.5M KOH, and either nickel or silver electrodes were chosen.

Experimental Equipment and Procedures

The objective was to measure the variation of current density along a partially immersed electrode relative to the position of the bulk electrolyte surface. In order to accomplish this, sectioned electrodes (9) were employed. The sections must be insulated electrically from one another, and the insulating separators should not significantly disturb the geometry of the thin liquid film on the surface of the electrode. Also, the sections of the metal electrode must be at the same potential.

In order to satisfy these requirements as closely as possible, only two sections and a single separation were used (see Fig. 1). With this approach, the variation in the current from each section could be measured as a function of the distance, ΔL, of the bulk electrolyte level below the separation (see Fig. 1). The sum of the two currents equals the total; therefore, only one of the currents is independent. In order to compare the results of different total currents more easily, the per cent current out of the top section, defined as %C.O.T. = (Current out top section) (100)/(Total Current), was used as the independent variable.

The experimental procedure involved determination of the %C.O.T. as a function of ΔL at various total currents on nickel and silver electrodes. To determine the actual current density variation, one plots the %C.O.T. *vs.* ΔL and takes the slope of this curve. The slope at a given value of ΔL, in cm^{-1}, times the applied current, I, in microamperes per centimeter of electrode circumference, gives the transfer current density at a height ΔL above the electrolyte level. The readings were consistent to within 3% for a single run except at the lowest current levels when variations up to 10% of the measured current were inherent in the circuit design.

To avoid edge effects cylindrical electrodes were used. Electrodes of both 0.8045 and 1.465 in. in diameter were used. The current, I, in microamperes per centimeter times the electrode diameter, gives the total current. The working length of the electrode was approximately 12 cm; this was found to be long enough to avoid appreciable end effects at the top and bottom. The electrode was constructed using a cylindrical plexiglass spindle over which two cylinders of nickel[2] (or silver[3]) were slipped (see Fig. 2.). These were

[2] The nickel was 99.5% pure. The principal impurities were Mn and Fe.

[3] The silver was 99.95% pure.

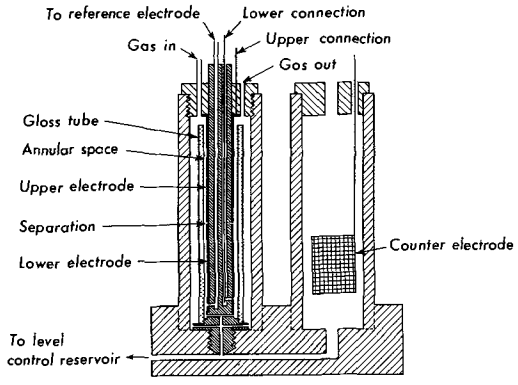

Fig. 2. Cross-sectional view of cell used for measurement of distribution of current relative to position of meniscus.

separated by a thin "gasket" made from a sheet of oriented polystyrene 25μ thick. This thickness was necessary to insure that no metallic electrical connection occurred between the two sections.

In order to avoid the possibility of systematic errors and to confirm the reproducibility of the data, 2 different silver cells and 5 separate nickel cells were built. The procedures in constructing the separations in the working electrodes (such as rounding the corners of the electrode where it contacts the insulating jacket) were modified slightly to see if the results were affected. No effects on the results were noted from these changes. For one of the silver electrodes, runs were also made with the 25μ thick polystyrene gasket replaced by a separator made from filter paper approximately 70 microns thick. This was done to check the results for any dependence on the nature of the material used as the separator.

The cell consisted of two cylindrical compartments as shown in Fig. 2. The cylindrical electrode spindle described above was screwed into the left-hand compartment. In the right-hand compartment, nickel screens served as the counter electrode. The over-all reaction at the working electrode was

$$O_2 + 2H_2O + 4e^- = 4\,OH^-$$

The reaction at the counter electrode was the reverse of the above reaction. The reactions were driven externally by a constant current power supply.[4]

The two compartments mentioned above were connected to a storage reservoir, not shown in Fig. 2. By carefully adjusting the height of the reservoir, the liquid level in the cell compartments could be accurately adjusted. The value of ΔL was determined by measuring the height of the bulk liquid and the height of the separation, to ± 0.05 mm, using a cathetometer.

The electrolyte entered the working electrode compartment through radial holes drilled in the lower part of the plexiglass spindle. This provided for an axially symmetric electric field. To align the electric field more nearly parallel to the electrode and to reduce convection effects, a precision-bore glass tube was placed over the electrode as shown in Fig. 2. The bulk electrolyte was confined in an annular space about 1 mm wide. The bottom of the meniscus was used as the reference level for measuring ΔL. The distance from the bottom of the meniscus to the top of the apparent or "intrinsic" meniscus was in the range of 0.6-1.1 mm. The electrolyte in the cell outside the jacket did not participate in the reaction and need not be considered.

Convection currents in the electrolyte below the meniscus would tend to give abnormally high currents from the bottom section. The precision-bore glass jacket which confined the electrolyte next to the electrode in an annular region reduced this effect. Smaller

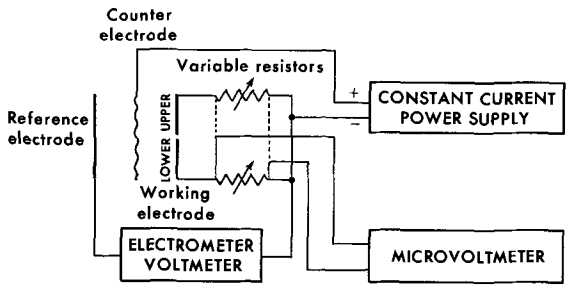

Fig. 3. Power and measurement circuit for sectioned electrode cell.

spacing would have reduced the probability of convection further (10), but this would have caused more severe relative variations in the annular space. The value chosen was considered to be a suitable compromise.

The readings were sensitive to the surface conditions of the electrodes. If any oxide formed on either the nickel or silver electrodes, the results were not reproducible. Care was always taken that, following polishing,[5] the electrode was immediately placed in the cell and cathodically polarized to prevent oxide formation. The current was increased to approximately 200 ma yielding vigorous hydrogen evolution. During the 24-48 hr cleaning period, the electrolyte was changed each 2-5 hr The cleanliness of the surface was considered satisfactory when, on lowering the electrolytic level, the surface remained uniformly wetted.

Electrolytic contact was made to a Hg, HgO reference electrode through a hole drilled lengthwise down the spindle and out through a small hole at the bottom of the metal electrode (11). Electrical connection to the bottom section of the electrode was made with a nickel rod down a hole in the spindle. A stainless steel screw went through the electrode and was threaded into the nickel rod. The electrical connection to the top section was made by a nickel plate in the bottom of the cap. When the cap was screwed down, the nickel plate pressed down on the upper electrode section and completed the contact. The resistances due to these connections were less than 0.1 ohm.

Figure 3 shows a schematic drawing of the electrical circuit. Before the measurements were started, the variable resistors[6] were set at zero; the two electrode sections were then shorted together and thus were at the same potential. When measurements were to be made, the resistances were increased until a measurable voltage drop[7] was obtained. When properly adjusted, the potential drop across each resistor was equal. As small a voltage drop as practical was used so that errors in balancing would be negligible. These potential differences varied between 10 and 1000 μv for the lowest and highest total applied currents. From the voltage drop and the known resistance, the current from each section could be calculated. The potential of the working electrode with respect to the Hg, HgO reference cell was measured with an electrometer.[8]

The start-up procedure was to refill the cell with 3.5M KOH, begin bleeding in O_2 saturated with water with respect to 3.5M KOH, and to set the total current at a fixed level. The liquid level was then lowered to near the bottom of the electrode, corresponding to a large value of ΔL. The cell was left for about 15 hr to allow the liquid film to drain and reach an equilibrium thickness. The level was next raised a small distance and a set of readings were taken. After each set of readings, the level was raised again and in this manner a series of readings for different values of ΔL were obtained. Observations were made at 30-min intervals to allow steady-state conditions to prevail during readings. At each electrolyte level the value of %C.O.T. could easily be calculated.

[5] Of the various polishing compounds, "Flow-five" aluminum oxide proved to be the most satisfactory. Although the roughness of surfaces was different depending on the polishing compounds used, no significant differences in the pattern of current distribution resulted.

[6] General Radio type 1432-U or 1432-K decade resistance boxes were used.

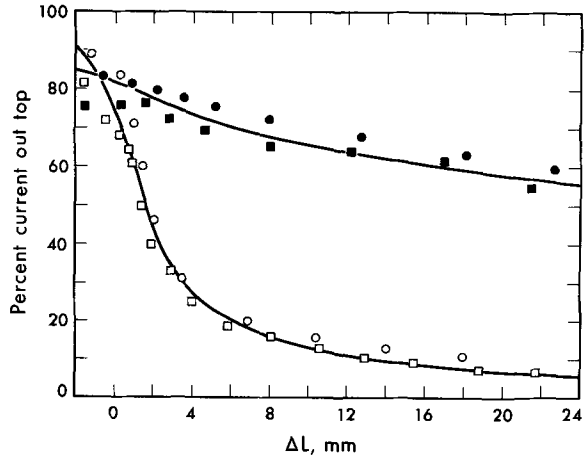

Fig. 4. Penetration of current in the electrolyte film. I = 4.84 μa/cm. Upper curve: nickel cathode, cells No. 2 and 3, runs 6 and 6'; lower curve: silver cathode, cell No. 4, runs No. 6 and 15.

Experimental Results

Exploratory experiments showed (12) that after the electrolyte level was lowered, a thin electrolyte film was left behind on the exposed electrode. The fraction of current from the upper section was very high but it dropped off with time. This decrease with time continued for up to 90 hours, after which a steady-state value remained as long as the run was continued, for several more days in some cases. This behavior was attributed to the draining of the electrolytic film which was initially thick but became thinner as draining progressed. Thicker films have a small resistance and thus tend to allow penetration of the current higher into the film.

Simple optical observations were made in an attempt to observe the film and determine its thickness by light interference techniques. The existence of the film was confirmed by the observation of weak interference colors when white incident light was used and by the observation of a "wake" when a small corner of tissue paper was drawn over the surface. Quantitative measurements of the film thickness were beyond the scope of this work. Müller (13) has made a detailed investigation of the optical properties of thin electrolytic films on nickel electrodes and found that in the range of 2-5 mm above the meniscus the film thickness is in the order of 1μ for 3.5M KOH.

Plots showing %C.O.T. as a function of ΔL are shown in Fig. 4, 5, and 6 for 4.84, 15.4, and 48.4 μa/cm applied current, respectively. Figure 7 shows the observed dependence of the electrode potential on the applied current.

A feature to be noted is that at higher currents the reaction tends to be concentrated nearer the top of the intrinsic meniscus. A comparison of the results for equal applied currents shows that the reaction on nickel spreads significantly more into the film than on silver.

One of the requirements of the sectioned electrode was that the separation should not disrupt the film. This becomes especially important when it is realized that the electrolyte film is about 1μ thick and the separation is 25μ wide. Such a wide gasket obviously causes some distortion. The possible distortion effects can be broken down into three categories as follows:

[7] This voltage drop was measured using a Keithly model 149 millimicrovoltmeter.

[8] Keithly Model 610R electrometer was used here. Its internal resistance is rated at 10^{14} ohms or greater.

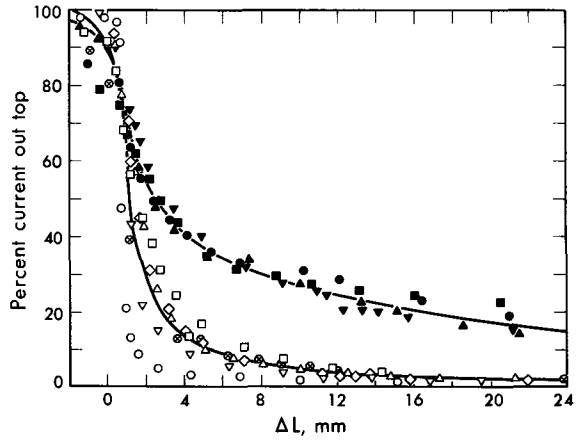

Fig. 5. Penetration of current in the electrolyte film. $I = 15.4$ μa/cm. Upper curve: solid symbols, experimental points, nickel cathode, cells No. 2 and 3, runs 5 and 5'; lower curve: open symbols, experimental points, silver cathode, cell No. 4, runs 5, 11, and 14.

1. Assume that the insulating gasket is perfectly flush with the metal surface and that the film thickness does not vary. The only error from such an ideal situation results from no electrode reaction occurring along the insulating section. This inactive length of the film will act as an "unnatural" resistance. If this occurs near the bottom of the film where the current might reach 100 μa/cm as a maximum and if the film is 1μ thick, the "unnatural" resistance will cause a potential drop of 4.2 mv. This compares to a total potential drop in the film of about 140 mv.

2. Referring to case 1, the net effect of the separation might be such that the film appears to be thicker as it passes the separation. For this situation, the "unnatural" resistance will be lowered, and the error will be less than for case 1.

3. The situation might also be an effective thinning of the film as it passes the separation. At worst, this thinning will occur along the full length of the separation. A thinning of this type, for example, to one-fourth of the normal thickness, will increase the "unnatural" resistance so that, using the example of case 1, the added potential drop would be 19 mv. Such an added potential drop would cause a shift in the results, such that less current would pass to the upper section than on an uninterrupted surface.

The reproducibility of the data was confirmed by using different cells of slightly modified design. Similarly, no change in the results was detected by replacing the 25μ thick polystyrene separator with a 70μ thick separator made from filter paper (see Fig. 5 and 6).

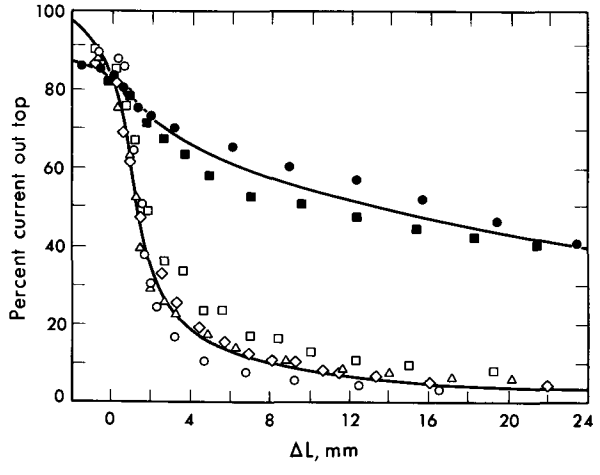

Fig. 6. Penetration of current in the electrolyte film. $I = 48.4$ μa/cm. Upper curve: solid symbols, experimental points, nickel cathode, cells No. 2, 3, and 7; runs 4, 4', 19, 20; lower curve: open symbols, experimental points, silver cathode, cells No. 4 and 6, runs 4, 10, 13, 19, 20.

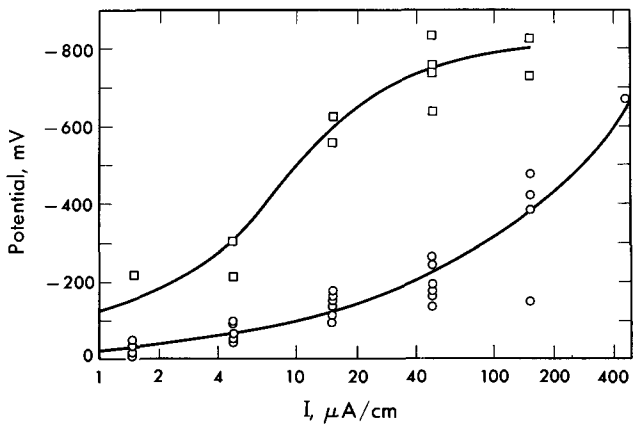

Fig. 7. Potential of the oxygen cathode (not corrected for ohmic drop) relative to the Hg/HgO reference electrode. Upper curve, nickel cathode; lower curve, silver cathode.

From these observations it is concluded that the film on the separator was not significantly thinner than on the adjacent metal surfaces. The maximum error in the current out the top, due to the presence of the separator, is estimated to be 3%.

Discussion

These experiments have confirmed that a stable, thin film of electrolyte adheres to the electrode surface above the top of the intrinsic meniscus. A large part of the reaction takes place on the surface of the electrode exposed to this film. The reaction rate drops off very rapidly within the visible meniscus and is very small along the electrode area exposed to the bulk electrolyte. The obvious reason for the abrupt decrease in reaction rate on the electrode surface below the intrinsic meniscus is mass transport limitation of the molecular oxygen. However, the controlling factors in the film region can arise from other sources.

Will (7, 8) concluded that the rate-limiting step was the mass transfer of gaseous reactant, hydrogen in this case, through the film to the electrode surface. He also found that the reaction rate dropped off very rapidly above the "top of the intrinsic meniscus." The observations with the oxygen-KOH system show that the reaction rate remains appreciable for several millimeters above the "top of the intrinsic meniscus." In addition, it is observed that the reaction extends further up the film for nickel than for silver.

It is also possible that the limiting step can be charge transfer at the electrode surface. It is known that silver is a better catalyst for the reduction of oxygen than is nickel (14). Thus one would expect that if the dependence of charge transfer "overpotential" on current density were higher for nickel than for silver, the reaction would tend to "spread out" or be distributed over a wider area, thus further up into the film.

Both the charge transfer and mass transfer overpotential tend to cause the reaction to spread out farther. It is the potential drop in the film which limits the extension of the reaction up into the film. From either standpoint, if the film were thicker, the reaction would tend to extend further into the film. Observations made during the initial stages when the film was draining confirm this argument.[9]

[9] A greater penetration of current up into the film on nickel relative to silver could be explained qualitatively by a significantly larger film thickness on nickel. Although precise observations regarding the film thickness on nickel were not available at the time this work was concluded, preliminary data by Müller (13) indicated that the film thickness on silver is actually somewhat greater than on nickel.

Conclusions[10]

1. The existence of a thin film of electrolyte above the intrinsic meniscus on clean nickel and silver has been confirmed. The thickness of this film is established as being in the order of magnitude of wave length of visible light.

2. For the cathodic oxygen electrode, current density distribution measurements on cylindrical nickel and silver electrodes established that a large portion of the current arises in the thin electrolytic film above the intrinsic meniscus. The fraction of current transferred as much as 10-20 mm above the bottom of the intrinsic meniscus is not negligible.

3. The thicker the film and the smaller the applied current, the further the current spreads over the electrode surface covered by the film. At a given value of applied current, the reaction is concentrated nearer the intrinsic meniscus on silver than on nickel surfaces.

[10] After the completion of this manuscript, an account of the work of Yu A. Mazitov *et al.* (15) has come to the authors' attention. Current distribution along a silver wire in the reduction of oxygen in 10.6*N* KOH was measured by the method originally used by Will (7, 8). Although their experimental observations are in qualitative agreement with the results presented above, the reader's attention is called to the use of an uninterrupted cathode and the much shorter draining times (3-4 min) reported by Mazitov *et al.*

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Current Distribution at a Gas-Electrode-Electrolyte Interface

II. Theoretical Treatment

Douglas N. Bennion[1] and Charles W. Tobias

Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The dynamic behavior of a cathodic oxygen electrode is critically dependent on charge and mass transport preceding and following the charge transfer recation at the electrolyte-electrode interface. A mathematical model is presented which takes into account diffusion and migration of relevant substances and the solubility of oxygen in the electrolyte. The model accounts for the concentration dependence of transport properties. A comparison of the theoretical and experimental results indicates that the current density distribution is controlled by a balance between charge transfer overpotential and ohmic resistance drop in the electrolyte film. Because of the much greater length of diffusion paths, and consequent slowness of oxygen transport, a relatively small fraction of the charge transfer reaction occurs on the electrode area below the top of the intrinsic meniscus.

An experimental study (1) in this laboratory has shown that on partially immersed gas electrodes a thin film of electrolyte may exist on the electrode above the bulk electrolyte, and when this film exists the electrochemical reaction takes place primarily on the surface of the electrode which contacts the thin film.

By considering several possible physical models Wagner (2), in 1957, demonstrated the likelihood of the importance of thin electrolyte films in actual gas electrodes. Since then, various models have been proposed which attempt to duplicate more closely actual physical conditions. Will (3, 4) was able to explain his experimental results obtained on partially immersed, plane electrodes in terms of a theoretical model. His model did not include consideration of charge transfer overpotential, and the only transport property of the electrolyte employed was the conductivity which he assumed to be invariant. Grens *et al.* (5) in a model geometrically similar to the one by Will included an Erdey-Gruz-Volmer-type charge transfer overpotential expression. Transport of ions by both diffusion and migration is accounted for, and the movement of water is assumed to occur only in the electrolyte phase. Grens *et al.* were able to show how systems can become charge transfer or mass transfer limited depending on the magnitude of the physical parameters involved. Although variations of transport properties were not considered, their model predicts large concentration gradients in the thin film. It should be noted that, of these models, only that of Will has been compared directly to experiments, and that his model incorporated features characteristic of the hydrogen, sulfuric acid, platinum system.

The above theories provide primarily a guide to understanding the detailed behavior of the electrode reaction within and near a thin electrolyte film which

[1] Present address: Department of Engineering, University of California, Los Angeles, California.

may exist on plane, metal electrodes. Other models have been proposed which attempt to explain the behavior of porous electrodes in terms of certain assumed microstructures of the porous matrix. Some recent models by Gurevich (6), Rockett (7), Iczkowski (8), and Burshtein *et al.* (9), have incorporated the possibility of a thin film existing on the walls of the gas filled pores or cavities within the electrode. Of these, the one by Burshtein *et al.* is of particular interest, since it includes a transformation of a rather sophisticated model into one where equations developed for two-phase porous electrodes can be applied (10-12). In Burshtein *et al.'s* model, a detailed description of what is taking place within the thin film is not undertaken, and a simple, linear relation between the local overpotential and the current being transferred is assumed.

The theoretical model to be presented here is one in which the details of the film behavior are described. Our model is to be for the oxygen, KOH, silver system and is to include a realistic charge transfer overpotential relation. It also allows for variation of electrolyte composition and consequent changes in the solubility of oxygen and in the transport properties of oxygen and KOH. Consideration is given to whether water transport occurs in the gas phase or the liquid phase. Direct comparison of the theoretical model and experimental results is designed to further our understanding of the system and its controlling features.

The Mathematical Model

Geometric considerations.—The model describes an oxygen half-cell operating cathodically in aqueous KOH electrolyte. From the analysis of experimental results (1) it has been concluded that a large portion of the reaction takes place in a thin film which extends above the bulk electrolyte on the surface of the electrode. Measurements of the film thickness by Müller (13) show that the thickness of this film decreases with height above the bulk liquid. However, the per cent change in thickness is small compared to the observed per cent changes in the reaction rate over comparable distances (15). In our model, to avoid unnecessary mathematical difficulties, the thin film is assumed to have a constant thickness, δ.

Since the current density was observed to spread out over a comparatively large area, the charge transferred in the vicinity of the curved meniscus is small compared to the total current. This suggests that the precise geometry of the meniscus is not important (1, 3, 4). Consequently, in our model (see Fig. 1) the thin film is assumed to change its thickness abruptly.

Mass transport considerations.—Mathematically, the model is one dimensional. No variations in concentration, c, or current density, i, across the width of the film are considered. Oxygen is assumed to reach the electrode by diffusion in the x direction through the upper film (see Fig. 1). In the lower (bulk) electrolyte region oxygen is assumed to move only in the negative y direction. The consumption of oxygen through reaction at the electrode is treated as a homogeneous sink term (see Eq. [10]).

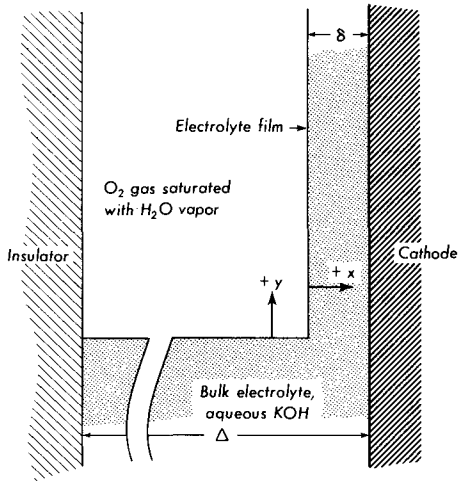

Fig. 1. Mathematical model of the gas-electrolyte-electrode interface.

The system is assumed to be at steady state. The over-all electrode reaction is

$$O_2 + 2H_2O + 4e^- = 4\,OH^-$$

The rate of reaction at the electrode is proportional to the transfer current density, J. J is taken as positive when the reaction proceeds from left to right as written. In the thin film, O_2 migrates toward the electrode in the x direction, OH^- ions move down the film, and the K^+ ions remain stationary at steady state. The water can reach a reaction site by two mechanisms or combinations thereof. It can diffuse up into the film countercurrently to the OH^- ions or condense from the gas phase onto the film surface and diffuse cocurrently with the oxygen. Convection is assumed to be negligible.

Equations for electrolytic transport.—Algebraically, the ionic fluxes and the water flux can be written as

$$N_+ = 0$$

$$N_- = -i/F$$

$$N_o = -\tfrac{1}{2}\,Q\,N_-$$

$$v^\star = \frac{1}{c_T}(N_+ + N_- + N_o) = \frac{-i}{c_T F}\left(1 - \frac{Q}{2}\right) \qquad [1]$$

By electroneutrality

$$c_+ = c_- = c \qquad [2]$$

Q is equal to unity if the water is supplied wholly by diffusion up the film, and it is equal to zero if supplied totally by condensation from the gas phase. It seems reasonable that one mechanism or the other will be controlling so that Q will be assumed to equal either one or zero. The model is not suitable for fractional values of Q.

The equations representing the flow of current and movement of the K^+ and OH^- ions have been discussed elsewhere (14, 15). Incorporating the concentration dependence of the transport properties, and assuming use of a Hg/HgO reference electrode, we obtain

$$i = \kappa\nabla\Phi - \frac{\kappa}{F}RT\,\nabla \ln a\left[\frac{2B}{A+B} + \frac{c}{c_o}\right] \qquad [3]$$

$$N_+ = \frac{-\mathcal{D}}{RT}\frac{\nu_+}{\nu}c\nabla\mu_e + \frac{t_+^\star\, i}{Fz_+} + c_+ v^\star \qquad [4]$$

$$N_- = \frac{-\mathcal{D}}{RT}\frac{\nu_-}{\nu}c\nabla\mu_e + \frac{t_-^\star\, i}{Fz_-} + c_- v^\star \qquad [5]$$

$$\frac{-z_+ z_- eF\sqrt{\nu c c_T}}{\kappa\mu} = G + \frac{AB}{\nu_+ A + \nu_- B}\frac{\sqrt{\nu c_o}}{\sqrt{c c_T}} \qquad [6]$$

$$\mathcal{D} = \frac{\nu kT/\mu}{\nu_+ A + \nu_- B} \qquad [7]$$

$$t_+^\star = 1 - t_-^\star = \frac{c_-}{c_T} + \frac{c_o}{c_T}\frac{B}{A+B} \qquad [8]$$

Values of A, B, and G for KOH are (14, 15): $A = 28.89 \times 10^{-8}$ cm; $B = 8.63 \times 10^{-8}$ cm; $G = 9.63 \times 10^{-8}$ cm.

Equations for oxygen transport.—In the thin film, oxygen diffusion can be represented by

$$J = \frac{FD_1[(p/p^o)c_1^o - c_1]}{\delta}, \quad (y \geqq 0) \qquad [9]$$

The transfer current density, J, is equal to the oxygen flux times $4F$. It is assumed that Henry's law holds and that p is the partial pressure of oxygen in atmospheres. D_1 is the diffusion coefficient of oxygen at the concentration of KOH existing at the point under consideration in the film. The numerical calculations were easily adapted to allow for the variation of D_1 as a function of the KOH concentration (16) at different positions in the film.

In the lower or bulk electrolyte region the following equation applies to steady-state oxygen transport.

$$D_1 \frac{d^2c_1}{dy^2} = \frac{J}{4F\Delta}, \quad (y \leqq 0) \qquad [10]$$

Equations relating current and overpotential[2].—A relationship between local overpotential and local transfer current density, J, is still needed. A review of the literature on the kinetics of the oxygen electrode (15, 36) indicates that a generally accepted kinetic description for the oxygen electrode is not yet available (17-19). Based on work by Krasilshchikov, Nefodova, Belina, and Andreeva (20-25) and by Bagotskii and Yablokova (26), a sequence of elementary steps emerges which seems to be satisfactory for use with Ag, Au, and Hg electrodes. From this reaction sequence, summarized by Vetter (36), the following kinetic expression can be developed (15)

$$J = k[O_2]^{\alpha}[OH^-]^{\lambda}[H_2O]^{\gamma} \left\{ e^{\frac{4(\alpha-1)F\eta}{RT}} - e^{\frac{4\alpha F\eta}{RT}} \right\} \qquad [11]$$

where k is a constant, square brackets indicate the activity of the enclosed species, and η is the overpotential defined as the potential of the working electrode compared to a reversible oxygen electrode located just outside the double layer. For a silver electrode in alkaline solution

$$\alpha = 0.625, \lambda = 0.5, \gamma = 0.5 \qquad [12]$$

Work on carbon electrodes (27-30) also seems to support the above mentioned reaction sequence. As mentioned in the Appendix, the kinetics of oxygen reduction on nickel seems more complex. For the case of silver it is assumed that Eq. [11] is applicable at any point on the electrode, *i.e.*, k and α are true constants without any dependence on η or position on the surface. For nickel electrodes Eq. [11] would have to be replaced by an expression of a probably more complex nature, accounting for the dependence of the rate-controlling step (or steps) with η. A generally applicable reaction sequence or kinetic rate expression for the reduction of oxygen on nickel does not appear available (17, 18, 31, 32). For this reason no attempt is made to apply the present mathematical model to the nickel electrode.

Equations relating charge transfer current density and current density in the solution.—Two relations are needed in addition to the equations already mentioned. Since charge must be conserved, the transfer current density, J, and the current density in the solution, i, which is assumed to vary only in the y direction, are related by

$$J = -\delta \frac{di}{dy}, \quad (y \geqq 0); \quad J = -\Delta \frac{di}{dy}, \quad (y \leqq 0) \qquad [13]$$

It is convenient to replace the potential of the reversible oxygen electrode by that of a Hg/HgO reference electrode

$$\eta = -\Phi - \frac{RT}{4F} \ln \{[O_2]/p\} \qquad [14]$$

Here Φ is the potential of the Hg/HgO reference electrode with respect to the working electrode.

[2] A more detailed discussion is given in the Appendix.

Activities used in kinetic equation.—The activities of the reacting species are assumed to be represented by the following:

$[O_2]$ is assumed to be the concentration of oxygen with unit activity being the concentration of oxygen in equilibrium with gaseous oxygen at a partial pressure of one atmosphere. In the numerical work it was possible to allow the solubility of the oxygen to depend on the concentration of KOH.[3]

$[OH^-]$ is assumed to be the same as the mean ionic activity, a, of the KOH. The activity coefficients were taken from Robinson and Stokes (33). The activity at a KOH concentration of 3.866M is taken to be unity.

$[c_o]$ is assumed to be the concentration of free water. This is determined by subtracting from the total water concentration the concentration of water that is associated with the KOH ions (14, 15). Unit activity is assumed to be the activity of water in 3.866M KOH solution.

Numerical solution.—There are 5 dependent variables, c, c_1, J, η, and i. These are related by Eq. [3], [4], [9] or [10], [11], and [13]. Equation [9] is used in the upper film and Eq. [10] in the lower region. Equation [14] allows one to convert from η to Φ when desirable. The equations are slightly different for the upper and lower sections. The two sections are solved for separately and their boundary conditions matched, since the potential and current are continuous in the electrolyte.

The boundary conditions at the top of the upper film are $y \to +\infty$, $\eta \to 0$, and $i \to 0$.

The boundary conditions at the bottom of electrode are: at y = bottom of electrode, $\eta = \eta_o$ or $i = i_o$.

The equations are nonlinear, 1st, and 2nd order differential equations. They were transformed into finite difference form and solved numerically using an IBM 7090 digital computer. In a numerical sense, it was possible to solve the equations for the thin film region exactly. That is, no iterations were necessary. This was accomplished through an appropriate change of variables. In the lower section, it was necessary to linearize the equations, put them in matrix form, and solve the matrix (15). The nonlinearities were mild, and only three or four iterations were necessary. The method appeared to be stable and to converge rapidly to the correct answer.

Theoretical Results and Comparison with Experimental Observations

Explanation of figures.—Experimental results are summarized in Fig. 2 through 6. A comparison between the calculated variation of current above a

[3] The solubility of oxygen at 25°C in aqueous KOH and for a total pressure of 1 atm as determined in this laboratory (16) may be represented by

fixed point on the electrode, ΔL, and the experimental observations corresponding to similar conditions is given in Fig. 2. Experimental observations at 48.4, 15.4, and 1.48 μa/cm were presented in Part I, Fig. 4-6. In these figures the curves referring to the silver electrode are those calculated by using parameters as described below, while those for nickel represent a qualitative fitting of the data. No experimental data are available for the voltage variation in the film.

Figure 3 shows the theoretical variation of potential and the per cent current above a fixed point on the electrode as a function of applied current. Figures 4 and 5 present the calculated current density variation along the electrode. The curves in Fig. 3 are the integrals of the curves in Fig. 4 and 5 for corresponding total applied currents. Figure 6 shows computed examples of variation in the concentration of KOH in the film as a function of electrode height. A comparison is made between the concentration variations for both modes of water transport to the reaction sites.

Current distribution and the square meniscus assumption.—ΔL is the independent variable used in the experimental work which indicates position on the electrode relative to the bottom of the intrinsic or visible meniscus. The variable y is used in the theoretical work to indicate position along the electrode relative to the sudden, right-angle widening of the thin film. In order to make direct comparison between the two approaches, y and ΔL must be properly related.

The distance from the top of the intrinsic meniscus over which the current density remains appreciable is to be noted. Even at the lowest currents observed (1.45 μa/cm), the area lying under the level of the bottom of the intrinsic meniscus contributes less than a third to the total current. At the highest currents observed (154 μa/cm) this fraction falls to below a hundredth. The discontinuity of the current density distribution curves at ΔL of 1 mm (see Fig. 4 and 5) results from the square shaped meniscus used in the model. In reality, the transition from the charge transfer and conductance controlled region in the film to the oxygen mass transport controlled area below the top of the intrinsic meniscus occurs over a finite length near the top of the intrinsic meniscus. However, the current density drops off rapidly as the film begins to thicken from approximately 1μ to a thickness in the order of 1 mm at the bottom of the intrinsic meniscus, over a vertical distance of approximately 1 mm. The region of high current density at the bottom of the thin film contributes a large portion of the total current. However, the reaction remains appreciable for several millimeters above the intrinsic meniscus. Due to the large area available in the upper film, the contribution to the total current from that region is appreciable.

In matching the theoretical and experimental current distribution curves, it was found that $y = 0$ corresponded to a ΔL of 1 mm. This implies that below the level of 1 mm above the bottom of the intrinsic meniscus the film thickness is sufficient to cause oxygen transport to become controlling.

A theoretical treatment using a curved meniscus and a tapered film is possible. However, it appears this would greatly increase the numerical complexity due to a second geometric dimension. Such a modification is not expected to yield significant further information or insight. It is established by experimental evi-

dence (1) and a reasonably realistic, theoretical model that an overwhelming proportion of the current originates well above the bottom of the intrinsic meniscus. The changes in the pattern of the current density distribution that can be expected if one substitutes a smoothly curving meniscus for the square meniscus are not expected to be appreciable.

Effect of i_o.—Of the parameters which appear in the numerical calculations, several can be calculated from independent experimental data. Where values are not available, reasonable estimates have to be made.

The shape and position of the theoretical current distribution curves depends on the reaction orders, α, λ, and γ. These appear as the exponents of the OH^-, H_2O, and O_2 activities, respectively, in Eq. [11].[4] The values of α, λ, γ given in Eq. [12] were based on the reaction sequence, rate-controlling step, ($HO_2 + e^- = HO_2^-$), and the value of the transfer coefficient recommended by Krasilshchikov (18). There are, of course, a very large number of reaction sequences and rate-controlling steps which might be chosen. Calculations involving another rate-controlling step ($O_2 + e^- = O_2^-$) yielded a good fit of the experimental data only when unrealistic values of δ were employed.

The parameter known with the least certainty is k in Eq. [11]. When multiplied by the concentration terms raised to the appropriate power in Eq. [11], k can be identified with an exchange current density, i_o. A value for i_o in the order of 10^{-9} amp/cm^2 was found to "fit" the data best. However, this could be varied by plus or minus three orders of magnitude with little effect on the position or shape of the theoretical curve. Although literature reports on measurements of i_o for the oxygen electrode vary widely, a comparison to the Tafel lines shown by Belina and Krasilshchikov (25) indicate that the value used is not unreasonable. The relatively insignificant changes in distribution calculated for i_o's ranging from 10^{-6} to 10^{-12} amp/cm^2 are to be expected, since in the current density ranges used in the computations, except for large values of ΔL, the electrode operated in the Tafel region. Thus a change in i_o results in shifting the potential of the electrode by a constant value, not affecting the distribution of current at a fixed value of total current.

Effect of the film thickness parameter, δ.—The theoretical results were very sensitive to changes in the film thickness parameter, δ. It should be remembered that in reality the film tapers while the model assumed δ to be constant. Since the current extends further up the film at low currents, it is to be expected that the effective average film thickness will decrease with decreasing total current. For the indicated total applied currents, the following values of δ yielded good agreement between the experimental data and our model

I	1.48 μa/cm	4.84 μa/cm	15.4 μa/cm	48.4 μa/cm	154 μa/cm
δ	0.33μ	0.43μ	0.75μ	1.50μ	2.25μ

The values of δ used in the numerical solutions are in reasonable agreement with the average film thicknesses obtained by Müller (13, 15), who noted that the average film thickness increases significantly with increasing cathodic current.

As confirmed by our model, experimental observations have shown that the current density distribution varies a great deal while the film is draining, *i.e.*, while the film thickness is diminishing with time. In thinning films, the over-all overpotential increases and the reaction spreads less and less into the film.

Consideration of the tapering of the film may be justified after sufficient data on film thickness variations with position and current density become available. Otherwise, the introduction of a second geometric variable would require another adjustable parameter (the slope or curvature of the film) without appreciably contributing to the physical understanding of the phenomena observed.

Influence of variable transport parameters and water transport.—In the present work, current distributions were calculated both with constant and variable transport properties. Although the assumption of constant (average) properties did not yield significantly different distributions, this finding should be regarded as valid only under the specific experimental conditions employed. By providing water to the reaction sites through the film from the vapor phase, the steady-state concentration gradient in the film is quite mild compared to the case when water transport occurs by diffusion from the bulk electrolyte in the liquid phase (see Fig. 6).

The high concentration gradients which are predicted when water is assumed to be transported only within the film cause the KOH concentration to exceed the saturation limit. It is suggested that in actual porous gas electrodes water is supplied to the reaction site, at least in part, by condensation from the vapor phase.

Oxygen transport.—Except for the region below the meniscus, oxygen transport should not be a limiting factor. The numerical results show that throughout and across the entire length of the film, the activity of oxygen is very close to unity,[5] *i.e.*, nearly identical to the activity at the electrolyte-gas interface. However, once one moves below the meniscus where the diffusion path for the oxygen becomes large, the oxygen activity drops quickly resulting in the rapid decrease in current density below the top of the intrinsic meniscus.

Rate-controlling process.—Since our model shows that the oxygen activity does not vary noticeably in the thin film, it follows that the penetration of the reaction into the film depends on a balance between the charge transfer overpotential and resistance drop in the electrolyte. As stated in Part I, the significant differences between behavior of the nickel and silver electrodes suggest this to be the case.

Will (3) in his work with the hydrogen electrode on platinum found that the transport of hydrogen gas to the electrode surface through the thin film was controlling, along with ohmic resistance drop, except at very low currents. This is not in contradiction with the results found for the oxygen electrode. The hydrogen electrode on platinum is much more reversible than is oxygen on silver. Consequently, the concentration of current in the immediate vicinity of the intrinsic meniscus is rendered less possible in the case of oxygen, and charge transfer overpotential along with the ohmic drop in the film can be expected to control the current distribution.

Conclusion

In the foregoing treatment it is shown that the current distribution under an electrolyte film above the intrinsic meniscus of an oxygen cathode on silver may be quite successfully described by a rational theoretical model. Realistic geometric and kinetic parameters yield a good agreement between the calculated distributions and those observed experimentally.

Oxygen transport is not limiting in the thin upper film. The current density distribution in this region arises from a balance between charge transfer overpotential and resistance drop in the film. Below the intrinsic meniscus, the bulk electrolyte region, the oxygen activity decreases rapidly due to the mass transport limitations of dissolved oxygen. Thus, the current density is small in this region. The high con-

[4] Note that the parameter α is related to (but not the same as) the transfer coefficient.

[5] It should be remembered that, although the activity remains constant, the concentration of oxygen varies along the length of the film due to the decreasing solubility with increasing KOH concentration.

centration gradients which result when water is not supplied from the gas phase point to the desirability of supplying water as vapor in the oxygen gas.

NOMENCLATURE

A, B, C	subsidiary transport properties defined so as to reduce the concentration dependence, Å
a	mean molar activity of KOH $= f_{\pm}c$
c	$c_+/\nu_+ = c_-/\nu_-$ — concentration of KOH, mole/cm^3
c_1	concentration of oxygen, mole/cm^3
c_1^o	saturation concentration of oxygen under a partial pressure of 1 atm, mole/cm^3-atm
c_+	concentration of K^+, mole/cm^3
c_-	concentration of OH^-, mole/cm^3
c_o	concentration of water, mole/cm^3
c_T	$= c_+ + c_- + c_o$ — total concentration, including solvent
D_1	diffusion coefficient of oxygen in aqueous KOH, cm^2/sec
$\mathcal{D}$	molecular diffusion coefficient of KOH based on activity gradients, cm^2/sec
e	electronic charge, coulombs
e^-	symbol for an electron
$f_{\pm}$	mean molar activity coefficient. [Values from ref. (33) were used.]
F	Faraday's constant, coulombs/equivalent
i	current density in the solution, amp/cm^2
i_o	exchange current density, amp/cm^2
J	transfer current density, amp/cm^2
k	kinetic parameter related to exchange current density, amp/cm^2
N_+	flux of K^+, mole/cm^2-sec
N_-	flux of OH^-, mole/cm^2-sec
N_o	flux of H_2O, mole/cm^2-sec
p	partial pressure of oxygen, atm
p^o	reference pressure, 1 atm.
Q	one when H_2O is transferred in liquid phase; zero when H_2O transferred in the gas phase
R	universal gas constant, joule/mole-°K
t_i^*	transference number of species i with respect to molar average velocity
T	absolute temperature, °K
v^*	molar average velocity, cm/sec
x	coordinate perpendicular to the plane of the electrode, cm
y	coordinate parallel to the electrode in the vertical direction, the independent variable, cm
z_i	valence or charge number of species i, negative for anions
α	kinetic parameter related to reaction order of oxygen and to the transfer coefficient
γ	kinetic parameter indicating reaction order of H_2O
δ	film thickness, μ
Δ	width of annular electrolyte region below meniscus, cm
η	overpotential referred to a reversible oxygen electrode, volts
κ	conductivity, mho/cm
λ	kinetic parameter indicating reaction order of OH^-
μ_e	chemical potential of KOH, joule/mole. (RT ln $f_{\pm}$ c)
μ	viscosity, poise
ν_+	number of cations per molecule of electrolyte
ν_-	number of anions per molecule of electrolyte
ν	$= \nu_+ + \nu_-$
Φ	overpotential referred to a reversible Hg/HgO electrode, volts

APPENDIX

Notes of the Kinetics of the Oxygen Electrode

There has been accumulated a body of information which suggests that hydrogen peroxide is an intermediate in oxygen reduction (19-31, 34-36). Although the evidence is fairly conclusive for such electrodes as Ag, Hg, C, and Au, it appears that there may be competing sequences of steps on such electrodes as Pt and Ni (17, 18, 31, 34). At this point only the former category of electrodes appears amenable to a simple kinetic analysis.

A review of the above mentioned references indicates that the assumption of the following sequence of elementary kinetic steps is reasonable on Ag, Hg, C and Au electrodes.

1. $O_2 + M = MO_2$
2. $MO_2 + e^- = MO_2^-$
3. $MO_2^- + H_2O = MHO_2 + OH^-$
4. $MHO_2 + e^- = MHO_2^-$
5. $MHO_2^- + H_2O = MH_2O_2 + OH^-$
6. $MH_2O_2 + e^- = MOH + OH^-$
7. $MOH + e^- = M + OH^-$

The M represents an adsorption site and, when associated with a molecular symbol, implies that the molecule is adsorbed. It is possible for any adsorbed molecule on the right side of an equation to desorb before reacting in the next step. The O_2^- and HO_2 are so reactive that this is unlikely. The desorption of HO_2^- or H_2O_2 (depending on the pH) could occur. However, there is evidence (20, 25) which indicates that on silver and in alkaline solution the rate of desorption is small compared to reaction by steps 6 and 7. It should be noted that, because the O_2^- and HO_2 radicals are very reactive, they have not been positively identified.

It appears that the adsorption step is not rate controlling and that either step 2 or 4 is rate determining. The choice appears to depend on pH and on the electrode material. For silver in alkaline solution step 4 appears to be rate controlling. With these assumptions, the kinetic expression can be written as

$$J = k[O_2]^{\frac{\alpha_4 + 2}{4}} [H_2O]^{\alpha_4} [OH^-]^{(1-\alpha_4)} \left\{ e^{\frac{(\alpha_4 - 2)F\eta}{RT}} - e^{\frac{(\alpha_4 + 2)F\eta}{RT}} \right\}$$

where J is the local transfer current density, α_4 is the transfer coefficient for step 4, η is the local overpotential, and k is a kinetic rate constant. Brackets signify the activity of the enclosed species.

On electrode surfaces such as nickel and platinum it appears that other sequences of elementary steps may compete with those outlined above (17-19, 31, 34, 37). On such materials, metal oxides may appear in some of the elementary steps. It is likely that the rate-controlling step and indeed the whole rate-controlling sequence of steps may depend on the local potential. Until more precise information is available on the kinetic parameters the distribution of oxygen reduction on such a surface cannot be predicted.

Tracer Diffusion Measurements in Mixtures of Molten Alkali Carbonates

P. L. Spedding and R. Mills

Diffusion Research Unit, Research School of Physical Sciences,

Australian National University, Canberra, Australia

ABSTRACT

Tracer diffusion[1] coefficients have been measured for Na^+ ion in Li_2CO_3, for Na^+ and $CO_3^=$ ions in the binary eutectic $Li/NaCO_3$, for K^+ and $CO_3^=$ ions in the binary eutectic Li/KCO_3, and for Na^+, K^+, and $CO_3^=$ ions in the binary eutectic Na/KCO_3. The magnitudes of the diffusion coefficients and the derived experimental activation energies are discussed in relation to previous studies. Preliminary work designed to test the Lumsden model for interaction in binary mixtures is also presented.

We have recently reported (1) tracer diffusion measurements for the pure Na_2CO_3 melt and for various ions in the eutectic mixture $Li/Na/KCO_3$. As a result of this study, interesting comparisons became available of the experimental activation energies for the transport processes of conductance, viscous flow, and diffusion. This led us to believe that an extension of these studies to binary mixtures would be profitable. The work has now been extended to include Li_2CO_3 and the binary $Li/NaCO_3$, Li/KCO_3, and Na/KCO_3 eutectics.

A recent publication by Moynihan and Laity (2) uses the Lumsden (3) model to explain the change in mobility of ions in binary mixtures. In addition, we have, therefore, made some preliminary tracer diffusion measurements in certain binary systems with a view to being able to test this model further. As stated in the first paper of the series, we believe also that transport studies in the general area of molten alkali carbonates will be of value in high-temperature fuel cell work.

Experimental

Apparatus and materials.—Full details of the apparatus and materials used were given in a previous paper (1).

Procedure.—The major portion of the procedure used has also been reported previously (1). However, several modifications and refinements of this procedure have now been made. For example, originally the diffusion tubes were held vertically in a small auxiliary furnace and filled by manual placement of a charged filling capillary. Successful location of the capillary was difficult, and so the method was modified. The charged capillary was momentarily removed from the auxiliary furnace and placed in the diffusion tube. The capillary and attached tube were then placed in the furnace in an almost horizontal position for temperature equilibration. The tube was then brought to a vertical position on the top of an inclined plane (leading to a locating hole) and filled by a combination of manual manipulation and capillary air pressure. Occasionally bubbles were formed in the diffusion tube with this method (about 12% of tubes filled), but its rapidity made it more attractive than the more reliable vacuum filling technique.

Difficulty was experienced with the lithium carbonate experiments in removing the solid salt from the diffusion tubes due to binding of the vibratory drill bit. Consequently the salt was drilled out manually. To minimize this tedious procedure the initial activity was, in this case, determined by a weighing-counting method similar to that used by Angell and Tomlinson (4).

Problems arose in the counting analyses due to drift in the counting rates arising from various causes. Procedures have been developed in this laboratory which minimize this source of error, in particular a rotational counting technique due to Albright (5). With this technique the initial (C_o) and final (C_{av}) radio-

[1] In a previous study on the alkali carbonates (1) the term "trace-ion diffusion" has been used. However, it has been inferred from the measurements in that study that the unit involved in tracer diffusion is not necessarily a single ion so that the more general term is now preferred.

active solutions were counted alternatively in two separate counting trains, 1 and 2. The two counting containers, a and b, were then interchanged and the alternate counting procedure repeated. The count rate, in such a case, would be equal to the sum of products of the radioactive solution concentration, the container counting efficiency, α, and the equipment counting efficiency, β. The counts are then grouped so as to eliminate the long term drift

$$\text{Count ratio} = \frac{C_{av}\,(\alpha_a\beta_1 + \alpha_b\beta_2)}{C_o\,(\alpha_b\beta_1 + \alpha_a\beta_2)}$$

Assuming that $\alpha_b = (1 + x)\,\alpha_a$ and $\beta_2 = (1 + y)\beta_1$ where x and y are very small and also constant, then by substitution

$$\text{Count ratio} = \frac{C_{av}}{C_o}\,\frac{\alpha_a\beta_1\,[1 + (1 + x)\,(1 + y)]}{\alpha_a\beta_1\,[(1 + y) + (1 + x)]} \simeq \frac{C_{av}}{C_o}$$

With a sufficient number of counts, a counting reproducibility of better than ± 0.1% has been achieved using this method which is more than sufficient counting accuracy for the open-ended capillary.

Auxiliary Measurements

End Effects.—Errors due to the end effects associated with the open-ended capillary method were discussed in a preliminary way in the previous study (1), and it was concluded that an experimentally derived flow region existed in which the Δl effect was negligible. However, as there has been a certain amount of controversy in the literature concerning the effect, we have now made a more detailed analysis using boundary layer theory (6, 7).

The boundary layer refers to the region of progressive reduction of velocity from the main stream value to zero at the adhering molecular layer on the solid surface. When a liquid flows past an open-ended capillary at stream-lined velocities (Fig. 1), a boundary layer is formed at the leading edge and a point of three-way separation at the trailing edge of the capillary. This latter would cause a trailing turbulent region to be set up in the form of Karman's vortex streets. This latter condition occurs at $Re_0 \geq 1$ for a cylinder in cross flow (7), where Re_0 is the Reynolds number referred to the external capillary diameter. The boundary layer increases in thickness across the capillary tube face until it meets the turbulent front set up by the trailing edge. With increased flow velocity a turbulent profile would occur at a steadily decreasing critical distance from the leading edge. The lower point of this turbulent profile would sweep down through the boundary layer disturbing the liquid in the vicinity of the capillary face and result in high diffusion coefficients being recorded. Calculation shows that this turbulent front begins to remove radioactivity from the bore of the capillary at high velocities (Re_0 = 1,484) *i.e.*, well beyond the range normally considered in relation to the Δl effect.

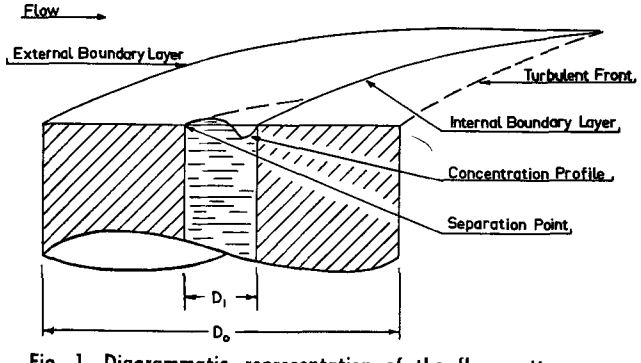

Fig. 1. Diagrammatic representation of the flow patterns over a capillary face.

Further, the measured diffusion coefficients for aqueous solution (Fig. 2) show an initial sharp rise and then a steady increase up to about Re_0 = 190 whereafter the rise is increasingly rapid. It is obvious, therefore, that the Δl effect is not primarily caused by the external boundary layer, but must be due to phenomena within its precincts. This conclusion is reinforced by consideration of plots of measured diffusion coefficients in various media against Re_0 (Fig. 3). These graphs exhibit no similarity among different media such as aqueous solutions and molten metals and salts; an occurrence which would be expected had the Δl effect depended primarily on the external boundary layer. The fact is that the dense molten media consistently show a more pronounced effect.

At first sight, it would seem more realistic to plot the measured diffusion data against Re_1, the Reynolds number determined by using the diameter of the capillary bore, since the phenomena causing the Δl effect are in the vicinity of the capillary bore and encompassed by the external boundary layer. Such plots do materially change the relative order among the different media shown in the lower part of Fig. 3, but reasonable agreement is still lacking. This helps

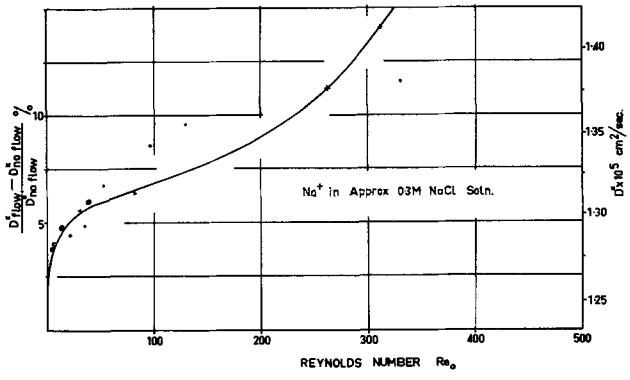

Fig. 2. Variation in measured diffusion coefficient with increasing flow over the capillary face. X, Mills (8); •, Rastas and Kivalo (9).

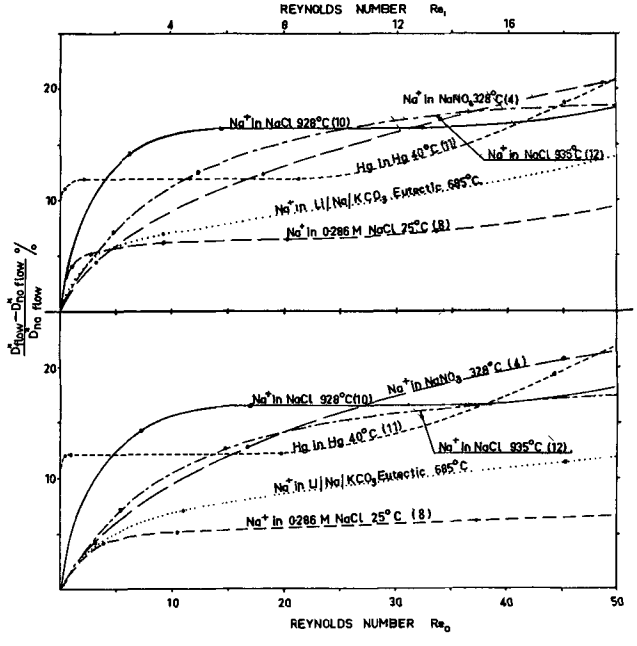

Fig. 3. Effect of flow conditions on the measured diffusion coefficients in various liquid media. In the upper section the flow is referred to the capillary bore and in the lower section to the external capillary diameter.

to confirm our conclusion that the flow phenomena causing the Δl effect are unconnected with the external boundary layer. Reference to Fig. 1 shows how we envisage the flow disturbance. The leading edge of the capillary bore constitutes a point of separation while another internal boundary layer is set up at its trailing edge. This latter formation would be very disturbed because of the concave nature of the surface of the bore wall presented to the flow. The total effect of these inner disturbances is that a wave-shaped profile is established over the mouth of the bore, rising above the datum of the capillary face at the leading edge and sweeping down into the capillary bore just prior to the trailing edge. Within a certain limited flow region these two effects would cancel (within experimental error), and the Δl effect would in essence be eliminated which is in line with the experimental findings of Mills (8). Dye experiments in aqueous solution have visually confirmed that these two opposing effects are, in fact, present.

The lack of similarity of the Re_1 plots of measured diffusion coefficients for the different media illustrated in the upper part of Fig. 3 could well be caused by the differing experimental conditions involved. A temperature gradient is imposed purposely in dense media to prevent the occurrence of thermal mixing. No such provision was made in the aqueous solution measurements where apparently the much narrower capillary diameter employed effectively suppressed thermal mixing. The imposed temperature gradient also would stabilize the no flow condition in the molten salts resulting in the much greater flow influence shown in the lower part of Fig. 3. The intermediate position of the alkali metal carbonate eutectic results substantiates this view as the temperature gradient employed was considerably smaller than that normally used for molten salts. The difference between the no flow and imposed flow conditions is affected also by the temperature of the bath. For example in Fig. 4 the diffusion coefficients determined for the no flow and $Re_0 = 12$ flow conditions are plotted as a function of temperature. It should be noted in passing that, due to the relatively large viscosity change involved, flow rates were altered with temperature to ensure a constant Reynolds number and consequently comparable flow conditions. The difference between the two values is observed to diminish with increased temperature as thermal movement in the main salt bath increasingly affects the conditions at the capillary mouth.

Effect of CO_2.—Certain $CO_3^=$ anion diffusion experiments in the Li/KCO_3 eutectic were conducted under conditions of excessive CO_2 pressure to ascertain if dissolved CO_2 in the melt would materially affect the results. Normally the apparatus was maintained under a CO_2 pressure well in excess of the respective dissociation pressures of the melts in order to ensure constant composition. With double the normal CO_2 pressure, no observable variation was detected in the measured diffusion coefficients so the possibility of a CO_2 effect could be discounted.

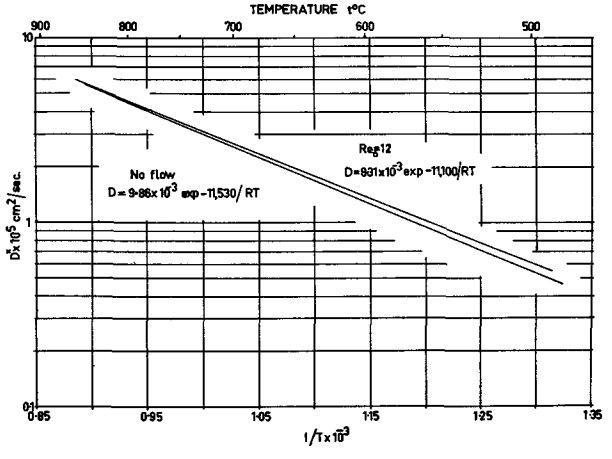

Fig. 4. Measured diffusion coefficients of Na^+ ion in $Li/Na/KCO_3$ ternary eutectic for the no flow and corrected flow conditions.

Results

The data for tracer diffusion of the various ions in the melts investigated are detailed in Tables I to IV.

Discussion

The diffusion data from this study together with those from our previous paper, are represented in Fig. 5 in the form of Arrhenius graphs (log D *vs.* $1/T$). Comparing first the magnitudes of the various diffusion coefficients it can be seen that for any given medium, the diffusion mobility varies inversely with the ionic radius. For ions isotopic to a species in the medium similar trends have been observed in alkali metal nitrates (13) and in their binary mixtures (14). It should be noted, however, that this type of dependence does not necessarily hold for nonisotopic trace species as has been shown by Ketelaar and Honig (15).

Another feature which is brought out by Fig. 5 is the marked change in diffusion mobility which is shown by both Na^+ and $CO_3^=$ ions in different media. The Na^+ ion, for instance, has a high coefficient in all the eutectics and in pure Na_2CO_3, but a much lower value in pure Li_2CO_3. This is contrary to what might have been expected if certain aspects of the Lumsden model (3) had been considered to apply. These aspects concern the preferential polarization of anions by the smaller cations in a binary melt. On this model, in Li_2CO_3 the $CO_3^=$ anions would presumably be strongly polarized thus leaving the Na^+ ions with more freedom of movement compared to that

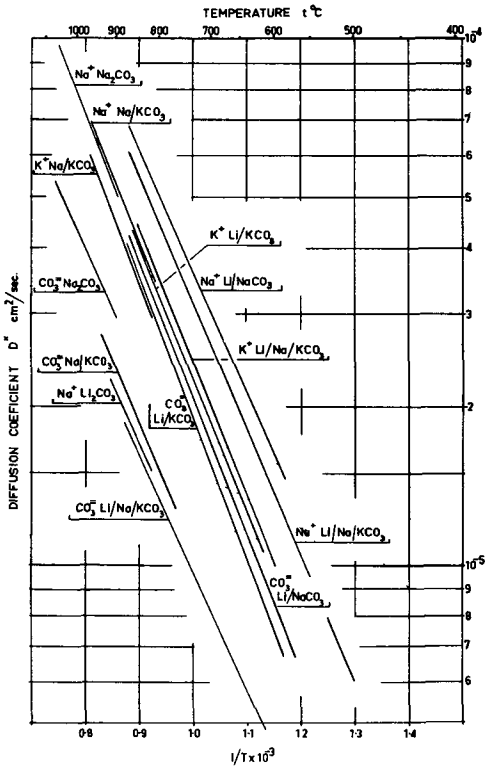

Fig. 5. Arrhenius graphs of the measured diffusion coefficients of various ions in pure alkali metal carbonates and their binary and ternary eutectics.

in the pure Na_2CO_3 melt. An explanation for the low Na^+ ion mobility can, however, be given if we accept a lattice picture for molten carbonates. The pure Li_2CO_3 melt can then be visualized as a fairly close-packed anion-type lattice, with the small Li^+ ions fitting into the interstices. The trace sodium ions introduced would slightly expand the lattice in their neighborhood, but basically it would remain as in the pure salt. Under these conditions a low diffusion mobility would be expected. As a cooperative act is probably involved, the $CO_3^=$ ion might be expected to have a fairly low mobility in this melt also, but further experiments will be made shortly to check this prediction.

The $CO_3^=$ ion has a low mobility in the Na/K and Li/Na/K eutectics and pure Na_2CO_3, but it almost exactly doubles in the Li/K and Li/Na eutectics. There is no obvious explanation for the marked change in diffusion mobility between the two groups of melts. One cannot attribute it solely to greater distortion arising from difference in ion size in the binary eutectics containing lithium because this factor would also operate in the ternary eutectic. The measurement of tracer-diffusion coefficients of the Li^+ ion may help to resolve this problem.

The slopes of the curves in Fig. 5 give the "Arrhenius activation energy" for tracer-diffusion. As stated in our previous paper (1) the exact significance of these energies and their relation to theory are not known. However, it is generally agreed that they have qualitative value in the interpretation of the mode of diffusion in molten salts. In Table V we have tabulated these experimental activation energies together with those available for other transport processes.

The differences between the experimental activation energies for conductance, viscous flow, and tracer diffusion, and possible qualitative explanations of these differences have been discussed in our first paper. In brief, the high activation energy for viscous flow in the pure melt was attributed in part to the necessity to shear a lattice which derives its stability from the coulombic forces between the ions. The low value for conductance was explained by the ability of cations to migrate through the lattice without appreciable disturbance whereas the constancy of the diffusion activation energies suggested some kind of cooperative act between anion and cation. The new data which have been added reinforce these conclusions. In particular the similarity between the diffusional activation energies for all ions studied in the six media is again most striking. The inference that diffusional movement in these melts proceeds by some cooperative act, which may be a coupled vacancy mechanism, ion-pair motion, or cluster movement, seems inescapable. At the moment evidence from other fields as summarized by Janz and co-workers (16) favors the ion-pair concept of the form $(M^+CO_3^=)^-$.

The appearance of a recent paper by Moynihan and Laity (2) in which they predicted that tracer diffusion coefficients in binary melts might be expected to show a closer linear dependence with composition than the

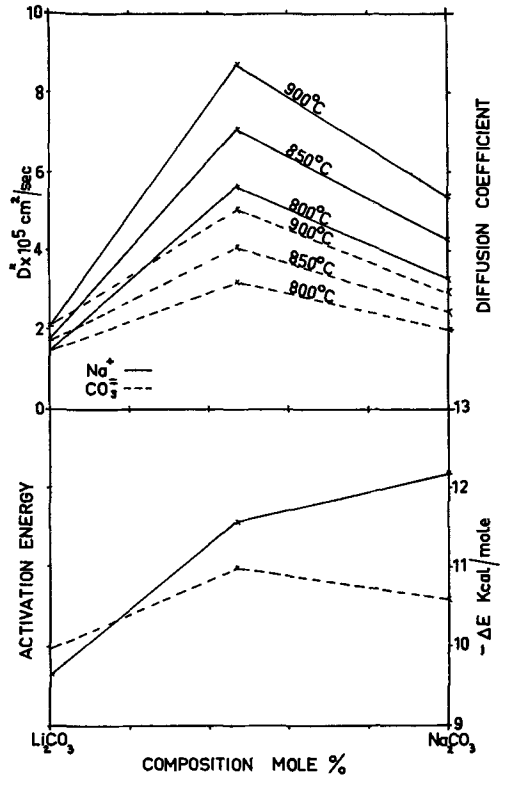

Fig. 6. Activation energies and tracer-diffusion coefficients of Na^+ cation and $CO_3^=$ anion in Li_2CO_3/Na_2CO_3 mixtures.

ionic conductances, prompted us to make preliminary measurements of this kind. These measurements are for Na^+ and $CO_3^=$ ions at the eutectic composition of the $Li/NaCO_3$ binary mixture, Na^+ in Li_2CO_3 and Na_2CO_3 and $CO_3^=$ in Na_2CO_3. The results are shown in graphical form in Fig. 6. For the reasons outlined earlier, we have tentatively assigned a value for $CO_3^=$ ion in Li_2CO_3 equivalent to that for Na^+ ion. It is evident that the tracer diffusion coefficients for Na^+ and $CO_3^=$ at the indicated temperatures are by no means linear with composition, but instead show a marked positive deviation from the additivity line. This is to be compared with the results of Lantelme and Chemla (14) in the alkali nitrates who have reported a positive deviation for K^+ in $KNO_3/LiNO_3$ mixtures. Other cations, however, exhibit a near linear dependence. Further points of interest are that the Na^+ ion diffusion mobility is lower in Li_2CO_3 than in Na_2CO_3 which is in contrast to cation diffusion in the alkali nitrates. Lantelme and Chemla (14) have shown that Li^+, Na^+, and K^+ ions diffuse faster when going over a composition range from KNO_3 to $LiNO_3$. However they have reported more recently (17) that for NO_3^- ion the values diminish as the mixtures are enriched in $LiNO_3$. The high values of the coefficients at the eutectic point are also noteworthy, and these may well represent maxima on the curves. As our measurements were made at a series of temperatures, we have also been able to determine experimental activation energies and these are shown in the lower part of Fig. 6. The values for Na^+ ion rise fairly steadily, and those for $CO_3^=$ ion indicate a maximum. Such trends are not readily explained, and we therefore propose to make measurements to explore this type of behavior further.

We have also made a detailed study of the conductance for this binary system and obtained a negative deviation from the addition line for two of the binary systems. These differences between the two processes serve to reemphasize that the mechanisms of conduction and tracer diffusion in molten salts may differ considerably. (The reservation should be made that the tracer diffusion of Li^+ ion would also need to be measured in order to say definitely that the processes are different in character.) This fact of course has previously been inferred from attempts to apply the Nernst-Einstein equation and from the marked difference between the Arrhenius activation energies for the two processes.

In the context of the fuel cell electrolyte problem, it may be noted that, although $CO_3^=$ ion diffusion is considerably faster in the binary than the ternary eutectics, this seems to have little or no effect in reducing polarization in molten salt cells. Both the binary $Li/NaCO_3$ and the ternary $Li/Na/KCO_3$ eutectics have been used as fuel cell electrolytes and the voltage losses are very comparable in each case (18).

Acknowledgment

Grateful acknowledgment is made to the Reserve Bank of Australia for a grant for fuel cell research, part of which has been used to finance the above study.

The Role of Crystalline Orientation on the Behavior of Copper as Electrode in Chloride Solutions[1]

Ugo Bertocci

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Single crystal copper electrodes having (100), (110), (111), and (321) orientations, as well as polycrystalline specimens, have been used as electrodes in chloride solutions containing cuprous ions, previously equilibrated with copper metal under a hydrogen atmosphere. Anodic and cathodic overvoltages as a function of current density have been recorded in the range from 10^{-7} to 10^{-3} amp/cm^2. Faceting patterns formed by electrolysis at various current densities, as well as those formed by corrosion in nonequilibrated solutions, have been examined, using both the optical microscope and the double-circle reflection goniometer. In all instances, it has been found that the behavior of (100) oriented surfaces was quite different from that of all other orientations investigated. The overvoltages recorded for (100) electrodes were considerably higher, exhibiting an extremely high $(d\eta/di)_{i=0}$ of the order of 10^5 ohm-cm^2. Lower overvoltages were found on the other close-packed orientations, differences between them being only minor, and the lowest values were exhibited by (321) oriented electrodes.

The faceting behavior of (100) surfaces was also different from that of all other orientations: whereas (100) developed only facets vicinal to {100}, the other surfaces formed a completely different set of facets, including {111} and {110}. By correlating the overvoltage data and the faceting structure, some suggestions are made concerning the relative influence of elementary processes, such as nucleation of new steps and their motion across the surfaces on the kinetic behavior. The most likely conclusion at this stage seems to be that the rate-determining step is linked to the removal or addition of atoms to the surface steps.

The study of the electrochemical behavior of copper in halide solutions presents the possibility of examining the electrode reaction between copper metal and cuprous ions, since divalent copper plays only a minor role. In addition, in such solutions the etching pattern can be made very sensitive to the structure of the crystalline phase, as evidenced by the formation of pits at dislocations (1). Overvoltage data for copper in chloride solutions being relatively scarce, it was interesting to collect information on the kinetic behavior in such systems as a function of crystal orientation, particularly in the low current density range, where the properties of the metal surface can be rate determining.

In this paper the results of some experiments showing the influence of crystal orientation on the electrochemical behavior of copper are described and discussed.

Experimental Methods

The copper crystals used for the experiments were disk-shaped slices cut from 99.999% Cu single crystal slugs. The dislocation density was of the order of 10^5/cm^2. The cutting method has already been described (2). In order to obtain orientations as close as possible to the desired ones (usually within one half of a degree or less), before polishing the surfaces on the lapping wheel, the etched crystals were positioned on an adjustable holder, using a microscope fitted with the Nomarski interference contrast attachment to control their orientation. The technique employed to measure the orientation of etching facets, as well as the modifications to the microscope, are described elsewhere (3).

After a final electropolishing in a phosphoric acid bath, the crystals were mounted in the electrolysis cell against glass tubings, having beveled Teflon gaskets at their ends, so that the electrodes exposed only one orientation to the solution. Three crystals were mounted in the same cell. A more detailed description of the cell has been given in a previous paper (4). The cell was evacuated and filled with purified hydrogen several times, and then the solution, which had been equilibrated with copper metal, was transferred in the cell under hydrogen pressure.

Overvoltage measurements were carried out by passing a constant current pulse between the electrode under investigation and an auxiliary electrode by means of a group of dry cells and a large resistance in series. The voltage *vs.* time curves were recorded on a strip chart recorder coupled to a high-impedance amplifier. In most experiments the reference electrode was a saturated calomel electrode. Sometimes the curves were recorded on a cathode-ray oscilloscope, a suitable timing device giving the required synchronization to display the signal on the scope screen.

Because of the small currents employed and the high conductivity of the solution, no device for minimizing the errors due to ohmic drop was used; checks carried out comparing data taken from reference electrodes positioned at different distances from the electrode under study, as well as inspection of the voltage-time curves on the cathode ray oscilloscope, showed that the ohmic drops included in the readings were always negligible.

For qualitative information on the relative rate of attack of different orientations, some etching experiments were also carried out on spherical single crystals; their surfaces were prepared by electropolishing in a phosphoric acid bath.

After the experiments the copper electrodes were examined under the optical microscope, and the orientation of the faceting pattern obtained was studied by means of a double circle reflection goniometer.

Experimental Results

Preliminary investigations were directed to finding whether specimens having different surface orientation exhibited different equilibrium potentials. It was soon realized, however, that the solutions always contained cupric ions in excess of the equilibrium concentration and therefore the electrodes were corroding. The corrosion rate, due to oxygen leakage into the cell, was estimated to be of the order of 20-50 μa/cm^2,

[1] Research sponsored by the U. S. Atomic Energy Commission under contract with Union Carbide Corporation.

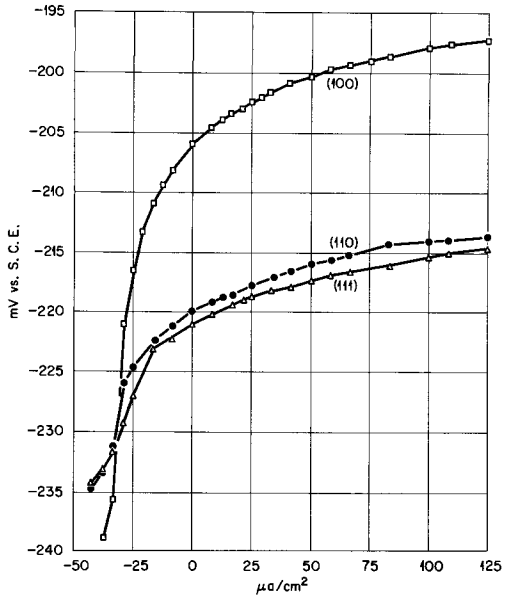

Fig. 1. Overvoltages of Cu single crystals in 0.03M Cu, 2.7M HCl under slow corrosion; temperature 23.5°C.

as calculated from the increase of Cu concentration in solution.

Further improvements in the experimental setup reduced the corrosion rate below any detectable value; accordingly, the former experiments will be referred to as experiments under corrosion, and the latter ones as experiments in absence of detectable corrosion. Even in the latter case, however, it is believed that the solution composition was not that corresponding to equilibrium, and the experimental results are interpreted according to this assumption.

Experiments under corrosion.—The potential differences between different surface orientations under slow corrosion conditions showed that after a very short period of time a steady state was reached in which the (100) orientation was nobler than (110) and (111) by about 15 mv. This potential difference could be maintained within 3 to 5 mv for periods of time as long as 16 days, after which the experiment was stopped. (111) crystals were slightly more negative than (110). Potential *vs.* current density curves recorded on these slowly corroding specimens are shown in Fig. 1. The overvoltage curves for the various orientations intersect at a certain value of cathodic current density. This value is approximately equal to the corrosion rate determined from the increase with time in copper concentration in solution.

Inspection of the surfaces after the test showed extensive faceting on all orientations. On (100) crystals shallow square pits were formed at an early stage, and they subsequently grew to cover the whole surface, leaving it uniformly faceted. The (111) crystals had large plateaus of the original (111) orientation, bounded by steep walls; (110) surfaces were covered by grooves oriented toward <110>. Examination with the reflection goniometer revealed that the original (100) orientation had disappeared completely, and the facets formed lay in a region between 2° and 4° from (100), producing a square reflection pattern with corners toward <100>. The reflection patterns for (110), (111), and (321) orientations were remarkably similar to each other: sharp reflections were found at {111} and {110}, and also there was a diffuse reflection around {100} approximately square-shaped with corners about 15° from {100} toward <100>.

Experiments in absence of detectable corrosion.—The overvoltage *vs.* current density curves obtained in absence of detectable corrosion are given in Fig. 2 and 3. In order to determine the point where the curves relative to different surface orientations intersect and where they exhibit the maximum slope, the extremely low anodic and cathodic current density range was examined in detail (Fig. 4 and 5). The results show that the cathodic and anodic branches of

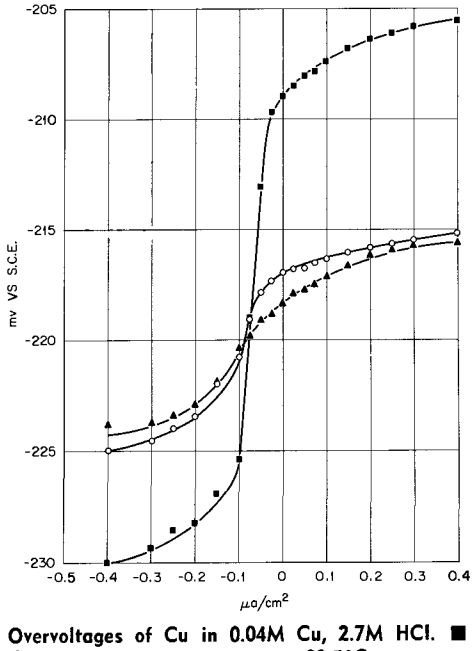

Fig. 4. Overvoltages of Cu in 0.04M Cu, 2.7M HCl. ■ (100), ▲ (321), ○ polycrystalline; temperature 23.5°C.

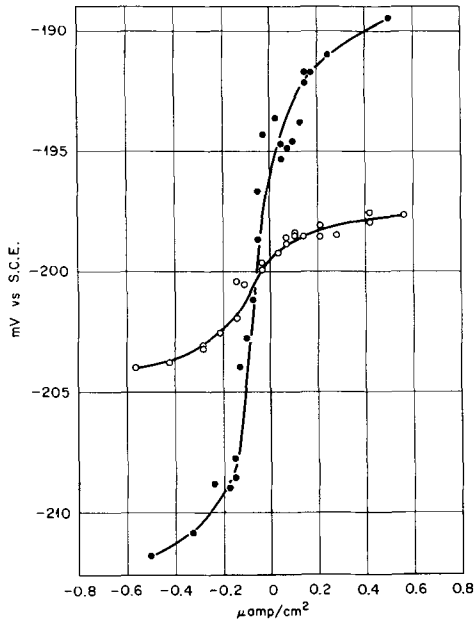

Fig. 5. Overvoltages of Cu in 0.09M Cu, 2M KCl, 1M HCl. ● (100), ○ (111); temperature 23.5°C.

the overvoltage curves are symmetric with respect to a middle point which, within the accuracy of the experimental method, is common to all crystal orientations. The point of intersection corresponds to a cathodic current density, whose value tended to become smaller with time: typically it was about 0.8-0.5 $\mu a/cm^2$ on the first few days after introduction of the solution and then decreased to less than 0.1 $\mu a/cm^2$. During this period the overvoltage curves did not vary except for a translation along the current density axis.

Evaluation of the maximum slope of the overvoltage curves is rather inaccurate: for (100) crystals the value ranges from 10^5 to 4.10^5 ohm-cm^2, whereas the other orientations give values from 10^4 to 7.10^4 ohm-cm^2.

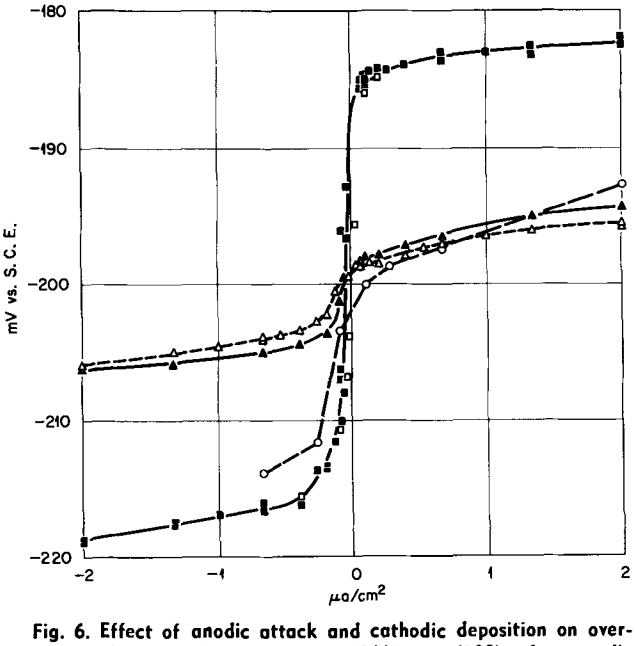

Fig. 6. Effect of anodic attack and cathodic deposition on overvoltages of Cu single crystals. ■ (100); □ (100) after anodic attack at 3.3 $\mu a/cm^2$ (12.8 mcoul/cm^2); ○ (100) after cathodic deposition at 3.3 $\mu a/cm^2$ (13.4 mcoul/cm^2); ▲ (111); △ (111) after anodic attack at 3.3 $\mu a/cm^2$ (0.298 coul/cm^2). Solution: 0.09M Cu, 2M KCl, 1M HCl; temperature 23.5°C.

The effect of extensive electrolysis on the overvoltage curves was investigated, and some of the results are given in Fig. 6. For (111) orientations and also for all orientations other than (100), anodic attack tends to lower slightly the overvoltage curves, whereas (100) surfaces are hardly affected. Extended cathodic deposition on (100) crystals greatly affects the anodic branch of the overvoltage curve, which becomes similar to that found for other orientations, but has a much smaller effect on the cathodic values. An anodic attack approximately equal to one-half of the preceding cathodic pulse is generally sufficient for restoring the usual overvoltage curve.

After a cathodic current pulse the electrode potential decayed to its open-circuit value in two stages, separated by an inflection point of minimum slope; the potential value of the inflection point was found to be very close to that of the middle point about which the overvoltage *vs.* current density curves are symmetric. The decay time was longer the greater the quantity of electricity of the preceding cathodic pulse, the inflection point becoming a plateau of almost constant potential. The phenomenon is similar to that observed on polycrystalline zinc in acidic solutions (5).

After a sufficiently long anodic attack the faceting pattern could be observed. It was found that the surface structure as well as the reflection pattern was the same as that observed under corrosion conditions, provided that the current density chosen was of the same order of magnitude. Some changes were detected in the faceting pattern for dissolution at higher current densities; for instance, a reflection spot corresponding to {47,20,0} was quite clearly observed on (111) and (321) crystals attacked at 1 ma/cm^2, whereas at the same current density (100) surfaces developed, besides the usual pattern, facets very close to the {100} orientations at 90° from the original one. On the whole, however, the etching pattern was found to be rather insensitive to anodic current density in the range studied.

After etching spherical single crystals, small bright areas were found at {111} and {110}, as well as a square-shaped area around {100}, with corners about 15° from [100] toward <100>. The remainder of the sphere was heavily faceted, but no attempt was made to measure the orientations of the facets formed.

Discussion

The high resistance for the electrode reaction in the low current density range as deduced by the slope of the overvoltage curves places such stringent requirements on the magnitude of the rate of spontaneous processes, (for example, corrosion caused by an excess of cupric ions over the equilibrium concentration), which can be allowed without significant departure of the electrodes from the equilibrium potential, that it is impossible to attach thermodynamic significance to the open-circuit potentials. The fact, however, that the curves relative to different orientations as measured in the same solution intersect for the same value of potential and current density, plus the fact that the overvoltage curves are symmetric with respect to the intersection point, which lies on the point of maximum slope, lend support to the conclusion that the potential associated with the intersection point is the equilibrium potential for all copper electrodes investigated. If the validity of this criterion for determining the equilibrium potential is accepted, it can be concluded that single crystals of different orientation, as well as polycrystalline electrodes, have the same equilibrium potential, or at least that the differences are smaller than 1 to 2 mv. Analogous conclusions had been previously reached for copper single crystals in sulfate solutions (4). All the differences recorded between rest potentials can be easily accounted for in terms of differences in their kinetic behavior.

If the point where the various curves intersect can be assumed to correspond to the equilibrium potential,

the cathodic current density necessary to maintain such a potential will correspond to the reduction of cupric ions diffusing from the bulk of the solution to the electrode

$$(i)_{\eta=0} = \frac{FD_{Cu^{++}}}{\delta}\left[Cu^{++}_{eq} \exp\left(\frac{\mathbf{F}}{RT}\eta'\right) - Cu^{++}_{bulk} \right] \quad [1]$$

where δ is the thickness of the diffusion layer, Cu^{++}_{eq} and Cu^{++}_{bulk} are total concentrations of Cu^{++} ions, whether free or as chloride complexes, at equilibrium and in the bulk, $D_{Cu^{++}}$ is the diffusion coefficient valid for the solution composition in which the experiment is carried out, and η' is the overvoltage for the reaction

$$Cu^{+} \rightleftarrows Cu^{++} + \theta \quad [2]$$

Here the assumption is made that homogeneous equilibria are fast and that transference numbers for copper ions are negligibly small, because of the large excess of indifferent electrolyte. The results shown in Fig. 1, where even for relatively large values for $(i)_{\eta=0}$ ($\sim$ 30 μa/cm^2) the point of maximum slope in the overvoltage curves corresponds to the same current density for (100), (110), and (111) crystals, indicate either that η' is relatively insensitive to orientation or that it is negligibly small. The second alternative can be reasonably accepted when the current density is of the order of 10^{-7} amp/cm^2. In this case formula [1] can be employed to estimate the excess of Cu^{++} in the bulk over the equilibrium concentration. The evaluation of the product $D_{Cu^{++}}(Cu^{++})$ is unfortunately very difficult, since the values of the stability constants for cupric chloride complexes, as quoted in the literature, vary considerably from author to author (6). The diffusion coefficient is probably abnormally large, as shown by the negative transference number of copper in complex cupric chloride solutions (7). By assuming a value of 100 amp cm/mole for $FD_{Cu^{++}}/\delta$ and considering that Cu^{++}_{eq} should be of the order of 10^{-11} mole/cm^3, a current density of 10^{-7} amp/cm^2 would indicate that the concentration in the bulk of the solution was from 20 to 100 times greater than the equilibrium value.

Because of the extreme steepness of the overvoltage curve at very low current densities, particularly in the case of (100) surfaces, the question can be raised as to whether any process involving dissolution or deposition actually takes place in this range, or only the redox reaction [2], which does not involve any alteration of the metal surface, occurs at the electrode. If one assumes that reaction [2] occurs without appreciable overvoltage, around the equilibrium potential the slope of the overvoltage curve as given by reaction [2] alone is (8)

$$\left(\frac{d\eta}{di}\right)_{\eta=0} = \frac{RT\,\delta}{F^2 D_{Cu^{++}}(Cu^{++}_{eq})}$$

Again the calculation entails the knowledge of the product $D_{Cu^{++}}$ (Cu^{++}_{eq}), and it is subject to the uncertainties already mentioned. Using the most reliable data, the reaction resistance due only to reaction [2] should be about 10 megaohms-cm^2, that is, more than a factor of ten higher than the value measured on (100) surfaces. This would support the conclusion that deposition or dissolution occur at a nonzero rate for every overvoltage value.

The homogeneous reaction

$$CuCl'_2 \rightleftarrows Cu^{+} + 2Cl' \quad [3]$$

which in chloride solution is coupled to the electrode reaction, was not found to have any effect on the over-all reaction rate in the range of current densities investigated. Since the equilibrium potential of Cu with respect to SCE is about —0.2v, the Cu^{+} ion activity is of the order of 10^{-8} mole/liter. If reaction [3] were slow, a small limiting current for the cathodic discharge should be found. The experimental results, however, have shown that no limiting current phenomena can be detected.

The shape of the decay curves after short cathodic pulses, as well as the effect of extensive deposition on (100) crystals on the subsequent anodic overvoltages can be explained by assuming that the surface structure of the deposits is different from that formed by anodic attack. Therefore, after a cathodic pulse under conditions of slight corrosion, the freshly deposited copper will exhibit a low anodic overvoltage, giving rise to an inflection in the decay curve. Accordingly, the potential of the inflection was the closer to the point of maximum slope of the overvoltage curve, the smaller was the departure from equilibrium in solution, and it was found to be in general more positive, by a few millivolts, than the equilibrium value as determined in the way outlined in the first part of this discussion. After extensive deposition on a (100) surface, anodic overvoltages similar to those on the other orientations could be measured, until dissolution eliminated the surfaces having low overvoltage. Although no systematic examination of the surface structure of cathodic deposits has been made, some instances of formation of facets never observed after anodic attack on (100) crystals were found.

Conclusions

Examination of the experimental results does not indicate that on any orientation the nucleation of new steps is rate determining, since extensive anodic attack leading to a faceted surface has little influence on the overvoltage values. Comparison of the overvoltage curves of (111) and (321) crystals supports the same conclusion. On (321) surfaces no nucleation is theoretically required for the dissolution or crystallization process; nevertheless, the overvoltages are very close to those measured on a close-packed surface like the (111). The facets formed on (111) and (321) have the same orientation, but on the latter the number of edges is significantly greater, which would account for the slightly lower reaction resistance, but fails to single out the formation of new steps as the kinetically decisive phenomenon.

It is therefore likely that the motion of steps is rate controlling; on (100) crystals such a motion is very slow and difficult, so that the surface is left covered by steps giving the characteristic faceting pattern slightly misoriented from (100); on the other orientations, steps move at a much higher speed, and this accounts for the lower overvoltages as well as for the faceting pattern: smooth (111) facets are formed, and the steps interact easily forming orientations at large angles from the original surfaces. Not all difficulties in interpreting the results are eliminated by such a conclusion; one would expect a greater influence of the number of steps on the surface if their motion were the slowest process. Above a relatively low current density, however, the overvoltage curve flattens out considerably, so that an increase in number of steps will cause a small decrease in overvoltage. Moreover. microscopic observation shows that on (111), (110), and (321) crystals a large part of the new surface area created by faceting is oriented about 15° from (100), an orientation having rather high reaction resistance, as evidenced by the etching pattern on spherical single crystals.

On the cathodic side, the remarkable influence of extended deposition on the subsequent anodic overvoltages of (100) orientations indicated that the deposit does not have the same surface structure as the substrate. Incorporation of the deposited copper into the lattice occurs slowly, as indicated by the inflection points in the decay curve after short cathodic pulses.

The shape of the overvoltage curves, however, suggests the hypothesis that a nucleation process is necessary to initiate the removal of copper from the steps or its addition to them.

Induced Polarization of Porous and Tubular Electrodes[1]

F. A. Posey and S. S. Misra

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The apparent resistance of solutions contained in porous or tubular electrodes is affected by the presence of oxidizable and reducible substances in solution. Passage of current is accompanied by a gradient of potential in the solution phase so that a gradient of the interfacial potential difference is induced throughout the length of the electrode. As a consequence of the induced polarization, anodic and cathodic reactions occur near opposite ends of the electrode. A number of boundary value problems corresponding to this physical situation have been solved. The relations suggest that induced polarization measurements can be used to determine the concentration of oxidizable and reducible substances in flowing streams, to measure corrosion rates of pipes or porous metals, and to estimate transfer coefficients and exchange current densities of electrochemical reactions.

The conductivity of electrolytes in porous nonconducting materials is not difficult to measure in principle, and measurements of this type have been made for various purposes. As noted by Ksenzhek, Kalinovskii, and Baskin (1), it is more difficult to measure the conductivity of solutions inside porous or tubular metallic electrodes. This is particularly true when oxidation reduction reactions can occur at the metal-solution interface. Passage of current through the solution phase induces a gradient of the interfacial potential difference throughout the length of the electrode. As a consequence of this gradient, anodic reactions occur at the pore walls near one end of the electrode, and cathodic reactions take place near the other end. A fraction of the total current is conducted by ions in the solution phase, and the rest of the current is conducted by electrons in the metallic phase; this fraction depends on the geometrical properties of the electrode, the characteristics of the electrolyte and the electrochemical reactions, and the position inside the electrode. A number of boundary value problems corresponding to this physical situation have been solved by use of methods for the calculation of polarization in porous electrodes (2). The results are presented below together with some experimental measurements which support the theory. The relations obtained suggest that induced polarization of porous and tubular electrodes can be used to determine the concentration of oxidizable and reducible substances in flowing streams, to measure corrosion rates of pipes or porous metals, and to estimate certain parameters of electrochemical reactions.

Experimental Configuration

A schematic diagram of the experimental arrangement for measurement of induced polarization of porous or tubular electrodes is shown in Fig. 1. The total current (i) is passed from the front side ($x = 0$) to the back side ($x = l$) of the electrode by use of auxiliary polarizing electrodes. No current lead is attached to the porous electrode itself; potential changes which occur in this electrode are induced by passage of current between the polarizing electrodes. The potential of the front or back sides and the total potential drop through the electrode may be measured by use of reference electrodes situated at $x = 0$ and $x = l$. Passage of current in the direction shown in Fig. 1 induces a negative change in interfacial potential difference (negative polarization) near $x = 0$ and a positive polarization near $x = l$. When oxidizable and reducible substances are present in solution, cathodic reactions can occur near $x = 0$ as a consequence of the induced negative polarization and, correspondingly, anodic reactions can occur near $x = l$. This electrode configuration is essentially the same as the bipolar electrode studied by Tomassi and co-workers (3-6) as a means of coupling electrochemical processes.

Induced Polarization with Linear Rate Law

The solution resistance in porous or tubular electrodes, measured in the absence of oxidizable and reducible substances by use of the configuration of Fig. 1, is given simply by Eq. [1], where R_o is the resistance of electrolyte

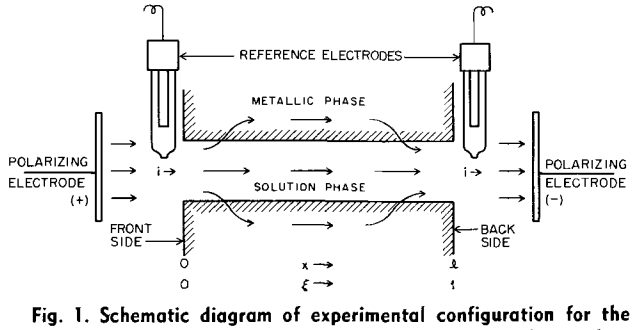

Fig. 1. Schematic diagram of experimental configuration for the measurement of induced polarization of porous and tubular electrodes.

[1] Research sponsored by The Office of Saline Water, U. S. Department of the Interior, under Union Carbide Corporation's contract with the U. S. Atomic Energy Commission.

$$R_o = \frac{\phi_s(0) - \phi_s(l)}{i} = \frac{l}{\sigma A} \quad [1]$$

in the pores (ohm), $\phi_s(0)$ and $\phi_s(l)$ are potentials in the solution phase at $x = 0$ and $x = l$ (volt), i is total current (amp), l is pore length (cm), σ is specific conductance of the electrolyte (ohm^{-1}cm^{-1}), and A is total cross-sectional area of electrolyte (cm^2). In the presence of oxidation reduction reactions the measured or apparent resistance, R_{app}, is less than R_o because of the shunting effect of the current carried by the metallic phase, which is assumed to have negligible resistivity (see below, however). The apparent resistance may be calculated in certain cases by solution of Eq. [2], which is the fundamental differential equation for potential

$$\frac{d^2\eta(x)}{dx^2} = \frac{S}{\sigma A} j(x) \quad [2]$$

distributions in one-dimensional porous electrodes (2, 7-9). In Eq. [2], $\eta(x)$ is the polarization or change in interfacial potential difference at the point x induced by passage of current (i), S is interfacial surface area per unit length of electrode (cm^2/cm), and $j(x)$ is the current density of the interfacial reaction (amp/cm^2). Boundary conditions corresponding to the configuration of Fig. 1 are given by Eq. [3]. For the case of a simple

$$\left(\frac{d\eta(x)}{dx}\right)_{x=0} = \left(\frac{d\eta(x)}{dx}\right)_{x=l} = \frac{i}{\sigma A} \quad [3]$$

oxidation reduction reaction, the rate law may be assumed to be of the conventional form given by Eq. [4], where j_o is the exchange current density

$$j(x) = j_o\{\exp[\beta n F\eta(x)/RT] - \exp[-(1-\beta)nF\eta(x)/RT]\} \quad [4]$$

(amp/cm^2), n is the electron number, β is the (anodic) transfer coefficient, and RT/F is the thermal volt equivalent. We assume that non-Faradaic currents and changes of reactant concentrations because of the electrochemical reaction are negligible as well as effects due to diffusion, migration, and convection of reactants and to the structure of the double layer.[2]

For sufficiently small values of polarization, Eq. [4] may be linearized to give the rate law of Eq. [5]. Substitution of Eq. [5] into Eq. [2]

$$j(x) = \frac{nj_oF\eta(x)}{RT} \quad [5]$$

and integration of the resulting expression with use of the conditions of Eq. [3] lead to the potential distribution of Eq. [6] in terms of the

$$\frac{\eta(\xi)}{i\,R_o} = \frac{\cosh[\sqrt{\kappa}\cdot\xi] - \cosh[\sqrt{\kappa}(1-\xi)]}{\sqrt{\kappa}\cdot\sinh(\sqrt{\kappa})} \quad [6]$$

dimensionless parameters $\xi = x/l$ and $\kappa = Sj_ol^2nF/\sigma ART$. The parameter κ is essentially a ratio of solution impedance to interfacial impedance. Relative potential distributions calculated from Eq. [6] are shown in Fig. 2 as a function of the parameter κ. When κ is less than unity, no appreciable interfacial reaction occurs and the measured resistance should be essentially that given by Eq. [1]. For values of κ large with respect to unity, an appreciable fraction of the current is carried by the metallic phase and R_{app} is less than R_o.

Equation [7] gives the ratio of the apparent resistance to the resistance

$$\frac{R_{app}}{R_o} = 2\frac{\cosh(\sqrt{\kappa}) - 1}{\sqrt{\kappa}\cdot\sinh(\sqrt{\kappa})} \quad [7]$$

[2] Concentration effects may be minimized experimentally by use of flowing solutions. Some of the restrictions cited above are relaxed later in considering transient effects.

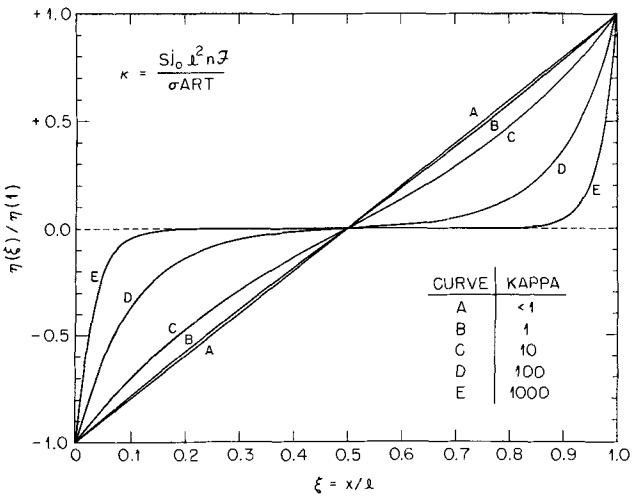

Fig. 2. Relative potential distribution in porous or tubular electrodes as a function of the dimensionless parameter κ.

of the electrolyte (cf. Eq. [1]). The fraction of the total current which is carried by the metallic phase is given by Eq. [8]. For large values of κ,

$$\text{Current fraction} = \frac{\cosh\left(\frac{1}{2}\sqrt{\kappa}\right) - 1}{\cosh\left(\frac{1}{2}\sqrt{\kappa}\right)} \quad [8]$$

an appreciable region exists inside the electrode where essentially no polarization occurs on passage of current (cf. curve E of Fig. 2). This behavior resembles the phenomenon of the Faraday shield. Variation of the apparent resistance with the parameter κ as predicted by Eq. [7] is shown in Fig. 3. For large values of κ the apparent resistance is inversely proportional to $\sqrt{\kappa}$. The curve in Fig. 3 may be used to estimate κ from measurements of R_{app} if R_o is known. The quotient $1/\sqrt{\kappa}$ is a measure of the degree of penetration of an electrochemical process into a porous electrode (2). Since κ is proportional to j_o, and j_o depends on the concentrations of oxidizable and reducible species (cf. Eq. [10]), Eq. [7] should be applicable to analysis of concentrations of oxidation reduction couples in flowing streams. The relation given by Eq. [7] and shown in Fig. 3 may also be used to estimate corrosion rates of pipes or porous metals from measurements of the apparent resistance. In this case κ is replaced by κ_{corr} of Eq. [9], where j_{corr} is

$$\kappa_{corr} = \frac{S\,j_{corr}\,l^2\,(\beta_a n_a + \beta_c n_c)F}{\sigma ART} \quad [9]$$

the current density of the corrosion reaction in the absence of external polarization (amp/cm^2), β_a and β_c are transfer coefficients of the anodic and cathodic

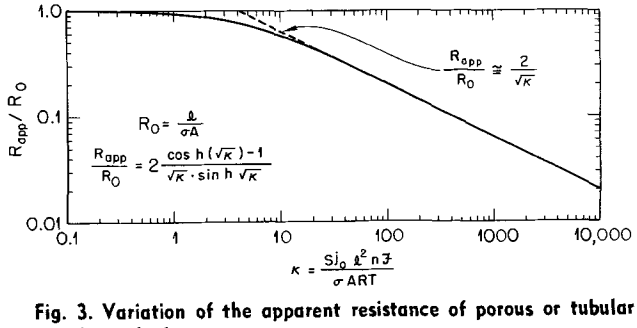

Fig. 3. Variation of the apparent resistance of porous or tubular electrodes with the parameter κ.

processes, and n_a and n_c are the corresponding electron numbers.

Determination of the Transfer Coefficient by Induced Polarization

The transfer coefficient of oxidation reduction reactions may be determined by measurement of induced polarization when the linear rate of law of Eq. [5] is a good approximation. The exchange current density may be expressed by Eq. [10] where j_o^o is the standard exchange current density including

$$j_o = j_o^o C_R^{(1-\beta)} C_o^{\beta} \qquad [10]$$

activity coefficients (amp-cm/mole) and C_R and C_o (mole/cm^3) are concentrations of anodic and cathodic reactants, respectively (10). When C_R and C_o are large enough so that R_{app}/R_o is less than about 0.5 (cf. Fig. 3), Eq. [7] reduces to $R_{app}/R_o = 2/\sqrt{\kappa}$ and substitution of the relation for κ leads to Eq. [11]. In Eq. [11], $\kappa_o = S\, j_o^o\, l^2\, nF/\sigma ART$. Combination of Eq. [10]

$$\frac{j_o}{j_o^o} = \frac{4}{\kappa_o}\left(\frac{R_o}{R_{app}}\right)^2 \qquad [11]$$

and [11] leads to Eq. [12] which shows that a log-log plot of $C_R(R_{app}/R_o)^2$

$$C_R\left(\frac{R_{app}}{R_o}\right)^2 = \frac{4}{\kappa_o}\left(\frac{C_R}{C_o}\right)^{\beta} \qquad [12]$$

against (C_o/C_R) should be linear with a slope of $-\beta$.

Figure 4 shows a plot of the type suggested by Eq. [12] for induced polarization of the ferrocyanide-ferricyanide couple in 0.5M K_2SO_4 at 25°C in a gold tube. The apparent resistance was measured as a function of the ratio of concentrations of oxidized and reduced species (ferricyanide and ferrocyanide concentrations varied in the range 10^{-3} to $10^{-2}M$). The line shown in Fig. 4 corresponds to a transfer coefficient of 1/2. Our data seem to support this value of the transfer coefficient, which was also reported by others (11). The data of Fig. 4 correspond to $R_{app}/R_o \cong 0.15$ so that $\kappa \cong 2 \times 10^2$.

Induced Polarization Curves

Solution of Eq. [2] for the more general rate law of Eq. [4] cannot be accomplished explicitly for arbitrary values of the transfer coefficient. However, numerical methods of solution may be used and Fig. 5

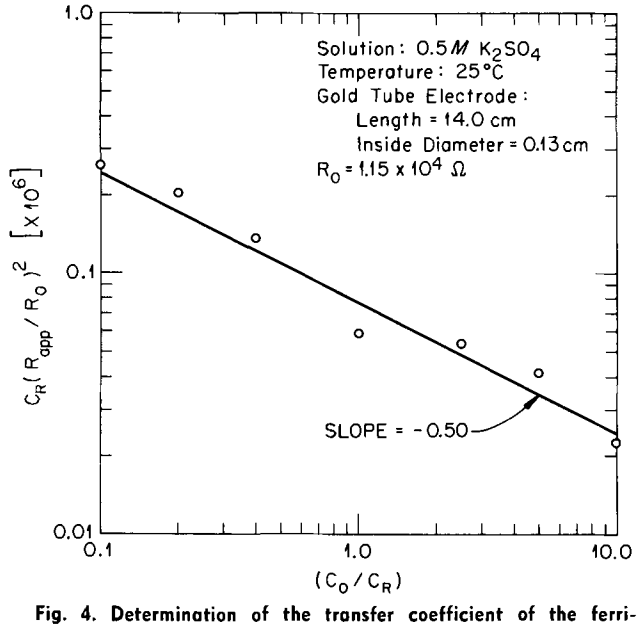

Fig. 4. Determination of the transfer coefficient of the ferricyanide-ferrocyanide couple by induced polarization of a tubular gold electrode.

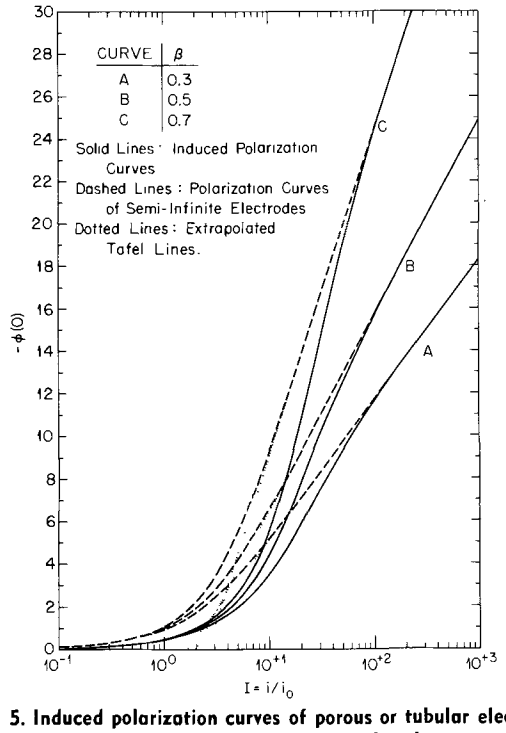

Fig. 5. Induced polarization curves of porous or tubular electrodes as a function of the transfer coefficient, β, for the case $\kappa = 1$.

shows a set of induced polarization curves calculated by use of a high-speed digital computer[3] as a function of the transfer coefficient (β) for the case, $\kappa = 1$. Combination of Eq. [2] and [4] leads to Eq. [13] in which $\phi(\xi) = nF\eta(\xi)/RT$.

$$\frac{d^2\phi(\xi)}{d\xi^2} = \kappa\{\exp[\beta\phi(\xi)] - \exp[-(1-\beta)\phi(\xi)]\} \qquad [13]$$

The sigmoid solid curves in Fig. 5 are solutions of Eq. [13]; $\phi(0)$ is the (reduced) polarization at $\xi = 0$ and $I = i/i_o = i/Slj_o$ is a dimensionless current variable [i_o is the total exchange current (amp)]. At high currents ($i >> i_o$), the induced polarization curve approaches that of a semi-infinite porous or tubular electrode (2). Equation [14] gives the Tafel line

$$I = \left(\frac{2}{\beta\kappa}\right)^{1/2} \exp[-\beta\phi(0)/2] \qquad [14]$$

for this region. At low currents ($i << i_o$), the linear rate law of Eq. [5] is a good approximation and the polarization curve may be calculated from Eq. [6]; this result is given by Eq. [15]. No simple relation can be derived

$$\frac{\phi(0)}{I} = -\sqrt{\kappa}\,\frac{\cosh(\sqrt{\kappa}) - 1}{\sinh(\sqrt{\kappa})} \qquad [15]$$

for the transition region between low and high currents.

Dissymmetry Potentials

One of the unique aspects of induced polarization measurements is the fact that the magnitude of the

[3] Equation [13] was integrated numerically on a computer (Control Data Corporation Model 1604-A) with boundary conditions analogous to those of Eq. [3] by use of a Runge-Kutta method. An initial value of $\phi(0)$ was assumed and the corresponding potential distribution computed from an explicit difference scheme. The interfacial reaction rate distribution was then computed and tested for equality of total anodic and cathodic currents. The sign and magnitude of any difference determined a new value for $\phi(0)$ and the computation cycle was repeated until successive iterations showed little improvement. A similar procedure was used to compute the initial potential distribution in the solution of Eq. [19] and [20]. Concentration changes in successive time intervals were determined by Eq. [20] in difference form; substitution of new concentrations into Eq. [18] then allowed computation of a new potential distribution by solution of Eq. [19] using the iterative procedure noted above.

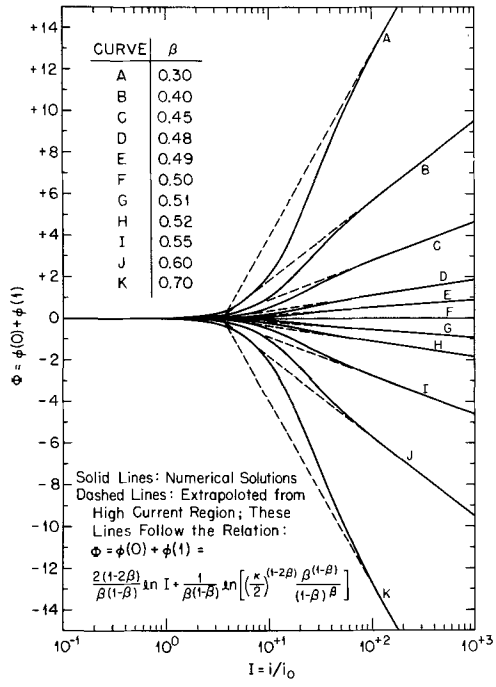

Fig. 6. Dissymmetry potential as a function of applied current and of the transfer coefficient, β, for induced polarization of porous or tubular electrodes ($\kappa = 1$).

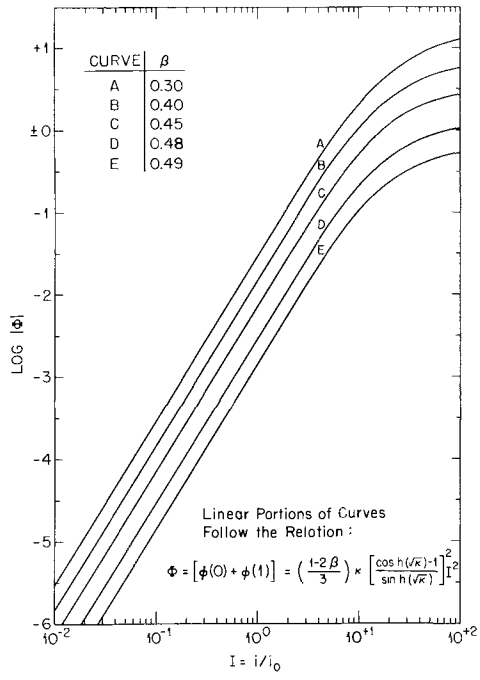

Fig. 7. Dissymmetry potential of porous or tubular electrodes in the region of small currents as a function of the transfer coefficient, β, for the case $\kappa = 1$.

observed polarization of the front side ($x = 0$) may be different from that of the back side ($x = l$). This occurs when $\beta \neq 1/2$ in Eq. [4] so that the rate law is not symmetrical. The sum $\Phi = \phi(0) + \phi(1)$ may be defined as the dissymmetry potential. It is positive or negative depending on whether β is less than or greater than 1/2, respectively. Measurements of the dissymmetry potential (Φ) may be used to determine both β and κ for an oxidation reduction reaction in a porous or tubular electrode.

Figure 6 shows dissymmetry potentials for induced polarization as a function of the reduced current ($I = i/i_o$) and of the (anodic) transfer coefficient (β) for the case, $\kappa = 1$. A Tafel region is observed at sufficiently high currents and the relation for the Tafel line is given by Eq. [16] which was derived by combination of Tafel expressions like Eq. [14]

$$\Phi = \frac{2(1-2\beta)}{\beta(1-\beta)} \ln I + \frac{1}{\beta(1-\beta)} \ln \left[\left(\frac{\kappa}{2}\right)^{(1-2\beta)} \frac{\beta^{(1-\beta)}}{(1-\beta)^{\beta}} \right] \quad [16]$$

for $\phi(0)$ and $\phi(1)$. The slope of the Tafel line depends only on β, and the intercept at $\Phi = 0$ depends on both κ and β. The parameter $\kappa(Sj_o l^2 nF/\sigma ART)$ may be expressed as $\kappa = i_o R_o f$, where $f = nF/RT$ (volt^{-1}), so that the total exchange current of the oxidation reduction reaction (i_o) may be determined easily if R_o is known.

The dissymmetry potential remains finite even at very low currents. Figure 7 shows Φ plotted as a function of current (log-log plot) for a number of values of β when $\kappa = 1$. This type of plot should be useful in detecting small deviations of β from the value 1/2. Expansion of Eq. [4] to quadratic terms and substitution into Eq. [2] yield an expression which can be solved to give Φ in the region of low currents; this relation is given by Eq. [17]

$$\Phi = \left(\frac{1-2\beta}{3}\right)\kappa \left[\frac{\cosh(\sqrt{\kappa}) - 1}{\sinh(\sqrt{\kappa})}\right]^2 I^2 \quad [17]$$

Figure 7 shows that Eq. [17] holds up to $I \cong 5$. The dissymmetry potential varies with the square of the applied current for $I < 5$. If $\kappa = i_o R_o f$ is known, β may be calculated by use of Eq. [17].

Concentration Transients

The solutions for induced polarization effects discussed above apply only when reactant concentrations are essentially constant during a measurement both with respect to time and with respect to position inside the electrode. In the absence of solution flow through the electrode, however, reactant concentrations will change as a result of the Faradaic reactions at the metal-solution interface. The reaction rate at the interface for a simple oxidation-reduction reaction can be expressed as usual (10) by Eq. [18], where $\rho(\xi, t)$ is the reduced reaction rate, $C_R(\xi, t)$ and $C_o(\xi, t)$

$$\rho(\xi,t) = \frac{j(\xi,t)}{j_o} = \frac{C_R(\xi,t)}{C^o} \exp[\beta\phi(\xi,t)] - \frac{C_o(\xi,t)}{C^o} \exp[-(1-\beta)\phi(\xi,t)] \quad [18]$$

are concentrations of reduced and oxidized species, respectively (mole/cm^3), C^o is the initial concentration (we assume for simplicity that $C_R(\xi,0) = C_o(\xi,0) = C^o$), and j_o is the initial exchange current density. The potential distribution obeys Eq. [19], which is a form of Eq. [2], providing excess

$$\frac{\partial^2\phi(\xi,t)}{\partial\xi^2} = \kappa \cdot \rho(\xi,t) \quad [19]$$

inert electrolyte is present or reactant and product have the same conductivity contribution. The concentrations may be assumed to change with time approximately according to Eq. [20], where $\theta = nFC^oAl/i_o$ is a time constant

$$\frac{\partial[C_o(\xi,t)/C^o]}{\partial t} = -\frac{\partial[C_R(\xi,t)/C^o]}{\partial t} = \frac{\rho(\xi,t)}{\theta} \quad [20]$$

(sec). We assume that tube or pore sizes are small compared with distances over which appreciable concentration changes occur. The time constant θ is the ratio of the total coulombs available from complete

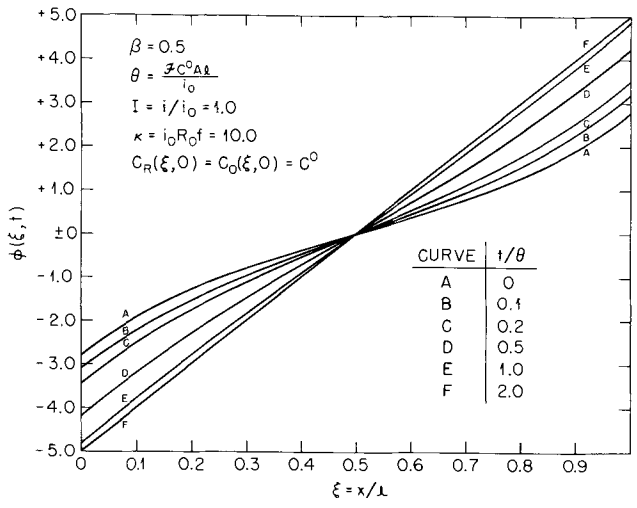

Fig. 8. Variation of induced polarization with time due to oxidation reduction reactions in the interior of a porous or tubular electrode.

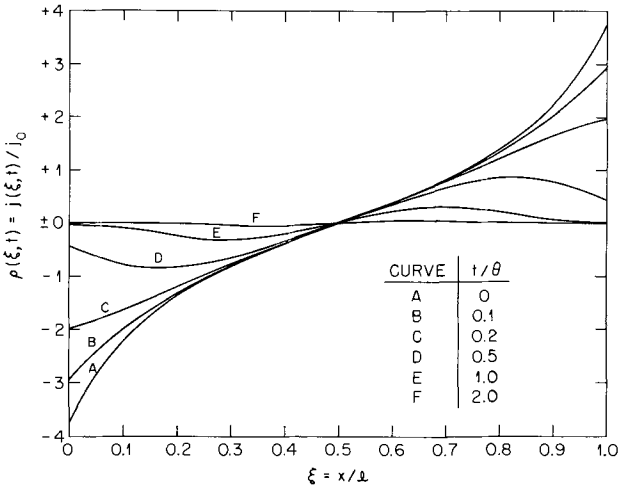

Fig. 10. Variation of current density profile with time due to oxidation reduction reactions in the interior of a porous or tubular electrode ($\beta = 0.5$; $\kappa = 10.0$; $I = 1.0$).

reaction of either the oxidized or reduced species to the initial exchange current of the reaction. Potential and concentration transients are obtained by simultaneous solution of Eq. [19] and [20] with use of the boundary conditions of Eq. [21].

$$\left(\frac{\partial\phi(\xi,t)}{\partial\xi}\right)_{\xi=0} = \left(\frac{\partial\phi(\xi,t)}{\partial\xi}\right)_{\xi=1} = \kappa I \qquad [21]$$

Although general solutions of this system of equations are not obtainable in terms of explicit functions, numerical methods may be used to find solutions for particular values of the parameters, β, κ, and I.

Figures 8, 9, and 10 show how the polarization, the reactant concentrations, and the reaction rate change with time and with position in the electrode during the course of a transient. These results were obtained by use of a high-speed digital computer;[3] parameters used were $\beta = 1/2$, $I = 1.0$, and $\kappa = 10.0$. Initially most of the reaction occurs near the ends of the electrode (cf. Fig. 10). With time a reaction "wave" is propagated toward the center of the electrode. Oxidized species react to form reduced species near $\xi = 0$, and the reverse reaction occurs near $\xi = 1$ (cf. Fig. 9). In the new steady state the gradient of the polarization is constant throughout the length of the electrode so that $\phi(1) - \phi(0) = \kappa I$ (cf. curve F of Fig. 8), interfacial reactions no longer occur anywhere in

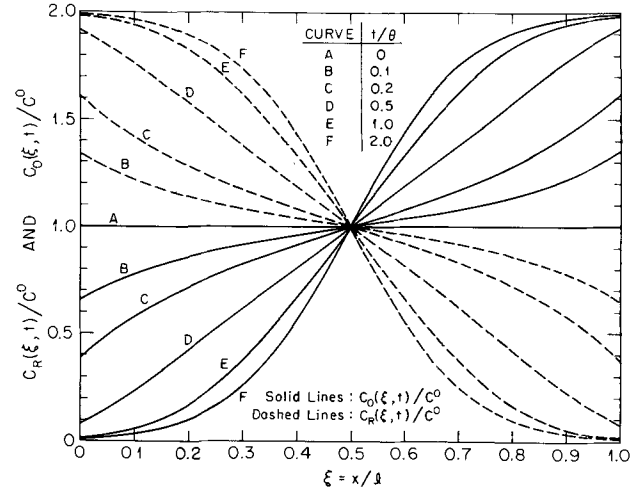

Fig. 9. Variation of reactant concentration profiles with time due to oxidation reduction reactions in the interior of a porous or tubular electrode ($\beta = 0.5$; $\kappa = 10.0$; $I = 1.0$).

the electrode, and concentrations of oxidized and reduced species are related by the Nernst equation, $C_O(\xi,\infty)/C_R(\xi,\infty) = \exp[\phi(\xi,\infty)]$. During the concentration transient the apparent resistance increases from its initial value up to the limit R_o, the electrolyte resistance which would be observed if no oxidation reduction couple were present in the solution. The time constant θ may be useful as a semi-quantitative measure of the time required for concentration transients in induced polarization measurements. If measurements of apparent resistance are made within about 0.01 θ, no significant concentration changes should occur.

Induced Charging of the Double Layer

Induced charging of the double layer in porous or tubular electrodes in which no Faradaic reactions can occur produces charging transients similar to those obtained by direct galvanostatic charging of porous electrodes. The induced double layer charging transient may be obtained by solution of Eq. [22] (12, 13). The time constant τ is equal to $SCl^2/\sigma A$ where C is the

$$\frac{\partial^2\phi(\xi,t)}{\partial\xi^2} = \tau\frac{\partial\phi(\xi,t)}{\partial\tau} \qquad [22]$$

differential capacity per unit area (farad/cm²). Alternatively, $\tau = R_oC_T$ where $R_o = l/\sigma A$ is the resistance of the electrolyte as before and $C_T = SCl$ is the total differential capacity (farad). The initial condition is given by $\phi(\xi,0) = 0$ and the boundary conditions are the same as those of Eq. [21]. The induced double layer charging transient is given by Eq. [23] and Fig. 11

$$\frac{\phi(\xi,t)}{\kappa I} = \frac{2}{\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k^2}\{\cos[\pi k\xi] - \cos[\pi k(1-\xi]\}\{1-\exp[-\pi^2k^2t/\tau]\} \qquad [23]$$

shows a plot of the measurable potential transients against t/τ and against $(t/\tau)^{1/2}$. During the initial moments the potentials $\phi(0,t)$ and $\phi(1,t)$ follow the $\sqrt{t}$ law of Eq. [24]. In a plot of $\phi(0,t)$ or $\phi(1,t)$ against $\sqrt{t}$, the

$$\lim_{t\to0} -\frac{\phi(0,t)}{\kappa I} = \lim_{t\to0}\frac{\phi(1,t)}{\kappa I} = 2\left(\frac{t}{\pi\tau}\right)^{1/2} \qquad [24]$$

initial slope of the charging transient is inversely proportional to $(R_oC_T)^{1/2}$. The final steady state is given by $\phi(\xi,\infty)/\kappa I = \xi - (1/2)$ so that $\phi(1,\infty) - \phi(0,\infty) = \kappa I$, which is equivalent to Eq. [1]. Both R_o

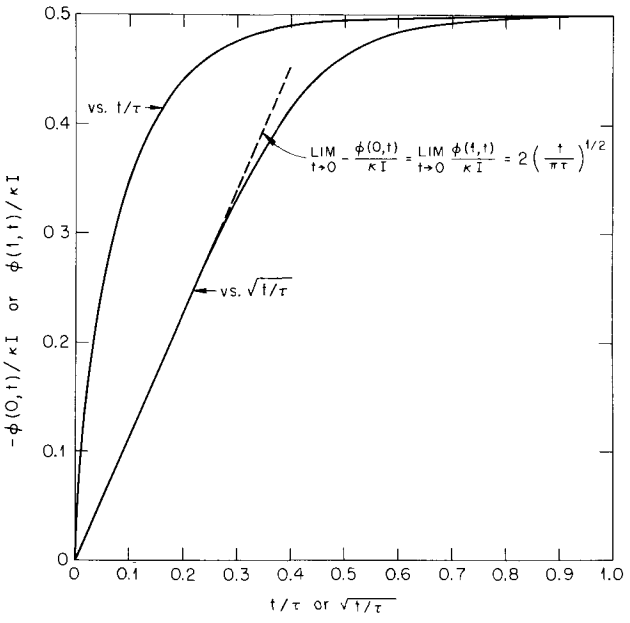

Fig. 11. Induced charging of the double layer in porous or tubular electrodes in the absence of faradaic reactions.

and C_T may be determined from induced charging transients by use of these relations.

Effect of Conductance of Metallic Phase

The relations derived above for induced polarization and charging transients may be corrected for situations where the conductivity of the metallic phase is comparable to that of the liquid phase. When potential gradients can occur in the metallic (electron conducting) phase, Eq. [2] may be replaced by Eq. [25], where σ_s and σ_m are specific conductances of solution and metal

$$\frac{d^2\eta(x)}{dx^2} = S\left(\frac{1}{\sigma_s A_s} + \frac{1}{\sigma_m A_m}\right) j(x) \qquad [25]$$

phases, respectively, and A_s and A_m are the corresponding cross-sectional areas. The net result of this correction is that κ must be replaced by

$$\kappa' = \frac{Sj_o \ln F}{RT}\left(\frac{l}{\sigma_s A_s} + \frac{l}{\sigma_m A_m}\right) = i_o\,(R_o + R_m) f$$

where $R_m = l/\sigma_m A_m$ is the resistance of the metallic phase (ohm). In a similar manner the time constant for charging of the double layer (τ) must be replaced by $\tau' = C_T(R_o + R_m)$. The forms of all equations in which κ and τ appear (*e.g.*, Eq. [6] and [22]) are left unchanged by this substitution.

Summary

Solutions are presented above to several one-dimensional boundary value problems which occur in the theory of induced polarization of porous or tubular electrodes. Measurements of induced polarization may find application in analysis of flowing streams because the apparent resistance is sensitive to the presence of oxidation reduction reactions which can occur at the interface. Induced polarization may also prove to be useful as a monitor of corrosion rates of pipes or porous metals. In addition, certain parameters of importance in electrode kinetics (transfer coefficient and exchange current density) may be estimated in a unique manner from measurements of the dissymmetry potential or the apparent resistance. More elaborate models which include factors not treated here (diffusion and convection of reactants, reactions with consecutive charge-transfer steps, etc.) may be devised which might suggest other possibilities for the utilization of induced polarization measurements on porous and tubular electrodes.

Manuscript received Sept. 7, 1965; revised manuscript received Feb. 24, 1966. This paper was presented at the Cleveland Meeting, May 1-6, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

SYMBOLS

A, A_s	cross-sectional area of electrolyte in porous or tubular electrode, cm^2
A_m	cross-sectional area of metallic phase in porous or tubular electrode, cm^2
C	differential capacity per unit area, farad/cm^2
C_T	total differential capacity, farad.
$C_R, C_R(\xi,t)$	concentration of reduced species in solution, mole/cm^3
$C_o, C_o(\xi,t)$	concentration of oxidized species in solution, mole/cm^3
C^o	$=C_R(\xi,0) = C_o(\xi,0)$; initial concentration of oxidized and reduced species, mole/cm^3
f	$= nF/RT$, reciprocal thermal volt equivalent, volt^{-1}
F	Faraday constant, coulomb/equivalent
i	total current passed through porous or tubular electrode, amp
i_o	$= Sj_o l$; total exchange current, amp
I	$= i/i_o$; dimensionless reduced total current
$j(x), j(\xi,t)$	current density of interfacial reaction, amp/cm^2
j_o	exchange current density, amp/cm^2
j_o^o	standard exchange current density, amp-cm/mole
j_{corr}	corrosion current density, amp/cm^2
k	summation index
l	length of porous or tubular electrode, cm
n	electron number of oxidation reduction reaction
n_a, n_c	electron numbers of anodic and cathodic reactions, respectively
RT/F	thermal volt equivalent, v
R_o	$= l/\sigma A = l/\sigma_s A_s$; resistance of solution phase in absence of oxidation reduction reactions, ohm
R_m	$= l/\sigma_m A_m$; resistance of metallic phase, ohm
R_{app}	$= [\eta(l) - \eta(0)]/i$; apparent resistance of porous or tubular electrode, ohm
S	interfacial area of porous or tubular electrode per unit length, cm^2/cm
t	time, sec
x	distance coordinate, cm
β, β_a	anodic transfer coefficient.
β_c	cathodic transfer coefficient
$\eta(x)$	change of interfacial potential difference by induced polarization, volt
θ	$= nFC^oAl/i_o$; time constant for concentration transients, sec

κ = $Sj_0l^2n\ F/\sigma ART = i_oR_of$; dimensionless resistance parameter, a ratio of solution impedance to interfacial impedance

κ_O = $\kappa j_o^o/j_o$

κ' = $i_o(R_o + R_m)f = \kappa(R_o + R_M)/R_o$

κ_{corr} = $Sj_{corr}l^2(\beta_an_a + \beta_cn_c)\ F/\sigma ART$; dimensionless resistance parameter useful for estimating corrosion rates of pipes or porous metals

ξ = x/l; dimensionless distance coordinate

$\rho(\xi,t)$ = $j(\xi,t)/j_o$; dimensionless reduced reaction rate.

σ,σ_s specific conductance of solution phase, $ohm^{-1}cm^{-1}$

σ_m specific conductance of metallic phase, $ohm^{-1}cm^{-1}$

τ = $SCl^2/\sigma A = R_oC_T$; time constant for charging of double layer, sec

τ' = $C_T(R_o + R_M)$

$\phi_s(x)$ potential of solution phase, volt

$\phi(\xi),\phi(\xi,t)$ = $f\cdot\eta(\xi,t)$; dimensionless reduced change in interfacial potential difference induced by passage of current

Φ = $\phi(0) + \phi(1)$; dimensionless dissymmetry potential.

Electrochemical Processes in Thin Films

1. Preliminary Survey of the Roles of Convection and Concentration Polarization

E. N. Lightfoot

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin

ABSTRACT

An analysis is made of the roles of convection and concentration polarization during oxidation of hydrogen in acidic supermeniscus films. In this preliminary analysis activation overvoltage is assumed constant throughout the reaction zone. It is concluded that both convection and concentration polarization are important, and that they are in part responsible for formation of films above the normal meniscus. It is postulated that concentration polarization induces water recirculation, up in the surrounding vapor phase, and down as a gravity-driven falling film on the anode surface. Calculated film heights and thicknesses are in agreement with published observations.

Recently there has been considerable interest in electrochemical processes taking place at the wetted surfaces of metallic rods partially immersed in electrolyte solutions. This interest stems in large part from the outstanding work of Will (1) and from the belief that studies in such systems will give improved insight into the behavior of porous electrodes.

Up to the present, however, analysis of the diffusional processes contributing to the electrolytic current have been incomplete, and the postulated presence of very thin films above the equilibrium meniscus has not been adequately explained. It is felt by the author that more thorough study of these factors is in order, and, indeed, that electrode behavior cannot be adequately understood until these uncertainties are resolved.

The present paper reports a preliminary analysis of convection and concentration polarization relative to immobilization of electrochemically inactive solutes. In spite of the approximations introduced, this development indicates that both convection and concentration polarization are important and that their effects should be further studied. Of particular importance is the strong probability that systems of this type can be influenced by gravitational forces and hence both by configuration and orientation of the electrode.

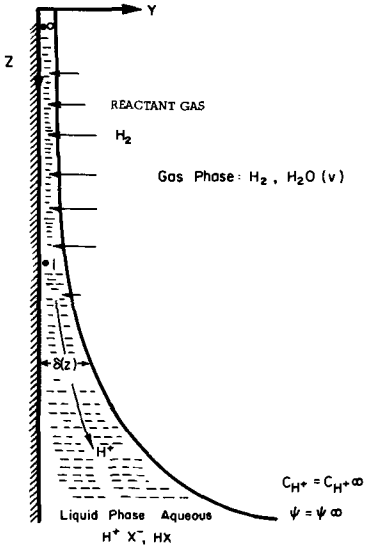

Fig. 1. System considered

The system considered is pictured in Fig. 1. It consists of an electrolyte meniscus adjacent to a vertical electrode surface and quite possibly distorted from normal meniscus shape in its upper regions. This distortion may be due to hydrodynamic effects, as discussed below, or to the presence of a liquid film of as yet undetermined origin. In any event, it is assumed that the gas-diffusion path is short compared to that for the discharging ions, so that migration of the two will be one-dimensional in each case, and mutually perpendicular.

Behavior of the system can be described in terms of conservation relations for the diffusing species, and of electric charge, the Nernst equation, and Kirchoff's voltage law. Where convection is to be considered the equation of fluid motion must also be used, with possible serious complication of the problem at hand. Only simple falling films will be considered in this initial development, but a more thorough analysis is planned in which natural convection and the effects of surface-tension forces will be taken into account.

Continuity Relations

For our present purposes we shall consider the solution to contain only hydrogen ions, one unspecified anion X^-, a very small amount of dissolved hydrogen, and water.[1] It will be further assumed that diffusion coefficients are concentration independent throughout the reaction zone and that diffusional coupling between species is unimportant. Finally, it will be assumed that water is the major constituent so that the

[1] Partially dissociated electrolytes can be handled by an extension of the development presented here, but in this case both the dissociation equilibrium and rate constants must be known.

divergences of both the mass-average and molar-average velocities are zero. We then need explicit continuity equations only for hydrogen and the two ionic species.

The continuity equation for hydrogen is particularly simple and may be written directly in integral form as

$$N_{H_2} = \frac{\mathcal{D}H_2 m}{\delta(z)} [c_{H_2}{}^{o} - c_{H_2}(0,z)] \quad [1]$$

where $c_{H_2}{}^{o}$ is the solubility of hydrogen in the electrolyte. This equation may be rewritten in terms of the rate of increase of electrolytic current in the z-direction, since this current is produced solely by oxidation of hydrogen. We thus obtain

$$\boxed{dI/dz = [2PF\mathcal{D}_{H_2 m}/\delta(z)][c_{H_2}{}^{o} - c_{H_2}(0,z)]} \quad [2]$$

Since the entire electrolytic current is carried by the hydrogen ions, we may write the continuity equations for the ionic species as

$$H^+: \; I_z = -FP\delta(z)\left\{\mathcal{D}_{H^+ m}\left(\frac{dc_{H^+}}{dz} + c_{H^+}\frac{d\Psi}{dz}\right) - c_{H^+}v_z^*\right\} \text{ (hydrogen ion)} \quad [3]$$

$$X^-: \; 0 = -\mathcal{D}_{x-m}\left(\frac{dc_{H^+}}{dz} - c_H + \frac{d\Psi}{dz}\right) + c_{H^+}v_z^* \text{ (anion, } X^-) \quad [4]$$

Use of these pseudobinary diffusion expressions has been amply justified for reasonably dilute electrolytes and should be satisfactory for our limited present purposes. The assumptions of uniform electrolytic current density and negligible curvature of the electrode perimeter are consistent with the assumption of thin films underlying the entire development.

Equation [4] states the requirements for immobilization of the anion: a balance between concentration-diffusion, forced-diffusion, and convective fluxes. Simultaneous consideration of all three fluxes is difficult because it requires detailed knowledge of water transport across the gas-liquid interface. For the present, when it is only desired to obtain a semi-quantitative understanding of system behavior, a simpler approach seems in order, and two limiting cases are considered for this purpose:

1. No water transport across the liquid-gas interface: $v_w = v_{x-} = 0$; $v^* - x_H + v_{H^+}$. Under these conditions convection is of minor importance, and the primary mechanism of immobilization is concentration polarization.

2. No resistance to water transport: $dc_{H^+}/dz = dc_{H^+}/dy = 0$. Under these conditions anion immobilization is entirely by convection. Since this requires a very substantial solution velocity, large amounts of water will have to condense into the liquid film and be transported downward by gravitational action, or else there will have to be very substantial spontaneous mixing. Real behavior should be intermediate between predictions for these two limiting situations.

For the case of no water transport across the gas-liquid interface and no spontaneous mixing, *i.e.*, negligible convection, Eq. [3] and [4] reduce to

$$I_z = -2FP\delta(z)\mathcal{D}_{H^+ m}c_{H^+}\frac{d\Psi}{dz} \text{ (negligible convection)} \quad [5]$$

$$\frac{dc_{H^+}}{dz} = c_{H^+}\frac{d\Psi}{dz} \text{ (negligible convection)} \quad [6]$$

Equation [6] may be readily integrated and the result substituted into Eq. [5] to obtain[2]

[2] Other available analyses taking concentration polarization into account include (2-4).

$$I_z = -2FP\delta(z)\, c_{H^+\infty}\mathcal{D}_{H^+ m}\, e^{(\Psi-\Psi_\infty)}\frac{d\Psi}{dz} \text{ (negligible convection)} \quad [7]$$

Then, for conditions of negligible convection the effective conductivity of the film is a function of applied voltage, through the dependence on Ψ_∞, the potential at large z.

When fluid convection prevents the development of appreciable concentration gradients, Eq. [4] reduces to

$$v^* = -\mathcal{D}_{x-m}\frac{d\Psi}{dz} \text{ (convection dominant)} \quad [8]$$

This may be put into Eq. [3] to obtain

$$I = -P\delta(z)\{Fc_{H^+}(\mathcal{D}_{H^+ m} + \mathcal{D}_{x-m})\}\frac{d\Psi}{dz} \text{ (convection dominant)} \quad [9]$$

The expression in braces is defined as $\kappa = KRT/F$ where K is the conductance of the electrolyte, mhos/cm. We may then write

$$I = -P\delta(z)\,\kappa\frac{d\Psi}{dz} \text{ (convection dominant)} \quad [10]$$

This is the expression used by Will, and it is, therefore, important to recognize both the restrictions on it and its physical significance:

(*i*) *Restrictions.*—Equation [10] is valid only when concentration gradients are substantially eliminated by convective mechanisms. This implies a substantial flow of solvent down the film, either because of effective equilibriation with the gas phase, natural convection, or the action of surface forces. These requirements clearly imply a sensitivity to geometry, scale factors, and orientation with respect to gravitational fields.

(*ii*) *Physical significance.*—The effect of convection is to oppose electrodiffusion of X^- and to reinforce that of H^+, in each case by exactly the same amount. Since its effect on X^- must exactly cancel out the corresponding electrodiffusion, its contribution to H^+ movement, *i.e.*, to the electrolytic current, is exactly that of electrodiffusion of X^- in an alternating voltage field.

It should also be noted that $\mathcal{D}_{X-m}$ is always much smaller than $\mathcal{D}_{H+m}$. It follows that effective electrolyte resistance for conditions of negligible convection is only about half that for conditions of negligible concentration polarization, even at quite low applied voltages. At higher voltages the differences are even larger.

Then for the one-one electrolyte considered here, it should not be hard to determine from experimental data whether convection or concentration polarization is primarily responsible for immobilization of electrochemically inactive ions. This can be seen rather clearly by rewriting Eq. [7] and [10] in the common form

$$\boxed{I = -P\delta(z)\,\kappa_\infty\alpha\frac{d\Psi}{dz}} \quad [11]$$

with

$$\alpha = 1 \text{ (convection dominant)} \quad [12]$$

$$\alpha = 2\exp[\Psi(z) - \Psi(\infty)]/\left(1 + \frac{\mathcal{D}_{x-m}}{\mathcal{D}_{H+m}}\right) \text{ (convection negligible)} \quad [13]$$

Equations [2] and [11] through [13] summarize the useful continuity relations for this system. It should be kept in mind, however, that the situation is much more complicated for partially dissociated electrolytes.

Development of Current-Voltage Relations for Thin Films

Here, the hydrogen concentration $c_{H_2}(0, z)$ will be eliminated from Eq. [2] through use of Kirchoff's law and a modification of the Nernst equation, in a manner similar to that used by Will. In this way it may be shown that

$$\Psi_0 - \Psi_1 \doteq \ln \left[\frac{(c_{H^+})_1}{(c_{H^+})_0} \sqrt{\frac{(c_{H_2})_0}{(c_{H_2})_1}} \right] + \frac{F}{RT} (\eta_1 - \eta_0) \quad [14]$$

In the present analysis overvoltage η will be assumed constant. This is a major assumption which may result in serious error for many electrochemical reactions of practical interest. It should however be acceptable for our present limited purposes, for hydrogen oxidation. Variation in overvoltage, but not hydrodynamic flow, is treated by Grens, Turner, and Katan (4). We may thus rewrite Eq. [14] as

$$\frac{(c_{H_2})_1}{(c_{H_2})_0} = e^{-\beta(\Psi_0 - \Psi_1)} \quad [15]$$

with

$$\beta = 2 \text{ (convection dominant)} \quad [16]$$

$$\beta = 4 \text{ (convection negligible)} \quad [17]$$

Equation [15] may be rewritten more conveniently as

$$\boxed{c_{H_2}/c_{H_2}^{\circ} = \exp [-\beta\psi + (\beta - 2)\psi_\infty]} \quad [18]$$

with

$$\psi = \Psi_e - \Psi \quad [19]$$

Here Ψ_e is the solution potential for $c_{H_2} = c_{H_2}^{\circ}$ and $c_{H^+} = (c_{H^+})_\infty$. Equations [2] and [18] can now be combined to eliminate concentration and the result put in dimensionless form for convenience. The result is

$$\frac{dH}{d\zeta} = 1 - e^{-\beta\psi + (\beta - 2)\psi_\infty} \quad [20]$$

where the dimensionless current H and position ζ are defined as in the nomenclature list. The corresponding form of Eq. [11] is

$$H = \frac{1}{2} \epsilon\alpha \frac{d\psi}{d\zeta} \quad [21]$$

where ϵ is also defined in the nomenclature list. These two equations may now be combined and integrated to yield the desired current-voltage relations

$$H = \sqrt{\epsilon} \sqrt{\psi - \frac{1}{2}(1 - e^{-2\psi})} \quad \text{(convection dominant)} \quad [22]$$

$$H = \sqrt{\frac{2\epsilon}{1 + (\mathcal{D}_{x-m}/\mathcal{D}_{H+m})}} \sqrt{\frac{4}{5} e^{\psi_\infty/2} + \frac{1}{5} e^{-5\psi + 3\psi_\infty} - e^{-\psi + \psi_\infty}} \quad [23]$$

convection negligible

To evaluate the integration constants in these two expressions use was made of the fact that $H = 0$ when $c_{H_2} = c_{H_2}^{\circ}$. Note that the total applied voltage can be defined as ψ_∞ and that the total current is H_∞. Therefore, to obtain an expression for total electrode performance from Eq. [22] or [23], it is only necessary to replace ψ by ψ_∞ and H by H_∞.

It may be noted that:

1. Both relations are completely independent of film shape, provided only that the film is thin enough to provide mutually perpendicular gas and ion diffusion, and, of course, that $\gamma(\eta_0 - \eta_1)$ be zero.
2. The current-voltage relation at intermediate points in the film is dependent on total applied voltage when concentration polarization is appreciable, but not otherwise.
3. Current-voltage characteristics are quite different for the two limiting cases considered, so that it may be possible to determine the relative importance of convection and concentration polarization from experimental measurements. For acid hydrogen anodes, as considered here, greater currents are obtained when concentration polarization is appreciable. For alkaline hydrogen anodes or acid oxygen cathodes the reverse should, of course, be true.

The last of these points is the most important for our present purposes, and is worth considering in more detail.

To facilitate comparison of Eq. [22] and [23] we define r as the ratio of potentials for convection negligible and dominant

$$r \doteq 2/[1 + (\mathcal{D}_{x-m}/\mathcal{D}_{H+m})]^{1/2} \qquad (\text{Limit}, \psi_\infty \to 0)$$

For a rather typical value of 0.2 for $(\mathcal{D}_{X-m}/\mathcal{D}_{H+m})$ one thus obtains a value of the order of 2 for r, at low applied voltages. Since $RT/F \doteq 0.025$v at normal temperature, this expression would only be expected to be valid for applied potentials of about 10 mv or lower. At very high applied voltages

$$r \doteq \sqrt{\frac{8}{5} \frac{\exp(\psi_\infty/2)}{\left(1 + \frac{\mathcal{D}_{x-m}}{\mathcal{D}_{H^+}}\right)\left(\psi_\infty - \frac{1}{2}\right)}} \quad [25]$$

so that r rapidly becomes large.

Comparison of Predicted Behavior with Available Data

The most complete available data directly applicable to the above analysis appear to be the experimental results of Will for cylindrical platinum electrodes immersed in 1*N* and 8*N* H_2SO_4 at 25°C. Representative results are reproduced in Fig. 2 and 3, along with predictions for the assumption of convection dominant in immobilization of the anions. Calculated results for the assumption of concentration polarization dominance are not shown because they are not directly applicable to a partially dissociated dibasic acid such as H_2SO_4.

At very low applied voltages (see Fig. 2) experimental results are in fair agreement with the assumption of convection dominance, although the experimental currents are slightly lower than predicted for the case of 8*N* acid. This result may be a consequence of activation polarization or inaccuracies in the assumed values of physical properties. The dif-

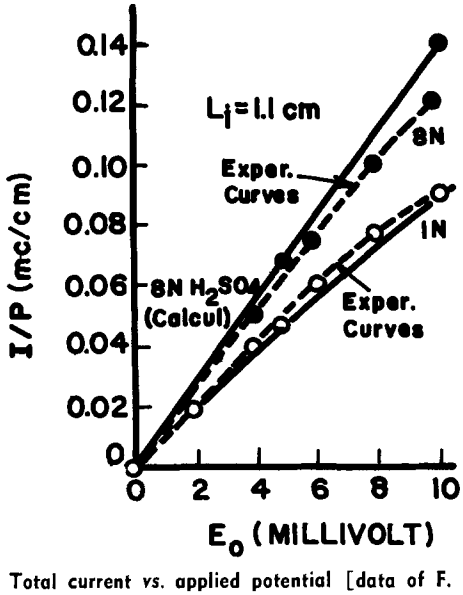

Fig. 2. Total current vs. applied potential [data of F. G. Will, ref. (1)].

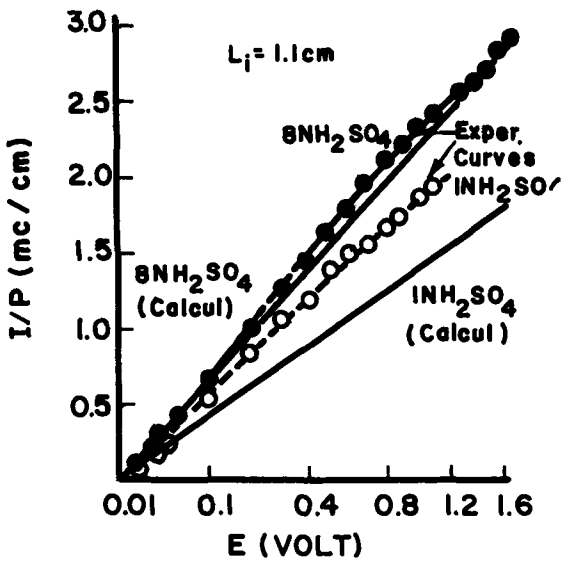

Fig. 3. Total current vs. applied potential [data of F. G. Will, ref. (1)].

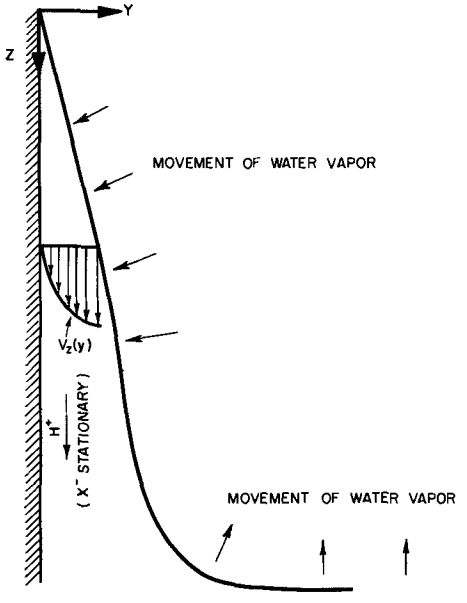

Fig. 4. Convection in film by vapor recirculation mechanism

fusivity of dissolved hydrogen, for example, is not accurately known. However, it may also be a result of concentration polarization superimposed on convection since 8*N* is very nearly the concentration of maximum sulfuric acid conductivity.

At higher applied voltages experimental currents for 1*N* acid are about 1/3 higher than those predicted, and, as previously stated by Will, this is an indication of concentration polarization. The magnitude of this effect is, however, far lower than can be explained by the above analysis for a 1-1 electrolyte with negligible convection. It would appear then, either that convection is important here, or that the effect of concentration polarization is markedly reduced, either by the partial dissociation of the acid, or by kinetic limitations. It is the opinion of the author that convection is important, but the complexities of sulfuric acid dissociation make a convincing analysis impossible at present. For 8*N* acid there is almost complete agreement with the assumption of convection dominance, but once again caution is indicated. At this rather high acid concentration diffusional interaction between the ions and between these and the undissociated acid must also be considered. This is impossible at present, and it is clear that sulfuric acid is too complex an electrolyte to permit meaningful interpretation of experimental results.

In summary then it appears reasonable to agree with Will that concentration polarization plays only a minor role in these experiments, but this is by no means certain.

It is also important to note that Will found strong indirect evidence of a liquid film, approximately 1μ in thickness, above the equilibrium meniscus, and that an appreciable fraction of the hydrogen oxidation took place in this super-meniscus region. The existence of such films has since been demonstrated experimentally by Muller (5, 6), using interferometric techniques, during reduction of oxygen on nickel cathodes partially immersed in aqueous sodium hydroxide. Muller found his films to be stable during the passage of the current, and that they increased in thickness with current density. The existence of such a film during this reaction was later used by Bennion and Tobias (2, 3) in their analysis of electrode behavior.

To date no convincing explanation for stable supermeniscus films with thickness of the order of microns has been offered for equilibrium conditions, *i.e.*, in the absence of a current. Their presence requires an appreciable charge density in the bulk of liquid in the film, or other equivalent repulsive force. Such forces have been observed, for example, in soap films (7), but it is easily shown (8) that they are not large enough to stabilize 1μ films under conditions being considered here.

Such films can be explained qualitatively in the presence of a current by water-condensation and gravitational flow, as explained above for hydrogen oxidation in an acid electrolyte. This is also true for oxygen reduction in a basic reaction, in spite of water consumption in the electrochemical reaction, and for the same reasons. It remains to determine if such an explanation is quantitatively appealing. This is the purpose of the next section.

Tentative Analysis of Convection

From the above analysis and the experimental observations of Will (1) and of Muller (5, 6) substantial fluid motion in the film-meniscus system appears quite possible. There are at least three possible causes of such motion, each basically dependent on the concentration polarization which must accompany a direct electrolyte current. These are: (*a*) surface-tension gradients, which must be considered in combination with density gradients; (*b*) natural convection; and (*c*) recirculation of water through the gas phase driven by differences in equilibrium water vapor pressure.

All of these should be considered, and it is planned ultimately to do so, but only the third is treated here. This is in part because it produces the simplest and most believable type of fluid motion, closely analogous to the classic Nusselt condensed-steam film. Natural convection or surface-tension driven flows, on the other hand, require both rising and descending currents in the same thin film.

The goal of the following analysis is then a simple and restricted one: to determine whether the falling film required to immobilize anions at an acid hydrogen anode has characteristics consistent with our knowledge of electrode reactions in film-meniscus systems. The acid hydrogen anode is used not only because it is the best understood, but also because convection is downward. Thus, a first approximate description can be attempted without detailed knowledge of surface forces. The procedure then will be first to relate film thickness to the mass average velocity in the film and then to relate this velocity to the total current.

Since the film will be thin and the Reynolds number of the flow in it extremely small the integrated equation of motion may be written down directly in the form

$$v = \rho g \delta^2 / 3\mu \quad [26]$$

where v is the flow-average value of the mass-average velocity in the axial direction. Next Eq. [3] is rewritten in the form

$$I = P \delta c_{H+} v_{H+} \quad [27]$$

where v_{H+} is the flow-average velocity of the hydrogen ion. Next the velocity of water in the film is related to that of hydrogen through combination of Eq. [8], [9], and [27].

$$v^* = x_{H+} v_{H+} + x_w v_w = v_{H+} \Big/ \left[1 + \frac{\mathcal{D}_{H+m}}{\mathcal{D}_{X-m}} \right] \quad [28]$$

where v^* is again a flow-average value. Note that to write Eq. [28] in flow-average terms it is necessary to neglect changes in species velocity ratios across the film. Since $x_w = 1 - 2x_{H+}$ it follows that

$$v_w = v_{H+} \left[\frac{1 - \left(1 + \dfrac{\mathcal{D}_{H+m}}{\mathcal{D}_{x-m}} \right) x_{H+}}{(1 - 2x_{H+}) \left(1 + \dfrac{\mathcal{D}_{H+m}}{\mathcal{D}_{x-m}} \right)} \right] \quad [29]$$

and, therefore, that the mass-average velocity

$$v = w_{H+} v_{H+} + w_w v_w = A v_{H+} \quad [30]$$

with

$$A = w_{H+} + w_w \left[\frac{1 - \left(1 + \dfrac{\mathcal{D}_{H+m}}{\mathcal{D}_{x-m}} \right) x_{H+}}{(1 - 2x_{H+}) \left(1 + \dfrac{\mathcal{D}_{H+m}}{\mathcal{D}_{x-m}} \right)} \right] \quad [31]$$

Equations [27] and [31] may now be combined to yield

$$I = P \delta c_{H+} v / A \quad [32]$$

or, introducing Eq. [26]

$$I = \frac{F P \rho g c_{H+} \delta^3}{3\mu A}; \quad H = \left(\frac{\rho g \delta^3}{6\mu A \mathcal{D}_{H2m}} \frac{c_{H+\infty}}{c_{H_2}^{\circ}} \right) \quad [33\text{-a, b}]$$

Then, within the limits of this development, film thickness is simply related to local current in a way strongly reminiscent of the Nusselt condensate films. This expression is, however, only useful in the upper region of the meniscus, and there only if the calculated δ is much greater than the film thickness in absence of a current. It is not applicable at all to systems in which ion flow is upward. With all these limitations, however, Eq. [33] does permit an estimate of the contribution of convection to film thickness.

Consider then as an illustrative example the following hypothetical, but reasonable, conditions

$$I/P = 0.05 \text{ ma/cm}$$
$$c_{H+} = 10^{-3} \text{ eqts/cm}^3$$
$$\mu/\rho = 10^{-2} \text{ cm}^2/\text{sec}$$
$$\mathcal{D}_{H+m}/\mathcal{D}_{x-m} = 4.5$$

Then

$$A \doteq 0.001 + 0.999 \left[\frac{1 - \dfrac{(1 + 4.5)}{55}}{\left(1 - \dfrac{2}{55} \right)(1 + 4.5)} \right] \quad [34]$$

$$= 0.17$$

$$\delta = \left[\frac{(0.17) \left(5 \times 10^{-5} \dfrac{\text{coulombs}}{\text{sec cm}} \right) (3) \left(10^{-2} \dfrac{\text{cm}^2}{\text{sec}} \right)}{\left(980 \dfrac{\text{cm}}{\text{sec}^2} \right) \left(9.65 \times 10^4 \dfrac{\text{coulombs}}{\text{equivalent}} \right) \left(10^{-3} \dfrac{\text{eqts}}{\text{cm}^3} \right)} \right]^{1/3} = 1.4\mu \quad [35]$$

This corresponds remarkably well with the estimated thickness of 1.5μ suggested by Will for very similar conditions but a somewhat different physical model. While this degree of agreement must be considered coincidental, it is nevertheless encouraging.

Film height can also be determined readily. For the low current of the above numerical example acceptable results may be obtained quite readily. Here

$$H \doteq \sqrt{\epsilon}\, \psi \quad [36]$$

and

$$\frac{dH}{d\zeta} = \delta \frac{dH}{dz} \doteq 2\psi$$

$$\doteq 2H/\sqrt{\epsilon} \quad [37]$$

Combining this result with Eq. [33] yields the desired relation for film shape

$$\frac{d\delta}{dz} = \frac{2}{3\sqrt{\epsilon}} \quad [38]$$

Then $L/\delta = 3/2\sqrt{\epsilon}$ where L is distance from top of film to level at which thickness is δ. For sulfuric acid at 25°C

$$F/RT = 39.0 \text{ volt}^{-1}$$

$$c_{H_2}^{\circ} = 7.67 \times 10^{-7} \frac{\text{moles}}{\text{cm}^3} \; (1N \; H_2SO_4); \quad 7.17 \times 10^{-7} \; (8N)$$

$$\mathcal{D}_{H2m} = 3.1 \times 10^{-5} \frac{\text{cm}^2}{\text{sec}} \; (1N); \quad 2.2 \times 10^{-5} \; (8N)$$

$$K = 0.215 \text{ mhos/cm } (1N); \quad 0.826 \; (8N)$$

Then for these conditions $\epsilon = 2.40 \times 10^3$ and $(L/\delta) = 73.5$ ($1N$ H_2SO_4) or 118 ($8N$ H_2SO_4).

By way of contrast, Will found the electrochemically active region to extend about 100 to 200 film thickness above the visible meniscus. In view of the uncertainties, both in analysis and experiment, these predictions are in reasonable agreement with Will's data.

The only experimental evidence of meniscus thickening to date appears to be that of Muller for reduction of oxygen on a nickel tube in 3.5N KOH. Film thickness was found to increase with current density for this system, for example, thickening from about 0.3 to about 0.5μ at 15 mm above bulk liquid level, when the current was raised from 0.0047 to 0.047 ma/cm. This thickening was ascribed to electrocapillary effects, but without proof. It is not possible at present to say more than that this degree of thickening is of the order predicted by the above convective development. It is also important to note that Muller's films were thinner at higher elevations, and, in fact, that available data as reported in ref. (3) indicate the triangular cross section predicted by Eq. [38].

In summary then, both the thickness and height of the falling film required to immobilize the anions are consistent with experimental observation. In fact, the agreement between prediction and experiment is much better than would be expected in view of the many approximations made in this development. It would be unwise to neglect other mechanisms of diffusional stabilization or other sources of thin liquid films on the metal electrode surface. It is also too early to speculate on the specific effects of geometry and orienation on electrode performance.

Nevertheless, two facts seem to be demonstrated by this analysis:

1. Superficial treatment of the current-carrying diffusional and convective processes in meniscus-film systems preclude thorough understanding of electrode performance.
2. Convective processes are likely to prove important in many practical situations.

Failure to consider these points would make full practical utilization of Dr. Will's outstanding work on thin films very unlikely.

Manuscript received Jan. 7, 1965; revised manuscript received Jan. 8, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Technical Notes

Studies on the Oxygen Gradients in Oxidizing Metals

IV. Kinetics of the Oxidation of Hafnium at High Temperatures

J. P. Pemsler

Ledgemont Laboratory, Kennecott Copper Corporation, Lexington, Massachusetts

Like zirconium, hafnium dissolves significant quantities of oxygen during oxidation so that a metal zone rich in oxygen forms beneath the oxide layer. In a previous paper the author has shown that the oxygen gradient beneath the oxide film may be calculated with an appropriate diffusion equation and that the experimentally determined gradient is in good agreement with the theoretical expression (1). In addition, it was found that a remarkable anisotropy of the oxidation film growth occurred which persisted to the thick film region and that the effect was associated with a variation in the stoichiometry of the oxide film covering differently oriented grains (1). In previous studies of zirconium it has been shown that, while the oxygen solution obeys diffusion kinetics and remains parabolic for sufficiently thick samples, film growth does not obey normal rate laws (2).

It is the purpose of this paper to attempt to separate quantitatively the film growth and oxygen dissolution processes and to attempt to gain insight into the film growth mechanism.

Experimental

Hafnium in the form of ¾-in. rod was obtained from the Carborundum Metals Climax Company. The vendor's analysis lists Zr as 2.5 w/o and the following in ppm: Al < 80, Cu < 40, Nb < 50, Ta < 100, Ti < 20, Fe-475, and N-33. The purity of the oxygen used has been reported previously (3). Experimental details concerning the preparation of spherical sam-

ples, oxidation, and weight gain and film thickness measurements are similar to those used for zirconium (3).

Results

Total weight gain.—Data for the total weight gain between 850° and 1400°C are given in Fig. 1 in the form of a logarithmic plot. With the exception of the data at 1400°C where the separate data points are indicated, the results were obtained as a continuous weight gain record. The slopes of the log-log plots are about 0.42 and indicate a kinetic behavior between cubic and parabolic. Since the total weight gain is the sum of the film growth and oxygen solution and the latter two do not conform to the same kinetic behavior, no mechanistic interpretation of the total weight gain data can be made at this time.

Film thickness.—Examination of cross sections of the oxidized spheres indicate that at all times and temperatures there is a high degree of irregularity of the film thickness. This may be presumed to be associated with the high degree of anisotropy of oxide film formation on hafnium (1). In order to present the data it was found desirable to plot maximum, minimum, and average thicknesses of the film, and a parabolic plot of these data is shown in Fig. 2, 3, and 4. Data at the lowest temperature may be approximated as parabolic. At the intermediate temperatures the film growth is characterized by a continuously decreasing rate of higher power than parabolic. At the highest temperatures the film growth rate may again be approximated as parabolic.

During film formation grain growth occurs in the metal and becomes pronounced at high temperatures and long times. Oxygen in high concentration retards grain growth so that metal grains within the oxygen gradient may be smaller than those beyond the depth

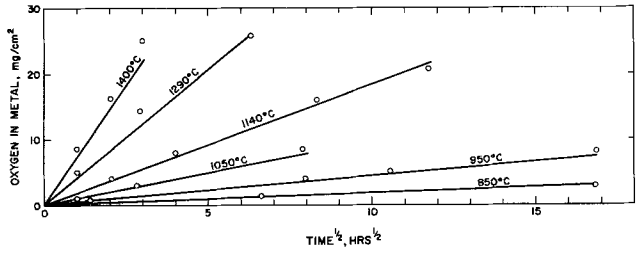

Fig. 5. Oxygen in solution in oxidized hafnium

of appreciable oxygen penetration. Since grain growth is apt to result in a preferred orientation, it is likely that grain growth coupled with the anisotropy of film formation might alter the film growth process. Thus, at the lowest temperatures grain growth is sufficiently slow so that the orientation of the different oxidizing grains is roughly constant. At intermediate temperatures grain growth becomes more pronounced, and the degree of preferred orientation is consequently altered, thereby altering the film growth. At the highest temperatures grain growth is exceedingly rapid, and the retarding effect of the oxygen gradient is absent, so that after a short time the characteristic grains develop which will be present for the remainder of the oxidation.

Oxygen in the metal.—A knowledge of the total weight gain and the measurement of the oxide film thickness enables computation of the quantity of oxygen dissolved in the metal substrate beneath the oxide film. Furthermore, the latter quantity can be calculated by equations previously given (3). Calculated and experimental data for oxygen dissolved in the metal are plotted as a function of a square root of time in Fig. 5. Here, the solid line represents calculated values, and the separate experimental points are indicated in the figure. Good agreement exists between calculated and observed oxygen content of

the metal and the data are parabolic as demanded by diffusion theory.

Discussion

During an investigation of the high-temperature oxidation of zirconium, it was postulated that there exists easy diffusion paths through the oxide which are not interconnected laterally (2). An hypothesis was also presented for the stabilization of the high-temperature tetragonal phase of zirconia at temperatures far below the normal transformation temperature and of different transport rates through the monoclinic and tetragonal oxides. It is possible that similar situations exist during the oxidation of hafnium. In order to understand the mechanism of film formation on hafnium, it is desirable to determine the contribution of nonlattice diffusion and tetragonal oxide to the film growth process. It is also necessary to determine the kinetics of film formation on single crystal material of well-defined orientations. This should give insight into the mechanism causing the pronounced anisotropy of film growth and yield meaningful film growth rates which are not affected by grain growth in the sample. The aforementioned investigations are being pursued in this laboratory.

A Chemical Polish for Tin Telluride

Marriner K. Norr

United States Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland

Until now there has been only one satisfactory method for chemically polishing SnTe (1, 2). It has had the disadvantage of frequently leaving a whitish haze (and sometimes dark stains) on the samples when they were polished for a long enough time (3-5 min) to remove the scratches formed by previous mechanical polishing (2).

This note describes a method of chemically polishing SnTe that gives a clean, somewhat flatter surface than (1, 2).

Procedure

The sample is mounted in a stainless steel jig assembly and ground flat on No. 600 grit SiC paper. It is then transferred to a polycarbonate jig assembly (to which it is attached with paraffin) and polished with Carborundum No. 50 grit Al_2O_3 optical finishing powder on a paraffin lap. Finally, it is polished with Linde A abrasive on a paraffin lap. Each of the abrasives is lubricated with a 1:1 solution of Joy detergent in ethanol. The sample, jig assembly, and hands should be thoroughly cleaned after each step of grinding and polishing.

The solution for chemical polishing is prepared by dissolving 0.35g I_2 in 40 ml ethanol (or methanol) and then adding 10 ml dist. H_2O and 4.0 ml 49% HF. A polyethylene beaker is used to avoid contamination from the container.

A piece of twill jean cloth[1] is stretched over a smooth Teflon plate and saturated with the solution at 25°C. It is recommended that the hands be protected from the solution with polyethylene gloves. The sample (still mounted in the polycarbonate jig assembly) is polished by lightly rubbing it over the wet twill jean cloth, using a figure eight motion, for 15-20 min. Periodically, additional solution must be added to keep the cloth saturated. The sample is then rinsed in a stream of methanol, followed by a stream of distilled water, and dried on lens paper. After demounting, it is soaked 2-3 times in fresh benzene to remove any adhering paraffin and dried on lens paper.

The SnTe crystals used in this work were grown by the Czochralski method. The polish produced a mirrorlike surface which has been used successfully for reflectivity measurements (3). Back-reflection Laue photographs, diffractometer measurements, and a Kossel photograph indicated that the surface was free of major strains.

[1] K. S. 2423 twill jean cloth, Exeter Manufacturing Company, Inc., Exeter, New Hampshire.

Acknowledgments

The author is indebted to Dr. Bland Houston for supplying the SnTe crystals and for helpful advice, to John V. Gilfrich for taking the Laue photographs and diffractometer measurements, and to Harvey Yakowitz for taking the Kossel photograph. The use of a cloth saturated with a chemical polishing solution was suggested to the author by a publication of Schmidt (4).

Segregation Coefficients of Some Rare Earth Niobates in $SrMoO_4$

L. H. Brixner

Pigments Department, Experimental Station

E. I. du Pont de Nemours & Company, Incorporated, Wilmington, Delaware

The original laser experiments employing scheelite-type hosts were carried out with $CaWO_4$ (1). Other scheelites such as $SrMoO_4$ (2, 3), $CaMoO_4$ (4, 5), $PbMoO_4$ (4), and $SrWO_4$ (2) also have been used as host materials for lasers employing rare earth ions. Because low thresholds and ease of excitation, rods containing Nd^{+3} have been studied most intensively. However, rods containing other infrared emitting rare

earth ions such as Ho^{+3} and Tm^{+3} (4) also have been studied. The above papers describe mostly laser experiments; there have been few comprehensive studies of all rare earths in a given host with details on preparative and analytical procedures, as for instance in (5) and (6). Even here, no attempts have been made to correlate the observed segregation (or distribution) coefficients with the structural fit of the rare earth into the cation site of a scheelite.

In this note, we should like to point out some relationships between the ionic radii and the segregation coefficients for the $LnNbO_4$-type rare earth niobates in $SrMoO_4$. All single crystals were grown by the Czochralski technique as previously described (5). Conditions were maintained as uniform as possible with respect to pulling speed, rotation, shape, and weight of crystal. The starting mixture of all compositions was prepared according to the following stoichiometry:

$$0.99SrMoO_4 + 0.005Ln_2O_3 + 0.005Nb_2O_5 \rightarrow Sr_{0.99}Ln_{0.01}Mo_{0.99}Nb_{0.01}O_4,$$

where Ln = Y^{+3}, La^{+3}, Ce^{+3}, Pr^{+3}, Nd^{+3}, Sm^{+3}, Eu^{+3}, Gd^{+3}, Tb^{+3}, Dy^{+3}, Ho^{+3}, and Er^{+3}. This resulted in an activator concentration of 1% in the melt for all rare earth niobates, and it should be remembered at this point that k can also be a function of the concentration of the dopant.

Analysis and computation of k was done as described in (5). Table I summarizes the results. Crystals with Sc^{+3}, Tm^{+3}, Yb^{+3}, and Lu^{+3} were not grown, and the ionic radii deviations are merely included for completeness. For the purpose of a comparison we have also given the ionic radii deviation for Ca^{+2}. The most striking result is the fact that the segregation coefficient varies directly with the deviation of the rare earth ion size from that of Sr^{+2} as is evident in Fig. 1.

In the case of the examples marked with an asterisk no crack-free crystal could be grown on repeated attempts. It is particularly interesting to note that this transition from sound to cracked crystals occurred for a cation size difference of around 15%, the amount of deviation generally accepted as the limit of isomorphous substitution. That this is observable in single crystals at such low concentration is interesting; in the case of Y, six crystals grown from the melt cracked while being cooled to room temperature,

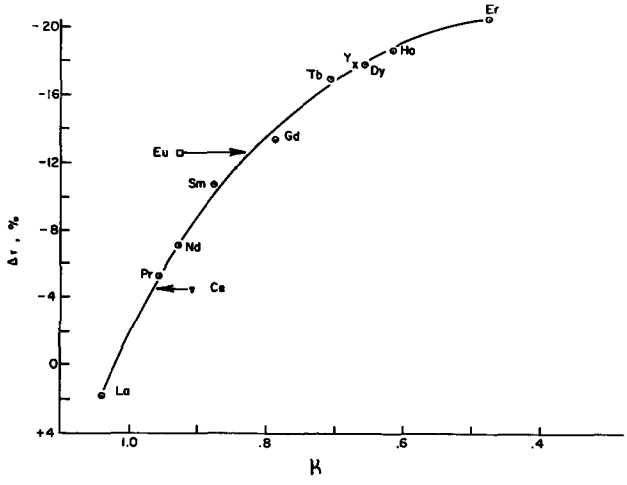

Fig. 1. Segregation coefficient k for $LnNbO_4$ in $SrMoO_4$ as a function of differential ionic radii ($r_{Ln+3} - r_{Sr+2}$).

indicating that true single crystalline solid solution are only stable at high temperature. There are two exceptions to the normal relationship, Ce^{+3} and Eu^{+3}; k for Ce seems too small and k for Eu^{+3}, too big. In the first case, we can only postulate that perhaps a small amount of Ce^{+4} causes this deviation as indicated by the intense yellow color, whereas in the Eu case we know that some Eu^{+2} enters the crystal, which has a deep red color. The better structural fit of Eu^{+2} in the Sr^{+2} site would account for the segregation coefficient nearer to unity. It is interesting to note that, contrary to the $CaMoO_4/EuNbO_4$ case, it was impossible to oxidize Eu^{+2} in $SrMoO_4$. After 100 hr under pure oxygen at 1400°C, the crystal was still deep red. A similar observation was made for $CaWO_4/Eu$ (6).

The column marked c_s/c_n gives the ratio of the concentration in the top of the crystal to the nominally charged concentration and in each case comes very close to k determined from analyses of top and bottom of the crystal. In the last column are the ratios of rare earth oxide to niobium pentoxide in top (T) and bottom (B) of crystal. Since the stoichiometric deviation is generally very small, it appears justified to treat the rare earth niobate in its entirety as we did for all computations. The general tendency is for this ratio to become smaller as the crystal grows, indicating somewhat stronger segregation of Nb_2O_5, but the change is certainly in no proportion to the change experienced by k itself. With the exception of Eu and Ce, a straightforward relationship between segregation coefficients and ionic radii has been established which permits the prediction of distribution coefficients from knowledge of the deviation of the substituted ion's size from that of the host ion. Failure to grow sound crystals with rare earths deviating more than 15% in size from that of Sr^{+2} indicates that these cannot be incorporated into the single crystalline $SrMoO_4$ lattice, at least not at this concentration and at room temperature. Compared to $SrMoO_4$, $CaMoO_4$ should be the better host for Nd^{+3}, although ultimately an appropriate solid solution of the two host compositions may be the best material, with essentially no segregation of the active constituent. This should also be possible for Ce and Pr, where the deviation of ionic radii in $CaMoO_4$ is opposite to the one in $SrMoO_4$.

Manuscript received Feb. 8, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Solubilities of Some II-VI Compounds in Bismuth

M. Rubenstein

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Attention was first focussed on some of the larger band gap II-VI compounds, *i.e.*, ZnS, CdS, ZnSe, and CdSe, because of the interest in various optical properties such as luminescence. Much effort was and is still being expended to prepare powders of such materials in doped and undoped states. More recently other II-VI compounds (ZnTe and CdTe) have been studied because of possible uses in electroluminescence and in solar battery materials.

Since more attention is now being centered on trying to understand the observed phenomena exhibited by these materials and since some of the devices cannot utilize powders, there has been a greater effort in preparing single crystals in pure and doped states. Such single crystals have been grown from a vapor state and from a melt state. It is also possible to grow these II-VI compounds from a solution having an excess amount of the II or VI element, *i.e.*, one can grow single crystals of ZnTe by cooling a solution in which the initial charge is ZnTe and an excess of zinc. In order to grow such crystals a knowledge of the phase diagrams is of importance. Liquidus phase diagrams of ZnSe (1), ZnTe (2), CdS (3), CdSe (4, 5), and CdTe (6, 7) are already in the literature.

Solution growth must involve a solute and a solvent. A solution of a II-VI compound as the solute and the II element as the solvent has just been mentioned. ZnTe can also be grown by cooling a solution in which the initial charge is ZnTe and an excess of tellurium. One may also use solvents other than one of the constituent elements. For example, although GaP and GaAs crystals may be grown from solutions of gallium, they can also be grown from lead, bismuth, tin, indium, selenium, tellurium, and germanium (8, 9). BP can be grown from a solution of BP dissolved in nickel (10).

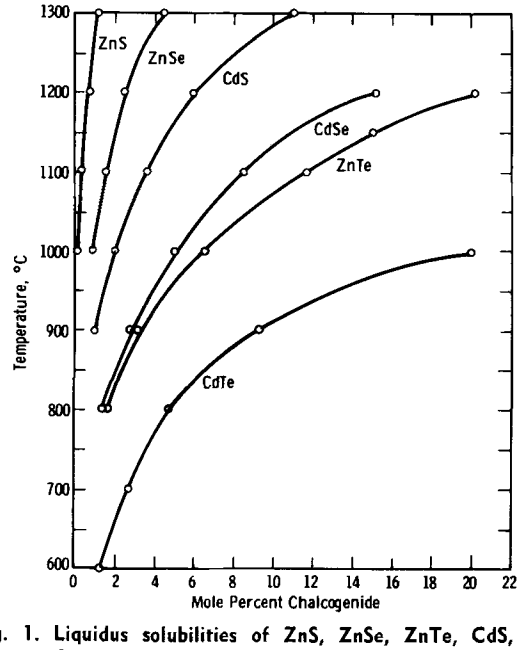

Fig. 1. Liquidus solubilities of ZnS, ZnSe, ZnTe, CdS, CdSe, CdTe as a function of temperature.

Data presented in this paper concern the liquidus solubilities of solutes ZnS, ZnSe, ZnTe, CdS, CdSe, and CdTe in a bismuth solvent.

The method used to obtain this data is the high-temperature filtration technique previously described (8). Temperature measurements were made using Pt-Pt 10% Rh thermocouples calibrated with the melting point of gold.

The bismuth used as the solvent was 99.999+% from ASARCO. The ZnS was RCA 33-Z-19 fired in H_2S at 1100°C, pressed into pellets, and fired in an evacuated tube (sealed off at a pressure less than 10^{-5} Torr) at 1100°-1200°C for 16 hr. The ZnSe was G.E. 118-8-3 purified by repeated sublimations in argon at 1300°C followed by a vapor transport (11) to produce either single crystals or masses with, at most, several crystals. The ZnTe was prepared from heating 99.999+% zinc and tellurium in argon to 500°C, and then the temperature was allowed to rise to 800°C. This material was heated in hydrogen at 600°C to remove excess tellurium. Single crystals were prepared using a vapor transport method (11). CdS was G.E. 118-8-2 material which was fired in H_2S at 1000°C followed by a vapor transport technique (11) to produce a sound mass of CdS. CdSe was prepared by sealing G.E. 118-8-4 material in a quartz tube at a pressure of less than 10^{-5} Torr and heating for several days at 950°C. The sintered material was removed from the tube and resealed at the same pressure and reheated for several days at 950°C. This yielded a hard sintered CdSe. The CdTe was prepared by heating 99.999+% cadmium and tellurium from ASARCO, sealed in a graphitized quartz ampule at a pressure less than 10^{-5} Torr, slowly to 1135°C and then slowly cooling this melt. Large single crystals were often prepared in this manner.

The mixtures of chalcogenide and bismuth were sealed in quartz tubes, maintained at temperature for 16 hr (the 1300°C experiments were maintained at temperature for 6 hr), filtered, and cooled. The filtrates and residues were separately weighed to the nearest 0.1 mg and treated with an excess of mercury at 150°C to remove the bismuth. The mercury-bismuth liquid solution was sucked off at 150°C using a small diameter tube, and finally small amounts of mercury were removed by heating the chalcogenide samples under vacuum. The chalcogenide samples were then separately weighed to the nearest 0.1 mg. Solubility measurements had a precision and accuracy of better than ±0.1 mole per cent for measurements in excess of 3 mole per cent chalcogenide and better than ±0.05 mole per cent for measurements less than 3 mole per cent chalcogenide.

The data obtained using this high-temperature filtration technique are shown in Fig. 1. It can easily be demonstrated, for the six chalcogenides, that solubility decreases as the molecular weight of the solute decreases and that solubility decreases as the sum of the tetrahedral covalent radii ($R^{II} + R^{VI}$) decreases. Needles of ZnS and platelets of the other five compounds were obtained from the filtrates.

Acknowledgments

The author would like to thank Dr. Willi Lehmann for preparing the samples of CdS, ZnSe, and ZnTe used in this paper. Also, thanks are extended to John

Burger for his assistance in the experimental phase of this work.

Manuscript received Feb. 15, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Reaction Rates on Partially Blocked Rotating Disks–Effect of Chemical Kinetic Limitations

Daniel E. Rosner

AeroChem Research Laboratories, Inc., Subsidiary of Ritter Pfaudler Corporation, Princeton, New Jersey

Gregory and Riddiford (1) noticed that a chemically inert center stud failed to appreciably alter the rate of dissolution of a zinc disk rotating in iodine solutions, despite the fact that the inert area comprised some 4% of the working surface of the disk. Pursuing this further, these authors reported data (2) on the effect of progressively blocking off the center of rotating copper disks in H_2SO_4 solutions. In a discussion of this work, Ibl (3) correctly pointed out that, if the reaction on the unblocked disk was completely diffusion controlled, then the relation between the fractional reduction in reaction rate, J/J_0, and the fractional area blockage, $f \equiv (r_0/R)^2$ (see Fig. 1), would be

$$(J/J_0)_{\text{diff}} = (1 - f^{3/2})^{2/3} \qquad [1]$$

This relation is a straightforward consequence of Levich's result for species transport to a rotating disk (4, 5), as generalized by Zaidel (4) to include the effect of an inert central region ("patch"). The resulting blockage effect is considerably different from the simple result

$$(J/J_0)_{\text{chem}} = 1 - f \qquad [2]$$

(expected if the reaction were chemically controlled) since in the partially blocked diffusion-controlled case the reduction of active area is partially compensated for by greatly improved local conditions of convective diffusion (initially thin diffusion boundary layer) in the active region.

Objective.—Clearly, Eq. [1] and [2] represent two limiting cases of a more general relation governing reactions which (in the unblocked case) are neither reaction rate controlled nor diffusion controlled. Indeed, if this more general relation were known, such measurements could offer an attractive new method for inferring the extent of diffusion control, and hence true rate constants for rapid heterogeneous reactions. The purpose of this note is to outline how this more general relation can be obtained exactly[1] and to present graphically the pertinent results. For a detailed account of the theory of partially blocked rotating disks and their interesting relation to short tubular reactors, the reader is referred to ref. (6). An excellent critical review of the now extensive use of the rotating disk system in electrochemical investigations is provided in ref. (7).

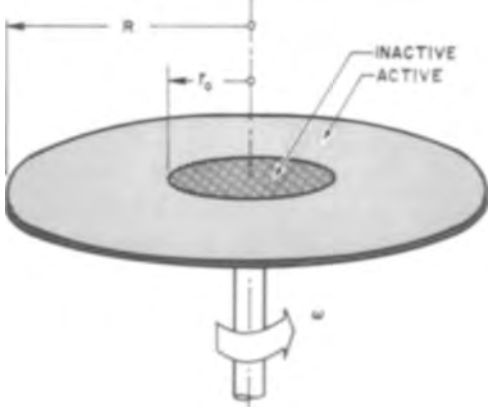

Fig. 1. Partially blocked rotating disk configuration

Outline of the analysis.—In the general case of species diffusion to a partially blocked reactive surface, outside of the nonreactive region a steady-state distribution of reactant concentration is established such that the local rate of diffusional transfer to the active disk surface is everywhere equal to that demanded by the concentration dependence of the surface reaction. While the reactant concentration (mass fraction) far from the surface, c_e, is uniform, a radial distribution of reactant concentration $c_w(r)$ is established along the surface in the region $R \geqq r \geqq r_0$. Both the local rate of convective diffusion and the local reaction rate depend on $c_w(r)$; hence, equating these two rates provides an equation for $c_w(r)$, from which all other quantities of interest can be obtained.

If δ_0 is the effective diffusion layer thickness as obtained from the Levich solution for the unblocked case,[2] then it can be shown (6) that the local mass rate of diffusional transport $-j''(r)$ to the active surface is related to the (as yet unknown) concentration distribution $c_w(r)$ by

$$-j''(r) = \frac{-D\rho}{\delta_0} \int_{\xi=r_0}^{\xi=r} \left[1 - \left(\frac{\xi}{r}\right)^3\right]^{-1/3} d[c_e - c_w(\xi)] \qquad [3]$$

At every $r > r_0$ this flux must be identically equal to the kinetic consumption rate, $-\mathcal{R}''$ independently expressible in terms of the local reactant concentration at the interface. In the special case of a first-order heterogeneous reaction $-\mathcal{R}''$ is given by $k_w \rho c_w$; hence, the reactant conservation equation at the interface

[1] *i.e.*, making no approximations other than those underlying the original Levich-Zaidel relation; *viz.* steady, laminar flow; constant physical properties (density, ρ, kinematic viscosity, ν, and Fick diffusivity, D); diffusional Prandtl (Schmidt) number $Pr (\equiv \nu/D) >> 1$; and negligible interfacial velocity.

[2] *i.e.*, $\delta_0 = [0.62048(Pr)^{1/3}(\omega/\nu)^{1/2}]^{-1}$, where ω is the disk speed.

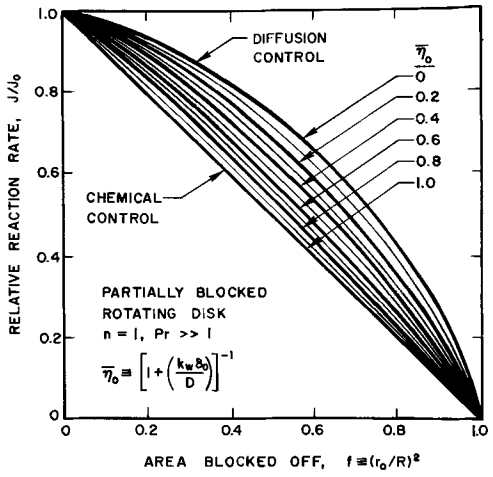

Fig. 2. Normalized reaction rate *vs.* fractional area blocked; first-order heterogeneous reaction.

takes the form of a linear, singular integral equation of the Volterra type[3]

$$k_w c_w(r) = \frac{-D}{\delta_0} \cdot \int_{\xi=r_0}^{\xi=r} \left[1-\left(\frac{\xi}{r}\right)^3 \right]^{-1/3} \frac{dc_w}{d\xi} \cdot d\xi \qquad [4]$$

Results

While local solutions to the dimensionless form of this equation can be obtained analytically, results over the entire $(k_w\delta_0/D)\,[(r/r_0)^3 - 1]^{1/3}$ range of interest are most readily obtained by numerical means on a digital computer. This has been done (6) and the results used to obtain the total reaction rate

$$-J \equiv k_w \rho \int_{r_0}^{R} c_w(r)\; 2\pi r\, dr \qquad [5]$$

from which the effects of partial blockage follow immediately. As expected, it is found that the reduction in reaction rate, J/J_0, depends not only on the fractional area blocked, $f \equiv (r_0/R)^2$ but also on the dimensionless chemical kinetic parameter $k_w\delta_0/D$. Equation [1] is recovered only when the unblocked reaction is diffusion controlled (*i.e.*, when $k_w\delta_0/D \to \infty$). Alternatively, Eq. [2] is recovered only when the unblocked reaction is chemically controlled (*i.e.*, when $k_w\delta_0/D \to 0$). Hence, by comparing the experimentally observed (J/J_0) *vs.* f relation with that predicted from Eq. [4], [5] (see Fig. 2),[4] one can infer the value of $k_w\delta_0/D$. However, rather than $k_w\delta_0/D$, we have chosen $\bar{\eta}_0$ as the parameter in Fig. 2, where

$$\bar{\eta}_0 \equiv [1 + (k_w\delta_0/D)]^{-1} \qquad (0 \leq \bar{\eta}_0 \leq 1) \qquad [6]$$

since this is the ratio of the actual reaction rate on the unblocked disk to the chemically controlled reaction rate on the same disk (5). Equivalently, $\bar{\eta}_0$ is the ratio of the apparent rate constant, $k_{w,a}$, to the true rate constant k_w. Thus, it now appears that diffusion corrections to apparent rate constants can be obtained directly[5] from careful reaction rate measurements on partially blocked disks.

It should be remarked that near the extreme of complete blockage (f near 1)[6] simple rational approximations can be obtained.[7] Thus, provided $\bar{\eta}_0$ is not too small, a first approximation to $\bar{\eta}_0$ (written $\bar{\eta}_0^{(0)}$) can be computed from

$$\bar{\eta}_0^{(0)} = (1-f)/(J/J_0)_{\text{observed}} \qquad [7]$$

which overestimates the true value of $\bar{\eta}_0$ with a relative error of about

$$\tfrac{3}{4}\,(0.8269934)\,[(1-\bar{\eta}_0^{(0)})/\bar{\eta}_0^{(0)}]\,(1-f)^{1/3} \qquad [8]$$

It is hoped that the present results, and similar exact "blockage effect" calculations under way for other flow reactor configurations, will provide the basis for a useful approach to the experimental inference of diffusion corrections and kinetic constants for rapid heterogeneous reactions.

Acknowledgments

It is a pleasure to acknowledge G. D. Bleich for programming the solution of Eq. [4] and A. Crossley for her assistance in presenting the results.

[3] An identical equation governs the finite rate dissolution problem. In that case the local dissolution rate, $\mathcal{R}''$, is expressible in the form $k_w\rho \cdot (c_{w,eq} - c_w)$, where $c_{w,eq}$ is the equilibrium (or "saturation") value of the transferred species mass fraction at the wall. The equation governing the ratio $(c_{w,eq} - c_w)/(c_{w,eq} - c_e)$ is the same as Eq. [4], and the results presented below for the total normalized reaction rate, J/J_0, therefore apply to the case of dissolution as well. It should be reiterated that the present results are exact only in the absence of appreciable interfacial velocities. As discussed in ref. (8), this implies that the condition $(c_{w,eq} - c_e) \ll (1 - c_{w,eq})$ must be satisfied.

[4] A full-scale plot of these results is available from the author on request.

[5] Incidentally, on treating the 25°C data of ref. (2) in this way (allowing for some experimental scatter) we estimate that $\bar{\eta}_0$ was between 0.1 and 0.2, corresponding to a nearly diffusion-controlled dissolution.

[6] This corresponds to the use of a "ring" (electrode or active surface) of width $\Delta r \ll r_0$ in which case $1 - f$ may be identified with $2(\Delta r/r_0)$.

[7] Perhaps the simplest function that can be constructed to approximate the exact J/J_0 *vs.* f relation over the entire range of f and $\bar{\eta}_0$ is

$$J/J_0 \approx \{[\bar{\eta}_0/(J/J_0)_{\text{chem}}] + [(1-\bar{\eta}_0)/(J/J_0)_{\text{diff}}]\}^{-1}$$

However, this relation is found to be inadequate for inferring accurate values of $\bar{\eta}_0$ from experimental rate *vs.* area blockage data.

Brief Communications

The Pseudobinary System Ge-GaAs

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Recently, several papers in which the liquid-solid equilibria in the Ge-GaAs pseudobinary system was discussed have appeared in the literature (1-3). Although there is agreement that the system is essentially simple binary eutectic in nature, there is considerable disagreement as to the position of the liquidus curve and the temperature and composition of the eutectic.

During studies of the Ga-As-Ge ternary system (4), this author determined the liquidus and eutectic temperatures at several compositions along the Ge-GaAs pseudobinary. These data, along with the previously reported data, are shown in Fig. 1.

It should be noted that Glazov and Malyutina (1), Takeda *et al.* (2), and this author agree quite well as to the eutectic composition (~ 16 mole % GaAs), while Lieth and Heyligers (3), Takeda *et al.* and this author agree very well on the eutectic temperature (663° ± 3°C). The major discrepancies are the liquidus and eutectic temperatures of Glazov and Malyutina, and the liquidus curve and eutectic composition of Lieth and Heyligers (3). The liquidus and eutectic temperatures of Takeda and this author are in fair agreement.

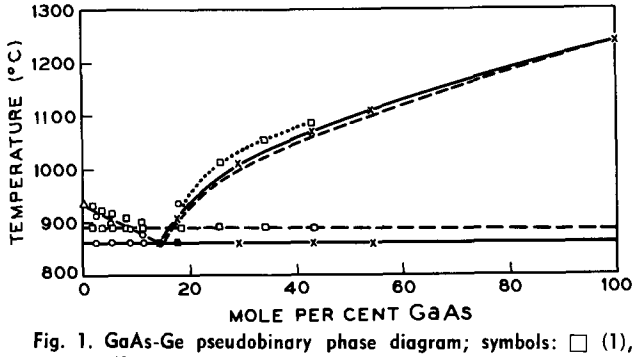

Fig. 1. GaAs-Ge pseudobinary phase diagram; symbols: □ (1), — — — (2), X this work, ○ (5), △ (6).

If the latter data are taken as essentially correct, the higher temperatures of Glazov and Malyutina may be ascribed to a thermometric discrepancy. It is more difficult to account for the data of Leith and Heyligers. The agreement between the eutectic temperatures eliminates any serious thermometric error or the possibility of serious component contamination by impurities. It is possible that the discrepancy between their data and that of Takeda and this author arises from an error in the way composition was reported. The assumption can be made that Lieth and Heyligers reported as mole per cent GaAs a quantity which was actually weight per cent GaAs. Their revised data (5) are shown in Fig. 1 and, except for one point, are in good agreement with the data of Takeda and this author.

Adsorption of Perchlorate Ions on Gold

J. D. Goodrich and G. M. Schmid

Department of Chemistry, University of Florida, Gainesville, Florida

In the course of a previous study of the differential capacity of the electrical double layer on a gold electrode in 1.0-0.01M perchloric acid solution (1) a hump in the capacity-potential curve at 0.4-0.8v *vs.* a standard hydrogen electrode (SHE) was ascribed to the adsorption of perchlorate ions on the electrode. To obtain experimental support for this assumption we attempted to measure the depletion of perchlorate ions from a very dilute solution in contact with gold foil polarized to various points in the indicated potential range.

Gold foil (fine gold, Engelhard Industries, Inc.) of 40 cm^2 apparent area was shaped into a tube and embedded at the bottom into Kel F-100 wax in a Pyrex cell. Electrical contact was provided by a gold wire welded to the foil. This test electrode was concentric to a polarizing electrode made of gold wire of about 1 cm^2 area. The reference electrode was a hydrogen saturated palladium wire (+ 50 mv *vs* SHE) (2). The volume of the cell was approximately 10 ml.

The test electrode was etched in aqua regia, cleaned in sulfuric acid-dichromate solution, and soaked in triple distilled water for several days. Helium, saturated with water vapor, was passed over the system for several hours prior to and during a run. The cell was polarized with a Sensitive Research Instrument model PV potentiometer; the potential was monitored with a Keithley model 610B electrometer.

Perchlorate ions, in 10 ml of solution, before and after a run, were determined spectrophotometrically after extraction with methylene blue according to Iwaski, Utsumi, and Kang (3) in the range 0.04-1.00

Table I. Polarization data: gold in perchloric acid

Concentration, M x 10^6	Potential, v *vs.* SHE	Time polarized, hr
2.072	0.50	2.5
2.072	0.25	6
1.036	0.30	3

ppm. By weighing all solutions to 0.01 mg and keeping the ambient temperature to 23° ± 1° the average deviation of the method could be kept to ±0.01 ppm (28 determinations).

Table I gives a sample of the perchloric acid concentrations used, the polarizing potentials, and the duration of polarization. No concentration change was noted in any of the experiments. With the method of determination used a concentration change of 0.01 ppm in 10 ml, or 6 x 10^{14} perchlorate ions, should have been detected. The coverage of the test electrode under the conditions employed here is therefore less than about 10^{13} perchlorate ions/cm^2 of apparent area, or less than about 1 % of a monolayer, not taking into account a roughness factor which is certainly greater than unity.

It should be pointed out that these results do not invalidate the assumption of perchlorate adsorption on gold made previously (1). The perchlorate ion adsorption we failed to detect here would be for a system in equilibrium with 10^{-6}M perchloric acid, whereas the assumption was originally based on work with 1.0-0.01M solutions.

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of the Electrochemical Society, Vol. 112, No. 1, 6, 7, 8, 9, 10, 11, and 12 (January and June to December 1965). Discussion not available for this issue will appear in the Discussion Section of the December 1966 JOURNAL.

Catalytic Decomposition of Aqueous Formic Acid on Platinum Electrodes

D. R. Rhodes and E. F. Steigelmann (pp. 16-21, Vol. 112, No. 1)

W. Vielstich and U. Vogel[1]: In a series of publications it has been shown by different investigators that during the anodic oxidation of formic acid in acid electrolytes an intermediate product is formed which blocks the surface in a certain potential region. Anodic potential scans show three current peaks (at 0.5, 0.8, and 1.3v *vs.* H_2 electrode). In the region of the first peak the intermediate is formed; at the potential of the second peak the intermediate is oxidized to CO_2.

Rhodes and Steigelmann assume that the intermediate product is carbon monoxide formed by catalytic decomposition of HCOOH into CO and H_2O. Potential scan diagrams with HCOOH and CO are performed in order to prove this hypothesis.

In their experiments the authors observe a small difference (30 mv at a sweep rate of 1.2 v/sec, see their Table I) between the potential of the peak for CO and the potential of the second formic acid peak, especially during the first sweep, their Fig. 1 and 3. Nevertheless Rhodes and Steigelmann suggest that two peaks are caused by the oxidation of the same species.

In our laboratory we have repeated the above mentioned experiment,[2] recording the current/potential diagrams (corresponding to their Fig. 1 and 3) on the same figure. This diagram (our Fig. 1) clearly shows:

[1] Institut fuer Physikalische Chemie der Universitaet Bonn, Wegelerstrasse 12, Bonn, Germany.

[2] W. Vielstich and U. Vogel, Unpublished results.

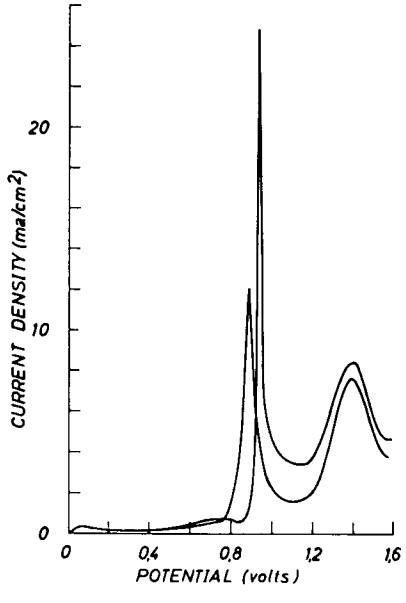

Fig. 1. First sweep of 0.085M HCOOH in 1*N* H_2SO_4 at 30°C on 1 cm^2 smooth Pt, sweep rate of 260 mv/sec; (*a*) N_2 stirring; (*b*) CO stirring.

(*a*) the difference in potential between the two peaks is very pronounced and amounts to about 60 mv; (*b*) the rising part of the CO peak is so sharp that due to adsorbed carbon monoxide only a very small current should be possible in the region of the formic acid peak.

In addition to the different shape of the current/potential diagrams there exists another strong argument against the assumption of carbon monoxide as intermediate product. Johnson and Kuhn[3] have made a simultaneous determination of the number of coulombs and the number of chemical equivalents of reduced CO_2; these species are identical with the intermediate product of formic acid oxidation.[4,5] Instead of the number of 2 electrons per particle stated in the paper[3] one of the authors recently informed us that, due to an error in calculation, the true number is one electron per particle.[5a]

Therefore, the results of Johnson and Kuhn[3, 5a] are in agreement with our own conclusion[4,5] that the intermediate product should be a formate radical, prob-

ably of the form 
.

D. R. Rhodes and E. F. Steigelmann: The figure presented by Vielstich and Vogel does clearly show a

[5a] A. T. Kuhn, private communication.

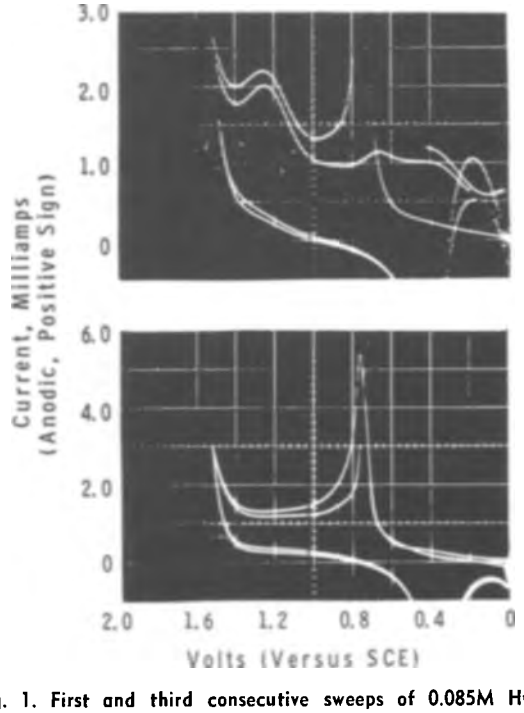

Fig. 1. First and third consecutive sweeps of 0.085M HCO_2H (top) and saturated CO (bottom) in 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 1.2 v/sec.

difference of 60 mv between the peaks for the first sweep of formic acid and carbon monoxide. Therefore, we have reexamined our curves from similar experiments.

One set of such curves is given in this discussion. These were used to sketch the figures given in our original article. They were obtained at a sweep rate of 1.2 v/sec and at a starting potential of 0.0v *vs.* SCE. The first sweep in each photograph is represented by the tallest peak at about +0.7v. The third sweep in each photograph, which was obtained by closing the camera shutter during the second sweep, shows that the peaks at about +0.7v have shifted slightly in the negative direction for both formic acid and CO. This effect was discussed in the original article.

Our figures show that we obtained a difference of 30 ± 10 mv between the formic acid and CO peak at about 0.7v during the first sweep. A check of the rest of our original data given in the article in Table I for the various sweep rates showed that the differences listed were accurate to ± 10 mv. Because we might have made some error during this series of experiments, we examined another set of similar data taken several days earlier. Once again the data fit to within ± 10 mv. We had also recorded sweeps of CO and formic acid oxidation on a recorder at sweep rates equal to 0.13 v/sec and lower. In each case the corresponding *dv/dt* curve had been recorded. At 0.13 v/sec the difference between the two peaks during the first sweeps was 20 ± 10 mv.

From the above discussion we conclude that the difference in peak voltages listed in Table I of the original article is a real effect and not an experimental error. Therefore, the difference between our results and that by Vielstich and Vogel must be a difference in experimental parameters. One obvious difference is that we started our sweeps at 0.0v *vs.* SCE (0.245v *vs.* NHE); whereas, they started their sweeps at 0.0v *vs.* NHE, which is well within the hydrogen region. It is known that the type of adsorption of CO affects the potential where it is oxidized [our figure here and Ref. (6)]. Perhaps the results by Vielstich and Vogel reflect the effect of hydrogen on CO oxidation and/or formic acid adsorption.

Perhaps the most important point brought out by Vielstich and Vogel is that Johnson and Kuhn[7] have changed from two electrons per particle to one electron per particle for the intermediate product of formic acid oxidation. We do not feel like making any comment on this change until it is made public.

On the Potential/*p*H Diagrams of the Cu-NH_3-H_2O and Zn-NH_3-H_2O Systems

H. E. Johnson and J. Leja (pp. 638-641, Vol. 112, No. 6)

F. Letowski and J. Niemiec[8]: The potential/*p*H diagrams given by Johnson and Leja as well as the potential/*p*H diagrams discussed by them and developed by Mattsson[9] enabled the authors to interpret the results of studies on the corrosion of brass in aqueous ammonia and ammonium salts solutions. Johnson and Leja disputed in their paper the correctness of the position of the stability ranges of Cu_2O and CuO oxides as well as those of the basic cupric sulfate $Cu(SO_4)_{0.25}(OH)_{1.5}$ on the potential/*p*H diagrams given by Mattsson. According to Johnson and Leja the oxides CuO_2 and CuO are stable, in 0.05M solution of Cu and 1.0M of NH_3 and NH_4^+ at *p*H values exceeding 11, but these compounds are not stable in the *p*H range 3-7.5 determined by Mattsson. In the discussion below it is shown, on the basis of the equilibria determined by Johnson and Leja and Mattsson,[9] that the solid phases in question are also stable in both of the *p*H ranges discussed.

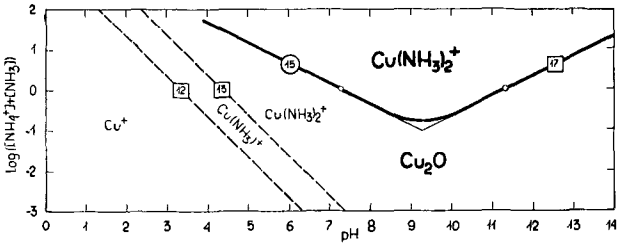

Fig. 1. Influence of pH and total NH_3 + NH_4^+ activities on the solubility ranges of Cu_2O at 25°C (total dissolved Cu =0.05M; □—equilibria according to Johnson and Leja; ○—according to Mattsson).

According to Johnson and Leja the equilibrium of their reaction [17], dissolution of Cu_2O in ammonia solution,

$$Cu_2O + 4NH_3 + 2H^+ = 2Cu(NH_3)_2^+ + H_2O \quad [17]$$

is described by

$$pH = 9.99 + 2\log[NH_3] - \log[Cu(NH_3)_2^+]$$

The equilibrium [17] is shown in the plot of log ($[NH_3 + NH_4^+]$) *vs.* pH at Cu activity 0.05M in Fig. 1. It is valid merely within the range of NH_3 predominance, *i.e.*, at *p*H values higher than 9.26. At *p*H values lower than 9.26 the NH_4^+ ions prevail and equilibrium [17] (Johnson and Leja) becomes senseless. As determined by Mattsson for the reaction

$$0.5Cu_2O + 2NH_4^+ = Cu(NH_3)_2^+ + H^+ + 0.5H_2O$$

the equilibrium

$$pH \quad 8.56 - 2\log[NH_4^+] + \log[Cu(NH_3)_2^+] \quad [15]$$

becomes valid in this region. A plot of this equilibrium is shown in Fig. 1 at Cu activity 0.05M. Near *p*H 9.26 the NH_3 and NH_4^+ concentration (or activities) change with *p*H logarithmically; in Eq. [17] and our [15] their sum $[NH_3]$ + $[NH_4^+]$ should be taken into account instead of the individual $[NH_3]$ and $[NH_4^+]$ activities. A gently transition of equilibrium [17] into [15] is thus obtained and, for *p*H 9.26, the logarithm of the sum of activities at which the solution over Cu_2O is saturated with $Cu(NH_3)_2^+$ is equal to —0.7. The ordinate values of the points situated in equilibrium curves [17] and [15] (Fig. 1) at a total $[NH_3]$ + $[NH_4^+]$ = 1.0M should define the positions of these equilibria on the potential/*p*H diagrams of a Cu-NH_3-H_2O system; the first one extends toward the right from *p*H 11.29 (Johnson and Leja) and the second one toward the left from *p*H 7.26 (Mattsson).

By plotting the CuO and $Cu(SO_4)_{0.25}(OH)_{1.5}$ dissolution equilibria as log ($[NH_3]$ + $[NH_4^+]$) against *p*H (Fig. 2) one obtains evidence that the stability

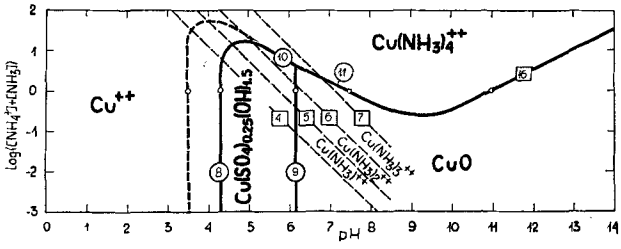

Fig. 2. Influence of pH and total NH_3 + HN_4^+ activities on the solubility ranges of CuO and $Cu(SO_4)_{0.25}(OH)_{1.5}$ at 25°C (total dissolved Cu = 0.05M; □—equilibria according to Johnson and Leja; ○—according to Mattsson; --- according to Bustorff and Muylder, and Letowski and Niemiec).

[9] E. Mattsson, *Electrochim. Acta*, 3, 279 (1961).

ranges of these solid phases were correctly placed by Johnson and Leja in the range of pH values higher than 10.95 and by Mattsson in the pH range 4.28-7.46. In conclusion, a correct image of the Cu-NH_3-H_2O system equilibria, based on thermodynamic data used by Johnson and Leja, and Mattsson, is obtained by superimposing their potential/pH diagrams [*This Journal*, **112**, 629, Fig. 2a and 2b]. The solubility limits of the basic cupric sulfate $Cu(SO_4)_{0.25}(OH)_{1.5}$ also seem to be controversial. Therefore, these limits in a 0.05M copper solution and 1.0M total ammonia and ammonium ions solution were also indicated in Fig. 2 by a dotted line, according to the potential/pH equilibria of the Cu-H_2O-H_2SO_4 system developed by Bustorff and Van Muylder[10] as well as the Cu-H_2O-NH_3-H_2SO_4 system developed by Letowski and Niemiec.[11] These differences in the solubility ranges of the basic cupric sulfate result from differences between the thermodynamic data used for elaboration of these systems.

Johnson and Leja have also argued the occurrence of the $Zn(OH)_2$ stability range in the potential/pH diagram of the Zn-NH_3-H_2O system made by Mattsson.[9] It follows, however, from the dissolution equilibria of zinc hydroxide shown in Fig. 3 that the presence of the $Zn(OH)_2$ stability range in the potential/pH diagram of the Zn-NH_3-H_2O system made by Mattsson is not in contradiction with the equilibria given by Johnson and Leja [*This Journal*, **112**, 640, Fig. 3a and 3b], as these diagrams are made for different zinc activities in solution (Mattsson, 0.01M; Johnson and Leja, 0.001M). The positions of the equilibria in Fig. 3 at $[NH_3] + [NH_4^+] = 1.0M$ are denoted by the points. The ordinate values of these points define the pH values at which the ZnO hydrat dissolution equilibria should be placed in the potential/pH diagram. For Zn activity = 0.01M (Mattsson), two stability ranges of zinc hydroxide should appear; the first one is comprised of the pH range 6.54-7.48 defined by equilibria [18] and [19] according to Mattsson[9]; the second one should be in the pH range from 11.19 to 13.89 limited by the equilibria of the reactions

$$Zn(NH_3)_4^{++} + H_2O = ZnO + 4NH_3 + 2H^+$$

$$pH = 10.19 + 2 \log [NH_3] - 0.5 \log [Zn(NH_3)_4^{++}]$$

according to the authors of the present discussion and

$$ZnO + H_2O = ZnO_2^{--} + 2H^+$$

$$pH = 14.89 + 0.5 \log [ZnO_2^{--}]$$

according to Pourbaix.[12] For Zn activity = 0.001M (Johnson and Leja) there should be only one ZnO hydrat stability region in the pH range from 11.69 to 13.39 which is determined by the above two equilibria.

Plotting of equilibria [21] and [22] in the potential/pH diagram of the Zn-NH_3-H_2O system of Johnson and Leja [*This Journal*, **112**, 640, Fig. 3b] does not seem to be justified. According to the Pourbaix's definition[12] these equilibria should separate the relative predominance ranges of Zn^{++} from those of $Zn(NH_3)_3^{++}$ and $Zn(NH_3)_3^{++}$ from $Zn(NH_3)_4^{++}$. However, because of the close positions of these equilibria such a situation never occurs. In Fig. 3 a dependence of pH and percentage contents of a more basic form in 1.0M total $NH_3 + NH_4^+$ solution is shown. The $Zn(NH_3)_3^{++}$ ions will never occur in concentrations equal to those of the neighboring ions. The maximum contents of the $Zn(NH_3)_3^{++}$ ions do not exceed 14%, so in the whole pH range in question the Zn^{++} or $Zn(NH_3)_4^{++}$ ions prevail.

The argument for the localization of oxide phases made by Johnson and Leja on the basis of ΔG° values as well as their questioning of the stability ranges of solid phases defined by Mattsson, seem to be unnecessary; ΔG° depends on the stability constants according to $\Delta G^\circ = -RT \ln K$, and the effect of the thermodynamic potential on equilibria is manifested in the equilibrium constants themselves which, on the other hand, determine the position of equilibria on the potential/pH diagram.

H. E. Johnson and J. Leja: We are grateful to Messrs. Letowski and Niemiec for their contribution which helped us to pin-point the source of error in the issue under discussion.

The attempt of theirs to strike a compromise between Mattsson's and our evaluation does not agree with our limited evidence that the system copper-ammonia does not show the development of Cu_2O tarnish in the pH range indicated by Mattsson (if precautions are taken to eliminate CO_2). Secondly, it seems inconceivable that the domains of stability of $Cu(NH_3)_2^+$ and Cu_2O, Fig. 1 of Letowski and Niemiec, can be separated by two lines thus endowing the same two species with an alternately reversed acid-basic characteristics.

We cannot agree that reaction [17] "becomes senseless" at pH values below 9.26 where NH_4^+ ions outnumber NH_3 groups; analogous reasoning would lead to the conclusion that reactions involving hydrogen ions are senseless at pH values above 7.0 where they are outnumbered by their hydroxyl ion counterparts. The crux of the present problem is the seeming inconsistency of Eq. [17] and [15]. Letowski and Niemiec have suggested a compromise which involves the sum of the $[NH_3]$ and $[NH_4^+]$ activities; it is interesting to note that a third modification of equations [17] and [15] can be written to express the dissolution of Cu_2O in terms of both NH_3 and NH_4^+ as follows

$$Cu_2O + 2NH_4^+ + 2NH_3 = 2\,Cu(NH_3)_2^+ + H_2O$$

Note that since this equation involves neither redox reactions no hydrogen ions it cannot be represented on a potential/pH diagram. Equation [17], on the other hand, considers the ligand rather than the undissociated ion, NH_4^+, and seems to represent the actual experimental observations.

Influence of pH and total $NH_3 + NH_4^+$ activities on the solubility of ZnO hydr. and the influence of pH on the percentage contents of Zn^{++}, $Zn(NH_3)_3^{++}$ and $Zn(NH_3)_4^{++}$ in 1.0M solution of $NH_3 + NH_4^+$ (□—equilibria according to Johnson and Leja; ○—according to Mattsson).

Hydrogen Peroxide Reactions on Gold Electrodes

A. K. M. S. Huq and A. C. Makrides (pp. 756-757, Vol. 112, No.7)

G. Bianchi, F. Mazza, and T. Mussini[13]: As far as gold in acid solutions of hydrogen peroxide is concerned, the reaction which determines the rest potential and the reaction which gives support to significant currents should be taken into account distinctly. In fact,

[13] Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy.

the reaction which determines the rest potential of gold has a very low exchange current, and cannot support currents significant and constant in the time.[14]

In our papers cited by Huq and Makrides, in a prior one,[15] and in a subsequent one[16] dealing explicitly with the process of oxygen and hydrogen peroxide on gold electrodes, we proposed the mechanism

$$H_2O_2 + 2H_{ads} \rightarrow 2H_2O$$

to explain the cathodic process at current densities ranging from 5×10^{-5} to 10^{-3} amp/cm^2. The range of electrode potentials corresponding to this range of current densities is + 0.4 to — 0.1v (NHE) and is not incompatible with the mechanism cited above, if the preceding reaction is rapid and no H_{ads} accumulation on the gold surface takes place.

As for the slope of the Tafel's line, the values one can draw from the Huq and Makrides' graph in the case of 10^{-3} m H_2O_2 solutions are 0.18 for increasing current densities and 0.30 for decreasing ones, respectively. Within the same range of current densities as above, we found a 0.18 slope in agreement with the previous results of Akopyan[17] who also made a distinction of processes occurring at currents either higher or lower than 5×10^{-5} amp/cm^2. Setting aside the question of the reaction which determines the rest potential of gold, as it is the subject of a next paper, we think that at present there is no argument to make inapplicable the mechanism we proposed for the cathodic reduction of hydrogen peroxide on gold at significant currents ranging from $5 \cdot 10^{-5}$ to 10^{-3} amp/cm^2.

As concerns the anodic reaction, we proposed a mechanism involving an adsorbed surface oxide and not the gold bulk oxide, the reactivity of the latter besides being the lower as the nobler is its anodic potential of formation.[17] The fact that at the + 1.4v (NHE) potential an anodic inhibition takes place, due to a beginning occurrence of the gold bulk oxide,[18] is not an argument against that mechanism since we proposed it in terms of a H_2O_2 anodic oxidation by reaction with an adsorbed surface oxide which forms within + 1.0 and + 1.4v (NHE), in the case of gold.

The Absorption of Electrolytically Generated Hydrogen

F. Matsuda and T. C. Franklin (pp. 767-771, Vol. 112, No. 8)

G. Dubpernell[19]: It is not believed that hydrogen can diffuse through solid iron at room temperature,[20] but rather that any diffusion is associated with pores or defects in the structure of the metal. It is noted that the iron membranes were prepared by etching shim steel sheet with 1M nitric acid, and that the membrane in Fig. 12 was 3.0×10^{-3} cm thick (0.0012 in.) and in Fig. 13, 2.5×10^{-3} (0.001 in.) thick.

It would be of interest to know how long the membranes were etched, and what was their original thickness. Was the loss in weight determined? How was the final thickness measured? Was any effort made to check whether or not the membranes had any pores or holes in them?

F. Matsuda and T. C. Franklin: The two membranes studied in this article were prepared from commercially available shim steel. The 3×10^{-3} cm membrane was prepared by severe etching of a sheet 0.003 in. thick in 1M nitric acid, while the 2.5×10^{-3} cm membrane was obtained by dipping a 0.001 in. sheet briefly in acid and immediately removing and rinsing. Thus the thinnest membrane was (as indicated by a micrometer caliper) essentially unetched 0.001 in. shim steel. In view of the fact that the results on the two membranes (prepared from different samples of starting material, etched in one case severely and in the other case negligibly, and having different final thickness) gave, when corrected for thickness, almost identical rate constants (4.3×10^{-5} and 4.8×10^{-5} cm/min) strongly indicates that migration could not have occurred by something so haphazard as holes.

In addition it should be pointed out that an iron membrane with a thickness of 0.003 in. (7.5×10^{-3} cm) (after degreasing and dipping briefly in nitric acid) was used in some early experiments. The results obtained were qualitatively the same as those indicated in the paper. This membrane was not used for quantitative runs because the increased thickness extended the time for a complete run beyond a convenient value. It is difficult to imagine pores in a membrane this thick.

In order to further check on this question two other experiments were run: (A) A new iron crucible with a wall thickness of 0.08 cm, after degreasing and a momentary dip in 1M nitric acid, was filled with 2*N* sodium hydroxide containing some potassium permanganate. Hydrogen was generated electrolytically on the exterior of the crucible immersed in 2*N* sodium hydroxide solution. The color of the permanganate solution was compared with that of a blank run, identical in every respect, except for the fact that hydrogen was not generated on the exterior wall of the crucible. Although the permanganate undergoes some decomposition on its own and there is some reduction by the iron, it was obvious after 1 hr, even to the naked eye, that the rate of reduction in the crucible acting as a hydrogen membrane was much greater than the rate of reaction in the blank. This increased reduction rate could only be caused by hydrogen passing through the iron crucible. Again, it is difficult to visualize the presence of pores in a new iron crucible. (B) Some measurements were made on the amount of hydrogen codeposited in the electrolytic deposition of iron. The plating bath consisted of 213g of ferrous sulfate ($FeSO_4 \cdot 7H_2O$) in one liter of solution with the pH maintained at 2.8-3.5 with sulfuric acid. The bath temperature was 45°C and the current density was 17.3 ma/cm^2. The cathode and the anode were prepared from Baker Analyzed Reagent Grade iron wire. The cathodes (21 cm long) were degreased in kerosine, rinsed in distilled water, dipped in 1-1 nitric acid and rinsed in distilled water. After plating, the amount of hydrogen codeposited with the iron was measured by the coulometric technique described in this paper and in the paper by Franklin and Goodwin.[21]

The amount of hydrogen found codeposited in iron by the coulometric method should increase linearly with increasing thickness of the deposit. However, at some thickness this increase should begin to depart from linearity because the method can only analyze for the amount of hydrogen that can diffuse to the surface during the time that the voltage sweeps through the hydrogen region. (Approximately 3 min.) Figure 1 shows the results obtained in a series of runs. It can be seen that the data is linear throughout the range covered by these experiments. Using the density of iron the largest deposit was calculated to be 2.3×10^{-3} cm thick. To explain this linear graph by migration only through pores or defects would require that such pores or defects be continuous throughout the deposit. Although possible, this does not seem probable. Migration along grain boundaries seems to

Oxygen Overvoltage Measurements on Bright Pt in Acid Solutions, III. Nitric Acid Passivated Bright Platinum

J. P. Hoare (pp. 849-853, Vol. 112, No. 8)

J. A. Shropshire[22]: In reading the author's analysis of the effect of concentrated HNO_3 on the oxygen reduction in acid solution, I was disappointed that he failed to mention possible effects other than formation of a complex oxide structure. It is well known, for instance, that a platinum electrode in H_2SO_4 solution containing HNO_3 can exhibit extremely noble potentials, comparable to those for reversible oxygen, as a result of the complex NO, HNO_2, *etc.*, equilibrium.[23,24] It would appear that much of the transient behavior reported in this work, both cathodic and anodic to the reversible oxygen potential could be explained in terms of strongly adsorbed NO, HNO_2, species which can be removed by severe cathodization or anodization. The reduction of adsorbed HNO_2 coupled with an oxygen regeneration of the reduced product *in situ* might well support the observed cathodic currents. The efficient function of an adsorbed molybdate species in just this fashion is known in the oxidation of HCHO and CH_3OH at a platinum electrode in H_2SO_4.[25]

Although no coulombic data are available from the paper it would be interesting to see if the quantity of anodic coulombs consumed in the initial anodic transition shown in, *e.g.*, Fig. 4 in the paper corresponds to oxidation of monolayer quantities of material. As mentioned previously, I think it would be desirable to have the author recognize and comment on these possibilities.

J. P. Hoare: The comments of Dr. Shropshire are well taken and were a source of some concern as pointed out earlier.[26] However, it was noted that the high anodic potentials (about 1.28v) were observed by Vetter[27] when the nitric acid concentration ranged from 7 to 14.5N. Nitric acid concentrations studied by Shropshire and Tarmy[28] extended from 0.2 to 1M. Since the nitric acid treated electrodes used in these polarization studies[29] and referred to as Pt-O-alloy electrodes[30] were soaked in triply distilled water for at least one-half hour with at least five changes of water before being plunged into O_2-saturated, H_2O_2-free, 2N H_2SO_4 solution, it was considered safe to assume that a NO_2/NO couple was not potential-determining.[26] The concentration of HNO_3 in this case is minuscule.

In some recent studies,[31] treated and untreated samples of Pt were examined with x-ray diffraction techniques. The results show that only Pt diffraction lines were obtained in both cases except that the lines were slightly shifted in the treated case. From the results of vacuum fusion studies, the treated samples in every case not only contained more oxygen but also contained the same or even less nitrogen than the untreated samples.

It is concluded[31] that the treatment of Pt with HNO_3[26] permits more oxygen to be dissolved in the surface layers of the metal. This oxygen exists as an alloy of Pt and O atoms in these surface layers. Finally, this skin of Pt-O alloy is a better catalyst for many electrode reactions[29,32] than bare Pt. It must be remembered that the presence of adsorbed oxygen on the metal surface may inhibit the reduction of oxygen[33,34] but oxygen dissolved in the metal accelerates the reduction of oxygen.[29]

Consequently, explanations for the electrochemical behavior of the Pt-O-alloy electrode involving adsorbed NO, HNO_2, and the like must be rejected.

Electrochemical Studies of NO^+ and NO_2^+ in Concentrated H_2SO_4

L. E. Topol, R. A. Osteryoung, and J. H. Christie (pp. 861-864, Vol. 112, No. 8)

G. Bianchi and T. Mussini[35]: As concerns reaction [i] $NO^+ + e \rightarrow NO$ with subsequent stage [ii] $2NO + 2H^+ + 2e \rightarrow H_2N_2O_2$ or the possible alternative stage [iii] $NO + 3e + 4H^+ \rightarrow NH_2OH_2^+$ depending on the appearance of hydroxylamine as a final product of reaction, it is to be pointed out that results obtained with mercury electrodes cannot apply validly to the case of platinum, apart from the fact that platinum can exert a catalytic intervention[36,37] in the reaction [iv] $4NH_2OH_2^+ \rightarrow 2NH_4^+ + H_2N_2O_2 + 2H_2O + 2H^+$. Moreover, reaction [v] $NH_2OH + NO^+ \rightarrow H_2N_2O_2 + H^+$ (or else $NH_2OH + HNO_2 \rightarrow N_2O + 2H_2O$) can take place[38,39]; this is very rapid in the intermediate concentration range of H_2SO_4 (from 4 to 14M). The results obtained by Masek and Przewlocka[40] working with a platinum vibration electrode show a wave at the + 0.43v (SCE) half-wave potential, very near the + 0.70v (NHE) potential we proposed for reaction [i].[41] On mercury the half-wave

potentials are[42] about 0.0v (SCE) for reaction [i] and about —1.0v (SCE) for reaction [iii].

As for the anodic process of NO^+ oxidation to N_2O_4 and the rapid disproportionation of N_2O_4 in 96% w/w H_2SO_4, it is to be pointed out that the N_2O_4 disproportionation is very rapid at low H_2SO_4 concentrations (< 58% w/w): $N_2O_4 + H_2O \rightarrow HNO_3 + HNO_2$; and also at higher H_2SO_4 concentrations (> 85% w/w): $N_2O_4 + H_2SO_4 \rightarrow HO{\cdot}SO_2{\cdot}NO_2 + HNO_3$. At intermediate concentrations of H_2SO_4, corresponding to the field where we observed the anodic wave of NO^+ oxidation to N_2O_4, the velocity of N_2O_4 disproportionation may verify a minimum.[43] In a recent paper[44] the results obtained with the rotating-disk electrode method proved that the process $2NO^+ + 2H_2O - 2e \rightarrow N_2O_4 + 4H^+$ is a first-order reaction, whose standard potential is $E^\circ = +1.25$v (NHE).

In our opinion platinum exerts a catalytic action on the processes of nitrogen oxides. The results, particularly anodic curves, may be really affected by the surface state of the electrode, as it has been shown also in the work under discussion. For analogy with order cases[45] we consider the degassing of platinum electrodes *in vacuo* at 500°C to be essential. No direct comparison is possible with results obtained working with different metals, like gold or mercury.

L. E. Topol, R. A. Osteryoung, and J. H. Christie: In regard to Bianchi and Mussini's comment on the formation of $H_2N_2O_2$ or $NH_2OH_2^+$ we would like to point out that the dispute actually concerns them and Masek[46,47] and Przewlocka.[47] We did not work in the acid concentration range where the occurrence of the above electrode reaction products were reported.

As for the oxidation of NO^+ to N_2O_4, even if the disproportionation of N_2O_4 is slow in intermediate acid concentrations as claimed, we did not see any sign of NO_2^+ in the 96% solution. The reported formation[48] of N_2O_4 in this solution with its rapid subsequent disproportionation would yield NO_2^+ as well as NO^+ and the NO_2^+ should be detected in our studies.

Preferential Vaporization of Carbon from Hafnium Carbide

R. L. Hansler (p. 881, Vol. 112, No. 8)

Charles P. Kempter[49]: Dr. Hansler has cited only one reference relating the lattice parameter of hafnium carbide to composition and no references relating the electrical resistivity to lattice parameter and/or composition. In addition to Avarbe *et al.*, Cotter and Kohn,[50] Krikorian, Witteman, and Bowman,[51] Goretzki,[52] Bittner and Goretzki,[53] Nowotny, Benesovsky, and Rudy,[54] Krikorian, Wallace, and Anderson,[55] Adams and Beall,[56] Zhelankin and Kutsev,[57] Houska,[58] and Sara[59] have studied the lattice parameters of known compositions of hafnium carbide. A plot of all of these data indicates that the lattice parameter of stoichiometric HfC, if it exists, is ~4.641Å. The value of 4.6450 ± 0.0005Å reported by Hansler is very high and might be explained by the presence of a significant percentage of zirconium carbide in solid solution with the hafnium monocarbide. A spectrographic analysis of the filament would have been advisable. The room temperature specific electrical resistivities, lattice parameters, and combined carbon contents reported by Goretzki[52] are 172, 200, 230, 242, 245 microohm-cm, 4.638, 4.637, 4.634, 4.632, 4.625Å, and 47.4, 46.5, 45.1, 43.8, 41.3 a/o, respectively. $Hf_{0.901}$ corresponds to 47.4 a/o combined carbon. According to Paderno[60] the specific electrical resistivity of $HfC_{0.999}$ is 45.0 microohm-cm at room temperature. Other resistivity values have been reported for "HfC," but the stoichiometry was not stated.

According to Lyon,[61] "hafnium carbide has a congruently vaporizing composition at a carbon concentration slightly less than stoichiometric." Since Goretzki's measurements show that the specific electrical resistivity increases markedly with decreasing carbon content, Hansler's results are not in disagreement with those reported by Lyon.

R. L. Hansler: I wish to thank Dr. Kempter for his discussion.

Theory of Organic Corrosion Inhibitors—Adsorption and Linear Free Energy Relationships

F. M. Donahue and K. Nobe (pp. 886-891, Vol. 112, No. 9)

R. R. Annand[62]: When I first saw this paper I enthusiastically thought that now we might have a workable relationship to use for seeking inhibitor structure correlations. I was particularly favorably impressed with the arguments and derivations which tend toward developments of a specific set of sigma values for inhibitor or adsorption situations. On further study, however, it seems to me that before a reliable set of specialized sigma values can be developed it will be necessary to establish better experimentally a point that is assumed by the authors.

Usual LFER theory applies to organic reactions in which the mesomeric demands during the course of the reaction result in a highly localized electron distribution at the reaction center [for a brief but lucid discussion see ref. (63)]. Indeed, from his data showing a linear relationship between substituent constants and the energy of adsorption (reproduced in Fig. 1 of Donahue and Nobe's paper), Snyder concluded that he was observing charge localization at the nitrogen atom in his compounds during adsorption onto alumina from a highly nonpolar solvent.[64]

Donahue and Nobe have taken charge localization at a specific atom as an assumption, and as a necessary part of their theory. It seems to me that this

assumption is sufficiently challenged by previously reported work that its validity will have to be solidly confirmed before reliable substituent constants can be developed for inhibitor situations. In adsorption (particularly at metal surfaces where proton acidity is not possible) or in inhibition, there is no *a priori* reason why electron localization should occur at a specific atom in an aromatic molecule.

Among the literature references which challenge the charge-localization assumption, the following are typical: Bockris and co-workers have found that when aromatic molecules adsorb to metal surfaces from solutions of electrolytes, the electrons in the conjugated system participate in the bonding.[65] Furthermore, they have found that the contribution to the free energy of adsorption of a hydrocarbon radical is greater by about 6 kcal/mole for the naphthyl radical than for the butyl radical.[66] Indeed, they have found that naphthalene itself will adsorb to metal surfaces in the flat position.[67] Finally, in every adsorption investigation of which I am aware where the configuration of the aromatic amine was examined critically, it was found that the aromatic molecules preferentially adsorbed parallel to the plane of the metal surface.[68-70] All of this body of evidence supports the thesis that participation is predominantly by the electron cloud of the conjugated system, not by electron localization at an individual atom.

In fact, interaction of the electron cloud of double bonds (without localization at one of the atoms connected by the bond) is observed in a rather wide range of circumstances including: olefins with metal ions[71]; olefins with metal surfaces from the gas phase[72]; and even with an acidic hydrogen as in hydrogen bonding.[73,74]

In view of this background, indicating that the electron cloud of the conjugate bonds of an aromatic system also participate in the adsorption of molecules at metal surfaces, it is disappointing when a large portion of the author's data points do not fall on the theoretical line supporting the single atom anchoring group hypothesis, and when in large measure the arguments revolve around reasons why the anomalous points do not fit the theoretical line. For example, in Fig. 2 it is argued that only four out of the eight points should fall on the theoretical line. It seems to me certainly possible that the theoretical line is not correct either when one can draw a straight line through six out of eight of the points, if the last six points are used instead of the first four.

To put this theory into a category worthy of working into inhibitor function correlations, or other aspects of inhibitor research, a carefully selected group of compounds should be critically examined to establish the statistical fit of the points to a line. Ideally there should be the widest spread possible, both on the inhibition axis and on the substituent constant axis. It should be possible to take these data relatively simply under controlled conditions of concentration, volume of acid, temperature and corroding time so that (*a*) the rate of corrosion is constant throughout the corroding period; (*b*) reproducibility is at least ± 10%; and (c) the effects from the poorer compounds are sufficiently different from the better ones that they can be reliably differentiated. Complex equipment and procedures are not necessary for this purpose; a judicious choice of compounds which are then reliably examined under identical experimental conditions is necessary.

I think this attempt to formalize the general approach to the structure-inhibition problem is possibly a useful one. It would be a great deal more useful if a reasonable amount of confidence could be found in experimental support for the approach. I hope this support will be put forth in the near future and that it will bear out the reliability of the theory.

Francis M. Donahue[75] and Ken Nobe: The authors wish to express their gratitude for Dr. Annand's interest in our work and his comments. However, we feel that he has not completely understood our intent.

We are not attempting to develop "a specific set of sigma values for inhibitor or adsorption situations." On the contrary, it is our intent to utilize the existing sigma values which are found in the literature (we cited four such references in the paper under discussion).

It appears that Dr. Annand has misread Snyder's[76] and our work concerning the correlation of the free energy of adsorption (Snyder's data) and substituent constants. The $\Delta\Delta G_{ads}$ data plotted in Fig. 1 of our paper were the differences between the "ΔF_p average" values of the substituted pyridine compounds and the ΔF_p average value of pyridine in Snyder's Table III.[76] On the other hand, in his LFER correlation, Snyder[76] plotted the $\Delta\Delta F_p$ values tabulated in his Table III. These values were the differences in the ΔF_p average (experimental results) and the ΔF_p calculated from his Eq. [5].[76] According to Snyder,[76] this equation accounts for contributions to the free energy of adsorption from all adsorbate groups within the molecule as well as the strongly adsorbing groups, but does not account for the electronic effects of the substituent on the strongly adsorbing groups (*e.g.*, the nitrogen in pyridine). Thus, the $\Delta\Delta F_p$ values in Snyder's Table III are a measure of the latter effects. He achieved a correlation for all his adsorbates (excluding the O-substituents).

Although Snyder's results showed that the nitrogen atom of the pyridines, pyrroles and anilines was strongly adsorbed, thus substantiating the anchoring group concept, he concluded that these compounds were all adsorbed parallel to the adsorbent surface. It is evident that adsorption at the anchoring group and parallel adsorption are not as mutually exclusive as Dr. Annand seems to imply.

Dr. Snyder[77] has pointed out that the method of plotting Fig. 1 in our paper assumes there is no contribution to the adsorption energy from the substituent group; results of other types of compounds show that the substituent groups could contribute to the adsorption energy. Therefore, according to Snyder,[77] our interpretation of the points in group B of Fig. 1 in our paper appears incorrect since the adsorption energies due to the substituents were not considered.

The concept of charge localization has indeed been utilized in the initial developments of LFER theory by organic chemists studying homogeneous reaction kinetics. However, in the opening paragraph we state "the assumption that the electron density at the 'anchoring group' uniquely determines the adsorbability still allows the possibility of π-interactions *provided* (emphasis added) that such interactions are assumed to vary in the same qualitative manner as the electron density at the functional group under consideration." Since the function group (nitrogen) in the pyridines is part of the conjugated system, it is not an outland-

ish assumption to suggest that the electron densities in the conjugated system are coupled to that at the nitrogen.

Annand's allegation notwithstanding, there is an *a priori* reason why there should be electron localization at specific atoms in an aromatic molecule provided that one defines electron localization in terms of the electronic charge densities which may be calculated based on Molecular Orbital Theory.[78,79]

Correlations have been obtained by us[80-82] utilizing the data of Blomgren and Bockris.[83] The latter showed rather conclusively, as Annand has pointed out, that the orientation is parallel to the surface. Such a correlation by us merely underlines the validity of the proviso which we added to the original premise and have enumerated above.

Annand suggests that Fig. 2 is a rather weak argument for the correlation since he feels that more collinear points are obtained by ignoring, among other things, the parent compound. Such an attempt is justified only if one is attempting to fit data. It was our intent that we test the extent of the theory. On the basis of the theory, four of the points were required to fall on the line. The others were not. We frankly admitted, however, that one of those points did and we likewise surmised that, on the basis of Fig. 2, we could not make a firm statement concerning the orientation of the pyridines on iron. It should be noted that Hackerman and Ayers[84] were likewise at a loss to choose whether the orientation was parallel or not on the basis of their data.

As Annand has pointed out, to verify the suggested relationships it will be necessary to study systems where the extent of inhibition is large as well as the range of sigma values. We have addressed ourselves to this problem in the past[80-82] and are currently extending the initial studies.[85]

It was not our intent in the paper under discussion to present a panacea to the problem of the structure-inhibition relationship. It was instead an attempt at formalizing an approach to inhibition in a manner which has been hinted by previous authors, but which has not been structured such that it could be tested quantitatively. We feel that this paper was, at best, a first approximation, but it is felt that it is a significant starting place.

The Effect of Electrode Pretreatment on the Oxygen Reduction on Platinum in Perchloric Acid

Y. L. Sandler and E. A. Pantier (pp. 928-931, Vol. 112, No. 9)

G. Bianchi and T. Mussini[86]: In a recent paper on cathodic reduction of oxygen on smooth platinum electrodes in acid solutions,[87] phenomena of platinum poisoning during the cathodic reduction of oxygen in acid solution (0.5M H_2SO_4) have been put in evidence. Such a poisoning can be destroyed either by a cathodic polarization at potentials lower than + 0.2v, NHE, or by an anodic polarization at potentials higher than + 1.2v, NHE. In our opinion, such a poisoning is not due merely to oxygen strongly embedded in the surface, but to an intermediate species reducible or oxidizable which we deduced to be the HO_2 radical stabilized on the platinum surface. In a previous paper on catalytic decomposition of acid hydrogen peroxide solutions on platinum, iridium, palladium, and gold surfaces,[88] of which the authors seem to be unaware, we showed that an anodic or a cathodic treatment of the platinum surface does not change the catalytic activity of platinum for the decomposition of hydrogen peroxide, provided such treatments (anodic or cathodic) are made for short times and with moderate overpotentials, so that significant amounts of hydrogen or oxygen are neither evolved nor absorbed on platinum. On the contrary, an increasing catalytic activity of platinum treated with hydrogen may result from the destruction of the oxygen embedded in the surface (or better, in our opinion, of the adsorbed HO_2 radical) by hydrogen diffusing from the bulk of platinum. For this reason we thing it is necessary to degas platinum *in vacuo* at 500°C in order to obtain reproducible and reliable results when studying the cathodic reduction of oxygen. Another important point to be taken into due account is that some impurities, like chloride ions (and halide ions in general), can poison the platinum surface and strongly affect the catalytic decomposition of hydrogen peroxide.

Y. L. Sandler and E. A. Pantier: We cannot express a definite opinion as to the reason for the very strong poisoning observed by Bianchi and Mussini in their experiments. It may be connected with the particular experimental methods used.

The main point in our paper was the demonstration of the effect of the existence of different modes of oxygen chemisorption on the characteristics of the platinum oxygen electrode. This possibility is not considered and no evidence for it is found in Bianchi's work. In our experiments, the very strongly bound oxygen was formed either by thermal pretreatment of the electrode with oxygen at a high-temperature (and transfer to the cell in a closed system) or by pretreatment *in situ* at a high anodic potential.

Bianchi and Mussini's argument that short term variations in potential (between +0.6 and 1.1v, Bianchi and Mussini's Ref. 88) do not essentially influence the catalytic activity, is not in disagreement with our results and presumably means that the strong oxygen chemisorption is not affected under these conditions.

Our samples, after hydrogen pretreatment, were flushed with pure helium at 600°C for about 10 min before cooling very slowly in helium. It is unlikely that this treatment is less effective in removing the hydrogen than Bianchi and Mussini's treatment *in vacuo* at 500°C for 3 hr; it is also unlikely that any remaining hydrogen could support a sufficient flux to the surface at room temperature for continuous removal of HO_2 radicals which Bianchi and Mussini consider to be the poisoning species.

Any difference in the results must be due to differences in the purity of the system and electrode pretreatment. Bianchi and Mussini's standard pretreatment consists of grinding the electrode with quartz powder while exposed to laboratory air. No sensitivity to oxygen pretreatment is found by these authors. They come to the conclusion that their pretreatment simply makes the platinum surface really bare (Bianchi and Mussini's ref. 87, p. 447). We find this hard to believe and suggest that this result merely emphasizes again the need for very careful control of purity in this type of research.

The Indous Ion: an Intermediate in the Electrochemical Oxidation of Indium Metal

R. E. Visco (pp. 932-937, Vol. 112, No. 9)

M. E. Straumanis[89]: Although it is known that In(I) ions exist even in aqueous solutions, nevertheless, there are observations which are not in accord with the electrochemical mechanism proposed, postulating that the irreversible electrochemical step is associated with the further oxidation of In(I) to In(III).

Davidson and Jiric[90] could not prove the presence of In^+ ions during the dissolution of the metal in acids; therefore they assumed, in order to explain the deviation from Faraday's law, that a secondary reaction occurs in acidic solutions with high speed

$$In^+ + 2H^+ \rightarrow In^{3+} + H_2 \qquad [1]$$

Stubbs[91] doubts whether there are In^+ and In^{2+} at all in form of oxides.

Straumanis and Martin[92] concluded from coulometric measurements that In (from an amalgam) goes into solution quantitatively (within the limits of error) only in the form of In^{3+}. Therefore, the first step is

$$In^o \rightarrow In^{3+} + 3e \qquad [2]$$

and there seems to be no justification for step 3:

$$In^o \rightarrow In^+ + e \qquad [3]$$

What might have happened in the experiments of Dr. Visco was the anodic partial disintegration of In. Already Davidson and Jirik[90] saw that, while the current was flowing, fine particles separated from the In anode and accumulated at the bottom of the vessel. This observation could be confirmed later.[92] Figure 1 shows such metallic In particles.

That the particles could not originate in a disproportionation process

$$3In^+ \rightarrow 2In + In^{3+} \qquad [4]$$

follows from the coulometric measurements, as no In^+ ions were formed.

Therefore, what is swept away from the In anode are not In^+ ions but very fine metallic In particles originating from the partially disintegrating anode. However, since small amounts of In^+ were detected polarographically, it might be that reaction [4] is slightly reversible: some In^{3+} are reduced by the fine

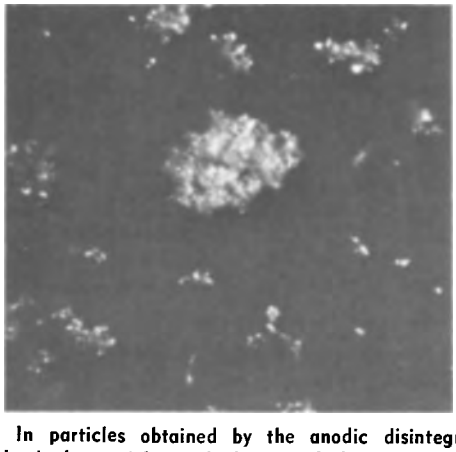

Fig. 1. In particles obtained by the anodic disintegration of the metal; single particles and clusters of them; current density, 70 ma/cm^2. 1430X, oil immersion.

In^o particles to In^+. The In-amalgam may act in the same manner. In fact the reducing ability of In metal or particles was even used by Dr. Visco to have In(I) in solution[93]:

$$In(III) + 2In(0) \rightleftharpoons 3In(I) \qquad [5]$$

Naturally, In(I) must then be found polarographically, if In(0) is present. Since finest In particles are formed continuously during anodic dissolution (at 70 ma/cm^{-2} streams of them can be detected already with the bare eye), a large surface of In metal is available for reaction [5]. Now the necessity of stirring becomes evident: it increases the outcome of In(I). This outcome also depends on the current density (see abstract) because the degree of surface disintegration of the anode changes with it.

Thus, Dr. Visco showed only that unstable In(I) is formed (in a secondary reaction) but not at all that the formation of In(I) is the first step in the dissolution of In(0) which also would be in contradiction to the coulometric measurements.[92]

Robert E. Visco: The observation by Professor Straumanis that an indium anode disintegrates when it is shorted to a large platinum cathode is doubtless quite real; but under these conditions, the initial current density is large (easily the order of 1A/cm^2) and it seems likely that preferential attack along grain boundaries could occur, thereby altering the anode surface and providing a mechanism for easy particle formation. One of the points of my paper was to investigate in a controlled way the low current density region in the anodic dissolution of indium metal where gross attack is less likely. I wished to determine (*a*) If measurable quantities of In^+ can be detected, and (*b*) if In^+ is formed, does it account for the apparent deviations from Faraday's law (based on an assumed 3 equivalents/mole for the oxidation of In). The answer to both questions is yes; In^+ can be found by polarography in the anolyte, and the quantity of In^+ formed as determined either independently by polarography or coulometry agree and they show that sufficient In^+ is formed to explain the apparent deviations from Faraday's law.

Further, I went on to point out in this and an earlier paper[93] that since indium electrodes do not corrode at an appreciable rate in In^{+++} solutions containing only $HClO_4$, the equilibrium:

$$In^{+++} + 2In \rightleftharpoons 3In^+$$

is difficult to achieve in acid solution containing no complexing anions and, further, it must lie far to the left. How then does one explain large quantities of In^+ observed on anodic dissolution? The simplest and I think the most rational explanation is to say that In oxidation occurs in unit steps to give In^+, then In^{+2}, and finally In^{+3} and that the reason In^+ can be observed in the dissolution is because the rate-determining step in the above sequence is after In^+ formation. Thus, In^+ can be transported away from the anode. Recently Losev[94] has reached the same conclusions, based on an entirely different set of experiments and procedures. These experiments, in effect, measured the same quantities which I have reported.

The above results were confirmed by studies of the anodic dissolution of dilute amalgams. Recent unpublished calculations indicate that the quantity of In^+ formed from metal and amalgam anodes seems to be dependent only on the activity of indium in the amalgam relative to that in the metal. This suggests that the initial unit step in the anodic dissolution, that is

$$In \rightleftharpoons In^+ + e^-$$

[93] R. E. Visco, *J. Phys. Chem.*, 69, 202 (1965).

[94] A. P. Pchelnikov and V. V. Losev, *Protection of Metals*, 1, 482 (1965).

is at equilibrium for both liquid and solid indium electrodes and that the rate-determining step is later in the sequence of unit steps which lead to In^{+++}.

The Hydrogen Evolution Kinetics and Hydrogen Entry into α-Iron

J. O'M. Bockris, J. McBreen, and L. Nanis (pp. 1025-1030, Vol. 112, No. 10)

F. E. DeBoer[95]: In the first part of the discussion section, the authors say that two simultaneous reactions are occurring: reaction A (the hydrogen evolution reaction), and reaction B (hydrogen permeation). According to the data, reaction B is 1% of the total. It seems unreasonable that from the characteristics of this very minor reaction one can make definite conclusions about the mechanism of the major reaction, as the authors have done.

Complicating matters is the fact that they have taken no account of the complex nature of their membrane; that is, α-iron was treated as a perfect membrane for hydrogen permeation. It is the hydrogen that has permeated the iron that is measured, and these measurements are used to make conclusions about the hydrogen that has not even entered the iron; no account at all is taken of the hydrogen that has entered the iron and has not come out (*i.e.*, the hydrogen atoms might combine at internal discontinuities, and so forth). It is feasible that the amount of internal hydrogen is far greater than that which is measured.

The fact that the single crystal data are similar to the polycrystalline data does not invalidate this criticism, since atoms can be rendered immobile inside the iron at sites other than crystal boundaries.

J. O'M. Bockris, J. McBreen, and L. Nanis: In Eq. [3] and [9] of our paper, we give the relationship between the H permeation rate, the coverage (θ), and the rate of H evolution. The only major assumption here is that the adsorbed H intermediate is the same for H entry into the metal and for H gas evolution. The fraction of H which passes through the metal is related to the diffusion coefficient, the membrane thickness, and the ratio of the rate constants of the surface to bulk reactions. For the membrane thickness used, the potential range covered, and the temperature of the investigation, it turns out that the rates are such that the H which permeates the metal is of the order 1% of the total H which is discharged per unit time. Variation in the permeation rate with potential for constant inhibitor concentration reflects changes in θ, *i.e.*, of the adsorbed intermediate concentration. However, $\partial\theta/\partial\eta$ is a function if the mechanism assumed for the evolution reaction and theoretical relations are known which principal mechanisms. Hence the permeation-potential relation gives evidence concerning the mechanism of the evolution reaction which runs parallel to the permeation.

The consistence of our results support the assumption of identical intermediates for both reactions. The fact that the permeation rate happens to be about 1% of the total discharge rate in our system is not directly relevant to a discussion of mechanism.

The matters concerning H in the metal are dealt with in detail in a paper by Beck, Bockris, McBreen, and Nanis* which will be published shortly. In the potential region referred to for mechanism indications, it was found that no trapping of H occurred in the metal. Such trapping did occur if the potential was made more negative than a certain value. Data obtained in this region were not used to deduce mechanism: hence the termination of the permeation potential plots at about −0.5v with respect to NHE.

U. R. Evans[97]: The research provides valuable information about the entry and movement of hydrogen, and is greatly to be welcomed. The picture of the mechanism in absence of "poisons" appears acceptable, particularly the idea that the adsorbed state assumed before entry into metal as atoms is the same as that assumed before evolution as molecular gas (p. 1027). I am not equally happy about the idea (p. 1030) that poisons directly favor entry by loosening the H-metal bond; most earlier theories have pictured the poison as interfering with H_2 gas formation, and thus indirectly favoring the alternative reaction, the entry into the metal as atoms. Such a view appears to me more probable.

If adsorbed anions loosen the $M\text{-}H_{ads}$ bond, then doubtless, provided that nothing else happens, the number of H atoms passing from an external (adsorbed) site to an internal (absorbed) site will be increased, say from n to $n + \Delta n$, so that the proportionate increase in hydrogen entry would be $\Delta n/n$. But the same loosening will surely increase the number of hydrogen pairs joining to form molecular (gaseous) H_2, say from N to $N + \Delta N$; since we are now dealing with pairs, the difference between squares must be taken and, if nothing else happens, the proportionate outward movement as H_2 gas will be

$$\frac{(N + \Delta N)^2 - N^2}{N^2} = \frac{2\Delta N}{N}, \text{ approximately}$$

Unless there is reason to think that $\Delta n/n$ is greater than $2\Delta N/N$, there is no reason to expect, on these grounds, that adsorption of CN or I will increase the entry of atomic hydrogen into the metal.

A more probable explanation, involving no *ad hoc* assumptions about bond loosening, is based on the fact that where a process involves two adjacent atoms, it will be more affected by coverage with a poison than a process involving only one atom. If α is the fraction of the surface not covered with poison (CN or I), then the rate of entry of atomic hydrogen (in absence of rival process) would be $k_1\alpha$, where k_1 is a constant, but the rate of evolution of *molecular* hydrogen would be

$$k_2\alpha p_{\alpha c}$$

where $p_{\alpha c}$ is the probability that a neighboring site is uncovered with a poison atom, which depends, not only on α, but also on c, the coordination number defining the number of "neighbors." Since two sites are involved in the H_2-evolution, it may be expected that

$$\frac{\text{Entry of atomic H}}{\text{Evolution of molecular } H_2} = \frac{k_1\alpha}{\frac{1}{2}k_2\alpha p_{\alpha c}} = \frac{2k_1/k_2}{p_{\alpha c}}$$

If c were known, $p_{\alpha c}$ could be calculated from simple probability theory. However, whatever the value of c, $p_{\alpha c}$ must decline as α declines, and immediately we reach the conclusion that, in absence of further complications, an increase of contamination with CN or I will diminish the fraction of hydrogen evolved as gas and increase that entering the metal as atoms.

This is only true of substances adsorbed as small ions or atomic groups. If the substance adsorbed consists of large molecules of irregular shape, there will be irregular gaps between the covered areas which, being left uncovered, will offer the same facilities for H-entry and H_2-evolution as a surface which is completely uncontaminated. Since the coverage of a large fraction of the area will, at constant potential, reduce the total current flowing, it follows that both H-entry and H_2-evolution will be reduced.

This seems to explain why CN and I favor the entry of hydrogen into metal, while organic nitriles diminish it. The effect of naphthalene is not so easily explained. It may be that single H atoms can enter the metal

[97] 19 Manor Court, Grange Road, Cambridge, England.

through the centers of the hexagonal rings, but that the points of entry are too much isolated from one another to allow union as H_2; this picture may seem rather fanciful, but it is difficult to think of an alternative.

J. O'M. Bockris, J. McBreen, and L. Nanis: Dr. Evans' view that additives effect the permeation rate of H through Fe by reduction of the rate of combination of H to H_2 is certainly a possible suggestion for such phenomena. However, it would only be tenable if the rate-detemining step (r. d. s.) in the hydrogen evolution reaction were combination; or is, in the sequence $2H^+ + 2e \rightarrow 2H_{ads} \rightarrow H_2$, the latter step were in equilibrium. In fact, the relation of the permeation rate to current density on the polarization side of the membrane

$$\partial P/\partial \ln J = 4\,RT/F$$

suggests strongly that $H^+ + e \rightarrow H_{ads}$ is the r. d. s. and is coupled to the following H combination reaction, with the reaction velocity $H_2 \rightarrow 2H_{ads}$ being negligible.

The most important of the points of experimental evidence in favor of this concerns the change of reaction rate associated with a change of permeation rate. As the r. d. s. for the over-all evolution reaction is not combination, the change reaction rate following additive additions (with constant mechanism) must arise from the effect of the adsorbed additive on bond strength. Thus, a decrease of the M-H bond strength would be consistent with an increase in overpotential for the same total current density,† but this would also lead to a corresponding increase of the permeation rate, as observed with CN^- and I^-.

We do not think that Dr. Evans' hypothesis is consistent with both the linked increase of over-potential and permeation and with the r. d. s. consistent with the $V/\log J$ relation.

In addition, the observations on the change of β with additions of additives has to be interpreted. Qualitatively, this arises from our model, for β depends on $\partial U/\partial x$, the slope of the potential energy-distance relation in stretching of the metal-hydrogen bond. It is easy to show that this coefficient is proportional to the bond strength. Finally, it may be noted that the interpretation given here to the permeation results in not a special theory but an application of independent interpretations previously made in respect to so-called "poisons" on the velocity of the hydrogen evolution reaction.

Electrode Potentials in Fused Systems, IX. Liquid Junction Potentials in the AgCl-AgBr System

K. Stern (pp. 1049-1050, Vol. 112, No. 10)

A. J. Easteal[98]: For the experimental cell

$$\mathrm{Ag}\,|\,\underset{\text{(electrolyte I)}}{\mathrm{AgCl(x_1),\ AgBr(x_2)}}\,\|\,\underset{\text{(electrolyte II)}}{\mathrm{AgCl(x_1'),\ AgBr(x_2')}}\,|\,\mathrm{Ag}$$

where ‖ represents a liquid junction, Stern states: "In this cell any nonzero emf is a liquid junction potential and must arise from differences in the anion mobilities and transport numbers."

It is not true however that $(E_t - \epsilon) = 0$, where E_t is the cell emf and ϵ the liquid junction potential, except in certain limiting conditions. Assuming that the electrolytes I and II are completely dissociated into the simple ions Ag^+, Cl^-, and Br^-, and setting z_i equal to the electrovalency of the ions ($z_i > 0$ for cations, $z_i < 0$ for anions), the emf of the cell is given by the relationship[99]

$$E_t = -(RT/F)\int_{\mathrm{I}}^{\mathrm{II}} \sum_i t_i \left(-\frac{1}{z_i} d\ln a_i + \frac{1}{z_{Ag^+}} d\ln a_{Ag^+} \right) \quad [1]$$

and the liquid junction potential by

$$\epsilon = -(RT/F)\int_{\mathrm{I}}^{\mathrm{II}} \sum_i t_i \left(-\frac{1}{z_i} d\ln a_i \right) \quad [2]$$

By Eq. [1] and [2]

$$E_t - \epsilon = -(RT/F)\int_{\mathrm{I}}^{\mathrm{II}} d\ln a_{Ag^+} = -(RT/F)\ln(a_{Ag^+}{}^{\mathrm{II}}/a_{Ag^+}{}^{\mathrm{I}}) \quad [3]$$

where $a_{Ag^+}{}^{\mathrm{I}}$ and $a_{Ag^+}{}^{\mathrm{II}}$ denote the activities of Ag^+ ions in electrolytes I and II, respectively. According to Eq. [3], $E_t = \epsilon$ only if the activity of Ag^+ ions is the same in the two electrolytes. The fact that the concentration of Ag^+ is the same in the two electrolytes does not necessarily imply that no difference in a_{Ag^+} exists. If the system AgCl + AgBr were thermodynamically ideal in the sense

$$\left.\begin{array}{l}\gamma_{AgCl} = \gamma_{AgBr} = 1, \text{ for all values of } x \\ \text{such that } x_1 \geq x_{AgCl} \geq x_1'\end{array}\right\} \quad [4]$$

(where γ denotes activity coefficient) then it would be reasonable to assume that

$$\left.\begin{array}{l}\gamma_{Ag^+} = 1 \\ x_1 \geq x_{AgCl} \geq x_1'\end{array}\right\} \quad [5]$$

However proposition [4] is not valid,[100] at least for mixtures whose composition is such that

$$0.60 \geq x_{AgCl} \geq 0.30$$

It is therefore not possible to assess the difference in the activity of Ag^+ ions in the two electrolytes. Consequently it may not be true that the whole of the cell emf arises from the liquid junction potential.

Stern also states that the cell emf can be zero only if $t_{Cl^-} = x_1$, $t_{Br^-} = x_2$. That this is not a necessary condition for vanishing cell emf, is shown by the following considerations: E_t is zero if and only if

$$-(RT/F)\int_{\mathrm{I}}^{\mathrm{II}} \{(t_{Cl^-}\cdot x_{AgBr} - t_{Br^-}\cdot x_{AgCl})/x_{AgBr}\}\, d\ln a_{AgCl} = 0 \quad [6]$$

Since $d\ln a_{AgCl} \neq 0$, a sufficient condition for $E_t = 0$ is, therefore

$$\left.\begin{array}{l}t_{Cl^-}/t_{Br^-} = x_{AgCl}/x_{AgBr} \\ \text{for all values of } x \text{ such that} \\ x_1 \geq x_{AgCl} \geq x_1'\end{array}\right\} \quad [7]$$

A particular circumstance for which this condition is fulfilled is

$$\left.\begin{array}{l}t_{Cl^-} = x_{AgCl} \\ t_{Br^-} = x_{AgBr} \\ x_1 \geq x_{AgCl} \geq x_1'\end{array}\right\} \quad [8]$$

The conditions expressed by Eq. [7] (and its special case, Eq. [8]), are not however, necessary conditions for $E_t = 0$.

K. H. Stern: Dr. Easteal has raised two points. The first of these is the old question of single-ion activity again. In essence the question is: "what is the single ion activity of Ag^+ in a AgCl-AgBr mixture," or "is the activity of Ag^+ in AgCl and AgBr the same?"

Now we certainly know the activities of the thermodynamic components AgCl and AgBr in AgCl-AgBr

† We refer to "the same" current density for hydrogen evolution because the fraction of H which passes through the membrane is about 1% of the total H discharged, so that, if the total current density is constant, the current used by hydrogen evolution is constant to better than 1%.

[98] Chemistry Department, University of Auckland, Auckland, New Zealand.

[99] This equation is readily derived by the method of E. A. Guggenheim, "Thermodynamics," p. 396 *et seq.*, North-Holland Publishing Co., Amsterdam (1959).

[100] I. G. Murgulescu and D. I. Marchidan, *Zh. Fiz. Khim*, 34, 2534 (1960).

mixtures. The activities of the pure components are unity if a Raoult's law standard state is used. But the difficulty is that we do not know how to split up $a_{AgCl} = a_{Ag^+} a_{Cl^-}$ into single ion activities either for the pure compound or for AgCl in the mixture.

For example, Dr. Easteal's Eq. [3] contains two unknowns, the liquid junction potential ϵ and the ratio $(a_{Ag^+}{}^{II}/a_{Ag^+}{}^{I})$. In order to evaluate one we must make some assumption about the other. The usual way out of this dilemma is to assign a value of unity to the activity ratio and to interpret the cell emf only in terms of events at the liquid junctions.[101] If Dr. Easteal has a better suggestion it does not appear in his comments.

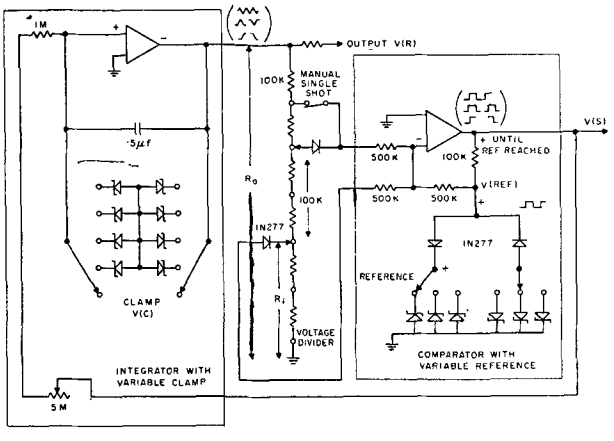
His second point concerns Eq. [6]. Since $d \ln a_{AgCl} \neq 0$ and $X_{AgBr} \neq 0$ $E_t = 0$ if and only if $t_{Cl^-} - X_{AgBr} - t_{Br^-} X_{AgCl} = 0$.

Now, since t_{Cl^-} and t_{Br^-} are transport numbers relative to t_{Ag^+}, $(t_{Cl^-} + t_{Br^-}) = 1$ and also $X_{AgBr} + X_{AgCl} = 1$ from which his Eq. [7] and [8] follow immediately. Thus these equations are not only sufficient but also necessary.

The Voltage Sweep Method—Electronic Device for Producing Triangle Pulse and Ramps

F. G. Will (pp. 1157-1159, Vol. 112, No. 11)

N. S. Clayton[102]: The paper by Will deals with a circuit to produce a slow linear voltage sweep. A solid-state circuit Fig. 1, which has identical functions is in



use here in conjunction with work on metal-oxide-silicon capacitors. Two operational amplifiers are used for integration and comparison, respectively. This allows the circuit to be constructed and modified simply and quickly.

Consider first the case with clamp switch open circuited. When the constant input to the integrator is positive, the output $V(R)$ ramps negative at a rate varied by the 5MΩ pot. R_1/R_0 of $V(R)$ is fed to the comparator.

The comparator operates in the noninverting mode in the sense that when the reference voltage V(ref) is reached the comparator switches to the same polarity as the input.[103] The sign of the feedback to the integrator $V(S)$ changes polarity causing the ramp to change direction. Note, $V(S)$ is always locked in positive or negative saturation due to positive feedback and thus provides a well-regulated input voltage to the integrator, while V(ref) is always clamped at the appropriate reference voltage.

$V(R)_m = (R_0/R_1)\ V$(ref), the height of wave form, is independently variable in each direction, provided the back biased diode on R_0 does not have significant leakage to the summing point.

It is now a simple matter to obtain single pulses or ramps starting from a prefixed voltage. A selection of back to back reference diodes may be switched in across the integrating capacitor which will clamp $V(R)$, *i.e.*, if $V(C) < (R_0/R_1)\ V$(ref). To unclamp or commence, a push button switch momentarily increases R_1 to change the state of the comparator.

The system is relatively insensitive to modifications: for example, the integrator feedback and interconnecting network have been varied by one or more orders of magnitude with no noticeable deterioration in performance. The integrating amplifier should be high quality, and the feedback network should allow little leakage current. The comparator amplifier is less critical. A high current amplifier (10 ma) is used to signal a stepping relay which automatically selects the next sample after one or half a cycle, as required.

F. G. Will: It is readily agreed that there are alternate methods of producing triangle pulses and ramps. It is the purpose of the original note to show how this can be done by a simple modification of commercial function generators that produce periodic waveforms. Dr. Clayton describes how operational amplifiers can be used to build a function generator as outlined in Textronix Manual 070-323. The addition of the back-to-back Zener diodes to clamp the integrator to several selected voltage levels is indeed a simple way of producing single pulses and ramps. It can be applied in cases where a continuous variation of clamping voltage levels is not required.

Logarithmic Oxidation Kinetics of Zinc

V. O. Nwoko and H. H. Uhlig (pp. 1181-1185, Vol. 112, No. 12)

F. E. DeBoer[104]: At the beginning of the paper, the authors say that the kinetics of this reaction have been described as parabolic as well as logarithmic. However, subsequently, they do not again refer to the possibility of parabolic behavior. On the contrary, they assert positively that they have proved that a two-stage logarithmic equation is obeyed. This is faulty on two counts: (*i*) the fact that a few points on semilog paper fit reasonably well on a straight line does not prove a logarithmic kinetic law. This is especially true when these points are closely bunched. Further, when it takes two straight lines to describe the form of these points, the possibility that this is indeed not a logarithmic relationship is high. (*ii*) The authors apparently did not test the parabolic law. In order to try this roughly, I used the curve labeled 206° of Fig. 2 and found that there was almost a perfect fit to a straight line described by $d = 2.35\ t^{1/2}$ (where d is oxide thickness in angstroms and t is time in minutes). Admittedly, it is difficult to determine data from a plot of the size presented (the other curves of Fig. 2 would be even harder to work with), but the fit was very good. Before assuming a two-stage logarithmic process, the authors should, at the least, show how well their original data fit when plotted in other ways, especially parabolically in this case.

A. Winterbottom in a discussion following Vernon's paper[105] pointed out that some of his low-temperature data would fit well on a parabolic plot. These were in the lower half of the temperature range discussed in the present paper. In view of this and the distinct possibility that the data discussed here conform to a parabolic law, it is probable that the oxidation is parabolic below 225° and logarithmic above 225° (see Vernon).

U. R. Evans[106]: The authors have done a service in showing that the oxidation of zinc shows the same

sudden breaks as does that of copper, nickel, cobalt, and iron. If the activation energy is almost the same for the two stages, that would suggest that the oxidation-mechanism is similar.

Figure 3 and Table I may convey the idea that oxidation is more rapid in the second stage than in the first. This is due to the fact that the time-scale in Fig. 3 is much more "open" for the first stage than for the second. The following table gives rough measurements of the time t_1 needed to produce the thickness L at which the second stage starts, and the additional time t_2 needed to produce an additional thickness equal to L (making $2L$ in all). Accurate measurements are impossible on any small-scale diagram, and the authors may care to provide a more accurate table. If they confirm that t_2 is greater than t_1, the conclusion will be that the second stage is the slower.*

Temperature, °C	L	t_1	t_2

175	12	95	145
206	24	130	275

"Breakdowns," leading to spurts of renewed oxidation, are not confined to metal obeying the logarithmic law. Often there are several successive breakdowns; about 40 years ago, Pilling and Bedworth,[107] studying copper, published curves with about four breakdowns. Curves showing repeated breakdowns have also been published by Vernon,[108] by Tylecote,[109] and by Caplan and Cohen,[110] studying aluminum, copper, and iron-chromium alloys, respectively.

The rational explanation of breakdown is springing a leak of the film where it has become unsupported through the outward movement of cations, leaving vacancies. The same outward movement provides a simple explanation of the logarithmic growth law. At high temperature, these vacancies generally coalesce to form cavities, which are visible under the microscope, so that their existence is not in doubt. That, however, involves diffusion of vacancies over considerable distances; Dunnington, Beck, and Fontana[111] record cases where vacancies have diffused right through a sheet, so that its scale has become loose on one side while remaining adherent to the other side. Where there is coalescence of many vacancies into a few big cavities, the area where oxide is out of contact with metal is small, and the oxidation-rate will not be greatly effected. At low temperatures, diffusion of vacancies can only occur over small distances; some vacancies are doubtless annihilated at dislocations or other "sinks," others by atoms subsiding into them from the film, but some will remain at the interface. The effect will be to impede movement across the interface. When the gap between metal and oxide becomes at some places sufficiently broad to prevent crossing altogether, the area available for the passage of metal into oxide will diminish with time.† It has been shown[112] that this leads, according to the assumption made regarding the growth law which would be obeyed if the whole area remained available for passage, either to the classical logarithmic equation

$$W = k \log (at + 1)$$

or to a "new" logarithmic equation

$$W = k \log (at^{1/2} + 1)$$

There are, of course, numerous examples of conformity to the classical equation, but when first I arrived at the "new" equation,[113] no experimentally established example was available. Shortly afterwards, T. Mills, studying the oxidation of copper, brought me results which failed to accord with the classical equation. I suggested that he tried the new equation, with which he was then unacquainted; the results fitted.[114]

If the falling off, much faster than the parabolic law would predict, is due to an increasing area of "no contact" between metal and oxide, a time will come when the "roof" will collapse or start to leak, and oxidation will be resumed, over the areas in question, at roughly the original pace. If the breakdown does not occur until conditions of "no contact" have spread over the whole area, the scale will flake off intact. If it remains adherent (as on zinc), that is proof that the "no contact" condition has not been established everywhere, and the renewed oxidation-rate of the specimen as a whole will be less than at the start of the first stage—which appears to be the case.

The discussion between the authors and Fromhold shows that they are strongly attached to interpretations based on space charges. This comment is addressed to those who prefer an explanation which, without *ad hoc* assumptions, offers an interpretation of the known facts up to the breakdown; after the breakdown, the geometry becomes complicated and the kinetics difficult. The simplicity of the interpretation may be an advantage, since, if there is a flaw in the argument, no reader can fail to detect it.

H. H. Uhlig: To prove whether a single equation fits a given set of data requires experimental points over a sufficient time interval; otherwise more than one equation may fit the points. One of the traditional difficulties of treating thin film oxidation data is that the time interval over which thin films exist is relatively limited. Therefore, the suggestion has sometimes been made, as F. De Boer mentions, that the parabolic as well as the logarithmic equation applies. If still fewer points than those presented in our Fig. 2 had been taken, it could also be demonstrated that the linear equation fits the data. However, several investigators have previously demonstrated that the logarithmic equation is commonly the only equation which fits thin film oxidation data when the data are carried out over a sufficient length of time so as to leave no doubt about the matter. Lustman and Mehl[116] showed that the data they obtained on oxidation of copper single crystals could be represented only by the logarithmic equation and the same conclusion is reached from low-temperature data by Tylcote,[117] and from our own measurements on copper. Kubaschewski and Hopkins[118] conclude that most thin film oxidation data for metals conform to the logarithmic equation or inverse logarithmic equation, with distinction between the two being difficult.

* The reason why Table I shows a higher value for the rate constant (k'_1) of the second stage than for that of the fast stage (k_1) is that τ' is much larger (110-140 min) than τ (5.5-7 min). The equations are $y = k_1 \log (t/\tau + 1)$ and $y = k'_1 \log (t/\tau' + 1)$. Clearly a time of, say, 10 min will only slightly increase $(t/\tau' + 1)$ above unity, but will greatly increase $(t/\tau + 1)$. Thus, even supposing that the oxidation rates were the same in both stages, k'_1 would need to be much larger than k_1, if the same value of t (10 min) is to produce the same increase of thickness, y.

† A small amount of oxidation can develop gradually even at the areas of "no contact" by the mechanism proposed by Dravnieks and McDonald.[115]

It was our intent, therefore, to show that our data for zinc obtained over a limited time interval are consistent with the logarithmic equation in accord with most thin film oxidation data. This we have done. In particular, our data are consistent with two-stage logarithmic kinetics, also found by other investigators, the theoretical significance of which is outlined.

Dr. Evans' comments deal first with the characteristics of any logarithmic relation. It is, of course, true that growth of oxides following the logarithmic equation decreases markedly as time proceeds. In fact, early investigators suggested that the oxide completely stopped growing after a given time, whereas it is now considered more likely that the oxide continues growing and that it is only the peculiar relation of oxide thickness to logarithm of time which makes it appear as if oxide growth ceases. In the two-stage logarithmic oxidation process, the important consideration is that the value of the reaction rate constant k'_1 in the relation $y - L = k'_1 \log(t/\tau' + 1)$ for second-stage oxidation is demonstrably greater than the corresponding value of k_1 during first-stage oxidation. The greater value of k'_1 compared to k_1 means that the corresponding thickness of oxide at any time beyond L is greater than it would otherwise have been had oxidation continued in accord with first-stage kinetics. This conclusion is clearly evident by examining our Fig. 3.

Dr. Evans is correct, of course, in pointing out that discontinuities in the oxidation rate have various causes. Most of the instances he cites are for relatively thick films where spalling and cracking of the oxide is the common cause. An example of discontinuous oxidation rate can also be seen in the data of Heindlhofer and Larsen for oxidation of iron at 700°C reproduced in the "Corrosion Handbook" on p. 633. However, spalling, blistering and cracking are not as likely to occur in thin film oxidation (100-10,000Å), and in fact we have never observed evidence for it in any of our numerous experiments on oxidation of copper, nickel, and chromium-iron alloys. Consideration should also be given to the fact that the beginning of second-stage logarithmic oxidation tends to be more reproducible than one would expect if accidental spalling and cracking, caused in part by thermal fluctuations, were the cause. The fact that second-stage logarithmic oxidation begins at about the same time and thickness for a given temperature of oxidation suggests that its cause lies in a different source. Our work on Volta potentials of growing thin oxide films suggested to us that space charge may enter as the important factor, and subsequent exploration of this possibility led to the conclusions that are outlined in our present and previous papers.

It is of some interest that Tylecote's data on oxidation of copper, cited as reference by Dr. Evans, lends support to our viewpoint. Tylecote found that the parabolic equation fitted his data only at high temperatures (615°-908°C) whereas the logarithmic equation fitted his data in the lower temperature range (350°-550°C) especially during the first stages of oxidation (thin films). The transition between logarithmic and parabolic kinetics is not sharply defined, but significantly Tylecote points out that the thickness at which the transition occurs is in the order of 10^5Å which he states is "the same order as the 'barrier layer' on copper/copper oxide rectifiers as determined by measurements of electrical capacity; this correspondence appears to support the contention of Campbell and Thomas[119] that the departure from the parabolic relationship at low temperatures is a consequence of the peculiar electrical conditions in these thin films." The maximum thickness of oxide, equal to 10^5Å, for which logarithmic oxidation kinetics apply, corresponds to our maximum thickness of space charge including both the constant density and diffuse space charge layers. Tylecote goes on to say that "the logarithmic curve appears to be in two portions" corresponding, of course, to our described first- and second-stage logarithmic kinetics.

I think it unlikely that any model of thin film oxidation based on movement of atoms or ions through an oxide lattice as the controlling mechanism can hope for much success in describing the facts as we now know them. For example, there is a marked effect of Curie temperature, crystal face and lattice type on the thin film oxidation rate. In general, any of these factors within the metal would not be expected to have an effect on rate of migration of species such as ions or vacancies in the oxide phase. For this reason, I believe that the work function of the metal which is affected by Curie temperature, crystal face and lattice type, plus a growing space charge in the thickening oxide (confirmed by Volta potential measurements) enter as the more important determining factors accounting for observed logarithmic oxidation kinetics.

On the Use of Galvanostatic Transients for the Study of Fuel Adsorption on Platinum

M. W. Breiter (pp. 1244-1245, Vol. 112, No. 12)

S. B. Brummer[120]: In a previous paper[121] a novel current-reversal method of estimating fuel adsorption on Pt was described. In this method, which was used both for HCOOH adsorption[121] and CO adsorption,[122] an anodic pulse is applied to strip the adsorbate partially (charge Q). Then a cathodic pulse is applied to determine how much of Q has gone toward electrode oxidation ($Q_{o,cath}$ in Breiter's terminology) and how much has gone toward cleaning the adsorbate off the electrode. The latter is determined as the fraction of the electrode available for H-atom deposition (θ_H). In the paper under discussion, the general point about this method is made that it has rarely been found that $Q_{o,an}$ (charge in oxidizing Pt) is the same as the charge found in reducing the oxide ($Q_{o,cath}$). This point was appreciated in the application of the current-reversal method and was fully discussed both for HCOOH[123] and for CO.[122] In the latter case, $Q_{o,cath}/Q_{o,an}$ ($= \theta_H$) was found to be unity. This would remove the substance of the objection. For HCOOH, as indicated by Breiter, the extent of electrode oxidation is small until almost all the adsorbate has been oxidized. (However it is not zero; the importance of which will be shown later.)

In the case of other adsorbates, one would certainly have to know the value of θ_o. In this connection, one may note that in two rather careful recent studies by Bold and Breiter[124] and Gilman[125] θ_o has been found to be unity although the reduction of the Pt(O) is rather irreversible.[125] This irreversibility could pose a problem since it might mean that some oxide reduction is pushed into the H-atom deposition region. Since the oxide reduction is much more reversible when electrode oxidation is small, as it is in the application of the current-reversal technique, there is no interference due to oxide reduction in the H-atom deposition region. It is very likely that the reason θ_o is often found as < 1[126,127] is due to the presence of impurities in the solution. These impurities would adsorb on the Pt and their oxidation during the anodic pulse makes

an additional contribution to $Q_{o,an}$. If this were so, θ_o would always be unity when a strongly adsorbing fuel is available to adsorb on the electrode since this would prevent the adsorption of the impurities. This was found for CO adsorption.[122]

The paper also makes a number of specific points about the comparison between earlier results for HCOOH adsorption[128] and those obtained with the current-reversal method. It was reported[128] that θ_H decreases linearly with increase of θ_F during adsorption of HCOOH up to about 0.5 in θ_F (θ_F = $HCOOH_{ads}$ coverage/maximum $HCOOH_{ads}$ coverage). Thereafter, a curvature convex to the θ_F axis (curve b of Fig. 1) was found. Using the current-reversal method, θ_H and θ_F were found to be completely linear (curve a of Fig. 1). Breiter claims that there is in fact curvature at high θ_H in Fig. 5 and 6 of ref. (121). This is most evident he says in Fig. 6. No curvature, within the significance of the data, is evident to me in Fig. 5 of ref. (121). In Fig. 6, it should be noted that the data is uncorrected for electrode oxidation and for oxidation of material in the solution during the anodic transient. Both of these are discussed in ref. (121) (p. 569). The former is the more important in this case, and the dotted region of curve a at high θ_H in Fig. 1 is just the region when electrode oxidation is not zero. When this correction is made, the points at high θ_H of Fig. 6 of ref. (121) fall right on the line and θ_H is completely linear in θ_F over the whole range of coverage. There is another important point in this connection. Breiter appears to assume that curvature at high θ_H in Fig. 5 and 6 of ref. (121) would improve the agreement between curves a and b of Fig. 1. This is not so. If this curvature were real, it would lead to curve c in Fig. 1. This is concave to the θ_F axis and curved at the low θ_F end.

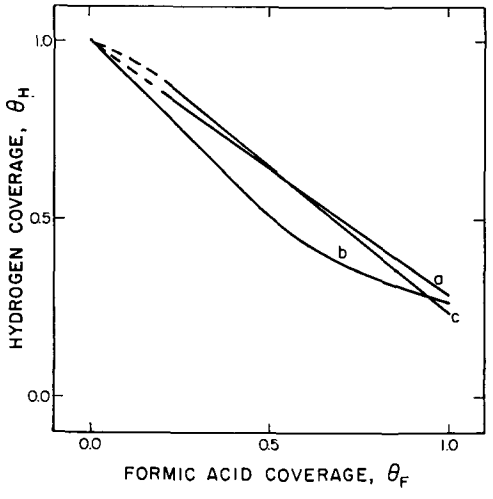

Fig. 1. Curve a, based on data of ref. (121) such that Q_{HCOOH}^{max} = 285 μcoul/real cm² and θ_H goes from 1.0 to ~0.28. Dotted region at low θ_H is omitted as described in ref. (121). Curve b, from paper under discussion, based on ref. (128). Curve c, based on ref. (1). Includes curvature suggested in paper under discussion, Q_{HCOOH}^{max} is taken as 356 μcoul/real cm².

The paper attempts to show that the estimate of Q_{HCOOH}^{max} in ref. (121) is too low, to improve agreement with data of ref. (128). Actually this would lead to further disagreement since the value of ref. (121) (285 μcoul/210 μcoul of H-atom charge, *i.e.*, per real cm²) is already higher than that of (128) (260 μcoul/real cm²). The agreement between these two values determined by two methods (10%) is already excellent considering that the comparison is based on 4 or 3 separate charge determinations, respectively, none of which is better than ± 1-2%.

The disagreement between curves a and b of Fig. 1 could arise as follows: Curve a represents the desorption of material adsorbed at a single potential: the slope gives the number of electrons released per site on oxidation of the adsorbate [~ 2, see ref (121)]. Curve b, on the other hand, represents the relationship between θ_F and θ_H when the HCOOH is adsorbed at various potentials. Specifically, the high θ_F end refers to material adsorbed at the lowest potentials. There is a considerable view growing that $HCOOH_{ads}$ is not HCOOH itself but some other species.[121,129,130,131] If this were so, we might not be surprised to find a more reduced species tending to accumulate on Pt during the last stages of HCOOH adsorption at low potentials. The slope of curve b at low θ_H is about 4 electrons per site, and this may represent evidence that some of the adsorbate at low potentials differs from that at higher potentials.[132]

M. W. Breiter: As stated in my paper, it was not mentioned in the fundamental paper[133] that the applicability of the technique depends upon the fulfillment of the condition $Q_{o,an}/Q_{o,cath}$ = 1. After this requirement was pointed out by me in the oral discussions at the Washington Meeting of the Electrochemical Society, it was dealt with in a subsequent paper[134] sent in for publication after the meeting. Reference (123) in Brummer's comments is not a publication. It is not clear why the above condition which represents a restriction of the technique was not discussed in the first paper[133] if it was known to its author. In the absence of fuel, the experimental result $Q_{o,an}/Q_{o,cath} \geq 1$ is due to a superposition of several effects: oxidation of adsorbed organic impurities, diffusion of oxygen atoms into the platinum, and O_2 evolution. It is not possible at present to separate the contributions of these processes.

With respect to the shape of the curves a and b in Fig. 1 of my paper, it should be pointed out that a straight curve implies that all the sites used for adsorption of H atoms are also used for the adsorption of HCOOH molecules or intermediates (COOH for instance). This assumption is not very likely. The specific points raised in Brummer's comments involve small corrections and extrapolations. The validity of the arguments falls in the realm of subjective judgment. The question of the nature of the adsorbed species has not been settled.

Equilibrium Pressures of Oxygen over Ag_2O-Ag at Various Temperatures

Earl M. Otto

National Bureau of Standards, Washington, D.C.

ABSTRACT

Although earlier investigators showed the dissociation of Ag_2O to be reversible and equilibrium points had been obtained, there was a range from 191° to 203°C that had not been studied. This region has now been studied. From all the data available and heat capacity data $\Delta H°_{298}$, $\Delta S°_{298}$, and $\Delta G°_{298}$ have been calculated to be 14.69 kcal, 31.92 kcal, and 5.17 kcal per mol O_2, respectively, for the dissociation reaction $2Ag_2O \rightarrow 4Ag + O_2$.

As early as 1887 LeChatelier (1) showed that the dissociation of Ag_2O into Ag and O_2 is reversible. Lewis (2) obtained three equilibrium points in the temperature range of 302°-445°C. Keyes and Hara (3) working in the range of 374°-500°C determined six equilibrium values, five of which were approached both by decomposition and by combination. Not until 1932 was this reversible reaction studied at 1 atm and lower. Benton and Drake (4) established equilibrium values at five temperatures from 173° to 191°C, similarly by combination as well as decomposition.

Since there was an intermediate range of 110°C that remained uninvestigated, and since there had been no overlapping of investigations at the lower temperatures, it seemed advisable to make a further study of the reaction. An examination of all the data of all four investigations should result in better calculated values for $\Delta H°$, $\Delta S°$, and $\Delta G°$.

Experimental

The apparatus used was essentially that described previously by the author (5). Silica gel desiccant was included in the system, located in the horizontal glass section between the reaction bulb and the first manometer. When the oxygen pressure was between 2 and 3 atm it was necessary to employ two manometers in series, outside the constant temperature cabinet. At higher pressures a nickel bomb with a Vycor insert was used to contain the sample, and the pressure was measured by a gauge, connections thereto having been made by means of stainless steel capillary tubing.

The experimental work consisted essentially in maintaining a sample of Merck's reagent grade Ag_2O at a constant temperature until the pO_2 ceased to increase, or in maintaining a more or less dissociated Ag_2O at a constant temperature while a small quantity of oxygen from an outside source was being consumed by the silver and was reaching a steady pressure. Temperatures were kept constant for 100 hr or more. Approximately four days were required for equilibrium pressures to be established from points 2 to 5% away from the equilibrium pressures and, in each case, both temperature and pressure had to be steady for about three days before equilibrium was as-

* 1 atm = 101325 newtons/square meter (N/m^2).
** From Lewis's dissociation data. Better to disregard his short duration slow recombination attempt.

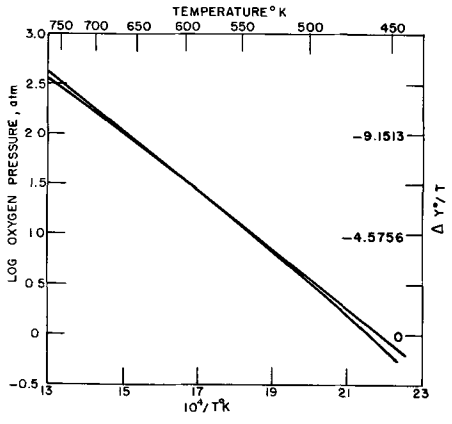

Fig. 1. Dissociation of Ag_2O. The curve (lower line) is a graph of all available data, given in Table I, columns 1 and 2. The straight line (upper) is obtained by application of the method of least squares to the data in Table I, columns 1 and 7.

sumed. (Since the decomposition of Ag_2O is hard to initiate, it was found most satisfactory to preheat each new sample to about 325°C until 5 to 10% decomposed and then to reduce the temperature to that at which equilibrium was to be sought.)

Treatment of Data

The data obtained are presented in columns 1 and 2 of Table I and on Fig. 1 along with the data reported by the three previous investigators. It is to be noted that the line drawn through the equilibrium points is not straight. The treatment of data is, in part, similar to that used by the author for the study of Mn_2O_3 (5) and MnO_2 (6), with the addition that molar volumes of Ag_2O and Ag were taken into consideration.

For the reaction $2Ag_2O \rightleftarrows 4Ag + O_2$

$$K = \frac{a^4\text{Ag} \times a\ O_2}{a^2Ag_2O}$$

where K is the equilibrium constant and a represents activity.

$$R\ln a\ O_2 = R\ln(p\ O_2 \times Z)$$

where $Z = pv/RT$. The values for Z, the compressibility factor, were obtained from NBS Circular 564 (7) by interpolations and by log log extrapolations (straight lines) for pressures in excess of 100 atm. These values, shown in column 3 of Table I, are multiplied by the corresponding pressures (column 2) to get the fugacities.

The method used by Pitzer and Smith (8) for calculating $R\ln(a_{Ag_2O}/a^2_{Ag})$ was adopted.

$$R\ln a_{Ag_2O}/a^2_{Ag} = 1/T \int_1^P (V_{Ag_2O} - 2V_{Ag})\,dp$$

$V_{Ag_2O} - 2V_{Ag}$ is considered constant and equal to 11.3 cm^3. By integration between P and 1 atm one obtains

$$R\ln(a_{Ag_2O}/a^2_{Ag}) = 1/T \times \frac{1.98717\ \text{cal/mol}}{82.056\ \text{cm}^3\ \text{atm}} \times 11.3\ \text{cm}^3\ (p-1)$$

The resulting values, multiplied by −2, give $R\ln(a^4_{Ag}/a^2_{Ag_2O})$ and these are shown in column 5.

The calculated $\Delta G°/T$ values gotten by adding columns 4 and 5 appear in column 6. By the use of the Cp equations given by Kelley (9) for Ag_2O, Ag, and O_2 the values in column 6 were projected to points (column 7) which would determine a straight line at 600°K, approximately the midpoint of the range of temperature over which the Ag_2O-Ag-O_2 system has been studied. (The heat capacity of Ag_2O has been determined only up to 500°K, but it is assumed here that the equation applies to 773°K.)

This portion of the method of treatment of the data has previously been given in detail by the author (5). The T_{AV} in the present case is 600°K and for the reaction $2Ag_2O \rightarrow 4Ag + O_2$

$$\Delta C_p° = 5.26 - 21.80 \times 10^{-3}T + 1.04 \times 10^5 T^{-2}$$

From the relations

$$\Delta Y°/T = (\Delta H°_{600}/T) - \Delta S°_{600}$$

and

$$\Delta Y°/T = \Delta G°_{600}/T + C$$

where the correction

$$C = -\Delta(H°_T - H°_{600})/T + \Delta(S°_T - S°_{600})$$
$$= -1/T\int \Delta C°_p\,dT + \int (\Delta C°_p/T)\,dT$$

one can obtain the correction to obtain $\Delta Y°/T$ for each temperature in column 1 of Table I.

The straight line obtained by the method of least squares for the data in Table I, columns 1 and 7, is shown in Fig. 1, and it has the following characteristics $\Delta H°_{600}$ (the slope) = 13.524 kcal;[1]

s.d. = 0.042 kcal

$\Delta S°_{600}$ (the intercept) = 29.502 cal/deg;

s.d. = 0.080 cal/deg

Standard deviation for the fit of the $\Delta Y°/T$ points to the equation

$$\Delta G°_{600} = \Delta H°_{600} - T\Delta S°_{600} \text{ is } 0.06994.$$

Again using the $Cp°$ equations of Kelley

$$\Delta H°_{298.15} = 14.69 \text{ kcal/mol } O_2$$
$$\Delta S°_{298.15} = 31.92 \text{ cal/deg mol } O_2$$
$$\text{Then } \Delta G°_{298.15} = 5.17 \text{ kcal/mol } O_2$$

In another treatment of the combined sets of data the heat of dissociation ($\Delta H°_{298}$) of $2Ag_2O$ (numerically equal to the heat of formation, but with opposite sign) is calculated from the equilibrium temperature-pressure data, the entropy ($\Delta S°_{298}$), the $\Delta(S°_T - S°_{298})$ and the $\Delta(H°_T - H°_{298})$, using the equation

$$\Delta H°_{298} = \Delta G°_T - \Delta(H°_T - H°_{298}) + T\Delta S°_{298} + T\Delta(S°_T - S°_{298})$$

$\Delta G°_T$ is gotten by multiplying the values given in column 6 of Table I by the corresponding temperatures of column 1. The heat content and entropy changes are based on data given by Kelley for Ag_2O up to 500°K, Ag and O_2. For Ag_2O above 500°K the equations of Kobayashi (10) are used, adjusting the results so that the data of Kobayashi agreed with the Kelley data at 500°K. The entropy of formation at 298°K of Ag_2O is taken as −15.9 cal/deg (11). For all of the 23 equilibrium points the $\Delta H°_{298}$ values are calculated and they appear in the last column of Table I. The average values of $\Delta H°_{298}$ shown for the four investigations are in good agreement. The grand average value of 14.62 kcal of the second method compares very favorably with the 14.69 kcal obtained by the first method. It is safe to assume that true equilibria were obtained in the experimental work. A word of caution should be given here. Although a plot of the $(H_T - H_{298})$ for Ag_2O looks much like a straight line, a straight line extrapolation to high temperatures results in $\Delta H°_{298}$ values in the neighborhood of 13.6 kcal. The curvature of the line has to be maintained above 500°K just like it obviously has to be for $(S_T - S_{298})$.

For calculation of the dependence of pO_2 on the temperature of the sample, without regard to the compressibility of the oxygen and the activities of the substances, the following empirical equations have been derived. Standard deviations are given for the fit of actually observed points to the equations. It

[1] One calorie = 4.1840 joules.

would appear that Eq. [3] or [4] may be used to give fairly precise pressures for given temperatures

$$\log pO_2 = 6.48773 - 2996.83/T; \quad \text{s.d.} = 0.02731 \quad [1]$$

$$\log pO_2 = -2493.13/T + 2.02688 \log T; \quad \text{s.d.} = 0.03709 \quad [2]$$

$$\log pO_2 = 94.6148 - 7438.44/T + 0.00991043T - 31.1855 \log T; \quad \text{s.d.} = 0.01281 \quad [3]$$

$$\log pO_2 = -292.9857 + 5301.69/T - 0.102885T + 120.944 \log T + 0.000031697T^2; \quad \text{s.d.} = 0.01278 \quad [4]$$

The least squares analyses in this paper were carried out on the National Bureau of Standards electronic computer, using the appropriate OMNITAB Program (12).

Conclusions

A study of the Ag_2O-Ag-O_2 system has been completed, overlapping the work of Benton and Drake, and closing the gap which existed between the temperature ranges used by Benton and Drake, and Lewis. It can now be said that the system has been studied from 446°K, the lowest temperature used by Benton and Drake, to 773°K, the highest temperature used by Keyes and Hara. All data have been included in the present determination of the thermodynamic constants.

Studies of Hydrocarbon Fuel Cell Anodes by the Multipulse Potentiodynamic Method

II. Behavior of Methane on Conducting Porous Teflon Electrodes

L. W. Niedrach

General Electric Company, Research and Development Center, Schenectady, New York

ABSTRACT

Rates of adsorption of methane on semimicro Teflon-bonded, platinum black fuel cell electrodes in the presence of a perchloric acid electrolyte are about an order of magnitude lower than those previously observed with ethane. At 65°C the measured rate of adsorption on a clean surface correlates well with the maximum anodic current that can be drawn from the electrode. The ad-layer on the surface of the electrode consists of C_1 species, some of which are partially oxidized. Similar C_1 species which form upon the adsorption of higher molecular weight hydrocarbons appear to play an important role in the over-all anodic oxidation of hydrocarbons. This implies that an efficient catalyst for hydrocarbon anodes should promote the cracking of higher molecular weight hydrocarbons to form C_1 radicals and also promote the reaction of these fragments with water.

The behavior of ethane and related hydrocarbons on smooth platinum electrodes in the presence of a perchloric acid electrolyte has been investigated with the multipulse potentiodynamic (MPP) method in this laboratory (1, 2). Recently the method has been extended to porous fuel cell anodes of more complex structure with which the behavior of ethane was examined in detail; a few preliminary experiments were performed with methane and propane (3). For this purpose a miniature version of a previously described (4) conducting-porous-Teflon fuel cell electrode (containing platinum black as catalyst) was employed.

This work showed that the behavior of ethane on the Teflon-bonded electrodes is both mechanistically and kinetically similar to that on smooth platinum (3). It also indicated that ethane and propane are similar in that their ad-layers on the electrode surface show two oxidation waves when a linear anodic sweep (l.a.s.) is applied. The first wave occurs at potentials below which (approximately 0.8v) the electrode surface is itself oxidized. This first wave generally exhibits a well-defined peak. The second wave is more diffuse and extends all the way from approximately 0.8v to oxygen-evolution potentials. Methane was found to differ markedly, however, in that only one wave could be detected during oxidation of its ad-layer. Because this wave corresponded to that of the more readily oxidized species from ethane and propane, it was felt desirable to investigate the behavior of methane in greater detail.

As in the previous study of ethane, a perchloric acid electrolyte was employed over a range of temperatures. Particular attention was given to the rates of adsorption and the nature of the species that form on the surface of the electrode. In addition data were again obtained to relate these properties to the over-all polarization curve for the fuel electrode.

Experimental

The equipment and general procedures utilized in these investigations have been described previously (3). In brief, the 0.2-cm diameter Teflon-bonded, platinum black electrode was mounted in a three-compartment, Teflon cell. Platinized platinum flags served as the hydrogen reference and counter electrodes. The former communicated with the working anode through

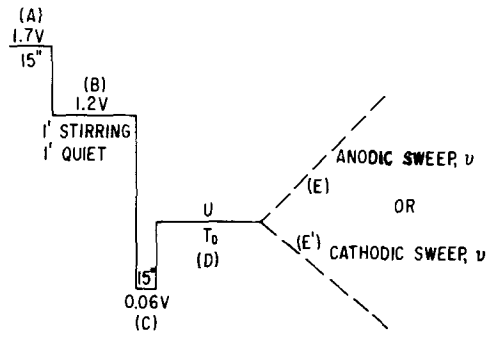

Fig. 1. Potential sequences applied to the test electrode

a Luggin capillary. The cell was operated in an air thermostat enabling control of the temperature to within 0.1°C.

The 4.3*N* perchloric acid electrolyte solution used for this work was prepared from reagent grade perchloric acid and quartz distilled water. Electrolytic grade hydrogen was used in the reference electrode chamber, and Phillips research grade methane was used as the fuel. Tank argon, deoxygenated by passage over heated copper turnings, was used as the "fuel" for obtaining solvent blanks. Tank argon was also used for degassing the solution.

The electronic instrumentation and circuit have been described previously (5).

The potential-time sequence applied to the anode for adsorption studies at constant potential is shown in Fig. 1. The rationale behind the various steps has been discussed in detail elsewhere (1-3, 5). Briefly, however, steps A through C serve to precondition the electrode and return it to a reproducible state before each equilibration. Following oxidation of impurities during step A, the electrode is taken to step B to allow the system to become quiescent while adsorption of fuel is prevented by an "adsorbed oxygen" layer on the electrode. In step C the oxygen layer is reduced at a potential sufficiently low that fuel adsorption is still prevented. Upon shifting to the potential of step D fuel adsorption occurs for the allotted time, T_D. Anodic sweep E is then applied to determine the charge required for the oxidation of the fuel ad-layer. The alternative cathodic sweep E' is used to determine the "real" surface area of the electrode from the charge corresponding to hydrogen deposition. In this case, argon is substituted for the fuel.

For the present electrode the useful range of sweep speed v for oxidation of the ad-layer was previously established by adsorbing a fixed amount of ethane (corresponding to T_D = 600 sec) and measuring the charge required for its oxidation over a range of sweep speeds (3). The useful range was found to extend from approximately 0.1 to 0.4 v/sec. Lower sweep rates resulted in additional charge from the oxidation of fuel that adsorbed during the sweep. At higher sweep rates the traces tended to lose definition, because of the diffuse structure of the electrode. A sweep speed of v = 0.1 v/sec was used routinely in the present work.

Steady-state polarization curves such as that in Fig. 7 were obtained in two ways. The first method involved application of steps (A-D) of Fig. 1 before each measurement of current at a particular potential U. Ten-minute equilibrations were allowed on each point before the final value of current was recorded. In the second method, steps (A-D) of Fig. 1 were applied only once, at the lowest value of U. The potential was then changed in increments and the current recorded for each potential after an apparent constant value was established. The two methods gave essentially identical results.

Results

The general form of the current-voltage trace obtained during oxidation of adsorbed methane with a linear anodic sweep is shown for a range of equilibration times, potentials, and temperatures in Fig. 2-4. For each experimental condition a trace corresponding to the background solvent blank is also presented. Figure 2 shows a series of traces for adsorbed methane at 65°C for various equilibration times at a potential of 0.3v. The effect of the equilibration potential at 65°C appears in Fig. 3. Similar data showing the effect of temperature appear in Fig. 4. In obtaining the data for the latter two figures 10-min equilibrations were used throughout.

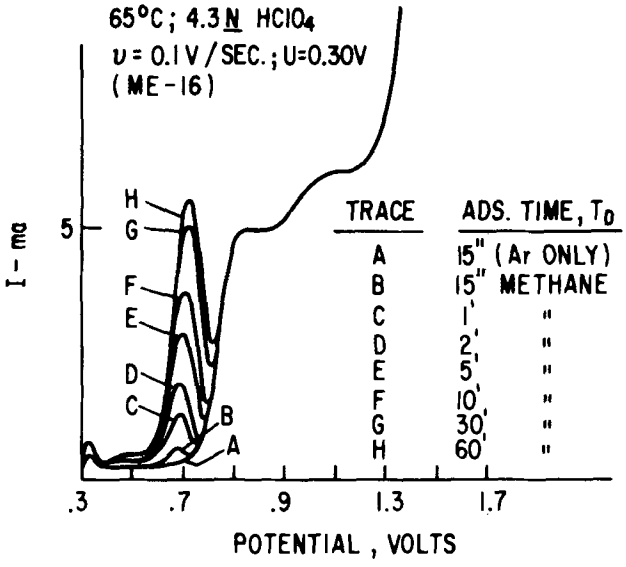

Fig. 2. Current-potential (time) traces for methane after different adsorption times.

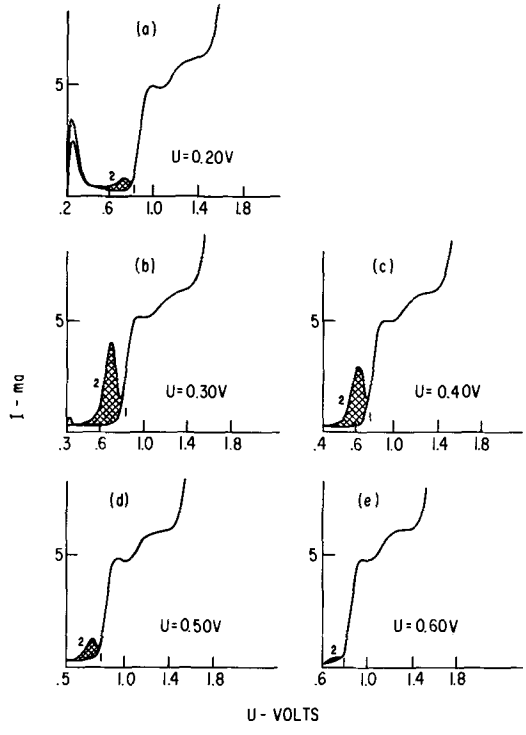

Fig. 3. Current-potential (time) traces for methane adsorbed at several potentials. 4.3*N* $HClO_4$; 65°C; V = 0.1 v/sec; T_D = 10 min; 1, Ar blank; 2, methane; ME-16.

It is clear from Fig. 2-4 that the amount of methane adsorbed is a strong function of the time, potential, and temperature. However, for all conditions of potential and temperature and for equilibration times as long as an hour only the single wave is obtained during oxidation of the ad-layer. This wave, like wave 1 for ethane (3), becomes more prominent as the tem-

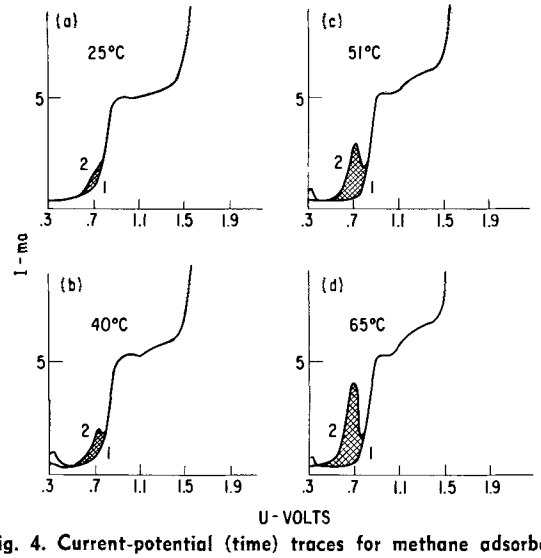

Fig. 4. Current-potential (time) traces for methane adsorbed at several temperatures. 4.3*N* $HClO_4$; *V* = 0.1 v/sec; T_D = 10 min; *U* = 0.3v; 1, Ar blank; 2, methane; ME-16.

perature is increased. Because the material is so readily oxidized it is no longer seen when equilibrations are performed as potentials greater than 0.5v.

The magnitude of the charge, Q_{E_1},[1] associated with the oxidation of the material adsorbed after any time, T_D, was obtained by integrating the area enclosed by the solvent (blank) curve and the methane curve. This is indicated by the shaded areas in the figures. It is to be noted that hydrogen formed by dissociation during the initial adsorption step is not included in these measurements.

Variations in Q_{E_1} with time at different potentials are shown in Fig. 5 for equilibrations performed at 65°C. The data have been normalized to charge per unit of "real" surface area as determined by cathodic deposition of hydrogen on the electrode. A conversion factor of 0.21 mcoul/cm² was used in calculating the "real" area (6).

As in the case of ethane (3) the rate of adsorption is initially constant and then follows an empirical Elovich relationship over a moderate range. Ultimately a steady-state coverage is achieved when the rate of adsorption equilibrates with the rate of oxidation. At 65°C the maximum (initial) adsorption rate for methane in terms of $\Delta Q_{E_1}/\Delta t$ is approximately 0.00030 mcoul/sec/cm² of real area.

[1] Q_{E_1} is used to designate this charge because the oxidation occurs in the same potential region as that of wave 1 for ethane and propane. In contrast to ethane and propane, however, $Q_{E_1} = Q_{E_{tot}}$ for methane; here $Q_{E_{tot}}$ is the charge required to oxidize all of the adsorbed surface species derived from the hydrocarbon fuel.

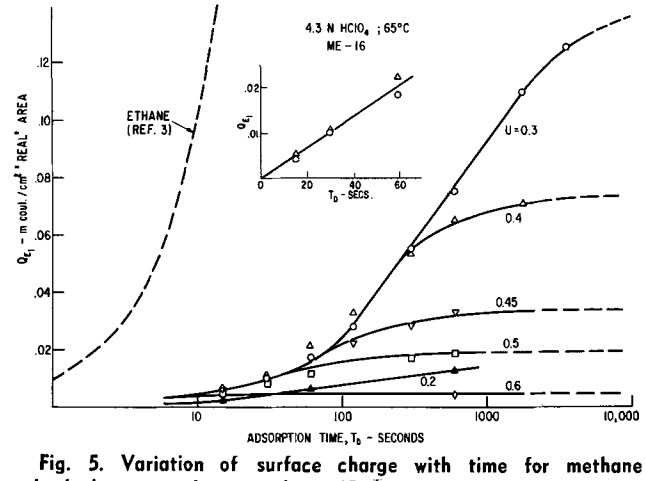

Fig. 5. Variation of surface charge with time for methane adsorbed at several potentials at 65°C.

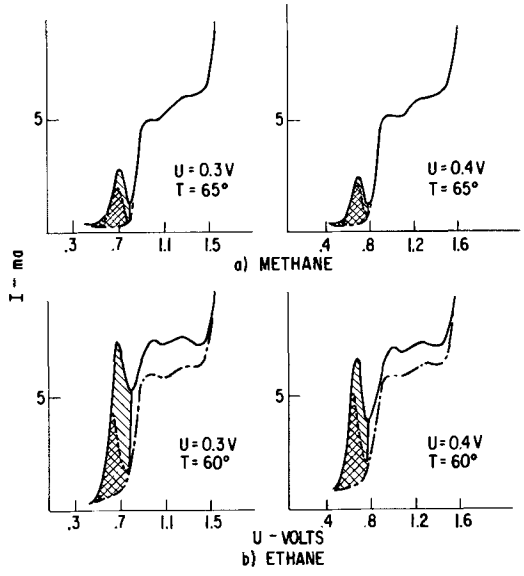

Fig. 6. Effect of cathodic hydrogenation on the current-potential (time) traces for adsorbed methane and ethane. 4.3*N* $HClO_4$; ——— initial; --- after hydrogenation; —·— argon blank; T_D = 5 min.

Because of the low rate, even at 65°C, detailed measurements of this type were not made at other temperatures. However, at 25°C Q_{E_1} = 0.0088 mcoul/cm² of real area after a 10-min equilibration. At this low coverage it is to be expected that the adsorption would still be in the linear region. Using such an assumption one calculates a rate of 0.000015 mcoul/sec/cm² of real area, or a magnitude less than that at 65°C. This corresponds to an activation energy of about 15 kcal/mole. For ethane a similar temperature effect was found by direct measurement of the initial rates at 25° and 60°C (3). The observed rates at the two temperatures, which were 0.0010 and 0.010 mcoul/sec/cm² of real area, respectively, correspond to an activation energy of 13 kcal/mole.

The single wave for methane occurs in the same potential range as wave 1 for ethane and propane, as well as such partially oxygenated species as CO, formic acid and "reduced CO_2" (3). It therefore appears that similar surface species are involved in these cases. To determine whether some of the species of this wave for methane are removable by cathodic hydrogenation and therefore probably unoxygenated, cathodic hydrogenations were performed after equilibrations of the electrode with methane at 0.3 and 0.4v. In these experiments, sequence A-D of Fig. 1 was first followed. After adsorption for time, T_D, the potential was again stepped down to 0.06v for 2 to 5 min before application of the linear anodic sweep. Similar experiments were also performed with ethane for comparison. The results of these experiments are summarized in Fig. 6 and Table I. It is clear that in each case a portion of the surface species was removed by this treatment. The amount removed decreased with increasing equilibration potential. In the case of ethane all of wave 2 was removed by the hydrogenation treatment. The present results for ethane differ

Table I. Effect of cathodic hydrogenation on wave 1 (T_D = 5 min; T_{Hyd} = 5 min)

from those of Gilman (1) who performed similar hydrogenations with the wire microelectrode after equilibrations at 0.4v. In that case no desorption of wave 1 species was observed after hydrogenation at 0.06v. The diffuse structure of the Teflon electrode as well as small differences in the catalytic behavior may account for the observed differences.

One additional point for consideration is the relationship between the adsorption data and the polarization curve for the electrode operating on methane. Such a polarization curve obtained at 65°C is shown in Fig. 7. The abscissa is expressed in terms of the current density per unit of real and geometrical area of the electrode. Therefore the data may be related to the adsorption studies as well as performance curves for fuel cells. Also shown in the figure is the measured surface coverage, Q_{E_1} as determined from linear anodic sweep measurements. The forms of the polarization and surface coverage curves are similar to those previously reported for ethane (3); however, the amplitudes of both are considerably less than for ethane.

Similar bell shaped curves relating surface coverage to potential have also been observed by others with platinum electrodes and a variety of fuels and electrolytes. For example such curves have been obtained electrochemically for ethane (1), ethylene (2) and acetylene (2) with a perchloric acid electrolyte, for methane (7), ethane (7), propane (7, 8) and butane (7) with a phosphoric acid electrolyte, and for ethane with a hydrofluoric acid electrolyte (7). Radiochemical tracer techniques have also given similar results for ethylene with a sodium hydroxide electrolyte (9) and a sulfuric acid electrolyte (10) and for butane with a sulfuric acid electrolyte (11).

Discussion

In considering the results for methane, it will be most useful to relate them to the previous observations with other fuels. As already noted, a most significant difference lies in the fact that but a single oxidation wave is obtained for the ad-layer from methane in contrast to the two waves from the ethane and propane. Gilman, after studies of ethane (1), ethylene (2), and acetylene (2) has concluded that wave 2 from ethane is associated with the oxidation of partially dehydrogenated C_2 species on the electrode surface. It is reasonable to conclude that similar multiple carbon species are associated with the second wave from propane and that a corresponding analogy will hold for higher hydrocarbons. With these higher molecular weight materials it is likely that a variety of species of different chain length will be present and contribute to the second wave. These would result from cracking and polymerization reactions which have been demonstrated to occur even at 25°C (12).

It has also been noted in past work that C_1 species are among the cracking products obtained from the higher hydrocarbons at 25° (12) and at 65°C (13). Furthermore, the cracking of propane on platinum in the absence of electrolyte has been observed to form methane and ethane and to have a pronounced temperature coefficient (14). In view of these observations and the fact that only wave 1 is observed with methane, it seems clear that the more readily oxidized surface material corresponds to C_1 species. Previous observations (1, 12) as well as the data in Table I and Fig. 6 indicate further that these species are partially oxygenated.

The adsorption rates and steady-state coverages for methane are considerably lower than those previously observed with ethane; however the variation in coverage with potential parallels that for ethane. With regard to the lower rate of adsorption for methane, this may relate to the somewhat higher dissociation energy required to break the first C-H bond than is required for ethane, 101-102 kcal *vs.* 97 kcal, respectively (15). Alternatively, it may reflect a weaker physical adsorption prior to dissociation on the surface to form the chemisorbed species. Sufficient detailed data are, however, unavailable at the present time to reach a definitive conclusion concerning the reason for the pronounced differences.

The shape of the curve relating surface coverage to potential reflects the influence of competing reactions. At low potentials (< 0.3v) adsorption is hindered because the required dissociation of the adsorbing hydrocarbon is repressed by the presence of atomic hydrogen on the electrode surface. At potentials above 0.3v the surface coverage again declines in order to permit the rate of adsorption to keep pace with the increasing rate of oxidation of the ad-layer. It is possible that the shape of the curve is further influenced by a potential-dependent, competitive adsorption with water which has been used in the interpretation of the effect of potential on the adsorption of ethylene (10).

The low adsorption rates for methane are reflected in the low current densities obtained with methane as seen in the polarization curve of Fig. 7. The maximum current density, at 0.5v, is about one tenth that obtained with ethane. In this connection it is of interest to relate the maximum current density to the adsorption rates on the clean surface, *e.g.* the initial rates at 0.3 and 0.4v.

To convert the adsorption rates to equivalent current densities, it must be recalled that the former are expressed in terms of the change in surface charge with time, $\Delta Q_{E_1}/\Delta t$. Allowance must therefore be made for any oxidation that occurred during the adsorption step itself, *e.g.*, immediate oxidation of dissociated hydrogen. This may be done by multiplying $\Delta Q_{E_1}/\Delta t$ by the ratio of the charge associated with oxidation of the hydrocarbon fuel molecule to that required for oxidation of the adsorbed species.

While the precise composition of the ad-layer has not been established for either methane or ethane, especially after short equilibrations, it is possible to calculate a range of limiting currents from the initial adsorption data at 0.3 and 0.4v. In the case of methane, depending on whether the ad-layer is assumed to have an average composition approaching that of methyl radicals or that of a highly oxygenated species, such as CO, the observed rate of adsorption would be equivalent to a steady state current density of from 0.30 to 1.2 $\mu a/cm^2$ of real area. The observed value of 0.3 $\mu a/cm^2$ is in good agreement in view of the evidence for a mixture of C_1 radicals and partially oxygenated species.

A similar calculation has been made for ethane (3). In this case the calculated maximum current density fell in a range from 14 to 35 $\mu a/cm^2$ and the ob-

served value was 2.5 μa/cm^2 of real area. For comparison, Rhodes (16) obtained adsorption rates equivalent to 22 μa/cm^2 (10^{13} molecules/cm^2/sec) for ethane on a rotated platinum electrode (600 rpm) at 80°C with a 1*N* H_2SO_4 electrolyte. While this value is in excellent agreement with the results with the Teflon bonded electrode, no data were obtained for the steady-state maximum current obtainable with the rotating electrode.

The discrepancy between the calculated and observed maximum current densities for ethane on the Teflon-bonded electrode undoubtedly reflects the fact that at the potential of the maximum steady-state current some of the more refractory species are present on the surface and lower the adsorption rate relative to that on the "clean" surface at 0.3v. The decline in the current density that occurs at higher potentials appears to reflect further reductions in adsorption rate as a result of such processes as surface oxidation, anion adsorption, and stronger bonding of water to the surface. These processes would also contribute to the similar decline in methane performance at potentials above 0.5v.

At low potentials, the effect of the adsorption rate on the polarization curve is minimal. Here it is clear that the overvoltage required for the further oxidation of surface intermediates to CO_2 is limiting. This is true, of course, under potentiostatic conditions as well as with the resistive loads of practical fuel cells.

The pronounced temperature coefficients for both the methane and ethane adsorptions (activation energy of about 14 kcal/mole) are reflected in the observed improvement in the performance of hydrocarbon fuel cells with increasing temperature. In particular, they relate to the regions of "unstable" performance observed with saturated hydrocarbon fuel cells operating on resistive load (17-19). Under these conditions, it will be recalled that at low current densities steady performance is obtained while at higher current densities the performance decays with time or, under certain conditions, oscillations set in (19, 20). As a result of the increasing adsorption rates with increasing temperature, the region of instability occurs at continuously higher current densities as the operating temperature is increased. When polarization curves are obtained potentiostatically, as in the present work, maximum currents are observed in place of the instability associated with resistive loads.

While it would be premature to discuss the mechanisms of the electrode reactions in any detail at this time, it is appropriate to consider briefly some of the possible paths suggested by the available information. In particular it is pertinent to speculate about the meaning of the two separate l.a.s. waves seen with ethane and propane, the single wave seen with methane, and the evidence for the partially oxidized surface species. In the discussion that follows, ethane will be used as the model with the expectation that higher molecular weight hydrocarbons will behave similarly. The behavior of methane, in turn, will be somewhat simpler.

The initial step must certainly involve adsorption of the fuel on the electrode surface. On the basis of careful kinetic studies with ethane on wire microelectrodes, Gilman has concluded (1, 2) that this primary adsorption step corresponds to the formation of an ethyl radical on the surface. This may be represented by

$$C_2H_6\ (\text{gas})^2 + S \rightarrow S - C_2H_5 + H^+ + e \qquad [2]$$

at potentials at which appreciable currents are drawn from the electrode. He points out that an equivalent route is given by

$$C_2H_6\ (\text{gas}) + 2S \rightarrow S - C_2H_5 + S - H \qquad [2a]$$

[2] More precisely, the gas will first dissolve in the electrolyte and be transported by diffusional processes to the electrode where it will adsorb from solution. While mass transport processes are not limiting in the work under discussion, it is obvious that they can become important under some conditions of operation. For practical fuel cell electrodes it is important that mass transport limitations be minimized.

in which case the adsorbed hydrogen is rapidly consumed by the Volmer reaction:

$$S - H \rightarrow S + H^+ + e \qquad [2b]$$

At low potentials, of course, some of the hydrogen will remain adsorbed on the surface.

Gilman then reasons that the ethyl radical follows two paths. The first results in the formation of four surface bonds to the surface without rupture of the C-C linkage

$$S - C_2H_5 + 3S \rightarrow S_4 - C_2H_2 + 3H^+ + 3e \qquad [3]$$

This species is associated with wave 2 obtained with a l.a.s. and is identical with the single adsorbed species obtained when ethylene and acetylene are adsorbed (2). The present work is in accord with this interpretation, and cathodic hydrogenations of adsorbed ethane at 25°C have shown that the major material on the surface at that temperature corresponds to C_2 species while that for propane corresponds to C_3 species (12).

The second reaction path of the ethyl radical results in the formation of the material associated with wave 1, which Gilman also obtained for ethane on the platinum wire microelectrode. In the absence of detailed kinetic data for the species associated with wave 1 Gilman did not speculate in detail on its identity.

The new data obtained with the Teflon-bonded electrodes are helpful in this area. The similarities between the single wave for methane and wave 1 for ethane, as well as other evidence noted above, strongly suggest that the second reaction path of the ethyl radical involves C-C bond fission as indicated in the following general equation

$$S - C_2H_5 + S \rightarrow 2S - CH_a + (5 - 2a)\ H^+ + (5 - 2a)\ e \qquad [4]$$

(The methylene radical with two carbon bonds to the surface may represent the principal species in parallel with the C_2H_2 of wave 2 which also has two surface bonds per carbon atom.)

The C_1 species in turn appear to react readily with water to form a partially oxygenated material which corresponds to the previously proposed "CO-like" species of Niedrach (12) and the "reduced CO_2" of Giner (21), and which Giner has also more recently found to be formed during the oxidation of hydrocarbons in the presence of a sulfuric acid electrolyte (22). Brummer and Turner (8) have also obtained evidence for the presence of partially oxygenated surface species in their studies of propane at higher temperatures with a phosphoric acid electrolyte, as have Niedrach and Tochner (7).

The specific identity of the oxygenated species is as yet unknown and the reaction can therefore best be represented by

$$S - CH_a + b\,H_2O + cS \rightarrow S_{(c+1)} - CH_dO_b + (a + 2b - d)\ H^+ + (a + 2b - d)\ e \qquad [5]$$

That both the C_1 species and the partially oxygenated species are present on the surface and oxidize over the same potential range is indicated by the new hydrogenation experiments with methane and ethane. Since Eq. [4] represents a "cracking" reaction and Eq. [5] a "reforming" reaction, these observations suggest that it would be profitable to direct attention toward the study of the behavior of alternative catalysts in promoting such reactions.

With regard to the more refractory species of wave 2, which oxidize only at higher potentials, it is likely that an entirely different mechanism of oxidation prevails. This conclusion is based on Gilman's observation that conversion to the species of wave 1 is slow (2). It is therefore likely that oxidative attack occurs before the C-C bonds are ruptured. This could result in the formation of alcohol-like species as intermediates. It should be emphasized, however, that such intermediates will undoubtedly be quite distinct from those involved in the direct oxidation of alcohol-

type fuels at moderate temperatures. The alcohol-like species derived from hydrocarbons would be strongly bound to the surface by multiple carbon-metal linkages, and hence complete oxidation to CO_2 would be assured. With alcohol fuels it is more likely that weaker bonds between the oxygen and the metal are involved. This is suggested by the incomplete oxidation to organic acids that is often observed with alcohols (23) at moderate temperatures. It is further supported by the behavior of alcohols towards deuterium exchange, where it is found that the hydroxylic hydrogen undergoes exchange most readily (24).

Relating to the oxidation of these multiple-carbon species is the work of Bockris and co-workers (25-27) dealing with the oxidation of ethylene and acetylene. They interpret Tafel plots and other evidence in terms of a slow step involving the production of hydroxyl radicals from water. Such a route would not be in conflict with the present results.

Summary and Conclusions

The behavior of methane on Teflon-bonded fuel cell electrodes parallels that of ethane in that adsorption at intermediate potentials varies linearly with time at low coverages, and a semilogarithmic relationship applies at higher coverages. Rates of adsorption of methane are, however, over an order of magnitude lower than those previously observed with ethane. At 65°C the measured rate of adsorption of methane on a "clean" surface correlates well with the maximum anodic current that can be drawn from the electrode. This is in marked contrast to the behavior of ethane where the observed maximum current is almost an order of magnitude lower than that calculated from the adsorption rate. The difference in behavior of the two fuels is related to the ad-layers formed during adsorption. In the case of methane only readily oxidized C_1 species, some of which are partially oxygenated, form. The ad-layer from ethane also contains relatively refractory C_2 species which block the surface and limit the adsorption rate at the potential of the maximum current.

On the basis of the behavior of methane and ethane it is possible to construct a tentative picture of the steps involved in the anodic oxidation of hydrocarbons on platinum catalyzed fuel cell electrodes. After a primary adsorption step, at least two distinct reaction paths are followed by ethane and higher hydrocarbons. One path results in the formation of the relatively refractory species. The most desirable path results in "cracking" of the carbon chain to form the more reactive C_1 radicals and the partially oxygenated species. At low current densities the overvoltage associated with oxidation of the ad-species to CO_2 limits performance. As the current density is increased the adsorption rate eventually becomes the limiting factor.

In view of the many species present on the electrode surface and the changes in coverage and composition with temperature, potential, and time, much attention to analytic detail will be required before a definitive mechanism can be derived. It seems unlikely that electrochemical measurements alone will be sufficient to unravel all of the steps. Instead, much supplementary information must be sought, particularly with regard to the identification of surface species and their roles as active intermediates or passive by-products. Radiotracer, infrared, chromatographic, and other related techniques should prove invaluable in identifying such species, in measuring "turnover" rates on the electrode surface, and in providing additional supporting information.

Acknowledgments

Anodic Oxidation of Cadmium and Reduction of Cadmium Hydroxide and Oxide in Alkaline Solutions

M. W. Breiter and J. L. Weininger

General Electric Company, Research and Development Center, Schenectady, New York

ABSTRACT

The anodic oxidation of smooth cadmium and the subsequent reduction of cadmium hydroxide and oxide were studied by voltammetric methods with and without superimposed a-c voltage. Under voltammetric conditions a layer of $Cd(OH)_2$ appears to be formed at potentials below the passivation potential. Passivation results from a continuous thin film which forms at potentials between 0.05 and 0.1v. The small capacitance and the large resistance of the interface electrode/solution are due to this film. On reduction the thin film is reduced first. A pseudocapacitance which is attributed to the adsorption of OH radicals is observed during the anodic sweep in a potential range where formation of $Cd(OH)_2$ or CdO is not yet possible.

The study of the electrochemical oxidation of cadmium and reduction of cadmium hydroxide and oxide in alkaline electrolytes has been of interest because of the use of Cd-electrodes as the negative plates in Ni-Cd batteries. Casey and Lake (1, 2) concluded that the anodic oxidation occurs by a two-step mechanism in the absence of carbonate

$$Cd \xrightarrow{\text{electrochemical}} CdO \xrightarrow{\text{chemical}} Cd(OH)_2 \qquad [1]$$

The primary reaction product, CdO, is converted to $Cd(OH)_2$ through a soluble intermediate. The conversion product, $Cd(OH)_2$, is porous. A film consisting of a dark, tightly adherent layer next to the metal and an outer layer of a loose, scaly or powdery yellow material was produced anodically. X-ray diffraction patterns showed the presence of crystalline $Cd(OH)_2$. The inner layer was assumed to be CdO since it has the dark color of CdO and since the observations of the composition of the outer layer were parallel to those of Huber (3). Huber had stated (3) that electron diffraction photographs of very thin coatings formed anodically on cadmium appeared to indicate that the initial oxidation product is CdO. Conclusions on the electrical properties of the film were drawn on the basis of potential decay curves after current interruption and of capacity measurements (2). The work of Huber (3) and Casey and Lake (1, 2) has received general recognition because it pointed out the importance of a soluble intermediate in the formation of $Cd(OH)_2$. However, the sequence of the two reactions in Eq. [1] has been open to question.

No evidence of CdO was found by Croft (4) who studied the oxidation of cadmium by cyclic voltammetry and by oxidation at constant potential. Again the existence of crystalline $Cd(OH)_2$ was established by x-ray diffraction. However, it should be pointed out that the absence of CdO-lines in the diffraction pattern excludes only the presence of crystalline CdO, not of amorphous CdO. The oxidation was attributed (4) to the reaction

$$Cd + 2\,OH^- = Cd(OH)_2 + 2e^- \qquad [2]$$

The rate depended in a similar way on the potential for both techniques. It has maxima at two potentials differing by 22 mv. After sufficient time had elapsed the rate of oxidation at constant potential followed a parabolic growth law. It was suggested that the growth of a film is controlled by the transport of mass and charge through the layer and that the process in the electrolyte is not relevant. A general formulation of this concept was given by Croft and Tuomi (5). The passivation of reaction [2] at more anodic potentials was attributed to properties of the semiconducting $Cd(OH)_2$ film.

Lange and Ohse (6, 7) pointed out that the primary formation of CdO is improbable on thermodynamic grounds. The standard affinity of reaction [2] is less negative with −1.04 kcal than that of the reaction

$$Cd + 2\,OH^- = CdO + H_2O + 2e^- \qquad [3]$$

with −2.9 kcal. Their reasoning involves the assumption that with anodic polarization the overvoltages of reactions [2] and [3] are such that reaction [3] is not favored. The close agreement between experimental and theoretical values of the potentials for each of the two plateaus which appeared after current interruption during intermittent anodic charging curves seems to confirm this assumption. However, it is not quite sure from the figures in ref. (7) that the potentials measured at a certain time after current interruption represent equilibrium values corresponding to reaction [2] or [3], respectively. It was suggested (7) that cadmium hydroxide which is formed initially dehydrates partially on the metal surface

$$Cd(OH)_2 = CdO + H_2O \qquad [4]$$

Thus the local arrangement $Cd/CdO/Cd(OH)_2/OH$ is produced in agreement with the results on the composition of the films. The occurrence of reaction [4] is attributed to a local decrease of the chemical potential of water toward the metal inside the $Cd(OH)_2$ film.

Other contributions to the elucidation of the mechanism of the cadmium oxidation either generally follow (8-10) the reaction scheme of Eq. [1] or assume (11, 12) that $Cd(OH)_2$ is the primary reaction product.

Thus the proposed mechanisms of the anodization of Cd either include or exclude CdO as primary reaction product. Each of the above interpretations explains certain experimental observations of the electrode reactions. It is the purpose of this communication to supply new experimental evidence which allows a more detailed description of the mechanism. The experiments were performed to investigate especially the possible role of CdO. Voltammetric measurements had proved useful in previous studies (13) of the anodic oxidation of nickel electrodes in alkaline solutions. Similar techniques were applied to examine the anodic oxidation of cadmium.

Experimental

Measurements were made in a Teflon vessel of standard design at room temperature in solutions bubbled vigorously with purified hydrogen. The solutions (0.2*N* KOH, 1*N* KOH, 5*N* KOH) were prepared from AR reagent chemicals and double-distilled water. Preelectrolysis of the electrolyte had no effect on the ex-

perimental results. This may be due to the removal of impurities by adsorption on the large platinized counter electrode (about 20 cm^2 geometric area) in a small volume (about 100 cm^3) of electrolyte. The potential U was measured *vs.* a hydrogen electrode in the same electrolyte as the test electrode. All potential measurements are referred to this reference electrode.

The Cd electrodes were prepared as follows. Pieces with a length of about 1 cm were cut from a rod (diameter 1 cm) of high purity (99.99%) supplied by Belmont Smelting and Refining Company. The cylindrical walls of these pieces were masked with Teflon sleeves which fitted tightly. Pt-wires were spot-welded as leads to the one end of the short Cd-rod inside the hollow Teflon rod. The other end was machined such that it formed a flat surface with the Teflon sleeve. It served as a test electrode.

The following pretreatment gave reproducible results. The new Cd-electrode was etched in concentrated nitric acid (50%) at room temperature. In preparation for each experiment the Cd electrode was chemically polished in a solution consisting of equal parts of glacial acetic acid and 30% H_2O_2 at room temperature. The electrode was washed thoroughly in distilled water saturated with hydrogen. The electrical connections were made before inserting the electrode at a potential of —0.8v in the vessel. The contact with air was minimized by the short duration of the insertion (2 sec) and by the water film on the electrode. The electrode was kept for 5 min at —0.8v to reduce cathodically traces of oxide or hydroxide. The reduction of traces of oxide is indicated by the decrease of the current with time. The cathodic current approaches a constant value within 5 min after the insertion. It was found that the shape of I-U curves is practically independent of the time of cathodic polarization after 5 min. Then the potential was rapidly changed potentiostatically to a less cathodic value (between —0.5 and —0.25v), and a periodic sweep of triangular shape was started by triggering manually the function generator. The capacity C_s measured by voltammetry with superimposed a-c current at 10,000 cps had values which are attributed to the capacitance of the Helmholtz layer at the starting potential of the sweeps (see subsequent discussion). Thus the surface is essentially free of oxides. The anodic sweep extended to a given potential; the subsequent cathodic sweep was reversed at about —0.7v. Measurements were made at sweep rates of 3 and 30 mv/sec. Results obtained at the slower sweep rate will be discussed here since certain features of the oxidation are more clearly observed at these slow rates. Measurements of the current I and the ohmic (R_s) and capacitive component ($1/\omega C_s$) of the impedance of the interface electrode/solution at a given frequency were made only during the first cycle. Before further measurements, the above procedure starting with chemical polishing was repeated. It was found that the electrode could be polished about 70 times before any deformation due to repeated use became noticeable. Then the electrode was machined and etched in nitric acid before continuing the experiments in the above way.

The experimental setup for the measurement of I-U curves, R_s-U curves, and $1/\omega C_s$-U curves was described previously (14). The large counter electrode was not appreciably polarized by cathodic currents up to several hundred ma and anodic currents up to 20 ma. The function generator type 250 of Exact Electronics was used. Data were recorded by the analog to digital recording equipment (14), and processed by the G. E. 235 computer in conjunction with the G. E. paper tape reader. During the a-c measurements the I-U curves were simultaneously recorded by the X-Y recorder F 80 Varian Associates. This served as a check of the reproducibility which was good. Impedance measurements were made and are subsequently discussed in a series analog circuit at 10,000, 1000, and 100 cps.

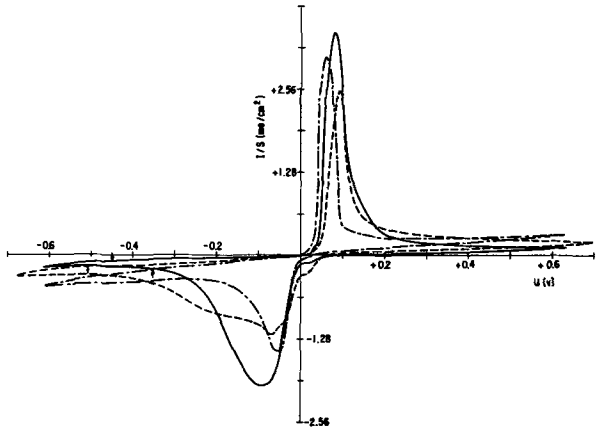

Fig. 1. Current-potential curves at 3 mv/sec on smooth Cd-electrodes. - - 0.2*N* KOH $S = 0.2$; ——— 1*N* KOH $S = 1$; -.-.- 5*N* KOH $S = 2$.

Some experiments were carried out in the assembly described in ref. (13) to study the oxidation of cadmium at constant potential in KOH by following the d-c current and the ohmic and capacitive component of the interfacial impedance at 1000 cps as functions of time. Again the freshly polished electrode was maintained for 5 min at —0.8v. Then the potential was switched rapidly by the Wenking potentiostat to a desired value in the vicinity of the reversible potential of reaction [2]. Readings were taken between 10 sec and 10 min after the change of potential.

Results

Typical I-U curves are shown in Fig. 1. The curves are reproductions of the actual traces on the chart of the X-Y recorder. The start of the cycle (anodic sweep) is marked by vertical arrows. In order to accommodate current densities obtained in three different solutions the ordinate has different units for each curve. The curves are self-explanatory except for the following points: The large anodic peak was observed by Croft (4). With increasing concentration of KOH, its voltage at maximum current shifts toward less positive potentials, and the maximum anodic current increases. At potentials above about 0.3v, the current is nearly independent of potential during the anodic sweep. A small wave appears between 0.1v and 0 in 0.2*N* KOH and 1*N* KOH at $U < 0.1$v. The height of the small wave decreases with the KOH concentration. It is absent in 5*N* KOH. The width of the big reduction wave between 0 and about —0.4v increases with decreasing KOH concentration. Simultaneously its height becomes smaller.

The I-U curves in Fig. 2 were measured in 1*N* KOH. Curves a and b demonstrate the effect of different po-

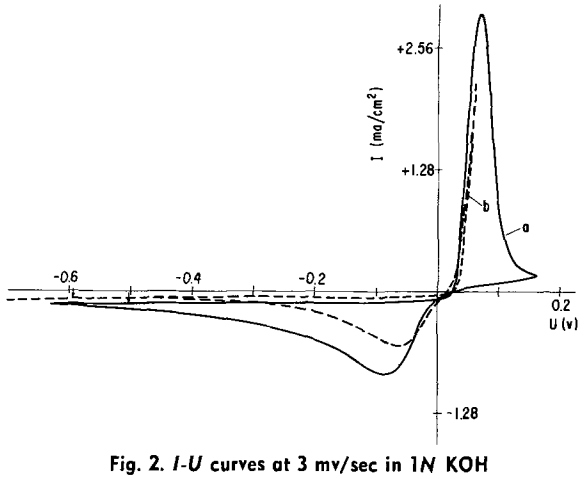

Fig. 2. I-U curves at 3 mv/sec in 1*N* KOH

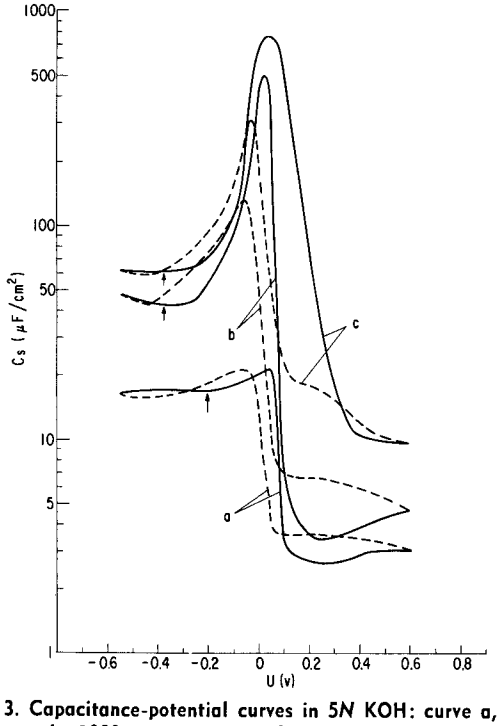

Fig. 3. Capacitance-potential curves in 5*N* KOH: curve a, 10,000 cps; curve b, 1000 cps; curve c, 100 cps; ——— anodic sweep; --- cathodic sweep.

tentials of reversal at the end of the anodic sweep on the shape of current-potential curves. Similar results were obtained in 0.2*N* and 5*N* KOH. The reduction of the layer formed during the preceding anodic sweep occurs at $U < 0.02$v. The cathodic wave is always wider than the main anodic wave which appears between 0.02 and 0.15v. The rate of layer formation is nearly the same at a given potential during the anodic and cathodic sweep for curve b. The *I-U* curves at 30 mv/sec are not shown here. They exhibit the same waves as the corresponding curves in Fig. 1 and 2. However, the waves are wider at larger currents. The details of the passivation of the layer formation during the anodic sweep above $U > 0.1$v and of the layer reduction during the cathodic sweep are better pronounced at the small sweep rate of 3 mv/sec.

The results of the impedance measurements in 5*N* KOH by voltammetry with superimposed a-c voltage are plotted in Fig. 3 and 4. The sweep rate was 3 mv/sec. The start of the measurements is marked by vertical arrows. A semilogarithmic plot was used to accommodate the curves measured at 10,000, 1000, and 100 cps. The general shape of the C_s-*U* curves and R_s-*U* curves of the anodic sweeps at $U > 0$ is similar to those of L'vova and Fortunatov (10) obtained under conditions of quasi-equilibrium. The remarkable feature of the C_s-*U* curves a and b in Fig. 3 is the rapid decrease of C_s with potential between 0.05 and 0.1v during the anodic sweep and the increase of C_s between 0.05 and —0.05v during the cathodic sweep. The potential range of the rapid decrease of C_s (10,000 cps) coincides with that of the decrease of *I* (Fig. 1 and 2) for each of the three solutions. The same behavior is reflected by the rapid increase of R_s between 0.05 and 0.1v during the anodic sweep and the decrease between 0.05 and —0.05v during the cathodic sweep (see curves a and b in Fig. 4). The C_s-*U* curves and R_s-*U* curves in 0.2*N* and 1*N* KOH look similar to the corresponding curves in Fig. 3 and 4.

The influence of the concentration of KOH is shown by the C_s-*U* curves of Fig. 5. These curves were obtained in 0.2*N* KOH. They differ only slightly from the corresponding curves in 1*N* KOH. Generally the capacitance is larger at a given potential and frequency in 5*N* KOH than in 0.2*N* KOH and 1*N* KOH at potentials $U < 0$v. At the smaller frequencies of 1000 and 100 cps the C_s-*U* curves exhibit an increase of C_s with *U* between about —0.3 and about 0v. This increase occurs for the three solutions in a potential range where layers of phase cadmium hydroxide or oxide cannot yet be formed on thermodynamic grounds.

If the sweep is reversed at the end of the anodic cycle at potentials smaller than the potential of the peak of the respective *I-U* curve, C_s-*U* curves of the type in Fig. 6 are obtained. The curve which is represented in a linear plot of C_s *vs.* *U* was measured at 1000 cps in 0.2*N* KOH. The C_s values nearly coincide during the anodic and cathodic sweep. The increase of C_s with *U*, starting at about —0.3v, is clearly pronounced.

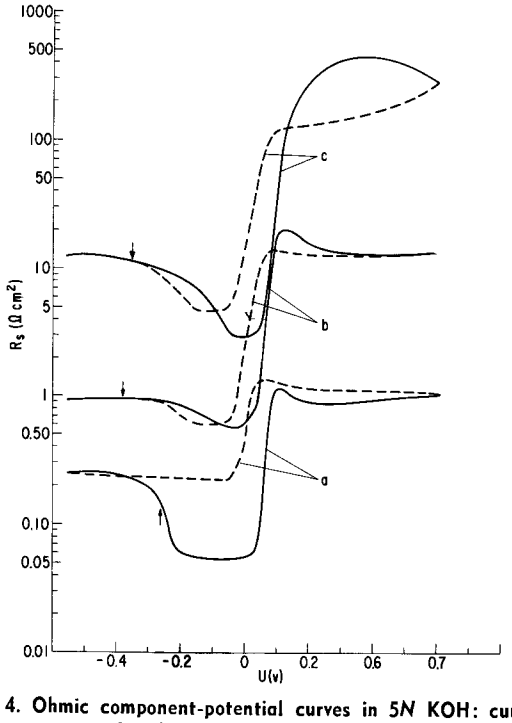

Fig. 4. Ohmic component-potential curves in 5*N* KOH: curve a, 10,000 cps; curve b, 1000 cps; curve c, 100 cps; ——— anodic sweep; --- cathodic sweep.

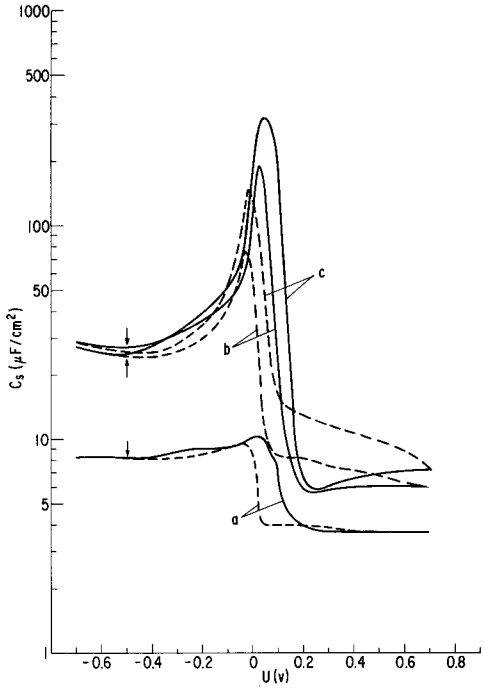

Fig. 5. Capacitance-potential curves in 0.2*N* KOH: curve a, 10,000 cps; curve b, 1000 cps; curve c, 100 cps; ——— anodic sweep; --- cathodic sweep.

Some of the results on the oxidation of cadmium at constant potential in 1*N* KOH are shown in Fig. 7. The capacity and the current density are plotted *vs.* the logarithm of time. At 0.02v the oxidation is very slow. At potentials between 0.02 and 0.1v, the *I*-log *t* curves have a maximum which is shifted toward shorter times with potential. A trace on the Varian F80 X-Y recorder showed that the maximum appeared after about 0.5 sec at 0.1v. The current decrease is linear with log *t* after 10 sec at 0.1v. The value of C_s after 10 sec is 550 μF/cm^2 during the oxidation at 0.02v. Then C_s decreases slowly with time. The C_s values at 10 sec become smaller with increasing potential. A marked decrease of C_s with time is observable between 10 and 500 sec for $U \leq 0.1$v. Above 0.1v the capacitance has values below 10 μF/cm^2 already after 10 sec. The subsequent decrease of C_s with time is small.

Discussion

Oxidation and reduction mechanism on the basis of I-U curves.—From the results shown in Fig. 1 and 2, it is suggested that cadmium hydroxide is formed under the present experimental conditions as the primary product, followed by the formation of a thin film with different physical properties at more anodic potentials. This conclusion is based on the following reasons:

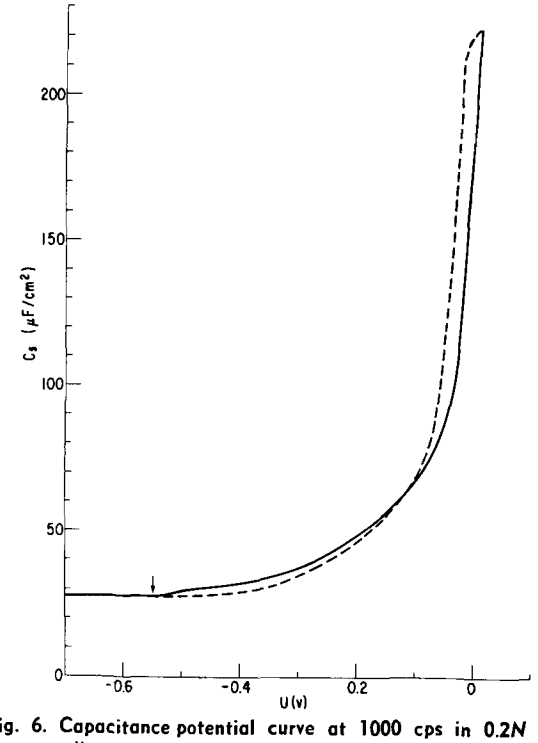

Fig. 6. Capacitance potential curve at 1000 cps in 0.2*N* KOH; ——— anodic sweep; --- cathodic sweep.

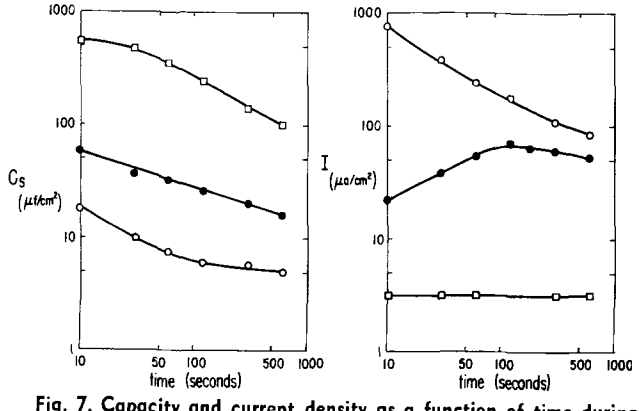

Fig. 7. Capacity and current density as a function of time during the oxidation at constant potential: □, 0.02v; ●, 0.035v; ○, 0.1v.

1. During the anodic sweep the current which is initially cathodic becomes anodic at potentials which are close to the theoretical value (0.019v) of reaction [2]. Reaction [3] cannot occur (6, 7) at these small potentials since the equilibrium potential of the respective reaction is slowly approached from the cathodic direction.

2. The rate of layer formation increases with potential, passes through a maximum, and then decreases. It is suggested that the passivation is due to the thin film located probably between the metal and the thick layer.

A distinction is made between a thick and a thin layer of oxidation products. It is suggested that the thick layer which begins to form below the passivation potential consists of $Cd(OH)_2$. Strong passivation is due to a continuous thin layer, probably CdO. The thick layer which continues to grow on top of the thin layer at more anodic potential need not have the same composition as the layer below the passivation potential. The integration of the *I-U* curves in 0.2*N*, 1*N*, and 5*N* KOH yields 2.2, 16, and 40 mC/cm^2, respectively, at 0.065v. This represents a substantial coverage of the Cd electrode with $Cd(OH)_2$ or CdO in concentrated solutions.

The thick layer continues to grow on top of the thin film. The driving force for the layer formation remains nearly constant during the anodic sweep above 0.3v. During the subsequent cathodic sweep the current decreases nearly linearly between 0.7 and 0.1v. This suggests that the rate of layer formation on top of the thin film is largely controlled by the resistance of this layer which remains nearly constant. The small cathodic waves at the foot of the big reduction wave (Fig. 1) appear in 1*N* KOH at potentials which are too anodic (6,7) for the reduction of $Cd(OH)_2$. The small waves are attributed to the cathodic reduction of the thin layer. Ohse (7) similarly concluded on the basis of three potential plateaus during intermittent cathodic charging curves that CdO is reduced. The reduction of the thin film and the anodic formation of the thick layer overlap between 0.065 and 0.02v during the cathodic sweep. The height of the small wave decreases with increasing KOH concentration because the production of the thick layer becomes more favorable. The small wave is absent in the *I-U* curve of Fig. 2 because the thickness of the layer was not yet close to the limiting thickness at the moment of the sweep reversal. Finally the thick layer is reduced in the range 0 to —0.4v during the cathodic sweep.

The anodic charge Q_{an} for the formation of the thick layer was obtained by integration of the *I-U* curves between about 0.02v and the potential of reversal during the anodic sweep and between the potential of reversal and about 0.1v during the cathodic sweep. The charge Q_s for the reduction of the CdO film was determined approximately by integrating the *I-U* curves in 0.2*N* and 1*N* KOH between about 0.07 and 0v. The overlapping of the reduction of the thin film and of the thick layer at $U < 0$ prevents an exact determination of Q_s. It is difficult to find the charge Q_{cath} corresponding to the reduction of the thick layer during the cathodic sweep. The upper limit of the integration is uncertain because of a residual cathodic current of H_2 evolution. The presence of the latter is apparent from the anodic sweep between —0.6 and 0v. The integrations were done by the computer. The values of Q_{an} and Q_s are compiled for the same potential of reversal at the end of the anodic sweep in Table I.

The data in Table I demonstrate an increase of Q_{an} with the KOH concentration. The increase from 0.2*N*

Table 1. Charges Q_{an} and Q_s for a potential of reversal of 0.6v

		0.2*N* KOH	1*N* KOH	5*N* KOH
Q_{an} in	mC/cm^2	44.10	156	215
Q_s in	mC/cm^2	0.88	0.91	—

to 1*N* KOH is larger than that from 1*N* to 5*N* KOH. It is not proportional to the solubility (15) of $Cd(OH)_2$ in KOH. The dependence of Q_{an} on the KOH concentration is in agreement with the general assumption that a soluble intermediate is involved in the formation of the thick layer. The charge equivalent Q_s is relatively small and nearly the same in 0.2*N* and 1*N* KOH. It is estimated on the assumption of a small wave with symmetry to the *I*-axis that the actual Q_s values may be up to twice as large as those in Table I. The assumption of the symmetry is supported by the C_s-*U* curves a in Fig. 3 and 5 (see next section). The Q_s values correspond to CdO films which consist of only a few atomic layers.

Properties of films on the basis of impedance measurements at 10,000 cps.—The mechanism which was proposed on the basis of *I-U* curves in the preceding section is substantiated by the results of the impedance measurements which give information on the semiconducting properties of the films and the potential range of formation and reduction of the CdO layer. The capacitance C_s (10,000 cps) in Fig. 3 is nearly independent of potential between —0.55 and —0.2v. It is attributed to the Helmholtz double layer in the solution. During the anodic sweep the capacitance decreases in 5*N* KOH from about 20 to about 3 $\mu F/cm^2$ between 0.06 and 0.1v. This rapid decrease is due to the formation of the thin film whose capacitance is in series with and smaller than the capacitance of the Helmholtz layer. Since the capacitance does not change much during both the anodic and cathodic sweep, it is concluded that the thin film does not grow at $U > 0.2$v anymore. The *I-U* curves demonstrate a considerable increase of the thickness of the total layer in the same potential range. This increase is not reflected by the C_s (10,000 cps)-*U* curve. During the cathodic sweep the capacitance C_s (10,000 cps) increases rapidly between 0.05 and —0.05v in Fig. 3 and 5. This is in the potential range where the thin film is reduced. The C_s values between —0.05 and —0.3v differ only slightly from those between —0.3 and —0.7v (curve a in Fig. 3 and 5). It may be concluded again that the thick layer does not affect C_s (10,000 cps) much since its reduction occurs between 0 and —0.3v during the cathodic sweep. This can be explained by a porous or more highly conducting structure. Similar conclusions follow from curve a in Fig. 4. The formation of the thin layer is reflected by a tenfold increase of R_s between 0.05 and 0.1v during the anodic sweep, resulting from its semiconducting properties. The continued formation of the thick layer between 0.1 and 0.6v has only a slight influence on R_s (10,000 cps). The ohmic component drops to a small value between 0.05 and —0.05v where the thin film is reduced during the cathodic sweep. The reduction of the thick layer between 0 and —0.3v during the cathodic sweep does not affect R_s (10,000 cps). The flat minimum of curve a between —0.4v and 0 is attributed to an additional effect discussed below.

Faradaic pseudocapacitance.—The conclusions in the preceding section were drawn on the basis of impedance measurements at 10,000 cps. The C_s-*U* curves at 1000 and 100 cps in Fig. 3 and 5 and the corresponding R_s-*U* curves in Fig. 4 confirm the previous deductions in general. However, they do not allow the determination of the potential ranges of formation and reduction of the thin layer because of the presence of pseudocapacitances originating from electrochemical processes.

The C_s-*U* curves b and c in Fig. 3 and 5 and the curve in Fig. 6 demonstrate an increase of C_s with *U* between about —0.3v and 0 during the anodic sweep. This increase is too large to result from changes in the structure of the Helmholtz layer. It becomes larger with the KOH concentration and depends on frequency. Since the formation of phase hydroxide or oxide is not possible in the said potential range, the capacitance increase is attributed to the reaction:

$$OH^- = OH_{ad} + e \qquad [5]$$

Here OH_{ad} represents adsorbed OH radicals. The adsorption of OH radicals was postulated in the oxidation mechanism given in ref. (10). It had been assumed (16) to be the primary process in the oxidation of several metals.

It is conceivable that the pseudocapacitance between 0 and 0.7v during the anodic sweep (curves c in Fig. 3 and 5) is also due to reaction [5] which may constitute the first step in the $Cd(OH)_2$ formation. Reaction [5] may be responsible for the arrest observed by Ohse (7) in potential decay curves after cathodic polarization. A more detailed study of the frequency dependence of reaction [5] is planned.

Oxidation at constant potential.—The large value of C_s after 10 sec during the oxidation at 0.02v in Fig. 7 is attributed to the faradaic pseudocapacitance of reaction [5]. The pseudocapacitance decreases slowly with time because parts of the surface become blocked with patches of $Cd(OH)_2$. The inhomogeneous growth of the layer formed at $U < 0.1$v could be confirmed by visual observations of the surface of electrodes which were removed from the electrolyte at constant potentials after some time of oxidation. The latter observation is in agreement with the corresponding results in ref. (9). The C_s values after 10 sec of oxidation become smaller with increasing potential because the initial rate of oxidation at constant potential increases, leading to a rapid blocking of the surface. At $U \geqq 0.1$v, the values of C_s after 10 sec are close to those of the thin layer observed during the anodic sweep (see Fig. 3 and 5). The above results are in agreement with the preceding results obtained by voltammetric measurements.

The Kinetics and Mechanism of Oxidation of Superpurity Aluminum in Dry Oxygen

I. Apparatus Description and the Growth of "Amorphous" Oxide

M. J. Dignam, W. R. Fawcett,[1] and H. Böhni[2]

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

A vacuum microbalance and furnace assembly was constructed and employed to determine the growth kinetics of oxide films on aluminum. Using electropolished foil samples of geometric area 80 cm^2, and making corrections for spurious weight changes arising from thermal diffusion effects, film thickness changes as small as 0.3Å could be reliably detected. In addition to kinetic data, the structure of representative oxide films was examined by electron microscopy. It was found that only "amorphous" oxide grew for about the first 10 hr at 454°C and for shorter periods at 478° and 505°C, the weight gain data being in good accord with an equation similar to that proposed by Mott and Cabrera for the growth of very thin oxide films, an approximate integrated form of which is sometimes referred to as the inverse logarithmic equation. The data could not be represented satisfactorily by either a parabolic oxidation law or a direct logarithmic law.

The kinetics of the oxidation of aluminum at high temperatures has been the subject of a number of experimental investigations in the past twenty years (1-6). In these experiments it has been common to follow the reaction kinetics by measuring the weight gain of a superpurity metal sample. The relevance of this type of data depends on the method of surface preparation (6), and indeed, mechanical surface preparations have been shown to lead to anomalous results in the case of aluminum (5). Other investigators have studied the morphology of the growing oxide (6-11), the main observation being that crystalline γ-alumina (defect spinel structure) nucleates beneath the continuous "amorphous" film at oxidation temperature in excess of about 450°C.

In the present investigation weight gain data were obtained in the temperature range 454°-601°C for superpurity aluminum samples whose surfaces had been prepared by electropolishing. This technique, rather than chemical polishing, was selected because of the excellent success obtained with it in this laboratory, both in the fields of anodic and thermal oxidation. In addition, representative oxide films were removed from oxidized samples and examined by electron microscopy. In the present paper the apparatus and experimental technique are described. Results for the growth of the continuous amorphous oxide film which forms exclusively for a period of about 10 hr at 454°C and for shorter periods at 478° and 505°C are presented.

The mechanism and kinetics of growth of the γ-alumina crystallites are considered in detail in Part II of this paper.

Experimental

Apparatus.—The apparatus used consisted principally of a recording vacuum microbalance, Sartorius Model Electrono I, in conjunction with a metal high vacuum system and quartz tubular furnace (see Fig. 1). The quartz tube was sealed into the system with O'rings housed in the metal heads H_2 and H_3. The sample, initially suspended from the end of rod R in a cooled section of the apparatus below the furnace, could be transferred into the furnace by raising R. The rod was sealed into the system by a double O'ring seal effected with specially constructed Teflon O'rings in housing H_1, and thus the transfer operation could be carried out either under vacuum or controlled atmosphere conditions.

Two metal bellows, B_1 and B_2, were incorporated to help isolate the balance from vibrations and to facilitate horizontal movement of the balance, necessary in order to transfer the sample from the rod to the balance arm. This operation was viewed through a glass window incorporated in the metal connector C. The sample was introduced by removing plate P_2, which was normally sealed to plate P_1 by an O'ring seal. Gases could be introduced through valves V_2, V_3, and V_4. The pumping system consisted of a three-stage oil diffusion pump backed by a rotary pump. With this system an ultimate vacuum of 1×10^{-6} Torr could be obtained. The section of metal tubing parallel to the furnace was included in the system to provide a convective cycling path in which gases could be rapidly mixed during addition of one gas to another. Valve V_1 provided a means of closing this path during oxida-

tion experiments. An ionization gauge with a cold cathode head (G_1) was used to measure pressures in the range $1x10^{-7}$ to $2.5x10^{-2}$ Torr. Pressures in the range 0-22 Torr were measured on gauge G_2.

The electrical tubular furnace, about 2 ft long and 2 in. ID, contained three windings; a central winding 16 in. long and two end windings, each 4 in. long. The power input to each was delivered by a separate controller in order to minimize thermal end effects. The central controller was a thyratron proportional controller similar to one described by Benedict (12), but modified to deliver larger currents. The sensing element was a 100 ohms (0°C) platinum resistance. The end windings were controlled by two "Acro-Relays" (Model 301 by Acromag Inc.), also employing a platinum resistance as sensing element. Each relay controlled only a portion of the power, this portion being adjusted to minimize temperature fluctuations. With the above system, the temperature in the sample region, about 6 in. long, was uniform to within ± 0.1°C, contained no measurable ripple, ($\lesssim$ 0.01°C), and was constant to a fraction of a degree for long periods of time. The temperature controllers have been described in detail elsewhere (13). A resistance thermometer, mounted in a hollow tube which could replace the rod R, allowed the temperature of the furnace to be measured at various positions under controlled atmosphere conditions. The optimum control conditions for each temperature and the resulting temperature profile were thus obtained.

The automatic microbalance when operated on its most sensitive scale had a sensitivity of better than 1 μg and a full-scale deflection of 100 μg. Differences in weight of up to 5 mg between the two balance arms could be compensated by changing the tension on the torsion wire on which the balance beam was suspended. Thus, during an experiment, changes in weight could be followed continuously on the most sensitive scale.

Materials.—Specimens were prepared from 99.996% aluminum foil (Republic Aluminum Foil Company) of thickness 7.6×10^{-3} cm. Strips of foil 33 x 1.6 cm were electropolished in one part by volume of 70% perchloric acid to five parts of ethanol. The electropolishing cell was designed so that, when the foil sample was clamped into position, its surfaces were parallel to those of two nickel cathodes. The electrolyte was circulated through the cell and a heat exchanger in series, the latter maintaining the electrolyte temperature between 18° and 22°C. The specimens were electropolished for 3 min at 23v, the current density being initially 1.5 amp cm^{-2} but falling to about 0.6 amp cm^{-2} within a minute. After polishing, the sample was given an immediate preliminary rinse in absolute ethanol, then rinsed thoroughly under a stream of distilled water for 3 min, and finally dried in a blast of air. It was then removed from the cell clamping device, and the several centimeters at each end where it had been clamped were cut off, leaving a specimen with a geometric surface area of about 80 cm^2. The polished samples were stored in a desiccator over anhydrous calcium sulfate.

Commercial tank grade oxygen (99.6% purity) was purified by distillation from a liquid nitrogen trap, the initial and final fractions being discarded. The middle fraction was stored in a glass bulb connected to the high vacuum system.

Argon (99.998% pure, from Matheson Company of Canada) which was used to inhibit oxidation of the specimen as it was being heated to the desired oxidation temperature was further purified by bubbling it through molten sodium and was stored as above.

Experimental procedure.—An electropolished sample was placed on a platinum frame suspended by a platinum wire from the end of rod R and then drawn into the water-cooled compartment below the furnace. The system was evacuated for about 8 hr with the furnace at the desired temperature, the ultimate vacuum achieved being better than 10^{-5} Torr. Purified argon was then introduced to a pressure of 9 Torr, the specimen was raised into the furnace, and the sample suspension system was transferred to the arm of the microbalance. The balance was then turned on, and the torsion wire adjusted to give a small displacement from zero on the most sensitive scale. After allowing 10 min for the sample to achieve thermal equilibrium, oxygen was introduced until the total pressure was 10 Torr. During this operation, valve V_1 was opened in order to guarantee thorough mixing of the gases. After closing valve V_1, about 30 sec were required for the balance to settle down. A continuous record of weight was then obtained. The weight changes were read from the recorder chart to the nearest 0.2 μg.

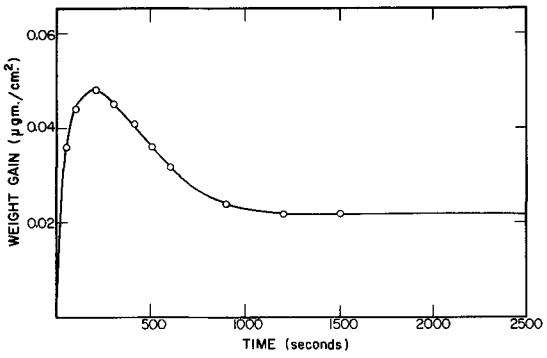

Fig. 2. Apparent weight gain data for "blank" oxidation run at 454°C.

When the rate of weight gain had fallen to a negligibly small value, the system was evacuated and argon and oxygen introduced as before. Such "blank" oxidation runs provided the data necessary to correct for changes in convective and buoyancy forces arising in the first instance when oxygen was introduced, and then as a result of the diffusive separation of the gases in the thermal gradients at the furnace ends (Soret effect). At 454°C (see Fig. 2) the blank runs indicate an apparent weight increase of 0.036 μg cm^{-2} at 50 sec, increasing to a maximum of 0.048 μg cm^{-2} at 200 sec, and then falling to a limiting value of 0.022 μg cm^{-2} for times of 1200 sec or greater. The effect, although similar at the other temperatures, differed in detail, the maximum apparent weight increase occurring at 601°C, where it reached a value of 0.077 μg cm^{-2}. Preliminary runs using helium as the inert gas gave rise to very much larger apparent weight increases, as expected, since the difference in diffusion rate between helium and oxygen is very much larger than that between argon and oxygen. To keep this apparent weight effect small and reproducible it was necessary to have a very uniform temperature zone in the neighborhood of the specimen, work at low total pressures, use an inert gas close in molecular weight to that of oxygen, and have one of the component gases present in considerable excess. On the other hand, too low a total pressure leads to insufficient damping of the pendulum motion of the specimen suspension system and hence to erratic balance performance. The procedure described was evolved with these considerations in mind.

The question arises as to whether or not the procedure outlined above represents a satisfactory one in relation to sorbed impurities present prior to initiating oxidation. The surface was, of course, far from clean, in that at the very least there was an oxide film some 25Å in thickness. In a number of previous studies, however, extensive outgassing of the sample at the oxidation temperature was carried out before initiating oxidation. It is in this connection that we raise the issue.

The outgassing of the sample at room temperature should remove loosely bound or physically adsorbed

surface impurities, the most important of these being water. On bringing the sample to temperature, the remaining sorbed water and oxygen will either desorb from the surface or react with the metal to form new film. This process will probably be completed within a few seconds, and certainly in far less than 10 min. Clearly no amount of vacuum outgassing will remove this newly formed film. Prolonged treatment *in vacuo* at high temperatures would therefore appear to be ineffective against reactive contaminants. On the other hand, such treatment will provide ample opportunity for extensive reaction with residual gases, and at a temperature where the reaction rates will be high. To be effective, therefore, outgassing must be carried out in ultrahigh vacuum ($\sim 10^{-10}$ Torr). The present procedure of introducing the sample into the hot furnace in purified argon, rather than *in vacuo*, was used in order to minimize surface contamination by reducing the rate of diffusion of the residual gases to the sample. Using this procedure, there was no observable change in weight during the several minutes prior to introducing oxygen.

The extensive outgassing observed in the case of metallographically polished metal (2) is to be expected since the mechanical polishing action is bound to lead to the formation of pockets of air and/or polishing lubricant in the surface region of the metal.

An electron micrographic examination of the oxide films formed was undertaken for selected specimens. The films were isolated by dissolving the metal in a solution of 2% bromine in methanol.

Experimental results.—The apparent weight of a superpurity aluminum specimen as a function of time was read from the recorder chart, the initial weight being taken as the recorded weight in argon prior to introducing the oxygen. Then the correction due to thermal diffusion and change in buoyancy was subtracted from the apparent weight gain readings. The resulting corrected weight gain data for typical runs at 454°, 478°, 505°, and 530°C are presented in Fig. 3. The geometric area was used in calculating the weight gain per unit area.

Typical electron micrographs and diffraction patterns for films formed at different temperatures and after different periods of time are shown in Fig. 4. The results, which are in accord with previous studies, may be summarized as follows. At 454°C for oxidation periods below about 10 hr the film consists primarily of amorphous alumina, the diffraction pattern being similar to that found for anodically formed oxide on aluminum. After prolonged oxidation at 454°C and following relatively short oxidation periods at the higher temperatures, a diffraction pattern characteristic of a cubic structure of lattice constant 7.9Å is evident, presumably indicating the presence of crystalline γ-alumina. At the same time, the transmission micrographs show dark areas of the order of a few thousand angstroms across, presumably crystallites of γ-alumina much thicker than the background amorphous film, very similar to that reported previously by one of us (6). The diameter of the crystallites is observed to increase with oxidation period until the entire film consists of close packed crystallites. Although dependent on metal grain orientation, the number density of these crystallites does not appear to change appreciably either with oxidation temperature or oxidation period.

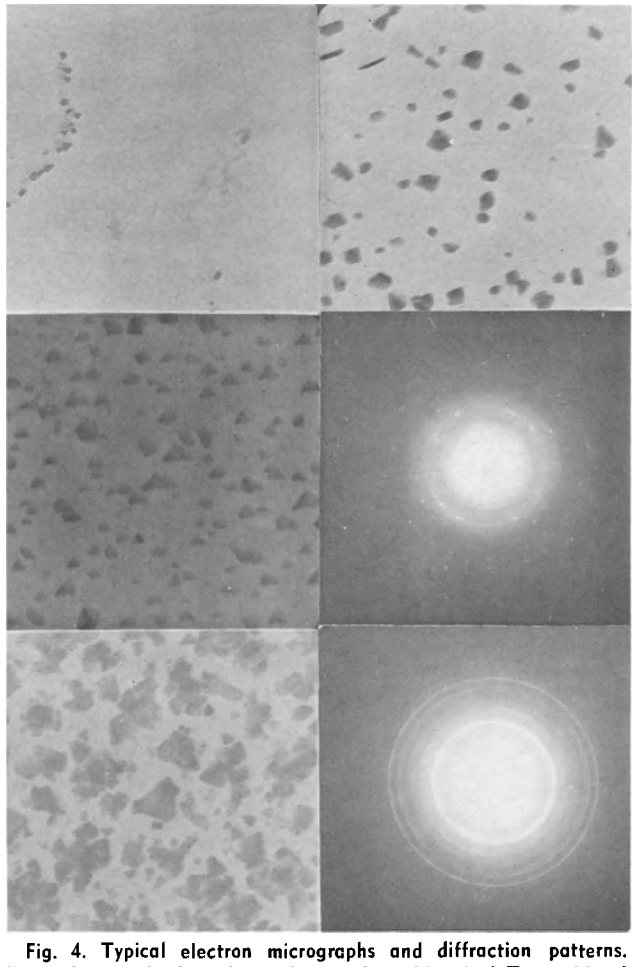

Fig. 4. Typical electron micrographs and diffraction patterns. (Magnification 24500 before reduction for publication) Top, oxidized at 454°C for 6 and 16 hr, respectively; center, oxidized at 454°C for 24 hr; bottom, oxidized at 601°C for about 2 hr.

Discussion of Results

From Fig. 3 it is seen that the kinetic characteristics of the oxidation process at 454°C change at about 10.5 hr. In the initial period the rate of weight gain steadily decreases with time, whereas in the second period it begins to increase slowly. The kinetic data in the initial period are characteristic of the growth of a protective oxide film and correspond to the thickening of the initially present "amorphous" film. The point of inflection is no doubt related to the onset of appreciable growth of crystalline oxide. Doherty and Davis (11) observed that crystallites of γ-alumina were nucleated at the surface between metal and amorphous oxide and grew down into the metal by diffusion of oxygen from the oxide-oxygen interface. Thus the onset of this process should be accompanied by an increase in the rate of oxidation over that due to the growth of the amorphous film alone, as observed.

The weight gain data for 478° and 505°C (Fig. 3) show the same features as those for 454°C, the onset

of growth of crystalline oxide, however, occurring very much sooner. At 530°C and above, the growth of crystalline oxide appears to commence at essentially time zero. An analysis of the kinetics of the growth of the amorphous film by the method of weight gain is therefore not possible for temperatures much in excess of 500°C. Data for the growth of the amorphous film at temperatures of 450°C and below have been presented previously (6) and will ultimately be discussed with the present data.

The growth of crystalline oxide commences at a lower value for the total weight gain as the temperature is increased above 450°C. The data at 450°C accordingly represents the most extensive data insofar as the growth of the amorphous film is concerned. These data were therefore used to determine the functional form of the kinetics, *i.e.*, parabolic, logarithmic, etc. The data for the higher temperatures enable an activation energy to be calculated once the functional form is known, and provide a somewhat insensitive test of the functional form itself. We shall proceed first with an analysis of the data for 454°C.

Data for 454°C.—As electron micrographic data indicate that the amorphous film grows as a compact, adherent film of uniform thickness, we shall limit our consideration to the following rate laws: the parabolic law; the direct logarithmic law; and the Mott-Cabrera rate law for the growth of thin oxide films (14), an approximate integrated form of which is commonly referred to as the inverse logarithmic law.

Although other forms of rate law have been justified on theoretical grounds, they are for one reason or another clearly not relevant to the present case and hence will not be considered. As the data are ultimately shown to be in accord with an equation of the form of that proposed by Mott and Cabrera, their theory and the resulting rate law will be considered first.

Mott and Cabrera assumed that, for oxide films of thickness substantially less than the characteristic space charge length for the oxide, the rate would be controlled by ion transport across the film under the influence of a homogeneous field established by the equilibration of electrons between the metal and surface levels associated with chemisorbed oxygen molcules or atoms. They further assumed that the potential, V, across the film, giving rise to the homogeneous field, was independent of both film thickness and temperature. Although Grimley's (15) theoretical treatment does indicate an insignificant dependence of V on film thickness, the validity of the assumption regarding the temperature dependence is somewhat less certain. We shall proceed, nevertheless, on this assumption. Mott and Cabrera further assumed that the rate-controlling process for very thin films, for which the homogeneous field would be very large, was the transport of cations across the metal-oxide interface. However, the same form of equation is obtained regardless of where the rate-controlling ion transport step occurs. As the thickness of the amorphous oxide film on alumina has been shown previously to be independent of the crystalographic orientation of the metal surface (6), we shall assume, in the present instance, the rate-controlling ion transport process to be transport within the film. This assumption has the further advantage that a single equation will represent both the "thin film," and the "very thin film" cases discussed by Mott and Cabrera (14).

Employing the above assumptions, the rate equation is derived in the following manner. According to Mott and Gurney's theory of conduction in solids (16) the most general expression for the velocity, v, of a charged mobile point defect due to an electrostatic field, E, is the following

$$v = 2\nu\alpha \exp(-U/kT) \sinh\left(\frac{\mu^* E}{kT}\right) \qquad [1]$$

where U is the zero field activation energy associated with movement of the species, μ^* the corresponding activation distance times the effective charge on the species, or the activation dipole, ν is the usual frequency term, and α the distance travelled per activation or the jump distance. Assuming that the field strength is sufficiently large that the contribution to ion flux arising from concentration gradients may be neglected, the rate of growth of a film is given by

$$\frac{dX}{dt} = 2A \sinh(B/X) \qquad [2]$$

$$A = \Omega\nu\alpha n \exp(-U/kT),\ B = (\mu^* EX/kT) = (\mu^* V/kT)$$

where X is the film thickness at time t, n the concentration of the mobile species, Ω the volume of oxide per cation or anion (depending on whether transport is cationic or anionic), and V the potential drop across the film. For films sufficiently thin such that $X<<B$, 2 sinh (B/X) may be replaced by exp (B/X) leading to an equation identical in form to that proposed by Mott and Cabrera for "very thin films." For somewhat thicker films such that $X>>B$, but still thinner than the characteristic space charge length, sinh (B/X) may be replaced by B/X leading to an equation identical to that proposed by Mott and Cabrera for "thin films."

To convert weight gain data per unit area to change in film thickness, Bernard and Cook's (17) value for the density of anodically grown amorphous oxide, 3.17 g cm^{-2} was used and the surface roughness factor assumed to be unity. On this basis a weight gain of 1 μg cm^{-2} corresponds to a film thickness increase of 66.4Å.

In order to illustrate the calculation procedure used to determine the values of A and B in Eq. [2] which give the best fit to the data, Eq. [2] is rewritten below in integrated form

$$\int_{B/X}^{B/X_0} \frac{\tfrac{1}{2}\,\mathrm{csch}\,u}{u^2}\,du = \frac{A}{B}\,t \qquad [3]$$

where X_0 is the film thickness at time zero, that is the thickness of the film initially present prior to oxidation. As the precise value of the initial film thickness is unknown, trial values for X_0 were assumed. Having chosen X_0, the data were fitted to Eq. [3] by a 7094 IBM computer using a nonlinear least squares program. For each trial value of X_0, values of A and B which minimized S (the root mean square deviation of the experimental points from the calculated curve) and the value of S itself were determined.

Values for parameters A and B were determined in this way for three values of X_0, 20, 25, and 30Å. These values were chosen in consideration of experimental studies of the room temperature oxidation of aluminum (8, 18-20) where it has been found that the limiting film thickness achieved in about a day is less than 50Å and probably lies within the range 20-30Å. These values, averaged for 5 runs, are given in Table I.

It can be seen that B and A vary considerably more rapidly with X_0 than does S; that is the agreement between the theory and the data is rather insensitive to the choice of X_0. Since a reliable experimental value of X_0 is not available, the parameters calculated assuming an initial thickness of 25Å are accepted as this value of X_0 minimizes S. The choice of this value

Table I. Kinetic parameters for oxidation of aluminum at 454°C

X_0, Å	B, Å	$-\log_{10} A$, A in Å-sec^{-1}	S, Å
20	95.2 ± 3.4	4.310 ± 0.034	0.27 ± 0.08
25	129.4 ± 4.4	4.509 ± 0.045	0.24 ± 0.04
30	167.4 ± 5.9	4.702 ± 0.049	0.27 ± 0.07

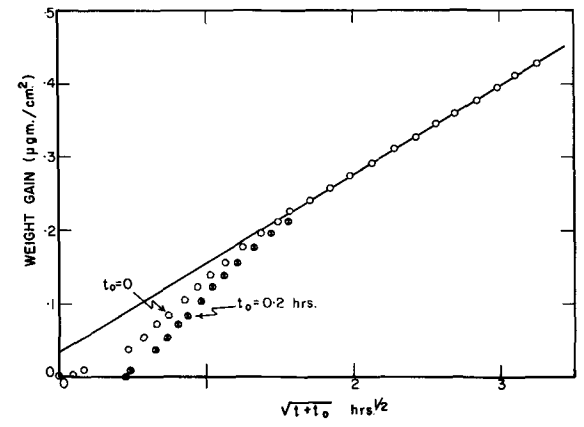

Fig. 5. Weight gain data at 450°C plotted according to the parabolic oxidation law for two choices of the parameter t_o.

for X_o is, however, further justified later. The solid curve shown in Fig. 3 was calculated using this set of parameters. As can be seen the agreement between the data and calculated curve is excellent. In fact, the average standard deviation of the experimental data from the calculated curve, 0.2$_4$Å, corresponds to a standard deviation in the weight measurements of only 0.3 μg for a sample with an area of 80 cm^2. Since this is of the order of the sensitivity of the balance, we may conclude that no detectable discrepancy exists between the data at 454°C and Eq. [2].

In Fig. 5, the data for 454°C have been plotted in accord with the most general form of the parabolic oxidation law [weight gain *vs.* $(t + t_o)^{1/2}$] for two values of the parameter t_o. It is apparent that no value for t_o will lead to a linear relationship over the entire range of the data. It is interesting to note, that for $t_o = 0.2$ hr, the data fall very nearly on two intersecting straight lines. An attempt to explain the kinetic data in this manner (*i.e.*, by two independent rate laws with a total of five disposable constants) is clearly far less satisfactory than that based on Eq. [2] and illustrates the danger of applying more than one rate equation to a single set of data. The linear region for large oxidation periods is expected, since Eq. [2] reduces to a parabolic law for sufficiently large film thickness.

In Fig. 6, the data for 454°C have been plotted in accord with the direct logarithmic oxidation law (curve a). Choosing the optimum value for the parameter t_o, the data fall on a good straight line over about ¾ of the full range of weight increments. As it stands, this fit is substantially inferior to that obtained with Eq. [2]. The question remains, however, as to

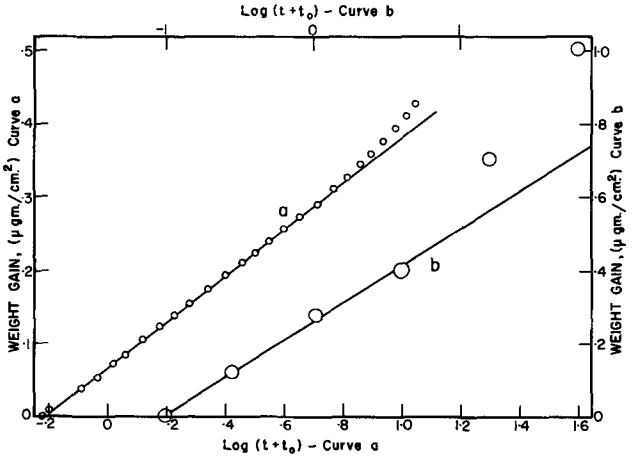

Fig. 6. Weight gain data plotted in accord with direct logarithmic law: curve a, present data for 454°C; curve b, previous data (6) for the oxidation of Al + 0.24% Si at 450°C.

whether the deviation from linearity apparent for high oxidation times (Fig. 6, curve a) might not possibly arise as a result of initiation of growth of crystallites of γ-alumina. To test this possibility, weight gain data published previously (6) for the oxidation at 450°C of aluminum with 0.24% Si added have also been plotted according to the direct logarithmic equation (Fig. 6, curve b). These data were selected since little or no crystalline oxide was found on this alloy following oxidation for 64 hr at 450°C (6). Furthermore, data for this alloy were indistinguishable from those for superpurity aluminum in so far as the kinetics of growth of the amorphous film were concerned (6). We see that these data as well deviate from the direct logarithmic law, the deviation commencing at about the same value for $(t + t_o)$ and becoming very large indeed at 64 hr. It should be noted that Eq. [2] predicts adherence to a direct logarithmic law to a good approximation for a range of data corresponding to an increase of about a factor of two in the film thickness.

It appears that the failure of the direct logarithmic law to represent the full range of the data cannot be attributed to growth of crystalline film so that we may conclude not only that Eq. [2] fits the data at 454°C with no deviation beyond experimental scatter, but that no other single rate law yet formulated does.

Data for 478° and 505°C.—At these temperatures, the following procedure was adopted in analyzing the data for the growth of the amorphous film. Equation [3] may be written in the form

$$f(B/X) = (A/B)(t + t_o) \qquad [4]$$

where

$$t_o = (B/A)\, f(B/X_o) \qquad [5]$$

and

$$f(z) = \int_z^\infty \frac{\frac{1}{2}\,\mathrm{csch}\, u}{u^2}\, du \qquad [6]$$

or alternatively as

$$\log[f(B/X)] = \log(t + t_o) + \log(A/B) \qquad [7]$$

If the data are in accord with Eq. [2], then B at 478° and 505°C (or for that matter any other temperature) may be calculated given B at 454°C and assuming $\mu^* V$ independent of temperature. Thus B/X may be calculated as a function of time, and the results plotted in accord with Eq. [7], *i.e.*, log $[f(B/X)]$ *vs.* log $(t + t_o)$. If the data are in accord with [2], then the resulting graph will be linear and of unit slope. The intercept will yield an experimental value for A. In plotting the data according to Eq. [7], an estimate of t_o is used initially, ultimately being adjusted in accord with Eq. [5] so that the final plot represents a single parameter fit, A being the only unknown parameter. Despite the inconvenience associated with Eq. [7] arising from the necessity for trial and error adjustment of t_o, it is preferable to plot the data according to this equation rather than [4], as the latter leads to crowding of most of the points close to the time zero intercept.

The relation between Eq. [7] and the so-called inverse logarithmic law can easily be found for the case $B/X >> 1$, since for $z >> 1$, $f(z) \simeq [\exp(-z)]/z^2$ so that Eq. [7] becomes

$$\frac{-B}{2.303\, X} + \log X^2 \simeq \log(t + t_o) + \log(A \cdot B)$$

For the present results, however, this equation represents a poor approximation to Eq. [7]. Accordingly, tables of values of log $[f(z)]$ were calculated as follows. Noting that $\frac{1}{2}\,\mathrm{csch}\, u = e^{-u}[1-e^{-2u}]^{-1} = (e^{-u} + e^{-3u} + e^{-5u} \ldots .)$ for $u > 0$, the expression for $f(z)$ may be written

$$f(z) = (1/z)\,[E_2(z) + E_2(3z) + E_2(5z) + \ldots\ldots] \qquad [8]$$

where $E_2(y)$ is the second degree exponential integral, tabulated values for which are available (21), and is defined as follows

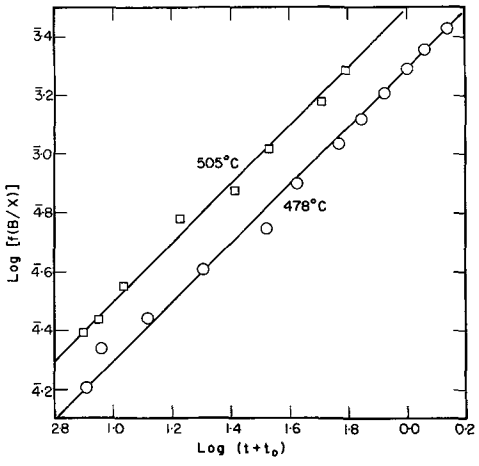

Fig. 7. Weight gain data for 478° and 505°C plotted according to Eq. [7], *i.e.*, according to the generalized Mott-Cabrera law.

$$E_2(y) = \int_1^\infty \frac{e^{-yu}}{u^2}\,du = y\int_y^\infty \frac{e^{-u}}{u^2}\,du$$

For $z > 1$, the series representation for $f(z)$ converges very rapidly, no more than the first few terms being required. Thus tables of the function log $[f(z)]$ may be readily calculated using [8].

The data for the initial period of oxidation at 478° and 505°C are plotted in Fig. 7 according to [7] using the values of X_o and $B(454°)$ giving the best fit at 454°C (*i.e.*, X_o = 25Å, B = 129.4 x 727/T). The straight lines on the graph are drawn with slope unity. It is clear that all the points shown fall on these lines well within experimental scatter. As one goes to oxidation periods greater than those shown in Fig. 7, however, the points lie increasingly above the line, a result expected following the onset of growth of crystalline oxide.

Analysis of previous data for 250°, 350°, and 450°C. —In order to test further the validity of Eq. [2] with regard to the growth of amorphous oxide on aluminum, previous data (6) covering the temperature range 250°-450°C was analyzed in the same manner as the data at 478° and 505°C. Before proceeding with the analysis, however, a brief discussion of the experimental method used to obtain these data is in order. Aluminum samples were electropolished, using essentially the same procedure as that employed for this investigation, oxidized for the desired period of time, then removed from the furnace and their film thickness determined by an electrometric method. The method involved placing the sample in an electrolytic cell and determining the minimum cell overpotential, V_b, required to cause significant ion current to flow through the oxide film. Provided that the conduction properties of all the films are the same, this potential, frequently referred to as the "barrier voltage," should be a linear function of the film thickness. In the previous paper, evidence was presented which showed that films formed in oxygen at 450°, 350°, and 250°C all had the same conduction properties. A re-examination of the data has indicated, however, that this conclusion should be qualified in that it only applies to samples which have been oxidized for a sufficient period of time at the temperature in question. Specifically, it appears that the oxidation period must be greater than approximately t_o before the conduction properties become independent of temperature and time, where t_o is given by [5] and is the time required to form a film of the initial thickness at the oxidation temperature in question. This is an interesting, although not entirely surprising, observation which we shall pursue no further as a discussion of the effect does not bear directly on the subject matter of this paper.

For the present analysis, values of V_b were obtained from Table I of (6) by averaging the results of superpurity aluminum and superpurity aluminum containing respectively 0.2% Ga, 0.01% Fe, 0.53% Mn, 0.011% Cu, as these alloys gave results indistinguishable from those of superpurity. Since all the alloys studied previously, except the superpurity plus 0.24% Si alloy, had formed γ-alumina crystallites following 16 hr oxidation at 450°C, only the data for this alloy were used for 16 and 64 hr at 450°C. Except for oxidation periods $< t_o$, this alloy also appears to give values of V_b indistinguishable from those for the above mentioned alloys.

In Fig. 8, values for V_b for oxidation at 450°C are plotted against film thickness values calculated from the values for A and B for X_o = 25Å deduced from the present results. The data fall within experimental error on a straight line, the equation for which is given by

$$X = 15.6\,V_b - 6.9\text{Å} \qquad [9]$$

The value of the conversion factor, 15.6 Å/v, is substantially larger than that used previously (6). For the most recent data relating to the anodic oxidation of aluminum (22) and an analysis of the shape of the polarization curves used to obtain V_b, a conversion factor of about 14.4 Å/v may be estimated. This would be in accord with the above value if the electropolished samples used for the present study had a roughness factor of (15.6/14.4) = 1.08, which is indeed about the expected roughness factor.

Using Eq. [9], the barrier voltage data for 350°C were converted to film thickness values and the results plotted in accord with Eq. [7], using precisely the same procedure as was used in processing the data for 478° and 505°C. As can be seen in Fig. 9, the points lie almost precisely on the straight line of unit slope. It should be emphasized again that this represents a one parameter fit. If the entire calculation involved in Fig. 8 and 9 is repeated assuming X_o = 20 or 30Å, rather than 25Å, a significantly poorer fit is obtained, lending further support to the choice X_o = 25Å.

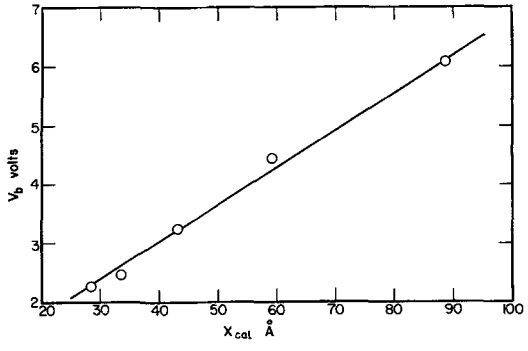

Fig. 8. Barrier voltage data for oxidation at 450°C, reported previously (6), plotted against film thickness calculated using the oxidation parameters determined in the present investigation.

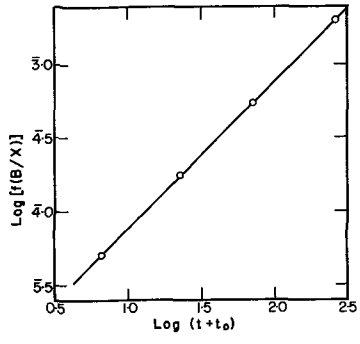

Fig. 9. Data reported previously (6) for oxidation at 350°C plotted according to Eq. [7], *i.e.*, according to the generalized Mott-Cabrera law.

Table II. Previously published barrier voltage data (6) converted to film thickness using [9]

	t, hr	$(t + t_o)$ hr	V_b, v	X, A
450°C	0	0.18_2		25.0
	0.25	0.43_2	2.27	28.3
	1	1.18_2	2.46	31.3
	4	4.18	3.25	43.8
	16	16.18	4.44	62.3
	64	64.18	6.09	88.1
350°C	0	6.6		25.0
	16	22.6	2.03	29.6
	64	70.6	2.70	35.3
	256	262.6	3.31	44.6
250°C	0	181		25.0
	600	781	2.35	29.7

Unfortunately, at 250°C only a single barrier voltage value corresponds to an oxidation period in excess of t_o, namely that for 600 hr. A value for A can nevertheless be determined from this single thickness (in addition to the time zero thickness of 25Å) using Eq. [7] or [4] as before. The value so determined cannot be considered very accurate, however, as the increase in film thickness from time zero amounts to only about 5Å.

The relevant barrier voltage values and film thicknesses calculated from [9] are presented in Table II along with the actual oxidation period, t, and the oxidation period from bare metal, $t + t_o$.

Values of log A obtained from Fig. 7 and 9 are plotted against reciprocal absolute temperature in Fig. 10, along with the value obtained at 454°C and the somewhat questionable value for 250°C. The points appear to be colinear within experimental error, the equation for the line being represented by

$$A = 2.5\text{x}10^6 \exp(-1.60/kT) \text{ Å/sec} \quad [10]$$

Summary

A careful analysis of precise weight gain data for the oxidation of electropolished aluminum foil at 454°C in dry oxygen shows that the growth of the continuous amorphous oxide film may be represented accurately (*i.e.*, within a standard deviation of 1/4Å) by an equation of the form $dX/dt = 2A \sinh(B/X)$ where A and B are constants under isothermal conditions. The same data cannot be represented even approximately by a parabolic law except in the final stages of growth when the above equation reduces approximately to parabolic form. A direct logarithmic equation represents the data well for the initial period of oxidation, but for long oxidation periods significant deviation from this law is apparent. Once again such behavior is expected for data in accord with the above equation since for a limited range of film thickness, and for $B/X >> 1$, it reduces approximately to a direct logarithmic equation.

Analysis of data for 478° and 505°C, along with previously published data for 250° and 350°C, showed agreement with the above equation with the temperature dependence of A and B given by

$$B = \mu^* V/kT, \quad \mu^* V = 8.2\, e\text{Å}V$$

$$A = A_o \exp(-Q/kT), \quad A_o = 2.5 \times 10^6 \text{ Å}\cdot\text{sec}^{-1}, \quad Q = 1.6 \text{ ev}$$

The extent of the data at temperatures other than 454°C was insufficient to verify the inverse temperature dependence of B.

Significant growth of crystallites of γ-alumina oxide, as evidenced by the initial inflection point in the weight gain curve, began after oxidation periods of about 12 hr at 454°C, 2 hr at 478°C, 1 hr at 505°C, and within less than 0.1 hr at 530°C. The induction period for growth of crystalline oxide is undoubtedly a function of the initial film thickness, X_o, as well as oxidation temperature (1).

The Kinetics and Mechanism of Oxidation of Superpurity Aluminum in Dry Oxygen

II. The Growth of Crystallites of γ-Alumina

M. J. Dignam and W. R. Fawcett[1]

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

Weight gain data for the oxidation of electropolished aluminum in the temperature range 475° to 600°C are presented and analyzed in terms of the following model. The γ-alumina crystallites, which nucleate beneath the amorphous oxide film, are assumed to achieve a terminal thickness rapidly, following which only radial growth takes place. This growth proceeds at a constant velocity, until the crystallites impinge on one another. The negative temperature coefficient, observed for the terminal thickness, and the terminal thickness itself follow from the proposed growth mechanism for the crystallites, which is given in sufficient detail to permit comparison of values of the experimental and theoretical pre-exponential factors. The proposed model is in complete accord with electron micrographic and other data for the system, the kinetic parameters also being in agreement with independent estimates.

Although a very considerable amount of information has been published on the high-temperature oxidation of aluminum in dry oxygen (1-8), only one quantitative treatment (9) of the oxidation kinetics in the temperature range 450°-600°C has been given which is reasonably consistent with the known morphology of the growing oxide (10, 7, 6).

In connection with the morphological features, the excellent data of Doherty and Davis (10) deserve special mention. The principal observations of these authors are that the crystallites of γ-alumina (spinel structure) nucleate beneath the amorphous film above 450°C and grow down into the metal substrate, and that the growth of the crystallites occurs by oxygen migration through the amorphous film.

The purpose of the present investigation was first to obtain weight gain data relating to the growth of the crystalline oxide for aluminum samples prepared by electropolishing, and second to provide a quantitative analysis of the data so obtained. Mechanical surface preparations were not used since such treatments are likely to lead to anomalous results, as pointed out previously by one of us (8).

The picture which emerges from the present study is that of oxygen species diffusing along a boundary between crystalline and amorphous oxides, the growth kinetics being controlled by the diffusion rate and the oxide "recrystallization" rate. Activation energies for both the diffusion and recrystallization processes are obtained, with the pre-exponential factors in excellent accord with those predicated on the basis of the model.

The kinetics of growth of the amorphous film have been treated in Part I of this paper (11).

Experimental

The apparatus and procedure used have been described previously (11).

The weight gain data for typical oxidation runs at 478°, 505°, 530°, 549°, and 601°C are illustrated in Fig. 1 to 5. Reproducibility from run to run was about ± 3%. It is interesting to observe that the limiting film thickness decreases with increasing temperature from 478° to 601°C, a result which has been noted by others (2-5).

The results of the present electron micrographic study are in accord with previous studies, with the main observations being presented in Part I of this paper (11). The pertinent points are summarized in the development of the model.

Discussion of Results

At 454°C for oxidation periods less than about 10 hr and for shorter periods at 478° and 505°C, the growth of the amorphous film has been shown previously (11) to be in accord with an equation of the form of that proposed on theoretical grounds by Mott

and Cabrera (12), an approximate integrated form of which is generally referred to as the inverse logarithmic law. The present analysis is concerned solely with the mechanism and kinetics of the formation and growth of the crystallites of γ-alumina.

Model

The model proposed in this section is based in large measure on the results reported by Doherty and Davis (10) from their excellent electron micrographic study of the formation of crystallites of γ-alumina on aluminum. The independent experimental results, *i.e.*, results apart from the kinetic data reported herein, on which the present model is to be based are summarized below.

1. The crystallites grow down into the metal rather than protrude from the surface and do not extend to the surface.
2. The crystallites grow as a result of transport of oxygen species, rather than metal species, through the amorphous film.
3. The crystallites form over a short period of time relative to their period of growth, in that the number density of crystallites, once formed, is independent of oxidation time within the limits of observation. It is also independent of oxidation temperature in the range 450°-600°C.
4. The local number density of crystallites varies somewhat within the boundaries of a single metal grain and very significantly from grain to grain.
5. As far as it is possible to tell by examination of the micrographs, the breadth of a crystallite increases approximately linearly with time, until coalescence occurs. The variation in shape of crystallites from one metal grain to another, however, makes size comparison difficult.
6. The amorphous film lying between the crystallites continues to grow. Thus contact between the amorphous film and the metal in these regions is maintained.
7. The amorphous film lying on top of the crystallites does not continue to grow.

Points 1 and 2 result from the work of Doherty and Davis, points 3 to 5 from the present and a previous electron micrographic examination (11, 7) and points 6 to 7 from data published previously by one of us (7, 8). Discussion of these latter two points follows.

In one of the previous papers (8) data for the oxidation of aluminum and aluminum containing 0.24% Si are presented. Of significance to the present paper are the following points. The growth of the oxide film on the two alloys was indistinguishable at temperatures of 350°C and below, and for oxidation periods less than about 7 hr at 450°C. For oxidation periods greater than about 7 hr at 450°C, crystallites of γ-alumina formed on superpurity aluminum, but did not form on the alloy doped with silicon even after 64-hr oxidation. Film conductance measurements were obtained for samples of the two alloys oxidized various lengths of time at 450°C, by applying to the specimens immersed in an aqueous borate electrolyte an anodic potential which increased linearly with time. The resulting polarization curve (current density *vs.* anodic overpotential) for superpurity aluminum oxidized 16 hr at 450°C is shown in Fig. 6 as the solid line. This

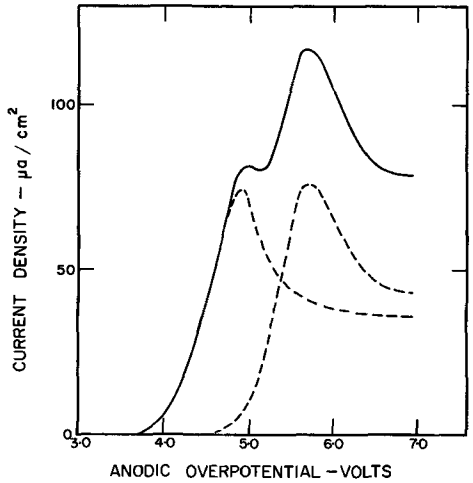

Fig. 6. Polarization curve for superpurity aluminum oxidized 16 hr at 450°C (solid line) (7). The polarization curve may be resolved into the sum of the two curves shown as broken lines.

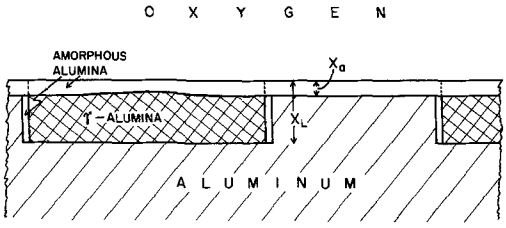

Fig. 7. Schematic representation of cross section of growing crystallite.

curve may be resolved into the sum of two curves (shown as broken lines) which resemble remarkably closely polarization curves for samples of the silicon doped alloy oxidized for about 9 and 16 hr, respectively (7), the current density values, however, being in both cases reduced by about a factor of 2. In other words, as far as the polarization measurement is concerned, the superpurity sample oxidized 16 hr at 450°C behaved as if half of its surface were covered with amorphous film of one thickness (corresponding to ~9 hr oxidation at 450°C) and the other half of another thickness (corresponding to ~16 hr oxidation at 450°C). As electron micrographs for such a sample indicated that roughly half of the surface was covered with crystallites of γ-alumina, the conclusion that the amorphous film lying on top of the crystallites does not continue to grow is strongly indicated. The same evidence, of course, indicates the continued growth of the amorphous film lying between the crystallites. Further discussion of these rather interesting conduction data is presented later.

Before proceeding with a development of the model we note that the above interpretation implies that the amorphous oxide between the crystallites remains in contact with the underlying metal. Since the growth of the crystallites into the metal is accompanied by about a 40% increase in volume, we must conclude that the stresses set up in the metal phase are relieved by the diffusion of metal from the regions of compressional stress to those of tensional stress. As the temperatures in question are close to the melting point of aluminum, rapid diffusion of aluminum along the phase boundary between the metal and the oxide is to be expected. Furthermore, as the number density of crystallites is about 10^9 cm^{-2}, the maximum diffusion length will be no more than a few thousand angstroms. The above mechanism for the relief of strain within the metal therefore appears entirely reasonable.

A cross section of a growing crystallite is represented schematically in Fig. 7. Certain detailed features of this diagram must await discussion until completion of the analysis; some, however, may be mentioned now. The variation of the thickness of the amorphous film on top of the crystallite from the central to peripheral regions follows from points 5, 6, and 7 above. Since the weight gain virtually ceases once the surface of the sample is completely covered with crystalline oxide, we conclude that, once formed, the crystalline oxide does not thicken appreciably. The picture which emerges, therefore, is that of nucleation of crystallites which rapidly achieve a limiting thickness and subsequently grow only laterally across the surface until they impinge on adjacent crystallites. Such a growth law would be expected if a growing crystallite is fed with oxygen at the periphery, the limiting thickness of the crystallite being determined by the rate at which oxygen can be supplied. A thin layer of amorphous film is shown on the peripheral surface of the schematic diagram of the growing crystallites (Fig. 3), the argument for this being that the initial product formed on contact of oxygen with bare metal is, in all probability, amorphous oxide. Since rapid migration of oxygen through the amorphous film is necessary for the growth of the crystallites, we are obliged to assume the existence of some sort of fault boundary through the amorphous oxide close to the periphery of the crystallites. Such faults might well be generated as a result of the volume expansion during formation of the crystalline oxide.

The picture which emerges, therefore, is one in which oxygen diffuses along the fault boundary in the amorphous film and the phase boundary between the amorphous and crystalline oxides. The lateral growth rate of the crystallites is controlled by the rate of recrystallization of the amorphous film to form the crystalline film, a steady-state thickness of amorphous film being maintained between the metal and the crystallite. The thickness of the crystallite is determined in part by the rate of oxygen diffusion along the fault and phase boundaries.

The detailed analysis of the model follows: In a region of the phase boundary where free oxygen is available, the advance of the crystalline boundary will be accompanied by consumption of the oxygen to form more amorphous film. The rate of consumption of oxygen will therefore be controlled by the "recrystallization" rate, a steady-state thickness of amorphous oxide being established between the metal and the growing faces of the crystalline oxide. At $x = X_L$, the concentration of oxygen species per unit area, n, will be zero, the thickness of the crystalline oxide therefore being controlled by the diffusion rate of the oxygen species and the recrystallization rate. For the diffusion process, the flux per unit length at position x, $J(x)$, is related to the diffusion constant, D, and the interfacial concentration gradient by the following equation

$$J(x) = -D dn/dx \qquad [1]$$

Since the oxygen species are being consumed at a rate controlled by the rate of recrystallization, K_2 units of length per unit time, the variation of $J(x)$ with x is given by

$$\begin{aligned} dJ(x)/dx &= -K_2/\Omega \quad \text{for } n > 0, x > X_a \\ &= 0 \quad \text{for } n = 0 \\ &= 0 \quad \text{for } X_a \geqq x \geqq 0 \end{aligned} \qquad [2]$$

where Ω is the volume per oxygen species in the crystalline oxide. For $X_L > x > X_a$, the equation to be solved is therefore

$$d^2n/dx^2 = K_2/\Omega D \qquad [3]$$

Applying the boundary conditions $dn/dx = 0 = n$ at $x = X_L$, the solution of [3] becomes

$$n = (K_2/2\Omega D)\ (X_L - x)^2 \qquad [4]$$

so that at $x = X_a$, where $n = n'$

$$n' = (K_2/2\Omega D)\ (X_L - X_a)^2 \qquad [5]$$

For $X_a > x > 0$, the equation to be solved is

$$d^2n/dx^2 = 0 \qquad [6]$$

Applying the boundary conditions that $J(x)$ is continuous at $x = X_a$, and $n = n_o$ at $x = 0$, the solution of [6] becomes

$$n = n_o - (K_2/\Omega D)\ (X_L - X_a)x \qquad [7]$$

so that at $x = X_a$

$$n' = n_o - (K_2/\Omega D)\ (X_L - X_a)\ X_a \qquad [8]$$

In deriving [7] and [8] it is assumed that to a satisfactory approximation the same value for the diffusion constant may be used in the two regions, $(0, X_a)$ and (X_a, X_L).

Eliminating n' from [5] and [8] leads to the following equation

$$X_L^2 - X_a^2 = 2\Omega D n_o/K_2 \qquad [9]$$

As the transformation of Al to its oxide takes place with an increase in volume, there should exist no actual crack at the crystalline oxide-amorphous oxide phase boundary, so that oxygen would not likely diffuse as molecular oxygen but rather as chemisorbed oxygen atoms or possibly ions. As the heat of chemisorption of oxygen at the phase boundary will almost certainly be large compared with kT, n_o should correspond very nearly to saturation conditions and hence be essentially independent of temperature and pressure and of the order of $\Omega^{-2/3}$. In accord with elementary kinetic theory, the expressions for D and K_2 are given below

$$D = \nu_D a^2 \exp(-U_D/kT) \quad [10]$$

$$K_2 = \nu_2 n_s \Omega \exp(-U_2/kT) \quad [11]$$

where a is the diffusion on "jump" distance, U_D the activation energy for diffusion, n_s the surface concentration of oxygen ions at the phase boundary, U_2 the activation energy for recrystallization, ν_D the vibrational frequency associated with a diffusing oxygen species, and ν_2 that associated with an oxygen ion in the amorphous oxide at the interface. In writing the expression for K_2 it has been assumed that the transport of oxygen ions, rather than metal ions, across the phase boundary is the rate-controlling step for the recrystallization process. No significant change in the present treatment is required, however, if metal ions are involved.

Proceeding now with Eq. [9], on substituting for K_2 and D, one obtains

$$X_L^2 - X_a^2 = 2(\nu_D/\nu_2)\ (n_o/n_s)\ a^2 \exp[(U_2 - U_D)/kT] \quad [12]$$

or since $\nu_D \simeq \nu_2$, $n_o \simeq n_s$, and from the experimental results $X_L >> X_a$, this becomes

$$X_L \simeq \sqrt{2}\, a \exp[(U_2 - U_D)/2kT] \quad [13]$$

In relation to the schematic diagram of Fig. 7, two points should be mentioned. Within the approximations made in obtaining [13], the total limiting film thickness, X_L, is a constant, as shown in Fig. 7. From [12], however, it is clear that some variation of X_L with X_a is to be expected. Examining a typical case in which $X_L \simeq$ 300Å and X_a varies from say 25 to 100Å as one moves from the central to peripheral regions of a crystallite, from [12] the corresponding change in X_L would be only 14Å, or less than 5% of X_L. On this basis, the approximation of constant limiting film thickness is seen to be a satisfactory one.

The second point concerns the shape of the growing face of a crystallite. In Fig. 7, the face is shown normal to the surface of the specimen. One would expect instead a variation of this angle with the crystallographic orientation of the substrate metal grain. In itself, this would not alter the lateral growth rate, but would lead to a range of values of X_L. Thus interpreting X_L as the mean limiting film thickness, the right hand side of [13] should be multiplied by the mean value of $|\sin\phi|$, where ϕ is the angle between the growing crystallite face and the surface of the specimen. Taking as one extreme the case where all angles are equally probable, we conclude that this correction factor should lie between 0.64 (*i.e.*, $2/\pi$) and unity. Again, neglect of this factor, whose value is unknown, lies within the approximation contained in the pre-exponential factor of [13].

In summary, for this model, apart from the nucleation and initial stages of growth of a crystallite, where a more detailed analysis than that given here is required, we see that within the approximations contained in [13], the film thickness X_L does not vary with time. The sign of the temperature coefficient of the limiting film thickness will be determined by the relative magnitudes of U_2 and U_D. As U_D corresponds to the activation energy for transport of oxygen along the phase boundary, and U_2 that for oxygen transport across the phase boundary, U_2 should be somewhat greater than U_D so that the limiting film thickness, X_L, is predicted to have a negative temperature coefficient, which is in agreement with the experimental observations (Fig. 1 to 5).

From the above model, we see that the oxidation kinetics (weight gain as a function of time) will be determined by the number density of crystal nucleation sites N, the nucleation probability K_1, the lateral growth rate K_2, and the limiting film thickness X_L. The analysis of the present nucleation problem differs only in a rather minor way from that presented by Avrami (13) for the kinetics of random volume nucleation associated with the thermal decomposition of a solid. The mathematical development of the following equation will therefore not be given. The result is recorded below.

$$-\ln(1-\alpha) = 2\pi N\,(K_2^2/K_1^2)\,[1 - \exp(-K_1 t') - K_1 t' + K_1^2 t'^2/2] \quad [14]$$

where α is the fraction of the surface covered with crystalline oxide and t' the time elapsed from the onset of the nucleation process. Equation [14] is derived by assuming the nucleation sites to be completely randomly distributed and their concentration independent of their position on the surface. Furthermore, the crystallites are assumed to be disk-shaped. Choosing a different crystallite shape will merely replace 2π by a constant of the same order. From the electron micrographs, all of the nuclei appear to form over a time period short compared with that required for the lateral growth of the crystallites. For such conditions we may set $K_1 t' >> 1$ for t' not too small. Equation [14] then becomes

$$-\ln(1-\alpha) \simeq N\pi K_2^2\,(t - t_o)^2 \text{ for } t > t_o \quad [15]$$

where t' has been replaced by $t - t_o$, t being the oxidation period and t_o the induction period for formation of crystal nuclei. Equation [15] may be written alternatively as

$$\alpha = 1 - \exp[-\beta(t - t_o)^2], \quad t > t_o \quad [16]$$

where

$$\beta = N\pi K_2^2$$

Equation [16] is only valid, as mentioned previously, if N is independent of position on the surface. By direct electron micrographic observation, N was found to vary considerably from one region of the surface of a sample to another. If we assume N, and hence β, to be distributed according to a distribution function, $P(\beta)$, then α will be given not by [16] but instead by the following equation

$$\alpha = 1 - [\int_o^\infty [\exp(-\beta[t - t_o]^2)]P(\beta)\,d\beta]/[\int_o^\infty P(\beta)\,d\beta] \quad [17]$$

Although one might assume the nuclei number density, N, to be distributed according to a Gaussian distribution, a Pearson type III distribution law (14) is preferable from the physical standpoint, as the probability density for this distribution goes to zero at $N = 0$. Furthermore, this law leads to a mathematically more tractable result. The most general form of the Pearson type III distribution law can be written

$$P(\beta) = K\beta^p \exp(-p\beta/a') \quad [18]$$

where $P(\beta)$ is the probability density for a given value of β, and K, p, and a' are constants which can readily be related to more familiar parameters.

From [17] and [18] above, we obtain the following expression for α (see Appendix).

$$\alpha = 1 - [1 + \bar{\beta}\epsilon^2(t - t_o)^2]^{-1/\epsilon^2}, \quad t > t_o \quad [19]$$

where $\bar{\beta}$ is the mean value of β (and is simply related to the mean value of N, $\bar{N}$; $\bar{\beta} = \bar{N}\pi K_2^2$) and ϵ is the standard deviation of the distribution of β (or N) expressed as a fraction of $\bar{\beta}$ (or $\bar{N}$).

We may relate the weight gain to α as follows. The total oxide weight per unit area associated with crystalline regions of the specimen, $g_c(t)$, and that associated with intercrystalline regions, $g_a(t)$, are given by

$$g_c(t) = \rho X_L \alpha$$

$$g_a(t) = \rho X_a(t)\ (1 - \alpha) \qquad [20]$$

where ρ is the crystalline oxide density and X_L and $X_a(t)$ the limiting and amorphous film thickness respectively, as defined previously (Fig. 7).

For simplicity, the density of the amorphous oxide has been set equal to that for the crystalline oxide. The error introduced by this approximation is small and such as to compensate for the approximation made in obtaining [13] from [12].

The weight gain per unit area at time t, $W(t)$, is given by

$$W(t) = (M_o/M_{ox})\,\rho[\alpha X_L + (1 - \alpha)X_a(t) - X_a(0)] \qquad [21]$$

where M_{ox} and M_o are the formula weight of oxide and the weight of oxygen per formula weight of oxide, respectively. From [21], the weight gain at $t = t_o$, corresponding to the initiation of nucleation, W_o, is given by

$$W_o = (M_o/M_{ox})\rho[X_a(t_o) - X_a(0)\ ] \qquad [22]$$

and the limiting weight gain, W_L, achieved after complete coverage of the surface with crystallites, by

$$W_L = (M_o/M_{ox})\rho[X_L - X_a(0)\,] \qquad [23]$$

Eliminating X_L and $X_a(0)$ from [21], [22], and [23] we obtain

$$W(t) = W_o + \alpha(W_L - W_o) + (M_o/M_{ox})\rho(1 - \alpha)\,[X_a(t) - X_a(t_o)] \qquad [24]$$

The final term in [24] represents the contribution to the weight gain made by the continued growth of the amorphous film following crystal nucleation. It is evident from the data, say for 504°C, that the contribution made by this final term is small, partly because $X_a(t)$ is small compared with X_L, and partly because of the factor $(1 - \alpha)$ which approaches zero for large times.

Before proceeding with an analysis of the data, equations for X_L and $\bar{\beta}$ are given below. They were obtained from [23], and from [11] and $\bar{\beta} = \bar{N}\pi K_2^2$, respectively.

$$X_L = X_a(0) + (M_{ox}/M_{o\rho})\,W_L \qquad [25]$$

$$\bar{\beta} = (\bar{N}\pi v_2^2 n_s^2 \Omega^2) \exp\,[-2U_2/kT] \qquad [26]$$

Since, as mentioned previously, the evidence indicates no appreciable temperature dependence of the number density of nuclei, we may presume that both $\bar{N}$ and ϵ are essentially independent of temperature, although they might vary somewhat from sample to sample.

Comparison of Data with Model

In Fig. 1-5 the weight gain data have been plotted on a reduced time scale $\tau = (t - t_o)\bar{\beta}^{1/2}$, in order to illustrate clearly the fact that the limiting weight gain per unit area decreases with increasing temperature. The solid lines represent curves calculated in the manner outlined below.

Combining Eq. [19] and [24], neglecting the final term in [24], we obtain

$$W(t) = W_L - (W_L - W_o)\,[1 + \bar{\beta}\epsilon^2(t - t_o)^2]^{-1/\epsilon^2},\ t > t_o \qquad [27]$$

Setting aside for the moment the small correction terms W_o and t_o, the principle parameters to be determined are W_L, $\bar{\beta}$, and ϵ. Using a digital computer, the most probable values of W_L and β were determined independently for each oxidation run, calculations being repeated for a number of trial values for ϵ. It was found that a value for ϵ of 0.7 ± 0.1 gave the best fit with the data at all temperatures, indicating that ϵ is independent of temperature, as it should be.

The pair of parameters (t_o, W_o) correspond to the time of crystal nucleation and the corresponding weight gain at that time. For the runs at temperatures of 530°C and above, the induction period for crystal nucleation appears to be very nearly zero (*i.e.*, $t_o \simeq 0$) so that for these runs t_o, W_o were set equal to zero. At 478° and 505°C, however, the induction period is appreciable (11) and may not be neglected. For runs at these temperatures, therefore, t_o was chosen to give the best fit with the data, the corresponding value of W_o being read from the oxidation curve.

An examination of Fig. 1 to 5 will show that the agreement between the curves calculated in the above manner and the experimental data is extremely good at 505°, 530°, and 549°C. At 601°C, a significant deviation for large times is apparent, a point we shall return to later. The agreement at 478°C, although not excellent, is quite good. The assumption of "instant nucleation" (*i.e.*, $K_1 t' >> 1$) is perhaps only a fair approximation at this temperature, the small discrepancy arising therefore as a result of formation of the crystal nuclei over an appreciable period of time. On the whole, the agreement must be regarded as quite satisfactory.

In Fig. 4, the best fit with the data which can be obtained neglecting the variation of the number density of crystal nucleation sites with position, is shown as a broken line. The broken line was calculated as before, but using [16] rather than [19] for α (*i.e.*, setting $\epsilon = 0$). The importance of allowing for the distribution is evident.

Table I gives the values of the parameters calculated for the various runs along with the standard deviations of the experimental points from the computed curves. In the worst case, the standard deviation amounts to only 2.3% of the limiting weight gain.

Before proceeding with an analysis of the temperature dependents of $\bar{\beta}$ and W_L, independent experimental justification for the choice of the distribution function and for the value of the distribution parameter, $\epsilon = 0.7 \pm 0.1$, will be given. Seventeen micrographs, obtained by random sampling of specimens oxidized at 601°C, and ten micrographs of specimens oxidized at 549°C, were analyzed in the following manner. A circular area, corresponding to about 10^{-8} cm² in the original sample, was selected at random within each micrograph and the number of crystallites lying in this area noted. From these measurements, the values of $\bar{N}$ and ϵ were calculated to be 1.27×10^9 cm^{-2} and 0.7_9, respectively, at 549°C, and 1.43×10^9 cm^{-2} and 0.6_0, respectively, at 601°C. Since neither the mean value of the number density of nuclei, $\bar{N}$,

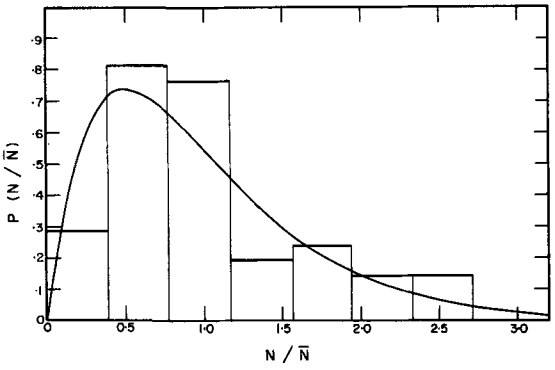

Fig. 8. Comparison of the histogram for the measurements of the number of crystallites per 10^{-8} cm^2, with the Pearson type III distribution curve, $P(N/\bar{N})$, for $\epsilon = 0.7$. (N and $\bar{N}$ are the local and mean number density of crystallites, respectively.)

nor the relative standard deviation, ϵ, show any significant temperature dependence, the data for 549° and 601°C were combined and a histogram constructed for comparison with the Pearson type III distribution curve. Both the histogram, and the Pearson type III distribution function for $\epsilon = 0.7$, are plotted in Fig. 8. The rectangular area at the extreme left-hand end has a height proportional to the number of samples having between 0 and 5 crystallites within the chosen area; the next rectangular area has a height proportional to the number of samples having between 5 and 10 crystallites within the chosen area, etc. To facilitate comparison with the distribution curve, the histogram has been plotted against $N/\bar{N}$ and a scaling factor applied to the height of the rectangles so that the total area under the histogram would be unity. The mean and the standard deviation for the entire 27 samples are given by $\bar{N} = 1.3 \times 10^9$ cm^{-2}, $\epsilon = 0.6_6$.

From the above we see that the value of the relative standard deviation, ϵ, deduced from the kinetic analysis is in excellent agreement with that measured by direct electron micrographic observation. Furthermore, the histogram obtained from the direct observation is in good accord with the Pearson type III distribution curve. This being the case, ϵ need not be regarded as a parameter adjusted to give agreement with the kinetic data, but rather as one determined by direct electron micrographic examination.

Thus the calculated curves for the oxidation runs at 530°C and above involve only two disposable constants, $\bar{\beta}$ and W_L. At the lower temperatures an additional parameter t_o is required.

At a sufficiently high temperature, we might expect that following complete coverage of the surface with crystallites, further oxidation could proceed by oxygen migration along the surfaces of impingement of the individual crystallites. Examination of Fig. 4 shows that, if such an effect exists, it makes a negligible contribution during oxidation at 549°C. The data of Fig. 5, however, indicate that such a contribution might be important during the final stages of oxidation at 601°C. If oxidation were taking place by oxygen diffusion along the surfaces of impingement of the crystallites, we would expect a direct logarithmic oxidation law in accord with the mechanism proposed by Evans (15, 16) in which it is assumed that a decrease in the number of diffusion paths with time results from blockage of paths due both to oxide growth at the bottom and also to compressional forces rising from the volume increase accompanying oxidation. To test this postulate, the experimental weight increase less the calculated weight increase for a typical run at 601°C is plotted against the logarithm of the oxidation period in Fig. 9. The majority of the points lie on a straight line, lending support to this hypothesis. Presumably a similar effect would be observed for oxidation at 549°C if the run were continued for a sufficiently long period of time.

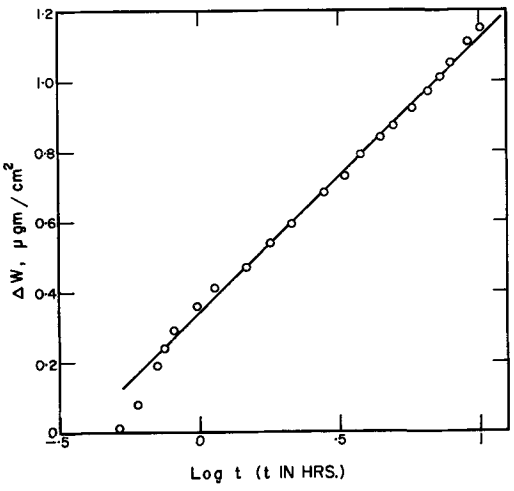

Fig. 9. Excess weight gain ΔW (experimental less calculated weight gain) plotted against the logarithm of the oxidation period, for oxidation data at 601°C.

Temperature Dependence of K_2 and X_L

In Fig. 10, the values of $\bar{\beta}$ given in Table I are plotted in the form log $\bar{\beta}$ against $1/kT$. The results lie on a straight line, in accord with [26], the equation for the least squares regression line being represented by

$$\bar{\beta} = 10^{27.1_6} \exp(-4.46/kT) \text{ hr}^{-2} \qquad [28]$$

when kT is expressed in electron volts. Comparing Eq. [28] and [26], and setting $\Omega = 1.56 \times 10^{-23}$ cm^3 for γ-Al_2O_3 of density 3.6 g cm^{-3}, $n_s \simeq \Omega^{-2/3}$ and $\bar{N} = 1.3 \times 10^9$ cm^{-2}, we obtain $U_2 = 2.2_3$ ev, $\nu_2 \simeq 6.7 \times 10^{12}$ sec^{-1}. The calculated value for ν_2 is clearly of the correct magnitude, indicating that the pre-exponential factor is in accord with that predicted on the basis of the proposed mechanism. It is not really possible to predict the value of U_2. However, we note that U_2, the activation energy for ion transfer across the amorphous oxide-crystalline oxide phase boundary, is very nearly equal to the activation energy for the steady-state anodic oxidation of aluminum in a glycol-borate electrolyte, 2.1_7 ev (17). According to a

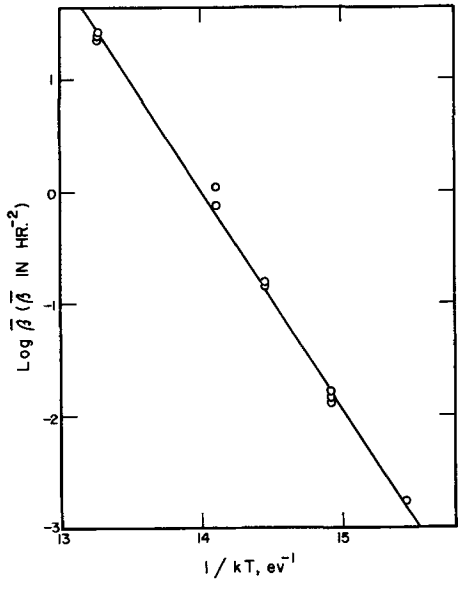

Fig. 10. Temperature dependence of the kinetic parameter, $\bar{\beta}$

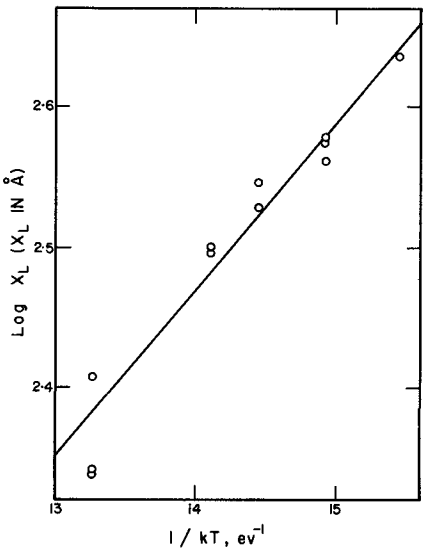

Fig. 11. Temperature dependence of the limiting film thickness, X_L

recent theory for the anodic oxidation of aluminum and tantalum (18, 19), the amorphous oxide film is assumed to consist of a mosaic of microcrystallites, or polymeric units, the activation energy being associated with ion transfer across the boundaries. On the basis of these two theories, therefore, the activation energies should in fact be the same, or very nearly the same.

Again, from the values of W_L in Table I and using Eq. [25], values of X_L have been calculated and plotted in the form log X_L against $1/kT$ in Fig. 11. A value of 25Å was used for $X_a(0)$, in accord with the results presented in Part I of this paper (11). The results presented in Fig. 11 lie on a straight line, within experimental scatter, in accord with [13]. The equation for the least squares regression line is represented by

$$X_L = 6.6 \exp (0.27/kT) \text{ Å} \qquad [29]$$

when kT is expressed in electron volts. Comparing Eq. [29] and [13], we have

$$(U_2 - U_D) = 0.54 \text{ ev}, \; a \simeq 4.7 \text{ Å}$$

Once again we see that the value for a, the "jump distance," is of the correct magnitude, the value of $U_2 - U_D$ also being reasonable. Combining the above value for $U_2 - U_D$ with the value for U_2 gives $U_D = 1.69$ ev.

General Discussion

Before summarizing the results, there remain several points, each of some importance, to discuss. The first concerns the well-known fact that amorphous oxide formed on aluminum by anodic oxidation or air oxidation at low temperature, will not "crystallize" to form γ-alumina in the absence of either oxygen or metal except at very high temperatures ($\gtrsim$ 1000°C). In the presence of oxygen and metal, γ-alumina does, of course, form, but at the expense of metal, not by transformation of the amorphous film present.

Contrasting these findings with the postulated model, according to which the thin layer of amorphous film which separates the growing faces of the crystallites of γ-alumina from the metal is continuously being transformed to γ-alumina, we see that an objection to the present interpretation arises which must be resolved in some fashion. Although a fully satisfactory justification is not possible at present, it appears to the authors not unreasonable that transformation of amorphous to crystalline oxide could occur under the extraordinary conditions which obtain according to the proposed model. It will be recalled that this very thin layer of amorphous oxide, in addition to transforming to crystalline oxide, is also continuously growing at the expense of the metal phase, the net effect being the maintenance of a constant thickness of amorphous film. Thus the oxide transformation is assumed to occur under extreme nonequilibrium conditions in which very high electrochemical potential gradients ($\sim 10^7$ ev/cm molecule) are present in the amorphous film. Such conditions are very likely to assist any sort of atomic reorganization.

A second point concerns the detailed interpretation of the conduction measurements presented in Fig. 6. We shall examine various possible explanations for these data, and compare the consequences of each with other data, and with the model. Because of the remarkable similarity between the resolved polarization curves of Fig. 6 and curves obtained in a similar manner for samples covered solely with amorphous oxide (7), it is assumed that the conduction processes involved are the same in all kinetically important aspects as those occurring during measurements involving only amorphous oxide. That such an assumption may not be valid need hardly be stated. With the information available, however, it appears to be the only assumption justifiable at present.

The immediate consequence of the above assumption is that during this polarization measurement, the crystalline oxide must have been acting as an ionic conductor of substantially lower resistance than the amorphous film. If the crystallites had been acting as good electronic conductors, there would have been no mechanism for increasing the thickness of the amorphous film lying on top of the crystallite, and hence nothing to check the increase in the current with increasing potential. The resulting polarization curve would therefore have been very different from that observed. Furthermore, oxygen evolution would have occurred, whereas the absence of such was specifically noted (7).[2]

We now examine the question of whether, during the polarization measurement, conduction through the crystallites was predominantly anionic or cationic. If anionic, the anodizing current would lead to the formation of new amorphous oxide beneath the crystallites, rather than to thickening of the thermally formed amorphous film lying on top of the crystallites. Transport through this thermally formed amorphous film would therefore take place only through the thinnest portions of it, with the new amorphous oxide being formed, however, under the entire crystallite. The resulting polarization curve would therefore resemble closely that for an aluminum sample covered with an amorphous film of thickness approximately equal to that of the thinnest regions on top of the crystallites, and of area approximately equal to that covered by the crystallites. Such a conclusion is not only in agreement with the conduction data (Fig. 6), but also consistent with the model proposed herein. It should perhaps be noted that "effective transport" of oxygen ions through the amorphous film can take place by high field ionic conduction regardless of the conduction mechanism, in that per Faraday of charge passed one electrochemical equivalent of oxygen will be removed from the electrolyte, and the same quantity of oxygen ions made available at the amorphous oxide-crystalline oxide interface.

If, during the polarization measurement, ionic conduction through the crystallites were cationic, the oxide formed during polarization would lead to thickening of the thermally formed amorphous film lying on top of the crystallites. According to the model presented herein (Fig. 7), the amorphous film lying on top of a crystallite is thinnest in the central region and increases steadily as one proceeds toward

[2] The statement appearing in ref. (7) "Electronic contribution to the measured current was shown experimentally to be small" refers mainly to the fact that no oxygen was evolved even after prolonged anodic oxidation.

the periphery, until at the periphery it is equal in thickness to the film lying between the crystallites. Such a distribution of film thickness would definitely not give rise to a polarization curve in accord with Fig. 6. The polarization curve, although broadened compared with that for a sample of nearly uniform oxide thickness, would not show two distinct peaks. Thus either the model must be incorrect, or the crystallites were acting as anionic rather than cationic conductors during the conduction measurement.

Assuming, tentatively, that the model is incorrect and that conduction through the crystallites is cationic, it follows from the polarization measurement that the crystallites are covered with an amorphous film of approximately uniform thickness somewhat less than that of the film between the crystallites. Revising the analytical treatment presented herein in accord with such a modified model in fact leads to no change in any of the final expressions, the minor alteration in the model being in effect eliminated in the approximations made in obtaining Eq. [13]. However, a serious objection to this revised model exists. If the amorphous film on top of the crystallites is uniform in thickness and thinner than that lying between the crystallites, then, as the crystallites grow laterally during thermal oxidation, they must also grow into the amorphous film above the crystallites by recrystallization. However, once one accepts this proposition, there appears to be no reason for the process to stop until the crystallites emerge at the oxygen-oxide interface. This, however, is contrary to the observations of Doherty and Davis (10).

On the basis of the assumption stated at the outset of this discussion, we conclude, therefore, that during the polarization measurement the crystallites acted as good anionic conductors, and further that the conduction data are consistent with the model illustrated in Fig. 7. The question arises, however, as to whether or not these crystallites act as good ionic conductors during thermal oxidation. If they do, then it is difficult to understand why the crystallites would not continue to increase in thickness once formed. The present kinetic evidence indicates that they do not. More direct evidence in this regard is provided, however, by the data of Hunter and Fowle (20). These authors studied the growth of oxide films on aluminum by measuring "barrier voltages" for oxide covered specimens prepared by thermal oxidation in dry oxygen. The barrier voltages were measured at room temperature by polarizing the specimens anodically in an electrolyte and noting the minimum voltage required to cause significant ion current to flow. The feature of these results to which we wish to refer is that as a specimen approaches complete coverage with crystallites of γ-alumina, the barrier voltage increases rapidly by a factor of three to four and then remains constant. Thus, for example, at 475°C, the barrier voltage remains constant at about 4v for oxidation periods varying from 1 to 9 hr. Following 21 hr oxidation, however, the barrier voltage value is nearly 12v. A similar rapid increase in the barrier voltage occurs for oxidation at 500°C. At higher temperatures, the first readings taken correspond already to high barrier voltage values.

Hunter and Fowle's results, coupled with the present weight gain data, indicate that the crystallites do not have a high conductivity, but instead a specific conductivity rather close to that for the amorphous film. We are faced, therefore, with an apparent contradiction, since the data of Fig. 6 indicate otherwise. There is, however, a fairly obvious explanation for these results. The coefficient of thermal expansion of aluminum is much larger than that for alumina. On quenching a thermally oxidized sample from 450°C or above to room temperature, compressional stresses will be applied to the crystallites, particularly since these are imbedded in the metal matrix. In addition, a shear stress will develop in the plane defined by the base of the crystallites. For specimens in which most of the surface is covered with crystallites, one would expect the stress to be relieved primarily by slippage in this shear plane. If, on the other hand, only a portion of the surface is so covered, the compressional stress could easily lead to structural damage of the crystallites. The high anionic conductivity of the crystallites, evidenced in the results of Fig. 6, could have arisen, therefore, as a result of thermal quenching, the compressional stresses leading to the formation of "short circuit" diffusion paths in the crystallites. Indeed, we have been unable to reconcile these data with those of Hunter and Fowle on any other satisfactory basis.

Before leaving this question, it is important to point out that the oxidation mechanism proposed herein is not dependent on the validity of the foregoing conclusion concerning the conduction properties of the crystallites. It is entirely possible that other interpretations of the conduction data can be found which are consistent with all available data. The interpretation given, however, is internally consistent, and consistent with available data, in addition to being in accord with the proposed oxidation mechanism.

Finally, the model presented herein, while somewhat similar to that proposed by Bartlett (9), differs from it considerably in detail. The present treatment provides very substantially better agreement with the data, while employing essentially the same number of disposable constants. Furthermore, the present treatment is more specific in its predictions, giving as it does theoretical values for the pre-exponential factor for $\bar{\beta}$ and X_L in agreement with the experimentally deduced values, as well as predicting a negative temperature coefficient for the limiting film thickness.

Summary and Conclusions

Data for the growth of crystalline γ-alumina have been obtained for the oxidation of electropolished superpurity aluminum in the temperature range 475°-600°C. These data have been quantitatively interpreted in terms of a model in which the γ-alumina crystallites nucleate beneath the amorphous film, rapidly achieve a terminal thickness, and grow radially at a linear velocity until they impinge on adjacent crystallites. The terminal thickness of the crystallites arises as a consequence of the mechanism by which oxygen is fed to the growing faces of the crystallites. It is proposed that this occurs by oxygen diffusion along the phase boundary at the periphery of the growing crystallite formed by the crystallite and a thin amorphous oxide layer next to the metal phase. The radial growth constant is determined by the rate of transformation of the thin amorphous oxide layer to crystalline oxide. The values for the pre-exponential factors and activation energies obtained from the analyses are in complete accord with the model.

The expressions for both the diffusion constant, D, for the diffusion of oxygen along the inter-oxide phase boundary, and the radial growth constant, K_2, for the transformation of the amorphous oxide layer to crystalline oxide, are given below

$$D = 2 \times 10^5 \exp(-1.6_9/kT) \text{ cm}^2/\text{sec} \quad [31]$$

$$K_2 = 1.5 \times 10^{-2} \exp(-2.2_3/kT) \text{ cm/sec} \quad [32]$$

when kT is expressed in electron volts. Equations [31] and [32] were obtained from [10] and [11] and the experimentally determined parameters, assuming as before

$$n_s \simeq \Omega^{-2/3} \text{ and } \nu_D \simeq \nu_2$$

APPENDIX

Modification of Law of Expanding Cylinders to Allow for a Nonuniform Distribution of Sites

The law of expanding cylinders, assuming a uniform number per unit area of cylinders, takes the form given in [16], *viz*,

$$\alpha = 1 - \exp[-\beta(t - t_o)^2], \quad t > t_o \qquad [A1]$$

where α is the fraction of the surface covered by the cylinders, t_o the time of commencement of their lateral growth, and $\beta = \pi N K_2^2$ where N is the number density or surface concentration of the cylinders, and K_2 their radial growth rate, assumed independent of time and radius. If N (and hence β) is not a constant, independent of position on the surface, but instead varies in accord with a Pearson type III distribution law (14)

$$P(\beta) = K\beta^p \exp(-p\beta/a') \qquad [A2]$$

(where K, p, and a' are constants of the distribution) then α is not given by [A1] but instead by

$$\alpha = 1 - \int_o^\infty [\exp(-\beta[t - t_o]^2)]P(\beta)\,d\beta \qquad [A3]$$

for $P(\beta)$ normalized. The normalization condition gives

$$\int_o^\infty K\beta^p \exp(-p\beta/a')\,d\beta = K[\Gamma(p+1)]/(p/a')^{p+1} = 1 \qquad [A4]$$

where Γ represents the usual gamma function (generalized factorial function). The mean value of β, $\bar{\beta}$, is given by the following integral

$$\bar{\beta} = \int_o^\infty K\beta^{p+1} \exp(-p\beta/a')\,d\beta = K[\Gamma(p+2)]/(p/a')^{p+2} \qquad [A5]$$

so that from [A4] and [A5] $K = (p/a')^{p+1}/\Gamma(p+1)$ and $\bar{\beta} = (a'/p)(p+1)$.

The standard deviation for the distribution of β values, σ, is given by

$$\sigma^2 = \int_o^\infty (\beta - \bar{\beta})^2 K\beta^p \exp(-p\beta/a')\,d\beta = (a'/p)^2(p+1) \qquad [A6]$$

Thus

$$\epsilon^2 \equiv \sigma^2/\bar{\beta}^2 = 1/(p+1)$$

so that

$$p = \epsilon^{-2} - 1, \quad a' = (1 - \epsilon^2)\bar{\beta}$$

The distribution function can now be rewritten

$$P(\beta) = \frac{(1/\epsilon^2\bar{\beta})\epsilon^{-2}}{\Gamma(\epsilon^{-2})} \beta^{\epsilon^{-2}-1} \exp(-\beta/\bar{\beta}\epsilon^2) \qquad [A7]$$

Substituting [A7] in [A3] gives the following expression for α

$$\alpha = 1 - [1 + \bar{\beta}\epsilon^2(t - t_o)^2]^{-1/\epsilon^2}, \quad t > t_o \qquad [A7]$$

which is identical to [19] in the body of the paper. Since ϵ represents the standard deviation of the distribution of N, expressed as a fraction of $\bar{N}$, Eq. [A7] should reduce to [A1] in the limit as $\epsilon \to 0$. It is readily shown that this is the case.

The Oxidation of Oxygen-Deficient Zirconia and Its Relationship to the Oxidation of Zirconium

D. L. Douglass

and Carl Wagner

Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

ABSTRACT

Upon heating black oxygen-deficient zirconia in oxygen of atmospheric pressure to 450° to 900°C, oxygen is taken up. The increase in the thickness $\Delta\xi_w$ of a white layer of virtually ideal composition with time t follows a parabolic rate law, $\Delta\xi_w^2/2t = k_p$. The rate constant k_p is about two orders of magnitude higher than Tammann's rate constant $k_T = (\Delta\xi_{oxide})^2/2t$ for the increase in thickness $\Delta\xi_{oxide}$ of a ZrO_2 layer during the oxidation of zirconium metal. Equations for the concentrations of ionic and electronic defects in zirconia as functions of the oxygen partial pressure are presented in order to derive theoretical equations for the rates of oxidation of oxygen-deficient zirconia and of zirconium metal.

According to various investigators (1-12) the oxidation of unalloyed zirconium conforms only in part to the parabolic rate law. It must be noticed that the weight gain of a sample is determined by two processes, *viz.*, formation of a ZrO_2 layer and diffusion of oxygen dissolved in the metal. Even under these conditions, however, the parabolic rate first deduced by Tammann (13) for diffusion as the rate-deter-

mining step should apply (8, 11, 12) if the oxide layer is dense, local equilibrium at the phase boundaries gas/oxide and oxide/metal is established, the thickness of the electrical double layers is small in comparison to the thickness of the ZrO_2 layer, and the oxygen concentration at the center of the metal is much less than the oxygen concentration in the metal in equilibrium with the oxide. Hussey and Smeltzer (9) have observed that the rate of oxidation depends on the kind of surface preparation. Chemically polished samples were found to oxidize more slowly than abraded samples. Moreover, it was observed that the oxidation rate is affected by a previous anneal of the sample. In view of these observations it is not surprising that results obtained in different laboratories differ to some extent. Some investigators (3, 6) have reported that their results conform to a cubic rather than a parabolic rate law. The dependence on surface preparation and deviations from the parabolic rate law indicate that in addition to diffusion there must be other factors which determine the rate of oxidation. In particular, local detachment of the scale from the metal may be an important factor. Thus diffusion studies in ZrO_2 free of complications due to processes occurring at the oxide/metal interface, especially spalling off of the oxide, are desirable. For this reason, in what follows results for the diffusion of oxygen into oxygen-deficient zirconia are reported and analyzed.

Experimental

Oxygen-deficient zirconia is black, whereas ZrO_2 of virtually ideal composition is white. Upon heating black oxygen-deficient zirconia in oxygen of atmospheric pressure, one observes the formation of a white zone which thickens in accord with the parabolic law

$$\Delta\xi_w^2/2t = k_p \qquad [1]$$

where $\Delta\xi_w$ is the thickness of the white zone at time t, and k_p is a constant. Details of the experimental technique and the determination of the extent of oxygen deficiency of the starting material with the help of gravimetric and manometric measurements have been described previously (14, 15). Measurements have been made with both samples free of foreign cations and samples containing additions such as Y_2O_3, Cr_2O_3, NiO, and Fe_3O_4. Data for oxygen diffusion into $ZrO_{1.994}$ between 450° and 900°C are represented by the Arrhenius equation

$$k_p = 0.055 \cdot \exp(-33{,}400/RT)\ \mathrm{cm^2/sec}$$

and data for oxygen diffusion into $Zr_{0.981}Y_{0.019}O_{1.980}$ by

$$k_p = 0.27 \cdot \exp(-27{,}200/RT)\ \mathrm{cm^2/sec}$$

Theoretical Analysis

The following analysis aims at an understanding of the salient features. Numerous approximations are introduced and, therefore, the final equations have only semi-quantitative significance. The finite thickness of space charge regions is neglected since the concentration of charged defects in black zirconia $ZrO_{2\text{-}0.006}$ is fairly high and, therefore, the effective thickness of a space charge layer is only about three times the diameter of an oxygen ion. The ideal law of mass action is used as an approximation, *i.e.*, interaction among charged defects is neglected.

Defect equilibria.—The electrical conductivity κ of zirconia without foreign cations has been measured as a function of oxygen partial pressure p_{O_2} by Rudolph (16), by Kofstad and Ruzicka (17), and most recently by Vest, Tallan, and Tripp (18). At 990°C κ rises with increasing values of p_{O_2} if $p_{O_2} > 10^{-6}$ atm in accord with prevailing p-type electronic conduction. In CO_2-CO and H_2O-H_2 mixtures involving values of p_{O_2} less than 10^{-20} atm, κ rises with decreasing values of p_{O_2} in accord with prevailing n-type electronic conduction. In an intermediate range of p_{O_2} with very small deviations from the ideal stoichiometry, ionic conduction prevails according to results of emf measurements on the cell $Zr|ZrO_2|Pt,O_2$ conducted by Dalgaard (19).

Since the lattice of ZrO_2 is a distorted CaF_2 lattice, one may assume the same type of ionic defects in ZrO_2 as in CaF_2 found by Ure (20), *i.e.*, interstitial anions and anion vacancies. Thus the following lattice defects in zirconia are considered: interstitial oxygen ions, oxygen ion vacancies, excess electrons, and electron holes, whose concentrations expressed as ratios of the number of defects to the number of Zr atoms are denoted by $x_{\circ}$, $x_{\square}$, x_n and x_p, respectively.

The oxygen deficiency δ in a sample represented by the formula $ZrO_{2-\delta}$ is equal to the difference $x_{\square} - x_{\circ}$

$$\delta = x_{\square} - x_{\circ} \qquad [2]$$

In order to satisfy the condition of electrical neutrality, the number of positive excess charges must equal the number of negative excess charges. Thus

$$2x_{\square} + x_p = 2x_{\circ} + x_n \qquad [3]$$

From Eq. [2] and [3] it follows that

$$\delta = \frac{1}{2}(x_n - x_p) \qquad [4]$$

For the internal reaction

$$\text{oxygen anion on a regular lattice site} = \text{interstitial oxygen ion} + \text{anion vacancy} \qquad [5]$$

one has the equilibrium condition

$$x_{\circ}x_{\square} = K_1 \qquad [6]$$

Similarly, for the internal reaction

$$\text{valence electron} = \text{excess electron} + \text{electron hole} \qquad [7]$$

one has the equilibrium condition

$$x_n x_p = K_2 \qquad [8]$$

For the oxygen uptake from the gas phase

$$\frac{1}{2}O_2(g) + 2\ \text{excess electrons} = \text{interstitial oxygen ion} \qquad [9]$$

one has the equilibrium condition

$$\frac{x_{\circ}}{p_{O_2}^{1/2}x_n^2} = K_3 \qquad [10]$$

Defect concentrations as functions of oxygen partial pressure.—Equations [2], [4], [6], [8], and [10] are sufficient in order to calculate the defect concentrations $x_{\circ}$, $x_{\square}$, x_n, and x_p and further the oxygen deficit δ as functions of p_{O_2} provided the constants K_1, K_2, and K_3 are known.

The following limiting cases involving two majority defects each are noted.

1. For nearly ideal stoichiometric composition

$$x_{\circ} \cong x_{\square} >> \delta \qquad [11]$$

one has in view of Eq. [6]

$$x_{\circ} \cong x_{\square} \cong K_1^{1/2} \qquad [12]$$

(a) If

$$x_p >> x_n \qquad [13]$$

one has in view of Eq. [4]

$$-\delta \cong \frac{1}{2}x_p \qquad [14]$$

where a negative value of δ indicates an excess of oxygen with respect to the ideal formula ZrO_2.

From Eq. [8], [10], [12], and [14] it follows that

$$x_p \cong -2\delta \cong \frac{K_2K_3^{1/2}}{K_1^{1/4}} p_{O_2}^{1/4} \quad [15]$$

(b) If

$$x_n >> x_p \quad [16]$$

one has in view of Eq. [4]

$$\delta \cong \frac{1}{2} x_n \quad [17]$$

From Eq. [10], [12], and [17] it follows that

$$x_n \cong 2\delta \cong \frac{K_1^{1/4}}{K_3^{1/2}} p_{O_2}^{-1/4} \quad [18]$$

2. For zirconia with a substantial excess of oxygen

$$-\delta \cong x_{\circ} \cong \frac{1}{2} x_p >> x_{\square} \quad [19]$$

it follows from Eq. [8], [10], and [19] that

$$x_{\circ} \cong \frac{1}{2} x_p \cong \left(\frac{1}{4} K_2^2K_3\right)^{1/3} p_{O_2}^{1/6} \quad [20]$$

Substituting Eq. [20] in Eq. [6], one obtains

$$x_{\square} = \frac{K_1}{x_{\circ}} = \frac{K_1}{\left(\frac{1}{4} K_2^2K_3\right)^{1/3}} p_{O_2}^{-1/6} \quad [21]$$

In view of Eq. [20] and [21], one may replace condition [19] by

$$p_{O_2} >> \frac{16K_1^3}{K_2^4K_3^2} = p_{O_2}^{I} \quad [22]$$

where $p_{O_2}^{I}$ is amid the oxygen partial pressure range in which the transition from limiting case 1 to limiting case 2 takes place.

3. For zirconia with a substantial deficiency of oxygen

$$\delta \cong x_{\square} \cong \frac{1}{2} x_n >> x_{\circ} \quad [23]$$

it follows from Eq. [6], [10], and [23]

$$x_{\square} \cong \frac{1}{2} x_n \cong \left(\frac{K_1}{4K_3}\right)^{1/3} p_{O_2}^{-1/6} \quad [24]$$

Substituting Eq. [24] in Eq. [6], one obtains

$$x_{\circ} = \frac{K_1}{x_{\square}} = (4K_1^2K_3)^{1/3} p_{O_2}^{1/6} \quad [25]$$

In view of Eq. [24] and [25], one may replace condition [23] by

$$p_{O_2} << \frac{1}{16K_1K_3^2} \equiv p_{O_2}^{V} \quad [26]$$

where $p_{O_2}^{V}$ is amid the oxygen partial pressure range in which the transition from limiting case 1 to limiting case 3 takes place.

Figure 1 shows schematically the various defect concentrations as functions of the oxygen partial pressures in accord with analogous diagrams presented by Kröger and Vink (21) for other systems. The pressures $p_{O_2}^{I}$ and $p_{O_2}^{V}$ differ by many orders of magnitude, whereas the corresponding change in δ is much less than unity.

Ionic and electronic conductivity of zirconia.— The partial electrical conductivity, κ_{ion}, due to the motion of oxygen ions either as interstitial ions or via vacancies may be written as

$$\kappa_{ion} = 2F(u_{\circ}x_{\circ} + u_{\square}x_{\square})/V_m \quad [27]$$

where $u_{\circ}$ and $u_{\square}$ are the electrochemical mobilities of interstitial oxygen ions and anion vacancies, respectively, F is the Faraday constant, and V_m is the molar volume.

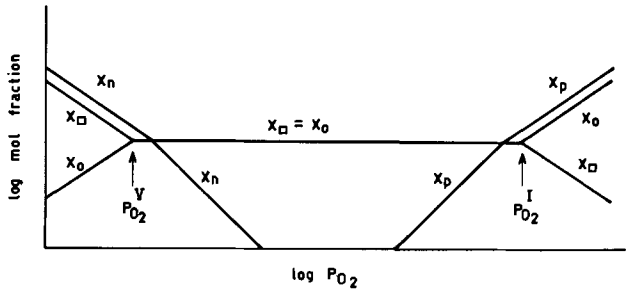

Fig. 1. Dependence of defect concentrations on oxygen partial pressure p_{O_2}.

Similarly, the partial electronic conductivity, κ_e is

$$\kappa_e = F(u_n x_n + u_p x_p)/V_m \quad [28]$$

where u_n and u_p are the mobilities of excess electrons and electron holes, respectively.

The mobility of an electron is in general much greater than that of an ion. Furthermore, in view of results obtained for CaF_2 (20) one may assume that the mobility of anion vacancies in zirconia is much greater than that of interstitial anions. Thus

$$u_n >> u_{\square} >> u_{\circ} \quad [29]$$

For the three limiting cases involving different majority defects, one obtains the following special relations.

1. If $x_{\circ} \cong x_{\square}$ and according to Eq. [22] and [26]

$$p_{O_2}^{V} << p_{O_2} << p_{O_2}^{I} \quad [30]$$

it follows on substitution of Eq. [12] in Eq. [27] that

$$\kappa_{ion} \cong 2F(u_{\circ} + u_{\square})K_1^{1/2}/V_m \quad [31]$$

(a) If $u_p x_p >> u_n x_n$, one obtains from Eq. [15] and [28]

$$\kappa_e \cong \frac{Fu_p}{V_m} \frac{K_2K_3^{1/2}}{K_1^{1/4}} p_{O_2}^{1/4} \quad [32]$$

(b) If conversely $u_n x_n >> u_p x_p$, one obtains from Eq. [18] and [28]

$$\kappa_e \cong \frac{Fu_n}{V_m} \frac{K_1^{1/4}}{K_3^{1/2}} p_{O_2}^{-1/4} \quad [33]$$

2. For zirconia with a substantial excess of oxygen

$$p_{O_2} >> p_{O_2}^{I} \quad [34]$$

it follows from Eq. [19], [20], [21], [27], and [28] that

$$\kappa_{ion} \cong \frac{2F}{V_m}\left[u_{\circ}\left(\frac{1}{4} K_2^2K_3\right)^{1/3} p_{O_2}^{1/6} + u_{\square} \frac{K_1}{\left(\frac{1}{4} K_2^2K_3\right)^{1/3}} p_{O_2}^{-1/6}\right] \quad [35]$$

$$\kappa_e \cong \frac{2Fu_p}{V_m}\left(\frac{1}{4} K_2^2K_3\right)^{1/3} p_{O_2}^{1/6} \text{ if } u_p x_p >> u_n x_n \quad [36]$$

3. For zirconia with a substantial deficiency of oxygen

$$p_{O_2} << p_{O_2}^{V} \quad [37]$$

it follows from Eq. [23], [24], [25], [27], [28], and [29] that

$$\kappa_{ion} \cong \frac{2Fu_{\square}}{V_m}\left(\frac{K_1}{4K_3}\right)^{1/3} p_{O_2}^{-1/6} \quad [38]$$

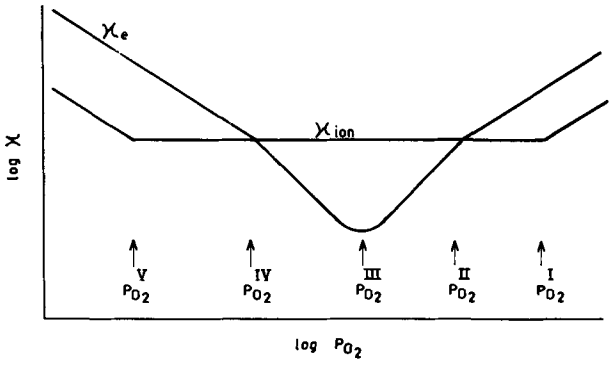

Fig. 2. Dependence of partial ionic and electronic conductivities on oxygen partial pressure p_{O_2}.

$$\kappa_e \cong \frac{2Fu_n}{V_m}\left(\frac{K_1}{4K_3}\right)^{1/3} p_{O_2}{}^{-1/6}, \text{ if } u_n x_n >> u_p x_p \quad [39]$$

Variations of the partial conductivities for ions and electrons are schematically shown in Fig. 2. The following characteristic oxygen partial pressure are marked: (*a*) $p_{O_2}{}^{II}$ at which the ionic conductivity equals the p-type electronic conductivity [$\sim 10^{-7}$ atm at 990°C (18)]; (*b*) $p_{O_2}{}^{III}$ for equal partial n-type and p-type conductivities corresponding to a minimum of the partial electronic conductivity κ_e; (c) $p_{O_2}{}^{IV}$ at which the ionic conductivity equals the n-type electronic conductivity [$\sim 10^{-21}$ atm at 990°C (18)].

Equations for oxygen diffusion.—Assuming ambipolar diffusion of oxygen ions and electrons for diffusion of oxygen in zirconia, one may write for the inward flux, j, of oxygen in equivalents per unit area per unit time for one-dimensional conditions (22)

$$j = -\frac{RT}{4F^2}\frac{\kappa_{ion}\kappa_e}{\kappa_{ion}+\kappa_e}\frac{d\ln p_{O_2}}{d\xi} \quad [40]$$

where κ_{ion} and κ_e are the partial conductivities for oxygen ions and electrons, respectively, p_{O_2} is the local oxygen equilibrium partial pressure, and ξ is the distance from the outer surface.

On the other hand, according to Fick's first law

$$j = Dd(2\delta/V_m)/d\xi \quad [41]$$

where D is the phenomenological diffusion coefficient, δ is the local oxygen deficit, V_m is the molar volume of ZrO_2, and accordingly, $2\delta/V_m$ is the local oxygen deficit in equivalents of oxygen per unit volume. From Eq. [40] and [41] it follows that

$$D = \frac{V_m RT}{8F^2\delta}\frac{\kappa_{ion}\kappa_e}{\kappa_{ion}+\kappa_e}\left(-\frac{d\ln p_{O_2}}{d\ln\delta}\right) \quad [42]$$

The dependence of D on p_{O_2} calculated from Eq. [42] and the foregoing equations for κ_{ion}, κ_e, and δ as functions of p_{O_2} is shown schematically in Fig. 3. The diffusion coefficient is high if ionic conduction prevails and low if electronic conduction prevails because the defect with the lower mobility determines the ambipolar diffusion coefficient D as is shown in what follows for special situations.

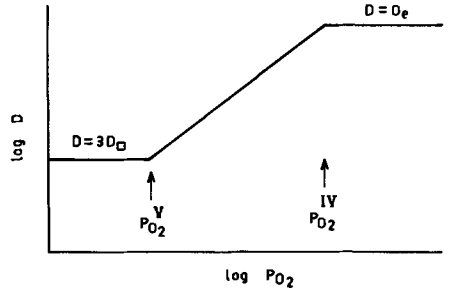

Fig. 3. Dependence of diffusion coefficient D on oxygen partial pressure p_{O_2}.

If

$$p_{O_2}{}^{III} << p_{O_2} << p_{O_2}{}^{II} \quad [43]$$

one has in view of Eq. [28]

$$\kappa_e \cong Fu_p x_p/V_m << \kappa_{ion}$$

The mobility u_p of defect electrons is related to their diffusivity D_p by the Nernst-Einstein equation

$$D_p = u_p RT/F$$

whereupon in view of Eq. [14], [15], and [42] for $\kappa_e >> \kappa_{ion}$

$$D = D_p \quad [44]$$

If

$$p_{O_2}{}^{IV} << p_{O_2} << p_{O_2}{}^{III} \quad [45]$$

one obtains similarly

$$D = D_n \quad [46]$$

If

$$p_{O_2} < p_{O_2}{}^{V} \quad [47]$$

one has in view of Eq. [23] and [27]

$$\kappa_{ion} = 2Fu_{□}x_{□}/V_m << \kappa_e \quad [48]$$

The diffusion coefficient of anion vacancies with a double change is according to the Nernst-Einstein equation

$$D_{□} = u_{□}RT/2F \quad [49]$$

Upon substitution of Eq. [23], [24], [48], and [49] in Eq. [42], it follows that

$$D = 3D_{□} \quad [50]$$

In this case the ambipolar diffusion coefficient D is three times the diffusion coefficient $D_{□}$ of anion vacancies because the movement of the anions is supported by a diffusion potential due to the tendency of the faster electrons to move ahead.

In the intermediate range

$$p_{O_2}{}^{V} << p_{O_2} << p_{O_2}{}^{IV} \quad [51]$$

zirconia has a slight oxygen deficiency with prevailing n-type electronic conduction, ($\kappa_{ion} << \kappa_e$). Upon substitution of Eq. [12] [17], [18], [29], [31], and [49] in Eq. [42] it follows that

$$D = 4D_{□}K_1{}^{1/4}K_3{}^{1/2}p_{O_2}{}^{1/4} \quad [52]$$

Diffusion of oxygen into oxygen-deficient zirconia without dope.—Let us now consider diffusion of oxygen into zirconia which has initially a uniform oxygen deficit δ_o, *e.g.*, $\delta_o = 0.006$. When the thickness of the diffusion zone represents a small fraction of the whole sample, one may use the conditions for one-dimensional diffusion into semi-infinite space.

Fick's second law reads

$$\frac{\partial\delta}{\partial t} = \frac{\partial j}{\partial\xi} = \frac{\partial}{\partial\xi}\left(D\frac{\partial\delta}{\partial\xi}\right) \quad [53]$$

The initial condition is

$$\delta = \delta_o \text{ at } \xi > 0,\ t = 0 \quad [54]$$

The deviation from the ideal stoichiometric composition at the outer surface in oxygen is denoted by δ_s. Thus

$$\delta = \delta_s \text{ at } \xi = 0,\ t > 0 \quad [55]$$

As an approximation let us use the relations for the four above limiting cases and let us disregard transient conditions. Denoting the oxygen deficit at the oxygen partial pressures $p_{O_2}{}^{I}$, $p_{O_2}{}^{II}$, etc., by δ^{I}, δ^{II}, etc., respectively, one has in view of Eq. [44], [46], [50], and [52]

$$D = D_p \text{ if } \delta^{II} \leqq \delta \leqq \delta^{III}$$

$$D = D_n \text{ if } \delta^{III} \leqq \delta \leqq \delta^{IV}$$

$$D \propto p_{O_2}^{1/4} \propto \delta^{-1} \text{ if } \delta^{IV} \leqq \delta \leqq \delta^{V}$$

$$D = 3\,D_{\square} \text{ if } \delta^{V} \leqq \delta$$

Writing all expressions in terms of that for the range $\delta^V \leqq \delta$, one obtains

$$D = 3(D_p/D_n)D_{\square}(\delta^V/\delta^{IV}) \text{ if } \delta^{II} \leqq \delta \leqq \delta^{III} \quad [56a]$$

$$D = 3D_{\square}(\delta^V/\delta^{IV}) \text{ if } \delta^{III} \leqq \delta \leqq \delta^{IV} \quad [56b]$$

$$D = 3D_{\square}(\delta^V/\delta) \text{ if } \delta^{IV} \leqq \delta \leqq \delta^{V} \quad [56c]$$

$$D = 3D_{\square} \text{ if } \delta^{V} \leqq \delta \quad [56d]$$

If $\delta_o >> \delta^V$, the dependence of D on δ has to be considered only if $\delta << \delta_o$. Under these conditions the flux is virtually independent of ξ. Thus

$$D\frac{\partial\delta}{\partial\xi} \cong \text{constant if } \delta << \delta_o \quad [57]$$

Integration of Eq. [67] yields

$$\xi(\delta) = A\int_{\delta_s}^{\delta} D(\delta)\cdot d\delta \text{ if } \delta << \delta_o \quad [58]$$

where A is a parameter which is proportional to $t^{1/2}$ as is calculated below in Eq. [62].

Conductivity data (16, 18) indicate that $p_{O_2} = 1$ atm is in the range between $p_{O_2}^{II}$ and $p_{O_2}^{III}$. Substituting Eq. [56a] to [56c] in Eq. [58], one obtains

$$\xi(\delta) = 3AD_{\square}\left\{\delta_V\left[\frac{\delta^{III}-\delta_s}{\delta^{IV}}\frac{D_p}{D_n} - \frac{\delta_{III}}{\delta_{IV}} + \ln(\delta^V/\delta^{IV})\right] + \delta\right\} \text{ if } \delta^V \leqq \delta << \delta_o \quad [59a]$$

The mobility of a defect electron is in general less than that of an excess electron and, therefore, $D_p < D_n$. Moreover, it can be assumed that δ^{III} and $\delta^{III} - \delta_s << \delta^{IV}$. Then the first and the second term in brackets may be neglected and Eq. [59a] becomes

$$\xi(\delta) = 3AD_{\square}[\delta^V \ln(\delta^V/\delta^{IV}) + \delta] \text{ if } \delta^V < \delta << \delta_o \quad [59b]$$

On the other hand, if $\delta > \delta^V$ and $D = 3D_{\square}$, differential Eq. [53] with the initial condition in Eq. [54] has the solution

$$\delta = \delta_o\{B \operatorname{erf}[\xi/2(3D_{\square}t)^{1/2}] - (B-1)\} \quad [60]$$

where B is a constant.

Using the first term of a series expansion for small values of the error function, one obtains

$$\delta = \delta_o\left[B\frac{\xi}{(3\pi D_{\square}t)^{1/2}} - (B-1)\right] \text{ if } \delta^V < \delta << \delta_o \quad [61]$$

Equating the expressions for δ and the fluxes, *i.e.*, $D(\partial\delta/\partial\xi)$ at $\delta = \delta^V$ according to Eq. [59] and [61], one obtains two equations from which the parameters A and B may be calculated. Thus

$$A = \frac{(3\pi D_{\square}t)^{1/2}}{3D_{\square}[\delta_o + \delta^V \ln(\delta^V/\delta^{IV})]} \quad [62]$$

$$B = 1 + [(\delta^V/\delta_o)\ln(\delta^V/\delta^{IV})] \quad [63]$$

Substitution of Eq. [62] in Eq. [59] yields for the distance at which $\delta = \delta^V$

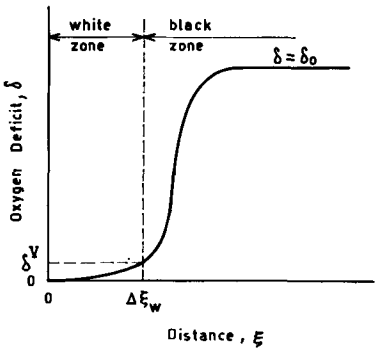

Fig. 4. Oxygen deficit *vs.* distance ξ during oxidation of oxygen-deficient zirconia.

$$\xi(\delta = \delta^V) = \frac{\delta^V[1 + \ln(\delta^V/\delta^{IV})]}{\delta_o + \delta^V \ln(\delta^V/\delta^{IV})}(3\pi D_{\square}t)^{1/2}$$

$$\cong \frac{\delta^V}{\delta_o}\left[1 + \ln\frac{\delta^V}{\delta^{IV}}\right](3\pi D_{\square}t)^{1/2} \text{ if } \delta^V << \delta^o \quad [64]$$

The variation of δ with ξ according to Eq. [58] and [60] is shown schematically in Fig. 4. A rapid change in composition occurs if $\xi \gtrsim \xi(\delta = \delta^V)$. This may account for the observation of the sharp boundary between the white and the black zone of oxygen-deficient samples oxidized in oxygen. Consequently, for the sake of an approximation, one may equate $\xi(\delta = \delta^V)$ to the observed thickness $\Delta\xi w$ of the white zone. Thus, on combining Eq. [1] and [64] the parabolic rate constant for the oxidation of oxygen-deficient zirconia is found to be

$$k_p = \frac{(\Delta\xi w)^2}{2t} \cong \ldots \frac{3\pi D_{\square}}{2}\left[\frac{\delta^V}{\delta_o}\left(1 + \ln\frac{\delta^V}{\delta^{IV}}\right)\right]^2 \quad [65]$$

Discussion

The rate of diffusion of oxygen into oxygen-deficient zirconia may be compared with the rate of oxidation of zirconium. For this purpose, it is especially appropriate to use the rate constant k_T introduced by Tammann (13), which has the same dimension as k_p (cm²/sec)

$$\frac{1}{2}\frac{(\Delta\xi_{oxide})^2}{t} = k_T \quad [66]$$

where $\Delta\xi_{oxide}$ is the thickness of the oxide layer at time t. From the foregoing analysis especially Eq. [56a] to [56c] and [57] it can be concluded that during the oxidation of zirconium most of the oxide layer is oxygen-deficient zirconia with virtually equivalent concentrations of anion vacancies and excess electrons in accord with Eq. [23]. Under these conditions the rate of oxygen diffusion is determined by $D = 3D_{\square}$ according to Eq. [50]. Accordingly, the rational rate k_r constant defined by Wagner (22) as the flux of equivalents of oxygen per unit area and unit time for unit thickness of the oxygen layer is

$$k_r = 3D_{\square}\cdot\frac{2(\delta_{eq} - \delta_s)}{V_m} \cong \frac{6D_{\square}\delta_{eq}}{V_m} \quad [67]$$

where δ_{eq} is the equilibrium oxygen deficit of zirconia coexisting with the metal, $\delta_s \cong 0$ is the oxygen deficit at the surface, and $2(\delta_{eq} - \delta_s)/V_m$ is the concentration difference in terms of equivalents per unit volume.

For the sake of an approximation, diffusion of oxygen into zirconium may be disregarded. Then the constants k_T and k_r are interrelated by the formula (22)

$$k_r = 4k_T/V_m \quad [68]$$

Table I. Comparison of rate constants k_p for the diffusion of oxygen into oxygen-deficient zirconia with $\delta_o = 0.006$ according to Douglass (14, 15) and rate constants k_T for the oxidation of zirconium metal according to Hussey and Smeltzer (9) for chemically polished samples with anneal

Temp, °C	k_p Eq. [1], cm²/sec	k_T Eq. [69], cm²/sec
400	0.7×10^{-13}	0.6×10^{-14}
450	4.4×10^{-13}	4.0×10^{-14}
500	18×10^{-13}	11×10^{-14}
550	70×10^{-13}	37×10^{-14}
600	230×10^{-13}	160×10^{-14}

and the rate constant k_T may be calculated from measurements of the weight gain per unit area ($\Delta m/A$) with the help of the formula (22)

$$k_T = \frac{1}{2} \frac{(\Delta m/A)^2}{t} \left(\frac{V_m}{2 \cdot 16} \right)^2 \qquad [69]$$

On combining Eq. [67] and [68], one obtains

$$k_T = \frac{3}{2} D_{\square} \delta_{eq} \qquad [70]$$

According to Eq. [65] and [70] the ratio of the rate constants k_p and k_T is found to be

$$\frac{k_p}{k_T} = \frac{\pi}{\delta_{eq}} \left[\frac{\delta^V}{\delta_o} \left(1 + \ln \frac{\delta^V}{\delta^{IV}} \right) \right]^2 \qquad [71]$$

These equations can be applied only to data which conform approximately to the parabolic rate law, *e.g.*, data reported by Hussey and Smeltzer (9). Numerical values for k_p and k_T are compiled in Table I. The ratio k_p/k_T is of the order of 10^2. Since in Eq. [71] only $\delta_o = 0.006$ is known but numerical values of δ^{IV}, δ^V, and δ_{eq} are lacking, it is not possible to check Eq. [71] and the underlying assumptions at the present. Data for the oxygen deficit δ_{eq} in zirconia coexisting with zirconium have been reported (23) only for temperatures above 800°C and cannot be extrapolated to lower temperatures with sufficient confidence. Future research is desirable especially in order to obtain reliable values for δ^{IV}, δ^V, and δ_{eq} and to check whether the rate constant k_p is inversely proportional to the initial oxygen deficit as predicted by Eq. [65].

Analogous calculations can be made for diffusion in zirconia doped with CaO or Y_2O_3 where the anion vacancy concentration at $p_{O_2} = 1$ atm is much greater than in ZrO_2 without dope. Thus in ZrO_2 doped with CaO or Y_2O_3, the characteristic values δ^{IV} and δ^V are greater than in ZrO_2 without dope, where in this context δ^V is the oxygen deficit at which the excess electron concentration is equivalent to the anion vacancy concentration at $p_{O_2} = 1$ atm, which is in essence given by the concentration of the dope. If the oxygen deficit characteristic of the boundary between the white and the black zone in a sample subject to diffusion, is greater than δ^V in doped ZrO_2, it follows from Eq. [65] that the parabolic rate constant k_p defined in Eq. [1] in doped ZrO_2 is greater than in ZrO_2 without dope. This is in accord with observations.

Manuscript received June 21, 1965; revised manuscript received March 16, 1966. This work was performed under the Joint USAC-EURATOM Research Development Program, Contract AT (04-3)-189, Project Agreement 24.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

ABSTRACT

The effects of inorganic anions, organic compounds, and combinations of the two on corrosion of mild steel in various acids were determined. From corrosion rates of steel in acids the order of the degree of adsorption of anions was concluded to be

$$I^- > Br^- > Cl^- > SO_4^= > ClO_4^-$$

The largest effects on corrosion mitigation were observed for I^- and I^- in combination with amines. The specificity of effects attributable to I^- suggests a strong interaction with the steel surface possibly through chemisorption. The enhancement of inhibitor efficiency by I^- is dependent on molecular structure of the inhibitor. The extent of synergism between I^- and organic amines was observed to be in the order: octamethyleneimine> di-n-butylamine>n-octylamine. Synergistic effects of anions and organic cations is greater than can be expected by a shift in the metal surface potential by anion adsorption and must be attributed in part to stabilization of the adsorbed anion layer by organic cations, possibly by covalent bonding.

Isolated examples of corrosion inhibition by simple anions have been noted for some time. In 1930, Walpert (1) showed that the addition of HCl slowed the corrosion rate of mild steel in H_2SO_4 by 78%. Putilova (2) gives numerous examples of corrosion inhibition by anions, *e.g.*, 90% inhibition efficiency of the corrosion of mild steel in *N* nitric acid by addition of KI, KBr, or KCl. The presence of certain anionic species often complements the efficiency of an organic inhibitor resulting in greater inhibition than achieved by either additive alone, *e.g.*, Malowan (3) patented the use of mixtures of iodide ion and organic amines for inhibition of the corrosion of steel in phosphoric acid.

Inhibition by anions and the synergistic effect of some anions and organic compounds (there is also an antagonistic effect) is a complex phenomena, and it is doubtful if one mechanism accounts for all the observations. Passivating potentials imposed by redox couples (4) accounts for the mechanism of ions in some systems. Mixed oxide formation (5) also is a plausible mechanism for other systems. A third mechanism is the strong adsorption of anions on metal surfaces; this is the one which best explains synergistic effects between anions and organic inhibitors and inhibition in the absence of alternate redox couples and/or bulk oxide formation.

The adsorption of anions on metal surfaces has been investigated by Conway (6), Hackerman (7), Schmid (8), Frumkin (9), and Kolotyrkin (10) by electrical double layer capacity measurements using a-c bridges and single-pulse techniques. For example, Murakawa and Hackerman (7) show the relative degree of adsorption of Cl^- and ClO_4^- ions by means of capacity-potential curves. The capacity-potential curve for zone-refined iron in $HClO_4$ alone shows a peak due to adsorption of ClO_4^-. As Cl^- is added to $HClO_4$, the ClO_4^- peak disappears, and a decrease in capacity occurs over the entire potential range investigated. These results indicate that Cl^- is more strongly adsorbed than is ClO_4^- on steel and can displace the latter. From similar work it is seen that the order of adsorption of anions on steel is shown as follows

$$\begin{matrix} & & F^- & & \\ I^- & > & Br^- & > & Cl^- > RCO_2^- > ClO_4^- \\ & & SO_4^= & & \end{matrix}$$

The relationship of the type of ion adsorbed to the zero point of charge and corrosion potentials of metal has been developed to a high degree by Antropov (11). From the above, one would expect the order of inhibition to be in the same order as the order of adsorption; however, no systematic survey of a wide range of anions in a single system is available. The purpose of this paper was to determine the inhibitor efficiencies of anions in various acids and the synergistic effects with organic cations in relation to the order of adsorption predicted by electrochemical methods.

Experimental

Mild steel coupons, ½ x 2 in., were cut from the same cold rolled sheet 0.065 in. thick. The coupons were abraided, polished, and degreased immediately before use. The steel analysis gave 0.09C, 0.40Mn, 0.02P, 0.037S, 0.03Si, and remainder Fe.

All solutions were made from reagent-grade chemicals used as-received, except for the HI which was distilled under inert atmosphere to remove preservative. Solutions containing I^- were stored for only short periods, under N_2, and in the dark.

Corrosion rates were calculated from slopes of curves giving total hydrogen evolved as a function of time. The data were programmed for a CDC 3200 computer which corrected hydrogen volume to standard temperature and pressure and calculated corrosion rates from root mean square fit of the data. Weight losses of the coupons were also measured, and these were used to check stoichiometry of the corrosion reaction and to validate the total volume of hydrogen observed. Duplicate runs were made of all experiments; reproducibility was within 4% for low rates of attack, but at high rates (<50% inhibition), results were only within 10%. Inhibitor efficiencies were calculated as follows

$$\% \text{ Inhibition} = \frac{R_o - R}{R_o} \times 100$$

where R_o is the corrosion rate in the absence of inhibitor and R is the corrosion rate in the presence of inhibitor.

Results

Uninhibited corrosion rates of mild steel were obtained in 3M solutions of HI, HBr, HCl, $HClO_4$, H_2SO_4,

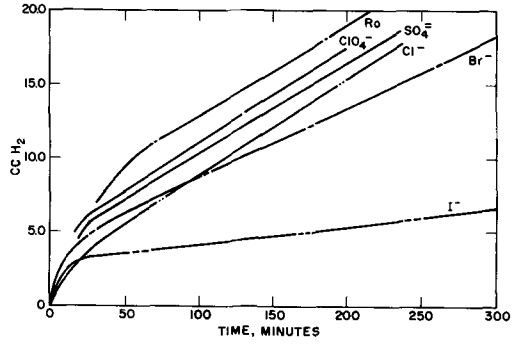

Fig. 1. Corrosion of mild steel in 3.0M H_3PO_4 containing 6.4 × 10^{-2}M of various anions; coupon area, 14.2 cm^2; temperature, 35°C.

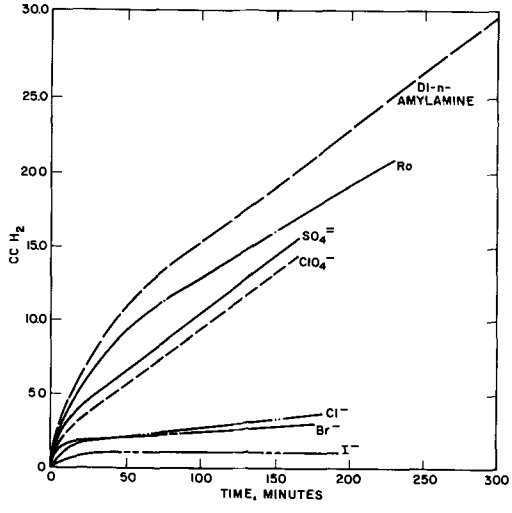

Fig. 2. Corrosion of mild steel in 3.0M H_3PO_4 containing 6.4 × 10^{-3}M di-n-amylamine and 6.4 × 10^{-2}M of various anions; coupon area, 14.2 cm^2; temperature, 35°C.

and H_3PO_4. These experiments were repeated using 3M acids containing 6.4 x 10^{-3}M diamylamine, n-decylamine, and propargyl alcohol. The effects of added anions were determined by adding sufficient quantities of acid to five of the above 3M acids, both with and without the organic inhibitor, to make solutions 6.4 x 10^{-2}M in the desired anion.

Hydrogen evolution as a function of time is given in Fig. 1 for the corrosion of mild steel in 3.0M H_3PO_4 and 3.0M H_3PO_4 + 6.4 x 10^{-2}M additions of various anions. Note that in the absence of organic additives, bromide ion has only a small effect on the corrosion reaction, and the slope for chloride ion is the same as for the pure acid. The addition of 6.4 x 10^{-3}M (1000 ppm) di-n-amylamine to 3.0M H_3PO_4 has no effect on the corrosion of mild steel as shown in Fig. 2. In this system, however, chloride and bromide ions show a strong synergism with di-n-amylamine in mitigating the corrosion of steel. The same strong inhibition effect of I^-, Br^-, and Cl^- is evident in solutions of n-decylamine and propargyl alcohol in 3.0M H_3PO_4 as shown in Fig. 3 and 4.

Data for the corrosion of mild steel in 3.0M solutions of pure acids containing 6.4 x 10^{-2}M additions of various inorganic anions are summarized in Table I. In general, the only effects on corrosion by added anions occur in halogen-containing acids or by addition of halogen ions to other acids which may or may not be halogen acids. More specifically, all the anions studied inhibited corrosion of steel in 3.0M HI, and the addition of HI inhibited corrosion in all the acids studied. The dissolution rate of mild steel in 3.0M HI without the additives is about the same as in HCl, *i.e.*, 3700 mdd. Bromide ion has the next most frequent effect, showing some inhibition effect in all the acids except HCl. It is significant to note

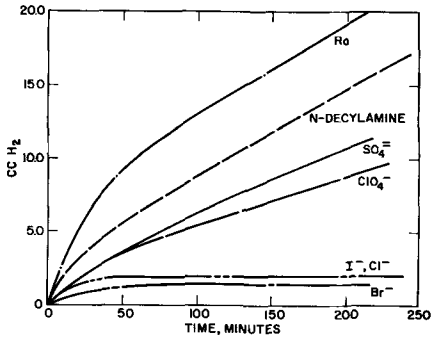

Fig. 3. Corrosion of mild steel in 3.0M H_3PO_4 containing 6.4 × 10^{-3}M n-decylamine and 6.4 × 10^{-2}M of various anions; coupon area, 14.2 cm^2; temperature, 35°C.

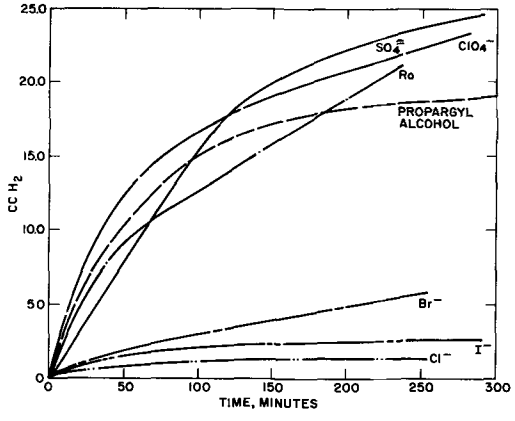

Fig. 4. Corrosion of mild steel in 3.0M H_3PO_4 containing 6.4 × 10^{-3}M propargyl alcohol and 6.4 × 10^{-2}M of various anions; coupon area, 14.2 cm^2; temperature, 35°C.

that the order of inhibition of the halogen anions concurs with the observed order of adsorption, *viz.*, $I^->Br^->Cl^-$, except in HI where the order is reversed. The absence of inhibition by Cl^- in 3.0M H_2SO_4 does not contradict the results of Walpert (1) since he used much higher concentrations of HCl in H_2SO_4. Also HI is the only acid in which inhibiting effects of Cl^-, ClO_4^-, $SO_4^=$, and $PO_4^=$ were noted at the concentrations employed.

Results obtained in solutions containing 6.4 x 10^{-3}M di-n-amylamine and inorganic anions are shown in Table II. Di-n-amylamine is a corrosion inhibitor

H_3PO_4	99	86	98	39	0	0

only in 3.0M HI at the concentration employed. No significant effect was noted in 3.0M HBr, HCl, or $HClO_4$, and an accelerating effect occurred in 3.0M H_2SO_4 and H_3PO_4. In these experiments all the added ions had an inhibiting effect in the presence of di-n-amylamine, and numerous examples of synergism were observed. Notable examples are inhibition by Br^- and Cl^- in H_3PO_4, $PO_4^{\equiv}$, and $SO_4^=$ in $HClO_4$, and Br^- and $SO_4^=$ in HI where little, if any, effects were obtained in the absence of di-n-amylamine.

Inhibition by n-decylamine was greater than 90% in all the acids investigated except $HClO_4$ (71%) and H_3PO_4 (0). In these two acids inhibition was increased to over 90% by added halogen ions and was increased to a lesser degree by addition of ClO_4^-, $SO_4^=$, and $PO_4^{\equiv}$. Instances of antagonism are also evident in Table III; inhibition of 96% by n-decylamine in H_2SO_4 was decreased to 72% and 58% by ClO_4^- and $PO_4^{\equiv}$ ions, respectively.

Propargyl alcohol inhibited all acids greater than 90%, except for H_3PO_4 in which it had no effect as shown in Table IV. The high inhibition achieved by propargyl alcohol alone makes the effects of added anions less evident. The only anion effects are the increased inhibition by Cl^- and Br^- in H_3PO_4 solutions containing propargyl alcohol and the antagonism of ClO_4^- ion in H_2SO_4 which was also evident in the presence of n-decylamine as shown previously in Table III.

Structural Effects of Amines

Comparisons were made of the effects of various concentrations of I^- (as HI) on enhancing corrosion inhibition of mild steel in 3.0M HCl by octamethyleneimine, di-n-butylamine, and n-octylamine. The octamethyleneimine was synthesized here. The starting material, cyclooctanone, was converted to the lactam by the Schmidt reaction (12). The lactam was reduced to the cyclic imine by reduction with lithium aluminum hydride. The resulting impure imine was purified by gas chromatographic trapping. Its structure and purity were verified by nuclear magnetic resonance spectra. Di-n-butylamine was purchased and purified by recrystallization as the hydrochloride; n-octylamine was also purchased, but required no purification as shown by gas chromatographic analysis.

The greatest synergistic effect between I^- and the organics was observed for octamethyleneimine as shown in Fig. 5. This chart shows the observed inhibitor efficiencies (in parentheses) of various concentrations of I^- and octamethyleneimine alone and in mixtures of concentrations up to 1000 ppm. The results are also given as isocorrosion curves which were plotted by interpolation of the experimental data. The molecular weight of octamethyleneimine and the atomic weight of iodine are approximately equal, therefore equal ppm's of the two also correspond to equal molar concentrations. This is approximately true for the other two amines. The enhancing effect of I^- is shown by noting that the inhibitor efficiency of 1000 ppm I^- alone is 86%, 1000 ppm octamethyleneimine alone is 89%, and a mixture of only 10 ppm of each is 85%.

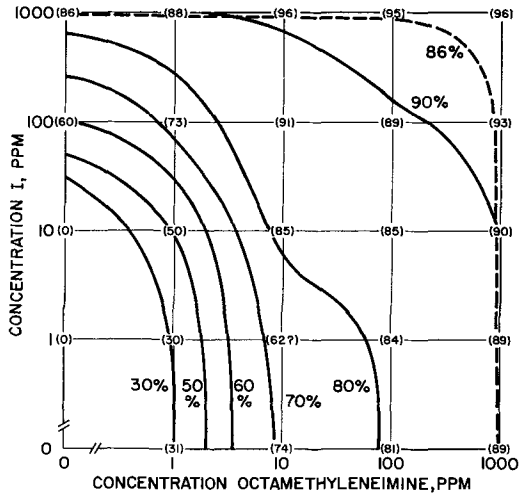

Fig. 5. Isocorrosion curves of mild steel in 3N HCl at 35°C; iodide and octamethyleneimine inhibitors. (Figures in parentheses are observed per cent inhibition.)

The synergism of octamethyleneimine and iodide ion is shown more clearly by the isocorrosion curves in Fig. 5. The dashed curve represents the shape of curve one would expect in the absence of synergistic effects between the iodide and octamethyleneimine. For example, the intersection of the dashed curve and the 100 ppm octamethyleneimine line represents the concentration of iodide required to give 86% inhibitor efficiency if the mixture behaved as either iodide or octamethyleneimine alone. The observed 90% curve occurs at concentrations far less than one would expect if iodide and octamethyleneimine behaved independently.

The cooperative effects of iodide and di-n-butylamine occur mostly at lower concentrations, at 100 ppm and below, and are negligible or entirely absent at higher concentrations as shown by the observed

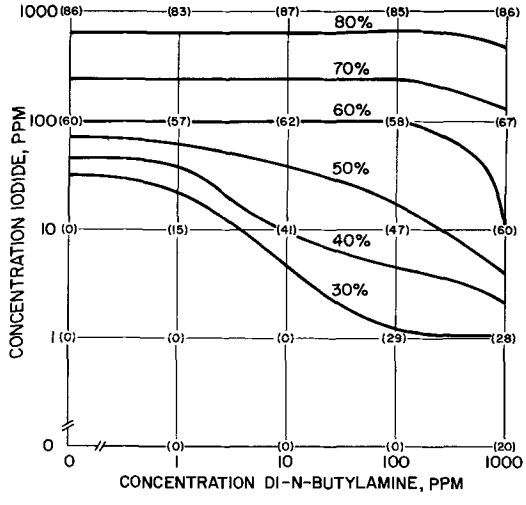

Fig. 6. Isocorrosion curves of mild steel in 3N HCl at 35°C; iodide and di-n-butylamine inhibitors. (Figures in parentheses are observed per cent inhibition.)

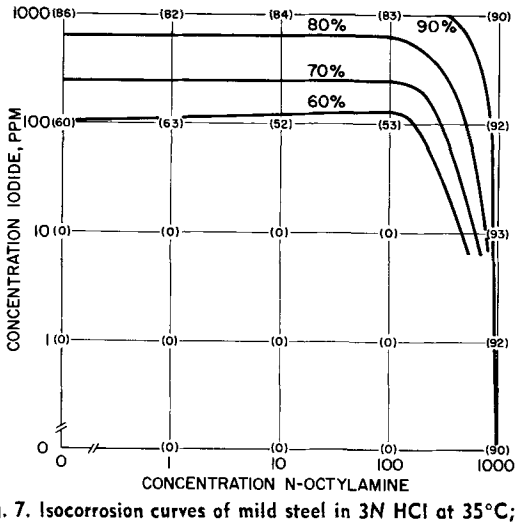

Fig. 7. Isocorrosion curves of mild steel in 3N HCl at 35°C; iodide and n-octylamine inhibitors. (Figures in parentheses are observed per cent inhibition.)

inhibitor efficiencies in Fig. 6. Corrosion inhibition by 1000 ppm iodide is not improved by the addition of 1000 ppm di-n-butylamine; however, 41% inhibitor efficiency is obtained by a mixture of 10 ppm of each additive although no inhibition occurs on the addition of 20 ppm of either species alone. The absence of synergistic effects at higher concentrations is also reflected in the isocorrosion curves of Fig. 6. The slopes of the isocorrosion curves become negative at increasingly lower amine concentrations as the concentration of iodide is decreased.

Little or no synergism is observed in the n-octylamine-iodide system. Both additives are essentially inert in combination or alone for concentrations of up to 100 ppm n-octylamine and 10 ppm I^- as shown in Fig. 7. The isocorrosion curves for this system (Fig. 7) have essentially the shape one would expect for a nonsynergistic system as shown previously in Fig. 5.

Discussion

In the absence of organic additives anionic effects were noted only in halogen acids or by the addition of halogen ions to other acids. The anionic effects in all acids except HI are in the order $I^->Br^->Cl^-$ as predicted from electrochemical methods. The effects of ClO_4^-, $SO_4^=$, and $PO_4^{\equiv}$ were small and within experimental error so that no conclusion can be drawn concerning their order of adsorption under the conditions employed. The only instances of inhibition by the latter ions are noted in HI, where one would not expect any effects by other ions in the presence of 3.0M strongly adsorbed I^-.

In the absence of a preservative, solutions of HI are unstable so traces of free iodine are inevitable. It is likely that results in 3.0M HI are influenced by the presence of the $I_3^- \rightleftarrows 3I^-$ couple. In this case a shift of the corrosion potential to more positive values with respect to the zero point of charge must be assumed to account for inhibition by foreign anions. This can be accomplished by depolarization of the cathode reaction or increased polarization of the anode reaction. These effects appear reasonable for all the added anions including Cl^- which is usually considered an anodic depolarizer, but has been shown by Lorenz (13) to polarize the anodic reaction of steel in H_2SO_4 solutions. The specificity of halogen ions in general, and especially iodide, suggests chemisorption as the means of inhibition of steel.

The effects of all the anions studied are amplified by the addition of organic amines. Synergism of amine and foreign anions is noted most in acids containing di-n-amylamine which does not have much effect alone. Iofa (14) shows that iodide and sulfide

Ppm octamethyleneimine

ions increase the polarization of both the anodic and cathodic reactions on corroding steel in the presence of tribenzylammonium ion. This effect is attributed to an increased negative charge on the metal surface caused by adsorption of anions which then promote the adsorption of organic cations. If anions are adsorbed sufficiently to promote the adsorption of cations, one would expect the anions themselves to exhibit a partial inhibiting effect. This is not the case, however, as shown by the increase in inhibition from 0 to 70% for Cl^- in H_2SO_4 and H_3PO_4 in the presence of di-n-amylamine. The adsorption of the organic cation appears to stabilize the anion layer on the metal, possibly by displacement of the equilibrium between solution and adsorbed ions toward surface positions on the metal.

Simple measurements of the corrosion potential of steel in 3.0M HCl were made to aid in interpreting the mechanism of synergism by iodide with amines. Potentials were measured with respect to a saturated calomel electrode in nitrogen-stirred solutions.

Results of the measurements for additions of iodide and octamethyleneimine and combinations of the two are given in Table V. The corrosion potential of mild steel in 3.0M HCl shifts in a positive direction with additions of octamethyleneimine; however, the magnitude of the changes are small being only 13 mv for addition of 100 ppm of imine. These observations are in accord with those observed previously (15) for steel in HCl containing nonamethyleneimine. In this work it was observed that both the anodic and cathodic reactions are polarized by the addition of nonamethyleneimine. Additions of iodide have little, if any, effect on the corrosion potential as shown in Table V. This result is attributed also to polarization of both the anodic and cathodic reactions as observed by Iofa (14) for corrosion inhibition by KI in H_2SO_4.

The shift in corrosion potential to a more positive value affords a greater tendency for the metal to absorb anions. However, the additional observations in Table V that mixtures of iodide and octamethyleneimine, *e.g.*, 10 ppm of each, do not shift the corrosion potential yet inhibit corrosion to a greater extent than either additive alone indicate that covalent bonding of the halide also plays a part in the mechanism of synergistic inhibition.

Solution chemistry of the organic additive is, of course, a factor as shown by a comparison of results for di-n-amylamine, n-decylamine, and propargyl alcohol. Acetylenic compounds like propargyl alcohol form cationic complexes. Thus, in this respect, they are similar to nitrogen compounds (16). Mechanisms to account for the antagonism of ClO_4^- in the latter systems are not known. It is not feasible to assume that ClO_4^- would be adsorbed sufficiently to displace adsorbed amine or alcohol because ClO_4^- has no effect on the corrosion of steel in the absence of the organics. A complete explanation of the results must take into account the chemistry of the systems involved. For example, propargyl alcohol may undergo reduction or addition of halogen acids across the triple bond.

Molecular structure of the organic compounds is important in synergistic inhibition as shown by the results for octamethyleneimine, di-n-butylamine, and n-octylamine in HCl containing additions of iodide ion. It has been shown that, in the absence of foreign

anions, those organic cations that have the greatest tendency toward covalent bonding give the best corrosion inhibition. Covalent bonding of organic nitrogen compounds to iron has been discussed previously (15). Specifically, it was shown that, of the amines investigated, nonamethyleneimine had both the highest p character of the electron pair on N and the highest inhibition (15). Iofa (14) has shown that I^- alone polarizes both the anodic and cathodic reaction of iron over a wide potential range. It is apparent then that the effects of I^- are not due to electrostatic effects alone, but some covalent bonding to the metal must be involved. The large size and ease of polarizability of I^- facilitate electron pair bonding. The greatest synergistic inhibition is to be expected for an anion-cation pair, in which both ions have an appreciable tendency toward covalent bonding. For example, in the case of octamethyleneimine and I^- in HCl, the chemisorbed iodine serves as a link, or bridge, between the metal surface and the imine, as would an anion associated with the surface by purely electrostatic forces. However, the former is more effective, for reasons not yet fully apparent.

Conclusions

Of the ions studied, I^-, Br^-, Cl^-, ClO_4^-, $SO_4^=$, and $PO_4^{\equiv}$, the order of adsorption based on corrosion inhibition efficiency is $I^->Br^->Cl^-$, while insufficient effects were noted for the others on which to base an order of adsorption. The specificity of effects attributable to I^- suggests a strong interaction with the steel surface possibly through chemisorption.

Synergism of inhibitor efficiency between anions and organic cations is greater than can be expected by a shift in the metal surface potential by anion adsorption and must be attributed in part to stabilization of the adsorbed anion layer by organic cations.

Molecular structure of the organic compound may play a dominant role in the degree of enhancement of inhibition by a foreign anion, with the greatest enhancement occurring when both the anion and cation show a tendency toward electron pair bonding.

Some Aspects of the Mechanism of Hydrogen Evolution at a Mild Steel Electrode

J. S. Ll. Leach and S. R. J. Saunders

Department of Metallurgy, Imperial College of Science & Technology, London, England

ABSTRACT

The hydrogen evolution reaction on mild steel has been studied in both acid and alkaline solutions. The associated overvoltage at constant current increased under some conditions during the hydrogen permeation process through a foil electrode. This increase has been interpreted as resulting from an increase in the hydrogen content of the metal. The results suggest that the hydrogen evolution reaction in acid solution takes place on the surface of the electrode, whereas in alkaline solutions the evolution process involves dissolution of hydrogen in the metal.

The hydrogen evolution overvoltage at an iron electrode being cathodically charged under galvanostatic conditions has been observed to increase with time. The following interpretations have been proposed to account for this effect: (*a*) The adsorption of impurities in the system which may poison the electrode for the recombination of hydrogen atoms (1); (*b*) the adsorption of hydrogen atoms on the electrode surface (2); (*c*), the formation of iron hydride (3); (*d*) an increase in the hydrogen content of the metal (4). This last explanation is perhaps the most generally favored.

The nature of the electrode interface is important in determining both the hydrogen adsorption and desorption rates on a metal. The rate of adsorption of electrolytic hydrogen at an iron electrode is dependent on the pH and the imposed current density. Berg (5) has shown that the rate of hydrogen desorption in the presence of water is greater than the corresponding rate in air.

In view of the importance of hydrogen in corrosion processes (6-8), it was decided to re-examine, as a function of the environment, the hydrogen overvoltage at a mild steel electrode during the permeation process.

The observations reported here appear to lend support to the idea that the overvoltage increase arises from a change in hydrogen content of the electrode

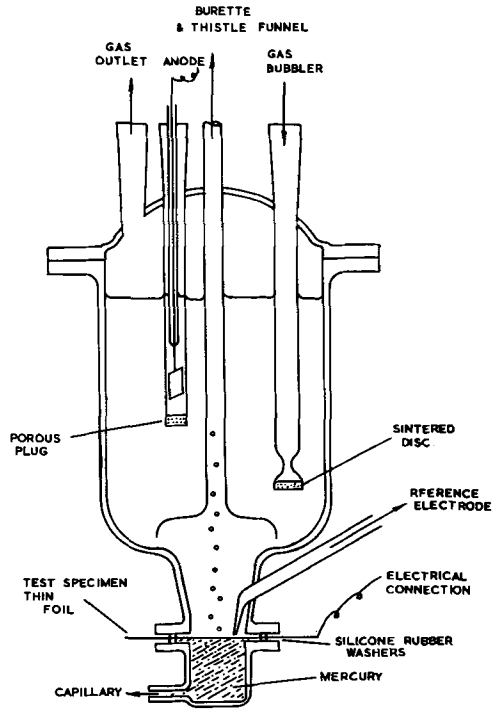

Fig. 1. Hydrogen pick-up test cell

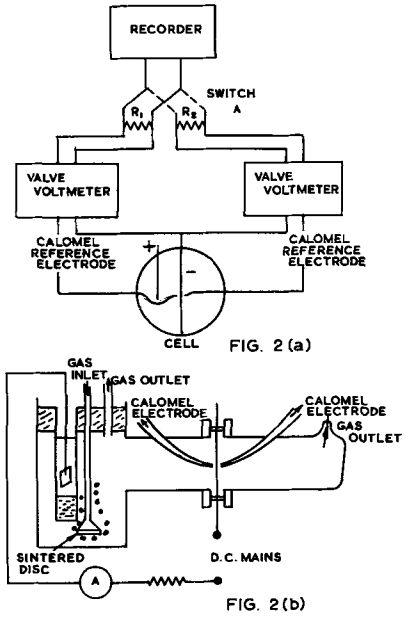

Fig. 2. Apparatus for measurement of transferred overvoltage. Fig. 2a. Electrical circuit; Fig. 2b. cell (diagrammatically).

and that under certain circumstances dissolution in the electrode may be a necessary step in the hydrogen evolution process.

Experimental Procedure

Simultaneous measurement was made of the hydrogen overvoltage, the hydrogen permeation rate through the foil, and the hydrogen evolution rate. The presence of an oxide on the surface of the electrode would be expected to produce complications; in the present work the *p*H of the solutions and the potential of the electrodes were such that oxides of iron were thermodynamically unstable and that no corrosion of the electrode occurred.

The cells employed for this work are shown diagrammatically in Fig. 1 and 2. Figure 1 illustrates the cell used to measure the hydrogen permeation rate. The position of the gas bubbler was chosen to minimize the diffusion of oxygen from the anode compartment to the cathode compartment. The permeation rate was measured by observing the movement of a mercury column in a capillary of known bore. The mercury was displaced from behind the electrode at the nonpolarized interface by the hydrogen permeating through the electrode. The capillary was placed at the same level as the electrode so that the permeating gas had only to overcome atmospheric pressure before moving the mercury. It was difficult to be certain exactly how much hydrogen must leave the electrode before the mercury begins to move; provided that the system is clean it is thought to be only a very small amount. However, the discussion is primarily concerned with steady-state conditions, and therefore this uncertainty becomes relatively unimportant. By changing the size of capillary, permeation rates from 0.0001 to 0.01 cc/cm^2/min could be measured. The hydrogen evolution rate was measured by placing a thistle funnel above the cathode and collecting the gas in a graduated buret by displacement of the solution inside. The volume was corrected to S.T.P. The potential of the electrode was measured with respect to a calomel half cell. A Luggin capillary was placed approximately ⅛ in. from the specimens, connection being made to the half cell by means of a polythene tube containing the solution. All potentials quoted in this paper are expressed on the standard hydrogen scale and are designated E_H.

Figure 2 illustrates the cell used to investigate the permeation-potential characteristics of the electrode when the nonpolarized interface was solid/aqueous. The permeation rate was not measured in this case, but an estimate of the time taken for hydrogen to reach the nonpolarized interface could be obtained from an observation of the potential at this interface. A change in potential toward more negative values at this interface can be associated with the arrival of hydrogen.

The solutions used were made from Analar reagents and distilled water. The distilled water was "equilibrium water" with a conductivity of 10^{-6} mho/cm. The *p*H of the water was 6.5 which was due to the presence of a low concentration of sulfurous impurities. The solutions used, which were degassed both before and during the experiments with oxygen-free nitrogen to reduce the oxygen concentration, had the following compositions: (*i*) carbonate/bicarbonate buffer (0.2*N* $NaHCO_3$ + 0.2*N* Na_2CO_3) *p*H 9.7; (*ii*) sodium sulfate of variable *p*H. (The *p*H was adjusted with sodium hydroxide or sulfuric acid.)

The presence of sulfurous impurities in the system was desirable since these increased the hydrogen permeation rate which otherwise would have been very slow under the experimental conditions. To confirm that these impurities only increased the permeation rate and did not change the mechanism of the process, some experiments were repeated with solutions prepared from the distilled water purified by a further distillation in the presence of alkaline permanganate. In order to prevent possible contamination of the solutions by impurities from the electrode, high-purity iron (analysis below) was used in these tests.

The electrode materials used in this investigation were cold rolled and wet ground with successively finer carborundum papers up to 600 grade and then carefully washed in distilled water. This treatment was chosen because it has been shown (9) that both cold rolling and a rough surface increase the permeation rate. The foil thickness was 0.0127 cm unless otherwise stated. The analysis of the electrode materials is as follows:

Mild steel: (w/o, weight per cent) carbon 0.15-0.25 w/o; manganese 0.4-0.9 w/o; sulfur 0.06 w/o; phosphorus 0.06 w/o; silicon 0.05 w/o; remainder iron.

Pure iron: carbon 0.00034 w/o; manganese 0.005 w/o; sulfur 0.004 w/o; phosphorus 0.01 w/o; silicon

0.006 w/o; oxygen 0.0006 w/o; nitrogen 0.0001 w/o; remainder iron.

The glass cells were cleaned with chromic acid, concentrated nitric acid, distilled water, and finally absolute alcohol. The silicone rubber washers were degreased with acetone and absolute alcohol.

Various constant current values were obtained by placing suitably large resistors in series with the d-c mains. The current was monitored and found to be constant within ± 1%.

The valve voltmeter (E.I.L. Model 23A) used for the potential measurements was of the differential amplifier design with high input impedance and high stability over long time periods. The electrode potential and polarizing current were automatically recorded.

The system was tested by measuring the current efficiency for the hydrogen evolution reaction. The number of coulombs passed agreed to within 1% with the number required to liberate the amount of hydrogen evolved plus that which permeated through the foil.

Results

The effect of current density and pH on the hydrogen permeation rate is shown in Fig. 3 and 4. Figure 3 shows that in acid solution the permeation rate is independent of the imposed current density, while in alkaline solution at high current density change in the imposed current changes the permeation rate. The low current density range shows a threshold effect which has been interpreted (10) in terms of the need for a minimum current density before permeation begins.

Further experiments were conducted in solutions of selected pH so that the transition between these two types of behavior could be observed (Fig. 4). At low

current densities the permeation rate is independent of the imposed current, but at higher currents, the permeation rate becomes dependent on the current density. In these experiments foil thickness of 0.0076 and 0.01 cm were used.

A change in the hydrogen evolution kinetics in acid solutions takes place on increasing the current den-

sity, which is illustrated by the Tafel curves obtained by Stern (11) for mild steel (Fig. 5). In Fig. 6 results obtained in the present work show the same effect. These results are plotted in a different way to show that a change of one pH unit results in a tenfold change in the current density at which a transition in the hydrogen evolution mechanism takes place.

Overvoltage changes observed at the polarized interface during the permeation of hydrogen through the mild steel foils under various conditions are shown in Fig. 7, 8, and 9. For the case of a mild steel electrode in alkaline solution with mercury initially making contact with the nonpolarized interface the results are shown in Fig. 7. The overvoltage increases during the first 10 min of the experiment; having changed by 0.1v, it then remains constant for approximately an hour. After this the overvoltage again increases and becomes constant when the permeation rate has attained a steady value. This second increase in the overvoltage appears to coincide with the evolution of hydrogen from the back of the foil. However, in acid solutions under otherwise similar conditions, the overvoltage increases gradually from the start of the experiment (Fig. 8), the total increase being smaller than the corresponding case in alkaline solution. The evolution of the hydrogen from the back of the foil starts about 40 min from the beginning of the experiment.

Using doubly distilled water for solutions and the pure iron electrode the same general trends are observed as in the impure system, but on a reduced scale and at longer times. These results suggest that

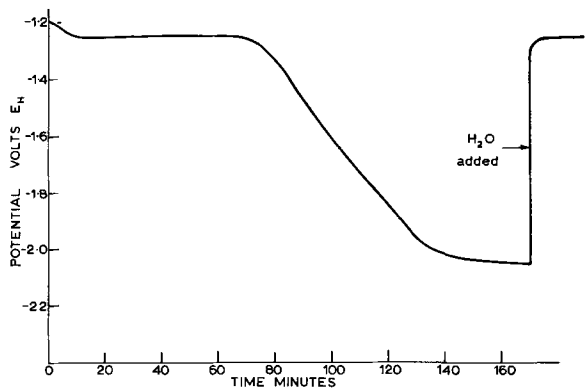

Fig. 10. Overvoltage changes at a mild steel electrode in pH 9.7 solution during permeation into an environment initially inert subsequently changed to aqueous.

the additional impurities do not change the mechanism but only the rate of the permeation process.

Results of overvoltage measurements made during the permeation of hydrogen into an aqueous environment (solution pH 9.7) appear in Fig. 9. Changes in potential at the nonpolarized interface are interpreted as corresponding to changes in the hydrogen permeation rate. The exact origin of these potential changes is considered in more detail in the discussion. With an alkaline solution at the polarized interface the overvoltage there increased by 0.1v in the first 10 min of the experiment (compare with Fig. 7); thereafter it remains constant. The overvoltage at the nonpolarized interface also increases but only after the overvoltage at the polarized interface has reached a constant value. With an acid solution at the polarized interface, the overvoltage there remains constant throughout the experiment while that at the nonpolarized interface increases soon after the experiment has commenced.

It will be noticed from Fig. 7, 8, and 9 that the environment of the nonpolarized interface influences both the time for breakthrough of hydrogen and the overvoltage at the polarized interface. This suggested an experiment in which an aqueous environment could be substituted for an inert environment at the nonpolarized interface. Results are shown in Fig. 10 where it will be seen that changing the environment after the second overvoltage change has occurred at the polarized interface causes the potential to rise rapidly to the value obtained after the first overvoltage increase.

This large increase in overvoltage in alkaline solutions was investigated further by measuring the Tafel slopes for mild steel during the permeation process with an inert environment behind the electrode. The results illustrated in Fig. 11 were obtained at various stages in the experiment as the overvoltage increases, and indicate that the slope remains approximately at 0.2 in all the overvoltage ranges.

Discussion

The mechanism of the hydrogen evolution reaction is believed (12) to be governed by the pH of the solution and the imposed current density. At low current densities in acid solution the reaction takes place by the reduction of hydronium ions. Increasing the pH causes the concentration of hydronium ions to decrease. For any given pH there is a maximum current which can be carried by the reduction of hydronium ions; imposing greater currents than this limiting value results in an increase in the overvoltage sufficient to allow the reduction of water by the following reaction

$$H_2O + e \rightarrow OH^- + M{-}H \qquad [1]$$

where M—H represents a hydrogen atom adsorbed on the metal surface. The adsorbed hydrogen atoms

may then recombine to form a molecule. Hydroxyl ions are produced at the electrode as a by-product of this reaction causing a local increase in the pH of the solution. It has been suggested (2, 12) that under these conditions the local pH near the electrode is constant regardless of the pH in the bulk solution. This may provide an explanation of the effect seen in Fig. 5 where the overvoltage-current relation is the same for solutions of different pH once the transition in the evolution kinetics has occurred. In the remainder of the discussion the differences observed between the evolution behavior in acid and in alkaline solution are interpreted as being associated with the change in the discharging species.

From Fig. 3 and 4 it may be seen that the permeation rate is independent of the imposed current density in acid solutions. In alkaline solutions, however, the permeation rate varies with the current density, and this has been plotted as a square root dependence after the work of Barrer (10). No significance is attached to the square root relation as an equally good line may be obtained for the present results by plotting a linear dependence on the current density. The exact form of the relationship is not considered in the subsequent discussion; only the fact that there is a change from current independent permeation rates

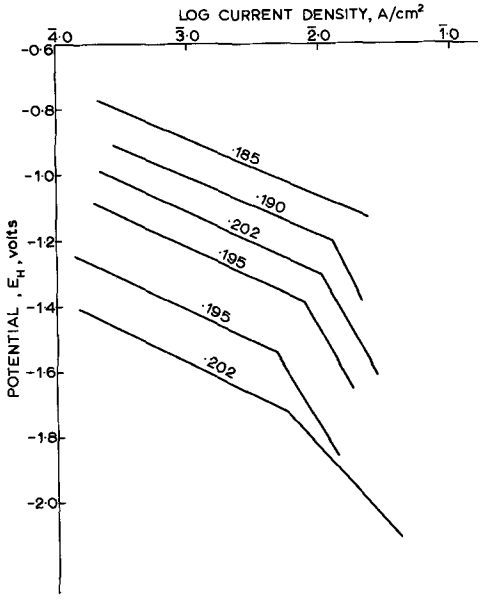

Fig. 11. Current-voltage relationship on mild steel in pH 9.7 solution at different overvoltages during hydrogen permeation into an inert environment.

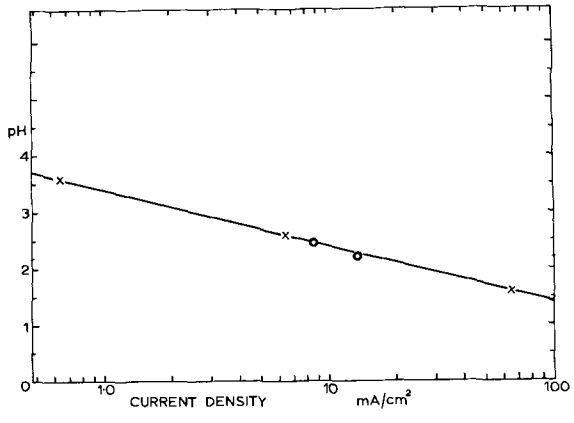

Fig. 12. Critical current density vs. pH for changes in the hydrogen evolution kinetics at a mild steel electrode: O changes in permeation kinetics derived from Fig. 4; x changes in evolution kinetics derived from Fig. 6.

in acid solutions to rates dependent on current density in alkaline solutions.

The values of pH and current density at which the hydrogen permeation kinetics change may be derived from Fig. 4. The relation between the current density and the solution pH at which the hydrogen evolution kinetics change may be deduced from Fig. 6. All these values are shown in Fig. 12, and it will be seen that the transitions in both processes show the same current density/pH relationship.

Before examining the way in which the hydrogen permeation and hydrogen evolution processes may be related it is relevant to consider the experimental observations shown in Fig. 7-10. These are concerned with the effects on the overvoltage for hydrogen evolution of the nature of the unpolarized interface of the electrode.

The overvoltage changes shown in Fig. 7 and 8, with the exception of the first change in the alkaline solutions (Fig. 7), do not arise from the presence of impurities. This is deduced from results shown in Fig. 9 where no such changes occur when an aqueous environment is at the back of the foil. This deduction is also supported by results shown in Fig. 10. Here the experimental conditions were similar to those pertaining to the results shown in Fig. 7, but after a steady state had been achieved at about —2.0v E_H an aqueous environment was substituted for the inert environment at the back of the foil electrode. The potential rose rapidly without further change in the conditions. These changes in overvoltage might arise from changes in the hydrogen evolution mechanism, but in general this should result in changes in the Tafel slope such as those seen in Fig. 5. Measurements made during the observed overvoltage increase in alkaline solution show the Tafel slope to be essentially constant (Fig. 11) suggesting that no change in the mechanism occurs.

If it can be shown that the large overvoltage increase is associated with increased hydrogen content of the electrode, then a satisfactory explanation for both the overvoltage behavior and the permeation kinetics may be proposed.

An aqueous environment has been shown (5) to assist the removal of hydrogen from the metal to a greater extent than an inert environment such as nitrogen or hydrogen. For a given rate of hydrogen removal from the metal at the nonpolarized interface, the concentration of hydrogen in the metal would be higher when the surface of the metal forms an interface with an inert environment rather than an aqueous environment. This increased concentration at the nonpolarized interface results in an increased concentration in the metal at the polarized interface.

Consider the effect on the hydrogen evolution reaction of the permeation process into an inert environment. Under these conditions it has been shown that an increased hydrogen concentration in the metal may be expected when compared with the permeation process into an aqueous environment. Figures 7 and 8 illustrate the overvoltage changes that occur at the polarized interface during the hydrogen evolution process when hydrogen is being generated from acid and from alkaline solutions, respectively. It can be seen that the overvoltage change at the polarized interface is considerably greater for alkaline solutions than for acid solutions.

Any mechanism proposed for the hydrogen evolution reaction should take into account the following observations: (*A*) In acid solution (i) the permeation rate is independent of the imposed current density, and (ii) the hydrogen evolution process is not markedly dependent on the hydrogen content of the electrode, as reflected by a small change in the overvoltage during the permeation process into an inert environment. (*B*) In alkaline solution (i) the permeation rate is dependent on the current density, and (ii) the evolution process is dependent on the hydrogen con-

tent of the metal, as reflected by a substantial change in the overvoltage during the permeation process into an inert environment.

The suggested differences between the mechanisms for hydrogen evolution in acid and in alkaline solutions which are described below afford an explanation of the experimental observations.

In acid solutions it is proposed that the evolution process takes place entirely on the surface of the electrode. Electrons would be removed from the metal by the field arising from the positively charged ionic species H_3O^+ adjacent to the metal surface so discharging the hydronium ion to form a water molecule and a hydrogen atom which may then combine with another. Any hydrogen entering the metal does so under existing potential and concentration gradients and not as a necessary step in the evolution reaction.

In alkaline solutions, on the other hand, it is proposed that the evolution reaction takes place *via* hydrogen dissolution in the metal. Due to the high concentration of hydroxyl ions at the electrode surface created as a by-product in the reduction of water, some hydroxyl ions should be adsorbed on the electrode. The hydroxyl ion is polar and would align itself with the hydrogen closer to the electrode. Since the net charge on the electrode is negative the removal of an electron from the metal would not be favored. It is suggested, therefore, that the following reaction may take place

$$[OH]_{ads} + H_2O \rightarrow 2\,OH^- + [H^+]_{in\ Fe} \qquad [2]$$

The undoubtedly large energy required to remove H^+ from OH^- might be supplied in part by the heat of solution of the proton in iron. This is of the order of −40 kcal/g atom for atomic hydrogen (13). The proton in metallic solution loses its charge and may either diffuse into the metal under a concentration gradient or recross the phase boundary, combine with another atom, and finally be evolved as molecular hydrogen. It is difficult to see how a reaction which takes place entirely on the surface of the electrode, as in the acid case, could explain both the dependence of the permeation rate on the current density and the dependence of the evolution reaction on the hydrogen content of the electrode.

There are some aspects of these results which, although not directly related to the hydrogen evolution process, require an explanation: (*a*) the nature of the first increase in overvoltage at the polarized interface during permeation from an alkaline solution into an inert environment (Fig. 7); (*b*) the time taken for hydrogen permeation into the different environments.

The first increase in the overvoltage at the polarized interface is believed to be associated with the cathodic reduction of an oxygen-containing species adsorbed on the electrode in alkaline solutions. Preliminary impedance measurements support this interpretation.

The time taken initially for hydrogen permeation through the foil apparently varies for different environments. However the time taken for hydrogen to diffuse through the metal is relatively short as shown by measurements in which a steady-state permeation process into an aqueous environment is distributed by changing the current density at the polarized interface. The resulting change in the potential at the nonpolarized interface occurs within one minute (see Table I). Further evidence for rapid diffusion appears in Fig. 10 where the recovery of overvoltage also occurs in about 1 min.

At the start of an experiment the drop in potential at the nonpolarized interface, in the presence of an aqueous solution which indicates the arrival of hydrogen at this interface, can occur in about 10 min or less. Evidence of the permeation of hydrogen into a gaseous environment as shown by the movement of the mercury takes under otherwise similar conditions approximately 1 hr. These differences in the time taken for hydrogen to be observed at the nonpolarized interface may be related to the presence of an oxygen containing layer. In the case of an inert environment, the reduction of this layer may be favored compared with diffusion out of the interface. For an aqueous environment, however, the potential which is reached at the nonpolarized interface is such that the reduction process would not occur and therefore the hydrogen leaves the surface immediately.

Table I. Time required for hydrogen to diffuse through the metal foil

Current density changes, ma/cm²	pH polarized interface	Time for change in potential for foil 0.0127 cm thick, sec
10 → 30	1.0	62
30 → 90	1.0	57
10 → 30	9.7	65
30 → 90	9.7	53

Summary

Of the mechanisms put forward to explain the increase in hydrogen overvoltage, the adsorption of impurities (1) or of hydrogen atoms (2) is not in itself sufficient to account for all the effects observed in the present experiments. The most probable cause appears to be the increase in the hydrogen content of the metal. Other measurements to be reported in a later paper indicate that a reversible reaction which might involve the formation of a hydride may be occurring at the most negative potentials. It is believed, however, that this is the result of the high concentration of hydrogen in the metal and is not in itself the cause of the increase in overvoltage. The observations support the mechanism for the hydrogen evolution reaction proposed by McGraw and co-workers (14).

The hydrogen permeation process has been shown to be related to the hydrogen evolution mechanism. In alkaline solutions the permeation rate depends on the evolution rate whereas in acid solution no such dependence is observed. This is interpreted in terms of a change in the evolution mechanism; it is suggested that in alkaline solutions this takes place *via* hydrogen dissolution in the metal whereas in acid solution the reaction occurs in the metal surface.

A possible consequence of the concepts developed in the present work lies in the field of hydrogen pick-up. The absorption of hydrogen by a specimen depends on the mechanisms of proton discharge. In particular, the ease with which the electrons can be transferred across the phase boundary to permit discharge of protons without their entry into the surface layers of the material implies a dependence on such parameters as the work function of the interface as well as the availability of electrons in the electrode surface layers.

Acknowledgments

The authors wish to acknowledge the support of the United Kingdom Atomic Energy Authority for financing the project and providing the stipend of one of them (S.R.J.S.). The National Physical Laboratory kindly supplied the pure iron and their cooperation is greatly appreciated. Finally the authors are indebted to Professor J. G. Ball in whose department the work was carried out.

Manuscript received Jan. 18, 1965; revised manuscript received March 22, 1966.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1967 JOURNAL.

Effect of NH_3 on Deposition from Alkaline Electroless Nickel and Cobalt Plating Baths

G. S. Alberts, R. H. Wright, and C. C. Parker

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

The ammonia generally used as a buffer in alkaline electroless nickel and cobalt plating baths has been shown to have a significant effect on both the rate of deposition of thin metal films and the magnetic and physical properties of such films. These effects have been studied on both metallic and nonmetallic substrates, using both ammonia and nonammine buffer systems, and attempts have been made to correlate them with spectral and polarographic observations.

Generally, ammonia is used as the buffer (1, 2) in alkaline electroless nickel and cobalt plating. However, from a control and reproducibility standpoint, the use of ammonia has several disadvantages. Among these are its volatility and, especially in the cobalt system, the formation of very stable cobalt(III) compounds, at least at room temperature. Furthermore, the effect of ammonia on the plating rate of alkaline cobalt and nickel electroless baths has not been defined clearly in the literature, and some disagreement exists. For instance, Brenner (3) states that "Ammonium salts increase the rate of deposition of nickel from the alkaline baths," but that "In the cobalt solution ammonium salts decrease the rate of deposition to a considerable extent . . ." (4). However, various Russian authors (5, 6) state that in alkaline cobalt solutions the rate increases slightly between 0 and 75 g/l NH_4Cl and then decreases rapidly, while in alkaline nickel solutions the rate increases between 0 and 50 g/l NH_4Cl and is level thereafter.

For the purpose of control and reproducibility the use of a different buffer system, sodium tetraborate, was investigated. In so doing, it was observed that there were some startling changes in the rate and deposit characteristics which appeared inconsistent with previous observations. This resulted in a more careful study of the effect of ammonia on the plating rate of baths of certain compositions and in the collection of spectral and polarographic data to try to explain these results.

The experiment.—Plating samples for all of the work to be reported were prepared on polyethylene terephthalate or copper substrates. The polyethylene terephthalate was prepared for plating by treatment in the normal caustic etch, tin presensitization, palladium sensitization sequence described by numerous authors (7, 8) to produce the initial catalytic surface. The copper substrate was simply cleaned in potassium dichromate-sulfuric acid solution and then treated in the palladium solution. All of the data to be presented on rate, magnetics, etc., are the average or range obtained from at least six samples plated for at least three different times, normally with a thickness of deposit between 300 and 10,000Å. When ammonia was present in the plating baths, the samples were plated from a semiclosed system, open to the atmosphere only through a reflux condenser. Ammonia analyses were run before and after the plates were made. In general, the total ammonia in the bath varied less than 3% over a 2-hr period. The metal and phosphorous content of the deposited films were measured by x-ray emission spectroscopy. A vibrating sample magnetometer was used to measure the magnetic characteristics of the films.

Results and Discussion

Table I shows some of the results of the electroless deposition of cobalt on polyethylene terephthalate, both as a function of *p*H and ammonia concentration. The composition of the bath is similar to baths reported in the literature (1-6). The plating rate is calculated by taking the amount of metal plated per unit area and dividing this by the plating time. The rate is reported as micrograms of metal deposited per square centimeter per minute. The data at 25 g/l $(NH_4)_2SO_4$ were taken at a different temperature, 160°F, because bath stability appeared to be an overriding problem at this concentration, even worse here apparently than at 0 g/l $(NH_4)_2SO_4$. The numbers in parentheses shown at this ammonia concentration are calculated to give a rough approximation of the rate at 180°F, assuming a doubling of rate for a 20° temperature change.

The important fact to be obtained from Table I is the relatively large increase in rate as the ammonia concentration is increased, even up to 100 g/l $(NH_4)_2SO_4$. It should also be pointed out that for the points on this matrix that were checked using copper

Table II. Effect of ammonia on the rate of electroless deposition of nickel on polyethylene terephthalate

Bath: 33 g/l $NiSO_4 \cdot 6H_2O$ (0.12*M*); 35 g/l $Na_3C_6H_5O_7 \cdot 2H_2O$ (0.12*M*); 20 g/l $NaH_2PO_2 \cdot H_2O$ (0.19*M*); X g/l $(NH_4)_2SO_4$; pH adjusted with NaOH, 160°F

g/l $(NH_4)_2SO_4$	Average plating rate, μg nickel/cm²/min pH 8.0	pH 8.5	pH 9
100	237	250	286
50	268	340	305
25	272	279	202
0	225	224	182

as the substrate the rates were almost identical to that on the plastic substrate. For example, at *p*H 9.0 and 100 g/l $(NH_4)_2SO_4$, the rate was 170 μg/min on copper as compared to 162 on polyethylene terephthalate. At *p*H 8.0 and 0 g/l $(NH_4)_2SO_4$ it was 33 compared to 29.

Table II shows the results of nickel plated from an electroless bath of the same composition as that used for the cobalt except that for this study, the temperature was kept at 160°F. In spite of this lower temperature, the rate is consistently higher than with cobalt and does not show any drastic change with ammonia concentration. It is possible that, if infinite accuracy is assigned to the data presented, one could see a change in rate with ammonia and might even predict maximum rates at different *p*H values as a function of ammonia concentration. However, the important point is that certainly the ammonia does not affect the rate of nickel plating as much as it did the cobalt.

Using copper substrates for the nickel deposition, the rate decreased somewhat, being about 2/3 of that observed with polyethylene terephthalate substrates.

Table III shows the range of coercivities obtained on the samples used to measure the plating rates of the electroless cobalt and nickel baths. As might be expected, the coercivities at a given bath composition are not constant, but appear to vary with the per cent phosphorus and/or thickness of the films. No real correlation with either of these variables could be made, however, from the data taken.

For all the cobalt samples, the amount of phosphorus was in the range 1-6%, even with those samples which show very low coercivities. In general, especially at *p*H 8.5 and 9.0, the coercivities of the films tend toward lower values as the ammonia concentration is decreased through 25 g/l $(NH_4)_2SO_4$. However, at 0 g/l $(NH_4)_2SO_4$ the coercivities are again as high as at 100 g/l. This is an unexplained and unexpected result which warrants further investigation.

For the alkaline electroless nickel samples, the coercivities at all of the ammonia concentrations except 0 g/l are in the range of 10-80 oe, and the per cent phosphorus in the films varies between 3 and 6%. However, as seen from Table III, at 0 g/l $(NH_4)_2SO_4$ the coercivity dropped to zero and, as might be expected from the low magnetics (9), the per cent phosphorus increased to between 10 and 17%.

Another interesting point observed from the magnetics measurements, especially with the cobalt samples, was that the range of coercivities obtained from a given bath using the copper substrate was much smaller than observed with the polyethylene terephthalate substrate, even though approximately the same variations in thickness, per cent phosphorus, etc., existed on both substrates. For example, at 100 g/l $(NH_4)_2SO_4$ and *p*H 8.0, where a range of 300-900 oe was observed on polyethylene terephthalate, a range of only 500-550 oe was observed on copper.

As mentioned previously, attempts were made to use a buffer system other than ammonia for the alkaline electroless nickel or cobalt plating. However, it was found that one could not simply replace the $(NH_4)_2SO_4$ with sodium tetraborate and obtain a stable bath. Several adjustments had to be made in the bath to make it useful. For example, metal ion solubility in the presence of borate appeared to be a problem, and the concentration of citrate had to be increased. However, a bath buffered with borate and with some of the other parameters adjusted can be used for electroless deposition.

Table IV shows the composition of the borate-buffered cobalt bath used in this investigation and some of the results obtained. Again, the rates are in micrograms of metal per square centimeter per minute. From the data in Table IV one can see that the rate of deposition from the borate baths is considerably less than even that for the 0 g/l $(NH_4)_2SO_4$ baths. Although some of this difference may be ascribed to the different bath composition (owing to different amounts of citrate, cobalt, hypophosphite, etc.), some of it probably is also due to the different buffer system. It is also noticeable that the magnetics from the borate-buffered cobalt bath are relatively low.

However, a more interesting result was obtained when the per cent phosphorus was measured on some of these samples. For samples prepared at *p*H 8.7 in the borate-buffered cobalt bath, the amount of phosphorus varied around a rather normal 4%. In the bath at *p*H 9.2, the amount of phosphorus varied up to an astonishing and almost unbelievable 60 w/o (weight per cent). Results on some of these films are suspect because of the thinness of the films and associated analysis problems, but quite definitely the films from some of these borate-buffered baths have exceedingly high phosphorus contents.

Table V shows the results obtained in the electroless nickel deposition from borate-buffered baths. The bath composition is the same as that used for cobalt. Once again, the plating rate for the borate-buffered bath is considerably less than that observed in even the 0 g/l $(NH_4)_2SO_4$ bath. Furthermore, the films are paramagnetic, and the amount of phosphorus was in the range of 15-18%. The magnetics and per

cent of phosphorus are similar to those in the 0 g/l $(NH_4)_2SO_4$ bath.

A further experiment with some of the borate-buffered cobalt baths involved adding $(NH_4)_2SO_4$ to them and again checking their rate and magnetics. It was found that even with relatively small amounts of added ammonia, 10 g/l or less, the rate of deposition increased markedly, and the magnetics went up to the range observed in ammine-buffered baths.

From the data presented, one can see that the effect of ammonia in the electroless deposition of cobalt is somewhat different from that in nickel deposition. The data indicate that ammonia increases the rate of cobalt deposition with a somewhat inconsistent effect on the magnetic characteristics of the film. On the other hand, ammonia does not affect the rate of nickel deposition as greatly and only affects the magnetics by its absence; that is to say, one observes paramagnetic films with no ammonia. In order to try to explain some of these results, spectral and polarographic studies of these baths were undertaken.

Based on the effect of ammonia on the cobalt rate, one might expect to see a large interaction of ammonia with the cobalt-citrate complexes using spectral measurements. However, such is not the case, as shown in Fig. 1.

Curve I in Fig. 1 shows the visible spectra of cobalt-citrate, and curve II is that of cobalt-citrate-ammonia. Of course, the samples with ammonia present were run under air-free conditions in order to prevent the formation of Co(III). Figure 1 shows that the spectra with and without ammonia are quite similar and no great spectral changes can be ascribed to ammonia in the visible region. This result is somewhat discouraging if one is to try to study the effect of ammonia on the electroless plating rate. However, on further consideration, this lack of spectral change due to ammonia can be rationalized by the fact that a small interaction of ammonia with a cobalt-citrate complex, such as occupying one or two of the cobalt coordination positions with NH_3 groups, might not affect the spectra greatly. This is made even more plausible when one realizes that the Co(II) ammonia complex has about the same extinction coefficient as the cobalt-citrate, and absorbs in the same region, having its absorption maximum at about 490 mμ.

Predicting from the apparent small effect of ammonia on the plating rate of the alkaline electroless nickel solutions, one might also expect to see little, if any, effect on the spectra of the nickel solutions. However, this is not the case; large shifts in the spectra can be observed even with the naked eye. With no ammonia in the solution, the nickel-citrate is a bright green. When ammonia is added, however, the solution changes to the typical deep blue nickel-ammonia color.

Thus, the spectral effects of ammonia on the cobalt and nickel solutions appear to be the opposite of the effects observed on the plating rates. That is, little spectral variation due to ammonia is observed for cobalt, while a large rate change is observed. On the other hand, a large spectral effect is observed with nickel, which does not show a large rate change. For this reason, another technique, polarography, was used to look at the systems involved.

The qualitative polarographic behavior of the electroless cobalt bath under different conditions is shown in Fig. 2. Curve I is typical of the behavior without ammonia present, and it can be seen that the normal cobalt wave expected around —1v has shifted cathodically until it can just be seen before the hydrogen wave. In fact, under some conditions, this wave shifts beyond hydrogen reduction and can no longer be seen. However, when ammonia is added to these solutions, the cobalt wave is again observed at about —1.3v as shown by curve II. Furthermore, at very low ammonia concentrations, the height of this wave is a function of time after the ammonia addition. Here, at last, would appear to be an independent measurement of the effect of ammonia on the electroless cobalt plating rate if it were not for the following observations.

Figure 3 shows the qualitative polarographic behavior of the nickel system. Again, one observes that without ammonia present (curve 1) the wave has shifted beyond the hydrogen reduction wave. However, when ammonia is added to the system (curve II) one observes the same sort of shift as is seen in the cobalt system. That is, the ammonia appears to affect the nickel wave in the same manner it did the cobalt wave, and it is apparent that the simple polaro-

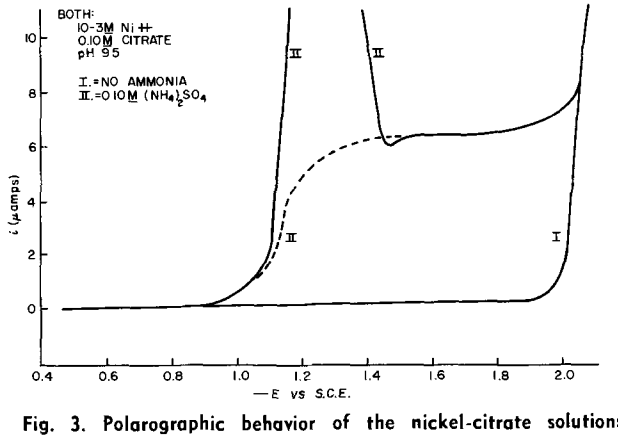

Fig. 3. Polarographic behavior of the nickel-citrate solutions with and without ammonia present.

graphic behavior cannot be used to explain the difference in plating rate of the two solutions.

Conclusions

In summary, several facts appear evident for the bath compositions and conditions used for these studies.

1. Ammonia increases the rate of alkaline electroless cobalt deposition.
2. Ammonia has little effect on the rate of alkaline electroless nickel deposition.
3. Relatively hard magnetic films are produced in alkaline electroless cobalt deposition and ammonia does not seem to be the primary variable influencing these magnetics.
4. In alkaline electroless nickel deposition, the absence of ammonia produces paramagnetic films and the presence of ammonia gives a soft magnetic material.
5. Spectral observations cannot be used at this time to explain the different effects of ammonia on alkaline electroless cobalt and nickel deposition.
6. The polarographic behavior of the cobalt and nickel systems is similar and to date has offered no evidence to explain the rate and magnetic differences observed.
7. New or modified techniques will have to be used to study the rate and magnetic variations caused by ammonia and to improve the understanding of the deposition processes.

Ohmic Electrical Contacts to High-Resistivity ZnS Crystals

George H. Blount, Mark W. Fisher, Robert G. Morrison, and Richard H. Bube

Department of Materials Science, Stanford University, Stanford, California

ABSTRACT

Ohmic electrical contacts to high-resistivity ZnS single crystals can be made by annealing crystals at 400°-475°C with In-Ga contacts in an inert atmosphere. Optimum contacts are obtained by annealing first at about 475°C and then at 400°C. The following four stages are indicated in contact formation through annealing at progressively higher temperatures: (*i*) poor quality contact determined primarily by the properties of an impurity transition layer on the surface, insensitive to temperature to 300°C; (*ii*) a deterioration in contact quality as this impurity layer is penetrated by the electrode metal and before diffusion of the metal into ZnS; (*iii*) a rapid improvement in the contact properties with increasing temperature as electrode metal diffuses into existing zinc vacancies in the crystal, terminated by an independence of electrode quality on increasing temperature when all zinc vacancies are occupied near the metal-semiconductor interface; and (*iv*) deterioration in contact quality as more vacancies are thermally formed and the electrode metal diffuses extensively into the crystal.

An ohmic contact is one that is able to provide a reservoir of carriers in an insulator or semiconductor sufficient to supply carriers as needed to maintain charge neutrality. In seeking to provide ohmic contacts for II-VI materials in general, the following three guidelines have been helpful. (*i*) Choose a metal for the contact electrode that has a smaller work function than the electron affinity of the semiconductor. If there are no surface layer or surface state effects of importance, then this criterion should be both necessary and sufficient for an ohmic contact. (*ii*) Within the requirements of the first guideline, choose a metal that, if diffused into the semiconductor, will provide majority carriers, *i.e.*, as an impurity in the semiconductor, the metal should be a donor if the conductivity is n-type, or an acceptor if it is p-type. (*iii*) Use some method of heating the contact-semiconductor interface to allow the metal to diffuse into the semiconductor.

In the case of CdS, satisfactory ohmic contacts can be produced following these guidelines, using In or Ga as the contact metal (1), and with only moderate heat-treatment, usually no more than that required to melt the metal in forming the contact. Mead (2) has shown that metal-semiconductor barriers for nonohmic contact vary with the work function of the metal on CdS, thus indicating that the work function criterion is meaningful. In addition it is a simple matter to produce high-conductivity CdS by diffusion of In or Ga, both of which are donors in n-type CdS. The work of Kröger *et al.* (3) has shown that diffusion of donor impurity from the electrode metal can play an important role in achieving ohmic contacts to n-type crystals.

Ohmic contacts to ZnS crystals, on the other hand, have been more difficult to obtain. ZnS has at least two distinctive properties that make ohmic contact formation difficult. First, it has a low electron affinity, about 1 ev less than that of CdS (4). Second, unless special precautions are taken, self-compensation of donor and acceptor imperfections is thermodynamically favored (5) so that high-conductivity ZnS is not easily prepared by simple impurity diffusion. The first property of ZnS suggests that metals like In and Ga with sufficiently low work function to provide ohmic contacts on CdS may not meet the requirement that the work function be less than the electron affinity in ZnS. The use of these metals, then, re-

quires that their diffusion into ZnS be the dominant factor in determining the nature of the contact, and the second property of ZnS indicates that self-compensation phenomena will act to prevent the easy formation of a region of graded conductivity.

Recently, Aven and Mead (4) have succeeded in making good, but not quite ohmic, contacts to highly conducting ZnS crystals. In general, the more insulating the crystal the more difficult is the forming of ohmic contacts, in spite of the fact that the density of carriers required of the contact is lower for insulating than for conducting crystals. Williams (6) has described a method for making useful transparent electrical contacts to ZnS crystals using In_2O_3 with Sn impurity.

It is the purpose of this paper to offer an explanation for some of the common problems encountered in making ohmic contacts to high-resistivity ZnS crystals, based on an investigation of contact quality control by annealing in an inert atmosphere. It is found that ohmic contacts can be produced in high-resistivity photosensitive ZnS crystals with proper annealing of the electrode-semiconductor interface.

Experimental

A simple strip-heater furnace with a flat molybdenum ribbon heater element was used for temperature annealing of contacts. Cooling from a higher to a lower kinetically stable temperature could be accomplished in a period of about a second, and the temperature could be maintained for hours to within less than a degree of a specified value. For the study of contact formation, crystals with their contacts were annealed at successively increasing temperatures, with quenching to room temperature and measurement of contact quality after each annealing. For such measurements, the annealing time was held fixed for each treatment at 3 or 4 min.

The contact alloy used was a mixture of In and Ga in the proportions of 50-50% or 25-75%. These mixtures are liquid at room temperature and show good wetting of the ZnS crystal, thus making a mechanical bond between electrode and crystal relatively easy to achieve.

Air was excluded during the annealing, and an atmosphere of dry hydrogen or nitrogen was maintained. No differences were observed between the two atmospheres, indicating that the possible formation of nitrides had no detectable effect. Because of the massive nature of the metal contacts it would be expected that any nitride formation would be restricted to the outer surfaces and would not affect the metal-semiconductor interface.

The crystals of ZnS used were grown by a chemical transport method with HCl as the transport agent. In the dark they had very high resistivity greater than 10^{10} ohm-cm, and they showed considerable photosensitivity.

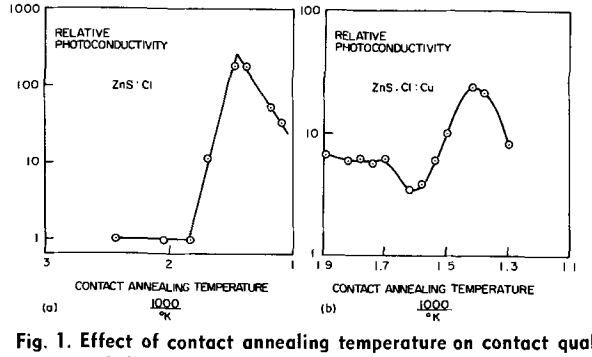

Fig. 1. Effect of contact annealing temperature on contact quality as measured by the room temperature photoconductivity of the crystal and contacts. The photosensitivity of the crystal in (a) is larger than that of the crystal in (b). The relationship between the scales in (a) and (b) is arbitrary.

Contact quality was judged in three ways. (*i*) The potential drop at each contact was measured when current was flowing in the crystal. (*ii*) The current *vs.* voltage characteristic of the crystal and its contacts was measured. (*iii*) The absolute magnitude of the photocurrent passed through the crystal for a fixed light intensity was measured. In every case where all three types of measurements were made, it was found that the lowest potential drops at the electrodes and the most nearly linear current-voltage curves were always accompanied by the highest photocurrents. Because of its simplicity, the magnitude of the photocurrent was therefore frequently used as a measure of the contact quality.[1] Other tests for ohmic contacts, such as the absence of photovoltaic effects and noise instabilities, were made only qualitatively.

Results

Typical dependence of photocurrent, measured at room temperature for fixed excitation intensity, on annealing temperature for two ZnS crystals is given in Fig. 1. The results on many such crystals can be described in terms of four temperature ranges for annealing. (*A*) Contacts applied at room temperature and subjected to no annealing are found to be grossly nonohmic. No improvement in contact quality is obtained by annealing below 300°C. (*B*) Annealing just below the temperature threshold at which contact quality improves generally causes a small decrease in contact quality below that found for no annealing at all. This proved to be the case for every measurement of sufficient detail to reveal the effect. (*C*) Beyond the temperature threshold, contact quality increases as the temperature of annealing is increased, until a maximum is reached. Typically contact quality, as measured quantitatively by the magnitude of the photocurrent, increases exponentially with $1/T$ in this range. (*D*) Annealing at still higher temperatures beyond the maximum results in poorer contact properties. The basic features of the dependence of contact quality on annealing temperature are summarized in Fig. 2.

A potential distribution typical of an unannealed contact is shown in Fig. 3a. 90% of the applied voltage is found across the metal-semiconductor cathode junction. The corresponding variation of current with voltage is shown in Fig. 3b. The potential profile of a crystal subjected to optimum annealing is shown in Fig. 3c. Small inhomogeneities in the crystal are

[1] This is clearly not an absolute measure, since its sensitivity, *i.e.*, the magnitude of the increase in photocurrent accompanying proper annealing, is governed by the photosensitivity of the crystal. The photocurrent obtained with unannealed contacts is determined primarily by the contact resistance. But when the contacts are nearly ohmic, the photocurrent is determined by the crystal resistance, which is a function of its photosensitivity and its geometry. Thus the difference between the photocurrents obtained without annealing and those obtained with proper annealing will vary from crystal to crystal.

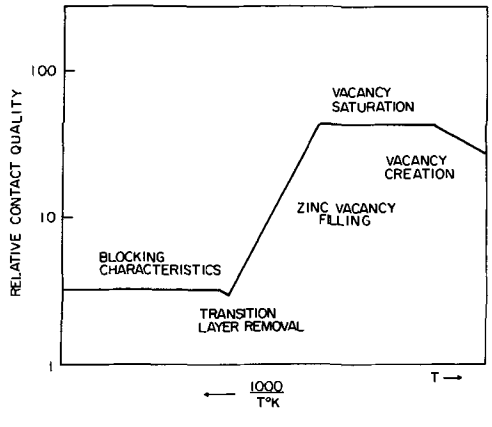

Fig. 2. Summary of the dependence of contact quality on annealing temperature.

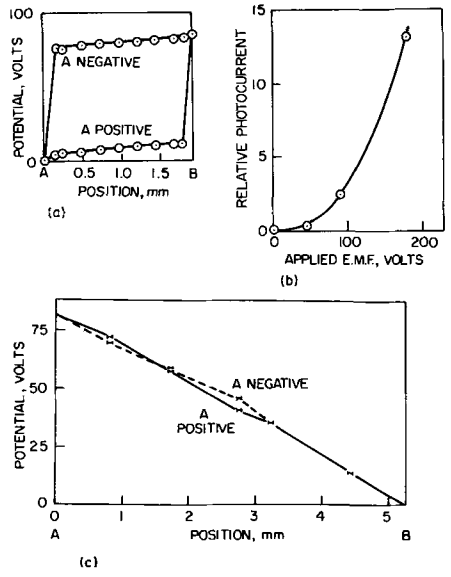

Fig. 3. Comparison of the quality of unannealed contacts, (a) and (b), and properly annealed contacts, (c), on ZnS:Cl:Ag crystals. The data of (a) and (b) are for the same crystal, and the data of (c) are for a similar crystal.

probably responsible for the departures from linearity in the potential profile of this crystal.

A comparison of contact quality for optimum and above optimum annealing is given in Fig. 4. It is evident that the contact quality is degraded by the higher temperature annealing. There is some disagreement here with the report of Alfrey and Cooke (7) that annealing contacts to 600°C was necessary for making ohmic contacts to high-resistivity ZnS crystals.

The dynamics of the annealing effects on contact quality are quite different at temperatures above and below the optimum temperature. For lower temperatures the changes produced by annealing are irreversible, whereas for higher temperatures the changes produced are reversible. At the optimum temperature or above, the properties of the contact are established by the final annealing regardless of the previous history. A convenient operating procedure for obtaining optimum contacts has been to anneal first for a period at about 475°C, followed by annealing at about 400°C.

Measurements of dark conductivity reveal no effect of annealing except for long annealing times at high annealing temperatures. In the dark the resistance of the crystal is much greater than the resistance of even poor contacts, and the quality of the contacts does not introduce significant effects.

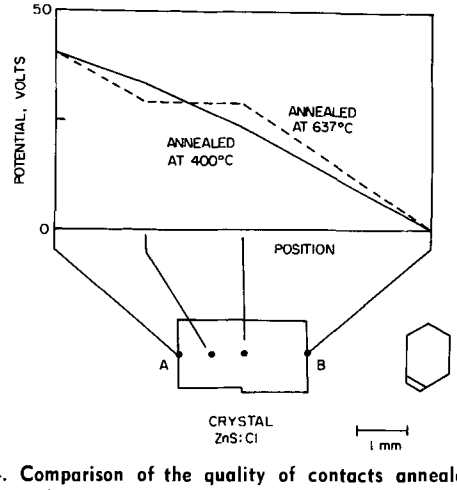

Fig. 4. Comparison of the quality of contacts annealed at optimum and above optimum temperature.

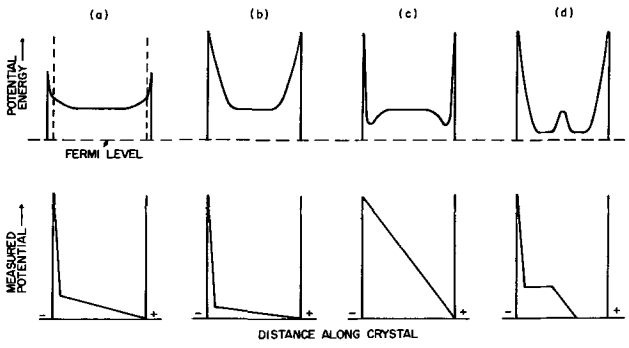

Fig. 5. Contact potential energy diagrams and typical measured potential profiles for the four principal regions found in annealing contacts. (a) Contact to the crystal through a surface layer transition region at low temperatures; (b) penetration of the electrode metal through the surface layer but without diffusion into the crystal, just below the threshold temperature for contact improvement; (c) ohmic contacts obtained by diffusion of metal donors without formation of new zinc vacancies; (d) result of annealing at a temperature above the optimum, showing wider barrier at the contact because of vacancy compensation of diffused metal donors near the surface, with high conductivity region due to uncompensated metal donors which have diffused further into the crystal.

Cooling to liquid nitrogen temperature does not greatly affect the contact quality provided that the contacts have been annealed to provide good ohmic contacts at room temperature. The greater the departure from ohmic behavior at room temperature, the greater is the deterioration of contact quality caused by cooling.

Discussion

The four temperature ranges for annealing effects summarized at the beginning of the previous section and illustrated in Fig. 2 may be correlated with the nature of the electrode-semiconductor barrier and with measured potential profiles along the crystal, as indicated in Fig. 5.

In the low-temperature annealing range, the contacts between metal and semiconductor can be considered as simply the junction of different materials. An explanation for the nonohmic character of this junction can be sought either in the presence of an insulating surface layer on the ZnS that is penetrated only after the temperature is made sufficiently high, or in an intrinsic mismatch of metal work function and ZnS electron affinity that prevents an approach to ohmic behavior unless the crystal becomes highly doped with the electrode material. That the latter condition exists is indicated by the work of Aven and Mead (4). Neither of these possibilities by itself, however, explains the decrease in contact quality just below the threshold temperature for contact improvement.

The observed decrease can be explained in terms of both a mismatch of work functions and a surface layer. If a surface layer exists on the ZnS crystal with a larger electron affinity than ZnS, the junction barrier height between metal and surface layer will be less than between metal and ZnS. The surface layer can therefore provide a transition region between metal and ZnS, giving a slightly better contact than would be obtained by metal-ZnS contact directly. At the threshold temperature, the surface layer is penetrated or removed, and therefore the contact quality deteriorates until the electrode metal can diffuse into the ZnS at higher annealing temperatures. The transition at the threshold is between the situation pictured in Fig. 5a and that in 5b.

The increase in contact quality beyond the threshold temperature can be explained in terms of diffusion of the electrode metal into the ZnS where it acts as a donor impurity, thus increasing the conductivity of the ZnS and creating a bulk transition re-

gion. The situation is pictured in Fig. 5c; the remaining barrier at the surface has been reduced to a sufficiently narrow width to permit tunneling. The importance of tunneling through such a barrier at the surface is probably the reason that it is easier to make ohmic contacts to high-conductivity ZnS than to high-resistivity ZnS crystals.

As long as the annealing temperature is sufficiently low, zinc vacancies present in the crystal are immobile and new zinc vacancies cannot be thermally created. Since the vacancies present are immobile, diffusion of the metal donors will be restricted to a narrow region near the contact interface. The quality of contact formation should not increase with lengthy annealing, and this is found to be the case. Since new zinc vacancies cannot be thermally created, the diffusing metal ions occupy those vacancies already present and compensated by donors in the crystal. The occupation of such zinc vacancies by metal donors frees electrons to increase the conductivity of the transition region. Since new vacancies cannot be formed, the self-compensation tendency in ZnS is inhibited.

The importance of existing zinc vacancies is indicated by the experimental observation that the optimum annealing temperature is a function of the history of the crystal, as well as of the composition of the electrode material. If zinc is added to the contact alloy, the optimum temperature is reduced, but the ohmic character of this contact is not as good as that made with the zinc-free alloy. It is reasonable to propose that the zinc diffuses into the crystal to occupy zinc vacancies, thus decreasing the density of vacancies available for occupancy by metal donors.

Contacts that are annealed above about 480°C are generally not as good as those annealed at a lower temperature. When the temperature exceeds 480°C it is proposed both that vacancies present in the ZnS become mobile and that new vacancies are thermally created. The increased mobility of vacancies present in the crystal makes it possible for uncompensated metal donors to diffuse further into the crystal, thus creating a high-conductivity region well removed from the contact interface. The creation of new vacancies begins at the surface of the crystal. The result is that between the contact interface and the high-conductivity region in the volume of the crystal there is a region where newly created zinc vacancies have compensated diffusing metal donors. The contact is now no longer between the electrode metal and a high-conductivity transition region in the ZnS, but between the electrode metal and a high-resistivity region in the ZnS. The result is the observed deterioration in contact quality as pictured in Fig. 5d.

The experimental observations are in agreement with the proposals just made. Crystals whose contacts are annealed above 480°C show changes in electronic properties in macroscopic regions near, but separate from, the contacts. In such regions the crystals become visibly cloudy, fluorescence becomes green, and electrical conductivity becomes very high. There is still a large potential drop at the contact interface, however, which indicates the inferior nature of these high-temperature annealed electrodes.

Independent confirmation of the probability of zinc vacancy mobility and creation at these temperatures may be obtained from the work of Mandel (5), and of Aven and Halsted (8), who noted that heating ZnSe to about 600°C produces rapid changes in stoichiometry.

Properties of Amorphous Silicon Nitride Films

S. M. Hu

Systems Development Division, East Fishkill Facility, International Business Machines Corporation, Hopewell Junction, New York

ABSTRACT

This paper describes insulating films of silicon nitride as deposited on silicon substrates by pyrolytic reaction and reactive sputtering. The following physical properties were investigated: amorphism, surface electron micrography, Si-N atomic distance, infrared adsorption spectrum, index of refraction, dielectric constant, electrical resistivity, ionic conductivity and polarization, breakdown voltage, MIS CV characteristics and silicon surface charge, and related phenomena.

Surface films of silicon dioxide have been a convenient and excellent material for passivating silicon electronic devices. Nevertheless, there is room for improvement, such as increased resistance to impurity diffusion, *e.g.*, sodium ions, and more inertness to electrode reaction. Materials such as silicon nitride therefore deserve some attention as a substitute for silicon dioxide under certain specific or stringent conditions. Some physical properties of crystalline silicon nitride have been compiled by Popper and Ruddlesdon (1) and Rabenau (2). There are recent publications concerning silicon nitride films. However, close examination of these published data, as compared to data obtained in this laboratory, indicates that these films reported are really something other than silicon nitride. It appears that the first published successful attempt to prepare films of silicon-nitride is the recent work of Sterling and Swann (3). Silicon nitride films have also been prepared in the laboratories of Doo (4), Pennebaker (5), and the author. This work

summarizes the preliminary results of extensive evaluations of a wide range of physical and electrical properties of silicon nitride films and a discussion of their implications. Emphasis of the silicon nitride studies is made from the point of view of its application to the semiconductor device industry.

The films studied were prepared by the pyrolytic deposition method from a reaction of anhydrous NH_3 and SiH_4 and by r.f. and d-c reactive sputtering of a silicon cathode in pure nitrogen, respectively. Evaluations discussed pertain to films formed on silicon substrates with resistivity of 2-5 ohm-cm, both p- and n-type, although films have also been prepared on quartz and on vitreous silica substrates.

Structure of Films of Silicon Nitride

Amorphism.—In most applications for electrical insulation, surface passivation, and masking, it is generally better to have the film in an amorphous form because of the reduced interfacial strain and greater continuity. There are exceptions as in the case of semiconductor device isolation where an epitaxial growth of another layer of single-crystalline semiconductor on the insulating film is desired. All silicon nitride films studied in this work are essentially amorphous. This is not surprising when one considers the complexity of the crystalline structure of both the α- and the β-silicon nitride, and the relatively low temperatures, 20°-900°C, at which the films were prepared. Attempts have been made in our laboratories to prepare films of silicon nitride at higher temperatures. Direct nitridation of substrate silicon wafers at 1300°-1400° and pyrolytic decomposition at 1100°C invariably yielded crystalline silicon nitride in the form of either small crystals or microcrystallites rather than a continuous film. Besides the reason of relatively high vapor pressure of silicon nitride at these temperatures to facilitate the growth in the third dimension, one has to consider the characteristic difference between the crystal structure of silicon and that of silicon nitride. Assuming the [0001] direction of silicon nitride crystal is parallel to the [111] direction of the substrate silicon, one may note that the lattice parameter of the former, $a = b = 7.75$Å (α-Si_3N_4), is approximately equal to the face-diagonal period [$1\bar{1}0$] of a unit cell of the latter (7.67Å). Unfortunately, although both are axes of threefold symmetry, there are screw axes in the silicon nitride which causes an elevation mismatch of silicon atoms in one-half of the unit cell in the basal plane. The actual atomic positions are also different. Thus, the feasibility of epitaxial growth is doubtful, unless a new phase of crystalline silicon nitride could be formed.

X-ray diffraction patterns were made of the silicon nitride films by first etching a hole in the silicon substrate, leaving the film over the window. X-ray diffraction did not reveal any pattern and exhibits only a uniformly dark exposure, indicating a completely amorphous structure. However, electron diffraction did show patterns of diffused rings, indicating the existence of extremely short range order, Fig. 1. The electron beam wavelength was 0.0385Å. The outer ring corresponds to a spacing of approximately 1.4-1.5Å. It is considered to be the distance between neighboring silicon and nitrogen atoms. It is interesting to compare this bond length of 1.4-1.5Å with the published values of 1.72-1.75Å (6). If the published structure is correct, the α-silicon nitride should have a density of 7.18 g cm^{-3}. The actual density of α-silicon nitride is 3.44 g cm^{-3}. Of course, one must note the flexibility of an amorphous structure as compared to the rigid structure of a crystalline phase. A high degree of covalent nature is indicated here. The ill-defined inner ring may actually be a mixture of a large variety of spacings, ranging from 2.2 to 4.7Å.

Surface topography of films.—The surface texture of films of silicon nitride varies greatly according to the method and the conditions of preparation. Figures 2-4 show various surface topographies on the electron microscopic scale. The electron micrographs were taken of collodion surface replicas shadowed with a carbon-platinum mixture. The magnification is 54,000X for all pictures.

Figure 2 shows the surface topography of a film formed by the pyrolitic deposition method at 800°C. The surface texture is seen to be featureless down to the limit of resolution of the collodion replica. Although microscopic variation of film thickness over the entire wafer were observed, there was no observable electron microscopic variation. Figure 3 shows the surface texture of a film prepared by r.f. sputtering. Blisterlike spots, about 500Å in diameter, are seen over the entire wafer. This type of surface roughness, however, is not peculiar to sputtered films of silicon nitride. Occasionally, it is observed in other types of sputtered films, such as silicon dioxide, although the degree of roughness varies (18). The origin of these raised spots is not understood, but it is doubtful that they are blisters in the usual sense because of the small size of the spots ($\sim 0.05\mu$) compared to the thickness of the film ($\sim 1.4\mu$). If these were real blisters, there would exist a tremendous amount of vertical slippage of the film, because it is impossible for

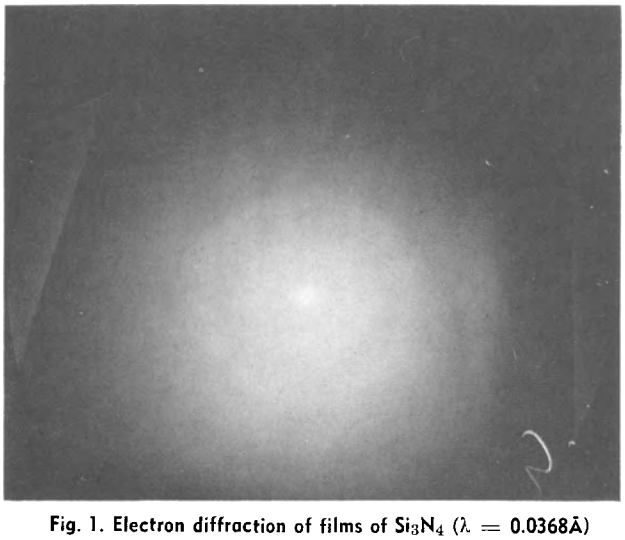

Fig. 1. Electron diffraction of films of Si_3N_4 ($\lambda = 0.0368$Å)

a rigid beam with such a thickness to undergo a deflection of such magnitude of curvature without breaking. Frequently, one also obtains r.f. reactively sputtered films with surface smoothness comparable to pyrolytic films (see Fig. 4). Typical films prepared by means of d-c reactive sputtering are usually rougher. Since films with this type of surface texture were found to be leaky in moderate electric field, it is assumed that submicroscopic cracks exist in these d-c sputtered films. The grain texture became finer and less pronounced as the d-c voltage decreased. Thus, it is thought that high intensity electron and perhaps negative ion bombardment together with the evolution of gases are the causes of this surface roughness. The surface topography of the silicon substrate after the formation of the sputtered film is revealed in an electron micrograph taken after the silicon nitride

film has just been removed by dissolution in hydrofluoric acid. The silicon substrate surface underneath the nitride film appeared to be smooth down to the resolution of collodion replica. Electron bombardment was minimized by confining the plasma in a magnetic field and placing the substrate outside the plasma confinement. Relatively pin-hole-free films were obtained this way. It is not certain whether an appreciable concentration of negative ions could exist in the plasma because of the small probability of electron attachment. It was found that the deposition rate was an order of magnitude greater when the substrate was outside than when it was inside the plasma.

Infrared spectra of films of silicon nitride.—Infrared spectra were taken for all samples prepared. For the purpose of comparison, an infrared spectrum of β-Si_3N_4 is included here. This spectrum was taken with potassium bromide disk method by Pliskin (7). Finely divided β-silicon nitride powder was dispersed in the KBr disk. The absorption peak occurs at 10.7μ in the KBr disk sample. This is identified as the Si-N stretching band, see curve I in Fig. 5a. Amorphous films of silicon nitride deposited on silicon by both methods mentioned show a considerable amount of shift toward longer wavelength of the Si-N stretching band. This is expected because of the looser structure of the amorphous film. Pliskin has observed similar phenomenon in the case of films of silicon dioxide (8). Curve III of Fig. 5a is a typical spectrum for a film prepared by the pyrolytic process. The Si-N stretching band has been shifted to a wave length of 12.0μ, and has been considerably broadened. The broadening is not unexpected because of the distribution of the interatomic distances. This is consistent with the decrease of the density and of the index of refraction. A typical reactively sputtered silicon film has an I.R. spectrum as shown in curve II of Fig. 5a.

The Si-N stretching band is seen to be shifted to ~11.3μ, an intermediate position between the crystalline phase and pyrolytic films. Curves 1-4 in Fig. 5b are arbitrarily selected infrared spectra taken of films prepared by d-c reactive sputtering. In addition, under certain conditions there exists an absorption peak at 4.7μ, which is absent in films of crystalline phase as well as films from the pyrolytic process. The peak at 4.7μ is seen to increase with the d-c voltage in the sputtering process and may become very pronounced when the d-c voltage is 3-4 kv. It is thought that this peak is probably due to triply bonded Si≡N. This occurs when the sputtering rate is high and the diffusion time is short for the sputtered ions and atoms, causing insufficient chemical reaction with the excited nitrogen and leading to the formation of unsaturated bonds. Thus, a slow rate is preferred for closer stoichiometry to the normal silicon nitride. Oxidation at 1100°C for 30 min in an oxygen stream did not change the characteristics of the infrared spectrum. This may not necessarily indicate the resistance of the Si≡N group toward oxidation, for one

must note that diffusion of oxygen through films of silicon nitride will encounter far greater resistance than the chemical reaction, and becomes the controlling step. Absorption bands corresponding to either Si-O (9.4μ) or N-H (2.9μ) were not observed.

Index of Refraction, Dielectric Constant, and Electric Resistivity of Amorphous Films of Silicon Nitride

The index of refraction of these nitride films were determined both by multiple-beam interferometry and by the Vamfo technique (9, 10). The Vamfo technique is believed to give more accurate results. Both methods, however, agree quite well. At $\lambda = 5460$Å, the index of refraction is 1.98-2.05, with small variations from film to film. The value 2.05 is for reactively sputtered films. Published value for α-Si_3N_4 is 2.1. The dielectric constant was measured using an MIS (Metal-Insulator-Semiconductor) varactor structure. The details of the structure and its measurement are described below. When the nitride films are formed on n-type silicon substrate, the dielectric constant can be measured directly. When the films are formed on p-type substrates, there will be an n-type inversion layer on the surface of the substrate which is removed by applying a small negative bias voltage (a negative bias is defined as one under which the metal electrode is negative with respect to the semiconductor electrode). For reactively sputtered silicon nitride films, the average dielectric constant measured at 10 kc is 6.5; for pyrolytic films, the average value is 6.2. Deviations from these values were observed, but were very small.

The electrical resistivity was determined from an analysis of I-V loop characteristics. Details of this experiment are also described below. Electrical resistivity data for crystalline silicon nitride reported in the literature are quite inconsistent and may differ by several orders of magnitude from each other. This is probably due to impurity incorporation in the materials. A value of 10^{13}-10^{14} ohm-cm as reported by Samsonov and Tsekulya (11) is perhaps closer to the intrinsic resistivity of silicon nitride, although it still may be somewhat low. Amorphous films studied show the resistivity to be too high at room temperature to be measured accurately as reported in the section on ion migration. At 400°C, the film resistivity was $\sim 1 \times 10^{15}$ ohm-cm. At 500°C, the resistivity decreased to 2×10^{13} ohm-cm. It should be noted that the I-V characteristic is nonohmic and depends greatly on the nature and condition of preparation. The breakdown voltage is $\sim 1 \times 10^7$ v cm^{-1}.

Interfacial Properties of Silicon Nitride Films on Silicon Substrates

The effect of a silicon nitride film on surface properties of silicon substrates is of prime significance to semiconductor devices, as the word passivation implies. Since most semiconductor devices are based on a potential barrier configuration, it is important that the potential near the surface not be altered or become unstable due to various surface processes. The surface potential is always altered when there are trapped charges or adsorbed dipoles or pile-up of ions at or near the interface. The surface potential, which is defined as the difference in potential between the surface and the bulk, can be determined in terms of charge removal from the surface to bring about a zero surface potential. An MOS, or more pertinently here MIS, varactor device is convenient for this measurement.

Aluminum of better than 99.999% purity was vacuum deposited on the silicon nitride film at room temperature through a tantalum mask, giving circular disk electrodes 20 mils in diameter and between 2500 to 3000Å in thickness. The C-V (capacitance *vs.* voltage) characteristics were traced out by applying a small a-c signal of 10 kc frequency for capacitance measurement, and a slow triangular wave of 2 v/sec

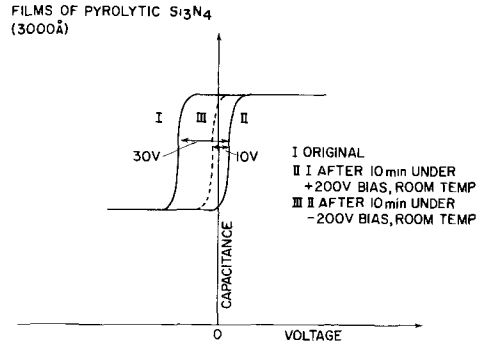

Fig. 6. Room temperature drifting of the surface potential at the Si_3N_4 interface.

for d-c bias. The analysis of the C-V characteristics has been described in the literature (13, 14) for this type of surface varactor. The term surface charge or trapped charge used here refers to the amount of charge (either positive or negative) removed to bring about a zero surface potential. A surface charge density of 1.2-1.4 x 10^{12} cm^{-2} was found for r.f. reactively sputtered films; a more uncertain value was found for d-c reactively sputtered films. Pyrolytic films of silicon nitride seem to have a higher surface charge density (15) of 3-5 x 10^{12} cm^{-2} (see Fig. 6).

The surface charge densities mentioned above were original values for fresh samples. The sign of the charge indicates an n-shift of the silicon surface under the silicon nitride film. The surface n-shift is defined as the increase of potential in the positive direction at the surface with respect to the bulk. Under continued application of a positive bias, the n-shift of the silicon surface continued to decrease, until finally the surface potential became slightly positive. It is interesting to note that the direction in which the surface potential shifted is opposite to that observed in the Si-SiO_2 interfacial system where the n-shift of the surface potential can be explained in terms of ion migration through the SiO_2 film in the applied field resulting in positive ion pile-up at the Si-SiO_2 interface. Thus, the drifting of the surface potential under a silicon nitride film must be explained as something other than ion migration. The drifting occurred at room temperature and appeared to require a threshold field. For pyrolytic silicon nitride films, a threshold field of about 2-4 x 10^6 v cm^{-1} was required (15). It may be noted that this is a rather high field and close to the breakdown field of a typical thermal SiO_2 film.

The surface potential drift at room temperature appeared to be largely irreversible. A continued negative bias caused a small amount of n-shift of the surface potential from that after positive bias. However, the "recovery" was less than one-third the magnitude of the p-shift under positive bias. The term recovery is

Table I. Physical properties of films of silicon nitride

Form	Films	Crystallites
Structure	Amorphous with extremely short range order	β-Si_3N_4
Si-N atomic distance	1.4-1.5Å (elec. diffr.)	
Si-N IR band	11.3μ (sputtered) 12.0μ (pyrolytic)	10.7μ
Index of refraction	2.05	2.1
Dielectric constant	6.5 (sputtered) 6.2 (pyrolytic)	9.4
Breakdown voltage	$\sim 10^7$ v cm^{-1}	
Electric resistivity	$\sim 1 \times 10^{15}$ ohm-cm (400°C) $\sim 2 \times 10^{13}$ ohm-cm (500°C)	10^{13}-10^{14} ohm-cm (?) (room temp.)
Ionic conductivity	Not detectable below 400°C	
Surface charge	1.2-1.4 x 10^{12} cm^{-2} (sputtered) 3-5 x 10^{12} cm^{-2} (pyrolytic)	
Threshold for room temp. drifting	2-4 x 10^6 v cm^{-1}	
Polarization ion concentration	3 x 10^{16} cm^{-3} (500°C)	

rather arbitrary since it is thought that the original surface potential of the fresh sample was not really the equilibrium value. Thus, the positive and negative bias cycle is merely a process of an electric stress annealing. Since, as discussed before, and as is to be elaborated on later, the ion migration process must be ruled out, it is proposed that two processes may occur during the electrical bias, *i.e.*, the reduction of hole traps inside the silicon nitride phase close to the interface via minor structural change or the high field annealing of the surface states at the silicon-silicon nitride interface.
