The Use of Ion Exchange Membranes as Separators in Batteries

Lloyd H. Shaffer

Research & Development Division, American Machine & Foundry Company, Springdale, Connecticut

ABSTRACT

The factors which influence selective transport are reviewed. In available membranes, selectivity is controlled primarily by concentration effects rather than by mobilities. The fluxes of electric current and matter through membranes are analyzed in terms of the thermodynamics of irreversible processes. The effects of a selective membrane on the operation of a silver/zinc battery are discussed. The charge-selective character of the membrane causes sharp changes in electrolyte concentration when current flows through the boundary between membrane and electrolyte. This introduces both a high resistance film and a concentration potential; both of these operate to reduce the power output of the cell.

In many kinds of batteries, separation of the components is maintained by virtue of the fact that the electrodes and the electrode reaction products are insoluble solids, while the electrolyte is a liquid phase. When the physical and/or mechanical properties of the electrode structures are inadequate, improved operation is obtainable if separators are introduced. These are usually porous materials which act as mechanical barriers. The use of barriers opens up possibilities for low grade structural substances or even liquid/liquid/liquid batteries, as long as the individual components are not mutually soluble. If the separator is an ion exchange material, we can even think in terms of electrode reactions which may produce soluble products. Three distinct types of separators are illustrated in Fig. 1. The first type of separator, a porous substance, functions solely as a mechanical barrier which holds back solid small particles. With proper design of pore size and control of surface tension through the addition of wet-proofing agents, such separators may also be used to maintain a boundary between a liquid and a gas. Fluids in the broad sense, including gases, may be most readily separated by continuous structures in which one or more of the battery components may be soluble. This is illustrated in part b of Fig. 1. Ion selective substances are a specialization of this type of barrier; they reject solutes primarily on the basis of the charge on each solute particle rather than because of its size or miscibility.

A variety of potentially useful ion exchange materials are available. Many have been developed for purposes other than battery separators, and often their resistivities appear to be intolerably high. However, one or two types have been manufactured as separators for use in batteries, and the others are potentially useful for this purpose as the resistance normal to the direction of the sheet is a strong function of the sheet thickness while the selectivity is not. Results of a recent survey of membrane properties are summarized in Table I.

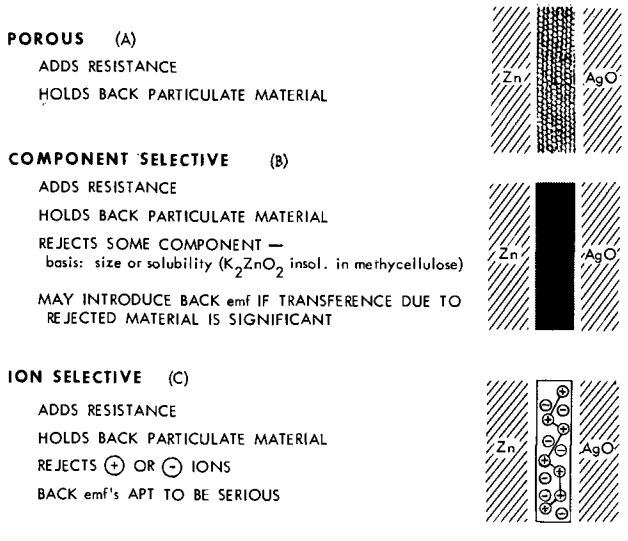

Fig. 1. Types of battery separators

Causes of Selectivity in Ion Exchange Membranes

A current of particles may be expressed as a mobility times a concentration times a force. Selective transport will occur if either the mobility or the concentration in a particular region that the current must pass through is very small. Selectivity in the usual kind of ion exchange membrane depends on the reduction of concentration of some species within the membrane; not too much is known about the effects of membrane on mobility.

The usual type of ion exchange membrane in which the selectivity is controlled by the exclusion of an ion of one sign, consists of an insoluble resin containing fixed ionic groups of the same charge as the excluded ion. The interior of the membrane may be regarded as a second phase and according to the Donnan principle the chemical potential of the salt in the solution external to the membrane must be equal to the chemical potential of the salt inside the membrane at equilibrium. This statement and its consequences are summarized in Eq. [1] to [4].

$$RT \ln a^2_{\pm} = \tilde{v}\Delta P + RT \ln \bar{a}^2_{\pm} \qquad [1]$$

$$\gamma^2_{\pm} C_k C_j = \bar{\gamma}^2_{\pm} (\bar{C}_r + \bar{C}_j)\bar{C}_j \quad \{j \text{ and } r \text{ have same sign}\} \qquad [2]$$

$$\bar{C}_j = \tfrac{1}{2} (\sqrt{\bar{C}^2_r + 4C^2_j} - C_r) \qquad [3]$$

$$\bar{C}_j = C^2_j/\bar{C}_r \ \{\text{dilute soln.}\} \qquad [4]$$

ΔP is the difference in internal pressure between the two phases, sometimes called the swelling pressure of the membrane, $\tilde{v}$ is the partial molar volume of any of the mobile species in the system, and a is its activity coefficient. The bar over the a is used to indicate activity within the membrane phase. This equation must hold for each and every component that is distributed between the two phases. Since both the solution and the membrane must be electrically neutral, and since the ion exchange material can be made to contain a very large concentration of ions of one sign, the concentration of mobile co-ion in the membrane will be smaller than it is in the solution outside. For example, suppose that j and k represent ions of opposite sign and r represents a monovalent fixed ion in the membrane. We will imagine that this ion has the same sign as j. Within the membrane electrical

neutrality requires that $\bar{C}_k = \bar{C}_r + \bar{C}_j$. In the absence of large pressure differences between the exterior and the interior phases, application of the Donnan principle leads to the results given by Eq. [3], or for very dilute external solutions, Eq. [4]. Typical resin manufacturing techniques produce materials in which $\bar{C}_r$ is the order of 5*M* and Table II shows several values of expected co-ion concentration within such resins as a function of the external solution concentration. It is apparent that resins which are quite selective in dilute solutions may show greatly reduced selectivity in very concentrated solutions.

Table II. Values of co-ion concentration[1]

Conc. in ext. soln. (m/kg)	5	3	2	1	0.5	0.3	0.2	0.1	0.01
Conc. of mobile co-ion in resin (m/kg)	3.09	1.36	0.70	0.19	0.05	0.018	8×10^{-3}	2×10^{-3}	2×10^{-5}

Effective fixed ion concentration in resin phase: 5 m/kg H_2O

[1] Values tabulated for moderate external solution concentrations are in rough agreement with observations on actual ion exchange resin system (see for example Gregor and Gottlieb (1)).

Quantitative Description of the Performance of Ion Exchange Membrane Separators

To assess the effect of an ion exchange membrane on battery performance, we have to consider what happens when a current flows through the membrane. When this occurs, several coupled processes occur simultaneously. It is helpful to make use of the theory of irreversible thermodynamics in examining the interdependence of the various interacting forces and flows. This provides convenient definitions of certain quantities that are important in transport theory and makes the relationships between them plain. The simplest electrolyte solution imaginable consists of one salt dissolved in a pure solvent. Equation [5] is suitable for the description of this system (2). Note that a minimum of four equations is needed even for this simple system.

$$J_1 = -\mathcal{L}_{11}\nabla_T\mu^*_1 - \mathcal{L}_{12}\nabla_T\mu^*_2 - \mathcal{L}_{13}\nabla_T\mu^*_3 - \mathcal{L}_{14}\nabla \ln T$$

$$J_2 = -\mathcal{L}_{12}\nabla_T\mu^*_1 - \mathcal{L}_{22}\nabla_T\mu^*_2 - \mathcal{L}_{23}\nabla_T\mu^*_3 - \mathcal{L}_{24}\nabla \ln T$$

$$J_3 = -\mathcal{L}_{13}\nabla_T\mu^*_1 - \mathcal{L}_{23}\nabla_T\mu^*_2 - \mathcal{L}_{33}\nabla_T\mu^*_3 - \mathcal{L}_{34}\nabla \ln T$$

$$Q = -\mathcal{L}_{14}\nabla_T\mu^*_1 - \mathcal{L}_{24}\nabla_T\mu^*_2 - \mathcal{L}_{34}\nabla_T\mu^*_3 - \mathcal{L}_{44}\nabla \ln T \quad [5]$$

The *J*'s are currents of the two ions and the solvent, while *Q* represents the flow of heat. The coefficients

$\mathcal{L}ij$ are phenomenological coefficients and the symbol $\nabla_{T\mu}{}^*$ is meant to represent the gradient of the total chemical potential[1] taken at constant temperature. It is obvious that setting any of the driving forces $\nabla_{T\mu}{}^*$ or $\nabla \ln T$ equal to zero in the equations above does not guarantee that the corresponding current J_i or Q will vanish. In particular, the last line of Eq. [5] suggests that it may be almost impossible to perform an isothermal experiment. However, work by Ikeda (4) and Shaffer (5) has shown that thermal effects due to the flow of current in an ion exchange membrane are small. In addition, in the analysis of most systems which contain electrical potentials large enough to be of practical interest, some of the other terms that arise as a result of the formalism above are small enough to be dropped. For example, suppose we are dealing with a system in which only gradients of electrical potential, pressure, and concentration need be considered; then,

$$\nabla_{T\mu}{}^* = zF\nabla\phi + \frac{\partial\mu}{\partial P}\nabla P + \frac{\partial\mu}{\partial C}\nabla C$$

$$C \simeq a,\ \partial\mu/\partial C \simeq RT\,\partial \ln C/\partial C$$

$$\nabla_{T\mu}{}^* = zF\nabla\phi + \tilde{v}\nabla P + \frac{RT}{C}\nabla C \qquad [6]$$

And the magnitudes of the forces that might be associated with the flow of current through the membrane in a typical battery system under these conditions are summarized in Table III. It is clear that the term $\tilde{v}\nabla P$ is relatively unimportant. Under any normal circumstances, gravitational and centrifugal fields are also insignificant compared to the very large magnitudes of $zF\nabla\phi$ and $RT\nabla$ ln c. This permits considerable simplification of Eq. [5]:

$$J_1 = \mathcal{L}_{11}X_1 + \mathcal{L}_{12}X_2 + \mathcal{L}_{13}X_3$$
$$J_2 = \mathcal{L}_{12}X_1 + \mathcal{L}_{22}X_2 + \mathcal{L}_{23}X_3$$
$$J_3 = \mathcal{L}_{13}X_1 + \mathcal{L}_{23}X_2 + \mathcal{L}_{33}X_3 \qquad [7]$$

in which we have to consider the flows of two kinds of ions and the flow of solvent, and where X, the generalized force, is given by [8].

$$X = -zF\nabla\phi - \frac{RT}{C}\nabla C \qquad [8]$$

The quantities that are important in further electrochemical calculations are: electric current, electrical conductivity, transport number of the k^{th} ion, and transference number of any uncharged species that may move along with the charged particles. (Note that transport number and transference number are related by $T_k = z_k\tau_k$). These quantities are readily defined in terms of Eq. [7] and [8].

Electric current

$$i = z_kFJ_k + z_jFJ_j$$

Electrical conductivity

$$\sigma = i/(-\nabla\phi) = \mathcal{L}_{kk}z_k{}^2F^2 + 2\mathcal{L}_{kj}z_kz_jF^2 + \mathcal{L}_{jj}z_j{}^2F^2$$

Transport number of the k^{th} ion

$$\bar{T}_k = \frac{(\mathcal{L}_{kk}z_k{}^2 + \mathcal{L}_{kj}z_kz_j)}{(\sigma/F)} \qquad [9]$$

Transference number

$$\bar{\tau}_w = \frac{\mathbf{J}_w}{\sigma/F} = \frac{\mathcal{L}_{kw}z_k + \mathcal{L}_{jw}z_j}{\sigma/F}$$

These defining equations do not of course tell us the numerical values of the conductivity or the transference numbers, unless we have the values of all of the phenomenological coefficients. However, the defining equations can be used to help in the interpretation of experimental situations even when the coefficients are not known. For example, consider the measurement of "membrane potential," an experiment which is often performed to determine the selectivity of the membrane.

Analysis of "Membrane Potentials"

"Membrane potential" is the electrical potential across the membrane when there is a concentration difference between the solutions on either side and no electric current. The situation is summarized by Eq. [10].

$$i = z_kJ_kF + z_jJF_j = 0 =$$
$$\mathcal{L}_{kk}z_kFX_k + \mathcal{L}_{kj}z_kFX_j + \mathcal{L}_{kw}z_kFX_w$$
$$+ \mathcal{L}_{kj}z_jFX_k + \mathcal{L}_{jj}z_jFX_j + \mathcal{L}_{jw}z_jFX_w \qquad [10a]$$

and, dividing through by the expression for conductivity

$$0 = \tau_kX_k + \tau_jX_j + \tau_wX_w = -T_kF\nabla\phi - T_jF\nabla\phi$$
$$-\tau_kRT\nabla \ln a_k - \tau_kKT\nabla \ln a_j - \tau_wRT\nabla \ln a_w$$
$$-\nabla\phi = \tau_k\frac{RT}{F}\nabla \ln a_k + \tau_j\frac{RT}{F}\nabla \ln a_j + \tau_w\frac{RT}{F}\nabla \ln a_w \qquad [10b]$$

where, as before, we have used X's to stand for the negative gradients of the total chemical potentials. The last line of Eq. [10b] shows clearly that the potential gradient depends on the transference numbers and the activities of all of the species present in the system, even though no current is flowing.

This important result has been obtained previously by Scatchard (6) using a more conventional thermodynamic approach to an analysis of a cell containing a membrane. However, it is not apparent from his approach that one can avoid an integration over the thickness of the barrier. In an analysis of the problem due to Kirkwood (7) it has been shown that one can use microscopic differences between the bulk phases rather than local gradients in setting up the phenomenological equations. Using this idea and Eq. [9] we can calculate apparent electrochemical characteristics for the membrane. Transport coefficients defined in this manner are "effective" quantities that apply over the whole thickness of the system interface'/membrane/interface" and we can avoid the question of integration entirely.

Effect of Selective Membrane on Resistance, Voltage, and Concentration under High Current Conditions

To illustrate the effects that an ion exchange membrane will have on the operation of an actual battery, it is convenient to consider a specific system. As an example a silver-zinc battery with an anion exchange membrane separator will be used. Because the membrane is selective, serious concentration gradients will develop in the solution adjacent to it under high current conditions. Concentration polarization arises because the current in the solution is carried by the motion of both positive and negative ions, while in the membrane the current is carried by the motion of only

[1] The total chemical potential is sometimes called the electrochemical potential; see for example Harned and Owen (3).

Table III. Approximate magnitudes of the terms which contribute to the electrochemical driving force

$\Delta\phi \simeq 0.2$v
$\Delta x \simeq 0.02$ cm (8 mils)
$\tilde{v} \simeq 20$-30 cm^3/mole
$\Delta P \simeq 1$ atm $= 0.1$ watt-sec/cm^3
T ~ 300°K
C ratio $\sim$ 10-1000 max.
$F = 96{,}487$ a-sec/eq.

$R = 8.315$ watt-sec/mole-°C
$zF\nabla\phi \sim 0.2 \times 10^5 \times 1/0.02 \sim 10^6$ watt-sec/mole-cm

$\tilde{v}\nabla P \sim 25 \times 10^{-1}/0.02 \sim 125$ watt-sec/mole-cm
$RT\nabla \ln C \sim 8 \times 300 \times 6.9/0.02 \sim 8 \times 10^5$ watt-sec/mole-cm

one kind of ion. In addition, each electrode in general acts as a source or a sink for only one kind of ion. These discontinuities in the conduction process lead to concentration gradients in the vicinity of both the membrane and the electrodes. When a load is first connected to the cell, the disturbances are confined to the immediate vicinity of the interfaces between membrane and solution and electrode and solution. However, in an unstirred system, the depleted and concentrated layers will spread until they run into each other. Steady-state concentration gradients as sketched in Fig. 2 will be reached in a time such that $Dt/\delta^2 \sim 1$;[2] and, with the small spacings, 1.0-0.1 mm, that are apt to be used in a typical battery, the characteristic time for reaching the steady state will lie in the range 1-100 sec. At a current density of 1 amp/cm^2, the corresponding variations in the concentration range from ± 1.67 to ± 16.7M.

Although the concentrated and the diluted layers appear to merge in a typical battery, their effects might be considered in terms of separate diluted and concentrated regions each having a characteristic thickness $\delta = l/2$. These layers of altered concentration will affect the operation of the cell in two different ways: they will increase its resistance, and they may produce serious back emf's. In exploring the effects due to the concentration layers, it is convenient to think about resistance effects and voltage effects separately; consider first the effect of the concentration layers on resistance.

Resistance.—For purposes of illustration, we shall assume that there is no solvent transfer through the membrane, and, that the membrane is perfectly selective. Figure 2b indicates schematically the nature of the resistances that will arise when a current is passed through the membrane/solution system. For the moment let us ignore the resistances which are associated with the electrodes and the electrode reactions. The resistance of the membrane is known in advance and presumably will be small in accordance with design selections. The resistance marked R_δ' will probably not differ greatly from the resistance of the 30 and 40% KOH solution used as the electrolyte in the cell. On the other hand the resistance marked R_δ'' being associated with a diluted layer, may be quite high, and it will therefore tend to control the total resistance of the cell. In assessing the contribution of the diluted layer to the total IR drop in the cell it is convenient to make use of the fact that the variations of C and R from the initial bulk solution values C_b and R_b to C_i and R_i at the membrane/solution interface are approximately linear. It then is fairly simple to develop an expression for the amount of extra resistance introduced by the diluted layer. The results of this calculation for extreme conditions of polarization are shown in Eq. [11].

[2] According to Rosebrugh and Miller (8)

$$\Delta c_i \text{ (moles/cc)} = \frac{i\delta}{zFD}\left[1 - \frac{8}{\pi^2}\sum_1^\infty \frac{1}{(2n-1)^2}\exp\left\{-\frac{(2n-1)^2\pi^2 Dt}{4\delta^2}\right\}\right]$$

For a typical electrolyte, $D = 3 \times 10^{-6}$ cm^2/sec; and, if $l = 0.1$ mm, $\delta = 5 \times 10^{-3}$ cm, and $Dt/\delta^2 = 1$ when $t = 8 \times 10^{-1}$ sec.

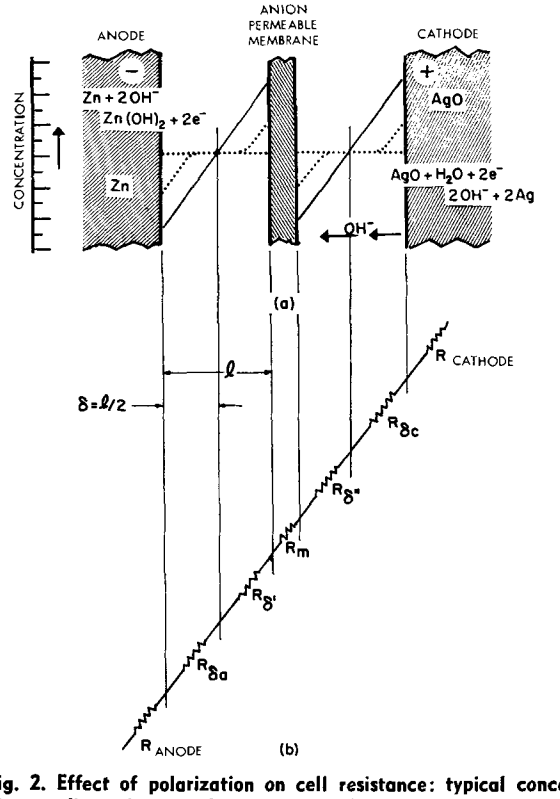

Fig. 2. Effect of polarization on cell resistance: typical concentration gradients (*a*) and the resulting cell resistances (*b*).

$$\Delta C \simeq C;\ C_i \simeq 10^{-2}\text{m};\ \omega_i \geqq 400 \text{ ohm-cm}$$

$$\omega_y = \frac{K}{(y/\delta)\Delta C + C_i},\quad dR = \frac{K dy}{(y/\delta)\Delta C + C_i}$$

$$R_\delta''(\text{ohm-cm}^2) = \int_0^l \frac{K\delta dY}{Y\Delta C + C} = \frac{K}{C_i}\odot\frac{\delta C_i}{\Delta C}\ln(1 + \Delta C/C_i)$$

$$K/\Delta C \simeq K/C_b \simeq \omega_b \text{ and } \Delta C/C_i \simeq (\omega_i - \omega_b)/\omega_b$$

$$R_\delta'' \sim \delta\omega_b \ln(\omega_i/\omega_b)^3 \qquad [11]$$

In these equations ω_i is the resistivity at the membrane/solution interface; ω_b is the bulk solution resistivity, and δ is the thickness of the concentration layer. It should be noted that the concentration effects which occur at the membrane solution interfaces when current is drawn from the cell are also duplicated at the electrodes. We can conclude that the actual resistance introduced by the membrane will be at least as great as the polarization resistance that would occur in the cell without any membrane being present.

Polarization potentials.—Consider also the voltages that may develop across the polarization layers when a current is passed through the system. The emf across each of the polarization layers and across the membrane can easily be calculated using Eq. [10]. It is obvious that concentration potentials should not occur whenever $\tau_+ = -\tau_- = 0.5$ and that the sign and magnitude of the concentration potentials under any other condition will depend on both the transference numbers and the actual concentrations. The situation as it is likely to exist if a high current is passed through an alkaline battery with an anion exchange separator is indicated in Fig. 3; Eq. [12]-[14] summarize the result obtained when the three voltages in the vicinity of the membrane, E_δ', $E_{m\phi}$ and E_δ'' are added up.

The polarization potential which arises as a result of adding a membrane to the battery system is:

$$\Delta\phi = \phi'' - \phi' = -\sum_i \tau_i \frac{RT}{F}\Delta \ln c_i = (-\tau_+ - \tau_-)\frac{RT}{F}\ln\frac{c + \Delta c}{c}$$

[3] Since $\Delta C = \dfrac{i\delta}{zFD}$ it is also true that

$$R_\delta'' \sim \frac{1}{i}\frac{RT}{F}\ln(\omega_i/\omega_b)$$

which agrees with the result recently obtained by Gregor and Peterson (9).

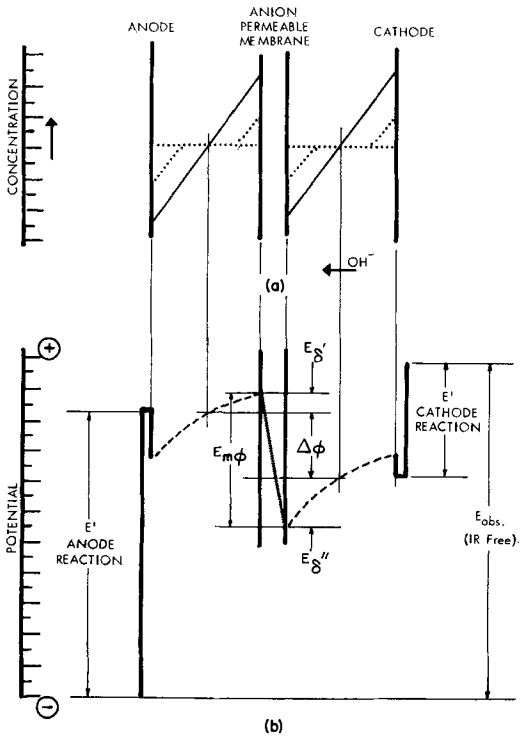

Fig. 3. Effect of polarization on cell potential—typical concentration gradients (*a*) and the resulting concentration potentials (*b*).

$$-\bar{\tau}_- \frac{RT}{F} \ln \frac{c - \Delta c}{c + \Delta c}$$

$$-(\tau_+ + \tau_-) \frac{RT}{F} \ln \frac{c}{c - \Delta c}$$

$$= -(\tau_+ + \tau_-) \frac{RT}{F} \ln \frac{c + \Delta c}{c - \Delta c} - \frac{RT}{F} \ln \frac{c + \Delta c}{c - \Delta c} \quad [12]$$

for a 1:1 electrolyte

$$-\tau_+ = -(1 - T_-); \; -\tau_- = T_-$$

and [12] simplifies to

$$\phi'' - \phi = \frac{RT}{F} 2(T_- - 1) \ln \frac{c + \Delta c}{c - \Delta c} = \frac{RT}{F} 2(T_- - 1)$$

$$\left\{ 2\left[\frac{\Delta c}{c} + \frac{1}{3}\left(\frac{\Delta c}{c}\right)^3 + \frac{1}{5}\left(\frac{\Delta c}{c}\right)^5 + \cdots \right] \right\} \quad [13]$$

This polarization, which appears as + on the left and as — on the right opposes the cell reaction and drastically reduces the power output.

If a cation permeable membrane were placed in the same spot, the initial polarization voltage associated with the membrane and its boundary layers would be

$$\phi'' - \phi' = -\frac{RT}{F} 2(T_-)$$

$$\left\{ 2\left[\frac{\Delta c}{c} + \frac{1}{3}\left(\frac{\Delta c}{c}\right)^3 + \frac{1}{5}\left(\frac{\Delta c}{c}\right)^5 + \cdots \right] \right\} \quad [14]$$

Equations [13] and [14] assume ideally selective membrane; if the membrane used is somewhat leaky, which it probably will be at these high concentrations, the back emf due to the membrane will be as given by Eq. [15] and [16]

$$\phi'' - \phi' = 2(T_- - \bar{T}_-) \frac{RT}{F}$$

$$\left\{ 2\left[\frac{\Delta c}{c} + \frac{1}{3}\left(\frac{\Delta c}{c}\right)^3 + \frac{1}{5}\left(\frac{\Delta c}{c}\right)^5 + \cdots \right] \right\} \quad [15]$$

$$\phi'' - \phi' = 2(T_+ - \bar{T}_+) \frac{RT}{F}$$

$$\left\{ 2\left[\frac{\Delta c}{c} + \frac{1}{3}\left(\frac{\Delta c}{c}\right)^3 + \frac{1}{5}\left(\frac{\Delta c}{c}\right)^5 + \cdots \right] \right\} \quad [16]$$

for anion and cation permeable membranes, respectively.

Up to this point, we have ignored the effects that may also occur at the electrodes. However, whatever else may be going on, the cathode is serving as a source of OH-ions and the anode is serving as a sink. Conceptually at least, we can imagine that the electrode/electrolyte interfaces are the equivalent of anion exchange membrane/solution interfaces. This means that when an anion exchange membrane is placed in a conventional silver/zinc cell, both the apparent IR drop and the observed concentration polarization will be twice as severe as when no membrane is present. We may conclude that even a low resistance anion exchange membrane may have undesirable effects when added to a high rate alkaline battery unless $T_- \simeq T_-$ under the expected conditions of use.[4] On the other hand, if the membrane can be made to replace the normal electrolyte entirely, the highest possible selectivity is desirable as this will tend to eliminate polarization effects at the electrode/electrolyte interfaces.

Manuscript received June 15, 1965; revised manuscript received Sept. 13, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

[4] If T_- is $\lesssim 0.5$, it is reasonable to place a cation permeable membrane in the battery. True, we'll always double the apparent IR drop in the cell but E_δ' and E_δ'' will just cancel the voltage due to the polarization layers at the anode and the cathode, respectively, and the net back emf in an alkaline cell containing an ideally selective cation permeable membrane will be the sum of the concentration potentials attributable to transferring ions (*a*) across the membrane/solution boundaries and (*b*) across the electrode/solution boundaries. Either of these processes in half the total and the initial back emf is

$$2E_{m\phi} = -2\frac{RT}{F} \ln \frac{c + \Delta c}{c - \Delta c}$$

$$= -2\frac{RT}{F}\left\{ 2\left[\frac{\Delta c}{c} + \frac{1}{3}\left(\frac{\Delta c}{c}\right)^3 + \frac{1}{5}\left(\frac{\Delta c}{c}\right)^5 + \cdots \right] \right\} \quad [17]$$

Lithium-Chlorine Battery

D. A. J. Swinkels

Allison Division, General Motors Corporation, Indianapolis, Indiana

ABSTRACT

Requirements for a high energy density, high power density electrochemical energy conversion device have led to the study of a lithium-chlorine battery. The system operates at 650°C using molten LiCl electrolyte. Several cells have been assembled and measurements of the open-circuit voltage, electrode polarization and coulombic efficiency are reported. The chlorine electrode, made of porous carbon or graphite, was found to be the main source of polarization. Limiting currents were determined and these have been compared with theoretical estimates based on a model for the porous electrode. The model differs fundamentally from those used with aqueous electrolytes since fused LiCl does not wet graphite, and hence little or no penetration of electrolyte into the pores occurs.

Electrochemical couples of high energy capacity (>500 whr/lb) capable of operating at high power densities (>5 w/cm²) offer many possibilities for obtaining light energy storage devices. The Li-Cl_2 system using molten LiCl as the electrolyte is one of the most promising systems (1) and is currently being investigated (2).

The system consists of a molten Li-electrode, molten LiCl electrolyte, and a porous carbon or graphite chlorine electrode and operates at about 650°C. The overall cell reaction is simply

$$\mathrm{Li} + \tfrac{1}{2}\mathrm{Cl_2} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} \mathrm{LiCl} \qquad [1]$$

At 650°C the open-circuit voltage is 3.467v, which leads to a theoretical energy capacity for the reactants of 990 whr/lb. The energy capacity which can actually be obtained depends on the polarization of the electrodes and the IR-drop in the electrolyte under the chosen operating conditions, as well as on the weight of containers and cell components. The open-circuit and the electrode polarization of this system have therefore been studied in detail.

Open-Circuit Voltage

The O.C.V. of the Li-Cl_2 system was measured from the melting point of LiCl to about 850°C at a pressure of 1 atm. The LiCl used for these experiments was purified by the Anderson Physical Laboratories using the method of Laitinen *et al.* (3). The melting point was determined by measuring cooling curves and extrapolating the linear sections. Some supercooling was observed in each case. Six cooling curves were determined using five different calibrated thermocouples, giving a mp of 608° ± 1°C, which compares well with the range of values found in the literature: 606°-610°C (4-8). Three sets of O.C.V. data were taken in an experimental arrangement shown in Fig. 1. The cell consisted of a porous carbon chlorine electrode dipped in molten LiCl. A quartz tube around the carbon electrode restricted the chlorine flow to this part of the cell to avoid corrosion of the metal outer container. The LiCl was contained in a slightly porous (porosity ≈ 15%) beryllia crucible, which served to separate mechanically the LiCl from the lithium without causing electrical separation. The whole assembly was placed in a cylindrical heater. Two thermocouples, one in the lithium and one close to the chlorine electrode, are placed in the cell to insure uniform temperature throughout the cell. It was found that an auxiliary heater was required near the chlorine electrode to compensate for heat lost by thermal conduction through the graphite electrode. The current through this auxiliary heater was increased until the two thermocouples showed the same temperature. All voltages were read to 0.1 mv using a Keithley 660 d-c differential voltmeter. A total of 132 points were determined giving

$$E = 3.4906 - 0.64 \times 10^{-4}\,(t-608)\,\text{volt} \qquad [2]$$

with a standard error of ± 5.4 mv.

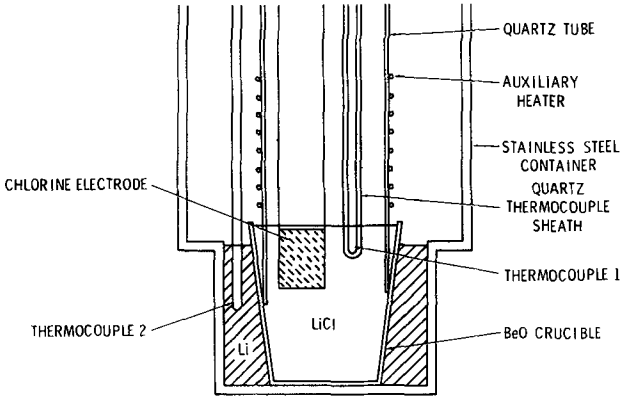

Fig. 1. Li-Cl_2 open-circuit voltage cell

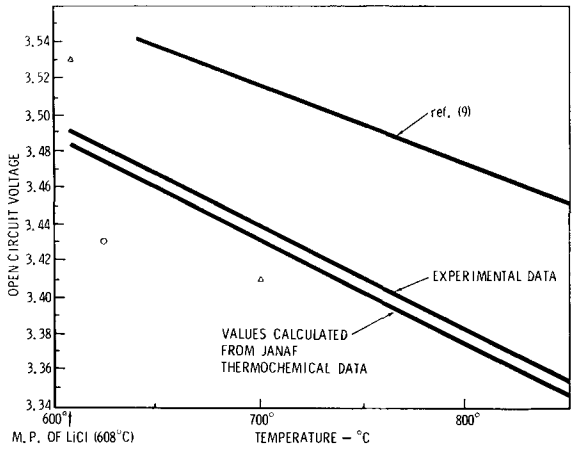

Fig. 2. Li-Cl_2 open-circuit voltage: △, ref. (2); ○, ref. (11)

This line is shown in Fig. 2 together with the O.C.V. calculated by Hamer *et al.* (9) and those calculated here from the free energy data given in a more recent compilation and evaluation of thermodynamic data known as the JANAF Thermochemical Tables (10). Some O.C.V. data reported by Werth *et al.* (2) and LiCl decomposition potentials given by Delimarski are also included (11). Taking only the uncertainty in the standard heat of formation of LiCl (c) at 25°C given in the JANAF tables then a standard error of ±12 mv results for the calculated O.C.V. line. Since the separation between the calculated and experimental lines is only 7 mv the two are in essential agreement.

Lithium Electrode

The exchange current density for metal electrodes in fused salts is generally high (12), and hence no polarization is expected at the Li/LiCl electrode. Constant current charge and discharge pulses of up to 40 amp/cm² were passed between two Li electrodes at 650° ± 5°C in the cell shown in Fig. 3. The cell consisted of a stainless steel outer container and a dense alumina crucible to contain the electrolyte. A chlorine electrode with a quartz sheath and two lithium electrodes were placed in the electrolyte. Each Li electrode consisted of a BeO tube with a cross-sectional area of 0.7 cm² with a stainless steel rod to make contact to the lithium and a thermocouple to measure the temperature of the actual electrode-electrolyte interface.

The experimental procedure here consisted of heating the cell components to 700°C on the day before a run was made, cooling and storing them overnight under vacuum. The cell was then assembled in a dry box, and pure dry LiCl was placed in the cell. After heating to 650°C to melt the LiCl, Li was formed on both Li electrodes by electrolysis against the carbon electrode. The experiment then consisted of charging Li back and forth between two Li electrodes using the chlorine electrode as a reference electrode. The voltage between each Li electrode and a Cl_2 reference electrode was observed on an oscilloscope 0.1 sec after switching on the current. Since the rise-time of the power supply used was about 50 μsec any activation polarization which was present could not be separated from the IR-drop between the reference and working electrodes. Since total cell resistances were typically 0.3 ohm, I^2R heating caused significant temperature changes at times greater than 1 sec (10°C/sec were observed). The current voltage relationship was found to be linear between cathodic and anodic current densities up to 40 amp/cm² (Fig. 4). Since activation polarization is nonlinear beyond about 100 mv most of the observed polarization must be due to the IR-drop and an exchange current density of at least 10 amp/cm² is indicated. On one occasion the amount of Li charged into the two Li electrodes was accurately measured (10 amp for 48 min), and a set of charge and discharge data was obtained. The cell was then left overnight with a slow flow of Cl_2 through the graphite electrode. Next morning, 23 hr after charging, the cell was discharged at a rate of 6 amp for 75.3 min. This corresponds to an over-all coulombic efficiency of 94%. The electrodes were then charged again at 10 amp for 48 min and immediately discharged at 6 amp for 77.3 min which corresponds to an over-all coulombic efficiency of 96.6%. Thus the Li/LiCl electrode shows negligible polarization at current densities up to 40 amp/cm², while the coulombic efficiency in the geometry used here approaches 100%. At closer electrode spacings coulombic efficiencies may well be less due to the solubility of both Li and Cl_2 in LiCl (13-15).

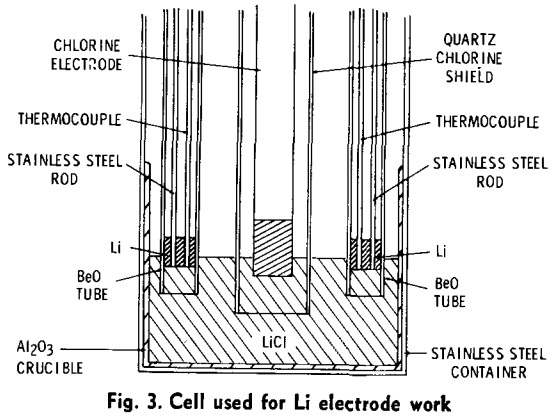

Fig. 3. Cell used for Li electrode work

Chlorine Electrode

The chlorine electrode consists of a porous carbon or graphite plug screwed onto a dense graphite feed tube which also serves as the current lead. The experimental cell used as well as the parts of one electrode are shown in Fig. 5. The cell consists of a quartz envelope into which three identical Cl_2 electrodes are placed. Cl_2 is fed to two of these (cathode and reference electrode) while a thermocouple is placed inside the anode. The cathode has a quartz sheath around it so that only the face of the porous plug is exposed to the electrolyte, thus giving a known electrode area. The essential difference between this electrode and many other porous fuel cell electrodes is the fact that LiCl does not wet the electrode. Hence the meniscus type of electrode geometry described by Will (16) cannot form in this electrode.

The over-all process at the Cl_2 electrode can still be divided into the following steps:

1. Flow of Cl_2 gas through the porous plug.
2. Dissolution of Cl_2 at the gas-liquid interface.
3. Diffusion of dissolved Cl_2 to the carbon-LiCl interface.
4. Dissociation and charge transfer.
5. Migration of Cl^- into the bulk electrolyte.

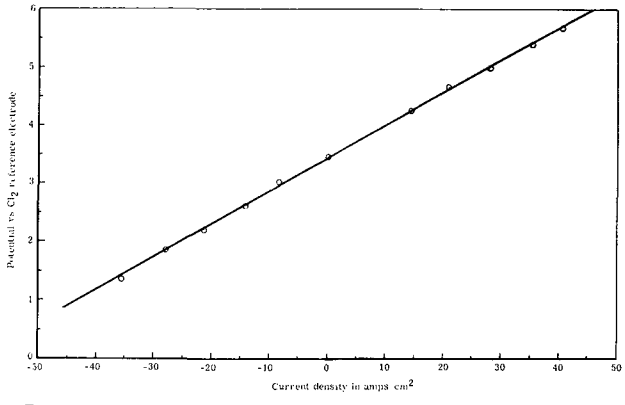

Fig. 4. Potential of a lithium electrode vs. a Cl_2 reference electrode in LiCl.

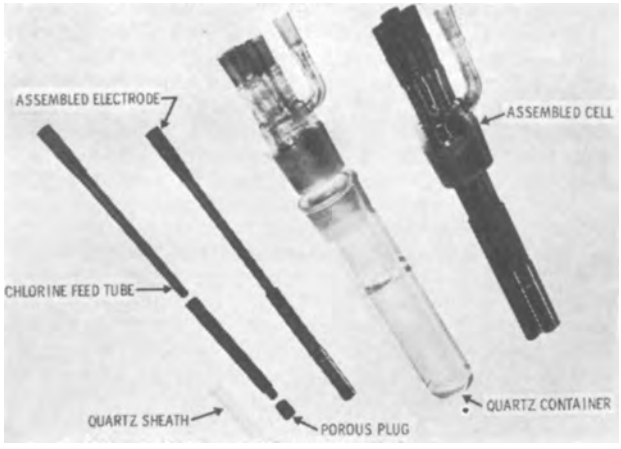

Fig. 5. Cell components for Cl_2 electrode work

The diffusion problem for a nonwetted pore (*i.e.*, step 3) has been treated by Austin *et al.* (17), who calculated the limiting current for both flooded and nonflooded pores for various boundary conditions at the gas-liquid interface. The solution in all cases is of the form

$$i_L = \frac{AnFDC_o}{r} \qquad [3]$$

where i_L is the limiting current density in amp/cm^2 of pore ends; A is a constant depending on the boundary condition assumed at the gas-liquid interface. A varies from $\approx$ 1.5 to 12 and a value of 8 has been used here; n is the number of electrons per molecule of Cl_2 = 2; **F** Faraday = 96,500 coulombs/mole; D the diffusion coefficient of Cl_2 in LiCl $\approx$ 4 x 10^{-5} cm^2/sec; C_o = equilibrium solubility of Cl_2 in LiCl = KP_2 where K = Henry's law constant; r the pore radius (cm); and P_2 chlorine pressure at the gas-liquid interface.

The diffusion coefficient of Cl_2 in LiCl at 650°C is estimated from measured diffusion coefficients of Cl^- in alkali halides (18, 19) by allowing for the larger size of the Cl_2 molecule and the lower temperature.

Von Wartenberg (14) measured the solubility of Cl_2 at 1 atm in LiCl at 620±5°C giving a Henry's law constant of 1.48 (±0.27) x 10^{-6} moles cm^{-3} atm^{-1}. Recent work in this laboratory indicates a somewhat lower solubility (15). Hence at 650°C K = 10^{-6} moles cm^{-3} atm^{-1} has been used here.

The fraction of the electrode surface made up of pore ends is equal to the porosity ψ. Hence

$$i_L = \frac{AnFDKP_2\psi}{r} \qquad [4]$$

Steps 2 and 4 above are assumed to be fast and hence essentially at equilibrium. Step 5 is the ionic conductivity of LiCl which at 650°C is 5.9 ohm^{-1}cm^{-1} (20). This leaves step 1 as the other possible rate-determining step.

For a single straight pore of length L with a circular cross section of radius r both viscous flow (Poiseuille flow) and molecular streaming (Knudsen flow) are observed (21). We have

$$Q = \pi r^2 \frac{\Delta P}{P}\left\{ = \frac{1.013 \times 10^6 r^2 (P_1 + P_2)}{16\eta L} + \frac{4\delta}{3}\sqrt{\frac{2RT}{\pi M}}\frac{r}{L}\right\} \qquad [5]$$

where Q is the flow in cc/sec at pressure P and temperature T (°K) through a single pore, P_1 the entrance pressure (atm), P_2 the exit pressure (atm), ΔP = $P_1 - P_2$, L is the length of pore = τt where t is thickness of the electrode, τ the tortuosity of the pores, η the gas viscosity (poise), m molecular weight = 70.9 g/mole, R = 8.317 x 10^7 erg/°mole, and δ = constant = 0.9.

Table I. Gas viscosity parameters

Gas	C	T_o, °K	η_o
Cl_2	325	273	1.23 × 10^{-4} poise
N_2	110	273	1.67 × 10^{-4} poise
He	70	298	2.0 × 10^{-4} poise

The number of pores per unit area is $\psi/\pi r^2$ so that the flow per square centimeter of electrode is $\psi Q/\pi r^2$. Winsauer *et al.* (22) measured the tortuosity (τ) for a number of sands with porosities in the range 0.06 < ψ < 0.4 and found the empirical relationship

$$\tau = 0.765\,\psi^{-0.65} \qquad [6]$$

This relationship has been used here to predict the flow of gas through porous graphite plugs, which was compared with experiment using three different gases at two different temperatures. The viscosity of the gases was calculated using the Sutherland equation

$$\eta = \eta_o\left(\frac{T_o + C}{T + C}\right)\left(\frac{T}{T_o}\right)^{3/2} \qquad [7]$$

The fit of experimental viscosity data to this equation, using the values of the parameters given in Table I, was very good. However experimental viscosity data for Cl_2 extend only to 146°C. Hence a large extrapolation is involved, and the purpose of these flow measurements was to check both the validity of this long extrapolation as well as the applicability of Winsauer's empirical relationship (Eq. [6]). The porosity and pore size distribution of the graphites used were measured using a mercury porosimeter. The actual pore size distribution was then approximated by a step function as shown in Fig. 6. To measure the flow of gases through porous graphite, plugs of the desired materials were sealed in Pyrex tubes by collapsing the Pyrex around the plugs under vacuum. The preheated gases were then forced through the plugs. The pressure difference, ΔP, across the plug was measured with a mercury U-tube manometer while the flow rate was measured after cooling the gas to room temperature by timing the movement of a soap film in a burette. A typical comparison of experimental and calculated flows is shown in Fig. 7. Similar agreement was obtained on other porous graphites and using other gases (He, N_2). Hence the use of Eq. [6] for the tortuosity and Eq. [7] for the viscosity of Cl_2 appears justified.

Multiplying Eq. [5] by (nFP/T) · (273/22,415) changes Q to amp/cm^2. This assumes ideal gas behavior for chlorine, which is necessary at the higher temperatures where no density measurements have been made for Cl_2 gas. The assumption is justified since at 0°C the ideal gas density of Cl_2 differs from the measured density by less than 2.5%.

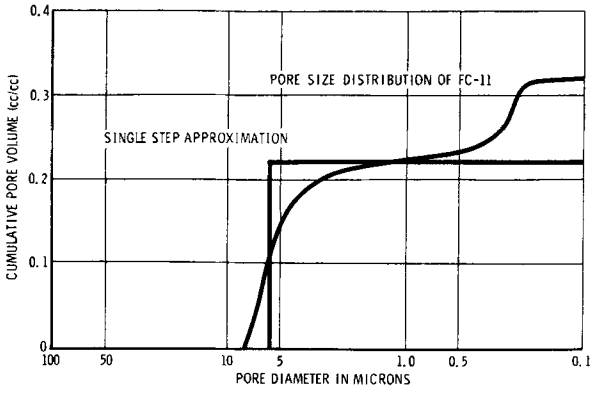

Fig. 6. Pore size distribution of FC-11

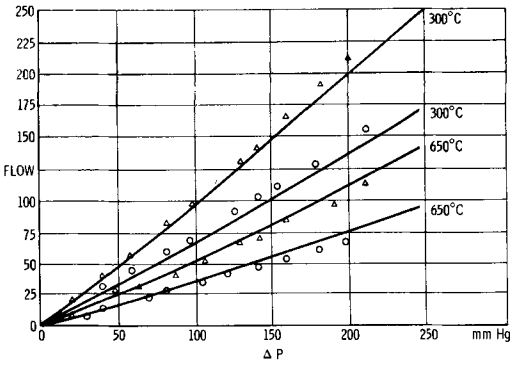

Fig. 7. Comparison of theoretical and experimental flow of N_2 through FC-11 plugs. Area of plugs, 2.8 cm^2; ○, thickness = 1.06 cm; △, thickness = 0.73 cm.

Hence

$$i_{flow} = \frac{nFP}{T} \cdot \frac{273}{22{,}415} \cdot \frac{\psi}{\pi r^2} \cdot Q \text{ amp/cm}^2 \qquad [8]$$

Converting to d = diameter in microns

$$i_{flow} = \frac{273}{T} \cdot \frac{nF\Delta P\psi}{22{,}415t\tau} \left\{ \frac{1.013d^2 (P_1 + P_2)}{6400\,\eta} + \frac{2\delta d}{3\times10^4} \sqrt{\frac{2RT}{\pi M}} \right\} \qquad [9]$$

For a dead-ended electrode, *i.e.*, one through which no excess chlorine flows, i_{flow} must equal the actual current passed through the electrode.

At the limiting current we can therefore equate Eq. [4] and [9]. Hence, for given values of all the external variables (T, P, ψ, d, t, τ) we can solve for P_2 and hence calculate i_L. This has been done for a hypothetical carbon with the following characteristics: ψ = 0.3; t = 0.5 cm; $\tau = 0.765\ \psi^{-0.65} = 1.67$; T = 650°C = 923°F. The results are shown in Fig. 8.

The curves of i_L *vs.* pore diameter all show a clear maximum. To the left of the maximum the current is limited by the flow of gas through the porous material while to the right of the maximum the diffusion of dissolved Cl_2 through the electrolyte is the main limiting step.

Using Eq. [4] and [9] limiting currents have been calculated for several commercially available porous carbons. These commercial materials generally do not have uniform size pores but rather a range of pore sizes.

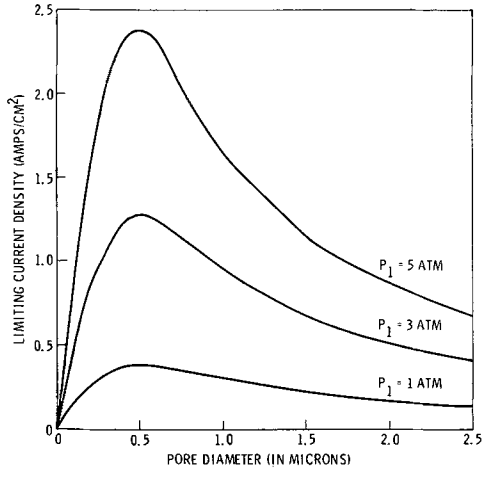

Fig. 8. Calculated limiting current according to Eq. [4] and [9]. Temperature, 650°C; porosity, 30%; electrode thickness, 0.5 cm; P_1, chlorine pressure.

The limiting current was therefore calculated in two ways. First, the pore size distribution for each material was approximated by a single step-function at the median pore diameter. The limiting currents so calculated are found to be low compared with the experimental data (Table II). A better approximation to the pore size distribution is obtained by using several steps and summing the flow and the diffusion current (Eq. [4] and [9]) over all the steps. The steps at large diameters contribute most to the total flow while the steps at smaller diameters contribute more to the diffusion current. With the exception of FC-1 the limiting currents calculated in this way are found to agree well with experimental data. This second method of calculation is more realistic since most of the flow in the bulk of the porous body no doubt occurs through the larger pores, while at the carbon-LiCl interface the small pores are the most active ones. This also suggests the use of a bi-porous carbon electrode consisting of say 0.5 cm of material with pores in the 10-20μ range with a thin surface layer (say 0.01 cm) of much finer pores ($\approx$ 0.05μ). In the multistep approximation it is necessary to limit the range of pores considered. If several 1 mm holes were drilled through a porous electrode and these holes were then treated as a step in the pore size distribution one would obviously obtain erroneous results. In this work only pores from 10 to 0.05μ were considered. Actually the only materials affected by setting these somewhat arbitrary limits were FC-13 and FC-50 both of which have a considerable number of pores smaller than 0.05μ. However, when these smaller pores are included the computed values of i_L become much too high.

Conclusion

The open-circuit voltage and electrode polarization of the Li-Cl_2 system using fused LiCl electrolyte have been investigated. Good agreement was obtained between the measured O.C.V. and those calculated from available thermodynamic data. The main source of polarization was found to be the mass transport of Cl_2 at the porous graphite electrode, either in the gas phase or in the electrolyte depending on the size of the pores. The porous electrode in this system differs in a fundamental way from porous electrodes in aqueous electrolytes in that molten LiCl does not wet graphite. Hence the thin film region at the top of the meniscus, which is of primary importance in the case of aqueous electrolytes does not exist in this electrode. A quantitative model for the nonwetted porous electrode was described and tested, and fair agreement with experiment was observed. The limiting currents found for dead-ended electrodes (Table II) appear disappointingly low in terms of obtaining high power densities. However the mass transport can be improved in a number of ways, *e.g.*, by increasing the system pressure to increase the solubility of Cl_2 in LiCl or by

Table II. Experimental and computed values of the limiting current of the Cl_2 electrode in LiCl at 650°C for various carbons

bubbling through excess Cl_2. The stirring caused by the growing bubbles at the electrode surface improves the mass transport sufficiently so that current densities of 3 amp/cm^2 can be obtained with only 0.3v of concentration polarization.

Complete power cells have been assembled using a porous electrode with excess Cl_2 flow. In these cells power densities of 6 w/cm^2 have been obtained (23). Further improvements in the performance of the porous electrode can come from suitable choice of pore size distribution and by increasing the system pressure so as to increase the chlorine solubility.

Manuscript received June 16, 1965; revised manuscript received Sept. 17, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Anodic Oxidation of the Basic Sulfates of Lead

Jeanne Burbank

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

$PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and $4PbO \cdot PbSO_4$ were prepared by reacting PbO and dilute H_2SO_4. The crystalline phases were identified by x-ray diffraction patterns, and electron microscope examination showed all three to be prismatic needles, The three basic sulfates were oxidized anodically in dilute sulfuric acid, and x-ray diffraction showed that each transformed to βPbO_2. The pellet made from $4PbO \cdot PbSO_4$ was mechanically strong, and the transformation to PbO_2 was largely metasomatic after the original crystals of the basic sulfate. The three anodic preparations were examined in the electron microscope and showed the presence of prismatic and nodular particles of PbO_2.

Studies on the lead acid battery have long been of interest to this Laboratory owing to the continued importance of this cell in submarine service. In recent years the so-called "lead-calcium" cell has replaced the conventional antimonial lead cell on the nuclear powered ships where the batteries were installed in float service. This change in cell type focused attention on the positive plate because, shortly after installation, the lead calcium cells began to fail by softening and disintegration of the positive active material. This loss of strength and electrical continuity in the positive mass was attributed to an unsuitable crystal morphology. Other simultaneous investigations revealed that mechanical strength and battery capacity were maintained when the active material paste was knit together by prismatic crystals of PbO_2 or $PbSO_4$ (1, 2). Because $PbSO_4$ is a discharge product in the plates, it is thermodynamically unstable in a float installation, and in order to retain its presence in the positive plates they must be carried in a partially discharged condition, and continuous float becomes impossible. In addition, fully charged batteries are almost universally desired. On the other hand, it is not known how the prismatic crystals of PbO_2 are produced in certain commercial battery pastes. Studies currently under way at this Laboratory are directed toward analysis of the factors affecting the structure of the positive active materials.

Battery plates are fabricated from a mixture of lead oxides, usually containing some free metallic lead, sulfuric acid, water, and miscellaneous additives. These materials are mixed for a brief period to form a stiff paste which is pressed into a metallic battery grid. The paste first stiffens or "sets," and the plates are then ready to be "cured." Curing is a combined setting and drying process during which several chemical reactions occur. Free metallic lead which may be present in finely divided form in the paste is spontaneously oxidized with the liberation of heat, and the reaction of the oxides and sulfuric acid is carried

essentially to completion. If the paste does not initially contain significant amounts of free lead, the curing process must be carried out in an oven in the presence of water vapor. After curing, the paste is a complex mixture of unreacted lead oxides, one or more basic sulfates of lead, perhaps basic carbonates and hydrated lead oxides (3-14). The cured plates are assembled into battery elements and electrochemically converted into the final active materials: PbO_2 at the positive and Pb at the negative plate.

Three basic sulfates are often encountered in the cured paste: $PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$ and $4PbO \cdot PbSO_4$. To determine whether any or all of these materials is a source of prismatic PbO_2 in the finished battery plate, each of these compounds was separately converted to PbO_2 and the morphologies of the resulting crystals examined.

Experimental

For this study the three commonly encountered basic sulfates of lead were prepared and anodized individually in dilute sulfuric acid. The starting materials and final electrochemical products were identified by x-ray diffraction and examined by electron microscopy.

$PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and $4PbO \cdot PbSO_4$ were synthesized from reagent grade PbO and the stoichiometric quantity of H_2SO_4. One mole of powdered PbO was mixed in a liter of distilled water, and the required amount of 1.250 sp gr H_2SO_4 solution was added dropwise with stirring which was continued 4 hr after addition of the acid. The mixture for the tetrabasic sulfate was heated during the initial reaction period to approximately 80°C and then allowed to cool to room temperature. The mixtures were digested for four days at room temperature, the solids collected on a filter, and air dried. The identity of the solid phases was verified by x-ray diffraction, and the crystals were examined directly in the electron microscope.

For the electrochemical formation, a thick paste of each basic sulfate and distilled water was pressed into a pellet in a frame cut from pure lead sheet 0.625 mm thick. Bibulous paper was applied to both sides of the pellet during fabrication and allowed to remain in place until the mass had dried in air at room temperature. These plates were then wrapped with filter paper held in position with rubber bands, and sheet lead electrodes of the same size were placed on both sides of each plate. These small elements were connected in series, and the pellets were anodized for 72 hr in 1.050 sp gr H_2SO_4 solution at a current density of 2.66 ma/cm^2 using the lead sheet as the counter electrodes, taking twice the apparent cross-sectional area as the surface area of the positive plates.

Following anodization, the cells were opened, and the pellets blotted dry. The formed material was analyzed by x-ray diffraction, examined in the optical microscope, and then extracted with saturated ammonium acetate solution. The residual particles of PbO_2 were again examined by x-ray diffraction and the optical microscope, and in addition they were studied with the electron microscope both directly and by means of carbon replicas (15).

Results and Discussion

The three basic sulfates prepared for this study were all prismatic crystalline materials and typical electron micrographs are shown in Fig. 1. The mono- and tribasic sulfates were colorless, and their prismatic forms are shown clearly in the electron micrographs, Fig. 1a and b. The tetrabasic lead sulfate, Fig. 1c, crystallized in rather large prisms with a pale yellow color. All three were readily and completely soluble in saturated ammonium acetate solution.

After anodization the pellet fabricated from $PbO \cdot PbSO_4$ had oxidized around the edges near the metal frame, but the center had not been converted to PbO_2 apparently owing to shrinkage accompanying the transformation which caused the center to lose contact with the edges. Upon extraction with ammonium acetate solution, the formed part of the pellet disintegrated readily, leaving a powder of PbO_2. Examination in the electron microscope showed that this was a mixture of nodular and prismatic crystals, Fig. 2.

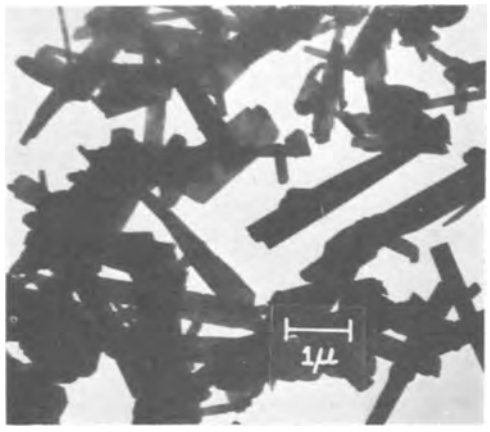

Fig. 1a. Electron micrograph of $PbO \cdot PbSO_4$ crystals. These appear to be rather thin blunted needles and were the smallest in average size of the basic sulfates prepared for this study.

Fig. 1b. Electron micrograph of $3PbO \cdot PbSO_4 \cdot H_2O$ crystals. The wide variation in size of these slender needles is apparent in this photograph. The surfaces of these crystals are covered with protrusions which may be incipient or vestiginal dendritic arms.

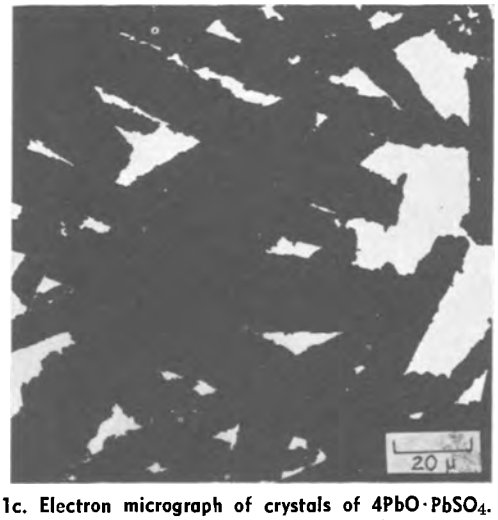

Fig. 1c. Electron micrograph of crystals of $4PbO \cdot PbSO_4$. These crystals were rather large for examination in the electron microscope, but are shown here for comparison with the other basic sulfates of lead. The surfaces of these crystals appear irregular and somewhat flokey at this magnification.

Fig. 2. Electron micrographs of carbon replicas of PbO_2 particles formed by anodization of $PbO \cdot PbSO_4$. (a) A mixture of nondescript and prismatic particles.

Fig. 2b. A cluster of small prismatic crystals

The anodized pellet made from $3PbO \cdot PbSO_4 \cdot H_2O$ had also formed around the edges near the metal frame, and shrinkage had left a smaller central area unformed than in the case of $PbO \cdot PbSO_4$. The formed mass was readily disintegrated into small particles on extraction with saturated ammonium acetate solution. Examination in the electron microscope showed again the presence of nodular and small prismatic crystals of PbO_2, Fig. 3.

The pellet fabricated from $4PbO \cdot PbSO_4$ appeared visually to be totally converted to PbO_2 by the anodic oxidation and was hard, mechanically strong, and well bonded to the metallic lead frame. Optical examination showed that the original crystal shapes of the basic sulfate had been retained intact during the oxidation. This pellet was extracted for several weeks with saturated ammonium acetate solution, and some fine particles were released from the mass, but the major portion of the pellet, comprising the distinct crystal forms related to the original $4PbO \cdot PbSO_4$ crystals, remained intact. Electron microscope examination of crystals obtained from this pellet showed that the fine particles were a mixture of nodular and prismatic forms, and that the surfaces of the large particles were very rough and irregular, Fig. 4.

X-ray diffraction analysis showed that all three basic sulfates had been converted to βPbO_2 by the electrolytic oxidation, in agreement with the earlier findings of Ikari, Yoshizawa, and Okada (10). As reported by these authors, it was also observed in this study that the pellet formed from $4PbO \cdot PbSO_4$ contained some residual unreacted material even though it appeared to be totally formed. This residue was readily extracted with saturated ammonium acetate solution so that subsequent x-ray diffraction patterns taken from the pellet showed only the presence of βPbO_2. It is considered that the retention of the crystal forms and pellet strength after extraction of all $4PbO \cdot PbSO_4$ detectable by x-ray diffraction shows that the prismatic forms of the large crystals of the basic sulfate are in fact retained by the PbO_2 and are not artifacts produced by a shallow conversion on the surface of the original basic sulfate crystals.

The conversion of one material into another by simultaneous addition and subtraction of matter, but without change in external form is called metasomatism or replacement by geologists (16-18). Petrified wood is one familiar and interesting example of metasomatism in which the wood structure is replaced by inorganic crystalline rock which retains the external form of the original tree trunk. The term metasomatism is used in this discussion because it so aptly describes the processes of charging battery pastes to form PbO_2 *in situ* within the original volume of the paste, and particularly the conversion of $4PbO \cdot PbSO_4$ to PbO_2. Electrochemical action has been thought to play a part in the formation of some geological deposits and in certain metasomatic transformations in the earth's crust, particularly when high temperatures and pressures were not active during a metamorphosis (19-22).

There is usually only a minimal volume change between host and metasome, and Table I lists the volume changes expected during formation of βPbO_2 from certain compounds likely to be present in the unformed active material of the lead acid cell. It is seen that free lead and PbO would be expected to give rise to a larger volume of PbO_2 than they themselves occupy, while the normal and basic sulfates of lead and Pb_3O_4 could produce shrinkage in volume. Thus a balance of these paste materials in the cured plate can result in zero change in total volume during electrochemical conversion to PbO_2. The pore structure does vary in battery plates depending on the relative amounts of oxide and acid used in fabrication (measured as paste density in the trade), and at least one study has shown an over-all expansion of the paste on formation (8, 23).

On the other hand, the large tetrabasic lead sulfate crystals have been shown in this study to transform by electrochemical metasomatic replacement, not accompanied by the expected shrinkage in volume. For every five molecules of PbO_2 formed from $4PbO \cdot PbSO_4$ only one sulfate ion need be removed from the body of the crystal with the simultaneous addition of six oxygen atoms as indicated by the reaction

$$5PbO_2 + 12H^+ + SO_4^= + 10e = 4PbO \cdot PbSO_4 + 6H_2O$$
$$E^* = 1.196 - 0.0709\,pH + 0.0059 \log a_{SO_4}$$

The volume change indicated in Table I for this compound may be eliminated if lead ions present in the electrolyte are electrodeposited within the volume occupied by the original crystals present in the unconverted paste mass. The initiation of the transformation may be the deposition of tetravalent lead ions at active sites on the surface of an original crystal, and transformation may then spread readily throughout the body of the crystal from this surface initiation by a diffusion mechanism across the interphase boundary. As indicated in Table I, there would be a 15% decrease in volume on conversion of a crystal of $4PbO \cdot PbSO_4$ to an equivalent amount of PbO_2. This may result in

* Calculated by assuming the standard free energy of formation of $4PbO \cdot PbSO_4$ is -374.88 kcal based on the free energies of formation of PbO and $PbSO_4$.

Table I. Volume changes during formation of βPbO_2

Compound	Molecular weight	Density	Gram molecular volume, cc	Moles PbO_2 formed per mole of compound	ΔV,* cc	% ΔV per Pb atom
Pb	207.21	11.341	18.28	1	6.56	35.87

** A very approximate value obtained from the material synthesized for this study.

porosity within the metasome, but if for example each molecule of $4PbO \cdot PbSO_4$ were replaced by six molecules of PbO_2, there would be a volume increase of 1%. The volume of the tetrabasic crystal could be replaced exactly by the addition of an appropriate number of lead ions from solution: approximately 9.083 for every 50 in the crystal. The replacement of one molecule of $4PbO \cdot PbSO_4 (Pb_5O_8S)$ with $5PbO_2 (Pb_5O_{10})$ would result in no change in weight. Taken on the basis of either the volume or the weight remaining constant, this conversion defines a reference state for a thermodynamic system as discussed by Thompson for metasomatic processes (24). This same mechanism could metasomatically replace any of the original basic sulfate crystals in the paste; however, a greater mass transfer would be involved in the conversion of the others.

The strength of the pellet of PbO_2 formed from $4PbO \cdot PbSO_4$ may be attributed to the interlocking of the large metasomatic crystals. This suggests that a suitable distribution of $4PbO \cdot PbSO_4$ crystals in a cured paste can impart strength to a fully formed plate by this same mechanism. Simon and Jones have shown that in certain battery plates there exists a network of hard PbO_2 that is continuous throughout the paste and suggested that this originated from a network of one of the basic sulfate crystals initially present in the unformed plates (25). It was further suggested that this hard network might be αPbO_2; however, only βPbO_2 was observed by x-ray diffraction as the anodic product from all three basic sulfates under the conditions used in this study. On the other hand, metasomes are frequently particularly hard and dense owing to their diffusional growth mechanism which somewhat resembles a zone refining process. On the basis of the results of this study it seems likely that the network described by Simon and Jones arises from tetrabasic lead sulfate crystallized in this pattern in the unformed plate.

In earlier investigations of the active material pastes of certain lead calcium batteries the small particles were consistently prismatic (1). However, none of the three basic sulfates examined in this study gave rise to prismatic crystals to such an extent: the fine-particle material was a mixture of nodular and prismatic crystals in all three instances. On the other hand, the crystals of $4PbO \cdot PbSO_4$ prepared for this study were of a fairly uniform and large size, and it is possible that fine-particle prismatic PbO_2 arises from small crystals of this same material when these are present in unformed battery plates.

Other mechanisms can give rise to prismatic PbO_2. For example it has been shown that antimony in the grid alloy leads to prismatic growth of PbO_2 (26), some appeared in the anodization of $PbO \cdot PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ in this study, and hydrothermal recrystallization also produces prismatic crystals (27). It is anticipated that future investigations of positive active materials will lead to further understanding and result in optimization of the physical structures required to give maximum plate durability thus extending battery life.

Manuscript received Aug. 16, 1965. This paper was presented at the Buffalo Meeting, Oct. 10-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Reaction of Flowing Steam with Refractory Metals

II. Rhenium (850°-1700°C)

Martin Kilpatrick[1] and Stanley K. Lott

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

When rhenium reacts with steam at 1 atm pressure, the rate of evolution of hydrogen is constant with time, and the metal remains bright with no evidence of a coating. The apparent energy of activation for the reaction is 30 kcal/mole, and the enthalpy of sublimation of Re_2O_7 is 33.5 kcal/mole, which suggests that the rate-determining step is the sublimation of the oxide.

Although the oxidation of rhenium has been studied in air (1-3), no study of the reaction of steam with rhenium has been reported. The oxide formed (Re_2O_7) melts at 296° and boils at 362°C under 1 atm pressure, and the reaction with oxygen takes place uniformly over the surface rather than preferentially at the grain boundaries. This paper reports the oxidation of rhenium with flowing steam for the temperature 850°-1700°C.

Experimental

The method was based on passing steam over an inductively heated specimen of metal, passing the products through a water-cooled condenser to separate the aqueous solution from the gas, and collecting the gas evolved in an eudiometer (4).

The apparatus, as shown in Fig. 1, consisted of an electrically heated 3-liter steam boiler (A) connected to a quartz tube (B) by a ball joint. The metal cylinder (C) was mounted on a two-hole alumina rod (D) which carried the Pt/Pt, 10% Rh thermocouple wires. The bottom of the quartz tube fitted into a female ball joint on a brass cup (F) which was connected to a copper tube leading to the gas burette (G). A copper spiral (H) was soldered to the copper tube to carry cooling water to condense the steam. The induction coil (E) was connected to a Reeve Electronic Generator.

To carry out an experiment, the polished and weighed specimen was mounted at (C), the boiler (A) turned on, and the apparatus steamed out to remove air. The experiment was started by turning on the induction heater and rapidly bringing the specimen to the desired temperature, as indicated by the millivolt reading on the recorder chart, and following the evolution of gas with time. At the end of the experiment, the specimen was removed, washed, and weighed, and the gas sample analyzed by mass spectrograph.

The rhenium was obtained from the Rembar Company as 5 to 10 mm diameter rods with a quoted purity of 99.9% The product metal had been sintered in hydrogen at 2700°C, compacted, cold swaged to finish size by 10% reduction per pass, and process annealed in hydrogen-nitrogen. The final annealing was carried out at 1650°C in a hydrogen atmosphere. Spectrographic analysis at Argonne showed only a faint trace of calcium (<0.0001%) and a trace of aluminum (<0.001%). The specimens were cut from the rods in 1 cm lengths and 1/10 and 3/32 in. holes drilled by Elox method for mounting the samples in the field of the induction furnace.

Flow rates were determined from the weight of the condensate, and the size of the annular opening as illustrated in Fig. 2.

Results

The rhenium at the end of a run was bright but examination of the surface showed many small crystals of metal randomly oriented. A graph (Fig. 3) of the hydrogen evolved *vs.* time was linear, and a comparison of the volume of hydrogen evolved with the weight loss of the specimen gave 3.41 ± 0.15 moles of hydro-

gen per gram atom of rhenium reacted. The stoichiometric equation is thus

$$2Re(c) + 7H_2O(g) \rightarrow R_2O_7(c) + 7H_2$$

The velocity constants calculated from the hydrogen evolved and from weight loss agreed fairly well. As shown in Table I, the effect of flow rate is small. The data are plotted in Fig. 4, and the least squares equations are given in Table II. All of the data can be represented by the equation $k = 0.962 \pm 0.384 \exp \frac{-29{,}800 \pm 1{,}000}{RT}$ gram atoms of Re per cm² per min.

Discussion

The value of 30 kcal for the energy of activation may be compared with $\Delta H_{sub} = 33.5 \pm 0.1$ for rhenium heptoxide at the melting point (5). This suggests the possibility that the rate-determining step is the desorption of the oxide.

Reaction of Flowing Steam with Refractory Metals

III. Tungsten (1000°-1700°C)

Martin Kilpatrick[1] and Stanley K. Lott

Argonne National Laboratory, Argonne, Illinois

ABSTRACT

The mechanism of the reaction of tungsten with steam over the temperature range 1000°-1450° is similar to that for the reaction of molybdenum. The rate-determining step consists of the oxidation of WO_2 (s) to the volatile $WO_2(OH)_2$ and WO_3 and its polymers. Above 1450° the reaction is complicated by the formation of a liquid phase on the surface of the metal.

Although the reaction of flowing steam with tungsten is similar in some respects to the reaction with molybdenum over the temperature range concerned, there are important differences. In the first place, the oxide product is relatively less volatile than the corresponding molybdenum compound, and the presence of a liquid phase around 1450°C complicates the kinetics. In addition, two oxides $W_{20}O_{58}$ and $W_{18}O_{49}$ are formed which are less volatile and less readily oxidized to WO_3 than is WO_2. Above 1530° WO_2 disproportionates to W and $W_{18}O_{49}$ (1).

Experimental Results

The experimental method was the same as that used for molybdenum and rhenium, and the experiments were carried out in similar fashion (2, 3). The tungsten was 99.9% pure, and both the 5 and 10 mm rods showed similar trace impurities which included traces of Fe, Cr, and Mo.

The stoichiometry of the reaction was established by comparing the moles of hydrogen evolved with the gram atoms of tungsten reacted as determined by weight loss. Although this ratio was 3.02 ± 0.04, the specimen at the end of the run was seldom free of black oxide or nonadhering dark violet oxide. Filings from the surface of the specimen after a typical run near 1200°C were examined by x-ray diffraction and found to contain tungsten dioxide with $W_{20}O_{58}$ as a minor constituent, in addition to tungsten. Filings from a specimen after a run just above 1500°C were found to contain $W_{18}O_{49}$ in addition to tungsten.

[1] Professor Emeritus, Illinois Institute of Technology, Chicago, Illinois.

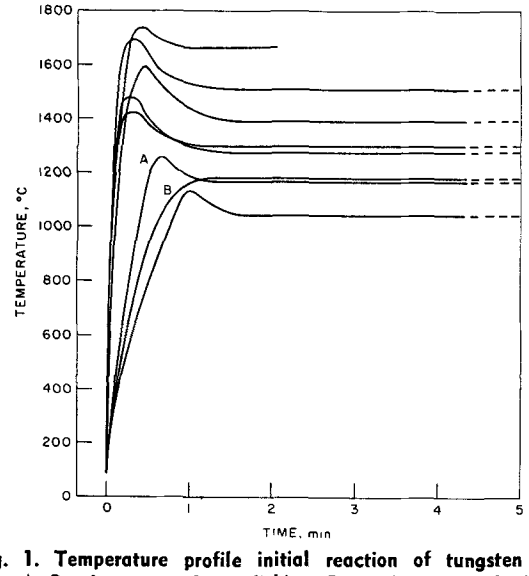

Fig. 1. Temperature profile initial reaction of tungsten with steam. A, Specimen run after polishing; B, specimen reused without removing tarnish.

As Fig. 1 indicates, there is considerable heat evolved when the polished metal initially reacts with steam, but the temperature rapidly becomes constant. When a specimen is rerun without polishing, this rise above the control temperature is absent, and the rate is the same. However, in cases where the temperature of the overshoot rises to 1500°C, with a very rapid evolution of hydrogen, when the temperature drops the evolution of gas decreases sharply. This is due to the fact that, as the molten oxide solidifies, the coating becomes impermeable to steam, and reaction does not continue normally until the temperature is raised above the melting point (1473°C).

In spite of the fact that not all of the product was converted to the volatile trioxide or its complex with water, the rate of evolution of hydrogen was constant (Fig. 2), and the velocity constants in terms of gram atoms of tungsten reacted per square centimeter per minute from the weight loss agreed well with the velocity constants calculated from hydrogen evolution. Above 1400°C, the aluminum oxide support reacted to some extent with the tungsten, and it was not always possible to remove the core and get the weight loss. In the experiments above 1400°C, the violet black oxide $W_{18}O_{49}$, flecked with the light yellow green oxide, remained as a coating on the sample and interfered with the flow pattern of the steam. The results are summarized in Fig. 3 by a plot of log k *vs.* $10^4/T$(°K). The Arrhenius equations for the two tem-

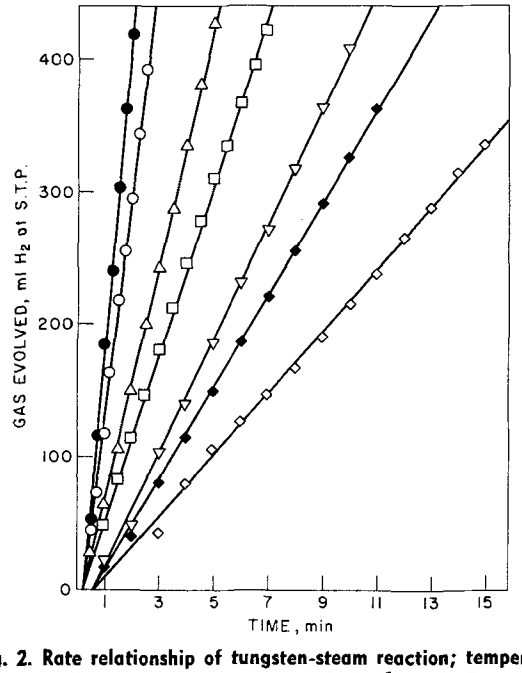

Fig. 2. Rate relationship of tungsten-steam reaction; temperature in °C, sample diameter in mm: ● 1663, 5; ○ 1505, 5; △ 1332, 10; □ 1392, 5; ▽ 1242, 10; ◆ 1217, 10; ◇ 1284, 5.

perature ranges for the velocity constants as gram atoms of tungsten reacted per square centimeter per minute are, for the temperature range 1050°-1450°C

$$k = 1.688 \pm 0.593 \exp \frac{-48{,}900 \pm 1{,}000}{RT}$$

and for the temperature range 1450°-1700°C,

$$k = 0.282 \pm 0.178 \exp \frac{-22{,}700 \pm 2{,}200}{RT}$$

The oxidation of tungsten by water vapor at 38 Torr has been reported by Farber (4) who measured the change in electrical resistance with time over the temperature range 1700°-2000°K and found a value of 14.5 kcal for the energy of activation.

Discussion

If the reaction of tungsten with steam follows the path for the reaction of molybdenum with steam outlined in a previous paper (2)

$$2H_2O(g) + W(c) \rightleftharpoons 2H_2 + WO_2(c) \qquad [1]$$

and the dioxide would then be oxidized to WO_3 and removed as a vapor of WO_3 and its polymers, or as the more volatile $WO_2(OH)_2(g)$, via the reactions

$$WO_2(c) + H_2O(g) \xrightarrow{k_3} WO_3(g) + H_2 \qquad [2]$$

$$WO_2(c) + 2H_2O(g) \xrightarrow{k_5} WO_2(OH)_2(g) + H_2 \qquad [3]$$

As in the case of molybdenum, the measured rate follows the linear law and shows that the steady state would be reached very quickly under the conditions used, and that the amount of metal stored as dioxide would be small. Assuming the dioxide to be removed via both [2] and [3] the rate constant would be

$$k = [WO_2(c)][H_2O]\{k_3 + k_5[H_2O]\} \qquad [4]$$

where $[WO_2(c)]$ represents the surface concentration of active sites.

The measured energy for the reaction of steam with tungsten over the range 1100°-1400°C is 49 kcal. It is of interest to compare this figure with the enthalpy changes accompanying reactions [2] and [3], respectively. Using the heats of formation (5) of $WO_2(c)$ and $WO_3(c)$, and the heat of sublimation of the trioxide from Glemser and Völz (6), one finds ΔH_2 at 1500°K to be 43 kcal. For the reaction

$$WO_3(c) + H_2O(g) \rightarrow WO_2(OH)_2(g) \qquad [5]$$

ΔH is ca. 40 kcal (6-8), and from this and the heats of formation ΔH_3 at 1500°K is estimated to be 41 kcal. It may also be mentioned that Battles (9) investigated the rate of volatilization of the trioxide in a flowing mixture of argon and water vapor and found the energy of activation to be 40 kcal/mole.

In a recent paper, Bartlett (10) has proposed that the reaction between oxygen and tungsten, below 2000°C, proceeds by the steps

(a) $s|W + \frac{1}{2} O_2 \rightleftharpoons s|W-O$

(b) $s|W-O + \frac{1}{2} O_2 \rightleftharpoons s|W(O)(O)$

(c) $s|W(O)(O) \rightarrow WO_2(g)$

(d) $2(s|W(O)(O)) \rightarrow WO_3(g) + s|W-O$

where $s|W-O$ indicates a covered site in a monolayer (of which there are two) of chemisorbed oxygen atoms. At low pressures, about equal amounts of WO_2 and WO_3 would form, the proportion of the latter increasing with increasing pressure of oxygen. The activation energy found by Bartlett was 42 kcal. Although there was discoloration of the tungsten rods in his experiments, he believed the surface film to have formed on cooling.

In view, however, of the results shown in Fig. 1, it appears that in the reaction of water vapor and tungsten there is an initial, rapid reaction with the bright metal, accompanied by evolution of heat. This leaves a film on the surface so that if the specimen is re-used without polishing a steady rise to control temperature occurs, with no overshoot. This phenomenon, illustrated by curves A and B in Fig. 1, was readily reproducible. The view of a thin layer of lower oxide therefore appears more tenable in the case of the reaction of water vapor with tungsten than does the scheme proposed by Bartlett for the reaction of oxygen with tungsten.

Manuscript received Nov. 20, 1964; revised manuscript received Sept. 15, 1965. This paper is based on work performed under the auspices of the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Solid-State Anodic Oxidation of Tantalum

D. M. Smyth

Research Laboratory, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

When an anodic potential is applied to a tantalum point contact to MnO_2, the current-voltage behavior is analogous to that observed during the anodic oxidation of a valve metal in an aqueous electrolyte. It is proposed that this represents a solid-state anodic oxidation whereby tantalum oxide is formed at the expense of the local oxygen content of the MnO_2, and that this process represents an important "healing" mechanism in the Ta-Ta_2O_5-MnO_2 solid electrolyte capacitor. This process requires that the conductivity of the reduced manganese oxide phase, which must be formed adjacent to the Ta_2O_5, have a finite ionic portion, and experimental support for this is described. The current efficiency of the solid-state anodization is very low and is dependent on ambient moisture. Similar behavior has been found for aluminum and niobium point anodes and with PbO_2 as the cathode.

The electrochemical formation of anodic oxide films on such metals as tantalum, niobium, and aluminum in electrolytic solutions is well known and is of considerable scientific and practical interest. In these cases the current efficiency of oxide formation may approach 100% under suitable conditions, and the ionic current which leads to oxide film growth can be expressed as

$$i_i = Ae^{BV/d} \qquad [1]$$

where i_i is the ionic current through the oxide, V is the voltage drop across the film whose thickness is d, and A and B are constants for a given experimental condition. Variations on this familiar theme have appeared in recent years. The preparation and properties of anodic oxides have been described where the source of oxide ions was a glow discharge rather than an electrolytic solution (1, 2). It has also been claimed that very thin anodic oxide films (15-20Å) can be grown when the cathode is a metal layer which has been evaporated in a poor vacuum and thus contains dissolved oxygen (1).

In recent years the solid electrolyte capacitor has become of great importance. This device is based on the Ta-Ta_2O_5-MnO_2 system and is prepared by the pyrolytic deposition of MnO_2 on anodized tantalum (3). The MnO_2 serves to maintain the highly insulating properties of the dielectric and thus replaces the electrolytic solution which acts as the cathode plate in conventional electrolytic capacitors. Publications on this device to date have been restricted largely to descriptions of the electrical behavior of completed capacitors (3-5). There have been no detailed hypotheses presented on the mechanisms by which the MnO_2 functions. In this paper, evidence will be presented which indicates that tantalum can be electrochemically oxidized by MnO_2 in a solid-state process which is analogous to the conventional aqueous anodic oxidation process. This mechanism is apparently related to the so-called "reformation" which is performed on solid electrolyte capacitors after the MnO_2 has been applied to the anodized tantalum.

Experimental

A schematic drawing of the experimental arrangement is shown in Fig. 1. The tantalum point was formed by clipping the end of 0.016 in. tantalum wire at an angle. The results did not seem to be affected by whether or not the point was then cleaned in an HNO_3-HF etch. The wire was attached to a phosphor-bronze sheet spring with Eccobond Solder 56C, a conducting epoxy produced by Emerson and Cuming, Inc., Canton, Massachusetts. The MnO_2 was produced by thermal decomposition of Fisher 50% $Mn(NO_3)_2$ solution in a Pyrex beaker. Decomposition was begun on a hot plate and, after most of the water had evaported, was completed in a muffle furnace at 350°-400°. The beaker was then broken away from the solid product, leaving a hard, smooth MnO_2 surface which had formed next to the glass. This surface was used in these experiments. The MnO_2 was affixed to a metal plate with the Eccobond Solder. The power supply was either a potentiometer-controlled battery-pack or a voltage regulated, electronic power supply, and the voltage was adjusted manually in steps. The current was measured with a Keithley Model 210 Electrometer with a decade shunt and was recorded on an Esterline-Angus Model AW Recorder. The high side of the circuit was completely shielded, and the sample jig was enclosed in a shielded box.

The tantalum dots on MnO_2 were obtained by cathodic sputtering of tantalum through a mask onto the glassy MnO_2 surface. The best results were obtained when the MnO_2 was in good thermal contact with a water-cooled block. With this arrangement and with a 2-min-on and 1-min-off cycle (controlled with a shutter), the temperature, as measured at the back side of the MnO_2, was kept below 200°. The tantalum thickness was generally about 2000Å. Electrical contact to the tantalum was made with a small drop of liquid In-Ga solder on the end of a tantalum wire.

A variety of other methods for obtaining Ta-MnO_2 area contacts were unsatisfactory. These included pressure contacts, pyrolysis of $Mn(NO_3)_2$ solutions on wires or masked areas, and electrochemical deposition by anodic oxidation of Mn^{++} solutions or by cathodic reduction of MnO_4^- solutions.

Cell emfs were measured with a Keithley Model 200B Electrometer in a completely shielded circuit.

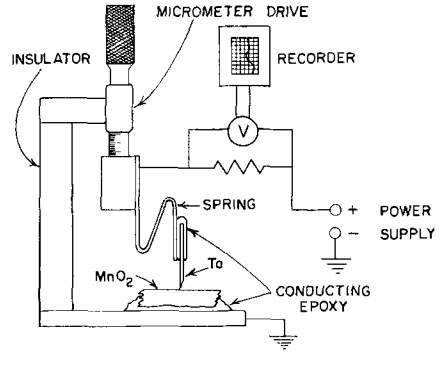

Fig. 1. Schematic diagram of point-contact experiment

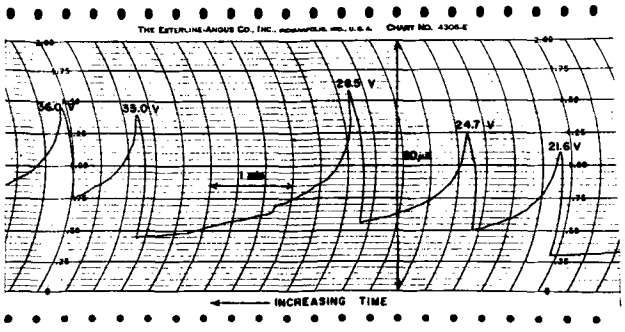

Fig. 2. Ta-MnO_2 point-contact experiment; current decay at successive constant voltages. (Note that time increases from right to left.)

Point-Contact Experiments

The behavior of the current, when the anodic potential on a tantalum point contact to MnO_2 is increased stepwise, is shown in Fig. 2. This is a photograph of a portion of the recorder trace for a typical experiment carried out in room air at room temperature. Each time the voltage is increased, the current rises immediately and then undergoes a smooth decay as the voltage is held constant. This behavior is repeated each time the voltage is increased. Each current decay at constant voltage will continue for hours as shown in Fig. 3 which has been redrawn from a similar recorder trace. (Strictly speaking, the meter reading, which is 0.8v for the full-scale reading of 80 μa, should be subtracted from the applied voltage to obtain the potential across the point contact.)

As the applied voltage is increased by approximately equal increments, the current decay becomes less and less steep; this also happens during anodic oxidation in aqueous electrolytes since the increase in oxide thickness, and hence resistance, created by the passage of a given amount of charge is a decreasing percentage of the total thickness as the oxide growth proceeds to higher anodization voltages. This decrease in the rate of current decay becomes much more pronounced in the case of these point contact experiments, however, as the applied voltage becomes larger than 50v. The beginning of the current decay becomes increasingly sluggish, and a gradual increase in current may even precede the decay. This behavior may be due to local resistive heating under the point contact which promotes the decay process. Above 80v the current decay process becomes vanishingly slow and can only be observed on recorder traces taken over several hours.

The current decay process represents a permanent and irreversible growth of resistance at the point. If a tantalum point which has been anodized on MnO_2 is moved to a new spot on the surface, the resistance created by the anodization moves with it, and further anodization proceeds from a high applied voltage without the low voltage formation observed with freshly cut points. This is not possible to verify quantitatively because of the uncertainty that the moved point is contacting the MnO_2 with exactly the same area, but the general validity is clearly apparent. An electrochemical growth of resistance is thus occurring on the metal point.

The efficiency of this solid-state, anodic oxidation depends on the presence of moisture in the ambient atmosphere. This is illustrated in Fig. 4 which summarizes an experiment carried out in a vacuum desiccator. During the course of the experiment the Ta-MnO_2 contact was alternately exposed to vacuum and to room air while the current was decaying at constant voltage. It is seen that the rate of current decay was reduced when the system was evacuated and quickly increased again when room air was admitted. If the room air was admitted through a desiccant, the increase in rate did not occur. This dependence on the presence of moisture was more striking when the entire system was baked out at 200°-300°C and placed in a sealed container with a desiccant. Under these conditions the anodization characteristics of the point contact were extremely poor.

This electrical behavior of metallic point contacts to MnO_2 is unique with valve metals with an anodic potential. In the case of a valve metal point contact to MnO_2 with a cathodic potential on the metal, or for noble metals such as platinum or rhodium with either polarity, the behavior is very different. The contact passes much higher current; there is no evidence of current decay; and when sufficient current is attained, *e.g.*, 20 ma with 5v across the point contact, the current drops abruptly and irreversibly to very low values such as 0.01 μa. Microscopic examination will then show a small crater blown in the MnO_2 and evidence of oxidation on oxidizable metal points. It is apparent that the MnO_2 has been thermally reduced to lower oxides which are insulators compared with MnO_2. This is not a surprising result since the power density under the point prior to breakdown will be of the order of 10^4 w/cm^2 if the contact area is assumed

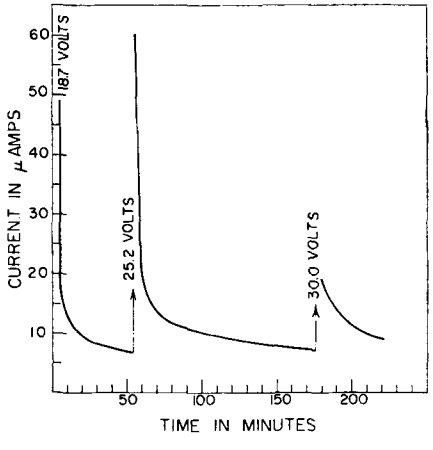

Fig. 3. Long-term current decay during Ta-MnO_2 point-contact experiment.

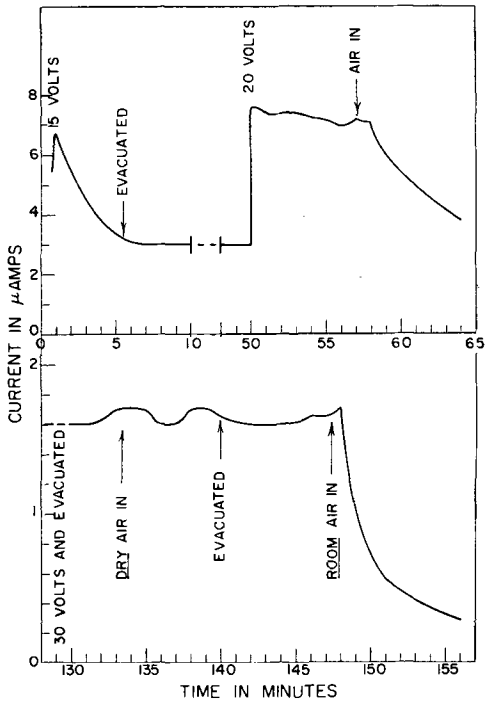

Fig. 4. Effect of ambient moisture on the solid-state anodization of Ta on MnO_2.

to be 1% of the cross-sectional area of the wire on which the point was cut.

Niobium and aluminum point contacts on MnO_2 behave very similarly, but have not been studied in great detail. All of these valve metals also give evidence of solid-state anodization on PbO_2. With the latter oxide the current level is about a decade less than is usually observed with MnO_2, and the current decay is not as smooth. No signs of anodic oxidation have been observed with CuO, NiO (doped with Li_2O), CdO, V_2O_5, and $Na_{0.7}WO_3$.

Area-Contact Experiments

The anodic oxidation of tantalum point-contacts on MnO_2 is a convenient demonstration of the basic current-voltage behavior of the system, but it has the great disadvantages of having an undefined contact area and of not being amenable to capacitance measurements. Thus numerous techniques were attempted in order to obtain an experimental contact of known and appreciable area. As previously described under Experimental, only the deposition of tantalum dots onto MnO_2 by cathodic sputtering gave satisfactory results. Several such samples were successfully anodized to the vicinity of 20v. Data from one of these are summarized in Table I. It is apparent that the general behavior is very similar to that of the point-contacts. The current decay in the case of sputtered contacts was much less dramatic since the current densities, and thus the fields, were held to a lower level (1-30 ma/cm^2 in Table I) to avoid local breakdown within the experimental area. The current efficiency of anodization is very low, 0.01-0.001% (based on the formation of 18Å of Ta_2O_5 per volt and a density for Ta_2O_5 of 8 g/cm^3). The quality of the dielectric is relatively poor as indicated by the high final current and the dissipation factor. The capacitances of such samples are substantially less than would be obtained by the conventional, aqueous anodization of tantalum to the same voltage.

Ionic Conduction in Lower Oxides of Manganese

If this phenomenon consists of the simultaneous electrochemical oxidation of the tantalum and reduction of the MnO_2, all phases between the metal and the MnO_2 must have some ionic conduction. This is obviously true for anodic oxides at high fields, but there is no comparable information available for the oxides of manganese. The following observations of battery-like behavior for the Ta-MnO_2 system give qualitative information on this point.

MnO_2 was applied to bare, porous tantalum pellets (about 3/8 in. high by 3/16 in. diameter, available surface area about 175 cm^2) by pyrolysis of a 50% aqueous solution of $Mn(NO_3)_2$. This can be accomplished with a maximum pyrolysis temperature of about 350°. At higher temperatures there is a tendency for the bare pellet to ignite and undergo catastrophic oxidation. Ta-MnO_2 samples prepared in this manner proved to be electrically inert. They exhibited erratic open-circuit voltages (OCV) of about 1 mv, and there was no current decay when an anodic potential of a few volts was applied to the tantalum. The samples were given 5-min heatings at increasing temperatures and tested electrically. After heat-treatment at some temperature between 400° and 500°, the particular temperature differing among the various samples, the electrical properties of some samples changed drastically. A stable OCV of 0.1-0.5v was observed, tantalum negative, which dropped slowly when loaded with 10^7 ohms. The voltage increased again after removal of the resistive load. There was clear evidence of current decay when an anodic potential was applied to the tantalum. The extent of decay varied from barely perceptible to a reduction of the current by half in 2 min. As in the case of the point-contact experiments, the increase of resistance corresponding to the current decay was a permanent effect. The anodic treatment was continued up to 26v in one case although very little permanent change occurred above 10v. When the anodic potential was removed, the OCV dropped steadily, changed polarity after 10-15 min, then continued to the order of tenths of a volt, tantalum negative. The observation of a stable OCV and an anodic current decay always appeared together; no sample exhibited one phenomenon without the other.

Table I. Anodization of 0.011 cm^2 Ta dot sputtered onto MnO_2 All measurements at room temperature; bridge measurements at 1000~

Anodization voltage	Initial current, μa	Anodization time, hr	Final current, μa	Parallel cap, μμf	% D.F.
0	—	—	—	5934	14.5
5.6	192	20	8	3974	9.38
7.0	68	40	13	3797	9.98
10.0	245	68	58	3554	10.6
17.0	—	~50	300	2665	8.99

There was a wide range of behavior among various samples, and some failed to exhibit anything other than electrical inertness. The above description is representative of those which did respond to heat-treatment. Once electrical activity appeared in a sample, the behavior described above could be repeated over and over.

It seems clear that the ability of the sample to undergo solid-state, anodic oxidation is accompanied by battery-like behavior. If the anodic oxidation process depends on the presence of a finite ionic contribution to the conduction of all phases between the tantalum and the MnO_2, then the basic requirements for an electrochemical cell are met: an active metal separated from an oxidizing agent by ionically conducting phases. The evidence that the observed OCV was an electrochemical emf is:

1. The polarity was correct (Ta negative).
2. The systems could deliver significant current (tenths of microamps) indefinitely.
3. The OCV rose quickly toward the original value when a resistive load was removed.
4. After extensive application of anodic biases (tantalum positive) of up to 20v, the OCV always quickly changed polarity back to that expected for an electrochemical emf.

The necessity for a thermal treatment to initiate described behavior can be compared with the initial behavior of the point-contact experiments. In the latter case there was usually no current decay at very low voltages. At some point, usually at an applied potential of about 5v, the decay began abruptly, frequently while the voltage was being increased. This may represent the need to supply sufficient resistive heating to create the required chemical situation which will allow the anodic oxidation to proceed.

In another experiment some current decay at constant voltage was observed for a tantalum point on a thin chip of Mn_2O_3. The high resistance of the Mn_2O_3 obscured the effect, but the current decreased by about 10% in 5 min at each of several successive voltage levels. This suggests that oxygen can be withdrawn electrochemically from even the Mn_2O_3 level, and that the reduced manganese oxide phase formed during the anodization process can have a lower oxygen content than Mn_2O_3.

Further experiments with electrochemical cells involved the use of specific manganese oxides as electrolytes. $Mn/Mn_2O_3/O_2$ cells made from pressed and sintered Mn_2O_3 pellets, sandwiched between metallic manganese and porous carbon electrodes, had barely perceptible emfs (0.1-1.0 mv). The d-c resistance of the Mn_2O_3 was about 30 megohms. This indicates a very small ionic contribution to the total conduction in Mn_2O_3, although such experiments must be interpreted cautiously since other manganese oxide phases may form spontaneously at the Mn-oxide and oxide-

air interfaces. Similar cells made from Mn_3O_4 pellets had no observable emf, but since the d-c resistance of the pellet was 10^{11} ohms it is dubious that the equipment was sufficiently sensitive.

Recent work by Otto on equilibria for the reactions

$$2Mn_2O_3 + O_2 \rightleftharpoons 4MnO_2 \quad [2]$$

$$4Mn_3O_4 + O_2 \rightleftharpoons 6Mn_2O_3 \quad [3]$$

gives evidence of oxide ion mobility at high temperatures in both Mn_2O_3 (6) and Mn_3O_4 (7). In the case of reaction [3], the recombination of Mn_3O_4 with O_2 at about 900° was only about five times slower than the dissociation of Mn_2O_3 at slightly higher temperatures. For reaction [2] the oxidation of Mn_2O_3 at 555° was extremely slow, but it was still detectable. In both cases the observation of a recombination reaction of finite rate implies oxide ion motion, although the results of the two oxide systems cannot be compared because of the different temperatures involved.

Discussion

All of the observations are consistent with the hypothesis that this phenomenon is a solid-state analog of the anodic oxidation of a valve metal in an aqueous electrolyte. Only typical valve metals demonstrate the effect and only when made anodic with respect to the oxide phase. The growth of resistance is permanent, and at least some of the resistance is associated with the valve metal as shown by the point-contact experiments.

The following mechanism is proposed for this solid-state anodic oxidation; Figure 5 is a cross section of such an experiment and illustrates aspects of the following discussion. At a contact between tantalum and MnO_2 there will occur a spontaneous chemical oxidation of the tantalum and reduction of the MnO_2. This will be enhanced by the local heating which will result from the passage of current when a potential is applied. Both Ta_2O_5 and reduced MnO_2 are poor conductors compared with tantalum and MnO_2 so that a voltage drop will build up across these regions. If these phases have finite ionic conductivities and, if the fields across them become sufficiently high, oxide ions will flow from the MnO_2 through the reduced oxides of manganese and tantalum ions will flow through the Ta_2O_5. These ions will combine to form Ta_2O_5 at the Ta_2O_5-MnO_x interface. [For simplicity of discussion, ion flow through the Ta_2O_5 will be assumed to consist only of tantalum ions, although this is probably not the case (8). Likewise, the ion current through the MnO_x, which will denote the reduced manganese oxide phase, may consist of oxide ion vacancies.] Thus there will be a simultaneous formation of Ta_2O_5 at this interface and of MnO_x which will extend into the original MnO_2. Both of these new phases will be poor conductors, and all phases between the tantalum and the MnO_2 must have some ionic conduction to support the ionic current necessary for further film growth. The current efficiency of the process will be roughly determined by the ratio of ionic to electronic conductivity in the phase having the least ionic conduction. For most experiments this efficiency is of the order 0.01-0.001%, although more information is needed for a quantitative evaluation of this figure.

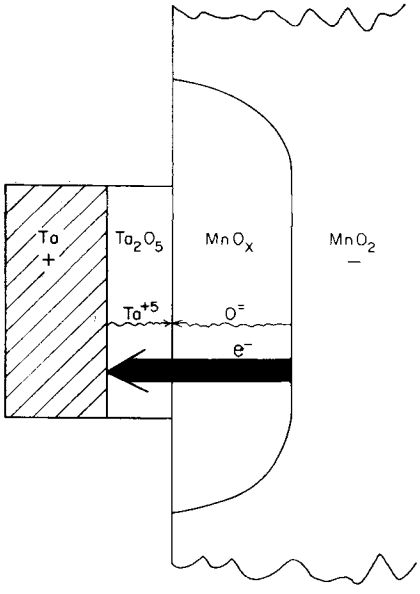

Fig. 5. Schematic representation of the solid-state anodization process.

We have been unable to characterize chemically the phases which are formed. Thus it is not known whether the MnO_x phase consists of one distinct oxide such as Mn_2O_3, Mn_3O_4, or MnO, a succession of oxide layers, or a continuous gradation of composition from MnO_2 to some oxygen-poor phase at the Ta_2O_5 surface. The small emfs observed for $Mn/Mn_2O_3/O_2$ cells and the evidence for thermal oxidation of Mn_2O_3 lend support to the idea of ionic mobility in this oxide, and the solid-state electrochemical reduction may proceed somewhat beyond this as indicated by the observation of some resistance build-up for a tantalum point on Mn_2O_3, and by the evidence of oxygen mobility in Mn_3O_4 at high temperatures.

The tantalum oxide phase created by this process has not been actually identified, although it is assumed to be essentially Ta_2O_5. The high electronic current densities observed for these experiments lead to the suspicion, however, that this Ta_2O_5 is defective in some sense. Possibly some Mn^{+3} is incorporated into the Ta_2O_5 since Mn^{+3} and Ta^{+5} have nearly equal ionic radii. An alternative explanation for the high current could be that the major rate-determining step in the electrochemical reaction is the flow of oxide ions across MnO_x which may be a predominantly electronic conductor. Thus sufficient voltage must be applied to supply adequate field across the MnO_x to obtain a detectable flow of oxide ions which can be accompanied by a relatively large electronic current. Meanwhile the flow of tantalum ions across the Ta_2O_5 will be restricted by polarization due to the limited supply of oxide ions with which they can combine. Thus the field across the Ta_2O_5 may exceed the normal fields for anodic oxidation in aqueous electrolytes and may lead to high electronic currents. In addition, the MnO_x may represent a good electron-injecting contact to the Ta_2O_5.

It is apparent that the cathodic oxide phase must meet certain requirements in order to support the anodic oxidation of valve metals. It must be a good source of oxygen and should be a fairly good conductor. The lower oxide phases formed by the extraction of oxygen to form the valve metal oxide must be poorer conductors than the parent oxide. If this were not the case, there would not be sufficient field across these lower oxides to sustain the required flow of oxide ions. Only MnO_2 and PbO_2 have been found to meet these requirements. Both are good conductors and good oxidizing agents, and the lower oxides of both are very poor conductors. These oxides are unusual in this respect since the oxides in which the metal is in its highest oxidation state, or is exhibiting the oxidation state typical of its column in the Periodic Table, are generally insulators whereas the lower oxides are conductors. This is best exemplified by such transition metal oxides as those of titanium and tantalum. Thus the range of suitable oxides is very narrow.

Although the solid-state anodization is analogous to the conventional anodization in a liquid electrolyte, the differences are very important and greatly complicate any quantitative interpretation. In the liquid system the reduction product is hydrogen gas which

escapes from the system. Ionic mobility in the electrolyte is high and, with the aid of agitation, the electrolyte remains homogeneous. On the other hand, the reduction product in the solid-state process must be a lower oxide of manganese, and it must be localized adjacent to the Ta_2O_5. Since the lower oxides of manganese are poor conductors, the applied voltage will be divided between the Ta_2O_5 and the MnO_x. The MnO_x layer may be substantially thicker than the Ta_2O_5. A simple calculation shows that, if MnO_x is MnO, the volume will be 1.3 times that of an equivalent amount of Ta_2O_5, and, if MnO_x is Mn_2O_3, the volume factor is 3.5. In the absence of detailed knowledge of the thicknesses and resistivities of all phases, the voltage distribution is unknown.

The initial capacitance of the sample described in Table I indicates that there is a significant thickness of dielectric prior to anodization. If this initial capacitance were due solely to Ta_2O_5 with a dielectric constant of 27.6, it would correspond to a thickness of about 450Å, which is unreasonably high for a thermally formed film. If this capacitance were determined by a layer of reduced manganese oxide having a dielectric constant of 5, it would correspond to a thickness of 80Å, which is reasonable. Since it is likely that the MnO_x has a dielectric constant which is substantially smaller than the unusually high value of 27.6 for Ta_2O_5, and since the MnO_x will be thicker than an electrochemically equivalent amount of Ta_2O_5, it is reasonable that the capacitance of these samples is determined essentially by the MnO_x.

Plots of equivalent series resistance *vs.* the reciprocal frequency and of the reciprocal series capacitance *vs.* log frequency were linear and the ratio $[\Delta 1/C_s/\Delta \log f]/[\Delta R_s/\Delta 1/f]$ was found to be 8.5 and 9.4 for two examples. These values are close to the value of 4 ln 10 = 9.2 which is typical of anodic oxides (9).

As the solid-state anodization proceeds, the current measured at any particular voltage below the anodization voltage decreases, giving further evidence that the process involves a permanent increase of resistance. Figure 6 shows a plot of log i *vs.* $(V/V_f)^{1/2}$ for a tantalum point contact formed on MnO_2. i represents the observed current, V the applied voltage, and V_f the formation voltage. The thickness of the oxide is assumed to be proportional to V_f, so V/V_f is proportional to the field across the oxide. For this experiment the point was anodized at successive 10v increments for 1 hr each. After each formation the current was measured at decreasing 5v intervals. The data shown are representative of several similar experiments.

The current is proportional to exp $(V)^{1/2}$ not only for voltages below the anodization voltage, but for the anodization voltage itself and for the initial, transient current which is observed as the voltage is increased

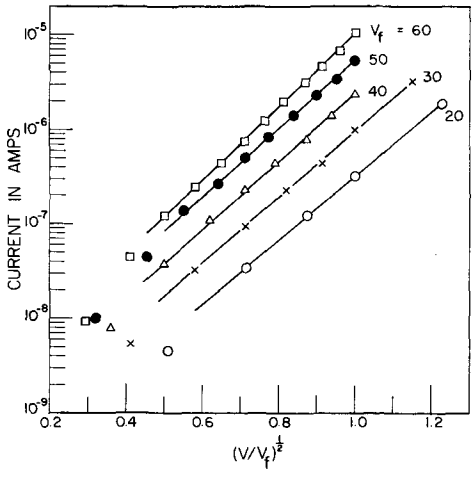

Fig. 6. Current-voltage characteristic for Ta-MnO_2 point-contact anodized for 1 hr at successive 10v intervals.

above the anodization voltage, *i.e.*, $(V/V_f)^{1/2} > 1$ in Fig. 6. This I-V behavior is a well-known characteristic of electronic leakage currents (10). This behavior suggests that the observed current in these experiments is essentially all electronic, even during the initial, rapid current decay, and that the current decay during anodic oxidation represents the electronic leakage current which is decreasing as the electrochemical reaction proceeds by means of an imperceptible ionic contribution to the total current. This concept is in accord with the estimated current efficiency of 0.01-0.001% since the latter figures also represent the overall ionic contribution to the total current.

When the point-contact anodizations are carried on until the current-decay essentially ceases (about 50 hr is generally sufficient), the data corresponding to that of Fig. 6 all fall on one line, indicating that the current-field relationship is independent of the thickness. The apparent thickness-dependence seen in Fig. 6 is merely a result of the fact that each successive anodization was less complete because of the decreasing current efficiency, and, as a consequence, the anodization voltage was not a valid measure of the relative dielectric thickness.

One can only speculate about the role of water in this mechanism. It is clear from the point-contact experiments that the process is aided by the presence of ambient water vapor. It is possible that the availability of water allows oxygen to move through the manganese oxides in the form of hydroxide ions rather than as oxide ions, since the attachment of a proton to an oxide ion reduces the charge by half but increases the size if the ion by only 10%. The lower charge and the polar nature of the hydroxide ion may reduce the barriers for oxide motion. A similar argument has been proposed for oxygen migration through anodic oxide films on aluminum by Hoar and Mott (11). Another possibility is that the water allows the manganese oxide to maintain the Mn:O ratio of MnO_2 even after reduction, thus eliminating the necessity of a change in structure. This would be analogous to current theories about the discharge of the MnO_2 cathode in the Leclanché cell where it has been suggested that the reduction requires only the migration of electrons and protons (12)

$$MnO_2 + e^- + H^+ \rightleftharpoons MnOOH$$

MnOOH is equivalent to $Mn_2O_3 \cdot H_2O$. The ramsdellite (MnO_2)-groutite (MnOOH) system is a good example of such a relationship (13).

The pertinence of the observations described here to the solid electrolyte capacitor will be readily apparent to those familiar with this component. In this device the MnO_2 replaces the liquid electrolyte which is used in conventional "wet-electrolytic" capacitors to maintain the electrical integrity of the oxide dielectric. The liquid electrolyte clearly serves as an electrochemical source of oxygen, but the mechanism by which the MnO_2 functions has never been clarified. The evidence presented here indicates that it can also seal off points of high leakage current when it is thermally decomposed by local, resistive heating to lower, insulating oxides. Evidence of both of these mechanisms can be observed during the reanodization of capacitors after the MnO_2 has been applied. The solid-state anodization results in a smooth decay of current at constant voltage, or increase of voltage at constant current; while sharp current spikes at constant voltage, or voltage dips at constant current, are believed to represent local breakdown of the dielectric which is healed by thermal decomposition of the adjacent MnO_2. If the amount of dielectric healing is sufficiently extensive, the characteristic battery-like behavior of these areas may become apparent. This effect, coupled with residual voltages of the type described by Dreiner (14), may account for some of the complicated open-circuit voltage behavior reported for Ta-Ta_2O_5-MnO_2 capacitors by Law and Richards (15).

Acknowledgments

The author wishes to express appreciation to Miss Marjorie Cutler, and to Drs. William Allison and Barry Noval for valuable experimental assistance.

The Spectral Response of the Short-Circuit Photocurrent in Anodized Niobium Electrodes

R. A. Schell[1] and R. E. Salomon

Department of Chemistry, Temple University, Philadelphia, Pennsylvania

ABSTRACT

The spectral response of the short-circuit photocurrent in anodized niobium electrodes of the form $Nb/Nb_2O_5/M$, where M is a thin semitransparent metal, has been determined. Measurements were performed as a function of the light intensity and oxygen pressure in the range 10^{-4}-760 mm Hg. The light intensities were of the order of 10^{11} photons/sec cm^2. The most unusual result was that structure was exhibited in these curves. This is interpreted in terms of interband transitions. Since the band structure of the oxide is unknown, the discussion is qualitative. The structure changes slightly with oxygen pressure. The photocurrent exhibited a maximum when viewed as a function of the oxide film thickness. A trapping scheme is postulated to explain the current-light curve characteristics. This is based on an exponential distribution of traps. The superlinearity is interpreted in terms of a redistribution of these trapping states on illumination.

A great deal of interest in anodic oxide films has been exhibited during the past fifteen years. Photovoltaic cells, consisting of an anodized metal and a semitransparent metal coating, were first demonstrated by van Geel *et al.* (1).

It is well known that the spectral response of the photocurrent can be as sensitive a device as the absorption spectrum for obtaining knowledge of the intrinsic absorption region in semiconductors and insulators. Anodic oxide films of niobium are insulators with the fundamental absorption edge falling around 3400Å (2-4). These measurements indicate strong absorption ($E \approx 10^5$-10^6 cm^{-1}) which has generally been assigned to band-to-band electronic transitions.

Photovoltaic effects are known to occur with anodized zirconium, niobium, tantalum, and aluminum electrodes (5). A great deal of difficulty has been experienced in attempts to elucidate the nature and mechanism of these effects. The convenient observable here is the short-circuit photocurrent. The open-circuit photovoltage is not convenient because an open-circuit photovoltage for a given set of parameters is generally not reproducible in these systems. There is also much difficulty encountered when making measurements of the normal photocurrent (*i.e.*, with an externally applied field). Precisely establishing the value of the dark current and re-establishing that value subsequent to the decay of the photocurrent is most difficult. The problem of electrical noise is also greatly reduced when one measures the short-circuit photocurrent. A spectral response study of the short-circuit photocurrent in these systems has never been reported. This paper deals with the determination of the spectral response of the short-circuit photocurrent in cells of the form $Nb/Nb_2O_5/M$, where M is a thin, semitransparent evaporated metal film. The oxide films ranged in thickness from 750 to 3000Å. The evaporated metals utilized were copper, silver, and gold. Polycrystals as well as single crystals of niobium were used in this study. These measurements were performed as a function of the light intensity (absolute) and oxygen pressure.

[1] Present address: United States Army, Picatinny Arsenal, Dover, New Jersey.

Experimental Procedure

Electrode preparation.—The niobium electrodes were prepared using both polycrystalline and single crystals. The impurity content of the single crystals was, in parts per million: O(50), C(100), H(10), N(400), Fe(<1000), W(<100), S(<30), Cd(<100), Si(<100), Cu(<10), Mn(<10), Ni(<10), and Mg(<1). The single crystals were pulled in the (100), (110), and (111) directions. The sample dimensions were approximately ⅜ in. in diameter and ½ in. long. A platinum wire, encased in a ceramic tube, was mounted in a hole drilled lengthwise through the specimen near the periphery. This was used to provide electrical contact to the evaporated, semitransparent metal film. Edge effects were eliminated by suitable masking. Care was taken to insure uniform thickness of the evaporated metal from one experiment to another. A surface of the specimen was abraded with various grades of emery paper. This was followed by wet-polishing and chemical etching in a solution consisting of 15 parts HF, 75 parts HNO_3, and 10 parts water. After etching, the pieces were washed thoroughly with distilled water.

Samples were then anodized at constant polarization voltages in a 0.05M sodium borated-boric acid solution buffered to pH 8. This was done in a constant temperature water bath at 20°C. For polarization voltages above a few volts, the oxide grows approximately 30 Å/v if the field is maintained for several hours (2, 6). Final leakage currents at a formation voltage of 75v were typically 2 μa/cm^2. Hereafter, the thickness of the oxide films will be given in terms of formation voltage. The oxide films exhibit interference colors characteristic of their thickness. An illustration of a completely prepared electrode is shown in Fig. 1. The time between anodization and measurement was kept below two days, and the time between completion of the electrode and measurement was a few hours. Electrodes were stored in vacuum desiccators when not in use.

Optical assembly.—The light source was a Hanovia 1000w, air-cooled, high-pressure mercury-xenon arc lamp. The source intensity was monitored by reflecting a portion of the light from an aluminum mirror on to a Photovolt type B photocell which served as the search unit of a model 500M photometer. A Bausch and Lomb monochromator with a linear dispersion of 66 Å/mm was utilized in this study. A Kipp thermopile was used to reduce the measurements to an absolute basis.

Cell compartment.—The electrode cell consisted of a demountable Dewar fabricated from standard-tapered glass joints of fairly large diameter with provisions for electrical, temperature, and pressure measurements. A quartz window was sealed into the cell. The cell was connected to a vacuum and gas inlet system.

For the oxygen pressure dependence measurements, the following procedure was adopted. The entire system was flushed repeatedly with oxygen and then evacuated to a pressure of about 10^{-4} mm Hg. This pressure was maintained for more than 12 hr by continual pumping. For measurements at other pressures, the electrode was first allowed to equilibrate for 1 to 2 hr. The system was such that the pressure could be maintained at a fixed value for more than 12 hr under static conditions.

Although photocurrents were detected at wavelengths as long as 4000Å, a thorough investigation of the spectral response for wavelengths greater than 3700Å was precluded because of the small signals.

For all measurements both entrance and exit slits of the monochromator were fixed at 0.40 mm. Greater resolution could only be obtained at the expense of light intensity. The weak intensity between 2400-2660Å and 3341-3660Å precluded any investigations of the light intensity dependence in these regions.

Photocurrents were measured in terms of the potential drop across a 20 megohm resistor. The current was not sensibly changed when a 5 megohm resistor was used and hence the parameter studied was a short circuit photocurrent.

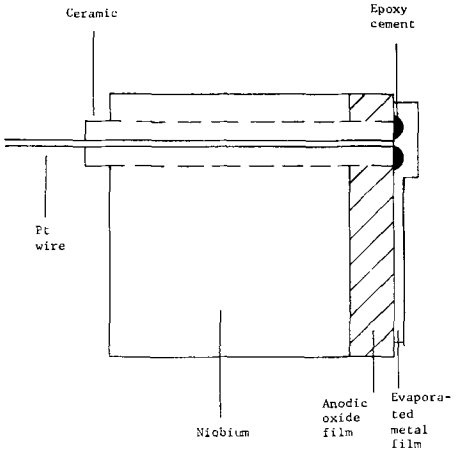

Fig. 1. Schematic illustration of a typical electrode

Results

Upon irradiation niobium always became negative. Short-circuit photocurrent measurements did not show any significant dependence on the crystallographic face. Consequently, results will be given only with reference to measurements obtained with polycrystalline samples.

The spectral response curves have been determined as a function of the radiation wavelength at a constant photon intensity. At a particular wavelength of incident radiation the short-circuit photocurrent varied with light intensity according to the relationship, $I_p = CL^n$, where C is a constant, L is the light intensity, and n is a constant whose value was found in general to lie between 0.5 and 1.0 although values as low as 0.3 and as high as 2.5 were found. A plot of the logarithm of the photocurrent *vs.* the logarithm of the light intensity always yielded straight lines.

The photocurrents were found to reach a steady value after a few seconds. Figure 2 shows a typical spectral response curve for the short-circuit photocurrent for a Nb/Nb_2O_5(100v)/Cu electrode. Similar curves were obtained if silver or gold were utilized as the second contact. The shape of these curves was quite reproducible although the actual photocurrent measured when two electrodes were treated similarly might differ by 10%. No simple relationship between photocurrent and oxygen pressure was found. However, comparison of Fig. 2 and 3 reveal a shift in a few peaks with oxygen pressure. The general shape of the curves remained the same however. The shapes of the spectral response curves were independent of oxide film thickness. If the photocurrent is plotted as a function of formation voltage a maximum occurs at 75v as can be seen by Fig. 4. The measurements are reduced to absolute incident intensities. No correction for reflec-

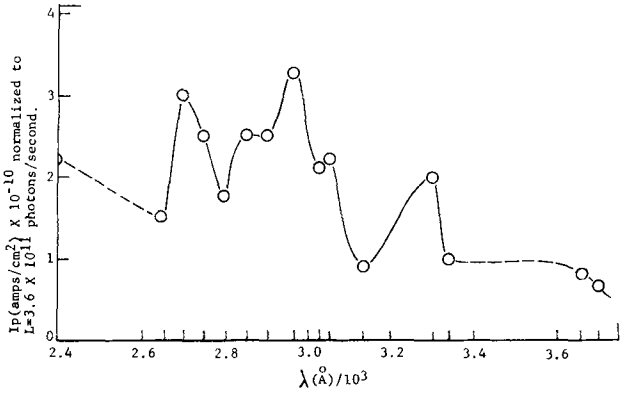

Fig. 3. Spectral response of the short-circuit photocurrent for a Nb/Nb_2O_5 (100v)/Cu electrode at P_{O_2} = 3.4 x 10^{-2} mm Hg; T = 20°C.

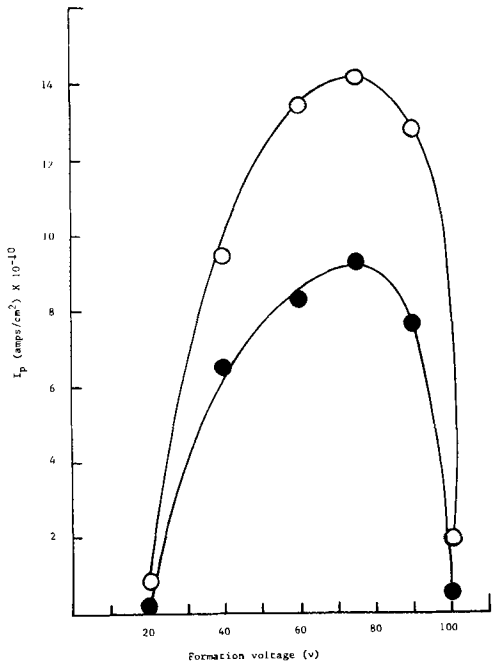

Fig. 4. Variation of short-circuit photocurrent with film thickness at light intensity of 3.6 x 10^{11} photons/sec. ○λ = 3130Å; ●λ = 2700Å; T = 20°C; P_{O_2} = 1.1 x 10^{-4} mm Hg.

tion and absorption by the evaporated metal film was made. However, a quartz microscope slide coated by evaporation with a thin semitransparent layer of copper was found to have a monotonic transmission spectrum down to 3200Å and transmitted more than 85% of the light.

The short-circuit photocurrent decreased with decreasing temperature and at liquid nitrogen temperatures the signals were too small to monitor by the method used. Activation energies were found to lie between 0.1 and 0.2 ev.

Discussion

The observation of structure in the spectral response curves of the short-circuit photocurrent was rather surprising in view of the fact that there is no concomitant structure in the absorption spectra of the isolated oxide films (2). A single peak, close to the absorption edge, in the spectral response curve could be explained in terms of a high recombination rate due to strong absorption (7).

The peaks and valleys cannot be ascribed to optical interference effects because the structure is independent of the oxide film thickness. It is also apparent that neither oxygen nor the nature of the evaporated metal contact determine the number and location of the peaks. This rules out photoexcitation from the evaporated metal contacts. In order to completely explain action spectra of this type, one must have a knowledge of spectral transition probabilities and the constant energy surfaces in $\vec{k}$ space. Although this information is not available, the observed monotonic absorption spectra might be due to oscillations in the dependence of effective mass on momentum.

It may be noted that recent work (8, 9) on shallow p-n junctions of silicon, germanium, and gallium arsenide show structure in the intrinsic region for reflectance and photoresponse measurements. There does not appear to be a one-to-one correspondence between photoresponse and reflectance for the measurements on silicon. The band structures of these materials have been extensively studied and are quite complex. The structure may be interpreted in terms of a nonequilibrium effect and recombination processes. This mechanism may also apply to the electrodes described in this paper.

The absorption spectra of isolated anodic niobium oxide films gives a long wavelength limit of absorption of about 3500Å (2). This value was in agreement with a previously reported value of 3400Å (3). Conlon and Doyle (4) determined the absorption spectrum of the evaporated oxide and arrived at a value of 3350Å. The latter spectrum extended down to 2000Å whereas that of Salomon *et al.* was determined to about 2700Å. However, both showed sharp absorption edges and very high absorbance indices values. Although Salomon *et al.* determined the absorption spectra using the anodic oxide films, these films were first removed from their bulk metal substrate. This would tend to remove a fair amount of stress and might cause some dissolution of the oxide. Hence differences in film behavior between mounted and free films should be recognized. This could account for the observation of photoconduction in these electrodes occurring at wavelengths as high as 4000Å.

It was found that if the photocurrent is plotted as a function of the oxide film thickness a maximum occurred. This can be readily accounted for by considering the oxide film to be optically anisotropic. By considering a small gradient in the absorption coefficient and using the relation, $dI = -I\alpha dx$ one may indeed show that the photocurrent-thickness curve will have a maximum.

The small activation energy for photoconduction combined with the slow decay may suggest the existence of a wide range of trap depths. Shallow traps would be thermally emptied and contribute to the small activation energy. Deep traps, which might be relatively unaffected by temperature variations, would lead to long decay times.

A model based on an exponential trap distribution (10) is able to account for the usual results of the dependence of the photocurrent on light intensity. Superlinearity (n-values > 1) in the photocurrent dependence on light intensity might be explained by modification of this model.

Manuscript received April 27, 1965; revised manuscript received Aug. 23, 1965. This research formed part of a dissertation submitted to the Temple University Graduate Board in partial fulfillment of the requirements for the Ph.D. degree. This work received financial support from the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Electrical Conductivities and the Structural Properties of Molten $PbCl_2$-PbS Mixtures

I. Structural Properties

M. C. Bell[1] and S. N. Flengas

The Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The phase diagram and the densities for the lead chloride-lead sulfide system were determined. The phase diagram is simple, with one weak incongruently melting compound for which the x-ray diffraction patterns were measured. Calculations from the phase diagram indicate that lead sulfide is dissociated in the liquid mixtures. The liquidus lines for PbS, NaCl, NaF, and KBr added to lead chloride were also determined and showed that pure liquid lead chloride contained ions other than simple lead and chloride ions. The molar volumes of the mixtures are almost ideal with only slight positive deviations from additivity occurring.

In previous publications (1, 2) some thermodynamic properties and the electrical conductivities of molten silver chloride-silver sulfide mixtures were determined. This paper presents the determination of the phase diagram and the densities for the molten lead chloride-lead sulfide system. The usefulness of these measurements in indicating the structural properties of the systems and their relationship to the electrical properties was illustrated in the previous work. Lead sulfide has the NaCl structure, a high melting point and a high heat of fusion, and is therefore expected to be fairly ionic in nature.

Experimental

Preparation of materials.—Lead sulfide was prepared by the direct reaction of stoichiometric amounts of zone-refined hydrogen-reduced lead and distilled sulfur, in sealed evacuated quartz capsules.

Reagent grade lead chloride was heated under vacuum for several days, melted, and then filtered through a fritted Pyrex disk by applying an argon pressure to the upper compartment of the tube containing the melt. The tube was allowed to cool slowly, and translucent crystals from the outside of the tube were taken for use.

Phase Diagram Studies.—Liquidus points were determined by cooling curves carried out in sealed Pyrex or quartz tubes. For the chloride-rich solutions, the cells were evacuated to a few microns pressure and then filled with enough dried purified argon to give approximately 1 atm pressure at the operating temperature. These cells had a sealed side arm feeding tube containing weighed pellets of solute and a small magnet, so that a number of liquidus points could be determined with the same cell. On the sulfide side, small quartz capsules, completely sealed, were used. The furnace was cooled at the desired rate, generally 0.5-2.0°C/min, by controlling the speed of a reversing d-c motor which drove down the furnace variac through a 250,000 to 1 gear reductor. The output from the thermocouples was recorded on a 1 mv full-scale L&N recorder, with most of the thermocouple output being compensated with a potentiometer. Generally, two thermocouples at different positions in the melt were recorded. The melt was mixed by rocking the entire furnace. The thermocouples were sheathed in close fitting Pyrex or quartz tubes blown into the cells. The bottom of these tubes was drawn out to a thin point to obtain the best possible thermal contact with the melt. A thermocouple depth of immersion of about 1¼ in. was used, as this immersion was required to obtain the same freezing point reading when cooling or heating a pure salt. The thermocouples were 24-gauge chromel-alumel, or 0.015 in. platinum-platinum rhodium, and were calibrated under identical experimental conditions, by cooling curves taken on zone-refined tin and silver. The sensitivity of the recorder was approximately 0.1°C for chromel-alumel thermocouples, and 0.25°C for the platinum-13% rhodium thermocouples. On calibration, the reproducibility of the measured freezing points was generally 0.25°C for the same sample, and up to 0.5°C for different samples with different cells and insulation in the furnace. Supercooling could generally be kept below 1.5°C by vigorous mixing or tapping the cell sharply. If more than this amount of supercooling occurred, the melt would not heat up to the correct liquidus temperature for the solutions.

Density measurements.—The densities for the molten mixtures were determined using the apparent loss in weight method described in a previous publication (1). The entire system was evacuated to a few microns pressure at 150°C and then filled with a positive pres-

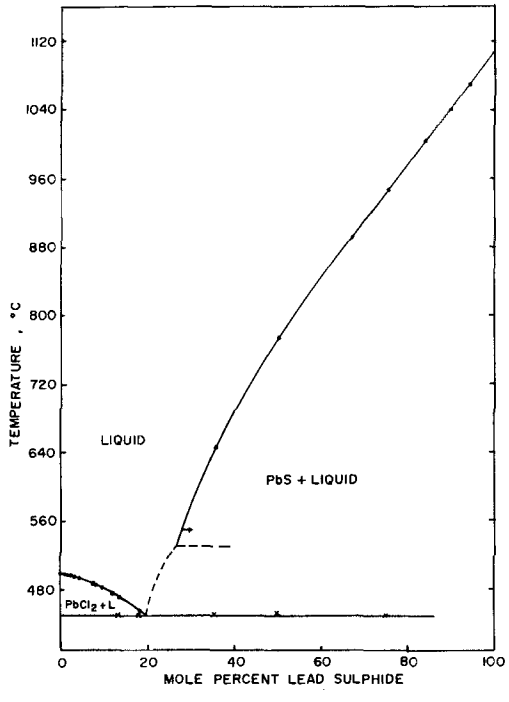

Fig. 1. Phase diagram of the PbS-$PbCl_2$ system

[1] Present address: Department of Metallurgy, Royal School of Mines, Imperial College, London, England.

sure of dried purified argon for the measurements. Small corrections due to material condensing on the quartz fiber were determined by weighing the quartz fiber suspension before and after a density determination.

Results and Discussion

Phase diagram measurements.—The determined phase diagram is shown in Fig. 1. Eight determinations of the melting point of lead chloride gave the value of 499.1°C with a standard deviation of 0.17°C. This value is quite close to values quoted in the literature (3, 4). The measured melting point of pure lead sulfide was 1111.9°C; this compares well with other reported values of 1112° and 1110°C (5, 3). The measured eutectic temperature is about 10°C higher than that reported by Winterhager (6), but very close to that reported by Urazov (7). It was observed in one cell that cracked that a small amount of air in the system rapidly lowered the measured eutectic temperature. Despite the high melting point of lead sulfide, there is seen to be a substantial liquid region in the phase diagram even at low temperatures.

X-ray analysis of material cooled from the chloride or the sulfide side of the diagram, showed no measurable shift in the lead chloride or the lead sulfide peaks, even at high diffraction angles. The measured relative intensity of the respective peaks was the same as observed for the pure components. Solid solubility in the system is then slight, if it occurs. Material which solidified at eutectic composition showed a new series of diffraction peaks, indicating that the phase diagram is not a simple eutectic diagram. The intensity of these peaks was much higher than the lead chloride peaks. The measured diffraction angles and relative intensities are given in Table I. The measured angles and intensities for pure lead chloride are also given in this table. Although the positions of the peaks were identical with the values reported by Swanson (8), in most instances, the relative intensities of the peaks are quite different.

Lead chloride prepared by fractional crystallization from an aqueous solution gave the same relative intensities with several methods of mounting the specimens. The diffraction peaks for lead sulfide were identical with those reported by Swanson.

Cooling curves taken on the sulfide side, close to the eutectic, could not detect any liquidus line, probably because of the slowness of the reaction to form the incongruently melting compound. The arrow on the phase diagram indicates that a decanted sample obtained from a melt held at 550°C showed that solid lead sulfide, identified by x-ray analysis, was in equilibrium with the melt. Since there is an incongruently melting compound in the system, the eutectic line on the sulfide side drawn through the points measured on continuous cooling may not represent part of the equilibrium diagram. It is evident from the phase diagram that the tendency toward compound formation is very slight in this system.

Cryoscopic Calculations.—The activity of the solvent at a liquidus temperature may be readily calculated from the van't Hoff equation

$$\ln a_{\text{solvent (at } T_L)} = \frac{\Delta H_F}{R}\left[\frac{1}{T_F} - \frac{1}{T_L}\right] \qquad [1]$$

where, the heat of fusion of the solvent may be assumed to be temperature independent over a narrow temperature range. T_F and T_L are the melting and the liquidus temperatures, respectively, and a_{T_L} represents the activity of the solvent at a liquidus temperature with respect to pure supercooled liquid solvent as the standard state.

Considering the solution to be ideal, the theoretical liquidus may be calculated from Eq. [1], using the appropriate expressions for the activity of an ionic salt in an ideal solution.

For an ideal ionic mixture, in which the component salts A^+X^- and $B^{++}Y^-_2$ are completely dissociated, and randomly distributed, the activity of the species $B^{++}Y^-_2$ is given by Temkin (9) as

$$a_{B^{++}Y^-_2} = N_{B^{++}} \cdot N^2_{Y^-} \qquad [2]$$

where the ionic fractions are defined as:

$$N_{B^{++}} = \frac{n_{B^{++}}}{(+\text{ve ions})}$$

and

$$N_{Y^-} = \frac{n_{Y^-}}{(-\text{ve ions})}$$

For a reciprocal system of this type, however, the activity relationship must be modified to include the partial molar heat of mixing that appears because of the heat of the following exchange reaction

$$B^{++}Y^-_2 + 2A^+X^- = 2A^+Y^- + B^{++}X^-_2 \qquad [3]$$

Considering only first order interactions, and a regular solution model, the partial molar heat of mixing in an ideal reciprocal system is given (10) by the equation

$$(\overline{\Delta H})_{B^{++}Y^-_2} = N_{A^+} \cdot N_{X^-} \cdot \Delta H^\circ_{\text{exch.}} \qquad [4]$$

where $\Delta H^\circ_{\text{exch.}}$ corresponds to the heat of the exchange reaction [3], calculated from the heat contents of the components in their standard states at the specified temperature of the mixture.

The activity of the components $B^{++}Y^-_2$ is then calculated from the relationship

$$\log a_{B^{++}Y^-_2} = \log N_{B^{++}} \cdot N^2_{Y^-} + (N_{A^+} \cdot N_{X^-}) \cdot \frac{\Delta H^\circ_{\text{exch.}}}{2.3\,RT}$$

The activity equation is expected to hold in concentrated solutions of the component $B^{++}Y^-_2$ and may be considered as particularly useful in cryoscopic calculations.

For a mixture having a common ion, *e.g.*, A^+Y^- and $B^{++}Y^-_2$, the equation simplifies to the familiar Temkin expression

$$a_{B^{++}Y^-_2} = N_{B^{++}} \cdot N^2_{Y^-} \qquad [6]$$

An enlargement of the phase diagram on the lead sulfide side and the "ideal" liquidus, calculated from the van't Hoff equation, is shown in Fig. 2.

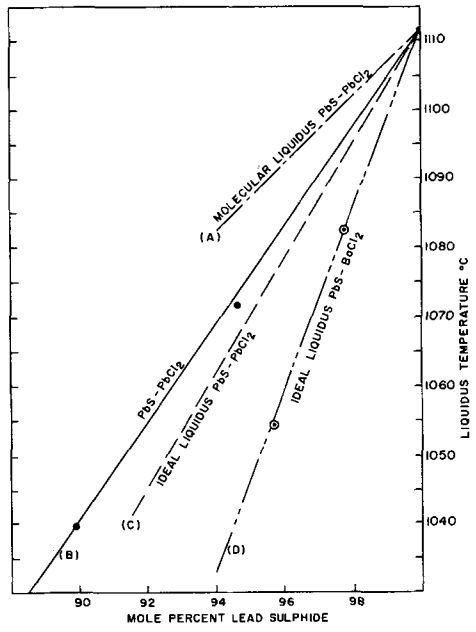

Fig. 2. Lead sulfide side of the phase diagram of the systems, PbS-$PbCl_2$, and PbS-$BaCl_2$: line A, calculated on the basis of the mole fraction; line B, experimental; line C, calculated on the basis of a'_{PbS} given in Table II; line D, calculated on the basis of a'_{PbS} given in Table II. The points are the measured liquidus temperatures. ● PbS-$PbCl_2$, ⊙ PbS-$BaCl_2$.

For the calculation, the reported heat of fusion of lead sulfide (3) was used, as well as the "ideal" activities given in Table II.

In Table II, column 1 gives the mole fraction composition, column 2 the Temkin activity which is valid only for systems having a common ion, and column 3, the "ideal" activity for a reciprocal salt mixture. The activity calculated from the experimental results, using the van't Hoff equation, is given in column 4. The activity coefficient is then obtained by dividing the experimental activity by the corresponding ideal activity.

For the PbS-$PbCl_2$ system, the measured liquidus lies above the ideal line, indicating positive deviations from ideality. The deviations could be caused by an error in the reported heat of fusion of lead sulfide, by a number of associated PbS species existing in solution, or by the presence of associated lead chloride. In order to differentiate between the most probable cause of the deviations, an ionic salt-like barium chloride was added to lead sulfide, and the new liquidus was determined. The ideal activity of lead sulfide in the PbS-$BaCl_2$ system was calculated and is given in Table II.

Table II. Activity calculations

System	X_{PbCl_2}	$N_{Pb^{++}} \cdot N^2_{a^-}$ (Temkin)	a'_{PbCl_2} (calc. ideal)	a_{PbCl_2} (expt.)	$\gamma PbCl_2$

The excellent agreement between the ideal and the experimental activities for lead sulfide indicates that this system is well described by the ionic model. The agreement indicates further that lead sulfide behaves as a dissociated liquid, suggesting indirectly that the positive deviations from ideality in the PbS-$PbCl_2$ system may be caused by association in lead chloride.

In Fig. 2, the calculation of the liquidus, when taking the activity as being equal to the mole fractions, gives line A which lies even higher than the experimental curve. This calculation corresponds to a totally molecular liquid, and accordingly lead chloride should be described as only partially associated.

Similar calculations were also made on the lead chloride side of the phase diagram.

The measured liquidus line for the $PbCl_2$-PbS binary system is shown in Fig. 3.

The ideal liquidus calculated from the Temkin activity and the heat of fusion of lead chloride (3), assuming complete dissociation of the components into their ionic species, is shown as line A which lies well below the experimental curve.

The x-ray data indicate that the deviations cannot be ascribed to solid solubility. The cryoscopic information on the sulfide side of the system has indicated that lead sulfide, rather than lead chloride, is dissociated. Accordingly, in order to provide some further evidence of association, several alkali metal halides were added to lead chloride, and the new liquidus lines were determined. The results of these measurements are also shown in Fig. 3.

The systems $PbCl_2$-NaF and $PbCl_2$KBr are reciprocal, while the $PbCl_2$-PbS and $PbCl_2$-NaCl have an ion in common. The ideal activities were calculated using the appropriate activity expressions, and the results are also given in Table II.

The ideal liquidus lines for these systems are given in Fig. 3 as curves A and B. It is evident from Table II that all systems, with the exception of the $PbCl_2$-

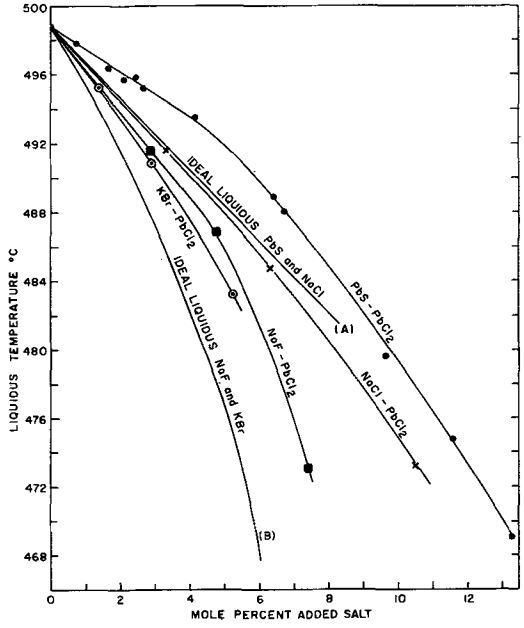

Fig. 3. Lead chloride side of the phase diagram of the systems, $PbCl_2$-PbS, $PbCl_2$-NaCl, $PbCl_2$-NaF, and $PbCl_2$-KBr. Lines A and B were calculated from the "ideal" activity data a'_{PbCl_2} given in Table II. ● PbS-$PbCl_2$; × NaCl-$PbCl_2$; ■ NaF-$PbCl_2$; ⊙ KBr-$PbCl_2$.

NaCl binary, indicate small positive deviations from ideality. The effect of such small deviations on the position of a liquidus line is shown by the large differences between the experimental and the ideal liquidus lines in Fig. 3. It is also evident that the liquidus temperature is very sensitive to small changes in activity. For example, an activity change of lead chloride from 0.971 to 0.963, would decrease the liquidus temperature by about 7°C.

The curves in Fig. 3 indicate clearly positive deviations, with the exception of the $PbCl_2$-NaCl system. Since the molten alkali metal halides are completely dissociated to their ions, the deviations may be accounted for by the tendency of lead chloride to associate in the liquid. Furthermore, the experimental activities for lead chloride are in better agreement to the mole fractions, representing a molecular model, than to the ionic activities.

In any case, the measured activities indicate deviations from ideality, which are too small to allow the calculation of any specific association scheme.

The transport properties of lead chloride also provide evidence of the existence of ions other than lead and chloride ions in pure lead chloride. In a calculation of the mobility coefficients and transport number, Laity (11) has shown that the calculated transport number of lead is about twice the measured value for lead chloride, while reasonable agreement was obtained for simple monovalent salts.

In the NaCl-$PbCl_2$ system, the Temkin activities and the molecular mole fractions are numerically equal, and therefore this is the only system where the calculation of an ideal activity cannot differentiate between association and dissociation. By comparison with the experimental activity, it appears that in this system only slight negative deviations from ideality do occur. This is in qualitative agreement with recent careful determinations of the heats of mixing in sodium chloride-lead chloride melts at 650°C by McCarty and Kleppa (12). No attempt has been made to compare the data because of the large temperature differences in the measurements.

Density measurements.—The measured densities were all linear functions of temperature. Linear regression of the experimental data yielded the constants for a and b and the standard deviations for the equation

$$\text{Density} = a - b(t°C - 500) \text{ in g/cm}^3$$

The values for the constants a and b at the compositions investigated are given in Table III. The standard deviation shows only the relative scatter of the experimental points and does not include absolute errors in density results.

The measured density of lead chloride is 0.6% higher than that reported by Heymans (13). Heyman's results for the density of molten silver chloride were also 0.8% lower than those determined by the present authors (1) and by Spooner and Wetmore (14). Lead chloride has a large expansivity, about three times that of strontium chloride, which might be expected to have somewhat similar properties. This abnormal expansivity would suggest, in agreement with the phase diagram measurements, that pure lead chloride contains ions other than simple lead and chloride ions. The expansivity of pure lead sulfide is small, about one-third that of lead chloride.

Table III. Density of PbS-$PbCl_2$-molten mixtures
Density = $a - b(t°C-500)$ (g/cm³)

Mole % PbS	a	$b \times 10^3$	Temperature range, °C	Standard deviation
0	4.985	1.50	500-650	0.003
14.97	5.160	1.56	490-650	0.002
34.35	5.306	1.07	670-840	0.004
50.00	5.554	1.01	800-960	0.003
70.54	6.003	1.06	920-1050	0.005
100.00	6.842	0.54	1120-1200	0.006

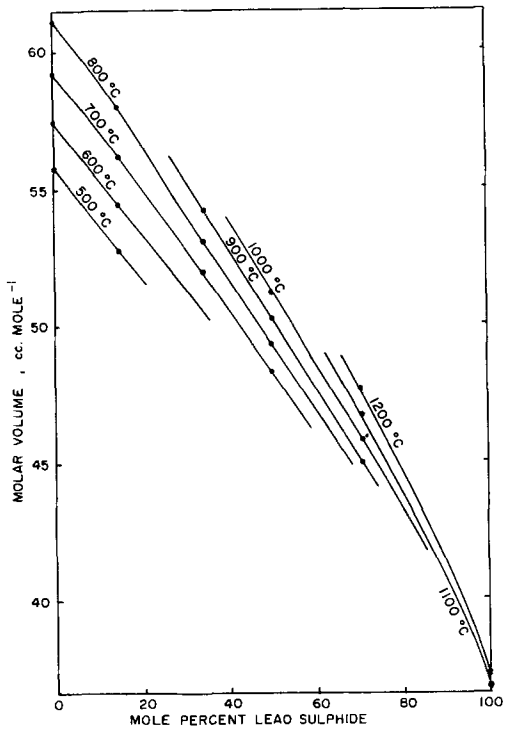

Fig. 4. Molar volume isotherms of the molten PbS-$PbCl_2$ system as a function of the lead sulfide content.

The molar volumes of the melts calculated from the density measurements are shown in Fig. 4. It is evident that the molar volumes of the mixtures are almost additive, the positive deviations from additivity being about 1 cm³/mole, or 2% of the total molar volume at 50 mole % sulfide. This positive deviation is of the same sign and magnitude as the excess molar volumes in lead chloride-potassium chloride mixtures (15) and is about half the excess volume at 35 mole % sulfide in the silver sulfide-silver chloride system. The density measurements indicate, in agreement with the phase diagram calculations, slight positive deviations from ideality. Lead sulfide in these melts is dissociated, while lead chloride behaves like a partially associated liquid. Furthermore, the tendency toward compound formation in the system is slight.

Summary

The phase diagram for lead chloride-lead sulfide is simple with one very weak incongruently melting compound occurring in the system. The x-ray diffraction pattern for the incongruently melting compound was determined. Calculations from the phase diagram indicate that liquid lead sulfide is dissociated. The liquidus lines for PbS, NaCl, NaF, and KBr added to lead chloride were also determined. Calculations from the phase diagram indicate positive deviations from ideality in the PbS-$PbCl_2$ system.

The density measurements show that the expansivity of lead chloride is high, while that for lead sulfide is small. The molar volumes of the mixtures are almost ideal, with slight positive deviations from additivity occurring.

The density and the phase diagram then indicate that the lead chloride-lead sulfide system is structurally simpler than the silver sulfide-silver chloride system previously investigated, and accordingly the electrical properties of the two systems would also be expected to be different.

The Electrical Conductivities and the Structural Properties of Molten $PbCl_2$-PbS Mixtures

II. Electrical Conductivities of the Systems PbS-$PbCl_2$ and Pb-PbS-$PbCl_2$

M. C. Bell[1] and S. N. Flengas

ABSTRACT

The specific conductivities of molten lead chloride-lead sulfide mixtures have been determined. On the addition of the sulfide to the chloride the conductivity decreases initially and then increases as electronic conductance sets in at about 35 mole % sulfide. The conductivity in this region is characterized by temperature independent activation energies, typical of semiconductive behavior. The electronic conduction in this system is analyzed on the basis that the melts are intrinsic semiconductors. The solubilities of lead in lead chloride, and in lead chloride-lead sulfide melts up to 50 mole % sulfide were determined. The electrical conductivities of these solutions were also investigated. It is found that the activation energies for electronic conduction in the melts containing added metal change by only a very small amount, indicating that the added metal is not acting as are electron donor.

The lead chloride-lead sulfide system was one of the first sulfide-chloride mixtures studied and was the subject of patents for the electrolytic recovery of lead as early as 1906. More recently German (1) and Japanese workers (2) have shown that the electrolysis of lead sulfide in solutions in lead chloride and sodium or potassium chloride melts could be carried out at high current efficiencies.

Lead sulfide has the NaCl crystal structure, a high melting point, and a large heat of fusion, and is therefore expected to be fairly ionic. The phase diagram and density measurements for the lead chloride-lead sulfide system reported in the previous paper in this series (3) have shown that lead sulfide behaves like a dissociated liquid while pure liquid lead chloride contains species other than simple lead and chloride ions. The system shows only a slight tendency toward compound formation.

Solid lead sulfide is a well-known intrinsic semiconductor (4, 5) even at high temperatures, having an energy gap of 0.35 ev. The conductivity of pure solid lead sulfide has been found to increase rapidly because of the loss of small amounts of sulfur at high temperatures (6). This fact has limited the accuracy with which the conductivity of the molten stoichiometric sulfide could be determined.

Previous investigations of the molten silver sulfide-silver chloride system (7) in this laboratory have shown that the onset and amount of electronic conduction in the sulfide-chloride melts could be determined readily from careful conductivity measurements.

In the present investigation the electrical conductivities for the molten lead chloride-lead sulfide mixtures are presented over the composition and temperature range allowed by the phase diagram and the thermal stability of the system.

Lead and lead sulfide are miscible at high temperatures, while the silver-silver sulfide system has a large immiscibility gap (8). The post transition metals which do not form subhalides generally have extremely limited solubilities in their molten chlorides (9). It is therefore of interest to determine the solubilities in these molten mixtures. The measurement of the effect of the added metal on the conductivity in these mixtures, some of which are semiconductors, gives some indication of the electron donor properties of the excess metal present.

Experimental

The preparation of the materials used in this investigation and the cell design were described in detail in a previous publication (3). Graphite electrodes were used for all measurements above 20 mole % lead sulfide, as tungsten, or platinum, dissolved readily in these melts. The conductivity cells were of the U-tube, capillary type. For high concentrations of sulfide the melts were thermally unstable and evolved small amounts of sulfur. In this range the conductivity cells were modified by introducing female silica ground joints about 2 in. above the capillary. The graphite

[1] Present address: Department of Metallurgy, Royal School of Mines, Imperial College, London, England.

electrodes were then machined and ground to fit the joints, and were connected to the molybdenum or graphite leads for the bridge connections. When assembled the electrodes could be lowered and seal the capillary part of the cell making a tight fitting in the hot zone of the furnace, thereby reducing sulfur evolution. All measurements were taken in an atmosphere of purified argon.

The solubility of lead in molten lead chloride-lead sulfide mixtures was determined by direct loss in weight of small amounts of lead equilibrated with about 30g of the required salts sealed in evacuated ½-in. quartz tubes terminating in a 4 mm ID quartz tube at the bottom. For these measurements zone refined lead was further purified by passing anhydrous hydrogen through the liquid metal at about 500°C to reduce the oxygen content.

The capsules were evacuated overnight to a few microns pressure before sealing. The cells were placed in vertical holes drilled in a graphite block in the furnace and maintained at the required temperature for several days. The temperature gradient along the samples was maintained at less than 1°C. The samples were then removed from the furnace and quenched in iced brine. Preliminary experiments showed that the rate of quenching did not affect the measured solubility. The lead button at the bottom of the 4 mm tube was separated from the salt and boiled in distilled water to remove traces of lead chloride. Blank lead buttons and some of the equilibrated buttons showed weight losses of less than a tenth of a milligram on boiling in water. It was found however that some of the solidified buttons still contained trapped salt. All the buttons were therefore dissolved in dilute nitric acid, containing a small amount of 0.001 normal silver nitrate solution. Any salt trapped in the buttons was precipitated as silver chloride, or silver sulfide. The amount of silver remaining in the solution was then determined by titration with potassium thiocyanate solution using ferric ammonium sulfate as the indicator. The corrections in most of the samples were negligible.

The conductivity measurements on the Pb-PbS-$PbCl_2$ ternary were taken in the same manner as previously described (7). Graphite electrodes were used in all the determinations. The additions of metal to the conductivity cell were made by pressing a very small weighed amount of metal in the center of a pellet of lead sulfide. The pellet was then introduced to the melt from a side arm feeding tube.

Results and Discussion

Electrical conductivities in the binary system PbS-$PbCl_2$.—In order to show the large amounts of electronic conductivity occurring in the lead sulfide-lead chloride melts, the over-all diagram of the measured conductivities is shown in Fig. 1. Pure lead sulfide has a specific conductivity from 110 to 120 reciprocal ohm-cm, and a positive temperature coefficient typical of semiconductive behavior. In this respect, liquid lead sulfide is similar to solid lead sulfide which is a well-known intrinsic semiconductor. Lead sulfide unfortunately is not too stable at high temperatures, and the melts continuously lost very small amounts of sulfur. A small loss in sulfur however produced a large change in conductivity. Similar behavior has also been observed with solid lead sulfide (6). The present measurements on pure lead sulfide were taken by heating the cell as quickly as possible to about 1150°C. Once the lead sulfide had melted, the sulfide in the capillary was protected from further dissociation by the melt above it. Since the capillary determined 99.9% of the cell constant, stable conductivities could be measured over short periods of time, provided the melts were not mixed. Readings taken in the first half hour of three runs using different preparations of lead sulfide gave results within 5% of the mean shown in Fig. 1 and Table II, and all showed the same temperature dependence. Thus while accurate readings could not be obtained, the observed conductivities appear to be approximately correct.

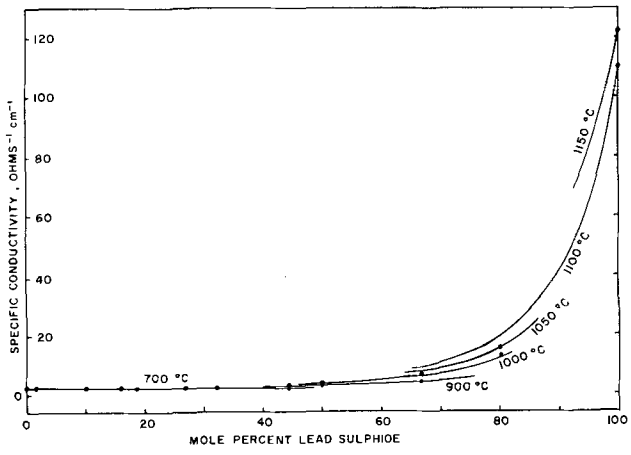

Fig. 1. Specific conductivity isotherms in the PbS-$PbCl_2$ system over the entire composition range.

The rapid decrease in conductivity on the addition of lead chloride to the sulfide is quite evident in Fig. 1. All the melts have a positive temperature dependence, unlike the silver chloride-silver sulfide system (7) which showed a metallic temperature dependence for the conductivity above 50% silver sulfide. The difference is attributed to the more ionic bonding of the lead sulfide as shown by the phase diagram and density measurements in the previous paper (3). It should also be noted that in the silver sulfide-silver chloride system at compositions below 50 mole % sulfide where the phase diagram and density measurements indicated that the melts became ionic, the temperature dependence of the conductivity also became positive.

The ionic conductivity on the chloride side of the system cannot be seen on the scale of this graph. An enlarged diagram of the specific conductivities in this region is shown in Fig. 2. The conductivities up to 36 mole % sulfide were all quadratic functions of temperature.

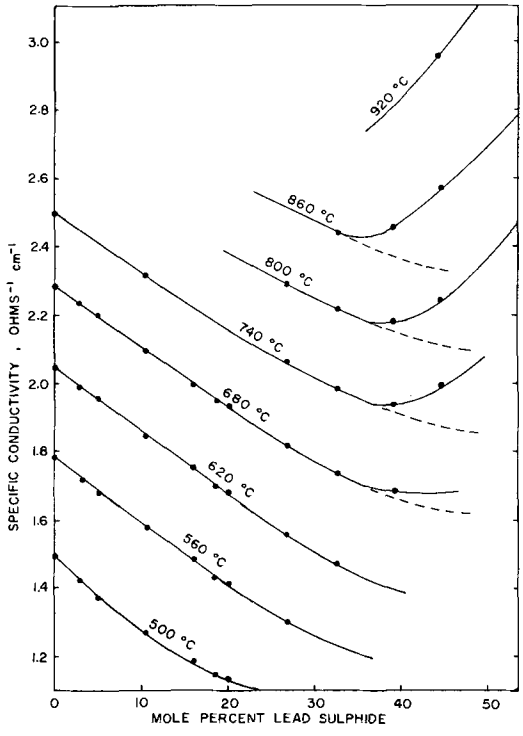

Fig. 2. Specific conductivity isotherms of the lead chloride rich solutions.

Table I. Specific ionic conductivity in the $PbCl_2$-PbS system

$k = a + b(t°C\text{-}500) - c(t°C\text{-}500)^2$, $ohm^{-1}\ cm^{-1}$

Mole % PbS	a	$b \times 10^3$	$c \times 10^5$	Standard deviation
0	1.486	0.511	0.414	0.004
2.79	1.445	0.508	0.307	0.004
10.58	1.283	0.502	0.295	0.002
16.03	1.190	0.501	0.293	0.003
18.64	1.148	0.499	0.256	0.005
25.20	1.032	0.497	0.22	0.006
26.89	1.006	0.496	0.22	0.003
32.71	0.906	0.495	0.19	0.001
35.94	0.863	0.494	0.17	
39.32	0.824	0.494	0.16	
44.61	0.770	0.492	0.14	
46.00	0.760	0.492	0.14	

In this region the measured conductivities were quite stable and were generally reproducible to ¼ of 1% on increasing and decreasing temperature. Multinomial regression about the quadratic equation

$$k = a + b(t°C - 500) - c(t°C - 500)^2 \qquad [1]$$

yielded the constants a, b, c, and the standard deviations of the measured conductivities from this equation. The constants for this equation, and the determined standard deviations are shown in Table I. A large number of readings were taken at each composition, and the standard deviation of the experimental data is seen to be small. The measured conductivities of lead chloride are about 3% higher than those reported by Harrap and Heymann (10). Harrap's values for the conductivities of silver chloride were also about 2.5% lower than those reported by Doucet (11), Wetmore (12), and in our previous investigation (7).

The densities for lead chloride and for the mixtures with lead sulfide have been previously determined (3), so that the equivalent conductivities could be calculated. Since the phase diagram measurements (3) have shown that lead chloride contains species other than simple lead and chloride ions, the conductance could not be defined per unit number of ions present. Similarly, the activation energy for conduction loses significance as an indication of an energy barrier, because the number of ions present per mole would be changing with temperature. Accordingly molar activation energies were calculated from the measured data and indicate a change from 4.32 kcal at 500°C to 3.48 kcal at 700°C. The apparent activation energies for ionic conduction change only slightly on the addition of lead sulfide to the chloride and are of the same magnitude as those for the alkaline earth halides (13).

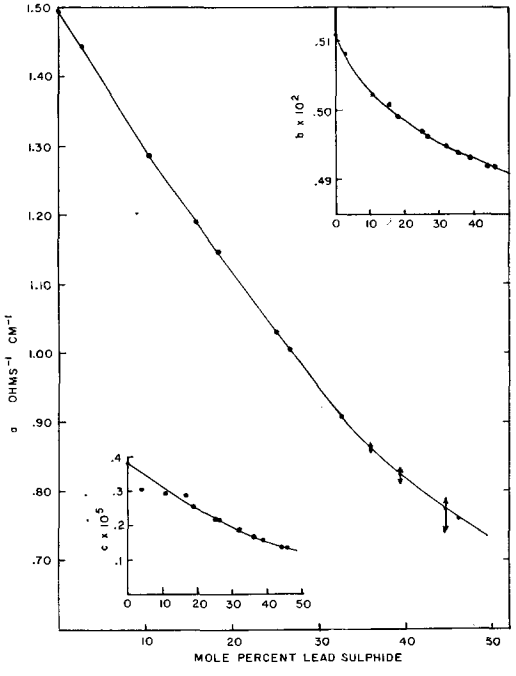

Fig. 3. Plot of the a, b, and c coefficients as a function of lead sulfide content.

The points shown on Fig. 2 are only those interpolated from the measured data at regular temperature intervals. The large temperature dependence of the conductivity is evident from the diagram. The general decrease in conductivity on the addition of the sulfide is quite evident. The decrease is similar to that observed on the addition of silver sulfide to silver chloride. In the present case, however, the isotherms are all essentially parallel, indicating that the effect of the added divalent ions is about the same at all temperatures.

The onset of electronic conductivity at about 40% lead sulfide is quite evident by the rapid increase in conductivity. The electronic conductivity rises steadily with further additions of sulfide to the large values observed on the lead sulfide side of this system. The onset of electronic conductivity is seen to occur at a much higher sulfide concentration than in the silver chloride-silver sulfide system. In order to determine the amount of electronic conductivity occurring in these mixtures it is necessary to extrapolate the ionic conductivity from lower sulfide concentrations. This was done by extrapolating the coefficients for quadratic equations for the specific conductivity. The extrapolation is shown in Fig. 3. The accuracy of the conductivities in the ionic region is evident in the smooth curves obtained for the coefficients. The change in the b and c coefficients is small, and possible errors in the extrapolation of these parameters are less likely than the uncertainty in the a term. Arbitrary limits for various possible extrapolations for the a coefficient past 32% sulfide are shown by the vertical arrows. The points given by the solid dots are those used in the calculation of the expected ionic conductivity for the higher concentrations and are given in Table I.

The difference between the measured conductivity and the expected ionic conductivity for concentrations above 32% lead sulfide, then gives the specific electronic conductivity. When multiplied by the molar volume of the melts, the molar electronic conductivity is obtained. The conductivity is then expressed per unit mole rather than per unit volume. The plot of the logarithm of the molar electronic conductivity *vs.* the reciprocal temperature is shown in Fig. 4. The points show the electronic conductivity calculated at 20°C intervals from the measured data. The electronic conductivity for these compositions is seen to be characterized by a temperature-independent activation energy over a wide temperature range, the deviations for the 44.6 mole % lead sulfide curve at low temperatures being on the borderline of being significant. The arrows on the lines show the uncertainty involved in the extrapolation for the expected ionic conductivity. If different extrapolations are made, the conductivities are all shifted in the same direction by the amount indicated by the arrows. The temperature dependence of the electronic conductivity in this region is then seen to be typical of an intrinsic semiconductor. A similar behavior was observed in the silver chloride-silver sulfide system when electronic conduction commenced. Exactly the same behavior with respect to the extrapolation for the ionic conductance is observed when excess soluble metal is added to the lead chloride-lead sulfide system.

The molar electronic conductivity of these mixtures was fitted to the equation

$$\Lambda_m = \Lambda_{oe} - \frac{\Delta H^*}{RT} \qquad [1]$$

and the results are shown in Table II. The standard deviations quoted are those determined graphically from the scatter of the measured points about the total conductivity predicted by the parameters given in Tables I and II. The uncertainty in the values for the

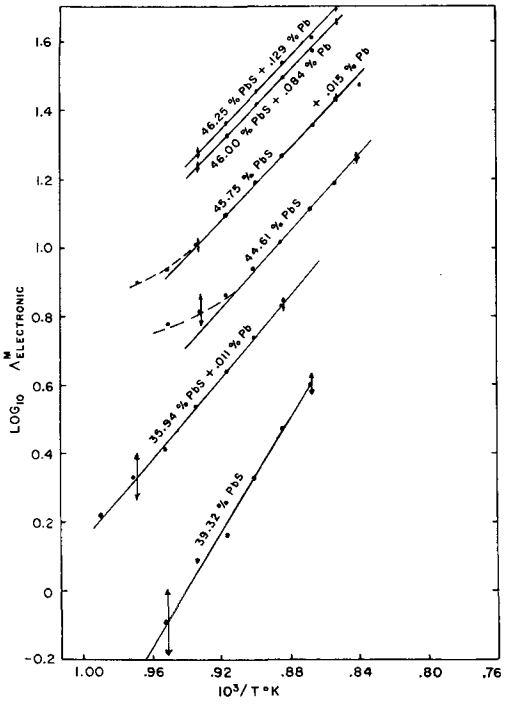

Fig. 4. Plot of the logarithm of the molar electronic conductivity vs. the reciprocal temperature.

activation energies correspond to the uncertainty in the extrapolation for the ionic conductivity shown in Fig. 3.

The data for the specific conductivities above 45 mole % sulfide are also shown in Table II, along with the determined activation energies. The errors shown are only approximate and are based on the fact that three determinations of the conductivity of pure liquid lead sulfide gave results within 5% of the mean value. The possible errors in the activation energies are difficult to assess, but the measured conductivities showed the same temperature dependence even after some decomposition of the sulfide had occurred.

The conductivity of liquid lead sulfide would appear to be about twice the value for the solid state when results from lower temperatures are extrapolated over a wide temperature range (6). This increase in conductivity is similar to the large increases in conductivity that occur on melting silicon, germanium, tellurium, tin sulfide, and a number of antimonide compounds (14-16).

The measured activation energy for pure liquid lead sulfide corresponds to an energy gap between the valence and conduction bands of 0.7 ev, if the liquid is considered as a semiconductor. This value compares with the value of 0.35 ev for solid lead sulfide (6). Similarly, the specific conductivity of liquid tin sulfide has a positive temperature dependence giving an energy gap of 1.9 ev (15) compared to a value of 1.2 ev for solid tin sulfide which is also an intrinsic semiconductor (17). Liquid selenium has also been shown to be a semiconductor having an energy gap of 2.3 ev, compared to 1.8 ev for the solid (18). This data would suggest that the positive temperature dependence of the conductivity in these systems is indicative of semiconductive behavior. In the solid state, the energy gap may be determined from conductivity measurements, as the mobility changes with temperature in a much slower manner than the exponential temperature dependence of the electrons raised to a conduction band.

From Table II, there is seen to be a large increase in the activation energy for electronic conduction, or in the energy gap, as lead chloride is added to the sulfide. The same observation was made in the silver sulfide-silver chloride melts in the region in which electronic conductivity commenced (7). This increase may be attributed to the more ionic bonding in these solutions as compared to the partially covalent pure sulfide.

The activation energy for electronic conduction in the silver sulfide-silver chloride system at 35 mole % added sulfide is less than half that in the lead sulfide-lead chloride system. This lower energy may also be attributed to the more covalent nature of silver sulfide, as indicated by the phase diagram and density measurements (3) of that system. Hall constants have not been measured in these systems, so that the number of charge carriers has not been determined experimentally. If the liquids are considered as semiconductors having a finite conduction band, the concentration of electrons n per unit volume, raised to the conduction band is given by the well-known expression

$$n = NT^x(m^* \cdot m)^y \cdot e^{-Eg/2KTG} \qquad [2]$$

where Eg represents the energy gap measured from the valence band, m^* is the effective electron mass, and m the normal electron mass. Such a relationship could be expected to hold for both the pure liquid sulfide and a solution, if both these liquids are intrinsic semiconductors.

The molar conductivities of these liquids may be expressed as

$$\Lambda m = 2k \cdot n \cdot \mu \cdot e \cdot Vm \qquad [3]$$

where e is the electron charge, μ is the mobility of the electrons, k is the conversion factor for the units, and Vm the molar volume of the liquid. The factor of 2 is introduced to account for positive hole conduction, as observed in solid lead sulfide at high temperatures (4, 5).

The ratio of electron mobilities in pure lead sulfide at 900°C, (μ_p), to that in a solution at 45 mole % sulfide, (μ_s), at the same temperature may be obtained by dividing the corresponding expressions

$$\frac{(\Lambda m)_p}{(\Lambda m)_s} = \frac{n_p \cdot \mu_p \cdot (V_m)_p}{n_s \cdot \mu_s \cdot (V_m)_s} \qquad [4]$$

where the constants shown in Eq. [3] cancel out.

The electron concentration ratio may be obtained from Eq. [2]. Since the comparison is made at the same temperature the pre-exponential terms in this equation will cancel out when substituted in Eq. [4].

The assumption is also made that the effective electron masses are the same in the two systems, or that both are equal to the normal electron mass. This assumption has some basis as Hall measurements in liquid metals and liquid germanium have been deter-

mined and show that the effective masses in these liquids are close to the normal electron mass (14). For the calculation, the energy gap is taken as being equal to twice the measured activation energies of conduction, *e.g.*

$$\frac{Eg}{2K'} = \frac{\Delta H^*}{R}$$

On substituting the corresponding values for the energy gaps and the measured molar electronic conductivities at 1100°C, the ratio of the mobilities in the two systems may be calculated as

$$\frac{\mu_p}{\mu_s} = 0.14 \text{ at } 1100°C$$

That is, the electron mobility in the solution is greater than the mobility in pure liquid lead sulfide. This could be accounted for by a lower scattering cross section of the chloride ion compared to the highly charged divalent sulfide ion present in the pure sulfide. The calculation indicates that the decrease in conductivity by a factor of 100 on going from the pure sulfide to a solution at 45 mole % sulfide is not necessarily caused by a decrease in the mobility of the electrons, but may be accounted for by the increase in the energy gap in the solutions on the addition of the ionic chloride.

Electrical conductivities and metal solubilities in the ternary system Pb-PbS-$PbCl_2$.—The interpretation of the electrical conductivities in the ternary system Pb-PbS-$PbCl_2$ requires the knowledge of the solubility of lead metal in the PbS-$PbCl_2$ melts.

Solubilities of lead were determined in melts containing only up to 50 mole % sulfide, because in this region the sulfide-chloride melts were quite stable, and accurate data on conductivities could be obtained. The measured solubilities are shown in Fig. 5. The solubility of lead in lead chloride is quite small, 0.008 mole % at 583°C to 0.056 mole % at 886°C. The measured solubilities are about one-third of those reported by Corbett (20). It was observed in the present investigation that if the reagent grade lead chloride was used as-received without previous purification, solubilities closer to those reported by Corbett (20) at 600°C were obtained.

It is evident that these small solubilities are very sensitive to the purity of the sample, and that the presence of oxygen or metallic impurities in the system may increase the measured solubility.

Despite the scatter in the results for the the mixtures of lead chloride and lead sulfide, it is apparent that the solubility at low temperatures (583°C) is very small, less than 0.02 mole %, for all the compositions studied. The solubility increases with increasing temperature and increasing sulfide concentration to a value of 0.65 mole % at 50 mole % sulfide and 886°C. Analysis of the lead buttons showed that most of the buttons contained no detectable amounts of chloride or sulfide, so that the solubility of lead chloride and lead sulfide in liquid lead is very small.

The measured solubilities of lead in pure lead chloride show less scatter than the data for the mixtures, and it is possible to obtain a value for the partial molar heat of solution of lead in lead chloride. A plot of the logarithm of the solubility *vs.* the reciprocal temperature is shown in Fig. 6. Despite the fact that only four readings were taken, a good straight line is obtained. The solubilities reported by Topol (21) are shown for comparison. The slope of the line for the present investigation gives a partial molar heat of mixing of +13.2 kcal, if the activity coefficient of lead in the solution is constant over the composition range involved. In view of the extremely small solubilities such an assumption is quite justified. Such a high positive heat at such low concentrations is indicative of the large immiscibility gap in the lead chloride-lead system. The scatter in the measured solubilities for the sulfide-chloride mixtures makes it impossible to determine the heat of solution with any precision in these mixtures.

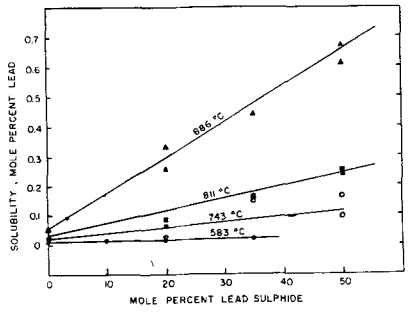

Fig. 5. Solubilities of lead metal in molten PbC-$PbCl_2$ mixtures as a function of the lead sulfide content.

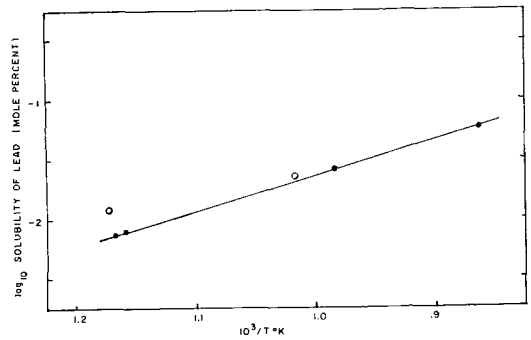

Fig. 6. Plot of the logarithm of the solubility of lead in lead chloride vs. the reciprocal temperature: ● this investigation; ○ Topol (21).

The effect of added soluble lead metal on the conductivity in the binary lead chloride-lead sulfide system was determined at three sulfide concentrations, 25, 36, and 46 mole % lead sulfide. The effect of added metal on the specific electronic conductivity is shown at one temperature in Fig. 7. The electronic conductivity was determined as the difference between the measured and the expected ionic conductivity. The values used for the ionic conductivity are shown in Table I. At 25.6 mole % lead sulfide, no electronic conductivity is occurring in the binary system, and the addition of 0.013 mole % lead metal produced no observable change in the conductivity even after standing overnight and thoroughly mixing. At 35.9 mole % lead sulfide, very little electronic conductivity is expected in the binary system, and the addition of metal increases the conductivity as shown. At 46 mole % sulfide, electronic conduction is occurring in the binary system, and the addition of metal increases the conductivity only slightly.

At the final metal concentration, the electronic conduction is about the same as the ionic conductivity in the system.

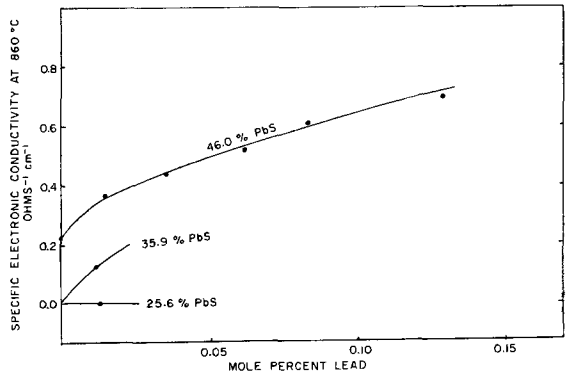

Fig. 7. Effect of added lead metal on the specific electronic conductivity of the PbS-$PbCl_2$ solutions at 860°C.

Table III. Electronic conduction in the Pb-PbS-$PbCl_2$ system: $\Lambda_m = \Lambda_o e^{-H^*/RT}$

Λ_m in ohm^{-1} mole^{-1} cm^2.

The temperature dependence of the electronic conductivity in this system is also shown in Fig. 4. The molar electronic conductivity was calculated in the same manner as for the binary system. The points on the lines again represent the electronic conductivity calculated at 20°C intervals from the measured data. It is evident that the electronic conductivity occurring in the systems with metal added, is characterized by a temperature independent activation energy of much the same value as that occurring in the binary systems. Not as many compositions are shown on this graph as in Fig. 7, because the conductivities of some of the metal concentrations were measured at a few temperatures only. The arrows on the lines again show the uncertainty in the extrapolations caused by the extrapolation for the ionic conductivity. Not as many readings were taken as in the binary systems, and the scatter in the measured values was greater. The resulting uncertainty in the determined activation energies is at least as great as the uncertainty caused by the extrapolation for the ionic component. Values for the constants in a simple exponential equation to give the measured molar electronic conductivity are shown in Table III. At 46 mole % sulfide the determined activation energy for conduction in the system with metal added are less than 0.8 kcal smaller than the activation energy in the binary system at 45 mole % lead sulfide. Such a change is very small and may not be significant within the accuracy of the data.

It may therefore be concluded that the added metal is not contributing electrons to the system at a donor level significantly different from the valence band in the binary system. This conclusion is consistent with the small increase in conductivity occurring. If the added metal atoms were all ionized giving free electrons in the conduction band, then at a metal concentration of 0.014 mole % metal, or approximately 2 x 10^{18} at., an increase of conductivity by about 1000 would be expected.

It then appears probable that the added metal is not acting as an electron donor, but is trapped by some mechanism which raises the valence band of the system slightly. Since this trapping does not occur in the pure sulfide where the conductivity changes extremely rapidly with small amounts of added metal, a complex involving chloride ion, such as $Pb+Cl^-$, is suggested as a possible trapping mechanism.

The rather low metal solubility in melts of this type may be accounted for by a "salting out" effect due to the free electrons. Thus, the dissolution process may be described by the reaction.

$$\underset{\text{(in metal)}}{M} = \underset{\text{(in melt)}}{M^+} + \underset{\text{(in melt)}}{e^-}$$

for which

$$Keq. = a_{M+} a_{e-} \qquad [5]$$

a_{M+}, and a_{e-} are the activities of the metal ions and of electrons in the salt phase, respectively.

In the present instance the salts are semiconductors and the relative concentration of "free" electrons is relatively high. This would cause the equilibrium in Eq. [5] to be shifted to the left. Preliminary experiments on the solubility of silver metal in molten silver chloride-silver sulfide mixtures at 25 mole % sulfide, have indicated a solubility of silver of less than 0.016 mole % at 890°C. This is much lower than the solubility of lead in lead chloride-lead sulfide melts at the same temperature (0.32%). Solutions of silver sulfide in this range have been shown to have much higher electronic conductivities. Accordingly they should also be expected to have a higher concentration of free electrons and a lower metal solubility.

Conclusions

Lead chloride has a low specific conductance (1.49 at 500°C) and a high "apparent" activation energy for ionic conduction (4.32 kcal at 500°C). The addition of lead sulfide to the chloride decreases the ionic conductivity in much the same manner as the addition of silver sulfide decreases the conductivity of silver chloride.

Liquid lead sulfide exhibits a positive temperature dependence for electronic conduction, typical of semiconductive behavior. The conductivity decreases very rapidly on the addition of lead chloride to the sulfide and always has a positive temperature coefficient. The metallic temperature dependence of the electronic conductivity observed in the AgCl-Ag_2S system above 50% silver sulfide is completely absent in the lead sulfide melts. The difference may be attributed to the more ionic nature of lead sulfide.

The activation energy for electronic conduction increases as lead chloride is added to lead sulfide from a value of 8 kcal in the pure liquid lead sulfide to 25 kcal at 45 mole % sulfide in lead chloride. The temperature dependence of the liquid mixtures it typical of intrinsic semiconductive behavior. If it is assumed that the effective mass of the electrons in the solution is the normal electron mass, the mobility of current carriers in a mixture of lead chloride with 45% lead sulfide is greater than in pure liquid lead sulfide. The large decrease in conductivity on adding lead chloride to the sulfide is then caused only by the increase in the energy gap on the addition of the chloride. The increase in the activation energy, or the energy gap, may be attributed to the more ionic behavior of the liquid mixtures, as compared to the partially covalently banded sulfide.

The solubilities of lead in lead chloride and in lead chloride-lead sulfide mixtures have been determined. The solubilities increase with increasing temperature and sulfide concentration to a value of 0.65 mole % lead at 50 mole % sulfide and 886°C.

The electronic conductivity is seen to increase only by a small amount when lead metal is added to the binary system. The data indicate that the added lead is not acting as an electron donor in these melts.

Thermodynamic Properties of Molybdenum (III) Chloride in Molten Alkali Metal Chlorides

Sidney M. Selis

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Using emf methods, partial thermodynamic values in molten LiCl-KCl have been precisely determined from 460° to 540°C in the Mo concentration range of 0.01 to 0.4 mole/liter. At 460°C, the free energy of formation of the molybdenum (III) chloride in a 1M solution is −63,700 ± 100 cal/mole and the corresponding entropy change is −34 ± 2 cal/deg/mole. Extrapolated to 450°C, the potential of Mo/Mo(III) (1M in LiCl-KCl) *vs.* Pt/Pt(II) (1M) is −0.603 ± 0.002v. There is a strong solvent cation effect due to coulombic, steric, and other contributions, and the excess free energy of $MoCl_3$ in KCl is much more negative than in LiCl-KCl.

The chlorides and bromides of metals in Groups IV-A, V-A, and VI-A ("refractory metals") have certainly not been the subjects of complete physicochemical investigations at elevated temperatures. Thermodynamic quantities, for instance, are not listed for many compounds, either pure or in solution. There are technical reasons for this. Physical behavior of melts results in real inconvenience for a number of experimental techniques, and the halides are unstable in the presence of moisture. Moreover, unambiguous definition of the chemical system may not be possible. Several valence states are exhibited by each of the elements, and oxidation or reduction from one to another takes place readily.

The present work is concerned with thermodynamic properties of liquid molybdenum (III) chloride. When heated, this compound vaporizes without melting, and it is not possible to study the pure liquid. But it is possible to prepare solutions in molten alkali metal chloride solvents and then to determine partial quantities. Values for LiCl-KCl have been compared with those available for pure potassium chloride, and there is an interesting solvent effect.

Furthermore, the electrode Mo/Mo(III) is now included in an emf series (for the solvent LiCl-KCl at 450°C).

Background.—In 1954 Senderoff and Brenner reported some preliminary experiments with molybdenum electrodes in molten mixtures of LiCl-KCl-K_3MoCl_6 (1). Although no rigorous proof was provided, they suggested that molybdenum metal is in equilibrium with Mo(III). It was shown that anodization of the metal occurs with unit efficiency assuming a three-electron change, and reduction of molybdenum (III) chloride to the metal also takes place with unit efficiency. Moreover, large anodic and cathodic current densities are accompanied by relatively small overpotentials.

Recently Ryzhik and Smirnov measured the equilibrium potentials of Mo/Mo(III) electrodes in molten KCl at 780°-940°C (2). They used the reference electrode Cl^-/Cl_2 (in pure liquid KCl), and their data were satisfactory for the calculation of partial thermodynamic quantities for molybdenum (III) chloride in the liquid potassium chloride solvent. Later in this paper there will be a comparison of these results with the present ones obtained at lower temperatures using the molten lithium chloride-potassium chloride solvent.

The present study was made with cells of the type Mo/$MoCl_3$ in LiCl-KCl//LiCl-KCl//$PtCl_2$ in LiCl-KCl/Pt. The solutions of molybdenum and platinum chlorides were dilute. Molybdenum (III) and platinum (II) ions were therefore unimportant carriers of current, and liquid junction potentials were consequently negligible. The temperature region was 460°-540°C, limited at the lower end by the solubility of the molybdenum (III) compound and at the upper end by the stability of the platinum (II) chloride in the reference electrode.

The platinum electrode was used for convenience instead of measuring against the chlorine electrode directly. The precise data of Laitinen and Pankey (3) are available for the cell Pt/$PtCl_2$ (1M) in LiCl-KCl// LiCl-KCl//Cl_2, C. Potential difference is given as a function of temperature, and with this, one can normalize the molybdenum electrode data, obtained with a platinum reference, to the reference Cl^-/Cl_2 (in liquid LiCl-KCl).[1] In this way, thermodynamic values are determined for the reaction

$$Mo(c) + 3/2Cl_2(g) \rightarrow MoCl_3(l, \text{ in solution})$$

Experimental

Materials.—The platinum wire (B & S 20 gauge) and sheet (0.3 mm in thickness) were over 99.99% pure. The molybdenum sheet (0.8 mm in thickness) was over 99.9% pure, the major impurity being carbon; it was obtained from the Climax Molybdenum Company. The carbon rods, 6 mm in diameter, were of spectrographic grade.

Chemically pure potassium hexachloromolybdate (III) was supplied by A. D. Mackay, Inc. Composition was verified by analysis for molybdenum using the photometric thiocyanate method (22.5% Mo calculated,

[1] Laitinen and Pankey measured platinum-chlorine cells in the temperature range 410°-490°C and arrived at relationship [1]. For the present work, it is assumed that the relationship remains valid and the electrode is usable up to 540°C.

22.3% Mo found). The chemical was dried at 110°C before use.

The LiCl-KCl mixture was of eutectic composition (58.8 mole % LiCl; 41.2 mole % KCl). It was purified by the procedure of Laitinen, Tischer, and Roe (4) which involves evacuation with gradual warming of the salts, melting under purified HCl gas, flushing with purified argon, and the use of magnesium metal which displaces heavy metal ion impurities from the alkali metal chloride electrolyte. The melts were not separately filtered and sealed in ampoules. Instead, purification was carried out in the cell container, and when the glass tubes with fritted disks were lowered and the electrolyte seeped through the porous diaphragms, the solid material was thereby filtered off and remained outside the electrode compartments. When an experiment was run in which electrolyte was subjected to the complete manipulation with opening and closing of the cell, except for actual addition of molybdenum (III), it was found that the polarographic residual reduction current was less than 1 μa with a platinum electrode area of 1 mm^2 at a potential of —2.0v *vs.* Pt/$PtCl_2$ (1M) in LiCl-KCl. Effective purification is therefore indicated, as is validity of the technique in terms of purity considerations.

Procedure.—Molybdenum electrode potentials were measured against the platinum reference with a technique similar to that used by Laitinen and Liu (5); the method involves a cell with compartments separated by fritted glass. In the present work the weight of electrolyte was 100g contained in a Vycor test tube with a diameter of 52 mm. The diameters of the compartment cups were 13 and 26 mm. The electrode leads of platinum wire were sealed in tubes at the upper ends, and the air in these tubes was replaced with argon before the electrodes were lowered. The platinum wire was connected to the molybdenum by spot-welding, using a short intervening piece of nickel.

Temperatures were measured with a chromel-alumel thermocouple calibrated at the melting points of zinc and aluminum. Temperatures could be maintained constant to within ± 0.5°C. The platinum electrode was generated by anodizing the platinum metal using a carbon counter cathode. Current density was 10-20 ma/cm^2, and the coulometric delivery was measured. The amount of electrolyte in the compartment

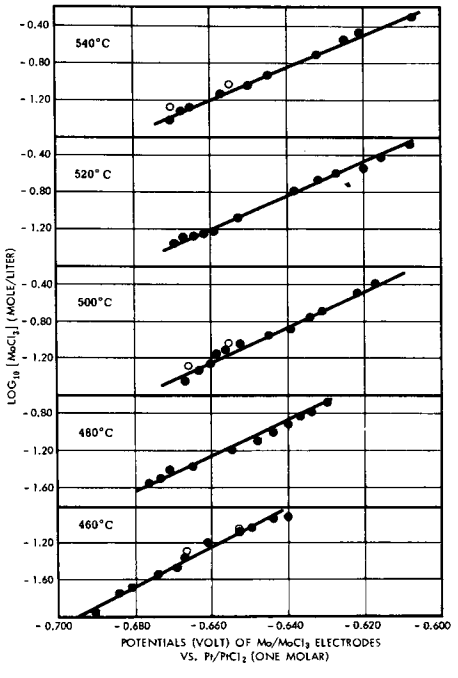

Fig. 1. Potentials of molybdenum electrodes with respect to the platinum reference: •, additions by current passage; ○, additions with K_3MoCl_6.

Table I. Nernst behavior of the molybdenum electrodes

Temperature, °C	$(\partial E/\partial \log [Mo^{+++}]_T$ (v) Calculated	Observed
460	0.0485	0.0471
480	0.0498	0.0550
500	0.0512	0.0508
520	0.0525	0.0578
540	0.0538	0.0569

was later determined using the Volhard procedure. Concentration of $PtCl_2$ in the compartment was about 0.05 mole/l (known precisely).

The molybdenum electrodes were similarly formed and later analyzed for quantity of electrolyte. After the potential was measured for one concentration, current passage was resumed to obtain the next composition. The concentration ranges are shown in Fig. 1. As much as an hour was required for a potential to become steady after a composition was changed, but once stable, the reading would generally not vary more than 1 or 2 mv in a half hour. These readings were made with a null-balancing potentiometer, the button switches being closed only momentarily.

As shown in Fig. 1, values were verified by using cells in which the molybdenum (III) was added at the beginning as K_3MoCl_6. This was weighed out with the lithium and potassium chlorides. Purification of the electrolyte was the same except that magnesium metal was not used.

Results

When the measurements with a cell were completed and the molybdenum and platinum compartments were analyzed, the molybdenum electrode composition could be defined and the potentials could be expressed with respect to Pt/$PtCl_2$ (1M in LiCl-KCl) through the use of the Nernst relationship. In Fig. 1 are plotted molybdenum electrode potentials *vs.* log concentration of molybdenum (III) for five temperatures; replicate experiments were run in order to obtain these data. The behavior is linear, and the slopes, determined by the method of least squares, are compared in Table I with the slopes calculated with the Nernst equation, assuming $n = 3$.

$$E_{Pt/PtCl_2//Cl^-/Cl_2} = -0.3223 + 0.000334\ (t - 450) \quad [1]$$

Relationship [1] gives the potentials of Pt/$PtCl_2$ (1M in LiCl-KCl) with respect to Cl^- (in LiCl-KCl)/Cl_2 at different temperatures as determined by Laitinen and Pankey (3); in their work and in the present study, temperature gradients occurred only in the platinum leads which were used from all electrodes, and so there are no corrections for thermoelectric emf. By using relationship [1], molybdenum electrode potentials with respect to the platinum electrode are normalized to the chlorine electrode, and these are numerically the same as the potential differences for the cells Mo/$MoCl_3$ (in LiCl-KCl)//LiCl-KCl/Cl_2. The reaction corresponding to these cells is the formation of molybdenum (III) chloride in solution as shown above; the partial thermodynamic quantities for the reaction are calculated from the data for these cells using relationships [2] through [4].

$$\overline{F} = nFE \quad [2]$$

$$\overline{S} = -nF(\partial E/\partial T)_P \quad [3]$$

$$\overline{H} = \overline{F} + T\overline{S} \quad [4]$$

E is the potential of the molybdenum electrode with respect to the chlorine electrode and has the negative sign when it is more anodic than the reference; n and F have the usual significance, and n is 3. Using these equations, thermodynamic quantities have been calculated; values are listed in Table II. $\overline{F}$, $\overline{S}$, and $\overline{H}$ are,

respectively, the partial molar free energy, entropy, and enthalpy of formation;[2] a negative value for $\bar{F}$ means that the formation occurs spontaneously. Concentrations are given on both molarity and mole fraction scales, the transformation being made with the density data of Van Artsdalen and Yaffe (6). Free energies and enthalpies in Table II are for a temperature of 460°C.

E was plotted against temperature for fixed concentrations, and Fig. 2 shows five of these curves. They are linear for the temperature region 460°-540°C and for the concentration ranges shown in Fig. 1. Using the method of least squares, a value of $(\partial E/\partial T)_P$ was found for each concentration and then plotted against log concentration. Again the behavior could be described as linear, and the method of least squares was again used to find the straight line. Referring to relationship [3], partial molar entropy was calculated for the concentrations as shown in Table II. The cells consist of electrodes which are metals in equilibrium with ions at about the same concentration, and so entropy differences of more than a few calories per degree per mole (positive or negative) are not to be expected. Partial entropies as large as −28 cal/deg/mole are given in Table II, but the major contribution to this (−23 cal/deg/mole) is by the chlorine electrode where the formation of $MoCl_3$ is accompanied by the disappearance of a gas phase.

[2] These partial thermodynamic quantities, having the general abbreviation $\bar{G}_{MoCl_3}$, are defined as $(\partial G \text{ system}/\partial n_{MoCl_3})_{n \text{ solvent}, T}$.

540		(−61,000)	(−63,300)

* Parentheses indicate that the values are based on extrapolation of data.

Partial enthalpies, shown in Table II, were determined according to relationship [4]. The average deviation is based on the deviations in the free energy and entropy determinations.

Of interest are partial free energies of formation of $MoCl_3$ at standard concentrations and at different temperatures. These are listed in Table III. Enclosure of the values within parentheses indicates that they were obtained by extrapolating the curves in Fig. 1.

Discussion

One of the contributions of the present work is the determination of the Mo/Mo(III) potential which can be put in the emf series developed by Laitinen and co-workers (3, 5). For this series, the metal chlorides are dissolved in LiCl-KCl to the extent of 1 mole/l at 450°C. By extrapolation the molybdenum value is −0.603 ± 0.002v with respect to $Pt/PtCl_2$ (1M). It is more noble than Sb/Sb(III) by 32 mv and less noble than Bi/Bi(III) by 50 mv.

As already seen, only partial quantities for $MoCl_3$ in solution can be determined, and they cannot be related to pure liquid $MoCl_3$ which does not actually exist and for which hypothetical thermodynamic data are not available. One might express the partial quantities relative to pure solid $MoCl_3$, but the numbers would have only a very limited usefulness.

There is another standard state which might be employed and that is the infinitely dilute solution in the LiCl-KCl electrolyte. But over the entire concentration range activity coefficients are constant for each temperature. With the present data, therefore, reference to the infinitely dilute solution is a trivial calculation.

The potential-temperature data of Ryzhik and Smirnov (2) are precisely linear, and the present author has extrapolated them to 500°C. For their cell containing 2.58 w/o Mo in molten KCl (2.12 mole % of $MoCl_3$), the potential *vs.* Cl^-/Cl_2 is −1.403v. The molybdenum electrode with the same mole fraction composition in the LiCl-KCl solvent exhibits a potential of −0.910v *vs.* Cl^-/Cl_2 at 500°C. Lithium ion is smaller than potassium ion. In the LiCl-KCl solvent, therefore, the anions are closer to the solvent cations and less available for solvation of the molybdenum ion. Thus a more negative potential in pure KCl is predicted, but the effect is greater than expected. It is equivalent to 34 kcal/mole, much too large to be explained by small variations in Mo-Cl distances. Perhaps it represents a real difference in the structure of solutions in molten LiCl and molten KCl. A general discussion of these effects is given by Blander (7). Further measurements with pure LiCl and NaCl would certainly be of interest and might clarify the situation.

Hyper-Maintenance of Electroluminescence

W. Lehmann

Westinghouse Electric Corporation, Research & Development Center, Pittsburgh, Pennsylvania

ABSTRACT

Electroluminescent ZnS:Cu becomes extremely deterioration-resistant after firing or refiring in pure sulfur. Additional air bake is permissible. The emission does not deteriorate toward zero, but toward a finite equilibrium which, in best cases, may be more than 50% of the original intensity. These "hyper-maintenance" phosphors permit high brightness (by excitation with high frequency) to be maintained over long time. The deterioration is considered to be due to sulfur vacancies diffusing from the particle surfaces into the interior.

The electroluminescence of powdered ZnS or (Zn, Cd)S phosphors embedded in an insulating medium and excited by an alternating electric field usually deteriorates with a rate which is nearly inversely proportional to the frequency, but which depends little or not on the amplitude of the exciting field (1). Therefore, it has become customary to characterize the maintenance behavior of a phosphor by the number of cycles required to deteriorate the emission intensity to 50% of its original value. This half-life is in the order of 10^7 to 10^8 cycles of continued operation in case of an ordinary ZnS:Cu,Cl phosphor embedded in a plastic dielectric and operated in dry air at room temperature. Thornton improved this half-life by a factor of roughly two to ten, *i.e.*, up to about 10^8 to 10^9 cycles, by means of air baking (2). A similar improvement is achieved if the phosphor is embedded in a ceramic (instead of a plastic) dielectric. Jaffe observed that replacement of the chlorine by bromine resulted in another improvement by a factor of 5 or more (3) which extended to obtainable half-life up to 10^9 to 10^{10} cycles.

We discovered that green emitting ZnS:Cu,Br or corresponding (Zn,Cd)S phosphors become extremely deterioration resistance if they are fired, or refired, in an atmosphere consisting of approximately 100% sulfur vapor provided only that the phosphor is in actual contact with the sulfur when it cools down after firing. The latter condition is essential. If the phosphor is fired and cooled in sulfur, the maintenance is good. If it is fired in sulfur but cooled in nitrogen or argon, the maintenance is poor. If it is fired in argon but shortly refired and cooled in sulfur, the maintenance is good. It is permissible also to use Thornton's air bake procedure on sulfur-fired phosphors and, in fact, this combination gave the longest living phosphors.

The emission intensity of an electroluminescent phosphor so prepared usually does not deteriorate with time to zero but to a finite level and, in some cases, this finite level may be higher than 50% of the zero-hour intensity so that the "half-lifes" of these phosphors appear to be infinitely long. This behavior was called "hyper-maintenance." The investigation on hyper-maintenance of electroluminescence is as yet not considered to be complete. Nevertheless, some observations and conclusions may be communicated.

Life tests on hyper-maintenance phosphors naturally require much time and, in contrast to ordinary electroluminescent phosphors, cannot be accelerated by excitation with a higher frequency since their deterioration is not inversely proportional to, but almost or completely independent of, the exciting frequency. For this reason, hyper-maintenance phosphors show their best performance at high frequency (typically in the order of 10 kcps) where ordinary phosphors would deteriorate within a relatively short time. It is thus possible with hyper-maintenance phosphors excited with high frequency to maintain substantial brightness over long times. However, an accelerated deterioration of hyper-maintenance phosphors with increasing electric field strength was observed, also in striking constrast to the behavior of ordinary electroluminescent phosphors whose maintenance is almost or completely independent of the field strength.

The zero-hour brightness of a good hyper-maintenance ZnS:Cu phosphor usually is somewhat lower (roughly between 50 and 100%) than that of a standard ZnS:Cu phosphor. However, several per cent of the ZnS may be replaced by CdS (4) which, beside the well-known color shift of the emission, causes all traps to become somewhat shallower (5) and, therefore, an extension between the approximate proportionality between emission intensity and frequency up to higher frequencies. Hence, hyper-maintenance is most successfully combined with (Zn,Cd)S phosphors to be excited by high frequencies and, under this condition, even the zero-hour brightness of a hyper-maintenance phosphor may be better than that of a standard ZnS phosphor. Typical data are compared in Table I.

Some deterioration curves measured on (Zn,Cd)S:Cu phosphors are shown in Fig. 1 and 2. The phosphors corresponding to Fig. 1 are fired in sulfur and air baked. They differ only in their CdS concentration (and, hence, somewhat in their emission color) but not in their maintenance (exceeding the unavoidable limit of accuracy of the measurements). Each curve in Fig. 2 is the average of measurements on four phosphors containing Cl, Br, or I, respectively. All samples containing Cl and Br are green emitters while the four iodine containing samples emit blue. The superiority

Table I. Zero-hour emission intensity of a hyper-maintenance ZnS(90%), CdS(10%):Cu,Br phosphor compared with a standard ZnS:Cu,Cl phosphor

Phosphor	(Zn,Cd)S:Cu,Br (hyper-maintenance)		ZnS:Cu,Cl (standard)	
Frequency (cps)	60	5000	60	5000
Brightness (ft-L)	2.2	230	3.2	140
Quanta (arb. units)	3.1	320	5.3	300
Emission color	Yellow-green		Green	

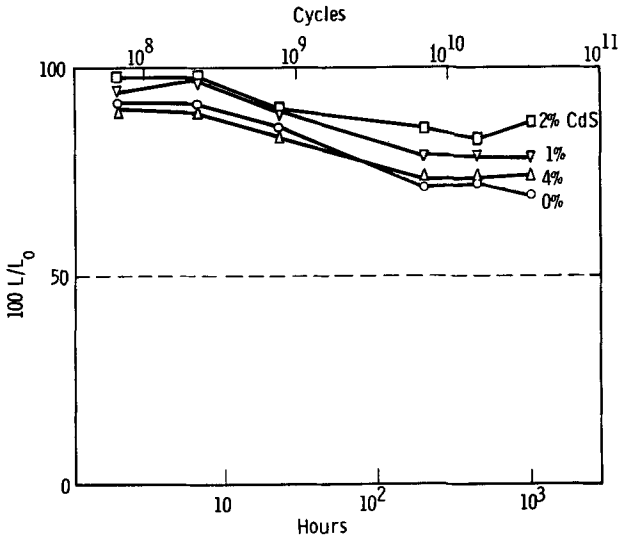

Fig. 1. Deterioration curves measured on several (Zn,Cd)S:Cu,Br phosphors, all sulfurized and air baked, operated in dry air at room temperature, 10 kcps.

of Br over Cl and I is clearly to be seen, and the approach of the curves corresponding to Br containing phosphors to finite and rather high brightness levels after long time of operation is quite obvious.

The observed effect of sulfur and air (*i.e.*, oxygen) on the maintenance of electroluminescence gives a clue as to a possible mechanism of deterioration. It is assumed that the phosphor deteriorates because of a creation of deep traps due to sulfur vacancies which, under the combined action of temperature and electric field, diffuse from the particle surface into the interior. This assumption is in agreement with many observations:

(*A*) Indications are that a commonly observed glow peak at about —125°C is due to sulfur vacancies (5, 6). However, the latter must be expected to be double donors producing two glow peaks. Although considerable uncertainty still exists, the second level may be the one responsible for a frequently observed glow peak at about —50° to —20°C which was observed by Jaffe (3) to increase strongly during deterioration.

(*B*) The deterioration effect is temperature dependent and proportional to $\exp(-E/kT)$ where E is some

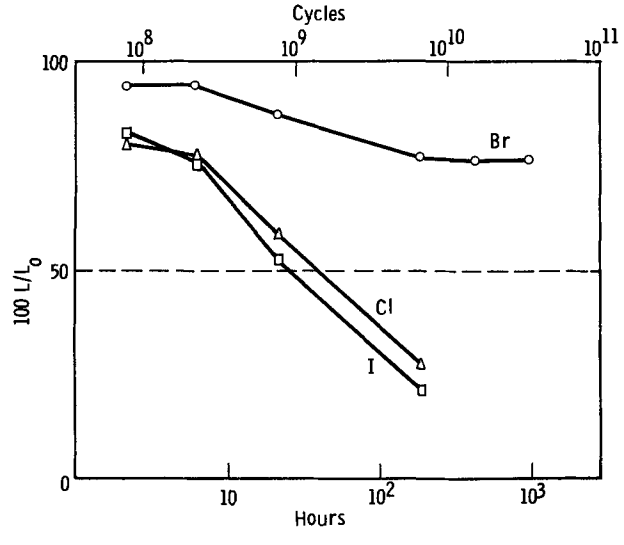

Fig. 2. Average deterioration curves (each 4 samples) measured on (Zn,Cd)S:Cu phosphors made with Cl, Br, or I, respectively. The phosphors are sulfurized and air baked, operated in dry air at room temperature 10 kcps.

energy (1). This indicates some kind of diffusion process involved, as already assumed by several workers.

(*C*) Maintenance improves with the particle size of the phosphor (1). Hence, an influence of a competition between particle surface (or surface-near parts) and the volume is indicated. Since glow peaks do build up during deterioration, a diffusion of something responsible for the additional glow peaks from the surface into the volume seems to take place.

(*D*) The most obvious way to improve the maintenance is to take care that little or no sulfur vacancies are available at the surface of a phosphor particle ready to diffuse into the volume, *i.e.*, the surface atoms of each particle shall be mostly sulfur rather than zinc atoms. Such a phosphor particle has only a limited number of sulfur vacancies available ready to diffuse into the volume, so that its emission does not deteriorate toward zero but toward a finite level. The particle has then used up all available sulfur vacancies from its surface and remains at a finite brightness level without any further deterioration provided only that no new sulfur vacancies are created at the surface.

(*E*) Sulfur vacancies may be occupied also by other anions, *e.g.*, by oxygen. Hence, a bake in oxygen [or in air (2)] improve the maintenance considerably while a bake in a neutral atmosphere (*e.g.*, argon) has little or no effect.

(*F*) ZnSe phosphors can be expected to contain fewer anion vacancies on their particle surfaces than ZnS because selenium is less volatile than sulfur. Hence, the life time of electroluminescence of ZnSe phosphors can be expected to be better than that of ZnS phosphors, in general agreement with experience.

(*G*) Water may cause a break of the Zn-S bond between surface atoms of a ZnS crystal so that, originally, equimolar amounts of Zn and S are effectively removed from the crystal. The reaction requires a certain energy which may be supplied by ultraviolet irradiation or, in case of electroluminescence by the same electric field which excites the phosphor. Various, and not too well understood, further reactions between the liberated Zn, the S, and the surrounding (*e.g.*, the water) are possible. These secondary reactions seem to cause a desulfurization of the particle surfaces. At least, liberated zinc frequently appears during exposure to ultraviolet (Lenard), or during electroluminescence in the presence of water (7), and can be observed visually as a very thin, dark deposit on the particle surfaces. Free surface zinc is identical to sulfur vacancies on the particle surfaces, ready to diffuse into the particles.

The proposed deterioration mechanism is accessible to a semiquantitative analysis. Let the time-average of steady-state emission be $L = \beta/M$ where M is the concentration of deep traps in the particle volume, and where β represents all other parameters. It must be supposed that the traps denoted by M are deep enough that a captured electron has little chance of escape during one cycle of the applied frequency. The concentration of sulfur vacancies at or near the surface may be C. When they diffuse into the volume, they decrease at a rate proportional to C which gives

$$C = C_o \exp(-\alpha t) \qquad [1]$$

where C_o and α are constants, and t is the time. Simultaneously, the concentration of deep traps in the volume increases with the same rate

$$dM/dt = -dC/dt = \alpha C_o \exp(-\alpha t)$$

which gives

$$M = M_o + C_o [1 - \exp(-\alpha t)] \qquad [2]$$

Hence, the emission intensity at any given time, normalized to the "zero-hour" intensity L_o, is

$$L/L_o = M_o/M = \{1 + (C_o/M_o)[1 - \exp(-\alpha t]\}^{-1} \qquad [3]$$

This is a function of the ratio L/L_o on the variable αt with one parameter, the ratio C_o/M_o. The function is

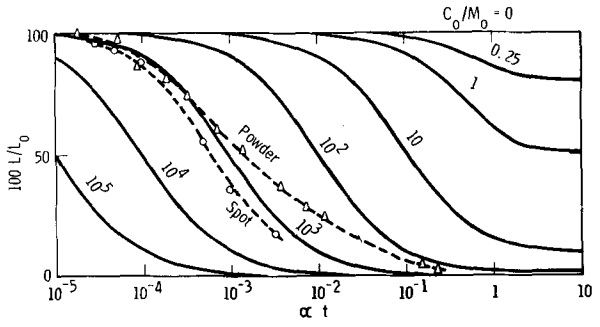

Fig. 3. Function of Eq. [3] for various values of C_o/M_o (solid curves). Experimental values measured on a powder (standard ZnS:Cu,Cl, dashed curve) and at a single emitting spot in a phosphor particle (dotted curve) are plotted on an arbitrary time scale.

shown in Fig. 3 where the curves with the lowest ratios of C_o/M_o, *i.e.*, those representing the best maintenance, do approach rather substantial values of L/L_o for $\alpha t \rightarrow \infty$. In contrast, the curves with high values of C_o/M_o, representing poor maintenance, do not only go down very soon, they also approach finite values of L/L_o very close to zero. In this case of $C_o >> M_o$, Eq. [3] reduces to $L/L_o = 1/(1 + t/\tau)$ where $\tau = M_o/(C_o\alpha)$ which is the hyperbolic decay first reported by Roberts (8).

These equations represent ideal cases only. In practice, the situation most certainly is obscured by many complications so that a more detailed calculation seems to have little sense. One complication is the fact that all real phosphors contain particles of many different sizes and, hence, different deterioration rates. If the deterioration curve of such real phosphor containing a wide particle size distribution is analyzed, one finds that the curve becomes somewhat shallower but never steeper than the ideal curves described by Eq. [3]. This is also in agreement with experiment. Figure 3 shows the deterioration curve measured on a real phosphor (a standard ZnS:Cu,Cl) which, indeed, is shallower than the ideal curves. The other experimental curve in Fig. 3 is that measured on a single emitting spot inside of one particle [measured by Haberland (9)]. One may safely assume that we are much closer to ideality in this case than in the case of a phosphor containing many particles and, indeed, the experimental curve follows the ideal ones very closely.

The proposed mechanism of a sulfur vacancy migrating from the particle surface into the volume is, of course, still a very crude approach to reality. Other atomic or ionic diffusions may occur besides those of sulfur vacancies. It is also possible that the assumption of only the outermost surface of a particle to be of influence is too extreme and that, in reality, surface-near layers several atoms deep are involved. These and other questions are still to be answered.

Anomalously Large Photovoltages in a New Photovoltaic Cell

P. N. Ramachandran and R. E. Salomon

Department of Chemistry, Temple University, Philadelphia, Pennsylvania

ABSTRACT

Unusual photoeffects have been observed in the cell Zr/ZrO_2/gas phase/M where M represents a metal plate of copper or brass and ZrO_2 is in the form of an anodic film. Photovoltages greatly in excess of the band gap of ZrO_2 are observed when Zr is cooled to liquid nitrogen temperatures and the anodized face of Zr and M are irradiated with ultraviolet light. The photovoltage increases with degassing time and with time of cooling and eventually reaches a steady maximum value. M can be replaced by a hot filament, and again large photovoltages are produced between Zr and the filament although only Zr need be irradiated in this case.

Photoeffects observed with anodized zirconium electrodes in which an electrolyte serves as a transparent contact have previously been reported (1, 2). The results of similar studies with aluminum and tantalum in which the electrolyte was replaced by a semitransparent evaporated metal coating have been described (3) and attributed to a work function difference between the contacts. Other workers (4) have interpreted the photoeffects arising with tantalum electrodes as due to a p-n junction within the oxide film. In a p-n junction photovoltaic cell the maximum photovoltage is limited to the width of the forbidden zone (5) which in the case of anodic ZrO_2 is about 5.5 ev (6). Photovoltages larger than this, as high as 90v, were reported by us (7) for anodized zirconium electrodes that were coated with a semitransparent metal, cooled to liquid nitrogen temperatures and then exposed to ultraviolet radiation of wavelength less than 2500Å. Although a number of other electrode systems have been reported to exhibit larger than band gap photovoltages (8, 9) the potential invariably appeared between contacts bounding a few centimeters of the photosensitive material and hence could be rationalized by various multiple junction mechanisms (10). Further studies on the low-temperature photoeffects occurring with anodized zirconium electrodes have led us to conclude that the electrical potential difference originally reported is actually developed between the zirconium and the grounded metallic cell chamber. The metallic chamber functioned as a photoemissive contact excited by stray ultraviolet light. This accidental finding led to the design of a new cell which

carefully defines the conduction path. It was also found that the evaporated metal film was unnecessary for the attainment of a larger than band gap photovoltage (LBGPV). Only a small voltage, less than 1v, was developed between zirconium and an evaporated metal coating on the oxide, when the electrode was cooled and irradiated with ultraviolet light. A somewhat larger photovoltage was obtained with this electrode when the experiment was carried out at room temperatures.

Since the LBGPV occurred in a system that was in some ways similar to an electrochemical cell, with the gas phase replacing the usual electrolyte, a new variable, namely the composition of the gas phase is available for study. It was therefore desirable to carefully define the conditions necessary for the attainment of a LBGPV in the cell Zr/anodic ZrO_2/gas phase/M. M refers to a photoemissive metal electrode, and both the anodic film and M are irradiated with ultraviolet light. In this paper a description of the construction, operation, and results obtained with this cell are given.

Experimental

Zirconium bars obtained from the Wah Chang Corporation, Albany, Oregon, containing about 1000 ppm total impurities were used in most of the studies. The use of other sources of supply did not lead to any noticeable differences in results. One face of the bar was mechanically abraded and polished and then etched in a manner previously described (7). The electrodes were rinsed in distilled water and transferred to an anodization beaker before the surface dried. Most of the anodizations were carried out at 30.0°C in a sodium borate-boric acid solution buffered at a *p*H of 8.

The formation voltage was raised slowly over a period of 5 min to the desired value and maintained for 24 hr. After anodization the electrode was washed, dried, and placed in the electrode chamber shown in Fig. 1.

The electrode chamber was fabricated from Pyrex except for the two quartz windows. The chamber was electrically shielded with ¼ in. copper plate. The electrode was mounted on a copper block which was soldered to a kovar seal. The copper block sealed the bottom of a demountable Dewar to which liquid nitrogen could be added for the attainment of low temperatures. A thermocouple was fastened to the Zr by means of a set screw. Electrode M was mounted in a similar manner at a distance of 5 cm from the Zr electrode. In this manner both Zr and M could be irradiated independently using the same light source. The light source was a GE UA-2 Uviarc mercury lamp. The lamp was positioned approximately 12 cm from the face of both electrodes. The lamp was air cooled and found to be steady in output after a short warmup time. Although the intensity could be varied by controlling the lamp voltage it was necessary to use neutral filters to vary the intensity because of the variation of spectral output with lamp voltage. Unfortunately, the intensity of the incident illumination cannot be given because the high light levels required could only be achieved through the use of polychromatic light.

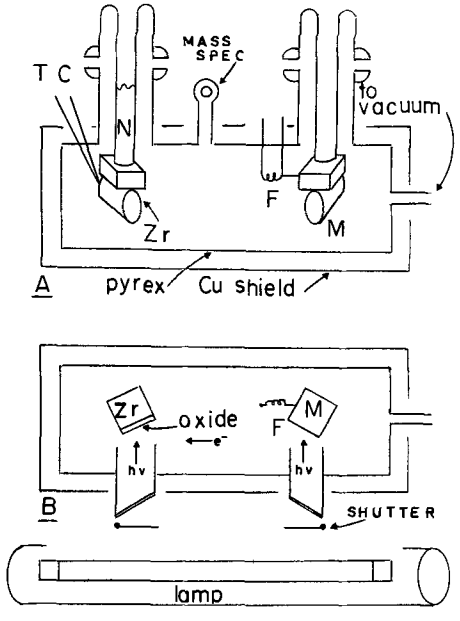

Fig. 1. Electrode chamber and light source: *A*, front view. *B*, top view.

Pressures as low as 10^{-6} Torr could be achieved by means of a liquid nitrogen trapped oil diffusion pump. A mass spectrometer was used to determine partial pressures. Potentials were measured with both a Keithley 621 electrometer and a L&N Millivolt Indicator in conjunction with a bucking circuit. These instruments essentially measure open-circuit potentials. By shunting the electrode with a 10 megohm resistor both instruments measure short circuit photocurrents because of the high impedance of the electrode.

In some cases metal M was replaced by a small tungsten filament which was permanently fixed in a position outside of the incident light beam.

The LBGPV was studied as a function of degassing time, cooling time, anodizing solution, formation voltage, light intensity, and partial pressure of oxygen. When M was replaced by the tungsten filament the LBGPV was studied as a function of filament current. Both open-circuit photovoltages and short circuit photocurrents were measured.

Results

A quantitative description of the photovoltaic effects associated with the cell described is precluded because of the complicated hysteresis of the system. Certain generalizations, however, are quite apparent, and an examination of the data to follow will show this.

The LBGPV could only be obtained on systems which were degassed for over 24 hr and in which the zirconium electrode was cooled to about 80°K for several minutes. In this temperature range the photovoltage was at most a slowly varying function of temperature. It was necessary to irradiate simultaneously both the anodized face of Zr and M with light of wavelength less than 2500Å or to replace M by an elec-

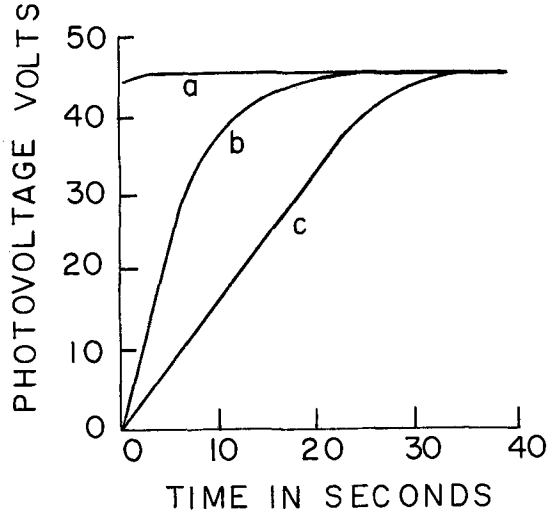

Fig. 2. Typical chronopotentiograms for a Zr/ZrO_2 (formation voltage of 60v)/gas phase (10^{-4} Torr)/Cu. a, pre-irradiated Zr, relative intensity 1.75; b, relative intensity 1.75; c, relative intensity 1.00.

trically heated tungsten filament, F, while Zr alone was irradiated in order to obtain the LBGPV. Stable measurements could only be obtained when the cell was well shielded and the potential measured with high impedance electrometers.

Zirconium always became negative with respect to M or F. The potential rises to a maximum value in a period of minutes. The rate of approach to this maximum depended on the light intensity although at the light levels used, the maximum photovoltage was independent of intensity as can be seen in Fig. 2. At room temperature the cell behaved as an electrically open circuit even when both electrodes were exposed to ultraviolet light.

In general it was found that electrodes anodized in sodium borate-boric acid buffer solutions developed somewhat higher photovoltages compared to electrodes anodized in citrate or phosphate buffers when all other parameters were held constant. When all other parameters were maintained at a constant value the maximum photovoltages increased as the logarithm of the oxygen pressure for the three pressures which were experimentally accessible. Some auxiliary experiments showed that only oxygen among all the residual gases caused an enhancement of the photovoltage. Photovoltages and short circuit photocurrents for the various gas mixtures are given in Table I.

The increase of the photovoltage with cooling time after a 48-hr degassing period can be seen by the data in Table II. The results indicate that the effect of cooling is not completely reversed by bringing the electrode to room temperature. This was the reason why the same sample was not anodized successively to higher voltages and the photovoltage measured at each point. In particular, it is to be noted that in several cases the photovoltage does not change after several hours of cooling.

When the filament was used in place of M it was found that small changes in filament current did not affect the maximum photovoltage, but did affect the rate of increase of the photovoltage. The results were similar to those shown in Fig. 2 with filament current replacing light intensity as the third variable. The short-circuit photocurrent, however, was quite sensitive to filament current as is shown in Fig. 3. It is to be noted that the system was not at saturation.

In some cases M consisted of an unanodized zirconium bar which was also cooled to liquid nitrogen temperatures. The observation of the LBGPV with this system indicates the importance of the anodic film and eliminated the necessity to consider thermoelectric effects.

One experiment which was considered quite revealing involved the simultaneous irradiation of M and Zr after Zr alone had been irradiated for over a minute. The open-circuit photovoltage reached its maximum value in a few seconds. When the sequence was reversed the photovoltage rise curve was identical to that obtained when both electrodes were irradiated without prior irradiation. This is shown in Fig. 2.

Discussion

It is easy to define the conduction path in the cell described and account for potentials up to 5 or 6v. The effect of oxygen is also quite understandable. Conduction in the gas phase is electronic and originates at the photoemissive or thermionic emissive electrode. The long degassing period at room temperature frees the oxide film from trapped oxygen. At low temperatures, oxygen is adsorbed at the oxide film-gas phase interface. An insulator which is bordered by a metal with a low work function and a strongly electronegative component such as oxygen will become polarized so that the electrochemical potential becomes uniform throughout. The absorption of light by the film leads to the creation of holes and electrons, the latter moving toward Zr and the former toward the adsorbed negative oxygen ions which thereby become discharged. Electrons arriving from the emissive contact recharge the adsorbed oxygen layer. The driving force in the process is the oxidation of zirconium. The linearity of the photovoltage with the logarithm of the oxygen pressure is suggestive of a reversible cell. Of course, even if such a reversible cell could be prepared the potential could hardly be expected to exceed 10v. The difference between the rise curves obtained when Zr or M is pre-irradiated, followed by the simultaneous irradiation of both, conforms to the general description presented. The lag is probably related to

deep lying traps in the oxide film. It was noted that the photopotential decayed extremely slowly when the illumination was discontinued and this is another characteristic of a photoconductor with deep lying traps.

The conventional mechanism for photovoltaic cells cannot be used to account for the effects reported. The reasons for this may lie in the nonuniform nature of the oxide although it is difficult to conceive of a circumstance which would enable the results to conform to the general theory. One cannot entirely rule out the possibility of multiple thin junctions which could add photovoltages in a series fashion, although their existence seems unlikely. Without invoking multiple junctions it would appear that the present day theory of photovoltaic effects is not generally applicable.

Precipitates of Phosphorus and of Arsenic in Silicon

M. L. Joshi

Systems Development Division, International Business Machines Corporation, East Fishkill, New York

ABSTRACT

Precipitate particles were observed through transmission electron microscopy at different depths in silicon wafers diffused with a very high concentration of phosphorus. The precipitates, believed to be phosphorus complexes, were of various shapes, square, rod-like, and hexagonal, with no definite orientation in the silicon matrix. Silicon wafers diffused with high concentration of arsenic also showed elongated precipitate structures with no definite orientation.

The electric properties of semiconducting materials such as germanium and silicon doped with impurities belonging to the III and V columns in the periodic table and in excess of 10^{19} at./cc are found sensitive to precipitation phenomena (1-4). The precipitates of phosphorus in Si diffused with phosphorus ($C_s \approx 10^{21}$/cc) have been directly observed with the technique of transmission electron microscopy (5, 6). Arsenic precipitation was also observed with the same technique in germanium (1). These precipitates have been reported to account for the difference between the total concentration and the electrically active concentration (1, 3, 7). It has been fairly well established that, in general, there is a limit to the substitutional accommodation of the III and V column impurities in silicon and germanium, and the amount exceeding this limit is expected to be in the interstitial sites or in precipitates.

In this paper, we are submitting further evidence of precipitates caused by diffusion of high amounts of phosphorus and arsenic in silicon and observed through transmission electron microscopy. Phosphorus precipitates are observed in specimens diffused from both P_2O_5 and PH_3 sources. Their growth has been shown to be sensitive to the rate of cooling from the diffusing temperature.

Experimental

Diffusion.—Phosphorus.—Two wafers (10-mil thick and 1 in. in diameter were cut parallel to (111) from a Czochralski-grown boron-doped ($\approx 10^{15}$ cm^{-3}) silicon single crystal of low dislocation density ($\approx 10^3$ cm^{-2}). The silicon wafers were lapped and chemically polished to remove any surface damage. The wafers were diffused (in an open tube furnace configuration at 1150°C) from a P_2O_5 source. One of the wafers was removed from the diffusion furnace and allowed to cool on a quartz platform in room air. The removal of the other wafer, through the furnace tube, was done with a slower speed than the above, allowing it to cool to about 600°C at the open end of the tube furnace and then was permitted to cool on the quartz platform.

A wafer lapped and polished similarly to remove the surface damage was diffused to about 2μ depth with phosphorus from a phosphine (PH_3) source. The diffusion was done in an open tube furnace configuration at 970°C with a proper mixture of PH_3, O_2, and N_2 flowing over the wafers. The phosphorus surface concentration was found to be $\approx 2 \times 10^{21}$ at./cc.

Arsenic.—Arsenic was diffused (surface concentration $\approx 5 \times 10^{20}$ cm^{-3} and junction depth = 2μ) in an evacuated closed quartz capsule (vacuum $\approx 10^{-6}$ Torr) into a boron-doped ($\approx 1.5 \times 10^{16}$ cm^{-3}) silicon wafer (at 1100°C) previously treated for the removal of the surface damage. Elemental arsenic was used as the source of diffusion. The quartz capsule prior to sealing was cleaned with a HF-HNO_3 mixture, rinsed, and heated to 1000°C to remove moisture.

Specimen preparation.—The specimen preparation was similar to that reported in the earlier article (5). To obtain transparency to the electron beam of the microscope, the samples were chemically polished down to a few thousand angstroms from the other side of the surface under study using the solution (5) usually used for chemical polishing of the lapped wafers. It is of advantage to use slightly warmer solution than that at the room temperature.

Observations

A Philips electron microscope (100B) was used for transmission electron microscopy of the specimens.

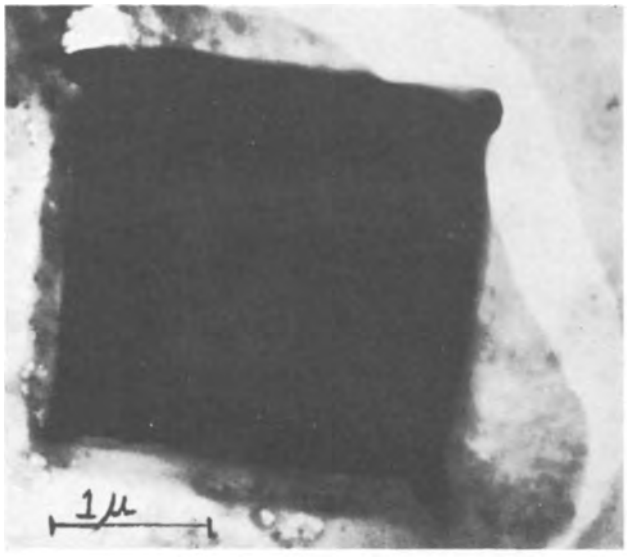

Fig. 1a. Phosphorus (source, P_2O_5) diffusion induced square particle in the layer $\frac{1}{4}\mu$ deep in the diffusion profile. Magnification 46,000X. The particle before acid washing.

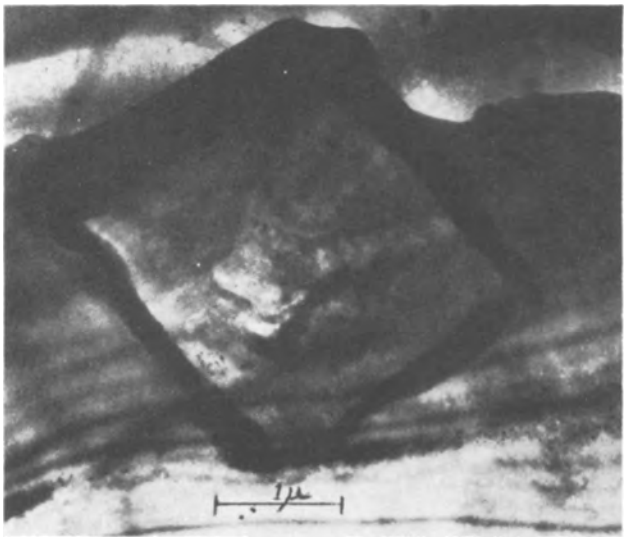

Fig. 1b. The same particle as shown in Fig. 1a after acid washing

Particles believed to be precipitates of phosphorus were observed throughout the diffused layers (P_2O_5 source). Figure 1a shows a dark square particle (at the depth of $\frac{1}{4}\mu$) with the broken film of silicon around. Mixtures used for electro- or chemical thinning have a tendency to leave a surface deposit on the specimen, sometimes as distinct foreign particles. Washing of the specimen in HNO_3 and subsequently in HF should remove some of these; washing in acetone and water removes "dirt" soluble in these solvents. This procedure of washing is illustrated in Fig. 1a and 1b. Figure 1b shows the square particle after washing for a short time (less than half a minute), and the dark film visible in Fig. 1a seems to be partially washed away. Since the specimen has a thickness of about 5000Å, a large particle like this could partially emerge on both sides of the film after intensive washing. Then it is found that the impurities intrinsic to the square particle start washing away very fast. However, the local misorientation in the matrix due to precipitation persists. Figure 2 shows phosphorus precipitates at the depth of $1\frac{1}{2}\mu$ in the same wafer; some of them are square, some rectangular, and some partly hexagonal. There is no significance with regard to the orientation of these precipitates in the silicon lattice. Figures 3a and 3b are the bright field and dark field micrographs (under a strong <220> operative reflection) of the

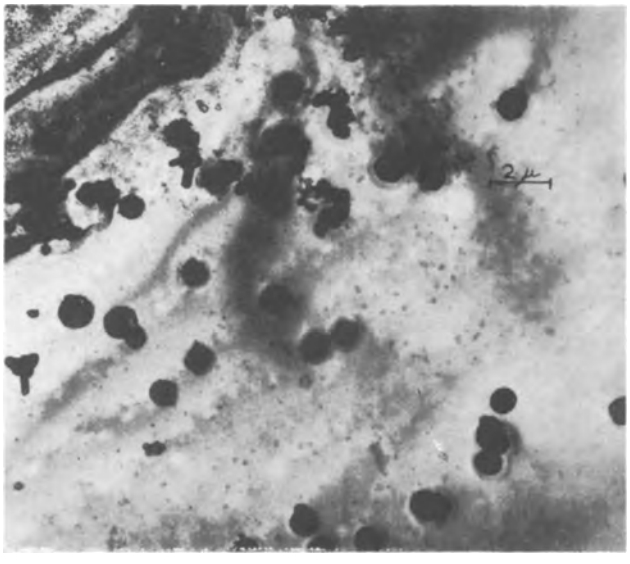

Fig. 3a. Phosphorus (source, PH_3) diffusion induced precipitates in the layer 0.2μ deep in the diffusion profile. Magnification 19,000X. Bright field view.

precipitates at the depth of 0.2μ in a sample diffused with phosphorus using the phosphine source. The similarity between these and those observed in Fig. 2 is obvious. Figures 4a and 4b are believed to represent the precipitates decorated with copper and are 5 to 10μ in size, as seen through reflection microscopy using white light.

The copper-decorated precipitates, observed by reflection microscopy, were found to lie at the depth of 1μ in the sample cooled with a deliberate slow speed from the diffusion temperature. Copper decoration of the precipitates was accomplished as follows: The method of the anodic oxidation with which we arrive at a particular depth in the diffused sample involves use of a jig in which the silicon strip rests on a copper block (anode); the other side of the strip is exposed to the anodizing solution connected to a platinum cathode. A small portion of the copper block exposed to the anodizing solution provides a source of copper atoms which were deposited preferentially on the precipitates instead of on to the platinum cathode. Although the mechanism of this copper deposition is not understood, the effect indicates that there exists a certain negative charge on these precipitates. The size of

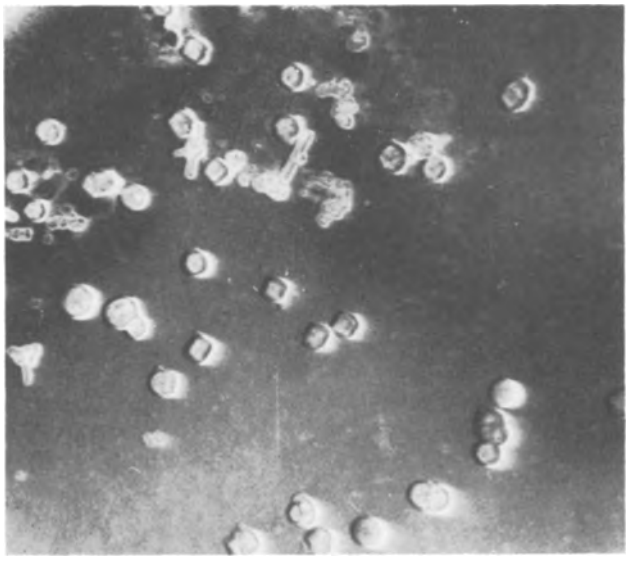

Fig. 3b. Dark field view corresponding to Fig. 3a

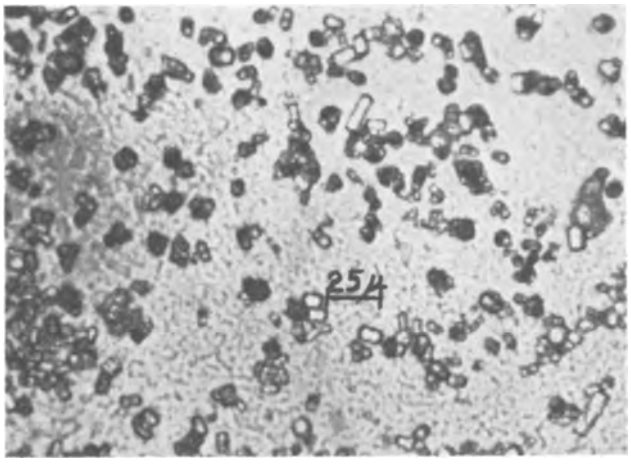

Fig. 4a. Particles developed by slow cooling from diffusion temperature and observed by optical microscopy. Magnification 530X.

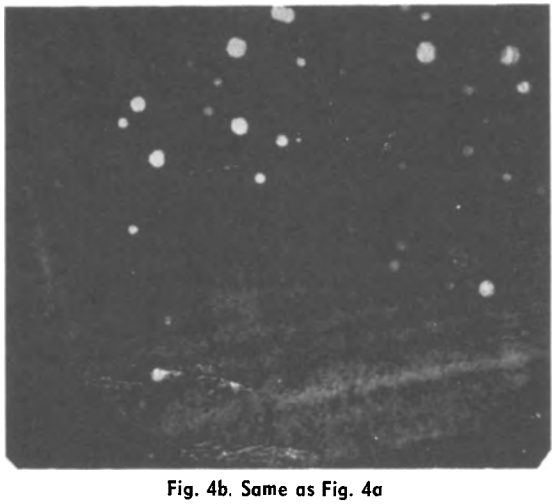

Fig. 4b. Same as Fig. 4a

these precipitates is much larger than those observed in the samples described earlier. The significant thing is that they are isomorphous with those observed by electron microscopy.

Figure 5 represents the observation under a strong <220> operative reflection of precipitates in the surface of an arsenic diffused sample. Again there are no specific directions in which the precipitates could be imagined to extend. No observation of precipitates could be made in the depths of the arsenic diffused profile.

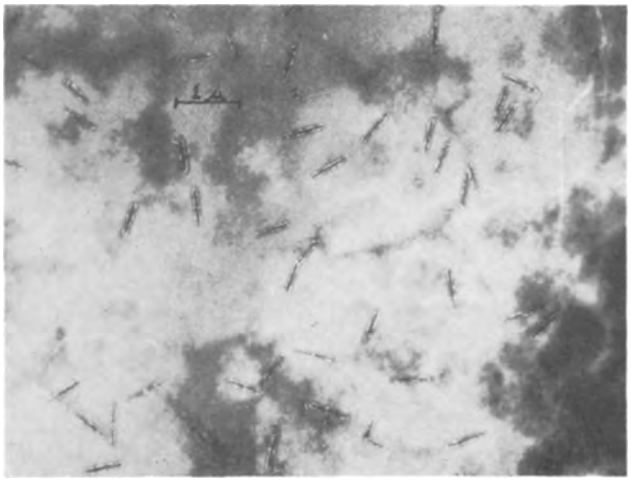

Fig. 5. Arsenic (source, elemental As) diffusion induced precipitates. Magnification 50,000X.

Only the particles of specific shapes are presented here, although diffused precipitation was often observed. Occasionally to determine whether a particular defect was structural or not, a dark field image was obtained (Fig. 3b). In thick regions Kikuchi lines were invariably observed in diffraction indicating that the strains involved in accommodation of these defects did not affect the lattice homogeneity. The selected area diffraction study is still inconclusive, since a rather speculative approach is needed regarding the definitive identification of their nature.

Discussion

Although it was not possible to establish positively the chemical nature of these precipitates, they can be reasonably assumed to originate during the diffusion. They could affect the electrical behavior of the junctions (8) and contribute to the deviations (1, 3). Recently neutron activation analysis was used to study the behavior of the phosphorus during its diffusion into silicon and silicon oxide films (7). This study confirms the existence of Si-P (7) phase in the surface layers of the silicon diffused with P_2O_5. The concentration of the phosphorus in the surface layer thinner than 0.1μ was shown to be of the order of 10^{22} at./cc which is an order of magnitude higher than the latest solid solubility limit established by the same technique. One could expect the precipitation of the second phase Si-P when the concentration is higher than this limit (7). However, the observation of the precipitates extends much deeper towards the junction indicating the formation of the second phase is not confined to the surface layers only. The growth of the precipitates (Fig. 4a, 4b) with slower cooling from the diffusion temperature is in agreement with the precipitation model (3). It is also important to note that the multiform precipitates of phosphorus and their indefinite orientation are not in accordance with the observations of Schmidt and Stickler (6). Consequently, it is not possible to support the crystal structure and the precipitation orientation of Si-P in relationship with silicon matrix, as deduced by the above authors.

Observation of the arsenic precipitates is also consistent with the interpretation of the deviation of diffusion profiles of arsenic from the strict erfc distribution (9). The precipitation in these samples is confined only to the surface. This implies that the arsenic surface concentration $\approx 5\times10^{20}$ cm^{-3} is not far away from the solid solubility limit. These precipitates also seem to be not isomorphous with those of Si-P.

Deposition of Silica Films on Germanium by the Carbon Dioxide Process

Myron J. Rand and John L. Ashworth

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

ABSTRACT

An ambient composed of hydrogen (≥ 95%), carbon dioxide (0.5-5%), and silicon tetrabromide (0.1-1%) will deposit a film of silica on a substrate heated to 800°-850°C. The process has particular application for coating germanium for high-speed planar device technology; it is useful for silicon also. The reaction may be carried out immediately after epitaxial germanium deposition in the same equipment.

Silica growth rates are of the order of 100 Å/min; rates for various temperatures and concentrations are presented. Apparent activation energy is 30 kcal/mole. The oxide films are clear, vitreous, and adherent, with no detectable structure. Electrical properties of MOS diodes made on silicon are comparable to, or superior to, conventional steam-grown oxide. The film is a satisfactory mask against 1200° boron diffusion. The silica contains about 2% residual bromine, apparently in a form in which it is not free to migrate.

A film of silica on germanium is useful in the production of germanium planar transistors, diodes, and field-effect devices. The silica may serve as a diffusion mask during processing, as an insulating layer, or as a surface passivator.

The usual method of applying such a film is by pyrolysis of an organosilane (1) such as ethyl orthosilicate or ethyl triethoxysilane, either on a hot substrate or aided by gaseous plasma discharge (2). There is evidence that the pyrolysis oxides contain organic residues (3); often they are observed to have a low refractive index and high etch rate, indicating a disordered or "strained" structure.

Ideally, an oxide process should be compatible with epitaxial deposition equipment, so that a freshly deposited epitaxial surface can be coated with the passivator immediately, without risk of contamination by removal to another system. This requirement is met by the carbon dioxide process (4), which has been adapted to semiconductor device technology by Steinmeier and Bloem (5). These investigators deposited epitaxial Si from H_2 and $SiCl_4$ and then, in the same equipment, added CO_2 to the gas mixture and obtained at 1150°-1300° an insulating film of glassy SiO_2. However, extrapolating from rate studies in the H_2-CO_2-$SiCl_4$ system (5-7) it is evident that at temperatures below the melting point of Ge (936°) no useful SiO_2 film will form in any reasonable time.

An ambient of H_2, CO_2, and $SiBr_4$ vapor has been found to produce adherent, vitreous silica films on Ge at a temperature as low as 775°. This paper reports experience with this system gained from some eighty runs in a multiple-slice apparatus. In many of these, deposition of 2-3μ of epitaxial Ge from $GeCl_4$ and H_2 preceded silica film deposition. The process is carried out conveniently at about 850° to produce a 0.4μ film with growth rates in the range 50 to 100 Å/min. Rates of 300-400 Å/min may be attained by adjusting reactant concentrations, temperature, and transport rate of reactants to the hot zone. Concentrations used were 0.1-1% $SiBr^4$, 0.5-5% CO_2, ≥ 95% H_2. Most of the information presented here is from Ge coating experiments, but the process has been used extensively on Si as well, where it is equally simple and reliable.[1]

Experimental

The train for introducing the reactants was constructed so that only glass, stainless steel, and Teflon were in contact with the gases. Carbon dioxide was Matheson Company Coleman grade. Passing it through a —78° trap had no effect on the silica deposition rate. Tank hydrogen was passed through a Pd-Ag diffusion purifier, and also through a liquid nitrogen trap. It was established that the H_2-CO_2 mixture (without the $SiBr_4$) at 850° had no effect on the appearance of the Ge substrate surfaces. Silicon tetrabromide (Stauffer Chemical Company) was revealed by infrared absorption (8) to have minor organic contamination; however, one batch which was passed through a packed column at 700° and then fractionally distilled did not appear to produce a superior oxide. The $SiBr_4$ saturator was usually operated near 25°, at which the vapor pressure is 7.7 Torr. Lower concentrations were obtained by diluting the saturated gas with pure hydrogen. The temperature of the $GeCl_4$ saturator (for Ge epitaxy) was controlled automatically by thermoelectric refrigeration and a thermistor sensing probe.

The arrangement of the deposition section of the apparatus is shown schematically in Fig. 1. Up to nine slices could be coated simultaneously on the r.f.-heated horizontal rotating molybdenum platform. The usual Ge substrates were 6 mil thick, 0.005 ohm-cm Ga doped, electropolished. Many experimental slices of other resistivities of both Si and Ge were coated also, as well as Mo, Ta, and fused silica. Any epitaxial Ge deposition was done at 850°.

Temperatures were measured by a Latronics Colo-

[1] An early experiment with the bromide system was carried out by S. K. Tung and P. Buchman of these Laboratories.

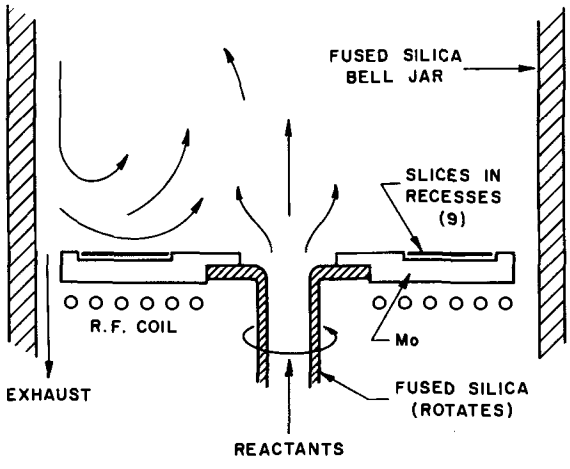

Fig. 1. Detail of deposition chamber

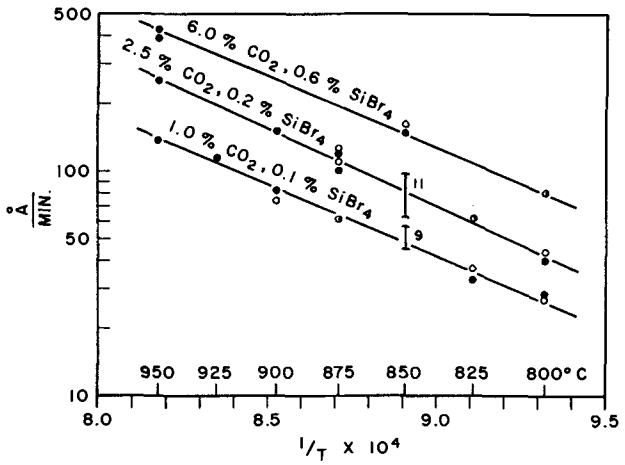

Fig. 2. Kinetics of silica deposition by the H_2-CO_2-$SiBr_4$ process. Rate of SiO_2 formation: ○, on Ge; ●, on Si. E_a = 30 kcal/mole.

ratio optical pyrometer,[2] which determines the ratio of the emission at two wavelengths in the visible range. This instrument has built-in calibration points, but it was also checked with chips of known melting-point materials resting on silica-coated Si slices. It is difficult to get an accurate temperature reading on a surface covered with a thin, transparent, growing film, owing mostly to interference colors; this is particularly true with a single wavelength optical pyrometer. This difficulty is probably responsible for much of the spread in activation energy reported by various investigators of the H_2-CO_2-$SiCl_4$ deposition process. Finally it should be realized that because the film is transparent the temperature being measured is mostly that of the substrate surface, which is not the surface where the reaction is taking place. A possible error of 20° in the temperature of the reaction site during oxide growth is a realistic estimate.

Oxide film thicknesses were determined from the pattern of interference minima in the reflection spectrum in the 190-750 mμ range (9), using a Perkin-Elmer 202 spectrophotometer. Thicknesses below 0.1μ were measured by ellipsometer.

Results

The H_2-CO_2-$SiBr_4$ reaction gives transparent, smooth, tightly adherent films on Ge substrates at any temperature from about 775° up to the melting-point of Ge. The films have no structure discernible by electron diffraction. Electron microscope examination rarely shows any surface features, pinholes, or cracks.

Figure 2 shows the rate of deposition of the oxide over the range 800°-950°C for three different combinations of reactant concentrations. Log rate *vs.* 1/T°K is linear; the plots for different concentrations have the same slope, and the rate is the same for Ge and Si substrates. (It is the same for Mo or SiO_2 substrates as well.) Probably a single reaction is the rate-determining step throughout the range, and this reaction does not involve the substrate surface. The 30 kcal/mole activation energy is substantially less than the 50-80 reported (5-7) for the H_2-CO_2-$SiCl_4$ system.

Within the range of conditions represented in Fig. 2, the deposition rate depends on temperature, $SiBr_4$ concentration, CO_2 concentration, and total flow rate, in decreasing order of importance. Careful examination of all the variables is not warranted since in a deposition chamber of different geometry and different gas flow pattern rates are somewhat different; each apparatus requires an experimental calibration, after which rates should be reproducible to ± 10%, as they were here. The total flow rate in the runs of Fig. 2 corresponds to about one displacement of the deposition chamber per minute.

Since total flow rate does have a minor, but not negligible, effect, it is probable that mass transport to the reaction zone limits the reaction rate, and that the observed rates are not quite true kinetic rates. In multislice equipment of several liters' capacity this situation is difficult to avoid without great waste of reactants.

Deposition rate is linear with $SiBr_4$ concentration up to 0.1-0.2%, above which there is progressively less effect. The influence of CO_2 concentration has been tested only well above the stoichiometric requirement; here doubling the concentration increases the rate by some 15%.

The oxide deposition rate is essentially linear with time. Germanium slices were put into the deposition chamber at various times during a run and removed after intervals, so that deposits sampling the effects of run duration and oxide thickness independently were obtained. There were some minor aberrations early in the run, but in general the slopes of the thickness *vs.* time plots were in excellent agreement. Deposition rate is thus little influenced by the duration of the run or the amount of oxide already present on the substrate.

On occasion a local area of the deposited oxide appeared cloudy and whitish. The film was obviously not vitreous here, but there was still no structure evident to electron diffraction. Tests with the electron beam microprobe showed no concentration of any impurity. They did show a significantly higher silicon count per unit area, indicating a thicker deposit. The cloudy areas were porous in tests as diffusion masks or dielectrics. Frequently they occurred on one Ge substrate and not on the neighboring one in the same run; they never appeared in films on Si substrates. No correlation was found with various Ge cleaning procedures; in fact, on many occasions hole-free films were made on substrates used as received, with no cleaning whatsoever. Some connection was observed, however, with substrate source, although it is not clear whether the original material or the preparation and polishing procedure was involved.

Cloudy oxide areas became much less common when regular removal of deposited silica from the molybdenum pedestal and other surfaces in the deposition chamber was instituted. The interpretation is that the silica adsorbs moisture from the atmosphere when the apparatus is opened, and then desorbs it on heating during the next run. It is well known that water vapor accelerates the devitrification of silica and other glasses. It is also known from studies on evaporated metal films that adatoms have more surface mobility on Ge than on Si.

Present evidence is that cloudy oxide areas are deposits of minute amorphous silica particles which constitute favored sites for the nucleation of still more of

this form of deposit. Both a germanium surface anomaly of some sort and an excessive water vapor concentration would be required; neither condition alone will account for the experimental observations.

Evaluation of the Oxide

A summary of various properties and tests of the H_2-CO_2-$SiBr_4$ deposited silica appears in Table I. It will be noted that there is residual bromine in the film, detected by x-ray fluorescence analysis. H_2-CO_2-$SiCl_4$ oxides made at 1150° contain 0.5% Cl. Bromide process oxides made at 850° contain about 2% Br, and proportionately higher amounts if > 0.2% $SiBr_4$ was used. Bromine is probably present as unreacted Si-Br linkages rather than bromine-containing by-products, *e.g.*, HBr, trapped in the reaction zone by the depositing silica. A 1-hr pump at 700°C and 10^{-6} Torr did not reduce the bromine content.

The bromine content of the film probably accounts for the slightly high refractive index. The infrared transmission spectrum (2-25μ) compares closely with that of steam-grown oxide, with slightly greater absorption band half-widths. The high water contact angle predicts excellent adherence of Kodak Photoresist (12), and this is what is found; in fact, on occasion the bromide process has been used to deposit ~ 1000Å silica over phosphorus glass to provide a more hydrophobic surface for KPR.

The higher etch rate of bromide process oxides is probably more a consequence of low deposition temperature than bromine content. Etch rate does not change as the film is thinned, at least down to 900Å.

Evaluation of electrical properties by MOS diode structures on both Ge and Si is included in Table I. A p-type surface apparently is produced on Ge, with a rather high acceptor state density; on Si the usual n-type surface is seen, with a surface-state density usually lower than that produced by steam. Breakdown voltages are superior, particularly on Si; generally there was little leakage in advance of breakdown. The behavior of the MOS diodes reinforces the belief that the bromine impurity is not ionic, or at least is not free to migrate in a field.

The bromide-process oxide has been used as the first oxide, following epitaxy, on both Ge and Si planar structures, with satisfactory performance. It is also an entirely adequate diffusion mask against severe conditions such as boron diffusion into Si at 1200° for 2 hr. In this test, it was established by step-etching that boron penetration into the oxide was no more rapid than it is in a 1200° steam oxide. Furthermore, the oxide remaining, beyond the boron front, etched at a rate little different from that of 1200° steam oxide, rather than the three-times factor before treatment. The obvious inference is that the as-deposited oxide film is rapidly "densified" by further heating and becomes indistinguishable from a high-temperature oxide in many of its properties.

Discussion

It has been demonstrated that the H_2-CO_2-$SiBr_4$ system produces good silica films at temperatures some 300° lower than the analogous chloride system and is consequently useful for germanium solid-state device technology. The mechanism of the reaction is less clear. In published reports the carbon dioxide process has been regarded as a combination of two reactions

$$H_2 + CO_2 \rightleftarrows H_2O + CO \quad [1]$$

$$SiCl_4 + 2H_2O \rightarrow SiO_2 + 4HCl \quad [2]$$

with [1] believed to be the slow step. Authors are undoubtedly aware that this picture is certainly much too simple. In spite of its commercial importance the kinetics of reaction [1] is not well understood, but very likely it proceeds by a chain mechanism involving free radicals. It would be surprising if the rate-determining step were not influenced by any of the species of reaction [2]. If the CO_2-H_2-$SiBr_4$ reaction goes as fast at 850° as the chloride reaction at 1100° obviously [1], as written, cannot be the sole rate-determining reaction. Reaction [2] could be, but it is more likely that the silicon halide somewhere enters into the mechanism of [1], or catalyzes it. The hydrogen halide by-product has no significant effect on the H_2-CO_2 reaction (13). All that may be said at present is that the existence of the low-temperature bromide process, with its different energy of activation, is evidence that the carbon dioxide process for oxide deposition must be complex.

Impurity Distributions in Single Crystals

I. Impurity Striations in Nonrotated InSb Crystals

K. Morizane, A. F. Witt, and H. C. Gatos

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Single crystals of InSb were pulled without rotation from the melt in the presence of tellurium or selenium impurity employing a Czochralski-type apparatus. The formation of pronounced periodic and nonperiodic impurity striations was observed; their appearance and origin were studied as a function of the thermal conditions prevailing in the immediate vicinity of the solid-melt interface. It was concluded that the formation of such striations is the result of temperature fluctuations at the interface brought about by convection currents in the melt which in turn are caused primarily by sharp temperature gradients in the growing crystal near the interface.

Semiconductor single crystals grown from the melt by the Czochralski technique frequently exhibit heterogeneous distributions of impurities. A commonly observed heterogeneity in crystals, grown in the <111> direction, is the so-called "coring" which consists in an (usually) increased impurity concentration in the central part of the grown crystal. This higher impurity concentration is associated with the presence of an (111) facet at the crystal melt interface and is limited in its lateral extent by the area of the facet (1, 2).

Another common type of impurity heterogeneity in rotated crystals is the impurity striations which appear as bands or lines of increased impurity concentration and assume the shape of the growing crystal-melt-interface. Such striations are attributed to nonsymmetric temperature profiles at the growing interface (3, 4).

Impurity striations have also been reported in nonrotated Czochralski grown crystals of InSb (5). These striations were attributed to temperature fluctuations resulting from a periodic release of latent heat of fusion. Recently impurity striations were reported in InSb grown in a horizontal boat (6).

The present investigation is concerned with the detailed study of the origin of striations appearing in nonrotated InSb single crystals grown by pulling from the melt.

Experimental Procedure

Single crystals of InSb were grown in the <111> direction from high-purity ingots on to seeds of 12.5 mm diameter and varying lengths in a purified hydrogen atmosphere. In order to permit the study of the role of temperature gradients in the growing crystals, a seed holder was designed with provisions (after cooler) to cool the seed by circulating various coolants or to heat the seed by means of a cylindrical heater (after heater). Neither the seed nor the crucible was submitted to rotation. The temperature in the melt and in the grown crystal was controlled and measured with chromel-alumel thermocouples. The pulling rates employed varied between 7 and 50 mm/hr.

Selenium or tellurium were used as impurities. The amount of InSb placed in a quartz or graphite crucible (30 mm ID) was in most experiments 50 g; the amount of impurity added was 2 mg of Se or Te corresponding to an average carrier concentration of about 1×10^{18}/cm^3 in the grown crystal. All crystals were cut along a (211) plane parallel to the growth direction. The (211) plane was polished and etched with a modified CP4 etchant (5 parts HNO_3, 3 parts HF, 3 parts CH_3COOH, and 11 parts H_2O).

Results and Discussion

Role of impurity.—In a series of experiments it was found that both selenium and tellurium impurities lead to the formation of striations exhibiting the same basic characteristics. The choice of selenium for most of the experiments was based on the greater ease with which its striations are revealed by the modified CP4 etchant.

The amount of impurity was varied between 2 and 10 mg for a 50g melt, but no difference could be detected in the ease of formation or the general characteristics of the striations.

Role of pulling rate.—Variations in the pulling rate between 7 and 50 mm/hr had no apparent effect on the formation, intensity, or the spacing of nonrotated striations. This result indicates that the pulling rate plays no significant role in the mechanism of striation formation under the present conditions.

It is often argued that impurity striations are due to nonuniform pulling rates ("jerking") caused by deficient pulling mechanisms. Such pulling irregularities were indeed detected in our system by employing a linear transducer. However, no correlation could be established between the pulling irregularities and the observed striations. Moreover, several striation-free crystals were grown under conditions in which, due to pulling irregularities, the instantaneous pulling rate ranged from 0 to well over 100 mm/hr. It, thus, appears that variations in impurity concentration expected from changes in pulling rate (7) are not revealed as striations.

Selenium striations and the role of orientation.—In crystals grown along the <111> direction, the selenium striations are revealed as lines on etched (211)

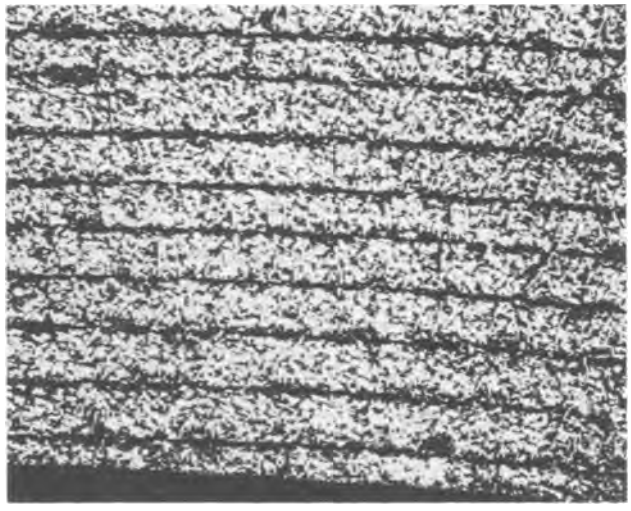

Fig. 1. Impurity striations in a Se-doped crystal of InSb grown without rotation. The surface shown is a (211) plane parallel to the growth direction. Magnification 50X.

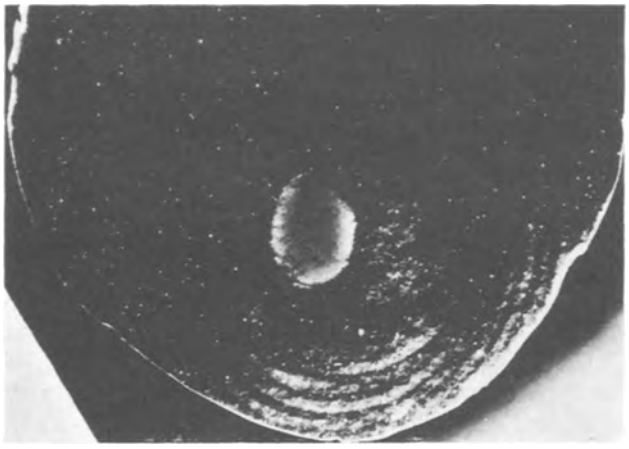

Fig. 2. Impurity striations in a Se-doped crystal of InSb grown without rotation. The surface shown is perpendicular to the growth direction. The part of the surface without rings corresponds to the (111) facet. Magnification approximately 5X.

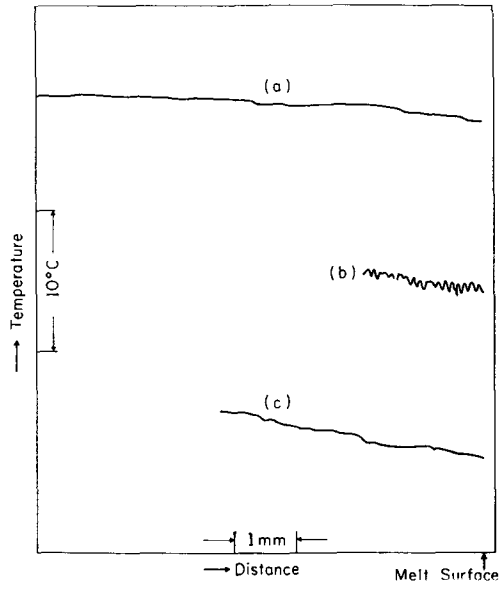

Fig. 3. Temperature profiles in the melt: (a) no seed is in contact with the melt; (b) growing crystal is in contact with melt but it is not being pulled nor rotated; (c) same as in (b) except the "afterheater" applied to reduce the temperature gradient in the seed.

planes (Fig. 1). On the (111) plane normal to the growth direction, the striations appear as more or less concentric rings on the "off-core" part of the plane which corresponds to the nonflat part of the growing interface (Fig. 2).

The formation of impurity striations was shown to be independent of orientation. Thus, striations invariably reflect the shape of the growing interface rather than show orientation affected characteristics. Actually in numerous instances of twinned or polycrystalline crystals, the striations exhibited no discontinuities. Occasionally, the striations appeared to terminate abruptly at a twin boundary. However, this behavior resulted from the fact that the twin in which the striations did not appear had an unfavorable orientation for revealing striations with that particular etchant. In all instances an appropriate etchant could be found to reveal the striations across the twin boundary.

Temperature measurements.—The thermal conditions in the crystal-melt system were determined with sheathed chromel-alumel thermocouples of 1 mm external diameter, which were introduced through the melt surface. Because of the considerable thermal conductivity of the sensor system, these measurements do not yield correct absolute temperature values, but the arrangement is considered quite adequate for the evaluation of temperature fluctuations.

The temperature profiles of the melt under varying experimental conditions are presented in Fig. 3. These measurements indicate that under the present experimental conditions the isolated melt (without a growing crystal) is free of major temperature fluctuations (curve a). Fluctuations are induced when the melt is contacted with the seed, as a result of the induced directional heat flow which leads to convection currents (curve b). Stable temperature conditions in the crystal-melt system can be readily re-established by reducing the temperature gradient in the seed by means of the afterheater (curve c). The same system exhibited extreme temperature instabilities with fluctuations up to 20°C when the upper end of the seed was water-cooled (aftercooler).

It was observed that non-rotated striations appear primarily under growth conditions which lead to a decreasing crystal diameter. Such conditions are obtained by raising the temperature of the melt while keeping all other parameters as constant as possible. Associated with any such raise in temperature is an upward shift of several millimeters in the location of the crystal-melt interface. (It is obvious that an excessive temperature increase will lead to the actual disruption of the solid-liquid contact.)

The temperature profile for a static system in which the melt was contacted with a water-cooled seed is given in Fig. 4. Curves (a) through (g) indicate the variations of the thermal conditions when the location of crystal-melt interface (meniscus height) was changed by increasing the melt temperature. The conditions corresponding to curves (e), (f), and (g) are characterized by major temperature fluctuations and were found to be most favorable for the formation of nonrotated striations.

The thermal conditions during crystal growth were determined by means of fixed thermocouples introduced through a channel drilled in the center of the seed. At the beginning of crystal growth the thermocouple protruded several millimeters into the melt; as the crystal was pulled the location of the thermo-

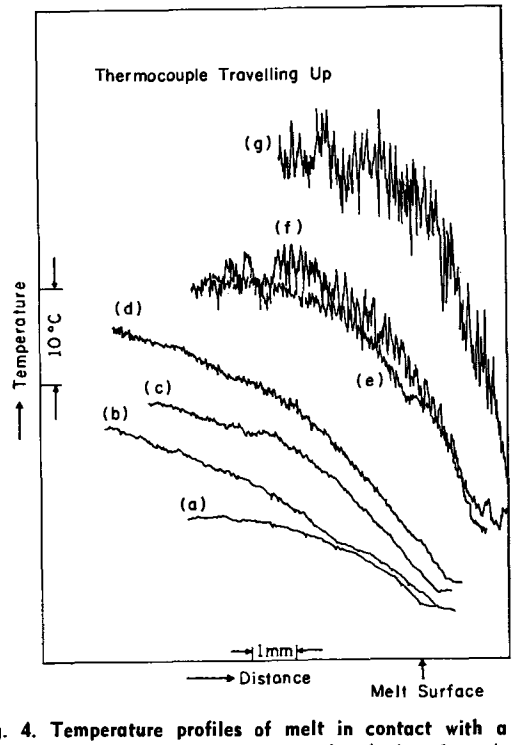

Fig. 4. Temperature profiles of melt in contact with a water-cooled seed. The height of the crystal-melt interface (meniscus height) increases from (a) to (g) as a result of increasing the melt temperature (see text).

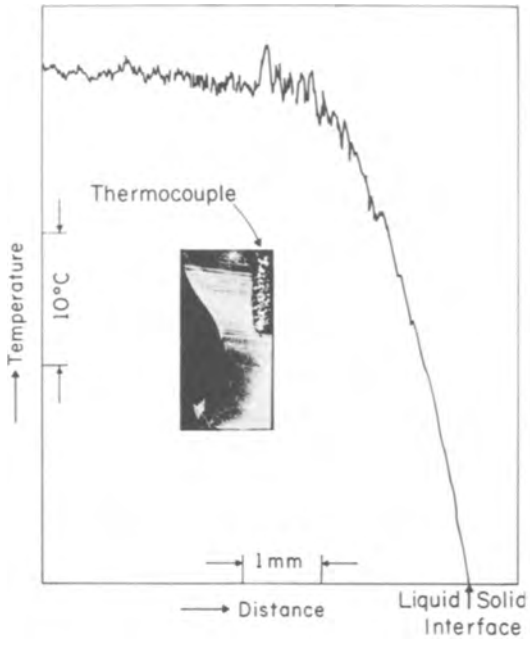

Fig. 5. Temperature fluctuations in the melt near the melt-solid interface during pulling of an InSb crystal (with aftercooler). Inserted photograph shows the impurity striations corresponding to the shown temperature fluctuation.

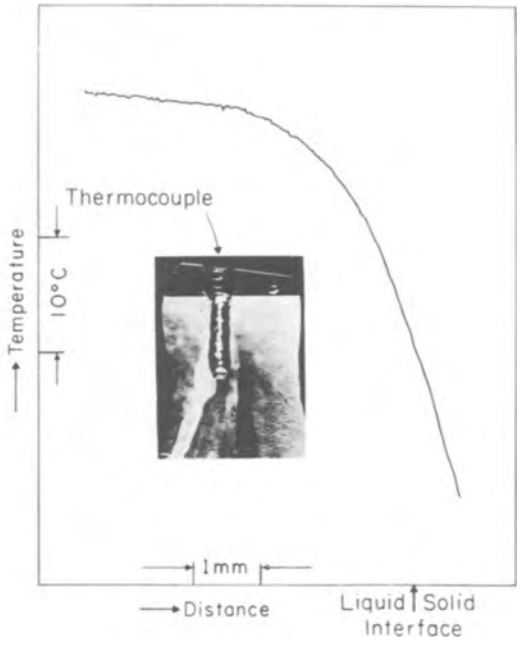

Fig. 6. Temperature profile of melt during pulling of an InSb crystal (with aftercooler). Note absence of temperature fluctuations and also absence of impurity striations in the inserted photograph (see text).

couple junction gradually approached the crystal-melt interface and finally was in the grown crystal itself. Figure 5 shows the results obtained with a water-cooled seed when the melt temperature was well above the melting point. Under these conditions the crystal-melt interface was several millimeters above the surface of the melt, and the grown crystal was of decreasing diameter. Temperature fluctuations as well as intensive striations can readily be observed. A decrease in the melt temperature brought the location of the crystal-melt interface closer to the melt surface and resulted in a crystal of constant diameter (Fig. 6). Neither temperature fluctuations nor striations are observed in this case. The pertinent facts as revealed by the temperature measurements are:

1. The temperature gradient in the seed crystal and the location of the crystal-melt interface (meniscus height) are primarily responsible for the presence of temperature fluctuations in the melt.
2. The convectively induced temperature fluctuations are generally irregular, but may in some instances assume a considerable degree of regularity.
3. Temperature fluctuations are virtually identical under static and dynamic (growth) conditions.
4. The amplitude and frequency of temperature fluctuations decreases with a decreasing amount of melt.
5. In actual crystal growth, a direct correlation exists between temperature fluctuations and striations.

Origin of striations.—As pointed out above, the formation of impurity striations in nonrotated pulled crystals is independent of such parameters as orientation, pulling rate fluctuations, or amount and type of impurity present. Consequently, it is believed that the formation of striations is not directly related to the mechanism of crystal growth. Impurity striations form only when the thermal conditions are such as to lead to temperature fluctuations at the crystal-melt interface. A direct correlation was unambiguously established between temperature fluctuations at the interface and the formation of impurity striations.

Under experimental conditions such as those employed in the present study, the cause of temperature fluctuations at the interface is given by the thermal gradients in the growing crystal which result in convection currents in the melt and affect the immediate vicinity of the interface. In the absence of pronounced thermal gradients, there are no temperature fluctuations at the interface (apparently no convection currents) and no impurity striations.

Impurity striations have invariantly been observed in these parts of the crystals where their diameter was decreasing (Fig. 5). They could not be observed in the part of the crystal where the diameter was increasing, a condition requiring thermal gradients into the melt. This observation is thus indicating that thermal fluctuations at the interface, brought about by convection currents and leading to impurity striations, are caused by sharp gradients in the direction of the crystal.

Under the present experimental conditions, the latent heat of fusion released during solidification apparently is not sufficient to cause temperature fluctuations at the interface as speculated earlier (5). If the latent heat were playing any significant role, then (at variance with the present results) sharp gradients in the crystal would enhance its dissipation and, thus, decrease its effectiveness in causing thermal fluctuations leading to striations.

Having established the presence of temperature fluctuations at the interface, the formation of impurity striations can be understood readily on the basis of changes in the microscopic rate of crystal growth

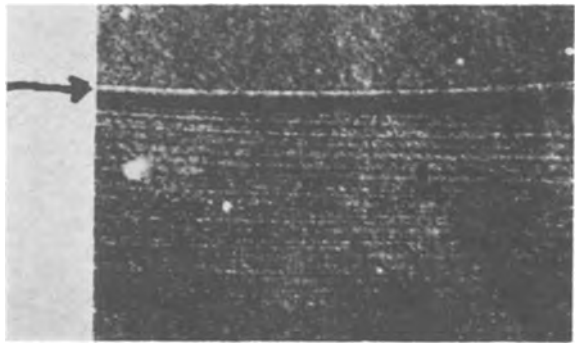

Fig. 7. Remelt line (arrow) and impurity striations in a Se-doped unrotated InSb crystal. Note sharpness of remelt line as compared to that of striations. Magnification 5X.

brought about by such temperature fluctuations (6, 8, 9). The rate of growth (the microscopic rate of growth is referred to here since the macroscopic rate is determined by the pulling rate) conforming to the prevailing temperature alters the deviation of the solidification process from equilibrium; thus, the amount of impurity incorporated in the solid is not constant with time. The increase in amount of impurity in the solid with increasing rate of growth is a well-established fact (7).

Temperature fluctuations determined in the present experiments were as large as 15°C. Others have reported even greater temperature fluctuations during crystal growth in similar systems. It is conceivable that the maximum temperature within each fluctuation does not reach the melting point of the supercooled solid so that no remelting takes place at any given time. However, depending on the prevailing convection current conditions, it is possible that the temperature at the interface approaches or even exceeds the melting point, as a flow of melt with bulk melt temperature passes by the interface (the bulk melt temperature is maintained above the melting point of the solid).

When remelting takes place, we believe that the impurity striations are more sharply delineated than the striations commonly formed. Their appearance in fact is quite similar to that of the demarkation lines formed when a growing crystal is allowed to remelt for an instant before proceeding with growth (Fig. 7).

This type of "remelt" striations appears to have a defect structure associated with it; however, a study on this aspect is now in progress.

Summary

Impurity striations in nonrotated crystals (at least under the given experimental conditions) are caused by temperature fluctuations in the melt. These temperature fluctuations which always increase with increasing meniscus height are due to convective currents induced by excessive temperature gradients in the growing crystal. In some instances periodic remelting leads to very sharp striations. In general, impurity striations are due to pronounced changes in growth rates and the associated variations of nonequilibrium distribution coefficients.

The fact that temperature fluctuations are substantially the same under static and dynamic growth conditions indicates that they are not induced by intermittent growth, as was suggested previously (10, 11). Our findings throw considerable doubt also on attempts to explain striations exclusively on the basis of supercooling and recovery phenomena (12).

It is quite likely that rotated, pulled crystals under particular conditions may exhibit rotational striations, which are caused by a nonsymmetric temperature distribution in the melt, and also a substructure of nonrotational striations.

Bourdon Gauge Determination of Equilibrium in the ZnSe(s)-I_2(g) System

T. O. Sedgwick and B. J. Agule

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

ABSTRACT

Bourdon gauge measurements of samples of I_2(g) plus ZnSe(s) have been made in the temperature range 900°-1200°K and over a fourfold range in pressure. The pressure *vs.* temperature behavior of the system can be described satisfactorily by the equilibria,

$$ZnSe(s) + I_2(g) \rightleftarrows ZnI_2(g) + \tfrac{1}{2}Se_2(g)$$
$$I_2(g) \rightleftarrows 2I(g)$$

The standard enthalpy and entropy of the first reaction between 900°-1200°K were calculated using the second law with the result; $\Delta H^\circ = 23.1$ kcal, $\Delta S^\circ = 21.1$ e.u. The standard heat of formation, ΔH°_{298f}, and entropy, S°_{298}, of ZnSe(s) were found to be 44.2 kcal and 15.4 e.u., respectively.

The compound ZnSe exhibits interesting and potentially useful photoelectric properties typical of the II-VI compounds. Because of the very high melting point of this compound, it is advantageous to grow single crystal material either by evaporation or chemical transport processes. In designing a transport system, it is of considerable value to have accurate thermodynamic data for the chemical species in question to facilitate the proper selection of operating pressures and temperatures. Although there have been three recent determinations (1-3) of the heat of formation and entropy of ZnSe, the agreement between these results is not good.

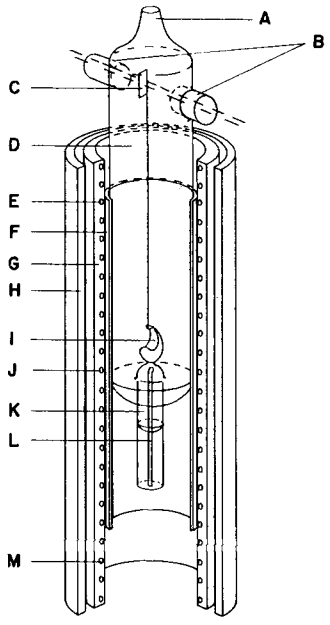

Fig. 1. Bourdon gauge and furnace arrangement: A, to pressure control; B, light pipes; C, flag; D, equalizing chamber; E, M, end windings; F, nickel pipe; G, quartz furnace; H, morganite heat reflector; I, asymmetric spoon; J, center winding; K, sample chamber; L, thermocouple well.

In the present investigation the automated Bourdon gauge described by Hochberg (4) and Sedgwick (5) was used to determine the equilibrium between ZnSe and the vapor solvent I_2, *i.e.*

$$ZnSe(s) + I_2(g) \rightleftarrows ZnI_2(g) + \tfrac{1}{2}Se_2(g) \qquad [1]$$

It was then possible to calculate the heat of formation and entropy of ZnSe from the measured data and other data already available in the literature.

Experimental

Apparatus and measuring procedure.—The quartz Bourdon gauge and furnace arrangement are shown in Fig. 1. The automatic pressure control system used to maintain equal pressure in the sample and measuring chambers has been described previously (4, 5). The measuring manometer, a Wallace and Tiernan Model FA129 dial gauge, was calibrated with a large bore Hg manometer. Both the pressure control and accuracy of measurement are within ± 0.4 mm Hg.

Before making any measurements, the Bourdon gauge assembly was thermally cycled several times over the temperature range of interest to stress relieve the sensitive spoon element. The particular gauge used in this study showed no significant variation of zero point with temperature.

The pressure of three samples of $I_2(g)$ plus ZnSe(s) was measured as a function of temperature over several cycles of increasing and decreasing temperature. The pressure was allowed to equilibrate at each temperature which required from one half hour up to several hours before taking the data. The reproducibility of the pressure readings at a given temperature and the variation of zero point during a run was within ± 1-2 mm Hg.

The temperature was measured with Pt-Pt 10% Rh thermocouples. One thermocouple was placed in a well at the bottom of the sample chamber near the ZnSe, and a second was placed in a well at the top of the sample chamber near the spoon. The temperature in the furnace was adjusted so that the top of the Bourdon gauge was 2°-10°C higher than the bottom (position of ZnSe) in order to avoid condensation of solids on the spoon. The temperature was controlled by a power proportioning controller to within 1°C.

Chemical purity and sample preparation.—High-purity crystals of ZnSe were supplied as a courtesy by Dr. M. Aven of the G. E. Research Laboratories, Schenectady, New York. They were grown by the vapor phase growth method from ZnSe powder synthesized by direct reaction between Zn and Se. They were then purified by firing in liquid Zn and etched with HCl and NaOH. The resulting crystals contained the following concentrations of impurities: S, Te ≤ 10 ppm; Cd, Mg, Si ≤ 3 ppm; Fe, Al, Co, Cu ≤ 1 ppm. In each run a predetermined weight consisting of several small crystal fragments of ZnSe was charged to the sample chamber which was evacuated and then heated slowly to 700°C, held for 10 min at 700° (ZnSe sublimes slowly at 700°C), cooled, and finally sealed off.

High-purity moisture-free iodine was prepared by the method of Washington and Naldrett (6). In this procedure PdI_2 was precipitated from solution by adding an excess of $PdCl_2$ in dilute HCl to a 0.5M NaI solution. The PdI_2 was dried and degassed under vacuum at 250°C and finally decomposed to Pd and I_2 at 350°C. The free iodine was transferred in an all-glass apparatus to the sample chamber.

Results

Figure 2 shows the pressure *vs.* temperature data for three samples of ZnSe(s) plus $I_2(g)$. The initial linear portions of the curves up to *ca.* 600°K are interpreted as the ideal gas pressure increase of $I_2(g)$ at constant volume. The absence of any measurable chemical reaction in this region is implied by the linearity of the curves. The initial slope and the calculated number of moles of I_2 in the sample chamber (estimated volume 16 cc) are compared with the moles of ZnSe used in each sample in Table I.

The rapid rise of pressure above *ca.* 750°K indicates reaction is taking place. The highest pressure points appear to be approaching a constant slope indicated by the short solid lines in Fig. 2. Unfortunately, it was not possible to exceed 1200°K without causing permanent distortions to occur in the thin walled quartz Bourdon spoon.

It should be noted that in all three samples the pressure curves increase smoothly with temperature and exhibit no "break points" (discontinuous dP/dT) indicative of the disappearance of solid phases. The pressure measurements of Nitsche and Richman (7) on the

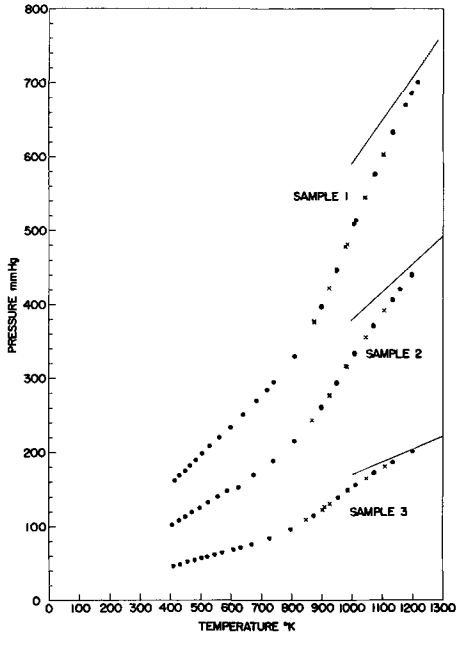

Fig. 2. Pressure *vs.* temperature data for three samples of ZnSe(s) plus $I_2(g)$ at constant volume: ●, temperature increasing; ×, temperature decreasing.

Table I. Quantities of ZnSe and I_2 used in Bourdon gauge runs

Sample No.	P/T, mm Hg/°C	Moles $I_2 \times 10^3$	Moles ZnSe $\times 10^3$
1	0.3921 ± 0.0007 (10)	0.101	0.25
2	0.2515 ± 0.0001 (8)	0.065	0.19
3	0.1129 ± 0.0003 (10)	0.029	0.086

Numbers in parenthesis indicate the number of data points averaged.

system CdS-I_2, for example, clearly exhibit abrupt decreases of dP/dT as solid phases of S and CdI_2 disappear with increasing temperature. Consequently, we will assume that no solid phases other than ZnSe(s) were present in our experiments.[1]

Equilibrium model.—An examination of the literature (8, 9) indicated that the major molecular and atomic species to be expected in the gas phase in the measured P-T range were $I_2(g)$, $I(g)$, $ZnI_2(g)$, $Se_2(g)$. (The presence of selenium vapor species other than Se_2 will be discussed later.) The equilibria between these species and ZnSe(s) may be written as follows

$$ZnSe(s) + I_2(g) \rightleftarrows ZnI_2(g) + \tfrac{1}{2}Se_2(g) \quad [1]$$

$$I_2(g) \rightleftarrows 2I(g) \quad [2]$$

In both equilibria $I_2(g)$ predominates at low temperatures. At higher temperatures both equilibria shift to the right, and since even rough estimates indicate that the Gibbs free energy, ΔF° for Eq. [1] is considerably smaller than ΔF° for Eq. [2] at high temperatures, it is expected that $ZnI_2(g)$ and $Se_2(g)$ will exist in much greater concentrations than $I(g)$ in the pressure range (200-700 mm Hg total pressure) under consideration here.

This model is qualitatively confirmed by the data since the P-T curve at high temperatures approaches a linear function with a slope 1½ times (see solid lines in Fig. 2) the slope of the low-temperature linear region. In order to test this model quantitatively as well as to obtain the thermodynamic constants for Eq. [1], the equilibrium constant Kp_1, has been calculated over a range of temperature and pressure.

$$Kp_1 = \frac{p_{ZnI_2}\, p_{Se_2}{}^{1/2}}{p_{I_2}} \quad [3]$$

In order to calculate the partial pressures in Eq. [3], we note that the total pressure, P_T, is the sum of partial pressures, *i.e.*,

$$P_T = p_{I_2} + p_I + p_{ZnI_2} + p_{Se_2} \quad [4]$$

and since the quantity of iodine is constant in the gas phase

$$\frac{V}{N_I R} \times T = 2p_{I_2} + p_I + 2p_{ZnI_2} \quad [5]$$

where V is the volume of the sample chamber, and N_I is the total number of moles of iodine atoms in the gas phase. Below 600°K $I_2(g)$ predominates and the terms p_I and p_{ZnI_2} in Eq. [5] are negligible. Therefore, the quantity $N_I R/2V$ is equal to the values of P/T tabulated in Table I for each sample.

From the stoichiometry of Eq. [1] and the presumed (see Discussion) stoichiometry of the ZnSe crystal it follows that

$$p_{ZnI_2} = 2p_{Se_2} \quad [6]$$

Finally, we note that the thermodynamic properties of the iodine dissociation are accurately known (10).

[1] It is possible that there was a very small amount of a second solid phase (ZnI_2,Se) formed in the region 600°-750°K. If this were the case, the apparent reaction rate was either extremely slow and/or the extent of reaction was very limited since the total pressure did not drop below the extrapolated $I_2(g)$ pressure line. Since our quantitative analysis is based on data taken only at much higher temperatures, we did not consider this temperature region further.

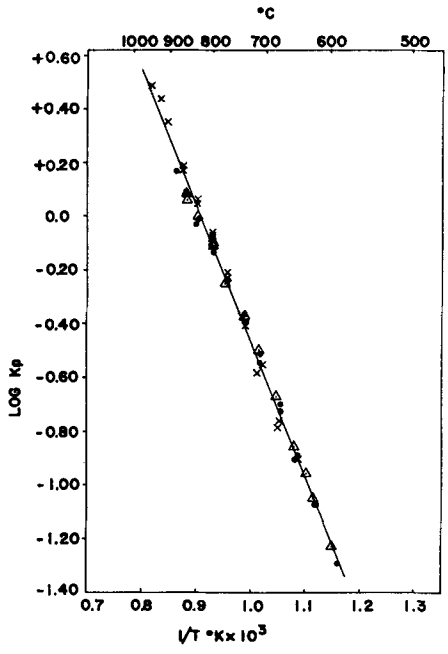

Fig. 3. Log K_p vs. $1/T$ for the equilibrium ZnSe(s) + $I_2(g)$ ⇄ $ZnI_2(g)$ + 1/2 $Se_2(g)$ for three different samples: ×, sample 1; ●, sample 2; △, sample 3.

$$\log K_{p2} = \log \frac{p_I{}^2}{p_{I_2}} = -\frac{7991}{T} + 5.481 \quad [7]$$

Equations [4]-[7] comprise a set of four independent equations in four unknown partial pressures which when solved simultaneously yield

$$p_I = \frac{K_{p2}}{4} \pm \sqrt{\frac{K_{p2}{}^2}{16} - K_{p2}\left(2P_T - \frac{3N_I RT}{2V}\right)} \quad [8]$$

$$p_{ZnI_2} = \frac{N_I R}{2V} \times T - p_{I_2} - \frac{p_I}{2} \quad [9]$$

The partial pressures p_{Se_2} and p_{I_2} are then readily obtained from Eq. [6] and [7].

A plot of the calculated $\log K_{p1}$ *vs.* $1/T$ for the three samples is shown in Fig. 3. The linear dependence of $\log K_p$ on $1/T$ and the lack of dependence of K_{p1} on pressure is reasonable confirmation that Eq. [1] and [2] constitute a satisfactory model for the equilibria. The standard enthalpy, ΔH° and entropy ΔS°, of reaction were obtained by the second law treatment using the relation

$$\log K_{p1} = -\frac{\Delta H^\circ}{2.303\, RT} + \frac{\Delta S^\circ}{2.303\, R} \quad [10]$$

where ΔH° and ΔS° are assumed independent of temperature. The best least square fit of Eq. [10] to the calculated results yields

$$\Delta H^\circ_{1000°K} = +23.1 \pm 1 \text{ kcal}$$

$$\Delta S^\circ_{1000°K} = +21.1 \pm 1 \text{ e.u.}$$

Discussion

Although the assumptions made in the above calculation appear straightforward, it is desirable to discuss several of them in somewhat greater detail. In order to insure the validity of Eq. [4]-[6], we have used a relatively small amount (see Table I) of ZnSe of the highest purity. Therefore, any errors in Eq. [4] and [5] caused by volatilization of an impurity or in Eq. [6] caused by a deviation from stoichiometry of the ZnSe (which is assumed to be less than 10^{-2}%) are negligible. Similarly the conservation of iodine in the vapor phase, Eq. [5], is valid if we assume that the solubility of I_2 in ZnSe does not greatly exceed the

solubility of I_2 in CdS which was reported by Nitsche, Bölsterli, and Lichtensteiger (11) to be *ca.* 10^{-2} mole %.

The assumption that Se_2 is the only selenium containing gas phase species is not strictly valid below *ca.* 900°K since at least some Se_6 is formed. By using the data of Stull and Sinke (8) for the equilibrium

$$3Se_2(g) \rightleftarrows Se_6(g)$$

we have excluded any point from Fig. 3 for which the ratio p_{Se_6}/p_{Se_2} exceeds more than a few per cent. A more important source of error may be the presence of Se_4[2] (or possibly some other species of selenium). In lieu of any quantitative information on Se_4 concentrations, we have neglected it in the above calculations and expect that in any case it would be negligible at somewhat higher temperatures. The satisfactory fit of the data to the model further indicates that neglecting Se_4 does not give rise to a large error.

Comparison with literature values.—In order to make a direct comparison of our results with those of other investigators, it was first necessary to calculate the heat of formation, $\Delta H°_{298f}$, and entropy, $S°_{298}$, of ZnSe. The heat and entropy of reaction at 298°K may be calculated from our measured data and the data in Table II using the usual formulas.

$$\Delta H°_{298} = \Delta H°_{1000} + \int_{1000}^{298} \Delta C_p\, dT = 23.1 + 1.9 = 25.0 \text{ kcal}$$

$$\Delta S°_{298} = \Delta S°_{1000} + \int_{1000}^{298} \frac{\Delta Cp}{T}\, dT = 21.1 + 3.2 = 24.3 \text{ e.u.}$$

The entropy of ZnSe at 298°K is calculated from the entropy of Eq. [1] at 298°K, $\Delta S°_{298}$, and the data in Table II.

$$S°_{ZnSe}(s) = S°_{ZnI_2}(g) + \tfrac{1}{2}\, S°_{Se_2}(g) - S°_{I_2}(g) - \Delta S°_{298} = 15.4 \text{ e.u.}$$

The standard heat of formation of ZnSe is calculated directly from literature data and the measured enthalpy, $\Delta H°_{298}$, in Table III.

We finally compare our results in Table IV with the results of previous investigations as tabulated by Goldfinger and Jeunehomme (3).

The agreement of our data with that of Wösten and Geers is probably within our combined experimental errors.

Conclusion

The heat of formation, $\Delta H°_{298f}$, and entropy $S°_{298}$ for ZnSe have been determined indirectly by measuring the equilibrium between ZnSe and $I_2(g)$. The resulting data are in agreement with the known experimental result (11) that ZnSe may be vapor grown via the iodine disproportionation reaction using a hot to cold process. The relatively slow rates at which the pressure equilibrated in the Bourdon gauge between 800°-900°K indicate that seed temperatures in a vapor growth process should not be too low for optimum growth rates.

[2] Extensive investigations of the composition of sulfur vapor by Braune, Peter, and Neveling (12) using a Bourdon gauge, and by Berkowitz and Chupka (13) using a mass spectrograph reveal the presence of all even-numbered polymers up through S_8. Mass spectrographic studies (14) of Se vapor reveal a qualitatively similar distribution of species. The similarity between the thermodynamic properties of the sulfur species and the known Se species, *i.e.*, Se_2, Se_6 suggests that Se_4 may be present in our experiments in somewhat greater concentrations than Se_6 as calculated above.

Solution Regrowth of Planar InSb Laser Structures

I. Melngailis and A. R. Calawa

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

A new technique has been developed for growing a thin layer of InSb on an InSb substrate from a saturated In-InSb melt. This type of growth from a solution has been used previously in the fabrication of GaAs and Ge p-n junctions; however, at the lower temperatures required for InSb (about 300°C) certain modifications were made, such as the use of hot liquid stearic acid which covers the InSb substrate and the In-InSb melt during the growth process. By doping the melt suitably, uniform planar InSb n^+-p junctions were grown on substrate areas of about 2 cm^2. Such InSb junctions have been used in large-volume injection lasers which emit coherent light in a direction normal to the junction plane.

The growth of thin crystal layers from a melt was first used by Nelson (1) as a technique of producing remarkably flat and abrupt p-n junctions for Ge tunnel diodes and GaAs junction lasers. In the case of InSb, this process is of particular interest for growing an n-type layer on a p-type substrate because of the difficulty of producing such layers by diffusion. The diffusion of the n-type impurities such as Se, Te, or S is impractical because these elements tend to form glasslike compounds on the substrate surface, and their diffusion coefficients in InSb are small at temperatures below the melting point of InSb (525°C). By the solution regrowth technique an n-type layer can be grown easily on a p-type substrate by simply adding an n-type dopant, such as Te, to the melt.

[1] Operated with support from the United States Air Force.

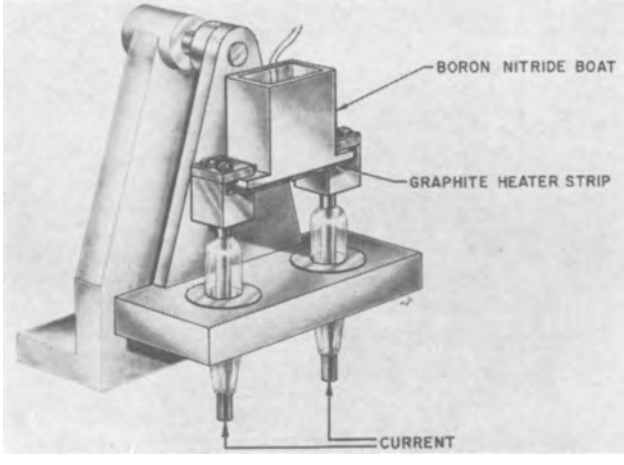

Fig. 1a. Apparatus for solution regrowth showing mount for the boron nitride boat.

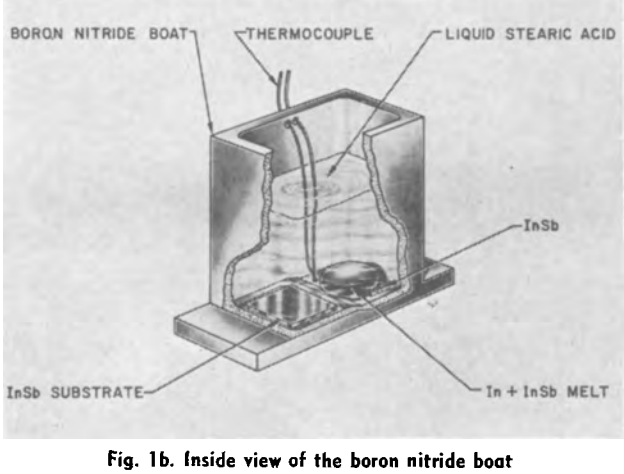

Fig. 1b. Inside view of the boron nitride boat

Method and Results

As shown in Fig. 1a and 1b the apparatus consists of a boron-nitride container which is heated from the bottom by passing current through a graphite heater strip and which can be tilted at various times during a run. The InSb substrate is placed on one side of the boat, while the opposite side contains In and a sufficient amount of InSb to produce a nearly saturated In-InSb solution at the maximum temperature of about 300°C. When growing n-type layers a small amount of Te is added to the solution. The melt and the substrate are kept apart during the first part of the run by a small ridge in the bottom of the boat. Molten stearic acid is then poured into the boat to cover the substrate and the melt. The purpose of the stearic acid is to keep the surface of the substrate and of the melt clean and to insure uniform wetting of the substrate surface by the melt. The boat is then heated by the graphite heater strip. At a temperature of about 300°C the boat is tilted so that the melt flows over the substrate, and the current in the heater is reduced immediately to begin cooling the boat. At the time when the melt first makes contact with the substrate the melt is not quite saturated with InSb, and a thin layer of the substrate surface goes into solution. This removes any surface damage. As the temperature is lowered InSb is forced out of the solution and grows in a uniform layer on top of the substrate. At about 200°-250°C the boat is tilted back and the remaining solution is wiped off the substrate. The stearic acid is then poured off before it solidifies. The grown surface generally has a clean mirrorlike appearance and the growth is quite uniform across the substrate. Figures 2a and 2b show the profile of a growth junction delineated by etching a cleaved (110) surface. All of our solution regrowths were done on a (100) crystal

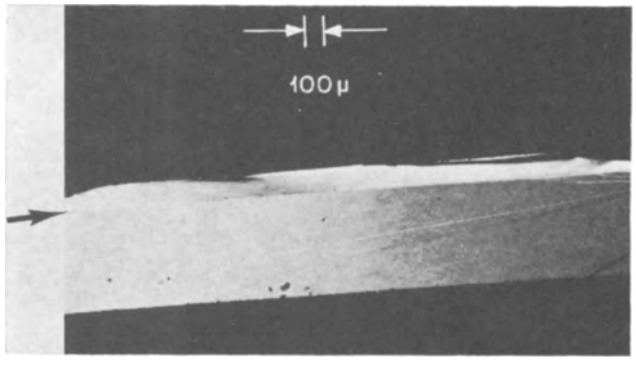

Fig. 2a. Profile of 120μ thick n^+ layer grown on the (100) face of a p-type InSb substrate. The junction indicated by an arrow has been delineated by etching a cleaved (110) face.

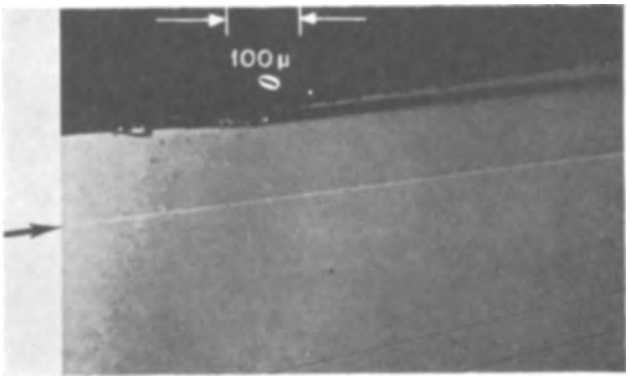

Fig. 2b. A further magnification of the profile in Fig. 2a

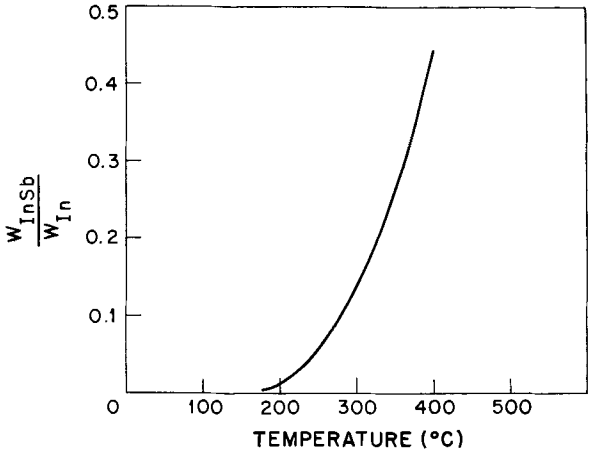

Fig. 3. Temperature dependence of the fractional weight of InSb required to produce a saturated solution, after Hall (4).

face to enable cleaving perpendicular to the junction plane.

The weights of the various ingredients of the melt used in growing a heavily doped n^+ region on a p-type substrate area of 12 x 12 mm were 4.0g of In, 0.6g of n-type InSb, and 4.0 mg of Te. The weight of the Te dopant in this case was chosen so as to produce the highest possible doping in the n^+ layer (8×10^{18} cm^{-3}) (2, 3). The ratio of the InSb weight to the weight of In in the melt was chosen from published solubility data (4). Figure 3 is the temperature variation of the fractional weight of InSb required to produce a saturated solution.

A typical heating cycle is shown in Fig. 4. The melt is poured over the substrate by tilting the boat at the maximum temperature of 315°C in this case. At about 225°C the melt is wiped off. Although most of our runs were similar to this one, the times and temperatures involved do not appear to be critical.

Discussion

The main innovation of our solution regrowth technique is the use of stearic acid, which facilitates growing at the low temperatures required for InSb. The use of a liquid instead of a gas atmosphere also greatly simplifies the apparatus and the process and permits visual observation during the process. Although the use of stearic acid is limited to temperatures not higher than 350°C, at which point it boils away too rapidly, other liquids such as boric oxide could be used for crystals which require higher growth temperatures than InSb.

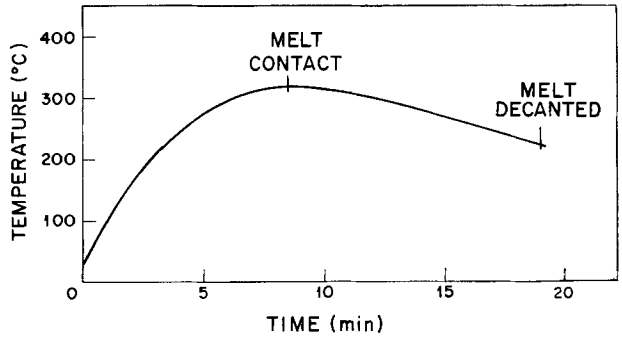

Fig. 4. Temperature cycle of a typical solution regrowth

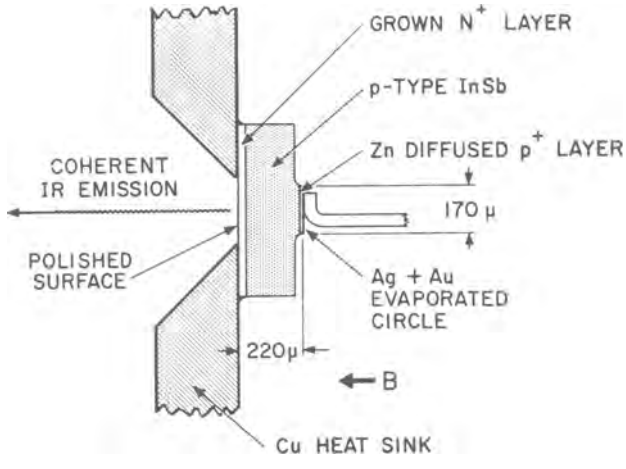

Fig. 5. Large volume InSb injection laser designed for coherent emission normal to the plane of the junction.

One of the applications of this method was in the fabrication of InSb injection lasers in which the light is emitted in a direction normal to the plane of the junction (5). Such a structure is shown in Fig. 5. The n^+ layer was grown on high resistivity p-type InSb by the above technique, and the p^+ layer in this case was made by Zn diffusion. In these diodes the lifetimes of injected carriers are sufficiently long (10^{-7} to 10^{-6} sec) and the mobilities are sufficiently high to permit population inversion across the entire region between the contacts. The radiation which is thus generated in the active region has to pass through the doped p^+ and n^+ layers; hence, these have to be of a good quality crystal which is transparent to the radiation. Solution regrowth proved to be the only satisfactory technique for making good n^+ layers.

The Electrodeposition of Coherent Deposits of Refractory Metals

III. Zirconium

G. W. Mellors and S. Senderoff

Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

ABSTRACT

Exploratory experiments in chloride, bromide, and mixed chloride-fluoride melts always produced dendritic zirconium deposits. Pure fluoride systems consisting of ZrF_4 dissolved in alkali fluoride solvents produced coherent deposits of metal, some as thick as 0.1 in. with no indication of reaching a thickness limit, on electrolysis at 750°C and 30 ma/cm^2 cathode current density. Analysis and material balance experiments showed that reduced compounds were absent in these fluoride systems. Chronopotentiometric measurements indicate that the zirconium is deposited from the tetravalent state in a single four-electron step which would appear to be irreversible. The addition of KBF_4, K_2TiF_6, and Al_2O_3 to a working zirconium bath results in the deposition in coherent form of the compound ZrB_2 and the alloys Zr-Ti and Zr-Al. The ZrB_2 plate was 11 mils thick and showed no evidence of reaching an upper limit of thickness, while both alloys were smooth and fine-grained in nature, the Zr-Al deposit showing a particularly interesting rhythmic banded structure.

Earlier papers in this series have described the electrolysis of fused fluorides to produce columbium and the mechanism for the electrodeposition of tantalum. In this paper the deposition of coherent deposits of zirconium and the mechanism and electrode reactions to form such deposits will be discussed.

A considerable amount of work has been reported on the electrolysis of zirconium-containing molten salts to yield the metal. Efforts to obtain the metal by electrolysis of aqueous or organic solutions have always ended in failure.

Troost (1) electrolyzed molten sodium and potassium fluozirconates, while later Wedekind (2) and Marden and Rich (3) obtained amorphous zirconium powder by this method. Driggs and Lilliendahl (4, 5) obtained zirconium by the electrolysis of molten baths of sodium and potassium chlorides containing potassium fluozirconate. Plotinkov and Kirichenko (6) electrolyzed a melt containing aluminum and potassium chlorides, sodium fluoride, and zirconium tetrachloride, held at 300°-500°C in a porcelain cell. The cathode was copper and the anode aluminum or graphite. Variations of the method were reported using molten sodium chloride, potassium chloride and potassium fluozirconate mixtures (7). Steinberg, Sibert, and Wainer intensively studied the above method and obtained zirconium of 99.8-99.9% purity with carbon content 0.05%, oxygen 0.05%, and nitrogen 0.003% (8, 9).

The above work was concerned with electrowinning the metal and always resulted in cathodic deposits that were in powder or crystal form. To compact the metal, expensive procedures such as vacuum fusion or electron beam melting are necessary; the compacted material may then be rolled into sheets or fabricated into other desired forms. In view of the above, it would be extremely valuable to be able to deposit coherent metal from an electrolytic bath, thus circumventing the aforementioned procedures.

Deposition of coherent plates of pure zirconium has undoubtedly been attempted, but no successful process has been reported. One may note in passing that, although pure refractory metals cannot be deposited from aqueous systems, coherent alloy plates with Fe, Ni, and Co are obtainable. In these processes the refractory metal content (W or Mo) is always less than 30% and usually less than 20%.

In the prior literature there are very few substantiated instances of the deposition of coherent refractory metals by the electrolysis of molten salts. In the case of molybdenum the deposition of coherent metal was reported in a series of papers by Senderoff and Brenner (10). The anode was a pure molybdenum sheet, and the electrolyte, which consisted of potassium hexachloromolybdate (III) (K_3MoCl_6) dissolved in KCl-LiCl eutectic, was contained in an ATJ graphite crucible under an atmosphere of purified argon.

Davis *et al.* (11) deposited coherent layers of pure tungsten from fused salt baths containing borates and tungstic oxide. Schlain and co-workers (12) working in similar systems developed and improved the performance of the baths. Stetson (13) described the deposition of coherent titanium, although in his work there were limitations on substrate material, and indeed in this work and the work on tungsten there appeared to be limits on the ultimate thickness of deposits.

In the electrorefining of Hf metal through NaCl-$HfCl_4$ electrolyte, Baker (14) obtained a thick ($\approx$ ⅛ in.) coherent plate of the metal. However, this appeared to have been a purely fortuitous situation since it was not reproducible, repetition under supposedly identical circumstances yielding a dendritic deposit.

The deposition of columbium (15, 16) and tantalum (17) by the electrolysis of pure fluoride melts has been described by the present authors, and a general method for deposition of a group of refractory metals has been disclosed in the patent literature (18). However, concurrent with this work exploratory experiments were performed in fused chloride and bromide systems as described below.

Experimental

Materials.—$ZrCl_4$ was purchased from Stauffer Chemical Company in crude form. The material, which was pale yellow, was resublimed under argon-10% hydrogen atmosphere. The function of the hydrogen was to reduce $FeCl_3$ to $FeCl_2$, the latter being involatile. Pure $ZrCl_4$ was collected as a snow-white powder in a cooled receiver.

$ZrBr_4$ was made by the interaction of heated Zr metal (450°C) and a stream of bromine gas diluted with argon. The product was sublimed into a collection vessel where it was sealed off and removed from the system.

ZrF_4 and K_2ZrF_6 were obtained from General Chemical Division, Allied Chemical and Dye Corporation. The ZrF_4 was used as-received, but the fluozirconate was purified by recrystallization from water.

Zirconium in sheet and rod form was obtained from Reactive Metals, Inc.

Alkali chlorides, bromides and fluorides (ACS specification) were obtained from Harshaw Chemical Company.

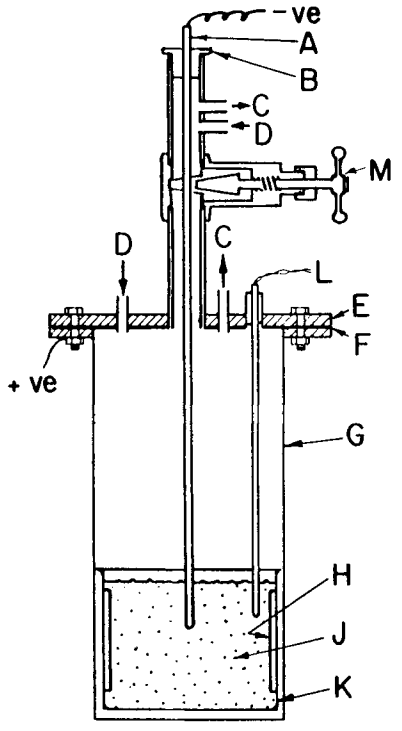

Fig. 1. Apparatus used in electrolysis of fluoride melts: A, stainless steel cathode; B, Teflon stopper; C, argon outlets; D, argon inlets; E, stainless steel lid; F, Teflon or Sauereisen gasket; G, "Hastelloy X" can; H, zirconium anode; J, fluoride melt; K, nickel or stainless crucible; L, thermocouple and well; M, gate valve (1 in.).

Argon was purified by passage through either Ti chips at 900°C or Cu turnings at 700°C.

Boron tribromide and boron trioxide were obtained from American Potash and Chemical Corporation.

Electrolytic cells.—The apparatus used is shown in Fig. 1 and has been fully described in an earlier publication (15).

Results

Chloride melts.—A series of exploratory experiments with melts of the series KCl-LiCl-$ZrCl_4$ and KCl-NaCl-$ZrCl_4$ confirmed that, after extended periods of electrolysis, the melts contained highly colored subhalides and that only dendrites could be deposited under all conditions of temperature, concentration, and cathode current density. In most cases, the dendrites overlay an initial layer of metal about 1 mil in thickness, and this coherent layer is in all probability a diffusion alloy with the material of the substrate. This work will not be discussed further in this paper since it confirms the results of earlier workers (8).

Bromide systems.—Experiments in this system were conducted in the NaBr-KBr eutectic mp 644°C (19) to which about 5 w/o (weight per cent) $ZrBr_4$ was added. The phase diagram of NaBr-KBr-$ZrBr_4$ is unknown, but by analogy with the NaCl-KCl-$ZrCl_4$ diagram a low melting eutectic rich in $ZrBr_4$ might be expected around 70-80% $ZrBr_4$ and 200°-250°C. Accordingly the temperature was held at 250°C for several hours and then slowly raised to the operating temperature.

The initial purification was performed at 800°C and 200 ma/cm² cathode current density (C.C.D.) with approximately 0.2v across the cell. However, polarization soon developed, the cell voltage rising to 6v, 5.8v of which was found to be potential drop at the anode. Simultaneously the current decreased but could be restored by tapping the anode. This suggests the presence of some insoluble film on the anode. No cathodic deposits were obtained, indicating that the species responsible for deposition was absent from the melt or present in insufficient concentration. The experiment was rerun at 950°C (to increase the solubility of such species) and 500 ma/cm². The polarization was to some extent overcome and a thin compacted powder deposit obtained, but on repetition of the experiment the polarization returned in more acute form. Under varying experimental conditions it proved impossible to extract clean dendritic Zr from this melt. A sample was taken from the liquid by means of a "Vycor" tube, and it was found that some crunchy, pulverizable solid was present in the crucible, thus lending some support to the idea of lower halide insolubility.

The bromide solutions on freezing were deep blue-black in color and reacted vigorously with water and dilute acid yielding impure hydrogen. An analysis showed the presence of 0.52% Zr and 69.0% Br and a reducing power of 0.988 milli-equiv/g corresponding to a mean Zr valence of 3.

Mixed chloride-fluoride melts.—In some of the preliminary work it was noted that a bath consisting of an alkali halide eutectic (*e.g.*, KCl-LiCl or NaCl-KCl) together with potassium fluozirconate (K_2ZrF_6 or 2 KF · ZrF_4) required far less "pre-electrolysis" to bring it to the required condition for the deposition of clean dendritic zirconium powders than did the all-chloride bath. Potassium fluozirconate may be purified very easily by recrystallization from water and subsequent drying. However, as in the pure chloride melt electrolysis, even at low temperatures and C.C.D.'s, this solution yielded dendritic powders plus the underlying 1 mil of coherent plate as reported previously (9).

On cooling, the NaCl-KCl-K_2ZrF_6 mixture was found to consist of two layers, the upper being very pale bluish-white and the lower black in color. The lighter material is inert with respect to water and dilute mineral acid, while the black material reacts vigorously, finally depositing a black powder, which again (*v.i.*) is probably zirconium metal formed by the disproportionation during cooling of a subfluoride.

In contradistinction to the fluoride systems, it should be noted that subhalides were always observed in the chloride, bromide, and mixed chloride fluoride systems. As will be seen below, an important feature of the pure fluoride systems is the complete absence of reduced species.

Fluoride systems.—Because of the encouraging results obtained with K_2ZrF_6, notably the ease of handling and involatility of ZrF_4 (sublimation point 910°C approximately) systems consisting of KF-LiF-ZrF_4 (KF-LiF-K_2ZrF_6) and LiF-NaF-KF-ZrF_4 were prepared. The melting point of the KF-LiF eutectic is 492°C and that of the ternary eutectic 454°C.

The ternary eutectic LiF-KF-NaF (Flinak) was used because of its very low melting point (454°C) (20). It had been hoped to deposit zirconium at temperatures in the 500°-600°C range, but this proved impossible, no deposit other than semiadherent powders being produced. It is likely that this occurs because, on the addition of ZrF_4 to the LiF-KF-NaF eutectic, a two-phase or highly viscous system exists up to about 650°C.

The anode was a zirconium sheet rolled in cylindrical form which fitted flush to the inner wall of the internal crucible. The cathode, which was a 1/4 or 3/16 in. diameter molybdenum rod, was centrally mounted. ZrF_4 (10 w/o) was dissolved in the ternary eutectic of NaF-KF-LiF contained in a seamless stainless steel crucible and some 4 hours of electrolysis at 750°C and approximately 400 ma/cm² C.C.D. was sufficient to bring the melt to a satisfactory operating condition. Runs were made at various temperatures, but the most efficient plating conditions were at 750°C with a C.C.D. of 10-30 ma/cm². However, further work showed that plates could be obtained from 675° to 800°C with C.C.D.'s of 5-30 ma/cm². Rotation of the cathode did little to improve the smoothness of the deposit in this particular instance.

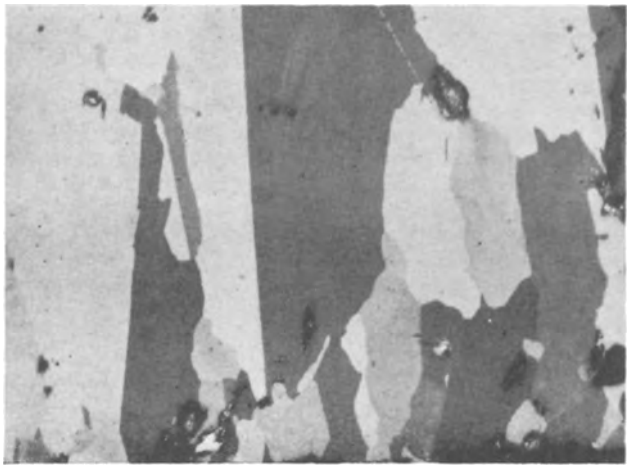

Fig. 2. Piece of detached Zr plate (X150)*

Spectroscopic analysis of the plates revealed them to be almost pure Zr metal, only traces (0.01%) of Fe, Mg, Mn, and Al being detected. A photomicrograph of the plate is shown in Fig. 2 and demonstrates (*a*) the columnar structure of the deposit, and (*b*) the cleanliness and sharpness of the grain boundaries. The grain size is very large compared with that of ZrB_2 and Zr-Ti deposits discussed below and probably indicates a deposit equivalent to a well annealed pure metal.

The residual electrolyte had no reducing power and contained 4.65 w/o Zr (average of two determinations differing by 0.1%).

An examination of the system KF-LiF-ZrF_4 was then made. The KF-LiF eutectic (50-50 M%) has a melting point of 492°C (21). ZrF_4 (14 w/o) was dissolved in the molten eutectic and the melt purified by 24-hr electrolysis at 850°C and 70 ma/cm² C.C.D. The temperature was lowered to 750°C and several runs carried out between 15 and 30 ma/cm² C.C.D. Smooth coherent plates of zirconium were obtained under these conditions.

To study the effects of solvent composition, a NaF-LiF eutectic (mp 652°C) was prepared and 12 w/o ZrF_4 added. The melt was purified by some 35 hr preelectrolysis, but under the identical conditions of temperature and current density leading to coherent plates in the KF-LiF-ZrF_4 and KF-LiF-NaF-ZrF_4 systems, the deposits produced from NaF-LiF-ZrF_4 melts tended to compacted powders although in a few cases an apparently coherent deposit was produced. Variation of experimental conditions of temperature and cathode current densities did not alter this situation materially. The presence of KF appears to be highly desirable for the reproducible production of coherent plates.

Experiments were conducted to assess the possibilities for coherent deposition of Zr from the molten KF-ZrF_4 system. Runs were made at the composition 0.88 KF·0.12 ZrF_4 (28.18 w/o ZrF_4). The lowest working temperature possible was around 800°C, the liquidus being 775°C (22). Unfortunately the melt became very viscous during the electrolysis, and no deposits of value were obtained at temperatures between 800° and 950°C with variations of C.C.D. from 10 to 400 ma/cm². It was thought that, if the ZrF_4 concentrations were less, the high viscosity problem would be overcome and the deposition run even at the higher temperature necessary to liquefy the composition. But electrolysis of 0.98 KF-0.02 ZrF_4 (mp 845°C) failed to produce a coherent deposit even with rotation of the cathode.

In general in the above work it was found that the cathode current efficiency based on the assumption of zirconium tetravalency was between 90 and 100%.

Effect of additives on deposition in chloride, chloride-fluoride, and fluoride baths.—A limited amount of work was done to determine the effect of additives on the electrodeposition of zirconium. In the deposition of molybdenum (23) it was found that electrolysis at 30 ma/cm² C.C.D. and 600°C under an inert atmosphere yielded a plate having a columnar structure and freedom from voids in the deposit, particularly in the presence of an addition of 1% by weight of "activated alumina." Other addition agents which showed promise in extending the range of current density and temperature for satisfactory metal deposition were ferrous chloride (0.1% by weight) and sodium fluosilicate (10% by weight) (24). The deposits obtained from baths containing the latter additive were particularly sound and could be built up to be as much as 0.02 in. in thickness without appreciable roughness. Current densities up to 300 ma/cm² could be used, but a temperature of 900°C was required. On the other hand, the addition of 10% by weight of nickel chloride to the system yielded bright, smooth Mo-Ni alloy deposits containing from 1 to 10% Ni when operated at 600°C and 30 ma/cm² C.C.D.

Addition of purified ZrO_2 (1.25 w/o) to the NaCl-KCl-K_2ZrF_6 bath was without visible effect on the electrolytic product. However, additions of SiO_2 or $ZrO_2 \cdot SiO_2$ made it impossible to obtain deposits of Zr metal at any reasonable temperature or current density, the effect of the additives leading to the production of black slimes. A similar effect was noted for additions of K_2SiF_6 to the chloride-fluoride baths.

The addition of 3 w/o K_2SiF_6 to an LiF-KF-K_2ZrF_6 melt had little effect on the deposit, but when 15 w/o K_2SiF_6 was added, silicon powder was the main cathodic product. It may be noted that silicon powders may be obtained by electrolysis of an LiF-KF-K_2SiF_6 melt, at 850°-900°C and at C.C.D.'s of 300 ma/cm².

The addition of 12 w/o KBF_4 to an electrolytically purified LiF-KF-K_2ZrF_6 solution resulted in the deposition of coherent coatings of ZrB_2 which adhered strongly to the molybdenum cathode. The optimum conditions for deposition (800°C and 30 ma/cm² C.C.D.) differed only slightly from those for depositing zirconium coatings, but it was noted that the requirements for depositing the boride were much less stringent. Purification requirements were less, the allowable range of current density and temperature greater, and the concentration of boron uncritical above the minimum requirement indicated above.

A ZrB_2 plate produced from this bath was 11 mils thick and showed no evidence of nearing an upper limit of thickness. A photomicrograph of the deposit is shown in Fig. 3. The deposit consists of dense columnar grains typical of electrodeposits of sound structure and mechanical properties. The cleanliness and sharpness of the grain boundaries attest to the high purity of this deposit. The major constituents were Zr and B, the minors (<0.1%) were Mn, Si, and Ca, and in addition traces of Fe and Ti were detected. An x-ray pattern showed only lines for ZrB_2. By analysis it was found

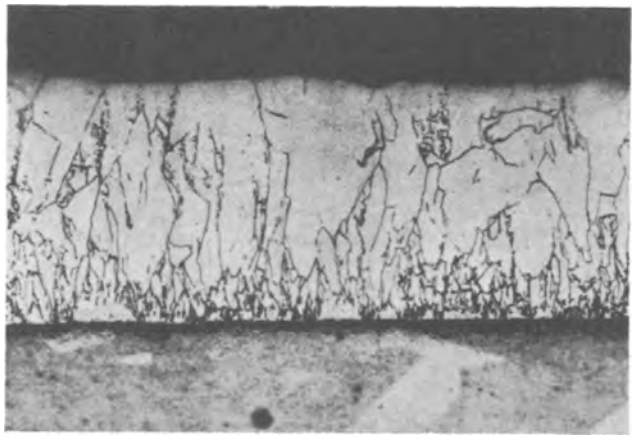

Fig. 3. Cross section of zirconium diboride coating (X150)

* All magnifications before reduction for printing.

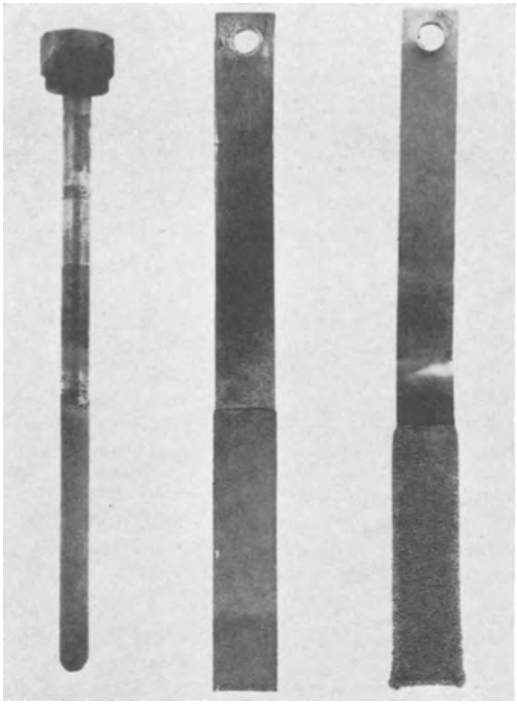

Fig. 4. Zirconium diboride articles

that the boron content of the solution was 0.85 w/o, the Zr 14.4 w/o.

Attempts were made to deposit ZrB_2 from this melt on graphite rods. Spectroscopic (AGKSP) rods, ¼ in. OD, were plated at 800°C and 150 ma/cm^2 with varying thicknesses of coherent ZrB_2. The analyses of the deposit indicated pure ZrB_2 as before, but the adherence was poorer than on molybdenum, perhaps owing to penetration of the substrates by the molten fluorides. A number of ZrB_2 plated articles are shown in Fig. 4.

The addition of KBF_4 to the purified Flinak-ZrF_4 bath also produced coherent plates of ZrB_2. However, when $NaBF_4$ was added to NaF-LiF-ZrF_4 melts it proved impossible to produce ZrB_2 plates, only dendrites and compacted powders being deposited. However, the addition of KBF_4 in sufficiently large amounts (~50 w/o) to NaF-LiF-ZrF_4 melts produced ZrB_2 plates on electrolysis. The systems NaCl-KCl-$ZrCl_4$-KBF_4 or NaCl-KCl-ZrF_4-KBF_4 would deposit only ZrB_2 powders under similar circumstances.

The addition of recrystallized Al_2O_3 to the purified LiF-KF-ZrF_4 or LiF-KF-K_2ZrF_6 melts produces a Zr-Al alloy in the form of smooth coherent plates. A cross section of this material is shown in Fig. 5. Approximately 1% by weight of Al_2O_3 was added to obtain this result. The rhythmic-banded structure is worthy of note.

Presumably the composition of this alloy could be altered by judicious handling of the relevant variables (*e.g.*, C.C.D., temperature and concentration of added alumina).

A few electrolyses were conducted in the system Flinak-ZrF_4-K_2TiF_6 (15 w/o). The anode was a rolled Zr sheet and the cathode a molybdenum rod. A smooth Ti-Zr alloy was produced and a cross section of this deposit is shown in Fig. 6. No further work has been done with this system, and the composition of the alloy is unknown. The surface of the plate is at the top of the picture. It will be noted that a dense columnar structure of sound metal alloy was produced. No voids are evident, grain boundary impurities are absent, and adhesion to the base metal is excellent. The streaks in Fig. 6 consist of thin regions of very fine-grain material which is apparently the same as the rest of the alloy except for grain size. Further, the metallographic treatment has brought out the detailed extremely fine-grain columnar structure, characteristic of a very

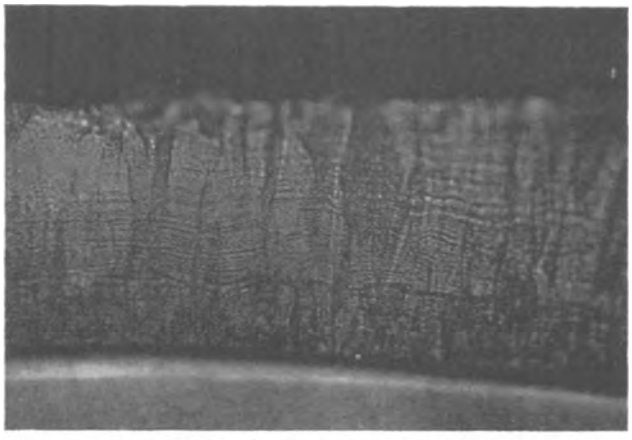

Fig. 5. Zirconium-aluminum alloy (X150)

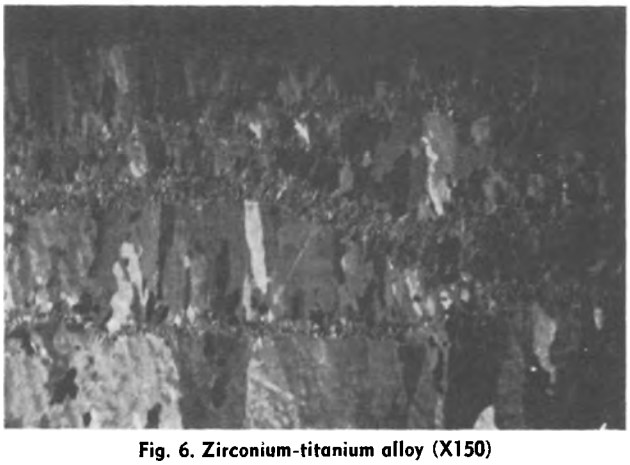

Fig. 6. Zirconium-titanium alloy (X150)

smooth, hard, deposit of high tensile strength. The variations in structure observed in Fig. 6 undoubtedly arose from accidental variations in the current density or other operating variables during the deposition. The effect of these variables on the structure and mechanical properties of the deposit requires further study. The lower criticality of the usual variables in alloy or compound deposition as compared with pure metal deposition was noted in the cases of Zr-Al, Zr-B, and Zr-Ti alloys also.

At this stage it seemed valuable to determine whether ZrB_2 might not be made by the addition of B_2O_3 to a chloride, etc., melt. A NaCl-KCl-$ZrCl_4$ melt was purified electrolytically until clean Zr dendrites were produced. About 3½ w/o dried B_2O_3 ("Trona") was added and after several electrolyses long crystalline needles were deposited. These turned out to be very pure iron containing but a trace of boron and undoubtedly came from the iron crucible. The experiment was rerun using an ATJ graphite crucible, and electrolysis finally resulted in the production of powdery cathode deposits showing Zr and B as main constituents. When the B_2O_3 of the bath was exhausted a further addition of this material was instrumental in producing further Zr-B powders. Unfortunately the x-ray pattern, in addition to demonstrating the presence of ZrB_2, showed also 5-10% of ZrO_2. This, of course, is not surprising in view of the oxidic nature of the melts, and it makes the ZrB_2 produced much inferior to powders and plates from the fluoride baths and to powders from the chloride-KBF_4 bath. It has proved impossible to produce plates from the chloride-B_2O_3 system, a result similar to that found for the chloride-KBF_4 bath described earlier.

The apparatus in which NaBr-KBr-$ZrBr_4$ was electrolyzed in an iron crucible was modified to permit admission of BBr_3 to the melt at operating temperature. BBr_3 is an orange-red liquid, but by shaking with

mercury metal the excess bromine responsible for the color may be removed. BBr_3 was boiled under a stream of purified argon and passed into the melt. No polarization troubles were encountered and a powder deposit of ZrB_2 was obtained at 750°C and 100 ma/cm² C.C.D. However, iron in the deposits, presumably entering the melt from the crucible, caused the termination of this experiment.

A further series of experiments with NaBr-KBr-$ZrBr_4$ melts was run in ATJ graphite crucibles. This time polarization was absent, though the reason is unclear, and clean Zr dendrites were obtained after some 4 hr electrolytic purification. But even at low C.C.D. (30 ma/cm²) and low temperature (750°C) coherent plates of Zr could not be obtained; the result was as observed in chloride and chloride-fluoride systems in that a 1-2 mil coherent plate was present under a dendritic deposit.

Again by bubbling BBr_3 into this melt it was possible to obtain ZrB_2 powders, but this method is wasteful of BBr_3 and inefficient with respect to electricity used as compared with additions of KBF_4 to fluoride melts.

Question of the Valency of Zirconium Species

The only systems from which coherent Zr metal could be plated were those based on pure fluorides, and in these systems the following rather interesting phenomena were observed.

Frequently during the operation of zirconium plating baths the presence of a blue volatile material and a silver liquid near the argon exit tube of the cells was noted. At first it was thought that this material was a subhalide (or perhaps a covalent complex) of zirconium. The presence of this material had been noted under electrolyzing conditions, but then was found to be formed if Zr metal, KF and ZrF_4, or more simply Zr + KF, were heated together to about 800°C.

The volatile material was collected and identified as potassium metal. Therefore, a reaction of the type

$$Zr + nKF \rightarrow ZrF_n + nK \qquad [1]$$

where $n = 1, 2, 3$ and possibly 4 had occurred.

The following experiment was performed to determine the value of n in the above equation. A weighed amount of pure potassium fluoride was held at 875°C in a stainless steel crucible under argon atmosphere and reacted for 30 hr with a weighed zirconium rod that was withdrawn from the system at the conclusion of the run and reweighed. At the temperature of operation the volatile material was evolved and conducted away from the reactor. The material remaining in the crucible was analyzed and it was found that; (*a*) all the zirconium lost from the weighed rod was now present in the crucible; (*b*) the loss of fluorine was negligible and could probably be accounted for on the basis of KF volatility; and (*c*) the molecular ratio of potassium lost by volatility to zirconium dissolved from the rod was 3.9, a close approximation to 4.

From these data it may be concluded that in reaction [1] $n = 4$ and that fluorides of lower valent zirconium do not exist in these melts. If such subfluorides existed they undoubtedly would have been formed in preference to ZrF_4 in the presence of excess Zr metal and would probably have disproportionated on cooling, leading to ZrF_4 and Zr powders. No Zr powders were found, and a trace of a metal powder found was identified as Cr, the source of which was probably the stainless steel crucible. Further, even if a lower fluoride had formed and later disproportionated, the observed ratio of K lost to Zr added would not have been 4, but would have been equal to the valence of the Zr in the intermediate compound. It may be concluded that reduced zirconium compounds are not involved in the metal deposition process. The reduction of KF by Zr metal proceeds in spite of the positive free energy change because of the volatility of potassium metal and the extremely stable fluozirconate complex formed between the excess KF and ZrF_4.

However, recently the synthesis of both zirconium di- and trifluoride has been reported (25, 26), but we have no evidence from the above results and those obtained from the chronopotentiometric investigations described below that reduced compounds or complexes of these materials are involved in the present system.

An experiment identical to the above was run to obtain cooling curve data on the system formed from Zr and KF. If the weights of Zr and KF are known, then it is possible from the known stoichiometry of the reaction to calculate the composition obtained in the KF-ZrF_4 system. In one such experiment, the calculated composition was 5.3 mole % ZrF_4 which has a liquidus at 834° and a solidus at 768°C. Accepted literature values for this composition are 830° and 765°C (27). This then is added confirmation that the end product of the Zr-KF reaction is a composition in the KF-ZrF_4 system in which $[ZrF_7]^{-3}$ is probably the dominant Zr-containing species. The latter may be inferred from the fact the K_3ZrF_7 melts congruently at 910°C and precipitates at the liquidus temperature. Similar conclusions may be drawn from surface tension (28, 29) and spectroscopic (30) measurements in these systems.

Chronopotentiometric Experiments

The apparatus used in this work has been described in a previous paper (17) and consists basically of a constant current pulsing device, an oscilloscope on which is displayed the resultant potential-time relationship, and a photographic recording device.

Since the reduction potentials of zirconium and aluminum are close together, it was thought desirable to replace the alumina bridge with a similar bridge constructed of BN. Unfortunately, even after prolonged soaking in an alkali-fluoride melt the resistance across a BN bridge was in excess of 10^5 ohms. In a second bridge a 0.067 in. (1/16 in.) hole through the bridge was merely filled with the melt and the resistance was approximately 70 ohms at 750°C. However, in operation this bridge proved unsatisfactory, and measurements were made with alumina, zirconia, and magnesia bridges and in one case measurements were made by using a platinum wire immersed in the melt as a quasi-reference.

A typical blank for the alkali-fluoride solvent is shown in Fig. 7; the $i\tau^{1/2}$ value being 1 x 10^{-2} amp cm^{-2} $sec^{1/2}$ at 750°C, 100 ma/cm² and —1.9v *vs.* the Ni/Ni^{2+} reference electrode.

With a zirconium concentration of 7.23 x 10^{-5} moles/cc added as K_2ZrF_6, chronopotentiograms were obtained at 750°C. At 50 to 100 ma/cm² C.C.D. no well-defined plateau was obtained. Figure 8 shows one such chronopotentiogram with the poorly defined plateau just under —1.5v. When the current density was raised to 300 ma/cm² and then to 500 ma/cm² and the

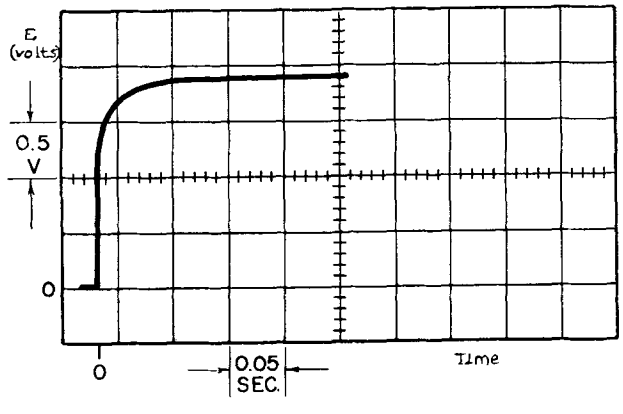

Fig. 7. Typical blank for KF-NaF-LiF solvent at 750°C C. D. 100 ma/cm².

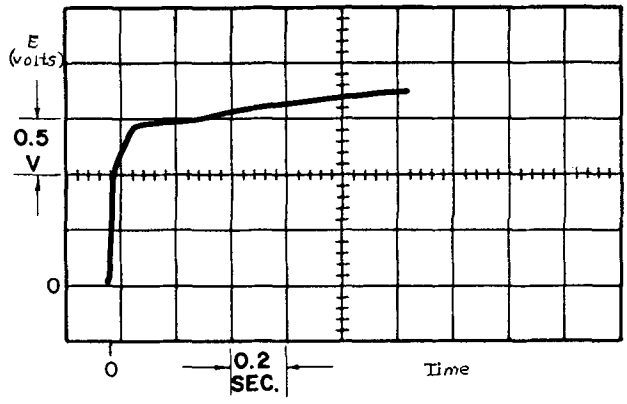

Fig. 8. Chronopotentiogram for KF-NaF-LiF-ZrF_4. C_{Zr} = 7.23 × 10^{-5} moles/cc; T = 750°C; C.D. = 100 ma/cm^2.

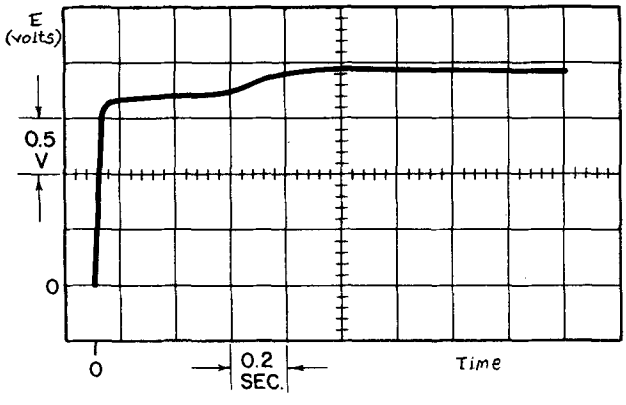

Fig. 9. Chronopotentiogram for KF-NaF-LiF-ZrF_4. C_{Zr} = 2.77 × 10^{-4} moles/cc; T = 750°C; C.D. = 500 ma/cm^2.

concentration also increased, a chronopotentiogram such as that shown in Fig. 9 was obtained, with $E_{1/4}$ value of —1.69v. The higher $E_{1/4}$ value can best be accounted for by the increased IR drop which resulted from the fivefold increase in current density.

Although potassium is apparently some 0.4 ~ 0.5v base to zirconium in this system, there is a chemical reaction between zirconium metal and KF as discussed earlier, and this occurs because of the volatility of potassium metal and the complexity of ZrF_4 produced with additional KF. Therefore, it is clear that with low concentrations of Zr in the bath at high temperatures there will be a corrosion reaction occurring which would distort the chronopotentiogram. However, if one increases the rate of Zr production by, for example, increasing the current density considerably, it is seen that the plateaus may be resolved (Fig. 9).

It has been suggested by Manning and Mamantov (31), on the basis of their polarographic measurements in KF-NaF-LiF-ZrF_4 at 500°C, that the zirconium reduction occurs in a single reversible four-electron step at —1.4v *vs.* the platinum quasi-reference electrode that they employed.[1] Since at 750°C we were not able to interpret our data with certainty except at very high current density, experiments were conducted at 500° and 650°C. Also, to eliminate any possible interference by alumina from the salt bridge, a platinum quasi-reference of the type mentioned above (31) was employed. Because of the undefined potential of this electrode, quantitative conclusions cannot be drawn regarding $E_{1/4}$ values, but the 500° and 650°C results show a single well-defined plateau (Fig. 10 and 11) at

[1] The authors have found in the course of the present investigation that this platinum quasi-reference is within 0.1v of their Ni/NiF_2 reference electrode. Since Manning and Mamantov reported the presence of iron in their solutions it is possible that the platinum quasi-reference is in fact an iron (II)-iron (III) electrode which would make it approximately 0.1v base to our reference.

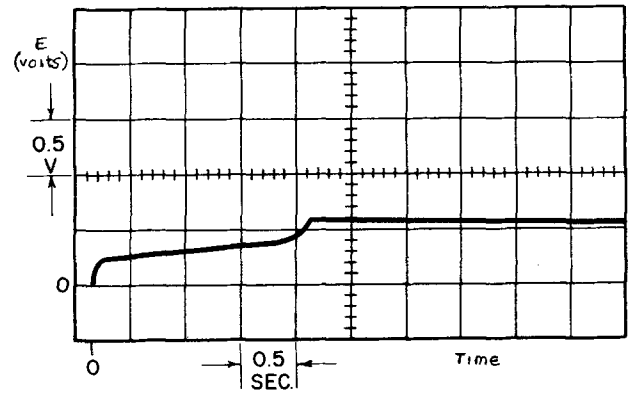

Fig. 10. Chronopotentiogram for KF-NaF-LiF-ZrF_4. C_{Zr} = 3.83 × 10^{-5} moles/cc; T = 500°C; C.D. = 100 ma/cm^2.

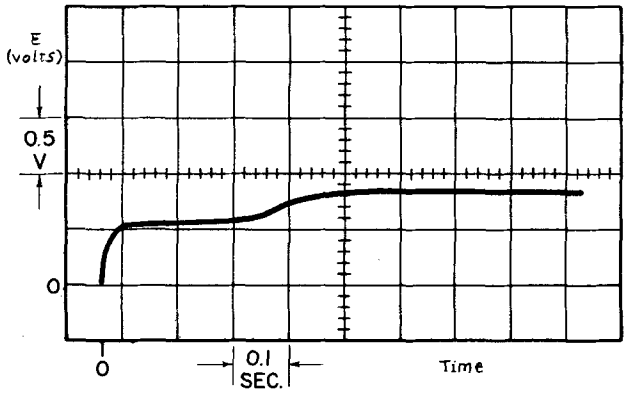

Fig. 11. Chronopotentiogram for KF-NaF-LiF-ZrF_4. C_{Zr} = 3.83 × 10^{-5} moles/cc; T = 650°C; C.D. = 200 ma/cm^2.

all current densities, whereas on returning to 750°C the ill-defined plateau was obtained.

At lower temperatures and higher zirconium melt concentrations the tendency for the corrosion of zirconium by KF to produce potassium is suppressed to the extent that the two processes, the deposition of zirconium and the deposition of alkali metal, are sufficiently resolved to permit observation of the former.

The plot of $i\tau^{1/2}$ *vs.* C for the system is still nonlinear and does not pass through the origin even at low temperature where a well-defined plateau is obtained.

In a reversible system $E = E_o + \frac{RT}{nF} \log \frac{\tau^{1/2} - t^{1/2}}{t^{1/2}}$

one may plot E *vs.* log t and derive n from the slope of this graph. This was done for 500° and 650°C and values of n equal to 2.99 at 500°C and varying between 2.6 and about 10 were obtained at 650°C. At 750°C it proved impossible to draw any plot of a satisfactory nature. This further confirms that the four-electron single step reduction of Zr is a highly irreversible process, but one can only speculate on why this should be so. Winand (32) reports on the basis of a study of electrode mechanisms in the electrolysis of NaCl-ZrF_4 mixtures that the reduction of zirconium occurs in a single, irreversible four-electron step in agreement with our findings in the present study in pure fluoride systems, but contrary to the polarographic results of Manning and Mamantov (31) who believed it to be reversible. In the systems so far examined, *viz.*, Nb, Ta, and Zr, the metal deposition step was always found to be more or less irreversible.

Conclusions

Several conclusions may be drawn from the results presented in previous sections:

1. By appropriate procedures zirconium powders and dendrites may be extracted from any of the baths investigated;

2. Electrolysis of fluoride melts, within certain temperature limits and over a specified range of current densities, results in the deposition of coherent plates of zirconium;

3. Electrolysis of fluoride melts containing both ZrF_4 and KBF_4 leads to the deposition of coherent plates of ZrB_2;

4. By the addition of Al_2O_3 to fluoride melts and subsequent electrolysis, plates of Zr-Al alloy may be obtained;

5. By the addition of K_2TiF_6 to a working zirconium bath, Ti-Zr alloy plates may be deposited;

6. The valency of the zirconium species involved is four and it is reduced to metal in a single four-electron step at —1.4v to the nickel-nickel fluoride reference electrode. This reduction is apparently irreversible.

Manuscript received Aug. 2, 1965; revised manuscript received Sept. 27, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Electrodeposition of Coherent Deposits of Refractory Metals

IV. The Electrode Reactions in the Deposition of Niobium

S. Senderoff and G. W. Mellors

Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

ABSTRACT

The mechanism for the electrodeposition of coherent deposits of niobium from a molten fluoride electrolyte has been studied by means of chronopotentiometry and compared with that of tantalum. The reduction of the pentavalent niobium in solution occurs in three steps: a reversible one-electron step to the tetravalent state at —0.11v (referred to the Ni/Ni^{2+} electrode), a reversible three-electron step to the monovalent state at —0.76v, and finally an irreversible one-electron reduction to metal at —1.02v. However, the reaction $3Nb^{V} + Nb^{I} \rightarrow 4Nb^{IV}$ interferes with coherent metal deposition from the pentavalent solutions, and consequently in order that coherent metal be produced at high efficiency the mean valence of the bath must be reduced to approximately four. In these circumstances the chronopotentiogram of a working bath shows two steps only: a three-electron reduction, $Nb^{4+} + 3e^{-} \rightarrow Nb^{1+}$ at —0.76v followed by the metal producing step $Nb^{1+} + e^{-} \rightarrow Nb^{0}$ at —1.02v. The diffusion coefficient of $[NbF_7]^{-2}$ has been found to be 2.03×10^{-5} cm^2 sec^{-1} at 750°C and its activation energy for diffusion to be 8.75 kcal/mole. The diffusion coefficient of the tetravalent species is 5×10^{-5} cm^2 sec^{-1} at 750°C.

This is one of a series of papers dealing with a general process for electrodeposition of coherent deposits of the metals of groups IV-B, V-B and VI-B from molten fluorides (1). In the first paper of this series (2) the process variables for the electrodeposition of niobium were discussed together with the properties of the resultant deposits. The second paper discussed the electrode reactions in the deposition of tantalum (3) as determined by means of chronopotentiometry. The third paper (4) discussed the deposition of zir-

conium, its alloys and compounds, and in this paper a study of the electrode reactions in niobium deposition is described.

Experimental

The procedure used for this investigation was essentially that used for the study of tantalum deposition (3). The solvent electrolyte was the eutectic mixture of LiF-NaF-KF (46.5-11.5-42 mole %, mp 454°C) which was purified by melting with NH_4HF_2, sparging the melt with hydrogen, and electrolyzing between graphite electrodes as described previously (3). The purified electrolyte when subjected to chronopotentiometry at 0.100 amp/cm^2 yielded values of $i\tau^{1/2}$ below

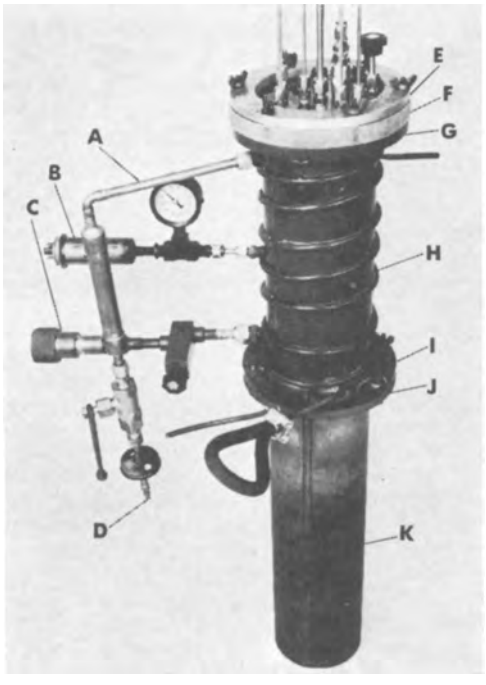

Fig. 1. Chronopotentiometric cell: A, gas exit line; B, vacuum gauge; C, vacuum or gas inlet line; D, gas exit bubbler tip; E, steel flange; F, plexiglas cover disk; G, steel flange; H, water-cooled stainless steel can; I, steel flange; J, steel flange; K, Hastelloy X can.

5 x 10^{-3} amp cm^{-2} sec$^{1/2}$ at —1.5v referred to the Ni/Ni^{2+} reference electrode. Niobium was added to this purified solvent as dried K_2NbF_7 obtained from Kawecki Chemical Company. NiF_2 for the reference electrode was prepared from $NiCl_2$ as previously and was added to the purified ternary alkali fluoride eutectic to a concentration of 1 mole % NiF_2. Furnace, circuitry, and porous Al_2O_3 salt bridges were the same as used in the earlier study as was the cell and its internal components shown in Fig. 1 and 2. It was necessary in this study to use a platinum crucible for the electrolyte (I, Fig. 2) rather than nickel or molybdenum as was done with the tantalum work, because the latter were slightly attacked by the pentavalent niobium solutions. No attack on the platinum was observed in pure solutions, and no platinum was detected chronopotentiometrically in the solutions. To prevent alloying with the platinum crucible by the nickel cradle which held it, the crucible was placed in a short alumina cup, which was placed in the nickel cradle. The sampling and addition cups (D and E, Fig. 2) were plated with silver to prevent attack on them by the pentavalent niobium solution.

The electrodes used most frequently as indicator electrodes were 0.005 in. platinum sheet disks, 0.9 cm^2 in area welded to 0.015 in. platinum wire. Counter electrodes in all cases were platinum strips. Niobium electrodes could not be used since they were attacked by the pentavalent niobium solutions. When it was desired to study a reduced solution it was reduced *in situ* by electrolyzing with a platinum cathode and niobium anode. Oxidation *in situ* was accomplished by using a spectrographic graphite anode. These "processing" electrodes were then replaced with the normal indicator and counter electrodes for measurements. The same reference electrode, Ni/NiF_2 (1 mole %), NaF-KF-LiF eutectic||, was used.

The general procedure for making the measurements was the same as used for tantalum (3). Chronopotentiograms at various current densities were recorded by use of a Polaroid camera on a Tektronix 535A oscilloscope on a solution of K_2CbF_7 in the alkali fluoride solvent at some concentration and temperature. The temperature was then changed, and another set of chronopotentiograms at various current densities were recorded. When the temperature range from 650° to 800°C was covered, a sample for analysis was taken, and a new solution was prepared at another concentration for a similar series. In a few cases the valence of the pentavalent niobium was reduced *in situ* by electrolysis at 15 ma/cm^2 with a niobium anode and platinum cathode, and a similar group of chronopotentiograms was run on the solution with the niobium in a mean valence state between 4 and 5. The total concentration and mean valence state were determined as previously (2).

Results

Chronopotentiograms were run at concentrations of K_2NbF_7 ranging from 0.025 to 0.08 millimole cm^{-3} at current densities between 0.05 and 0.4 amp/cm^2 and temperatures from 650° to 800°C. Figure 3 is a typical chronopotentiogram at 650°C showing two plateaus with $E_{1/4}$ values at —0.77 and —1.05v. The third near —1.5v is due to aluminum contamination from the Al_2O_3 salt bridge. When a porous BN salt bridge is used this disappears, but the BN salt bridge is inconvenient to use because of its structural weakness. Figure 4 is a chronopotentiogram on the solvent mixture (KF-LiF-NaF eutectic) alone showing essentially no reducible material present until the cathode reaches a potential of approximately —1.8v, at which potential the alkali metal of the solvent is reduced. Tables I and II summarize the data obtained at 750°C. The average $E_{1/4}$ values for the first and second plateaus are —0.756 ±0.015v and —1.02 ± 0.03v, respectively, and the transition time constant for the first plateau is 1.52 ± 0.03 amp sec$^{1/2}$ cm mole^{-1}. The ratio of the transition times

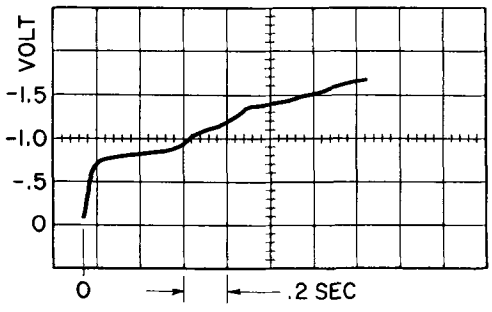

Fig. 3. Cathodic chronopotentiogram for K_2NbF_7 dissolved in KF-LiF-NaF eutectic mixture: concentration, 5×10^{-5} moles/cm^3; current density, 0.1 amp/cm^2; temperature, 650°C.

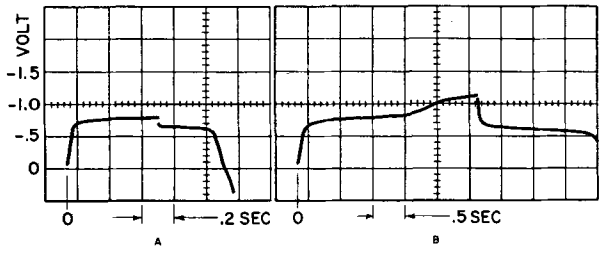

Fig. 5. Cathodic-anodic chronopotentiograms of K_2NbF_7 dissolved in Na-F-KF-LiF: cathodic portion on left, anodic on right. Concentration, (a) 5.6×10^{-5} moles/cm^3, (b) 5×10^{-5} moles/cm^3; current density, (a) 0.1 amp/cm^2, (b) 0.05 amp/cm^2; temperature, (a) 750°C, (b) 650°C.

for the two plateaus is 0.55 ± 0.11. The over-all average values are the averages of the results of five runs for each of the five concentrations. Each is thus the average of 25 chronopotentiometric runs. In Fig. 5 are shown two cathodic-anodic chronopotentiograms. In Fig. 5A the current was reversed before the first plateau was completed, and in Fig. 5B it was reversed before the second plateau was completed. Both give a single oxidation step corresponding to the lower (—0.76v) plateau.

Discussion

The values obtained for $E_{1/4}$ are each approximately 0.25v noble to those found for tantalum (3). This is consistent with the fact that in a plating solution containing equal concentrations of niobium and tantalum a plate is obtained at 35 ma/cm^2 which contains 99.8% niobium. The transition time constant, $i\tau^{1/2}/C$, for the first plateau is 50% greater than that for tantalum and the value of $i\tau^{1/2}/C$ for the second plateau is not constant but varies with concentration, indicating some degree of irreversibility of the final reduction step as in the case of tantalum. Let us now consider the details of each step as disclosed by the data.

Interpretation of the first plateau.—In all the data presented in Tables I and II the solutions contained niobium in its pentavalent state. The first wave, therefore, must represent the reduction of an ion containing pentavalent niobium to some lower valence state with the transfer of less than five electrons.

However, the first wave of the chronopotentiogram in Fig. 3 actually contains two reduction steps which were resolved as follows: by raising the temperature to 750°C and running a chronopotentiogram at the same current density as in Fig. 3, *i.e.*, 100 ma/cm^2, one obtains the chronopotentiogram shown in Fig. 6a. A very small plateau is seen here at about —0.1v. To resolve this more clearly, the current density was reduced to 30 ma/cm^2, and the chronopotentiogram in Fig. 6b was run. It can be seen from this that the $E_{1/4}$ value for this plateau is —0.11v. On electrolytically reducing the solution to a mean valence of 4.2 and running the chronopotentiogram, Fig. 6c is obtained. The —0.11v plateau has now disappeared and only that at 0.76v is seen. Reoxidizing the bath causes the —0.11v plateau to reappear as seen in Fig. 6d. It is clear from this that the —0.11v plateau corresponds to the reduction of the pentavalent ion and is the first step in the reduction to metal. For convenience, however, since the transition time, τ_1, of the first step is only about 2% that of the second step, τ_2, (the one at —0.76v) they will be treated together so that $\tau_s = \tau_1 + \tau_2$ in the following discussion.

If one can establish that this combined step is a reversible diffusion-controlled process one may obtain n_2, the electron number of the second step from

$$E = E_o' + \frac{RT}{n_2 F} \ln \frac{\tau_s^{1/2} - t^{1/2}}{t^{1/2}} \qquad [1]$$

(since $\tau_1 << \tau_2$) (5) by plotting the potential, E, at time, t, in a chronopotentiogram such as Fig. 3 against log $\tau_s^{1/2} - t^{1/2}/t^{1/2}$ where τ_s is the transition time, or time corresponding to the length of the plateau in the chronopotentiogram. A straight line of slope 2.3 $RT/n_2\mathbf{F}$ results (5). One criterion for a diffusion-controlled reaction without kinetic complications is that the equation,

$$i\tau^{1/2} = \tfrac{1}{2}\, nCD^{1/2}\mathbf{F}\pi^{1/2} \qquad [2]$$

where i is the current density, τ the transition time, n the number of electrons in reaction, C the concentration of the reacting species, D the diffusion coefficient of the reacting species, and $\mathbf{F}$ the Faraday constant, describes the chronopotentiogram (6). Thus the constant, $i\tau^{1/2}/C$ should be independent of current density and concentration and $i\tau^{1/2}$ plotted against C be linear and extrapolate to zero at zero concentration. In Table I it can be seen that $i\tau_s^{1/2}/C$ is independent of concentration and the data from which this table was prepared confirm its independence of current density. In Fig. 7 it is seen that the plot of $i\tau_s^{1/2}$ *vs.* C is linear and passes through the origin. In Fig. 5A one notes the very small difference in potential between the cathodic and anodic waves, and it can be shown that this difference is accounted for by twice the IR drop in the solution, so that no appreciable polarization is detectable. Thus, having demonstrated the reversibility of the first (combined) wave one may derive n_2 for the second step from the plot of E *vs.* the log term in Eq. [1]. A typical plot is shown in Fig. 8. Twelve such plots were made using data from runs over the full range of current density and concentration, the slopes of each determined, and n_2 for each calculated. The average value thus obtained was 3.05 ± 0.45. This indicates that the plateau at —0.76v corresponds to a three-electron reduction. Another method of determining n in a stepwise reduction is by examining the ratio of transition times of the two steps (5). Taking the first combined wave as one step with a transition time, τ_s, and the final wave (plateau at —1.02v) with a transition time, τ_3, then the n values for each step may be calculated from

$$\frac{\tau_3}{\tau_s} = \left(\frac{n_3}{n_s}\right)^2 + 2\left(\frac{n_3}{n_s}\right) \qquad [3]$$

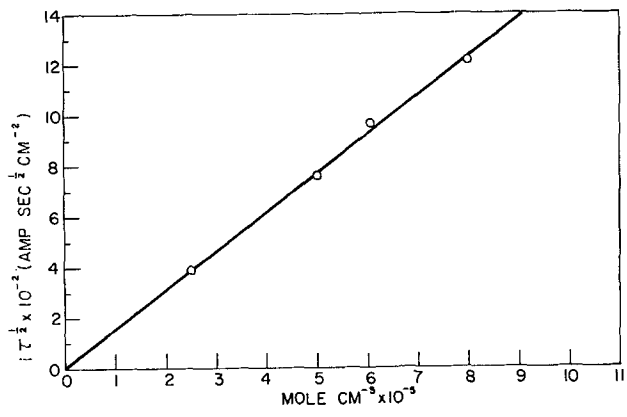

Fig. 7. Transition time, current, concentration relationship from cathodic chronopotentiograms of K_2NbF_7 in NaF-KF-LiF at 750°C.

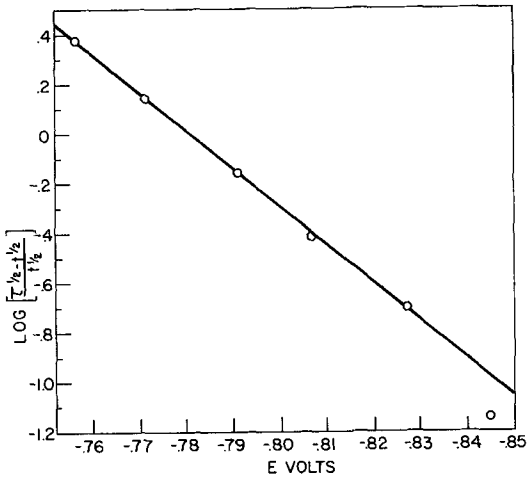

Fig. 8. Potential-time relationship during a chronopotentiometric run of K_2NbF_7 in NaF-KF-LiF: Concentration, 6 × 10^{-5} moles/cm^3; current density, 0.2 amp/cm^2; temperature, 750°C.

where n_3 is the electron number of the final step and $n_s = n_1 + n_2$, the total electron number of the first combined wave. Since in this case the sum of $n_s + n_3 = 5$, both may be calculated. On the basis of Eq. [3], $\tau_3/\tau_s = 1.8$ for $n_3 = 2$ and $n_s = 3$, and $\tau_3/\tau_s = 0.56$ for $n_3 = 1$ and $n_s = 4$. The value shown in Table II for the experimental $\tau_3/\tau_s = 0.55 \pm 0.11$ would indicate that $n_s = 4$ and $n_3 = 1$. Since n_2 has already been shown to be 3 by the method shown in Fig. 8, n_1, the unresolved first step, must be unity. It appears from these calculations, therefore, that the two steps of the first wave correspond to the reduction of pentavalent to tetravalent niobium at —0.11v and of tetravalent to monovalent niobium at —0.76v.

From chronopotentiograms run on solutions which had been reduced electrolytically to give a niobium of mean valence 4.2, the normal operating valence state of the plating bath, no evidence was found for any plateau below that at —0.76v; neither at 100 ma/cm^2 nor at 30 ma/cm^2 at any temperature. A plot of E *vs.* log $\tau^{1/2} - t^{1/2}/t^{1/2}$ on the —0.76v plateau for three such chronopotentiograms gave a value of $n = 3.04 \pm 0.49$ for this reduction step (in these reduced solutions the first reduction step) thus confirming the results obtained from the pentavalent solutions. It appears that the irreversibility of the final step at —1.02v discussed below does not affect the calculation based on transition time ratios because the proper coulombic relationship between the two steps is maintained, whatever the mechanism of the final step.

Figure 5A shows the cathodic-anodic chronopotentiogram at the —0.76v plateau. It is clear that the

monovalent product is quite soluble in the melt, the average value of τ_{ox}/τ_{red} being 0.54 for 12 such chronopotentiograms compared to the theoretical value of 0.33 for a completely soluble reduction product and 1.0 for an insoluble product. This compares with the reduction intermediate in the case of tantalum which was found to be only very slightly soluble. Further the solubility of this product in the case of Nb varies with the valence of the electrolyte. In Fig. 9a is shown the cathodic-anodic chronopotentiogram for a solution at mean valence 5.0 at a current density of 30 ma/cm². In this case no reverse wave at —0.77v is seen at all, the entire oxidation occurring at —0.1 at which the Nb^{5+} to Nb^{4+} reduction occurred. On raising the current density in the same solution to 100 ma/cm² we see in Fig. 9b an oxidation wave at —0.7v followed by one at —0.1v. However, if the valence of the electrolyte is reduced to 4.2, one can obtain an oxidation wave at —0.7v even at 30 ma/cm² as seen in Fig. 9c. Apparently the rate of attack of the pentavalent solution on the monovalent intermediate according to the reaction $Nb^{1+} + 3\,Nb^{5+} \rightarrow 4\,Nb^{4+}$ is so rapid that at 30 ma/cm² the quantity of Nb^{1+} remaining at the electrode for the oxidation step is negligible, while at 100 ma/cm² enough remains to be detected in the oxidation step. However, when the bath is reduced to a mean valence of niobium of 4.2 the monovalent intermediate is essentially unattacked so that the amount recovered at 30 ma/cm² roughly corresponds to that of an ordinary soluble reduction product. The long oxidation step seen in Fig. 9c at —0.1v corresponds to the oxidation of the Nb^{4+} in the tetravalent Nb solution.

From this it is apparent that the need to operate a niobium plating solution in the tetravalent state arises from the reactivity of the intermediate reduction product with pentavalent niobium. This reaction is so rapid in a pentavalent solution that at low current density the current efficiency for metal deposition becomes negligible, while at high enough current density to overcome this attack only dendritic deposits are obtained, as reported by Cumings and Cattoir (7). It will be remembered that in the case of tantalum the intermediate reduction product was only very slightly soluble in the pentavalent solution and that no soluble intermediate valence state was observed.

The nature of the initial process.—The plateau at —0.11v shown in Fig. 6 is a one-electron reduction of an ion containing pentavalent niobium. On the basis of infrared spectroscopy studies J. S. Fordyce of this laboratory has demonstrated that the predominant species present in the pentavalent electrolyte is $[NbF_7]^{-2}$. This will be reported in a separate publication. The predominant ionic species present in the tetravalent solution has not yet been identified, but since it is soluble and stable it is reasonable to presume that it is also a complex fluoniobate. This first step may, therefore, be written

$$[NbF_7]^{-2}\,(l) + 1e \rightarrow [NbF_{(7-x)}]^{(3-x)-}\,(l) + xF\,(l)^-$$

where x = 0, 1, or 2. An apparent anomaly exists in the magnitude of τ_2/τ_1 in that it seems too large. The theoretical value of τ_2/τ_1 for successive reactions with electron numbers of one followed by three is 15. If one measures the value of τ_1 in Fig. 6b at 30 ma/cm² and converts it to an equivalent value for 100 ma/cm² by the equation $\tau = k/i^2$ (where k is a constant), and then calculates τ_2/τ_1 using the measured value of τ_2 in Fig. 6a, one obtains a value of 45. The value obtained by measuring directly the very small τ_1 in Fig. 6a is 40, confirming this high value for τ_2/τ_1. This probably results from τ_2 being enlarged with respect to τ_1 by a catalytic wave resulting from the reaction discussed above, $Nb^{1+} + 3Nb^{5+} \rightarrow 4Nb^{4+}$, in which additional Nb^{4+} is supplied to the electrode, above the amount obtained from the first step.

Transport properties.—Since the combined step terminating with the plateau at —0.76v has been shown to be reversible and diffusion controlled, one may calculate the diffusion coefficient of the $[NbF_7]^{-2}$ ion from the slope of Fig. 7 by means of Eq. [2] and the value of the total number of electrons involved, $(n_1 + n_2) = n_s = 4$. At 750°C the diffusion coefficient thus obtained is 2.03 x 10^{-5} cm² sec^{-1} compared to that of $[TaF_7]^{-2}$ of 1.5 x 10^{-5} cm² sec^{-1}. The increase over tantalum would be expected in view of the smaller niobium ion. The activation energy for diffusion between 650° and 800°C obtained from Fig. 10 is 8.75 kcal/mole compared to 8.5 kcal/mole for tantalum. If one uses Eq. [2] to calculate the diffusion coefficient of the same ion by using the value of $i\tau_1^{1/2}/C$ for the first step alone in Fig. 6b and a value of $n = 1$, one obtains a diffusion coefficient at 750°C of 1.72 x 10^{-5} cm² sec^{-1}. This can be considered good agreement since the latter is based on five runs at a single low current density with a very small value of $i\tau^{1/2}$ while the former is derived from the wide variety of data shown in Table I. If, however, one calculates the diffusion coefficient from the first plateau obtained from a solution of valence 4.2 in which $Nb^{4+} + 3e^- \rightarrow Nb^{1+}$ is the first step, one obtains, using $n = 3$ ($Nb^{4+} \rightarrow Nb^{1+}$), a diffusion coefficient at 750°C for the tetravalent ion of 5.02 x 10^{-5} cm² sec^{-1}. This is in accordance with the observations discussed previously (3) regarding the increase in diffusion coefficient with decreasing valence, and from this it would appear that the tetravalent complex is probably lower in coordination number than the heptacoordinate pentavalent niobium complex. A spectroscopic study of the tetravalent niobium solutions would be required to establish this.

The nature of the final step.—The final step represented by the plateau at —1.02v does not satisfy the chronopotentiometric criteria for reversibility or diffusion control. The value $i\tau^{1/2}/C$ decreases with increasing concentration, as in tantalum, and this may

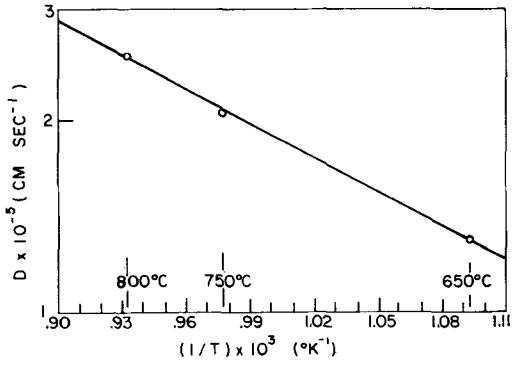

Fig. 10. Activation energy for diffusion of fluoniobate ion in KF-NaF-LiF.

result from incomplete solubility of the monovalent intermediate. This intermediate is much more soluble than in the case of tantalum as shown by the τ_{ox}/τ_{red} values (0.55 for Nb and 0.9 for Ta at similar current densities), however some film formation is still indicated since the value of 0.33 for τ_{ox}/τ_{red} is in all cases exceeded. The behavior of the final step may, therefore, also, as in the case of tantalum, be related to a film on the cathode as the product of the intermediate reduction step. The fact that niobium metal is not attacked when in contact with Nb^{4+} solution may be the result of the protective behavior of this film analogous to the suggested explanation for the inertness of tantalum in contact with Ta^{5+} solution (3). That there is a lack of reversibility is shown also in Fig. 5B in which the oxidation of the metal is seen to proceed directly to the tetravalent state (*ca.* —0.7v) with no indication of a plateau at the monovalent state (*ca.* —1.02v) as is observed in the reduction. Further study of the final step involving the reduction to metal is required.

Summary

The electrodeposition of niobium from a solution of K_2NbF_7 in the KF-LiF-NaF eutectic involves three steps, the first two of which are reversible and diffusion controlled. They are:

1. $[NbF_7]^{-2}$ (l) + $1e^-$ → $[NbF_{(7-x)}]^{(3-x)-}$ (l) + xF^- (l)
2. $[NbF_{(7-x)}]^{(3-x)-}$ (l) + $3e^-$ → NbF (s or l) + $(6-x)F^-$ (l)
3. NbF (s or l) + $1e^-$ → Nb^0 (s) + F^- (l)

Because of the rapid reaction between $[NbF_7]^{-2}$ and NbF to regenerate the tetravalent niobium ion, the current efficiency for niobium deposition falls to zero at low current density in the presence of appreciable $[NbF_7]^{-2}$, and at high current density only dendritic deposits can be obtained. If one operates from a solution with a niobium mean valence of 4.0-4.2 at low to moderate current densities, only steps 2 and 3 are operative and coherent deposits are produced. The product of step 2, NbF, is more soluble in the electrolyte than is the intermediate in the case of tantalum, but indications of some insolubility are noted and this may be responsible for the irreversible behavior of the final step. It may be significant that the final step of reduction to metal in both the tantalum and niobium plating systems and the single reduction step in the zirconium plating system are all irreversible. Work is in progress to determine whether irreversibility of the metal production step is a necessary condition for coherent metal deposition from molten salts.

The diffusion coefficient of the $[NbF_7]^{-2}$ ion has been found to be 2.03 x 10^{-5} cm^2 sec^{-1} at 750°C and its activation energy for diffusion as 8.75 kcal/mole. The diffusion coefficient of the tetravalent niobium-containing ion is approximately 5 x 10^{-5} cm^2 sec^{-1}.

The major difference between tantalum and niobium plating mechanisms arises from the interactions of the monovalent intermediate with the pentavalent species to form a stable tetravalent species in the case of niobium and the absence of such interaction in the case of tantalum. It is for this reason that a pentavalent solution may be used for plating tantalum and a tetravalent one is required for coherent deposition of niobium.

The Lead Oxide-Lead Sulfate System

J. D. Esdaile[1]

South Australian Institute of Technology, North Terrace, Adelaide, South Australia, Australia

ABSTRACT

The author's work confirms Lander's conclusion that monobasic, dibasic, and tetrabasic lead sulfates are the only stable lead sulfates in the lead oxide-lead sulfate system above 210°C. The author proposes a new room temperature x-ray pattern for dibasic lead sulfate. The decomposition temperature of dibasic lead sulfate in air is shown to be 631° ± 8°C by high-temperature x-ray analysis. The thermal inflection in the lead oxide-lead sulfate system at 450°C, first reported by Schenck and Rassbach, was found to be caused by a structural change in metastable dibasic lead sulfate.

This work was originally undertaken in order to insure positive identification of the basic lead sulfates present in the products resulting from high-temperature equilibrium studies (1). Serious disagreement was found between the x-ray patterns obtained by Lander (2) and the author (1) for dibasic lead sulfate.

The cause of the thermal inflection in the lead oxide-lead sulfate system at 450°C is obscure. Lander considered it to result from the decomposition of dibasic lead sulfate into a mixture of monobasic and tetrabasic lead sulfates. This conclusion is in conflict with the decomposition temperature of dibasic lead sulfate found by both Kellogg and Basu (3) (616°C) and the author (1) (634°C) during equilibrium measurements on the lead-oxygen-sulfur system. Kellogg and Basu attributed the discrepancy between their results and Lander's to supercooling, apparently unaware that Schenck (4) found the thermal inflection at 450°C to occur with both rising and falling temperature.

[1] Present address: C.S.I.R.O., Melbourne, Victoria, Australia.

The range of compositions over which the thermal inflections were found by Schenck and Rassbach (5), and Jaeger and Germs (6), differ widely. Schenck and Rassbach reported that these occurred between 51 and 89 mole % of lead monoxide while Jaeger and Germs detected thermal inflections between 50 and 75 mole % of lead monoxide and claimed that these were due to the decomposition of dibasic lead sulfate into a mixture of monobasic and tribasic lead sulfates. They also criticized the thermal analysis of Schenck and Rassbach, claiming that the latter had failed to homogenize their melts prior to thermal analysis. If this were so, it is possible that the thermal inflection at 450°C (observed by Schenck and Rassbach at 80.5, 84.8, and 89 mole % of lead monoxide) actually occurred in the segregated, sulfate-rich portions of these samples.

In view of these discrepancies, it was decided to investigate the thermal inflection at 450°C and to attempt to determine the decomposition temperature of dibasic lead sulfate, by means of high-temperature x-ray and thermal analysis.

Experimental Procedure

A Philips PW1009 generator operating on a copper target at 30 kv and 10 ma was used as the radiation source for the x-ray apparatus. A goniometer manufactured by Crystal Structures Ltd. was modified to give a focusing circle of 10 in. radius.

The body of the furnace used for the high-temperature x-ray analysis was formed from alumina powder. The alumina was moulded, when wet, around a wooden former on which nichrome resistance wire was wound. After drying, removal, and baking, the furnace proved to be satisfactory. A silver specimen holder was used, and this was supported by an Inconel alloy tube. Caps were placed on both the Inconel tube and the furnace, in order to reduce temperature gradients caused by convection currents. The temperature of the sample was controlled to ±3°C by an Ether transitrol anticipatory controller, using a 1 mm sheathed coaxial chromel alumel thermocouple for the hot junction. The specimen temperature was measured by using a similar, calibrated, thermocouple imbedded in the sample holder.

The basic lead sulphates were prepared from dry A.R. yellow lead monoxide and Merk's normal lead sulfate. These were mixed in the proportions corresponding to the formulas: $PbO \cdot PbSO_4$, $(PbO)_2 \cdot PbSO_4$, $(PbO)_3 \cdot PbSO_4$, and $(PbO)_4 \cdot PbSO_4$, heated in platinum crucibles for half an hour at temperatures 30°C above the liquidus temperatures determined by Lander, quenched, finely ground, reheated at 800°C, and finally quenched and ground before room temperature x-ray analyses and other treatments.

During the determination of the high-temperature patterns of the basic lead sulfates, sufficient time was allowed for equilibrium conditions to be reached. This was tested by repeating the x-ray analyses at regular time intervals until no changes in the patterns could be detected.

X-ray patterns of the fusions having the compositions corresponding to the formulas: $PbO \cdot PbSO_4$, $(PbO)_3 \cdot PbSO_4$, and $(PbO)_4 \cdot PbSO_4$, were made at temperatures ranging from ambient to 800°C.

The determination of the decomposition temperature of dibasic lead sulfate was attempted by using dibasic lead sulfate, and a mixture of monobasic and tetrabasic lead sulfates having the over-all composition of dibasic lead sulfate. Patterns of the dibasic lead sulfate fusion were taken at 36 hr intervals at 400°, 530°, and 690°C. Further analyses were made at 24-hr intervals in decreasing steps of 12°C. Patterns of the mixture of monobasic and tetrabasic lead sulfates were taken at 24 hr intervals at 425°, 530°, 610°, and 670°C.

For the thermal analysis of the lead oxide-lead sulfate system, suitably slow rates of cooling and heating, in addition to achieving a desired temperature, were obtained by adjusting the voltage input to a nichrome resistance wiring on a 3 in. diameter silica tube surrounding the sample mass. A series of samples of different lead monoxide content were prepared (Table I), each having a weight of at least 180g. These were prepared in cylindrical Triangle R.R. recrystallized alumina crucibles (1¼ in. ID) at temperatures 20°C above the liquidus values determined by Lander, and were stirred with an alumina rod until a homogeneous liquid was achieved. The alumina crucibles were used because no platinum crucible of sufficient size was available.

* Q, D, M, and N indicate tetrabasic, dibasic, monobasic, and normal lead sulfates, respectively.
† R indicates rising temperature, and F indicates falling temperature. Average thermocouple output in millivolts = 3.918 ± 0.023; accuracy of thermocouple calibration = ±1°C; temperature of the change in the samples = 449.6° ± 2.2°C.

Time-temperature curves were obtained using a Honeywell temperature recorder, and additional data for plotting the curves were gained by using a calibrated 13% rhodium-platinum, platinum thermocouple connected to a Tinsley type 418D potentiometer via a cold junction immersed in melting ice.

The procedure entailed prolonged heating of the sample masses at 600° or 700°C immediately prior to thermal analysis. Room temperature x-ray analyses of the products from the thermal analyses were also made.

Discussion of Results

The x-ray patterns obtained by the author and Lander for the basic lead sulfates are shown in Table II, together with the A.S.T.M. pattern for monobasic lead sulfate.

To determine whether contamination of the thermally prepared basic lead sulfates has occurred, it is convenient to compare the relative intensities at the d values of the major lines in each pattern.

The patterns obtained by the author for the basic lead sulfates show no evidence of contamination. For example, it may be argued that the appearance of the line $d = 2.95$, $I = 0.63$, results from the contamination of dibasic lead sulfate by monobasic lead sulfate, for which $I = 1.00$ at $d = 2.95$. However, there is no such appearance of the second most intense line of the monobasic lead sulfate pattern ($d = 3.35$, $I = 0.49$) in the pattern for dibasic lead sulfate. The other apparent agreements at $d = 3.22$ and $d = 3.25$, for normal and tetrabasic lead sulfates, and dibasic and monobasic lead sulfates, respectively, are susceptable to the same argument.

The patterns of the lead sulfates thermally prepared by Lander provide evidence of contamination of the dibasic and tetrabasic lead sulfates, although there is no evidence of contamination of his monobasic salt. The coincidence of three of the four major lines in the pattern for dibasic lead sulfate with weaker lines in the pattern for tetrabasic lead sulfate indicates that Lander's thermally prepared sample of tetrabasic lead sulfate was contaminated by dibasic lead sulfate; this conclusion is supported by the absence of the line at $d = 2.96$ for the tetrabasic lead sulfate prepared by Lander (7) by his wet method. Slight contamination of the tetrabasic lead sulfate by lead monoxide is

† Average of five determinations.
* Intensity relative to the strongest line of the pattern.

indicated by the presence of a weak line at $d = 2.92$, $I = 0.13$ for tetrabasic lead sulfate, corresponding to the strongest line obtained by Lander for lead monoxide. This conclusion is supported by the absence of this line in the pattern obtained by Lander by his wet method. The close agreement of the d values of the strongest lines for monobasic and dibasic lead sulfates ($d = 2.92$, $I = 1.0$, and $d = 2.93$, $I = 1.0$, respectively) precludes the use of either of these values as a reliable guide as to whether contamination has occurred of the dibasic lead sulfate. The coincidence of the next two major lines in the pattern of monobasic lead sulfate ($d = 1.96$, $I = 0.50$, and $d = 1.51$, $I = 0.11$) with the pattern for dibasic lead sulfate ($d = 1.96$, $I = 0.40$, and $d = 1.51$, $I = 0.10$) suggests that Lander's sample of dibasic lead sulfate was contaminated with monobasic lead sulfate.

Unfortunately, Lander, in assessing the final pattern for dibasic lead sulfate, removed lines which were close to those of the major lines in the patterns which he obtained for monobasic and tetrabasic lead sulfates by his wet method. In particular, those at the d values 7.8, 5.8, 3.47, 3.22, and 2.92 were removed by Lander.

For the reasons discussed above, the x-ray pattern obtained by the author for dibasic lead sulfate is considered to be more reliable than that given by Lander. Reasonable agreement exists between the x-ray patterns obtained by the author, Lander, and the A.S.T.M. values, for monobasic and tetrabasic lead sulfates.

The results obtained from x-ray analyses of monobasic and tetrabasic lead sulfates from room temperature to 800°C showed no evidence of phase changes in either compound.

The results obtained from the x-ray analyses of the sample having the over-all composition represented by the formula $(PbO)_3 \cdot PbSO_4$ showed that no compound of this composition occurred at 400°C or higher temperatures. It was found that tribasic lead sulfate yielded a mixture of dibasic and tetrabasic lead sulfates at 800°C, and a mixture of monobasic and tetrabasic lead sulfates at 400°C; this was shown by prolonged heating at these temperatures, followed by quenching and room temperature x-ray analyses. High-temperature x-ray analyses of "tribasic lead sulfate" at 400° and 530°C provided confirmatory evidence. Over-all, this investigation confirmed Lander's conclusion that tribasic lead sulfate was not stable at high temperatures.

The high-temperature x-ray patterns of a mixture of monobasic and tetrabasic lead sulfates (having the over-all composition of dibasic lead sulfate) and dibasic lead sulfate were compared at 400° and 530°C with patterns of pure monobasic lead sulfate and pure tetrabasic lead sulfate at these temperatures. These results showed that dibasic lead sulfate had decomposed into a mixture of monobasic and tetrabasic lead sulfates at these temperatures. Although there is very close agreement between the 2θ values of the peaks given by the dibasic lead sulfate sample and the mixture of monobasic and tetrabasic lead sulfates, the relative intensities of a number of these common peaks differ markedly. These differences are thought to result from the manner of formation of the two specimens, *i.e.*, one as the result of fusion, the other by simple mixing. A comparison of the 2θ values obtained from the decomposition products of dibasic lead sulfate was made with those obtained from the mixture of monobasic and tetrabasic lead sulfates between room temperature and 625°C. Apart from intensity variations, of the type discussed above, the agreement between the two patterns is sufficient to conclude that dibasic lead sulfate decomposes into a mixture of monobasic and tetrabasic lead sulfates at, and below, 625°C.

A comparison was made between the patterns obtained from dibasic lead sulfate and a mixture of monobasic and tetrabasic lead sulfates, having the over-all composition of dibasic lead sulfate, through the temperature range 610° to 800°C. The similar x-ray patterns obtained between 637° and 800°C are quite different from those obtained at, and below, 625°C. Since it has been shown that dibasic lead sulfate decomposes into a mixture of monobasic and tetrabasic lead sulfates at, and below, 625°C, and the room temperature patterns for dibasic lead sulfate prepared by quenching from just below the melting point of dibasic lead sulfate and at 800°C showed no significant differences, it is concluded that the change in the x-ray patterns at, and above, 637°C, is due to the formation of dibasic lead sulfate. An assessment of the accuracy of the temperature measurements at the sample surface extends these limits to 623° and 639°C. It is therefore concluded that dibasic lead sulfate de-

Table III. Results of thermal and x-ray analyses

Sulfate material	Heat-treatment before thermal analysis	Presence of a thermal inflection	Phases shown by room temperature x-ray analysis
That previously yielding a thermal inflection	600°C for two days	no	Monobasic and tetrabasic lead sulfates
That having the overall composition of dibasic lead sulfate	700°C for two days	yes	Dibasic lead sulfate
As above	700°C for two days	yes	Not done
As above	600°C for two days	no	Monobasic and tetrabasic lead sulfates

composes into a mixture of monobasic and tetrabasic lead sulfates below 631°±8°C. This conclusion is supported by the temperature of 634°C found by the author for the decomposition of dibasic lead sulfate at a pressure of 1.5 mm Hg during the course of equilibrium measurements on the lead-oxygen-sulfur system (1). It may easily be shown that the effect of a pressure change of 758.5 mm Hg on the decomposition temperature of dibasic lead sulfate is slight (1), *i.e.*, less than 1°C.

The results obtained during the initial thermal analysis of the specimens prepared in alumina crucibles, *i.e.*, after these had been heated to 700°C for 36 hr (Table I), show that thermal inflections at 450°±3°C occur between 20 and 50 mole % normal lead sulfate. These were found to occur with both rising and falling temperature, as originally reported by Schenck (4). Because the high-temperature x-ray analyses showed no evidence of any compound other than dibasic lead sulfate in this composition region, and that dibasic lead sulfate decomposed into a mixture of monobasic and tetrabasic lead sulfates below 631°± 8°C, it was provisionally concluded that the thermal inflections at 450°±3°C were due to a change in metastable dibasic lead sulfate. Further evidence for this was provided by room temperature x-ray analysis of the products, *i.e.*, it was found that the specimens yielding thermal inflections also contained dibasic lead sulfate.

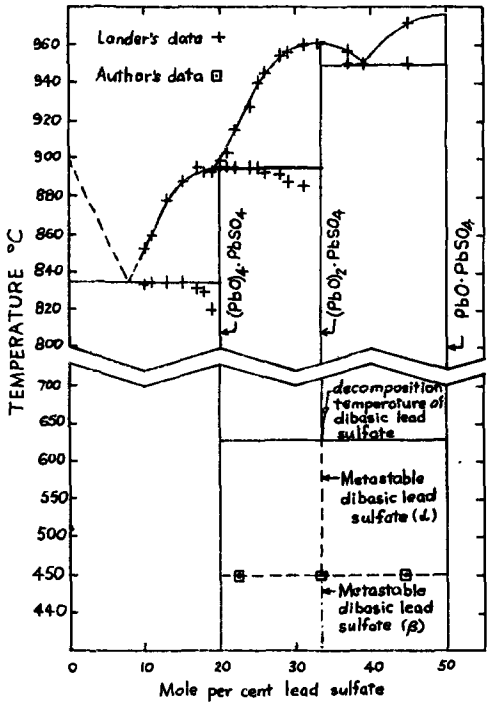

Fig. 1. PbO-$PbSO_4$ system: cross, Lander's data; square with a dot, author's data.

The results of a number of confirmatory tests on fused samples of dibasic lead sulfate are shown in Table III. These confirm that the thermal inflections are associated with the presence of dibasic lead sulfate and show that when specimens are heated for some time just below the decomposition temperature of dibasic lead sulfate (600°C for two days) no thermal inflections occur, and only monobasic and tetrabasic lead sulfates are present. To distinguish between the two types of dibasic lead sulfate, that which is metastable above 450°C is denoted by alpha, and that which is metastable below 450°C is denoted by beta, as shown by Fig. 1.

Although slight chemical attack on the alumina crucibles was noted during the preparation of the sulfate samples used for thermal analysis, this was not sufficient to cause any appreciable differences in the x-ray patterns obtained from these and all other samples which were prepared in platinum crucibles. This factor, and the fact that thermal inflections only occurred in the alumina prepared samples when dibasic lead sulfate was present, suggests that the fusion in alumina was justified for the preparation of the samples used for thermal analysis.

An attempt was made to determine whether the change in metastable dibasic lead sulfate was detectable by high-temperature x-ray analysis. This failed because the finely divided powder in the sample holder was found to decompose rapidly into a mixture of monobasic and tetrabasic lead sulfates at the temperatures involved. The coarsely crystalline form of dibasic lead sulfate thus seems to be necessary for preserving the metastable form of dibasic lead sulfate. It is thus possible that a single crystal could be used to determine whether any significant changes in metastable dibasic lead sulfate patterns occur above and below 450°C. This is, perhaps, a little doubtful, since the room temperature x-ray pattern for dibasic lead sulfate after thermal analysis, *i.e.*, after the change in dibasic lead sulfate has occurred, is very similar to that obtained by quenching from high temperatures. However, it is possible that the change at 450°C takes place very quickly and occurs even during quenching, or is completed at room temperature.

No thermal inflections could be detected at the decomposition temperature of dibasic lead sulfate. This finding is consistent with the prolonged times found necessary for the decomposition of dibasic lead sulfate during the high-temperature x-ray analyses around 631°C.

The liquidus of Lander's phase diagram, and the results of his thermal analyses, are unsatisfactory between 17 and 19 mole % of lead sulfate. The liquidus in this region of the phase diagram has been drawn in Fig. 1 so as to conform as closely as possible to Lander's data and the requirements of the phase rule.

Acknowledgment

To Dr. W. T. Denholm, formerly of the South Australian Institute of Technology, who was responsible for the design and construction of the furnace and enclosures used for the high-temperatue x-ray analysis the author expresses his thanks.

Some Effects of Small Displacements from Equilibrium on the Structure and Properties of Single Crystalline Copper Electrodes[1]

Leslie H. Jenkins

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Small displacements from equilibrium conditions were generated in systems of variously oriented copper single crystals exposed to acidic copper sulfate solutions by permitting a slow leak of air into the system and/or by application of an external emf. The effects of dissolution conditions on the orientation and shapes of structures formed on the surface was determined. An anomalous effect of a simultaneous corrosion reaction on electrolytic current-potential characteristics also was observed. Explanations for the phenomena in terms of kinetic processes occurring on the surface are offered.

Data obtained from copper single crystals exposed to a solution of copper sulfate under conditions both at and slightly removed from equilibrium have been used previously as supporting evidence for the argument that no crystal surface orientation is thermodynamically more favorable than another (1). Additional information concerning facet development and/or pit growth and movement of multi-atom high ledges over the surface can provide details of the effect of slow kinetic processes on changes in crystal surface habit. Generally it is agreed that areas immediately around points at which dislocations terminate in a surface are energetically more favorable reaction sites than a close-packed surface, and less favorable than kink-step sites. But once a reaction site has been nucleated and dissolution, for example, is proceeding by movement of atom steps over the crystal surface, it is not clear whether the gross changes in the structure of the crystal surface result primarily from thermodynamic factors, kinetic influences, or a combination of the two. The following is concerned with that problem.

Materials and Experimental Methods

All materials and their preparation and use were as previously reported (1), and all data included here were obtained from coin-shaped copper single crystals in the tripod-type cells described. Experimental results were reproduced numerous times in many different systems, and the observations which follow result from a study of more than forty different crystals. Likewise in the prior manner, all 0.2M $CuSO_4$ solutions, pH adjusted to ~1 with H_2SO_4, were, at the moment of introduction into the cells, under a hydrogen atmosphere and at equilibrium with copper metal.

When desired, air was permitted to leak into an assembly at a controlled rate by the same method previously used, a faulty platinum-through-glass seal at the side entry port of a tripod cell. The subsequent reaction of oxygen with copper(I) ions destroyed equilibrium in the cell

$$2Cu^+ + \tfrac{1}{2} O_2 + 2H^+ \leftrightharpoons 2Cu^{++} + H_2O \qquad [1]$$

Attempts to re-establish equilibrium in the assembly resulted in oxidation of the metal surface by copper(II) ions

$$Cu^{++} + Cu^0 \leftrightharpoons 2Cu^+ \qquad [2]$$

Overpotentials generated by the previous reactions occurring on crystal surfaces and/or those arising from dissolution due to application of an external emf were measured, and alterations in surface features resulting from such treatments subsequently observed. Orientations of facets developed as a result of reactions occurring on crystal surfaces were determined with a two-circle reflection goniometer. All potential differences were measured with a vibrating reed electrometer.

Experimental Results

Later it will become necessary to differentiate between removal of material from the surfaces by the over-all process described by Eq. [1] and [2] and dissolution resulting from the flow of current due to the application of an external emf. Unhappily, no unambiguous choice of terms is available, so arbitrarily in the following the former process will be referred to as corrosion and the latter as anodic or electrolytic dissolution.

Facet development.—Typical facets, which resulted from the corrosion process alone and which were produced at any corrosion rate up to ~50 $\mu a/cm^2$ (the greatest rate studied), were developed on different orientations as indicated in Fig. 1. The degree of structural development on all surfaces was dependent on the extent, but not the rate, of corrosion in the ranges studied. On the (001),[2] removal of material was restricted to a few, very large pits randomly distributed over the surface. As well as could be determined, corrosion did not occur on the surface area between pits. Calculations based on the average number and size of pits accounted for all material removed. Large, flat areas bounded by ledges of multi-atomic height were produced by the corrosion process on the (111). Presumably monatomic steps moved over the surface and eventually bunched together to form ledges separated by extensive flat areas. Step motion on the (011) apparently was not quite as easy as in the foregoing example, for immediately at the onset of corrosion small ridges, which quickly developed into facets, were observed on this surface.

In the case of the (001) and (111) decidedly different results were obtained when surfaces were subjected to anodic dissolution alone. Figure 2 illustrates that, even at a lower current density than for the corrosion reaction illustrated in Fig. 1, nucleation and reaction occurred over the entire (001) surface. Likewise no large, flat areas could be detected on the (111)

[1] Research sponsored by the U. S. Atomic Energy Commission under contract with Union Carbide Corporation.

[2] Standard crystallographic notations are used in that parenthesis, ( ), about indices indicate a single plane or set of parallel planes and curly brackets, { }, all the equivalent nonparallel planes of the indicated indices. Likewise, square brackets, [ ], indicate a single crystallograpnic direction and carets, < >, the complete set of equivalent directions.

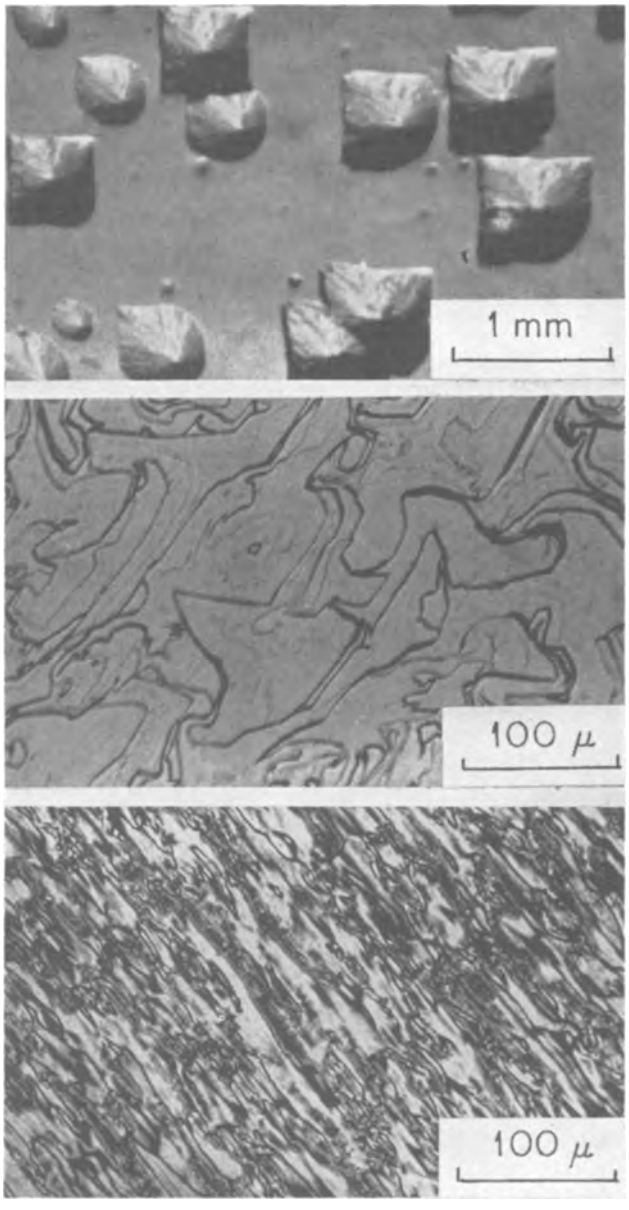

Fig. 1. Surface structures developed by cupric ion oxidation. Reading top to bottom, the surfaces shown are (001), (111), and (011). The latter two were photographed by interference contrast. In each system corrosion had occurred at approximately 50 $\mu a/cm^2$. The times permitted to react, although not equal, were not less than two nor more than four days.

following anodic dissolutions of about the same rate and duration as that illustrated for corrosion. Rather, the former surface was composed almost entirely of ledges of uniform average density and height. No such differences were observed for the (011) which developed approximately the same type of facets regardless of the mode of dissolution.

It was determined that, in a corroding system, small anodic currents could be superimposed on the corrosion current without effecting any changes in the typical structure developed by the corrosion process alone. The maximum anodic current which could be impressed on a given corrosion current without altering the development of surface topography typical of the latter process was not established. However, it was observed that an anodic current equal to the corrosion current did not result in any detectable change, but anodic currents about a factor of two larger than simultaneous corrosion currents did produce surfaces typical of the former process alone.

Orientation of facets.—Measurements with a two-circle reflecting goniometer showed that, regardless

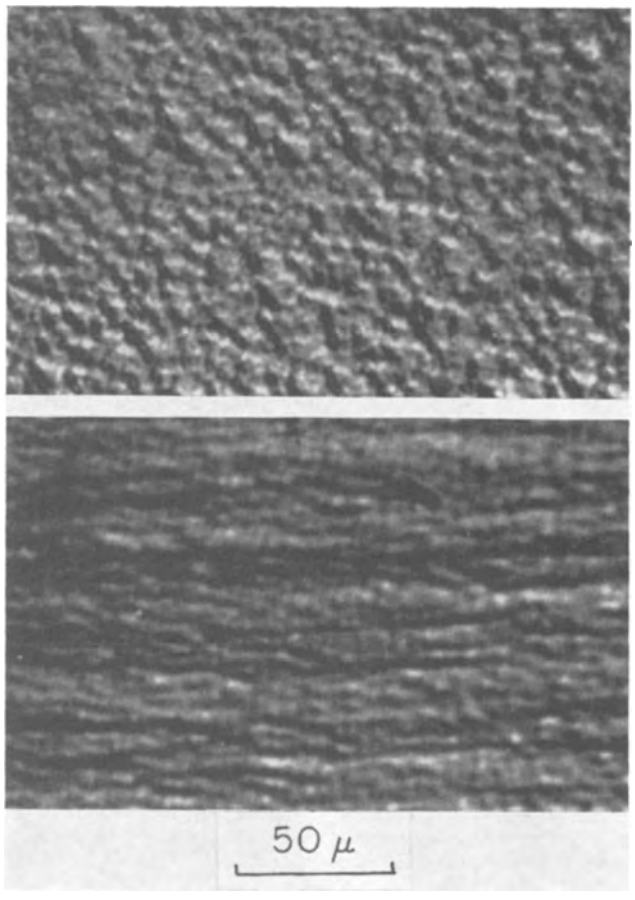

Fig. 2. Surface structures developed by anodic dissolution. The upper photograph is of an (001) surface and the lower a (111). Both are interference contrast photographs. The (001) resulted from dissolution at 3 $\mu a/cm^2$ for seven days. Note that less material has been removed, and at a slower rate, than for the corresponding surface shown in Fig. 1. Dissolution at 20 $\mu a/cm^2$ for four days produced the (111) surface illustrated above. Approximately the same amount of material has been removed at near the same rate as for the (111) surface of Fig. 1.

of means of dissolution, the orientations of facets developed on a certain surface were characteristic of that surface, but not of the process responsible for their development. Ultimately facets of like orientation developed from a surface of a certain orientation whether produced by corrosion or anodic dissolution or a mixture of the two processes. Also, the gross detail of surface structure was of no apparent importance in determining facet orientation. As an example, the small facets on the uniformly attacked (001) surface shown in Fig. 2 were oriented the same as facets developed on the bottoms of the pits on the (001) surface illustrated in Fig. 1.

It would be impossible to use data taken with a goniometer of the type employed to conclude that absolutely no orientations other than those recorded below were formed on the various crystals. But it is certain that the orientations reported account for approximately 90% of the total facet areas. Figure 3 indicates the geometry of pits formed on the (001). They were always relatively shallow with bottoms invariably approximately 4° from the (001) along the <001> zones. Sides of the pits were not quite normal to the surface under all conditions, but rather 4° from the {001} normal to the surface. Minor reflections from both sides and bottoms of pits indicated the presence of a very few facets of most orientations along the <001> zones. Under certain circumstances extensive faceting with near {012} orientations was observed, and occasionally a very few {111} and {011} orientations developed. But by far the preponderance of facets were those oriented 4° from the {001}.

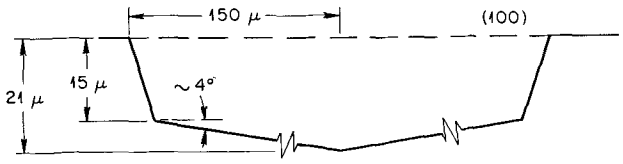

Fig. 3. Schematic profile of pits developed on the (001). Dimensions indicated are typical.

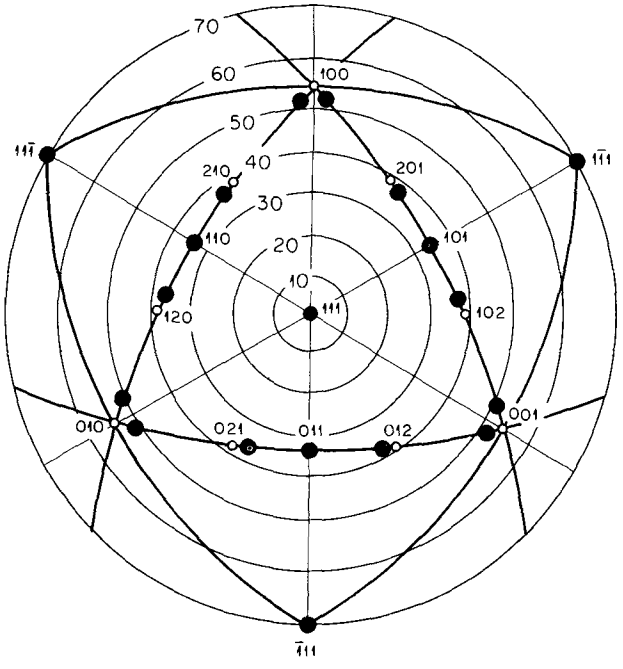

Fig. 4. Stereographic projection from (111) showing orientations of facets developed on that surface. Smaller, open circles indicate the orientations of major faces. No {001} facets were formed, but rather those "twins" ~4° away along the <001> zones.

As shown in Fig. 4 the orientations of facets developed on the (111) were not as restricted as those on the (001). Occasionally a few facets of the {111} 70° from the original surface could be detected, and as in the case of the (001), a very few facets of most orientations along the <001> zones were evident. Large areas of near {012} orientations always developed, and occasionally some few {011} were seen. Note particularly that in no case were {001} facets produced, but rather those orientations along the <001> zones about 4° from the {001} corresponding to the orientations of the bottoms and sides of pits developed on the (001).

With the occasional exception of a barely detectable amount of {111} facets, all orientations developed on (011) surfaces were along the <001> zones. Again no {001} surfaces were generated, only those about 4° removed along the <001> zones. Extensive production of near {012} and near {014} orientations were noticeable, and infrequently traces of {011} 60° from the original surface were perceptible.

Current-potential data.—Electrolytic current-potential relationships were affected in an unusual way by the existence of a simultaneous corrosion process on a crystal. Figure 5 shows typical galvanostatic data obtained from a crystal oriented (011) which was concurrently corroding at a very slow rate. While it is not absolutely certain in this case just what significance should be attached to the data, it is clear the electrode behavior is not that which reasonably could be anticipated. Although it was observed that anodic dissolution of similar value impressed on a corrosion process was also restricted to highly local areas, it is not obvious, for example, that deposition currents only slightly greater than the corrosion currents should

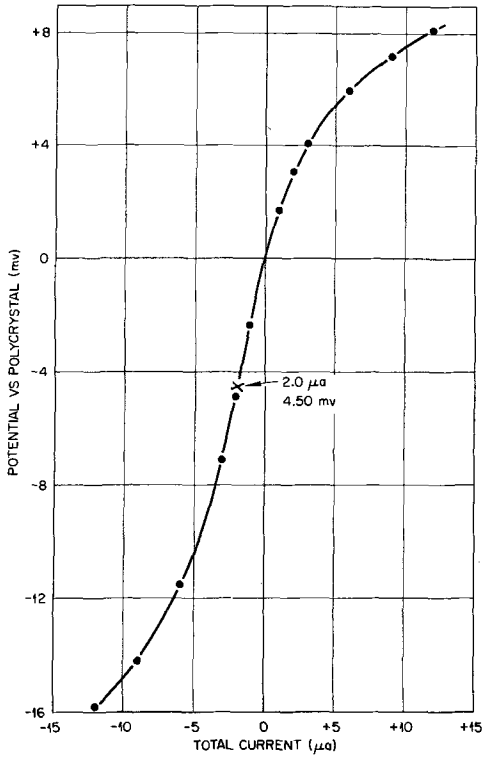

Fig. 5. Current-potential relationships for the (011) in a system corroding at a very slow rate. The inflection point, the current-potential value about which the curve is symmetric, is indicated.

also be local in nature.[3] Therefore, a highly asymmetric current *vs.* potential curve could be anticipated. However, after plotting data similar to that in Fig. 5 from any simultaneously corroding system, singular values for current and potential, about which the curve representing the data was symmetric, could be determined. Obviously, true current densities could not be calculated from geometric electrode areas and total current flow for in microscopic areas over the surface local current densities varied from zero to several times the average value. Nor could measured overpotentials be considered more than an effect of some nebulous local processes. Therefore, it must be concluded that under conditions discussed here curves of the type shown in Fig. 5 are not very useful in making conclusions about the processes occurring in the system.

The data shown in Fig. 6 further illustrate the effects of slight corrosion on anodic current-potential data. The information was collected on a system corroding for 11 days at a rate calculated to be equivalent to ~0.2 $\mu a/cm^2$. The leak in the system was then stopped and the assembly held at temperature for three weeks more. Initially the slight corrosion process probably restricted anodic dissolution to local regions, as has been shown, with the concomitant result that values of overpotentials measured were relatively high. When corrosion was stopped, normal anodic dissolution possibly occurred over the entire surface as the values for the geometric and "active" areas became more or less identical. When the crystal was removed and the surface examined, the extent of dissolution was so slight that only very few changes in surface structure could be established after diligent search. An alternative explanation is that, although not visually detectable, faceting resulting from corrosion increased the true surface area. The data do not suggest either explanation to be preferable.

[3] At the 1964 Washington meeting of the Society the author reported some results of deposition studies from $CuSO_4$ solutions on copper single crystals. It was shown that in systems initially at equilibrium deposition is uniform on the (001), for instance, at current densities as low as $3\mu a/cm^2$. This work is currently being prepared for publication.

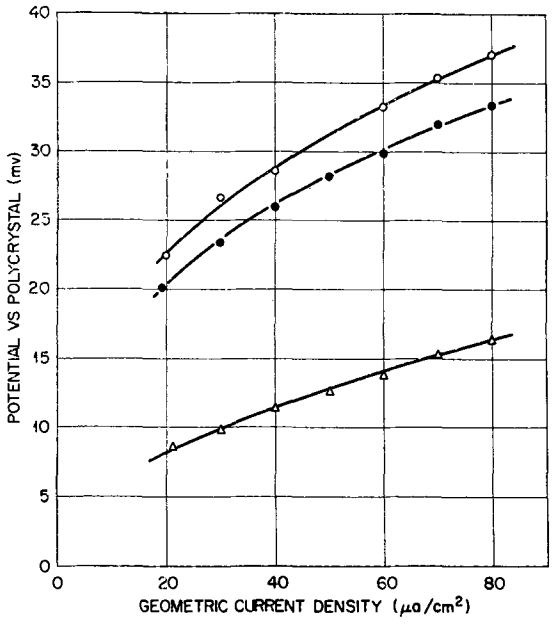

Fig. 6. Current-potential relationships for the (001) as a function of corrosion conditions. Initially the system was corroding at a rate equivalent to ~0.2 μa/cm² for a total of eleven days. The corrosion process was then stopped and the system allowed to stand for three weeks. Time after solution was admitted to system: ○, 2 days; ●, 12 days; △, 30 days.

Discussion

Corrosion in these systems containing copper metal, dissolved oxygen, copper ions, and hydrogen ions can be described by the general equation

$$Cu + \tfrac{1}{2} O_2 + 2H^+ \leftrightharpoons Cu^{++} + H_2O \qquad [3]$$

However, there are two possible types of reaction mechanisms which must be considered. The first type involves oxidation of the metal by oxygen, dissolution of the oxide by action of the acid, and possibly further oxidation of the newly formed cuprous ions by oxygen in the solution

$$2Cu + \tfrac{1}{2} O_2 \leftrightharpoons Cu_2O \qquad [4]$$

$$Cu_2O + 2H^+ \leftrightharpoons 2Cu^+ + H_2O \qquad [5]$$

$$2Cu^+ + \tfrac{1}{2} O_2 + 2H^+ \leftrightharpoons 2Cu^{++} + H_2O \qquad [6]$$

(It is impossible to differentiate experimentally between the preceding mechanism and one in which CuO is formed directly and subsequently dissolved.) Obviously the sum of reactions [4], [5], and [6] is twice reaction [3]. This type mechanism has been studied in this laboratory, and, as previously reported (3), produced a uniformly etched surface. It was presumed the homogenous attack was a consequence of the uniform diffusion of oxygen up to the surface of the metal. The second type of mechanism by which reaction [3] may occur is that in which equilibrium in the system is destroyed when cuprous ions are oxidized to cupric by dissolved oxygen, and the subsequent oxidation of copper metal by cupric ions in an attempt to re-establish equilibrium as outlined in Eq. [1] and [2]. Again, the sum of Eq. [1] and [2] is obviously Eq. [3]. However, when reaction proceeds by this latter mechanism the surface is not uniformly etched, for reaction does not occur homogeneously over the entire surface. Leidheiser and Gwathmey (2) first reported that large, square areas around the (001) poles of spherical copper single crystals were not etched when immersed in acidic copper sulfate solutions exposed to air, even though almost all the rest of the surface of the sphere was etched heavily. They also observed that solutions which had been boiled to remove dissolved gases and then maintained under a hydrogen atmosphere etched the spheres only slightly during 24 hr. These effects were confirmed at this laboratory (1) where it was also shown that, if in addition to freeing the solutions of dissolved gases and then maintaining under a hydrogen atmosphere the solution is at equilibrium with copper metal before the sphere is immersed, no evidence of etching could be detected at any orientation on the spheres even after several weeks' exposure. However, under corrosion conditions it was certain that, while most of the surface of the sphere was well etched, large areas near the {001}, and to a much smaller degree immediately around the {011} and {111}, were not attacked as heavily as the remainder of the surface, indeed, if at all. Therefore, it was concluded that etch patterns developed on the spheres were a consequence of the reaction proceeding by the second mechanism proposed in Eq. [1] and [2].

Since the rate at which cupric ions approached the spherical surface was (like oxygen in the first mechanism) diffusion controlled, it is reasonable to assume that reduction of cupric ion to cuprous occurred at all orientations. But since the anodic reaction occurred only at certain areas these observations serve as rather extreme examples of the existence of discrete, orientation-sensitive anodic and cathodic areas over a crystal supporting the cupric-cuprous redox reaction. Also, they suggest an interpretation for observations made on nonspherical crystals.

Obviously orientations which on spherical crystals did not sustain the anodic corrosion reaction were compelled to do so when those orientations alone were exposed to solutions. And again observations can be interpreted on the basis of the existence of discrete anodic and cathodic areas over corroding crystals. The pits formed by the corrosion process on the (001) support and extend such a supposition (Fig. 1). Surfaces undergoing corrosion alone permitted dissolution from only a few restricted areas. Even when small anodic currents were superimposed on the corrosion process, removal of material was still confined to these specific areas. However, when dissolution occurred solely as the result of an electrolytic current flow, even at current densities less than either of the components in the former cases, nucleation of reaction sites and removal of material was not restricted, but occurred uniformly over the entire surface. The effect was as if the cathodic part of the corrosion process effectively prevented the occurrence of anodic phenomena over most of the (001) surface. Similar conclusions can be drawn from data concerning the (111) surfaces illustrated in Fig. 1 and 2. Again, nucleation and dissolution occurred more or less uniformly over the surface in the absence of the corrosion process, but nonuniformly when accompanied by corrosion. That the reduction of cupric ions at the metal surface resulted in the dissolution process being resticted, if not prohibited, over large surface areas appears well established.

Perhaps a better understanding of the different etch patterns produced by the same over-all reaction can be gained from a consideration of the energies involved. Certainly the total free energy change in any one system due to reaction [3] will be the same. However, the mechanism of the reaction will determine the method by which the energy is dissipated. It is not unreasonable that, for the mechanism involving the direct attack on the surface by oxygen, most of the total free energy change can be expended in this step and a very high percentage of metal surface atoms possess sufficient energy to form the activated complex necessary for reaction. Conversely, if much of the free energy is expended first in oxidizing cuprous ions to cupric as in the second mechanism, relatively less energy remains to oxidize copper metal to cuprous ions. Then few surface atoms of the metal would possess energy sufficient to form the activated complex necessary for reaction, and dissolution becomes

not only a function of the crystallographic properties of the crystal, but possibly the defect structure as well.

The manner in which the local nature of the corrosion process affects current-potential relationships has been shown earlier. Data of the type shown in Fig. 5 have little value since, although the total current flow may be known, the current density associated with the measured over-potential cannot be determined. The data in Fig. 6 showing the variation in current-potential relationships for a system initially corroding, but not later, resulted at least partially from a change in the electrode process. Admittedly, it is still not certain whether the final data collected reflected only that corrosion had stopped or that also the true surface area of the electrode had changed. However, it is very clear that very low corrosion rates result in measurement of abnormally large values of potential associated with a geometric current density. This supports the previous suggestion that data, thought to indicate orientation sensitive equilibrium potential differences in similar systems, possibly were obtained from assemblies in which corrosion was occurring very slowly (1).

Although the orientation of facets developed on any one surface was independent of the dissolution process, this was not the case for their number and arrangement. Since there were local fluctuations in orientation $\sim \pm \frac{1}{4}°$ over all crystal surfaces, and since in all cases the dislocation density was at least of the order of $10^6/cm^2$, there were abundant steps on the surface to furnish reactive kink sites regardless of the means of dissolution. The appearance of the (001) after corrosion and after dissolution suggests that in both cases removal of material by motion of steps over the surface was relatively difficult, and the nucleation of new steps was more difficult in the corrosion case than in the latter. Comparison with (111) surfaces produced under similar circumstances indicate that movement of steps was more easily accomplished on this face than on the (001). Since it is not obvious that nucleation of new steps occurred on the (111) no inferences can be made. It is not at all impossible that the steps initially present on the surface were sufficient to sustain the dissolution processes without the necessity of nucleating new ones. In addition to the appearance of surfaces, this reasoning relies rather heavily on the concept of the degree to which the cathodic portion of the corrosion reaction changes what could be considered the normal appearance resulting from anodic dissolution alone.

In summary, the most significant observations concerning facet development were: (*A*) Although gross appearances were vastly different, the orientations of facets developed on any one orientation were always similar, regardless of the dissolution processes. (*B*) In no case were {001} facets ever produced, and extremely few {111} and {011} were detected. (*C*) On all surfaces most facets were oriented along the <001> zones. Since it has been shown that no orientation is measurably thermodynamically more stable in this system (1), the failure to develop facets of close-packed orientations is understandable. It seems reasonable then that the orientations of facets are determined more by the kinetic demands on the system than by any thermodynamic differences of the crystals. Certainly it is difficult to believe that an orientation about 4° from the {001} along the <001> zones is more stable than the closer packed {001}. The facets developed must represent the orientations which not only could be formed, but which also permitted relatively easier movement of steps on the surface in accommodating the dissolution process.

The apparent prohibition of {001} facet development, the frequency of formation of near {012} and near {014} orientations and the preponderance of faceting along the <001> zones, as well as the definition of broad cathodic and anodic areas by the corrosion process, are problems on which study is continuing.

Conclusions

Within the special meanings given to the terms "corrosion" and "anodic or electrolytic dissolution," and within the limitations of the experimental conditions, the following conclusions seem reasonable:

1. Copper single crystals with more than one orientation exposed to solution exhibit distinct, orientation-sensitive cathodic and anodic areas when subjected to oxidation by cupric ions.
2. If a crystal exposes only one orientation to solution, the corrosion process again results in the definition of distinct anodic and cathodic areas.
3. Since under conditions of anodic dissolution alone the surface of an electrode of singular orientation is uniformly attacked, corrosion and electrolytic dissolution are not electrochemically equivalent in the sense that equal areas of the electrode are not available to sustain the process in both cases.
4. Potential-current characteristics experimentally determined at very low current densities for a surface simultaneously corroding can be inexact and without obvious relationship to values obtained in noncorroding systems.
5. The orientations of structures developed on a surface as the result of dissolution processes are largely independent of the nature of the process and are determined more by the kinetic demands impressed on the surface than by any orientation-sensitive thermodynamic property of the crystal. The gross features developed on the surface are governed by the types and/or relative rates of the dissolution processes.

Electrical Conductivity Studies of Tetragonal Zirconia

L. A. McClaine and C. P. Coppel

Arthur D. Little, Incorporated, Cambridge, Massachusetts

ABSTRACT

The a-c and d-c resistances for tetragonal zirconia were measured over the temperature range of 1100°-1500°C and pressure range of 1 to 10^{-14} atm oxygen. Polarization studies indicated that in oxygen atmospheres an oxygen electrode reaction occurs at the platinum-zirconia interface so that it is not possible accurately to separate ionic and electronic conduction components from the resistance data. However, the data do indicate a significant ionic conduction component within the pressure and temperature range studied. Assuming that oxygen transport accounts for the ionic conduction some order of magnitude values for oxygen diffusion in zirconia at 1400°C were calculated.

Most chemical processes of interest in the fabrication and use of materials at high temperatures involve heterogeneous systems, and the kinetics of these processes are more often than not transport-controlled. However, experimental data on high-temperature diffusion processes is very limited, and we are not yet able to predict transport behavior.

In conjunction with recent studies in our laboratories, on the kinetics of oxidation of zirconium carbide and boride in the 1000°-2000°C range, we desired data on the mass transport properties of the ZrO_2 that can form as a surface coating during the oxidation process. In particular, information was sought on the diffusion of oxygen, the defect structure of the oxide, and the effect of temperature, atmosphere, and impurity content on the defect structure. As a result of this interest, we initiated a study of the a-c and d-c electrical conductivity of tetragonal zirconia in an attempt to provide some of the desired information.

From a-c and d-c resistance measurements we expected to be able to calculate transport numbers and separate ionic and electronic conduction components. From accurate knowledge of these components a defect structure model can be developed. In addition, knowledge of ionic conduction will permit the calculation of diffusion data for oxygen, providing that oxygen is the only ionic species contributing significantly to the ionic conduction.

Previous work on tetragonal zirconia has been extremely limited. Kofstad and Ruzicka (1) found that the direct current conductivity of tetragonal zirconia had a complex oxygen dependence. They proposed as a possible explanation for this behavior that zirconia is an ionic conductor with a coupled transport of oxygen vacancies and interstitials and pointed out that to confirm this explanation it would be desirable to study the relative importance of ionic and electronic conduction as a function of the partial pressure of oxygen. Vest and Tallan (2) have been studying tetragonal as well as monoclinic zirconia concurrently with this study utilizing a polarization technique. Their results have not yet been reported in detail.

Experimental Details

Sample material.—Very dense, high-purity sample boules were prepared from ZrO_2 by melting the oxide in an arc imaging furnace designed to permit a powder feed to the hot zone. Samples were cut from this material with a diamond sectioning saw.

The starting oxide for the preparation of the boules was either reactor grade oxide obtained from Wah Chang Corporation, or oxide prepared in our laboratories from Wah Chang sponge. The spectrographic analyses of these oxides labeled lot I and II, respectively, are presented in Table I. Also presented is a similar analysis on a boule prepared from lot II material. The fusion process has resulted in a much lower trace impurity concentration level. Quantitative spectrochemical analysis for Al and Fe in a boule made with lot II oxide gave values of 0.007 and 0.01% for Al and Fe, respectively, checking very well with the semiquantitative report.

Electrical leads.—In our initial work, thin disks were held in compression between two alundum rods carrying the electrical leads from outside the furnace area. Electrical contact was made by a bead or thin foil of platinum held against the sample. Results with this holder were easily affected by shocks and vibrations outside the furnace.

Therefore, most of our work including that reported here has been done with leads connected directly to the samples. These are made to the end of the sample by initially putting down a thin layer of platinum using either vapor deposition or "liquid platinum." In the a-c d-c resistance measurements reported here, the leads consisted of a Pt, Pt-Rh thermocouple attached to each end of the sample. In the d-c resistance measurements one set of thermocouple wires was used as current leads, while the other was used as potential leads.

Temperature and atmosphere control.—A resistance furnace wound with platinum-10% rhodium and operated with a constant voltage power unit was used to control the temperature of the sample. The atmosphere was fixed by using pure oxygen, an oxygen-helium mixture, CO-CO_2 mixtures, or H_2-H_2O mixtures at 1 atm total pressure.

Table I. Spectrochemical semi-quantitative analyses of ZrO_2 materials

Impurity	Starting oxide powders		Boule from lot II oxide
	Lot I	Lot II	
Al	125 ppm	0.01 to 1%	0.001-0.01%

Note: < = less than, and ND = not detected.

In some of the studies the temperature of the furnace was increased or decreased at a steady rate of 1 or 2 deg/min using a motor drive attached to the variac which feeds power to the furnace.

In the polarization studies which were carried to very low potential levels, too much a-c pickup was observed for meaningful measurements, and for these studies a d-c power source for the furnace was used to eliminate this difficulty.

Resistance measurements.—The a-c resistance was measured at 1 kc with a General Radio Type 1650A impedance bridge. The d-c resistance was determined by passing a known d-c current through the sample and measuring the emf across the sample using a L&N Type K potentiometer. The d-c measurements were made frequently with current flow reversed to detect errors introduced by any thermal emf.

Current-voltage curves were determined so that d-c measurements might be carried out below any apparent decomposition potential. For pure ZrO_2 we found a straight line I to E relationship below potentials of 0.1v. The curves began to break as potentials were increased beyond this point. For our sample geometry the straight line portion corresponded to currents up to about 100 μa. Our d-c measurements were generally made at currents of 10-20 μa.

Measurements were made at either a constant temperature while the atmosphere was varied, or, more frequently, the atmosphere or ratio of gases determining the atmosphere was fixed, and the temperature was increased or decreased at a fixed rate with intermittent measurements of a-c and d-c resistance on the sample.

Results

A-C and d-c resistance measurements.—The a-c and d-c electrical resistance of ZrO_2 samples was measured over the temperature range of 1100°-1500°C and over the pressure range from 1 to 10^{-14} atm oxygen. The data obtained for one sample, No. 12, are presented in Fig. 1 through 5. For these measurements both current and potential leads were connected to the completely coated ends of the sample, and the conductivity was calculated from the known geometry. The sample measured 0.385 in. long and 0.206 x 0.177 in. in cross section.

The results reported on sample No. 12 were obtained within a period of three weeks while an attempt was being made to keep the sample in the tetragonal phase. During this period it was necessary to cool the sample once through the monoclinic-tetragonal transition in order to replace a lead which became detached. In general, we have observed excellent reproducibility of results on successive runs up and down in temperature, while remaining within the tetragonal phase. However, sometimes after taking a sample back and forth through the phase transition, we observe increases on the order of several per cent in the resistance which we attribute to the formation of microcracks in the sample during the transition. In this particular case with sample No. 12, there was no sig-

nificant effect on the resistance from the passage back and forth through the phase transition. The initial runs were in pure oxygen and in H_2-H_2O mixture. After the cooling operation, the complete study in oxygen was repeated with agreement within 1%.

Frequently between the subsequent atmosphere studies the resistance in oxygen was measured again. The points in Fig. 1 represent the combined results of measurements made on seven different days during the period when all data reported here except the H_2-H_2O were obtained. On most of these days only individual points were determined after holding the sample overnight in an oxygen atmosphere at some temperature in the tetragonal region. The agreement is taken as an indication of a lack of change in the sample or electrical leads during this period. The scatter in the a-c measurements is on the order of ± 1%, and this is much less than the changes observed as the atmosphere is changed.

In Fig. 6 we present plots of zirconia conductivity as a function of oxygen pressure at different temperatures which are derived from the a-c resistance curves of Fig. 1-4. These curves show a minimum in total conductance at a pressure of 10^{-4}-10^{-5} atm. The total change in conductance with the greater than tenfold change in pressure is very slight, less than a factor of two. It may be noted that data presented in Fig. 4 and 5 represent almost identical oxygen pressures, but in

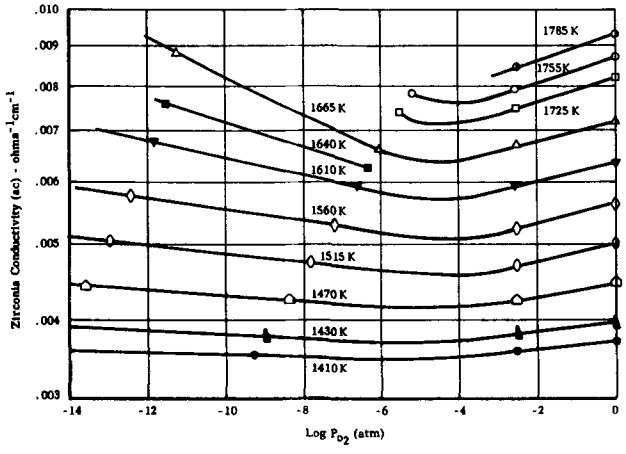

Fig. 6. Total conductivity *vs.* pressure of oxygen at selected temperatures.

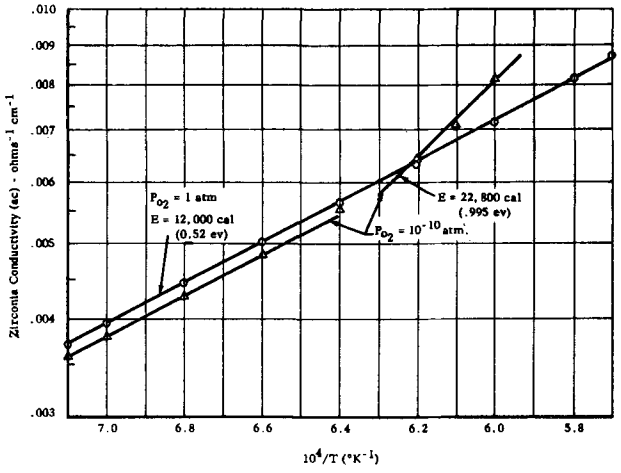

Fig. 7. Total conductivity *vs.* temperature at selected oxygen pressures.

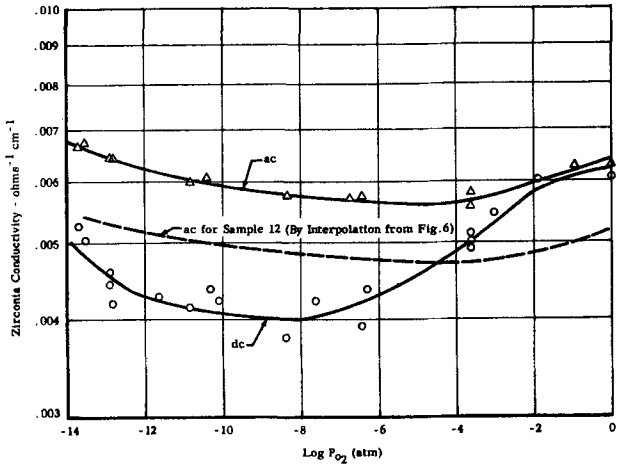

Fig. 8. Conductivity data for Sample No. 9 at 152°K.

one case CO-CO_2 was used to set the oxygen pressure, whereas in the other a H_2-H_2O mixture was used. In drawing the curves of Fig. 6, only the results from the CO-CO_2 mixtures have been used, for reasons which will be discussed shortly under atmosphere effects.

In Fig. 7 are plotted as log conductivity *vs.* reciprocal temperature data taken from Fig. 6 for pressures of 1 and 10^{-10} atm oxygen. These curves show that at low pressures there is an apparent increase in activation energy as temperature is increased while at 1 atm there is no apparent change over the temperature range studied.

Results obtained on samples prepared from both oxide sources were essentially identical. In Fig. 8 we plot results obtained on sample No. 9 which was cut from a boule prepared from the Wah Chang reactor grade oxide. These data were obtained at a constant temperature of 1525°K ± 10 while oxygen pressure was varied by means of atmosphere control. The dotted line represents comparable data for sample No. 12. It will be noted that although displaced somewhat in absolute conductance the behavior with variation in pressure is identical for the two samples.

It can be seen in Fig. 1-5 and 8 that d-c resistances measured are different than the a-c values. If there were no ionic component of conduction, we would expect the a-c and d-c values to be identical. The differences observed are evidence for a significant ionic component of conduction. In order to separate ionic and electronic components of conduction from the a-c and d-c resistance measurements two assumptions must be

made. One assumption is that under d-c conditions only electrons are transferred across the platinum-zirconia contact. That is to say that when a d-c potential is applied, both electrons and ions migrate toward the electrodes, but only the electrons can be discharged; the ions assume a concentration gradient which opposes the field. The second assumption is that the potential drop across this space charge resulting from the concentration gradient of the ions is small compared to the total potential drop across the sample. Providing that these assumptions are reasonably valid, ionic transference numbers may be calculated from the relationship

$$t_i = \frac{R_{dc} - R_{ac}}{R_{dc}}$$

In making the studies current-potential curves were determined and measurements were made at the small currents and potentials corresponding to the straight line portion of the curve; thus it was presumed that the measurement conditions were below the decomposition potential of the zirconia. On this basis we calculated ionic and electronic conductivities and a very reasonable picture evolved.

We were concerned, however, with establishing the limits of error introduced in our study by the two assumptions made in using the d-c resistance measurements to separate ionic and electronic conductivity. In studies on a lime-stabilized zirconia sample with the identical technique, we found about 90% ionic transport when measured in helium, but a much lower ionic transport indicated when measured in oxygen. This could be attributed only to some oxygen reaction at the electrodes in the oxygen atmosphere since we would expect that the lime content makes the transport properties atmosphere independent. To explore further the errors introduced by our assumptions, we carried out more detailed studies of the polarization behavior of several samples.

Polarization studies.—Further study of this problem was carried out using a sample of zirconia containing about 5 mole % CaO, which we obtained from the Norton Company. This material has about one third of the lime content of the sample studied by Kingery. We would expect a high ionic conductance which is virtually atmosphere independent.

We attached three potential electrodes along the sample as well as current leads on the end. The end leads covered the cross section of the sample and helped insure that current flux was uniform across the sample. The potential leads were spaced along the 1.3 cm length of the sample in the proportions indicated on the abscissa of Fig. 9, and were made by wrapping and twisting a piece of platinum wire around the sample. To reduce the contact resistance of these leads, a spot of "platinum paste" was used at about three or four points around the circumference of the sample to spot sinter the potential lead to the sample.

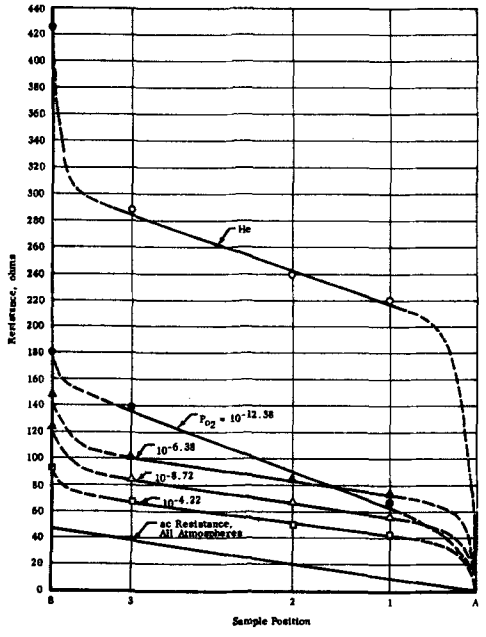

Fig. 9. Resistances calculated for various electrodes with respect to electrode A from potential measurements at 1390°C in various atmospheres.

In Fig. 9 we plot the resistance of the sample as calculated from end B to end A and to each of the three potential leads. The a-c potentials were measured using an oscilloscope to determine potential drops between the current and potential electrodes, and calculated resistances for all atmospheres fall on a straight line within the precision of the oscilloscope measurement. The fact that a straight line is obtained confirms the positioning of the leads as determined by measurement, and also indicates uniformity of the sample. Resistances calculated from d-c potential measurements, however, do not fall on a straight line. We attribute the high resistance at either end to space charge polarization. The fact that they are such a large portion of the total resistance indicates that separate potential leads such as on this sample should be used in the determination of d-c resistance. The three points calculated from the three potential leads do, in general, fall on a straight line, thus indicating sample uniformity and further indicating that the large potential gradient is very close to the end of the sample, as we would expect for space charge polarization.

Note, however, that when the sample is equilibrated in a high-oxygen atmosphere rather than helium, the d-c resistance calculated across the potential leads corresponds to that calculated from the a-c measurements. This behavior, assuming no oxygen reaction at the electrodes, indicates close to zero ionic transport contrary to results in helium. This occurs in a sample which we expect to be primarily an ionic conductor independent of atmosphere. This behavior in oxygen-containing atmospheres is confirmed in studies on other zirconia-lime samples of even higher lime content.

We conclude from these studies that the platinum electrodes cannot be assumed to be inert and blocking to an oxygen electrode reaction; in order to explain our observations, the reaction $\frac{1}{2}\ O_2 + 2e = O^{-2}$ must occur at a significant rate at the platinum-zirconia interface in atmospheres containing oxygen pressures of $10^{-8.72}$ atm and greater. We have found no evidence that reducing the area of the current electrode will modify the rate of this reaction and thus the behavior of the samples.

As a consequence of these results it is evident that an accurate separation of ionic and electronic components of conduction cannot be made from the a-c and d-c resistance data for pure zirconia reported in this paper. We now recognize that the assumptions necessary for such calculations are far from valid, and we see no way in which to eliminate with any degree of success the uncertainties introduced by using such assumptions. From the data in Fig. 9 one can see that the assumption of no oxygen electrode reaction is most in error at high-oxygen pressures, while the assumption that the potential drop across the space charge is small compared to the total potential drop across A-B is most in error at very low-oxygen pressures.

Vest and Tallan (3) have recently reported the application of a polarization technique to the study of $Ca_{0.15}Zr_{0.85}O_{1.85}$. Many of their data are from time dependent d-c measurements rather than a combination of a-c and d-c measurements, but the data resulting from either technique are comparable. In their work they also have recognized the oxygen gas reaction occurring at the platinum electrode and have proposed a means for interpreting their data which takes

into account this reaction. Their interpretation of their data recognizes that in certain pressure regions the various conductivity data recorded may be primarily due to either electronic, ionic, or the gas-electrode reaction. Thus by such assignment of their data to a specific conduction mechanism and by extrapolation of these data into the regions in which more than one conduction mechanism contributes significantly to the measured results they proposed to separate ionic and electronic conductivity in the mixed conduction region. Such a technique is not applicable to our data since we can recognize no region in which one conduction mechanism alone is predominant. Data collected over a much wider range of oxygen pressure might indicate such regions. However, in considering application of this technique one should recognize that a straight line extrapolation into the mixed conduction region is not necessarily correct since, in general, one can expect changes in the dependency of electronic and ionic conduction on oxygen pressure in different pressure regions. In addition Vest and Tallan assume that the ionic polarization is small and does not affect their measurements. Our studies show that a large polarization potential exists. We recognize no basis for assuming that the polarization potential will not affect the resulting measurements. To conclude, we believe that the means proposed by Vest and Tallan for treating their data can be useful as a first approximation to separating the conduction components when data are available over a sufficiently wide range. However, in our opinion the technique cannot be applied to our studies to produce the accurate and detailed separation of ionic and electronic conduction which we seek.

While we cannot, therefore, from the a-c d-c resistance data make a highly accurate and detailed separation of ionic and electronic conduction components as a function of temperature and oxygen pressure, our data do indicate that ion transport is a significant component in the over-all process and thus provide a basis for estimating the ionic conductivity. If the ionic conductivity was on the order of 1% or less, we would probably not have observed any significant difference in our a-c and d-c measurements; the differences noted, we believe, indicate that ionic conductivity must be on the order of several per cent of the total even at high partial pressures of oxygen. In Table II are presented transference numbers calculated from the a-c d-c resistance data of Fig. 4. The data in Fig. 4 are for oxygen pressures of 10^{-11} atm or less; under such conditions, as pointed out in a previous paragraph, the major error in using the data for transference numbers is the uncertainty with regard to the space charge polarization potential. However this error influences the results in such a manner that calculated electronic transference numbers are lower than the actual. As indicated in Table II calculated values increase from 0.39 at 1410°K to 0.78 at 1610°K. In spite of the fact that these values are probably on the low side it is still evident that electronic conduction is a large component at the high-temperature and low-pressure end of our studies. As shown in Fig. 7 this is the same region in which there is a marked change in activation energy for total conductivity indicating a radical change in the mechanism responsible for conduction. In our opinion these data indicate that over most of the pressure-temperature range studied the ionic conduction component represents several tens of per cent of the total conductivity.

Table II. Transference numbers calculated from data of Fig. 4

Temperature, °K	R_{ac}, ohm	R_{dc}, ohm	t_i	t_e
1410	1100	2820	0.61	0.39
1470	935	1740	0.46	0.54
1540	759	1150	0.34	0.66
1610	617	795	0.22	0.78

$\left(t_i = \dfrac{R_{dc} - R_{ac}}{R_{dc}},\ t_e = 1 - t_i\right)$

On the basis of these considerations of the data we estimate that the ionic conductivity of pure zirconia as represented by our sample No. 12 at 1400°C, falls within the limits of 0.0005 to 0.0025 ohm^{-1} cm^{-1} in the oxygen pressure range from 1 to 10^{-10} atm.

Having established an order of magnitude for ionic conduction in our zirconia material the next question is whether we can establish which ion provides the conduction component. Lime stabilized zirconia is generally recognized as an ionic conductor due to oxygen transport by a vacancy mechanism. Somewhat analogously we would expect the formation of oxygen vacancies in zirconia with decreasing oxygen pressure and thus an increase in ionic conduction with decreasing pressure. However our data indicate little change in ionic conductivity with pressure decrease, contrary to our initial expectation of oxygen transport by a vacancy mechanism. On the other hand, the behavior of the a-c and d-c measurements with increasing pressure can readily be interpreted as due to an oxygen reaction at the electrodes such as we concluded occurred with the lime stabilized sample we studied; this behavior tends to indicate that oxygen ion transport is important. One explanation could be that oxygen transport occurs, but that the vacancy content is controlled by impurities. Another alternative explanation could be that a combination of ionic conduction mechanisms exists which vary with oxygen pressure in opposite directions producing little net change in total ionic conduction. In our opinion a detailed interpretation of the defect structure and the ionic conduction mechanism will require a much more accurate separation of ionic and electronic conduction components than can be achieved by a polarization technique.

While our data do not permit us to assign the ionic conduction unequivocally to oxygen transport, it is worthwhile to assume that oxygen transport is the primary component and determine whether this assumption is consistent with other findings. If we assume that the estimated ionic conduction of 0.0005 to 0.0025 ohm^{-1} cm^{-1} at 1400°C is due to oxygen transport we can calculate the diffusion coefficient for oxygen in zirconia using the Nernst-Einstein relationship. On this basis we calculate that the diffusion coefficient of oxygen may fall within the limits of 0.22 to 1.1×10^{-8} cm^2/sec at 1400°C. Such values for the diffusion coefficient appear reasonable in relationship to the work at lower temperatures and somewhat different structures by Kingery *et al.* (4) on $Ca_{0.15}Zr_{0.85}O_{1.85}$, and Douglas (5) on $ZrO_{1.994}$. In addition a diffusion coefficient of the same order of magnitude as that calculated here was determined for oxygen in ThO_2 (6) at 1400°C.

Atmosphere effects.—In our work we have observed behavior which we interpret as evidence for interaction of the CO-CO_2 and H_2-H_2O atmospheres with our oxide samples. Apparently such interactions are not usually considered in work in this field, as most papers in which these atmospheres are used to fix oxygen pressure make no comment relative to possible interactions with sample materials.

For the same oxygen pressure we found a much lower d-c resistance when using H_2-H_2O than CO-CO_2 to control oxygen pressure as can be seen by comparing Fig. 4 and 5. The a-c resistance is also reduced but not as markedly. This behavior which indicates increased electronic conductivity in the H_2-H_2O atmospheres, we interpret as analogous to that observed by Mollwo (7) and Thomas and Lander (8) for a zinc oxide-hydrogen system. These authors found an increase in conductivity of ZnO when in an atmosphere of H_2. This was attributed to hydrogen entering the matrix as an interstitial positive ion with associated electron. Such an interaction will explain the trend of our results. In view of this observed behavior, the results with H_2-H_2O atmospheres were not used in

final calculations of ionic and electronic conductivities as a function of oxygen pressure.

In our opinion, the same atmosphere effect very likely influenced the results of Aronson's study (9) on ZrO_2 stoichiometry as a function of oxygen pressure. The results reported by Aronson were unusual in that they indicated a greater stability for a given ZrO_2 stoichiometry the higher the temperature. Comments made in Aronson's paper lend support to the belief that his results were affected by the H_2 atmosphere. He indicates that all of his reported data were obtained after reduction with small quantities of H_2-H_2O in an inert gas. When experiments were attempted using a pure H_2-H_2O environment, he reports that "spurious results" (a lower-weight gain on oxidation) were obtained. This might have been due to an increased H_2 solubility which would be in accord with observations on ZnO that the hydrogen atmosphere effect was increased with increased hydrogen pressure. We estimate that if hydrogen solubility in ZrO_2 is comparable in magnitude to that in zirconium metal (10), then weight changes due to hydrogen pickup would be of the same order of magnitude as the oxygen losses under study. In addition, of course, the presence of the hydrogen in ZrO_2 can be expected to influence the oxygen activity.

We also observed that the CO-CO_2 atmospheres had a slow effect on the measured a-c and d-c resistances. With increasing time in the atmospheres, the R_{dc} and R_{ac} values increased. After a day or more in CO-CO_2 mixture of high CO/CO_2 ratio results such as the curves in Fig. 3, labeled II, were obtained. After such changes, we observed corresponding changes in a-c and d-c resistance measured in pure oxygen atmosphere. However, we find that the increased resistance in both oxygen and CO-CO_2 atmospheres can be removed by a long period of heating in pure oxygen. We interpret this behavior as due to carbon building into the zirconia sample. Consequently, we did not permit a sample to remain for long periods in CO-CO_2 atmospheres and completed all measurements possible prior to using CO-CO_2 atmospheres. Kofstad (1) reported attempting to duplicate Aronson's study (9) using thermogravimetric studies in CO-CO_2 atmospheres with equilibration periods of up to one day. He observed much smaller oxygen losses in the CO-CO_2 mixtures than reported by Aronson for the H_2-H_2O-inert gas mixtures. Possibly Kofstad's results were affected also by sample interaction with the CO-CO_2 atmospheres, although, since we have no measurements on the amount of carbon picked up by ZrO_2 in our studies, it is difficult to judge.

One might consider that the effect of the atmospheres was on the rate of the oxygen electrode reaction, with a resulting change in concentration polarization, rather than chemical changes in the zirconia. Our information is not sufficient to prove that this does not occur. However, in the case of the CO-CO_2 atmosphere, we believe that the presence of changes in the a-c as well as the d-c resistance values argues against it. In the case of the H_2-H_2O atmosphere effect, this point is certainly not resolved, but the previous work on ZnO which was discussed and the reasonable interpretation of Aronson's observations as presented here argues for the existence of chemical effects.

Conclusions

We find from a-c and d-c resistance measurements on dense, high-purity tetragonal zirconia over the temperature range of 1100°-1500°C and an oxygen pressure range of 1 to 10^{-14} atm evidence that tetragonal zirconia is a mixed ionic and electronic conductor. The data show that electronic conduction is most important at the low-pressure and high-temperature end of the studies and that ionic conduction is a significant component of total conduction in the higher pressure regions.

We find from a-c and d-c resistance measurements on lime stabilized zirconia that the assumptions necessary for the desired, highly accurate separation of ionic and electronic conduction components from our data on tetragonal zirconia are not valid. Nevertheless we can conclude that the data on tetragonal zirconia will permit a reasonable estimate of the ionic component. We considered the nature of this ionic transport and conclude that an assignment primarily to oxygen transport is not incompatible with what we know at this time.

Technical Notes

Chemical Spray Deposition Process for Inorganic Films

R. R. Chamberlin and J. S. Skarman

The National Cash Register Company, Dayton, Ohio

A new chemical technique (1) has been developed for the deposition of thin films of the sulfides and selenides which consists basically of spraying a solution on a heated substrate. This method has some similarity to the chemical bath deposition methods (2, 3) which have been used with lead sulfide and selenide and to the techniques used in the spray deposition of conductive oxide films. However, the process which is described in this paper is unique from the standpoint that all of the necessary elements are contained in the solution which is being sprayed. Neither the gas being used to operate the spray nozzle (4), the ambient atmosphere (5), the substrate (6), nor any post-treatment contributes to or changes the chemical composition of the film which is being deposited.

Experimental

As mentioned, the spray solution contains at least all the necessary elements which are desired in the resultant film. A typical example of a spray solution which if sprayed (see parameter list below) on a heated substrate will yield an optically clear and very adherent film of cadmium sulfide consists simply of an aqueous solution of cadmium chloride and thiourea which is usually made with a concentration of 0.001-0.05M and with the sulfur and cadmium ions in a ratio of 1 to 1.

The apparatus needed to carry out the chemical spray process consists basically of a device to atomize the spray solution and some sort of substrate heater. Figure 1 shows a typical experimental setup. Here is shown a spray nozzle of the two-fluid type although, since neither the gas used to atomize the spray nor the ambient atmosphere contributes to the composition of the film being deposited, a single-fluid nozzle could be used in which atomization is achieved by pressurizing the liquid.

The substrate heater should be one which has sufficient thermal capacity to maintain a temperature of at least 400°C while the spray is incident on its surface. Obviously, the necessary thermal capacity is dependent on the spray parameters such as spray rate and the volume of the gas being used to atomize the solution and propel the atomized solution to the substrate.

The spray nozzle used was one which had a maximum spray rate of about 20 ml/min. Stainless steel 316 has been used with most solutions with little evidence of metal contamination, but Teflon spray heads have been used and the hand-operated chromatic spray bottle has been extremely useful for quick trials with new spray solutions. Because of the range of spray rates possible with different spray heads and the control which is possible with different substrate heaters, the deposition parameters such as rate, temperature, and solution concentration for different compounds can be determined experimentally. Generally, the sulfides deposit at a higher temperature than the selenides. Deposition temperatures have been found to vary from 115°C for Cu_2S to 375°C for ZnS. However, the ease with which parameters can be changed even during a film deposition allows quite rapid determination of conditions necessary for a uniform deposit.

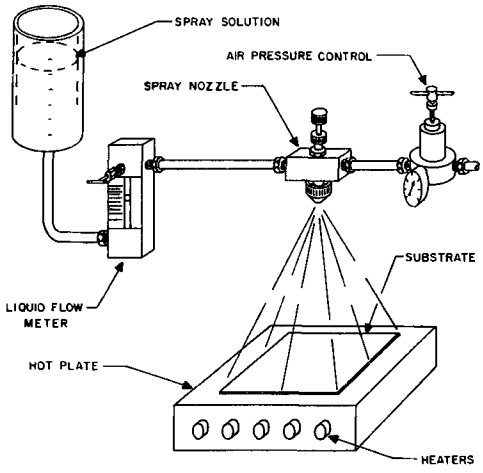

Fig. 1. Typical experimental setup

To obtain the desired semiconducting properties, separate additional experimentation will normally be required. The range in which a physically uniform film can be obtained is quite broad with definitely different electrical properties obtainable within this range.

The starting materials which can be used are many, and the choice will often depend only on what appears to yield the best results from a device standpoint.

The purity, freedom from other compounds or elements, and the film crystallinity which the various combinations yield are usually deciding factors. The compounds used to provide the elements need only be soluble in the liquid used, and the remainder of the starting components must be completely volatilized during the spray process. In the case of cadmium sulfide, many compounds could be used for the cadmium-ion source with still more choices for the sulfur ion as can be seen from Table II.

The choice of the starting material will determine the purity and crystallinity, deposition temperature, stability of the spray solution, and whether or in what way a doping impurity may be added. As an example, where a cadmium selenide film is to be spray deposited,

Table I. Typical CdS spray parameter values

	ammonium thiocyanate

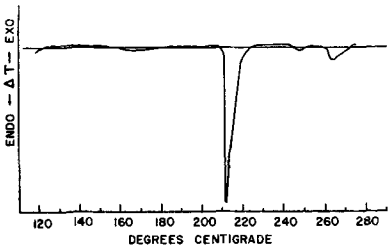

Fig. 2. Pyrolytic decomposition differential thermal analysis curve

substituted selenourea such as N,N,dimethyl selenourea is used to prevent free selenium from precipitating due to the decomposition action of both ambient heat and light. If a cadmium sulfide film is to be doped with copper, N,N,dimethyl thiourea is needed to prevent a copper hydroxide from immediately precipitating when the copper acetate is added to supply the copper to the starting solution.

Often it is found that best results can be obtained by using a combination that will precipitate a solid complex which is then subsequently redissolved to make a spray solution. A readily available complex, cadmium thiocyanate, if sprayed will yield a film of cadmium sulfide. This, of course, is equivalent to starting with cadmium chloride and ammonium thiocyanate. A solid complex which precipitates from mixing a 1M solution of cadmium chloride and thiourea has been found to be a convenient source of starting material for a cadmium sulfide spray and has generally proved satisfactory for films which have been used for semiconductor applications. Figure 2 is a differential thermal analysis curve describing the decomposition of a 2 to 1 sulfur-to-cadmium ratio complex. The decomposition of this complex is endothermic, and it occurs sharply at 210°C. This, then, clearly defines the minimum temperature that one could use when spray depositing cadmium sulfide from a solution containing this complex.

The semiconductor characteristics of a spray deposited film are most dependent on the solution composition (starting materials anion-to-cation ratio), substrate temperature, and the crystallinity of the substrate. Parameters such as spray rate, solution concentration, and the substrates thermal environment are the parameters which are adjusted such that a physically uniform film results. The crystallinity of a spray deposited film is dependent on the substrate and the starting material, particularly the cation material such as cadmium chloride or cadmium acetate in a cadmium thiourea solution. If cadmium chloride is used, a highly crystalline film can be expected with a given amorphous substrate, whereas, if cadmium acetate is used, the film would be amorphous as far as x-ray diffraction is concerned. Here amorphous is taken to mean that the crystallites are smaller than 400Å in size. If a cadmium chloride-thiourea solution is used for the deposition of cadmium sulfide, a crystalline film is normally expected; however, we find also that a variation in the extent of the crystallinity will be apparent if we vary substrate temperature even though at each temperature a physically uniform appearing film is being deposited. Examples of this variation are shown in Fig. 3 through 5 where the x-ray diffraction pattern shown in Fig. 5 is of a film deposited at the highest temperature and the diffraction pattern in Fig. 3 is that of a film deposited at the lowest temperature at which a physically uniform film could be deposited.

In general, the crystallinity of a film deposited using a cadmium halide-thio compound solution is more closely influenced by substrate temperature than substrate surface if the surface is inert to the deposition process and amorphous in nature. However, while very crystalline films can be deposited on noncrystalline material such as glass, when the substrate presents a more ordered surface such as a ceramic, the film crystallinity is often reduced (7). The highly crystalline metal surfaces will, in general, cause a film to be amorphous even though under other circumstances the same solutions would yield a film that would be very crystalline when deposited on an amorphous substrate.

The orientation of the crystallites with relation to a given substrate has been found to vary when the cation/anion ratio is varied. Variation as the result of changing this ratio can be seen in Fig. 6 through 8. Figure 6 is the typical orientation of a film from a 1:1 cadmium-to-sulfide ratio solution. Figure 7 is typical of a film deposited from a 2:1 cadmium-to-sulfur ratio, and Fig. 8 is typical of a film deposited from a solution with Cd:S ratio of 1:2.

Heat-treatment of chemically sprayed films in an inert atmosphere typically results in an increase in crystallinity with no significant change in orientation. The effect of heat-treatment can be seen by comparing Fig. 9 and Fig. 10 where two samples were examined by x-ray diffraction before and after heat-treatment. However, if a film is amorphous to x-ray diffraction, before heat-treatment, even a very long heat-treatment normally will not increase the crystallinity to the point where x-ray diffraction shows any significant change.

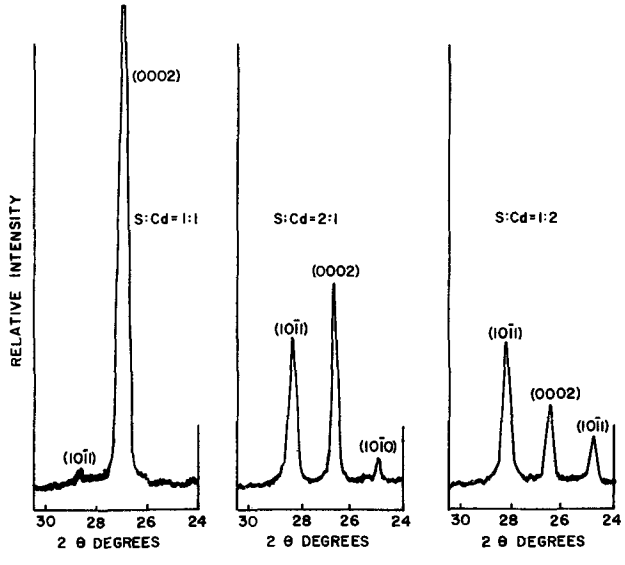

Fig. 6 (left), 7 (center), right). X-ray diffractographs of CdS films deposited from mixtures of different stoichiometric ratios.

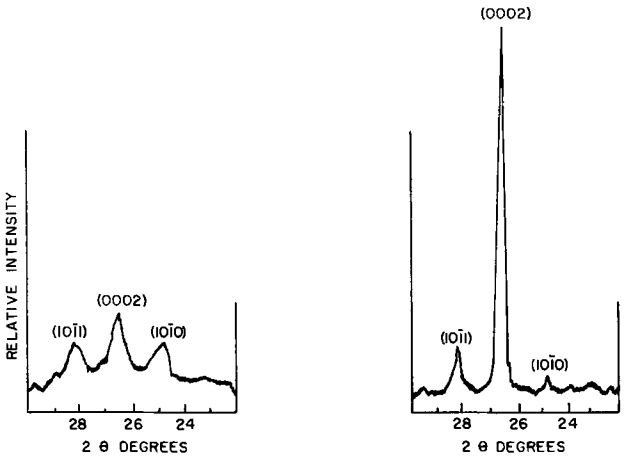

Fig. 9. X-ray diffractographs of two CdS films before heat treat, film A left, film B right.

Although x-ray fluorescence was the only means of checking stoichiometry, films deposited from a 1:1 cadmium-to-sulfur starting solution have always been found to be stoichiometric within the experimental error of the x-ray method used. With cadmium sulfide it is perhaps of interest to note that the undoped films are always a typical bright yellow and never show the darkening which is often attributed to excess cadmium in vacuum deposited films. It has been found that with any compounds the best initial approach is to start with the desired elements in the starting solution in the same ratio as desired (*e.g.*, antimony-to-sulfur ratio of 2:3 for Sb_2S_3) in the spray deposited film. This usually results in a film of the desired material over a quite broad (*e.g.*, ±70°C) deposition temperature range when binary or doped binary materials are being sprayed. However, when a solid solution film such as ZnCdS or CdSSe or films of ternary compounds such as $CdIn_2S_4$ is being deposited, the temperature range in which the desired ratio of the elements will deposit becomes quite narrow (*e.g.*, ±5°C). Because of the shift from stoichiometry with temperature in the solid-solution type films, adjustment of the initial ratio of the elements in the starting solution is sometimes necessary. Generally speaking though, the spray deposition process offers a great amount of versatility in the deposition of solid solution, ternary and impurity-doped films. The shifts of the x-ray diffraction peaks as the ratio of the anions was changed from 100% of one species to 100% of the other species, *e.g.*, in CdSSe, have been found to follow Vegard's law.

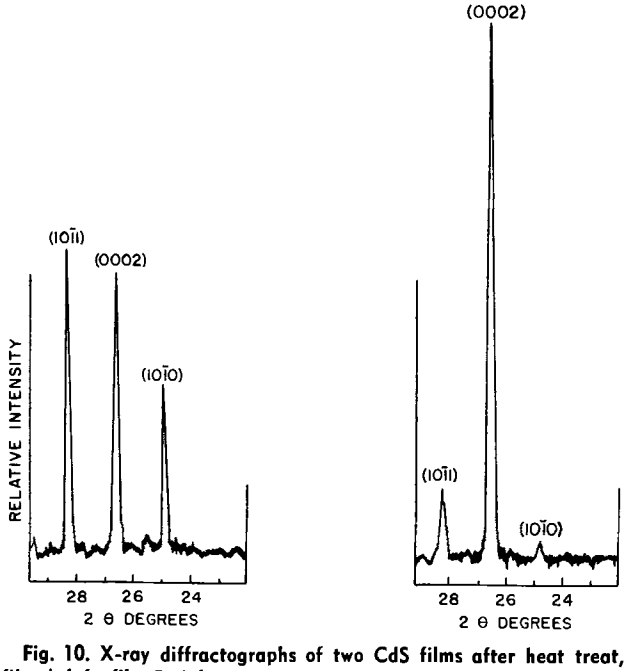

Fig. 10. X-ray diffractographs of two CdS films after heat treat, film A left, film B right.

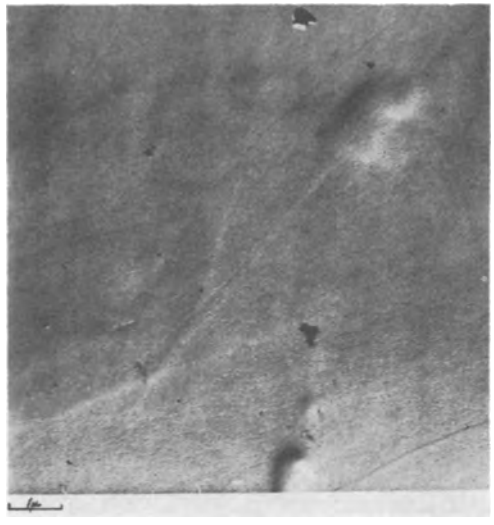

Fig. 11. Electronmicrograph of an amorphous CdS film

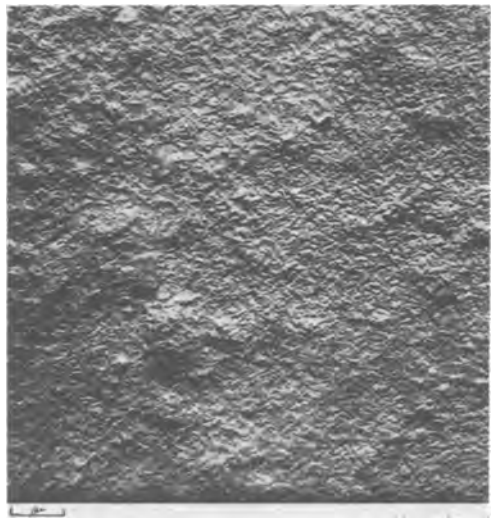

Fig. 12. Electronmicrograph of a highly oriented crystalline CdS film.

The physical characteristics of a spray deposited film are dependent on the degree of atomization, spray rate, temperature, and concentration of the spray solution and the film thickness. Generally, the finer the atomization, the higher the temperature and the less concentrated the solution, the greater the film's optical clarity will be. With proper parameter adjustment, the variation in surface can be less than 20Å. Figures 11 and 12 are electron micrographs of chemically sprayed films which appear amorphous and highly crystalline, respectively, when examined by x-ray diffraction. With an increase in the rate and solution concentration. it is possible to deposit films which range from glasslike to frosty in appearance. Whether the films are transparent or translucent, if they have been properly deposited, their adherence to the substrate should be such that mechanical abrasion is necessary to remove the film from the substrate.

Applications

The chemical spray process has been used successfully to deposit a great many compounds, some of which are listed in Table III.

Table III. Chemically spray deposited materials

I B VI A	II B VI A	III A VI A	III B VI A	IV A VI A	V A VI A	VIII	II B III A VI A	II B II B VI A

Ag_2S	ZnS ZnSe	Ga_2S_3 Ga_2Se_3	SmS	PbSe				

The electrical and physical characteristics of chemically sprayed films are such that several significant devices have been developed.

The original application of sprayed films was in the area of photoconductivity; this application resulted in photoconductors (using films of about 1μ in thickness) made of CdS, Cd(SSe), and CdSe whose sensitivities are at least equal, whose rise and fall response times are normally faster, and whose spectral responses are broader than photoconductors made of these compounds by other processes (8).

Subsequent applications of the chemical spray process have been in the areas of photoluminescent and cathodoluminescent thin film layers which have shown extremely high (> 3,000 line pairs/in.) resolution, and in the area of thin film solar cells (9) (photovoltaic converters) where through the use of two sprayed films, one deposited on another (0.1μ film of $Cu_{2-x}S$ on a 1μ film of CdS) cells have been made with efficiencies of 4% in small areas and open-circuit voltages as high as 1.04v have been measured.

Fast Etching Imperfections in Silicon Dioxide Films

A. D. Lopez

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Fast etching imperfections in silicon dioxide films can produce pinholes when the film is partially thinned in buffered hydrofluoric acid. This paper proposes a model for the formation of these pinholes and also describes a means of detecting the pinholes. Furthermore, it is shown that the diffusion rate of phosphorus is greater in the imperfection than in the pure silicon dioxide. The cause of these imperfections is shown to be surface contamination prior to oxidation.

Samples of silicon dioxide films were checked for dielectric breakdown by application of a field between the bulk silicon and an evaporated metallic contact on the surface of the film. In general the breakdown field is found to be approximately 80-90v per 1000Å of oxide. However, if the oxide film is thinned by etching in a hydrofluoric acid etch, the breakdown field drops to a value near zero indicating that the oxide film no longer acts as a dielectric barrier. This is attributed to pinholes in the oxide film.

Consider two samples of silicon, one oxidized in atmospheric steam to a thickness of 6000Å, and the other, which is a control, to 3000Å (see Fig. 1a). The pipe-like structures running through the oxide film are fast etching imperfections which will be called potential pinholes. The potential pinhole has two characteristics. First, it has a much faster etch rate than pure silicon dioxide in the hydrofluoric acid etch and, second, its breakdown field is comparable to that of silicon dioxide. The 6000Å sample is now etched to a thickness of 3000Å in the hydrofluoric acid solution. The proposed model is one in which the pipe-like structures or potential pinholes will etch away because the potential pinhole is a region which etches much faster than SiO_2. This leaves a physical hole in the oxide which may extend to the SiO_2-Si interface as shown in Fig. 1b.

This model is tested by evaporating metallic contacts on the surfaces of the etched and unetched oxide films. If the model is valid, the evaporated metal will fill up the pinholes and consequently make contact to the bulk silicon as shown in Fig. 1c. Actually, the metal will make contact to the 20-30Å of oxide which forms immediately after etching. The breakdown voltage of this small thickness of oxide can be neglected since it is so small. The dielectric breakdown is now measured on the etched and unetched oxide films both of which are now 3000Å thick. One finds that the breakdown voltage of the unetched oxide is approximately 250-300v whereas on the etched oxide the breakdown voltage is in the order of 5-10v. It is concluded that contact has been made to the bulk silicon in the etched sample via a pinhole which must have been created by partially etching the film. Furthermore, it can be seen that the breakdown voltage

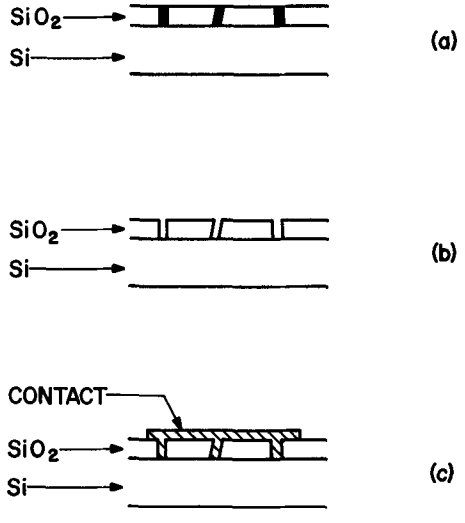

Fig. 1. Fast etching imperfections in SiO_2

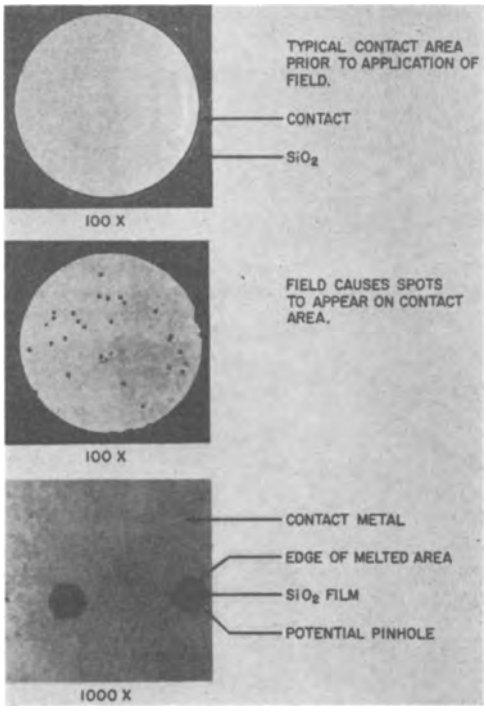

Fig. 2. Effect of applied field on contact metal

of the potential pinhole is comparable to pure SiO_2 since the unetched sample withstood 250-300v before breaking down.

Properties of the Potential Pinhole

Figure 2 shows metal contact areas on a film of silicon dioxide which was not etched. When a field is applied from the contact to the bulk silicon, the following observation is made: as the field is increased to a value near breakdown, spots begin to appear on the contact area. At first a few appear but as the field is increased to breakdown, the spots multiply until finally the oxide breaks down. Inspection of these spots at high magnification indicates that they are areas where the contact metal has melted. From a previous argument, it is reasonable to believe that the material which makes up the potential pinhole may have a dielectric strength somewhat less than pure SiO_2. Therefore, it seems reasonable that the spots are caused by conduction of current through a potential pinhole, where breakdown occurs first, causing the contact metal to heat up locally and melt. The contact material used was either gold or aluminum. The effect was not dependent on polarity.

It has been established that the material which makes up the potential pinhole is not pure SiO_2. Therefore, it is reasonable to expect a difference in the diffusion rate of phosphorus in SiO_2 and in the potential pinhole. This is borne out by the following experiment: a p-n junction was provided with a p-type layer approximately 1.5μ thick and a sheet resistance of 150 ohms per square. The sample was oxidized in 1 atm of steam to a thickness of 6000Å. Next, the sample received a phosphorus diffusion, such that only a part of the oxide was penetrated by the phosphorus. The penetrated oxide was then removed in buffered hydrofluoric acid, and metal contacts were evaporated on the oxide film. The breakdown voltage of each contact was measured, and on 25% of the dots the reverse characteristics of a p-n junction were observed with a breakdown of 6v. This breakdown voltage is what one would expect had the phosphorus penetrated completely through the oxide so that an n-p junction was made. It is concluded that where a 6v breakdown occurred, phosphorus must have diffused through the oxide forming an emitter base junction. Since the thickness of the masking oxide was great enough to mask the phosphorus diffusion, any phosphorus which appears in the "p" region must have diffused through a potential pinhole. If the phosphorus diffusion is omitted and contacts are applied to the oxide, no p-n junction reverse characteristics are observed. This indicates that any diffusion which takes place must be due to the presence of an external phosphorus source and not any source contained in the oxide.

In looking for the cause of the potential pinhole, it is reasonable to suspect surface contamination prior to oxidation. It has been found that if a sample of epitaxial silicon is oxidized directly after growth, the resulting oxide is essentially free of fast etching imperfections. Oxide films grown in this manner were subjected to repeated etchings and still were pinhole-free. It would seem, therefore, that surface contamination, which is minimized in this case, plays a significant role in the formation of fast etching imperfections.

Single Crystal Growth of SnTe and GeTe

P. F. Weller[1]

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York

Single crystals of SnTe and GeTe about 6 in. long and ⅜ in. in diameter were pulled from the melt by the Czochralski technique. A description is given of these crystals, together with the starting material synthesis and the crystal growth apparatus and procedures.

It was necessary to use a "graphite piston" puller with heated walls, similar to that used for PbTe (1), since SnTe and GeTe have vapor pressures at their melting points of 0.86 (2) and 17 (3) mm Hg, respectively.

Brief mention of Czochralski crystal growth of SnTe has been made by Allgaier and Houston (4) and by Brebrick (5), but no detailed information is generally available.

Starting Materials

Purification of elements.—SnTe was prepared from 99.9999% Sn shot obtained from Cominco Products, Inc. and 99.999% Te from American Smelting and Refining Company. The Sn, contained in a quartz boat, was fired in flowing H_2 at about 800°C for 1 hr. The charge was frozen and then refired in H_2 at 800°C for one more hour after the surface had been scraped clean. Tellurium was fired in flowing H_2 at 800°C for about ½ hr. Both the sublimed Te and the ingot remaining in the quartz boat were used for compound synthesis.

[1] Present address: Department of Chemistry, State University College, Fredonia, N. Y.

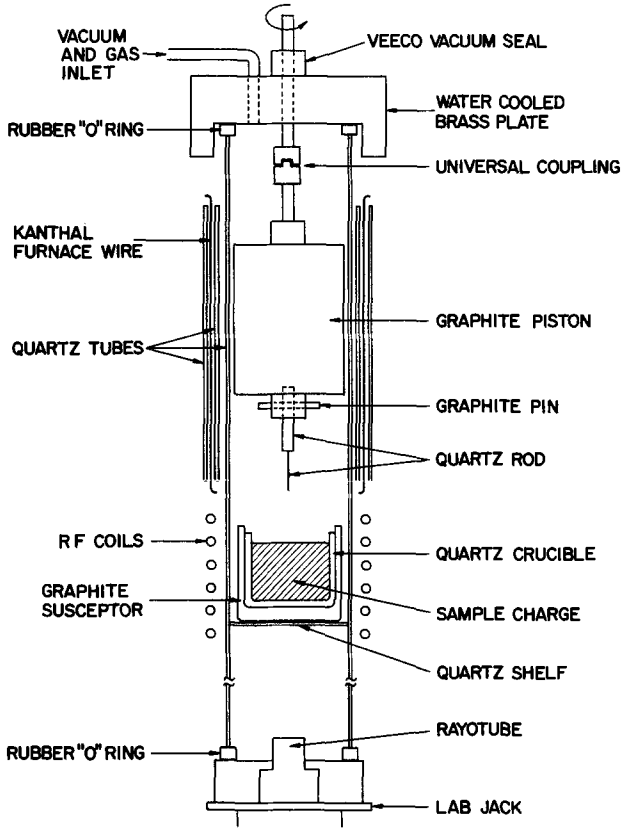

Fig. 1. Crystal puller

GeTe was prepared from instrument grade Ge, obtained from the Eagle-Picher Company, which had been zone refined until it was essentially intrinsic (resistivity of 45-50 ohm-cm). The Ge was then etched with a CP-4 solution and rinsed in water, ethyl alcohol, and finally acetone.

Compound synthesis—Stoichiometric amounts of Sn and Te were placed in a quartz tube, with the Sn resting above the Te in a quartz boat. The tube was evacuated to about 10^{-6} mm Hg and sealed off. Generally, this tube was placed in another quartz tube which was subsequently sealed under vacuum. This was purely a precautionary measure to prevent access to the air if the inner tube broke during synthesis. This had been a particular problem in PbTe synthesis (1).

The charge was then heated with a hand torch until the Sn began to melt (231.9°C) and to run down into the Te(mp 450°C). This had to be done carefully so that local overheating from the large heat of reaction did not occur. When the Sn and Te were entirely mixed and all visible reaction was complete, the tube was placed in a Kanthal furnace and heated to 825°C over a 6-hr period, and then cooled in the furnace to room temperature overnight.

The GeTe synthesis was similar, except for the initial heating procedures. Chunks of Ge and Te were premixed in the quartz tube and carefully heated with a hand torch until the visible reaction ceased. The higher melting point of the Ge (937°C) (6) permitted better control of the rate of reaction in this case. The above heating cycle was then used.

Apparatus

The crystal puller is shown in Fig. 1. A 2.1 in. OD quartz tube, 33-34 in. long, was clamped between rubber "O" rings by means of a "Lab Jack" at the bottom. A quartz shelf, located exactly 12 in. above the Rayotube temperature sensing device, divided the tube into two sections. A 1¾ in. tall, 1⅞ in. OD, ⅛ in. wall, graphite susceptor held the cylindrical quartz crucible (G.E. 204 A quartz, 1½ in. tall, 1½ in. OD, 1/16 in. wall) into which the sample charge was placed. A 3/32 in. quartz seeding rod, 1¾ in. long, was sealed to a ¼ in. quartz rod 2-2½ in. long, which was attached to the 5 in. long graphite piston with two graphite pins. The piston, machined to a 1/16 in. tolerance for a particular tube, was attached to a ¼ in. stainless steel rod, then to a similar rod through a universal coupling, and finally through a Veeco vacuum seal to the rotation motor.

The graphite susceptor was heated inductively, using a 5 kw Ecco RF generator at 450 kc/sec. Temperature was sensed by a Rayotube and controlled with a L&N, type H AZAR recorder and associated CAT controller. Temperature control was ±1°C or better, and desired changes were made easily and quickly.

An external furnace consisting of two concentric quartz tubes with longitudinal, Kanthal windings between the tubes kept the temperature of the upper chamber at the desired level with a minimum of visual obstruction. Temperatures were sensed with a chromel-alumel thermocouple and controlled with a West Gardsman controller.

Growth Procedure

About 200g of SnTe or GeTe chunks were packed in the crucible. This amount of material gave a melt volume about ¾ that of the crucible volume. Lower melt volumes caused difficulties in initial nucleation onto the quartz rod. This problem would probably be alleviated considerably if rather large diameter (about ¼ in. or more) SnTe or GeTe seeds were used.

After the external furnace had reached the desired temperature of 600°-650°C for SnTe and 400°-450°C for GeTe, the system was flushed several times and filled to about 3 psi with Ar or He. The charge was then melted [SnTe ~ 805°C (5, 7) and GeTe ~ 725°C (8)]. Generally, the melt surfaces were not completely clean. If too much surface scum was observed, the charge was frozen, the surface layer ground off, and the charge remelted. One such treatment usually reduced the surface contaminant to an acceptable level so that most of the remainder migrated to the crucible walls or to the first-formed polycrystalline boule. In either case the center portion of the melt was rendered essentially free of contaminants. [Care should be taken when melting a SnTe or GeTe charge if it fits snugly in the crucible. This would be the case, for example, with a charge that had solidified in place. Rapid heating, *i.e.*, to about 400°C in 5 min or so, caused several of the quartz crucibles to crack because of vastly different coefficients of expansion. Most of the charges were broken up to prevent this problem.]

When a sufficiently clean melt surface was obtained, an experimental crystallization temperature was determined by slowly lowering the temperature and noting the point at which freezing began. The temperature was then raised about 20°C. The quartz seed rod was dipped about ¼ in. into the melt, and the temperature was then decreased until nucleation on the rod was observed. Pulling was begun after temperature stabilization was attained. Pull speeds ranged from 1 to 3 in./hr, with the lower values generally preferable. A rotation rate of about 15 rpm was satisfactory.

The diameter of the polycrystalline boule was increased to about ¼ in. by slowly decreasing the temperature. The diameter was then slowly decreased again to 1/8-1/16 in. by carefully raising the temperature. This procedure generally yielded a single crystal, as indicated by reflections from developing faces as the crystal rotated. The crystal was then necked out to the desired diameter (usually less than ½ in.) by careful temperature control. Generally, rather large increases and decreases in temperature (2°-5°C or so) were necessary to show noticeable changes in crystal diameter. This is in sharp contrast to PbTe crystal growth where very small temperature variations cause large crystal diameter changes (1).

A problem was encountered in obtaining crystal diameters larger than about ⅜ in. A shelf formed at the side of the crucible and interfered with the growing crystal. The shelf was caused by the migration of surface impurities to a cold spot on the crucible. This problem could probably be helped considerably by rotation of the crucible. Other difficulties found in PbTe crystal growth (1) such as copious vaporization and rapid dendrite growth on the chamber walls and on the grown crystal, leading to poor visibility, were not severe problems with SnTe or GeTe.

The grown crystals were about 6 in. long and ⅜ in. in diameter and generally had large flats (faces). Crystal surfaces were sometimes shiny and metallic in appearance and sometimes had a powdery texture. All as-grown, undoped crystals showed p-type conductivity and grew with random orientation.

Preparation of Doped Germanium for Far Infrared Detectors

E. M. Swiggard and H. Shenker

United States Naval Research Laboratory, Washington, D. C.

Efficient, extrinsic germanium detectors for the far infrared are now well known (1, 2). In order to maximize the performance of these detectors it is necessary to have material with a low concentration of compensating impurities, *i.e.*, donor impurities in a p-type material or acceptor impurities in an n-type material. It is also necessary to have low-noise electrical contacts to the detector to realize maximum signal-to-noise ratios. This work deals with the procedures developed to prepare low-compensation ($<4\times10^{12}$ cm^{-3} compensating impurities) boron- and gallium-doped germanium detector material and low-noise grown contacts. Horizontal zone refining and crystal growth techniques were used throughout this work.

The concentration of compensating impurities (assumed singly ionized) was obtained by measuring the Hall effect *vs.* temperature characteristics of each sample and analyzing these measurements by the methods described by Blakemore (3) and Putley (4).

Boron-doped germanium is a natural choice for the manufacture of low-compensation materials since boron is the only electrically active impurity in germanium with a distribution coefficient greater than one. It, however, suffers from the difficulty that a large amount of the boron is lost from the ingot during the zone refining process. This is presumably due to the oxidation of the boron by trace oxidants in the system as discussed by Bridgers and Kolb (5). The use of high-purity palladium-diffused hydrogen did not remedy this difficulty. In order to obtain the desired material, the loss of boron per pass was measured, and sufficient extra boron was put in to correct for the boron loss. It was found that after eight zone passes only from 0.1 to 1% of the original boron remained as electrically active boron in the ingot. Several ingots were grown using this estimation procedure. One of these ingots contained a zone-leveled portion 6 cm long over which the concentration of boron remained within 20% of the average value. The concentration of compensating impurities was measured on two samples from another of the ingots and was found to be 1×10^{12} and 1.5×10^{12} cm^{-3}, respectively. Detectors made from this ingot yielded the excellent detectors described in ref. (1).

Because of the inevitable variability of the loss of boron in purifying an ingot, it was difficult to prepare zone leveled boron-doped germanium of a predetermined doping level. For this reason it was desirable to be able to prepare low-compensation germanium using another group III dopant. Two methods of preparing low-compensation gallium-doped germanium were developed.

The first method utilizes the fact (6) that the slope of the ultimate distribution of an impurity is very sensitive to the distribution coefficient of the impurity, the smaller the distribution coefficient the steeper the slope. Since gallium has one of the largest distribution coefficients ($k = 0.087$) of any dopant in germanium the slope of its ultimate distribution is less steep than the slopes for most other impurities. For example, if there are equal numbers of gallium and arsenic ($k = 0.02$) atoms in a germanium ingot, then the ratio of arsenic to gallium concentrations is 0.0009 at a point four zone lengths from the final end of the ingot having the ultimate distribution of each of these dopants. Essentially this method uses this purification effect for reducing the compensation. In practice, a small piece of gallium was placed on the end of a previously zone refined ingot of germanium and ten additional zone refining passes made. A zone about 2.5 zone lengths (the exact distance depends on the desired gallium concentration) from the final end of the ingot was then melted and carried to the beginning end of the ingot. The first 10 cm of the ingot was then zone leveled. A sample cut from this ingot was measured to have a gallium concentration of 1.2×10^{14} at. cm^{-3} and a compensating impurity concentration of 4×10^{12} at. cm^{-3}.

The second method of preparing low-compensation gallium-doped germanium used a pellet-dropping technique adapted to horizontal crystal growth. While pellet-dropping to achieve varying doping levels and p-n junctions is a common procedure in connection with the Czochralski method of crystal preparation, its adaptation to horizontal crystal growth appears to have been neglected. The experimental apparatus is shown in Fig. 1. A quartz spoon which holds the dropping pellet containing the proper amount of gallium-doped germanium was inserted into the zone refining tube through an "O" ring connector. Previously zone refined germanium was placed in the zoner with a seed crystal, and 6-10 zone refining passes were taken to remove any impurities introduced during the handling and etching of the germanium. A zone was then melted toward the front end of the ingot and the

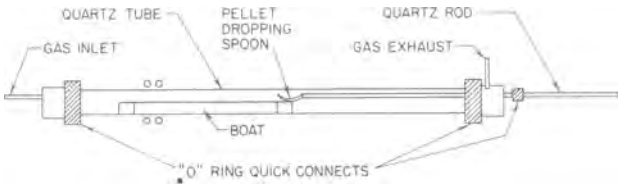

Fig. 1. Horizontal pellet dropping apparatus

pellet dropped into this molten zone. The pellet dissolved very rapidly, and the zone was backed up slightly to remelt the polycrystalline growth caused by the sudden temperature drop in the zone. The zone is then carried out to the end of the ingot. A sample cut from an ingot grown in this manner was measured to have a gallium concentration of 1.2×10^{14} at. cm^{-3} and a concentration of compensating impurities of 2×10^{12} at. cm^{-3}. Detectors made from material grown by either of these methods proved to be excellent detectors (2). A detector which used a piece of gallium-doped germanium grown by the pellet-dropping method was found to have a detectivity of 3.1×10^{11} cm-$cps^{1/2}$-W^{-1} at 104μ which is the highest detectivity for any detector of this type measured to date at NRL.

The chief source of extraneous current noise in these detectors appears to be associated with the contacts to the detector element. In order to reduce this current noise p^+-p single-crystal contacts were grown by placing a heavily doped piece of germanium on each end of a 1 cm section of gallium-doped germanium detector material. The boat containing these pieces was placed in the zone refining apparatus and the contact piece was melted. The rf coil was then moved until the molten contact piece wet the detector section and melted it back slightly; the coil was then slowly withdrawn (5 cm/hr) and a single crystal contact was grown. The same procedure was followed with the other contact. It was found that when boron was used for the p^+ dopant the lowest noise contacts were obtained (7); however when indium was used for the p^+ dopant relatively high noise contacts were obtained. Because the distribution coefficient of boron is greater than unity it forms a sharper junction than indium which has a distribution coefficient of 0.001 in germanium; it is presumed that an abrupt p^+-p junction is required for a low noise junction.

In order to carry out the procedures described above it is essential that single crystal growth be easily maintained. This was accomplished by using a quartz boat with a close-fitting graphite sleeve as shown in Fig. 2. The end pieces shown on top of the figure were used to raise the graphite sleeve off the quartz reaction tube and to prevent the boat from sliding out of the graphite sleeve. The boat was sand-blasted and blackened with soot from a paraffin candle. On top of the sooted layer there was deposited a thin layer of

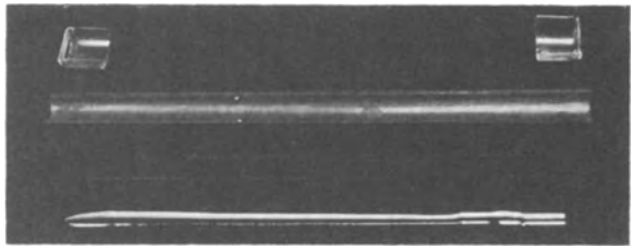

Fig. 2. Components of the crystal growing boat arrangement. The upper pieces are two quartz supports, the next lower piece is a graphite sleeve, the next lower piece is the quartz boat covered with soot and pyrolytic carbon. The bottom piece is a typical germanium ingot.

pyrolytic carbon which was obtained from the decomposition of acetone at 800°C. Before use the boat and graphite sleeve were heated at 1000°C in a stream of pure hydrogen to drive off any water or unreacted organic material. The graphite sleeve is a simple but effective method of obtaining a vertical, freezing interface in the germanium ingot. Single crystal growth was reliably maintained at all speeds up to 20 cm/hr. The pyrolytic carbon layer on top of the soot layer serves to stabilize the soot layer and has permitted the use of the same boat many times without recoating.

The Vapor Pressure of Iodine in the Temperature Interval 43°-80°C

M. Berkenblit and A. Reisman

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York

In an earlier study of the reactive transpiration in the system Ge-I_2-He, we had occasion to determine the vapor pressure of iodine at 50.5° and 61.8°C for comparison with literature values to insure against the possibility of large systematic errors affecting our results (1). The values obtained by us at the two temperatures were found to differ from those reported by Baxter and Grose (2), who also employed a transpiration technique, by 3.7% at 50.5° and 2.3% at 61.8°. Since our data showed an average deviation of 2-3% due, it is believed, to an end point inaccuracy in the thiosulfate titration as well as some tendency for solutions of the reducing agent to oxidize during the analysis (due to trace quantities of O_2 in the carrier gas),

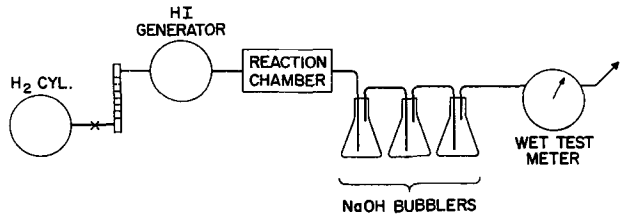

Fig. 1. HI determination apparatus schematic

we had no reason to question the earlier work at that time. Furthermore, as the absolute values of vapor pressures were less important than demonstrating that gas saturation was achievable at all flow rates in our system, subsequent Ge-I_2 reaction computations were based on iodine data reported by Baxter and Grose.

More recently, in quantitative kinetic studies of the Ge-HI reaction (3), the literature iodine data came under greater scrutiny because of the effect errors in the absolute values of the I_2 vapor pressure would have on determinations of the reaction order. We had developed an HI generator in the intervening time period which suggested a new approach to the determination of the vapor pressure of iodine in which the iodine was converted to hydrogen iodide and the latter was then quantitatively estimated via an acid-base volumetric procedure. This technique is clearly superior to the thiosulfate method employed in our earlier work. In addition, it seems subject to far less cumulative error than would be expected in the involved gravimetric analysis resorted to by Baxter and Grose.

During the course of the studies to be described, we demonstrated that the modified iodine source design employed was capable of equilibration with H_2 carrier gas input flow rates of up to *ca.* 8 liters/min in the temperature interval 43°-80°C.

Experimental Procedure

Figure 1 is a schematic representation of the HI analysis train. The system consists of a controlled carrier gas supply (Matheson "ultra pure" H_2 was used without further purification) to an HI generator followed by a reaction chamber. To this point, the apparatus is the same one employed in the Ge-HI kinetic studies of ref. (3). For the purpose of the present study it was necessary to provide a means for trapping and reacting HI and measuring the volume of carrier gas. This was accomplished via 3NaOH bubblers and a "Precision" wet test meter. The design of the HI generator and its operation has been described previously in detail (4), as have modifications in the iodine source bed length to accommodate high flow rates needed for the kinetic studies (3).

The experimental procedure followed was to place three traps in the line, each containing a measured quantity of standardized 0.1*N* NaOH solution diluted to a final volume of 100 cc. The entire system was flushed for 15 min with H_2 through the bypass portion of the HI generator. The carrier gas was then passed through the iodine source and catalyst chamber. The effluent HI-H_2 mixture is then depleted of HI in the standardized NaOH solution traps, the wet H_2 volume being finally measured in a calibrated wet test meter. After passage of given volumes of carrier gas, 6-21 liters, the iodine source was bypassed and the system was flushed for 30 min to insure complete removal of entrained HI. Analysis of the unreacted NaOH remaining in the bubblers was effected by titrating with a standardized 0.1*N* HCl solution. All of the HI generated was found to have reacted in the first two bubblers, with the final chamber providing a titration blank for the experiment. From these titrations the milliequivalents of HI and I_2 per volume of H_2 were determined.

Table I. Summary of I_2 vapor pressure calculations

T°C	p_{I_2} (Torr)	meq. HI titration
43.0	1.19	2.636 ± 0.004/21.00 l
49.35	1.90	4.195 ± 0.007/21.00 l
58.1	3.54	5.641 ± 0.002/15.00 l
68.0	6.86	8.788 ± 0.023/12.00 l
79.95	14.33	9.455 ± 0.002/ 6.00 l

Results and Discussion

Iodine vapor pressures were calculated with the aid of Eq. [1]. Assuming ideal gas behavior and a constant value of atmospheric pressure (1 atm), the partial pressure of iodine is given by

$$p_{I2(Torr)} = \frac{n_{I_2}}{\left[n_{I_2} + \frac{V}{RT_M}\left(\frac{760 - p_{H_2O(Torr)}}{760}\right)\right]} 0.760 \quad [1]$$

where n_{I_2} is the number of moles of iodine, determined by titration, that are carried in the volume V measured at a wet test meter whose temperature is T_M and where p_{H_2O} is the vapor pressure of water at T_M.

Table I contains the titration results and I_2 vapor pressures that were calculated from these data. The

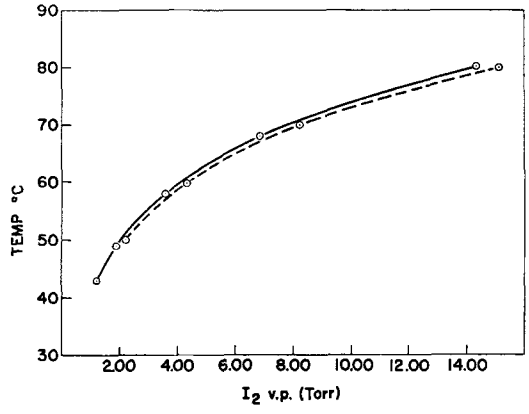

Fig. 2. Variation of I_2 vapor pressure with temperature: ---, Baxter and Grose; ——, present investigation.

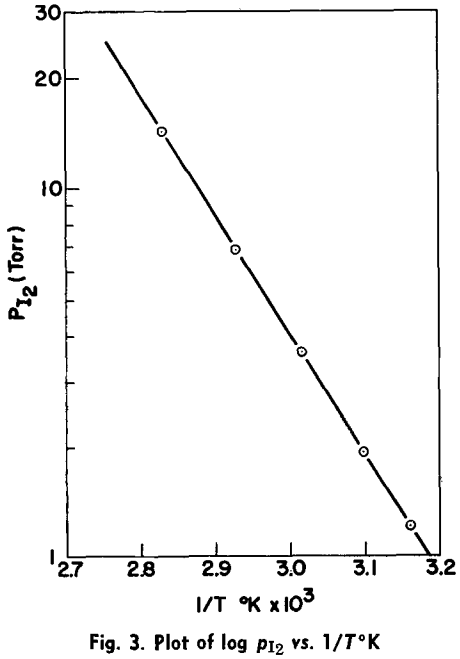

Fig. 3. Plot of log p_{I_2} vs. $1/T$°K

deviation observed was 0.2% in the worst case. A comparison of the Baxter and Grose data with those of the present study is shown by a plot of the variation of I_2 vapor pressure with temperature in Fig. 2. It can be seen that there is approximately a 5% difference between the two sets of results through the entire temperature range.

A plot of log p_{I_2} *vs.* 1/T°K, as shown in Fig. 3 yields a straight line described by Eq. [2]

$$\log p_{HI}(\text{Torr}) = \frac{-3.25 \times 10^3}{T°K} + 10.35 \qquad [2]$$

The slope of this curve has a value of 14.9 kcal/mole which is in exact agreement with $\Delta H°_{298}$, the heat of sublimation at 298°K, calculated from third law considerations using the free energy functions in Stull and Sinke (5). This is to be compared with the mean value of 14.7 kcal/mole reported by Baxter and Grose whose calculated values ranged between 14.6 and 15.0 kcal/mole.

Influence of Temperature on Illustrations of the Adoption of Limiting Values of Hydride Vapor Pressure and Hydrogen Contents by Highly Surface-active Cathodes of Palladium Alloys

J. A. S. Green and F. A. Lewis

Chemistry Department, The Queen's University of Belfast, Belfast, Northern Ireland

Measurements of the electrical resistance and electrode potential of cathodes of certain palladium alloys at 25°C have provided evidence (1) that, with highly catalytically active surfaces, the hydrogen content of the cathodes (expressed here as H/Me, the atomic ratio of hydrogen atoms to the total number of metal atoms) tends toward a limiting value over the range of current densities spanning the onset of the evolution of bubbles of gas. Such measurements also provided evidence that the adoption of limiting hydrogen contents results from the development of a limiting supersaturation of the catholyte with hydrogen molecules prior to the evolution of bubbles, and not to a limiting solubility of hydrogen within the cathodes.

At the limit of supersaturation, the concentration of dissolved hydrogen molecules, $C_{(\text{lim})}$, may be regarded as in equilibrium with a hypothetical equivalent pressure of hydrogen gas, $P_{(\text{lim})}$. The hydrogen content of the cathode under these conditions may, in turn, be designated H/Me$_{(\text{lim})}$, and its corresponding hydride vapor pressure designated $p_{(\text{lim})}$, where $p_{(\text{lim})}$ should equal $P_{(\text{lim})}$ in the steady state during electrolysis.

For palladium and some palladium alloys, electrical resistance (often conveniently expressed as relative resistance, R/R_o, where R_o is the "hydrogen-free" value) increases approximately linearly with increase of H/Me, and then exhibits a decrease following a relatively broad maximum. The relationships between H/Me and R/R_o can be virtually independent of temperature over appreciable ranges of H/Me (2).

The basis of illustrations of the attainment of limiting values by p and H/Me lies in the form of the pressure (p)-composition (H/Me) isotherms for the alloys. These should be such that there will be only a relatively small increase of H/Me for values of p up to $p_{(\text{lim})}$. This increase of H/Me then should be reflected by only a small increase of R/R_o up to $R/R_{o(\text{lim})}$. Any absorption of hydrogen in excess of H/Me$_{(\text{lim})}$ then can be reflected by substantial further changes of R/R_o.

At 25°C, alloys with ~20% Ni and ~25% Rh have been found satisfactory in these respects (1). Results in Fig. 1 indicate how other alloys can provide good demonstrations at other temperatures.

Figure 1a illustrates that, at 25°C, a highly catalytically active cathode of an 18.99% Pt alloy can exhibit relatively substantial increases of R/R_o during electrolysis at "160 ma cm^{-2}. This current density is sufficiently high for vigorous evolution of hydrogen bubbles to be occurring in the steady state. Changes of R/R_o during electrolysis were measured by an a-c bridge, and the electrolyte was in fairly low concentration in order to reduce errors in R/R_o due to co-conduction of the bridge current through the solution.

With increasing temperature, alloys of the Pd + Pt series exhibit (2, 3) a general decrease of the value of H/Me corresponding with any value of p. Results

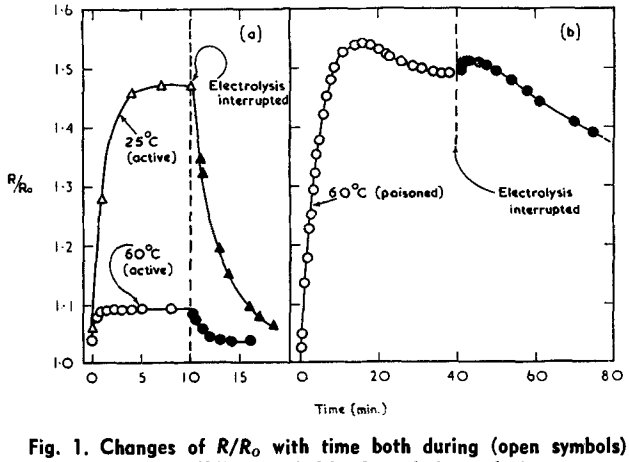

Fig. 1. Changes of R/R_o with time both during (open symbols) and subsequent to (filled symbols) electrolysis in hydrogen-saturated 0.02*N* HCl for ~8 cm lengths of a 0.0122 cm diameter wire of an 18.99% Pt-91.01% Pd alloy coated thinly with palladium black. Prior to electrolysis, the "active" specimens [Fig. 1(a)] had absorbed hydrogen from solution until they assumed a "zero" electrode potential with respect to a Pt/H_2 reference electrode in the same solution.

in Fig. 1(a) indicate that the value of H/Me corresponding to $p_{(lim)}$ had become so much lower at 60°C that the highest value of R/R_o which could be attained during electrolysis was now only ~1.1 in the case of a highly catalytically active specimen.

Prior to an otherwise duplicate experiment at 60°C, a further 18.99% Pt specimen was immersed in an arsenical solution. This caused its surface to be poisoned for equilibration with hydrogen molecules. Consequently the concentration of hydrogen atoms on its surface during subsequent electrolysis was likely to exceed (1, 4) the concentration of atoms complementary with $p_{(lim)}$.

Absorption of hydrogen by this poisoned specimen in excess of $p_{(lim)}$ is indicated in Fig. 1(b) by the substantial increase of R/R_o beyond 1.1, and by its subsequent passage through a maximum.

Figure 1(b) also shows that, after interruption of electrolysis, a maximum also is exhibited by plots of R/R_o against time during the relatively slow desorption of hydrogen from such poisoned specimens.

Acknowledgment

The authors are indebted to the International Nickel Company (Mond.) Limited for providing palladium alloys.

Brief Communication

Phase Diagram of the Pseudo-Binary System Ge-GaAs

R. M. A. Lieth and H. J. M. Heyligers

Solid State Physics Group, Department of Technical Physics, Technical University, Eindhoven, The Netherlands

The main object of the work of Jenny and Braunstein (1, 2) was to find the miscibility range for solid solutions of Ge and GaAs. In this paper we report the phase diagram for the system Ge-GaAs, determined by means of thermal analysis in the region 100% Ge to Ge-35 mol. % GaAs. The eutectic composition lies at 25 mol. % GaAs at a temperature of 862° ± 2°C. In the course of our work two articles appeared in the literature. Glazov *et al.* (3) report an eutectic alloy at 18.7 mol. % GaAs at a temperature of 888° ± 3°C. Takeda *et al.* (4) found the eutectic composition at 15 mol. % GaAs at a temperature of 865° ± 2°C.

The alloys were made by melting together the components[1] in silica ampoules with thermocouple holes in the top. These ampoules were sealed off after evacuation to 10^{-3} mm Hg. After fusion the Ge-GaAs melts were kept at 1250°C for 3 hr, while occasional shaking insured a thorough mixing of the contents. The thermal analysis of these alloys was made by recording the cooling curves with a Honeywell automatic measuring bridge.

From the constant part in the time-temperature curves a Tamman triangle was constructed, which enabled us to check the position of the eutectic composition.

The cooling rate was 10°C/min. Silver and sodium chloride were used as reference materials.

[1] Monocrystalline GaAs was obtained from Monsanto; monocrystalline Ge was provided by the Materials Science Group of our Physics Department.

In Table I the melting points of the various alloys are listed. The eutectic temperature of 860° ± 2°C is in good agreement with the work of Takeda *et al.* who reported 865° ± 2°C; however their eutectic composition of 15 mol. % GaAs differs from bur work.

The eutectic temperature of 888° ± 3°C found by Glazov *et al.* is higher than that found by Takeda and in our work. The corresponding eutectic composition of 18.7 mol. % GaAs, which is in good agreement with the work of Takeda, differs from our eutectic composition.

Acknowledgment

The authors thank Professor G. Diemer for his continuous interest in this work.

Polarization Studies on Sintered Plate Electrodes Containing Various Amounts of $Ni(OH)_2$

E. Jost and F. Rufenacht

Metals & Controls Inc., A Corporate Division of Texas Instruments Incorporated, Attleboro, Massachusetts

ABSTRACT

Porous, sintered plate, nickel oxide electrodes containing varied amounts of active material (nickel hydroxide) were investigated with a single pulse interruption technique. Double layer capacitance measurements and long time overvoltage decay suggest that the nickel hydroxide deposited in the pores in sequential impregnations is deposited as a sponge of discrete particles. The available surface area proves, therefore, to be proportional to the $Ni(OH)_2$ weight. The long decay times indicate solid-state diffusion or relaxation phenomena on top of liquid concentration overvoltage, which becomes increasingly important with heavily impregnated electrodes.

Some investigations on the film-type nickel oxide electrode seem to suggest that the thickness of the nickel hydroxide layer not only influences the polarization behavior but also strongly influences the coefficient of utilization of the active material. Wynne-Jones (1, 2) prepared film-type electrodes of thicknesses ranging from approximately 1000 to 250,000Å and found electron yields on discharge ranging from 1.5 to 0.2 electrons per Ni for thin and thick films, respectively. Thin films up to 10,000Å were prepared by electrodeposition of nickel hydroxide on nickel substrates, thick films by oxidation of nickel surfaces with hypochlorites, and the results of the two preparation methods may not be directly comparable. However, thickness effects were clearly present in films prepared by the same method.

The electrochemical measurements of Kuchinskij and Ershler (3) on a large grain of nickel oxide in an alkaline electrolyte established the existence of a controlling solid-state diffusion mechanism which leads to the depletion of conductive species in the surface layer of the grain and ultimately, to the formation of an insulating $Ni(OH)_2$ layer at the conductor/nickel oxide interphase, which prevents the reduction of the higher valence, conductive interior of the grain.

Such a mechanism would explain the lower coulombic efficiency of thicker nickel oxide layers if the surface-to-volume ratio decreases in thicker layers or, in other words, if the specific surface area of nickel oxide does not remain constant as the layer is increased.

The existence of such potential determining surface layers was also discussed by Conway *et al.* in the series of papers on the nickel oxide electrode (4-7). These authors used a technique for their investigation similar to the one described in this paper.

In view of these findings, it would seem reasonable to expect that porous sintered electrodes may show similar effects if the pores are coated with nickel oxide films of various thicknesses.

On the other hand, since the methods of preparation of film-type electrodes and porous electrodes differ, the morphology of these layers could vary greatly. On the one extreme, the successive impregnation cycles in porous electrodes could build up epitaxial nickel oxide layers, and the available surface would remain constant or slightly decrease with every impregnation step. This surface would be an image of the internal surface area of the porous nickel-carbonyl plaque structure or approximately 0.1-0.2 m^2/g of plaque.

On the other extreme, the nickel oxide would be deposited as very small discrete particles independent of the previous deposit. In this case, the available surface area would increase in proportion to the increase in nickel oxide weight or, in other words, the specific area of nickel oxide would be constant and of the order of magnitude of several square meters per gram of plaque.

Such differences in available surface area would result in widely different polarization behavior of the electrode.

Experimental

The porous plates used in this investigation were 5 x 5 cm squares and approximately 1 mm thick. The average pore size was approximately 10μ, the porosity approximately 80%, and the BET surface area 0.1-0.2 m^2/g.

Ten plaques were washed with trichloroethylene in a Soxhlet extraction apparatus and vacuum impregnated with a nickel nitrate solution containing 0.25g of nickel/cm^3. The plaques were then immersed in 25% NaOH at 100°C, cathodically polarized at 170 ma/cm^2 for 30 min, washed with distilled water for 3 hr, and dried. This impregnation cycle was repeated up to ten times. Test plates were withdrawn after one, three, six, and ten impregnation cycles, respectively. In addition, two plaques were impregnated with diluted nitrate solution with a nickel content equivalent to one-third of the normally concentrated nickel nitrate solution. These plates are referred to as one-third impregnation plates.

Table I shows the plate loading for these plates.

The plates were assembled into cells using porous sintered plate cadmium counter electrodes of approximately ten times excess capacity. The cells were flooded with 30% KOH electrolyte and equipped with Hg/HgO reference electrodes in 30% KOH solution.

The cells were closed to avoid access of atmospheric CO_2.

After conventional forming, the cells received five charge and discharge cycles at a rate corresponding to the one used during the particular experiment, usually the 1- or 2-hr rate. In all cycles, the charge put into the cells was 140% of the theoretical electrochemical capacity.

Results

The most straightforward method of studying battery electrode behavior is the recording of charge and discharge curves measured against a suitable reference electrode. These charge and discharge curves, deter-

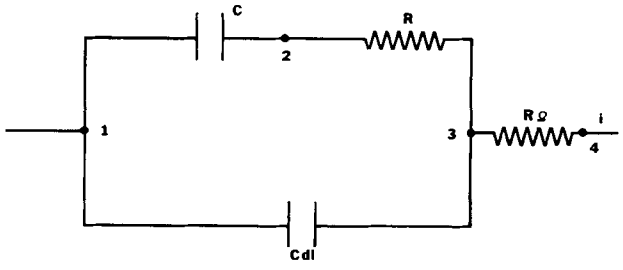

Fig. 1. Simplified equivalent circuit to illustrate double layer discharging after interruption of polarizing current: C, bulk capacity; R, faradaic impedance; R_Ω, ohmic impedance; C_{dl}, double layer capacitance.

mined at different temperatures and current densities, have practical importance, but are of little theoretical value, particularly with porous electrodes, because they only record the total overpotential. For more detailed studies, experimental methods distinguish between the individual components of the overpotential, namely, between ohmic, activation and concentration overpotential.

A method of great usefulness for this purpose is the measurement of the decay or build-up of overpotential as a function of time (4-7). If such measurements are carried out in the time interval from a few microseconds to several hours, it may be possible to measure the double layer capacitance and to distinguish between ohmic, activation, and concentration overpotentials by the rates of potential build-up or decay and by the slopes of the theoretically significant overvoltage decay or build-up against the logarithm of time.

The discharge process is given by the equivalent circuit, shown in Fig. 1 [see (8) for complete equivalent circuit], where C is the bulk or surface pseudocapacitance, and C_{dl} is the double layer contribution ($C >> C_{dl}$). R_Ω is the ohmic resistance. In the steady-state of discharge, the p.d. across C_{dl} is V_{13}. C will, in practice, be short-circuited by another reaction resistance corresponding to the rate of self-discharge on open circuit; however, this can be neglected. The p.d. across C during discharge is $V_{13} - iR$, *i. e.*, $V_{12}<V_{13}$. When the current is interrupted, R_Ω decays instantaneously. V_{13} will eventually become equal to V_{12} by an internal current flow from $C_{dl}C$. This is a fast process observable in the microsecond range and allows the determination of the double layer capacitance and thus the surface area of the electrolyte/nickel oxide interphase.

Activation and concentration overpotentials require longer decay times and with this type of electrode cannot be clearly discerned by decay rate measurement. Activation overpotential decay, however, should show one slope if plotted against the log of time regardless of current density or state-of-charge, provided there is only one operative mechanism. In any case, it would be expected that one mechanism will prevail over distinct regions of current density or state-of-charge. Therefore, if the decay slopes against the log of time change proportionally to current density or state-of-charge, a concentration overpotential mechanism is indicated.

The measurement of very short transients requires a fast-acting trigger circuit. Such a trigger circuit is shown in Fig. 2. It consists essentially of a 10-μsec monostable multivibrator, a 250 kc flip-flop, and a transistorized switch.

The typical sequence of operation consists of putting the cell on a selected load across the switching transistor in its conductive mode. The battery is then discharged for a predetermined period after which the switch is activated. The oscilloscope is triggered exactly 10 μsec before the switching transistor goes into its nonconducting mode.

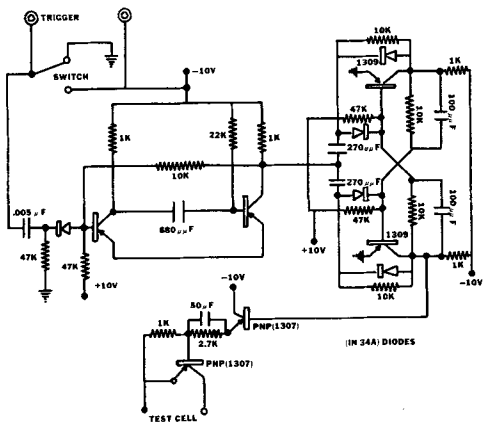

Fig. 2. Delayed-sweep trigger circuit used to obtain voltage time curves. (All diodes, 1N34A; all transistors, 2N1307's.)

Figure 3 shows typical voltage time plots covering the six time decades from 10 μsec to 10 sec for a cell at different state-of-discharge. Each of these curves represents six oscillographic traces.

This plot clearly shows three different regions in the curves of the overvoltage decay. Quite obviously, the ohmic overvoltage does not change markedly with state-of-discharge of the electrode. It should be understood that the voltage scale in this plot is relative, *i.e.*, the voltage level of the 10 μsec preinterruption sweep was arbitrarily taken as zero in order to allow a better comparison of the curves. The very small voltage drop in the interval from 10 μsec to approximately 100 msec is assigned to double layer charging, as explained, and reflects a large capacitance indicative of a very large surface area.

The portion from 100 msec to longer times is considered to be due to concentration and activation overvoltages and will be discussed in more detail later.

The very flat first portion of the curve is used for the estimation of the available area of the electrode.

Up to 1 msec, the overvoltage decay is almost linear with time, and the use of the relationship

$$C = i/(dE/dt)$$

where C is the double layer capacitance, i the preinterruption current, and dE/dt the time differential of the voltage, allows one to estimate the double layer capacitance and the area of the active materials.

In Fig. 4, the state-of-charge is plotted against the capacitance per gram of active material calculated from overvoltage decay traces for plates containing 0.18-2.5g of $Ni(OH)_2$. The discharge current per gram of active material was kept constant in all curves, and therefore, if the surface area of the active material in

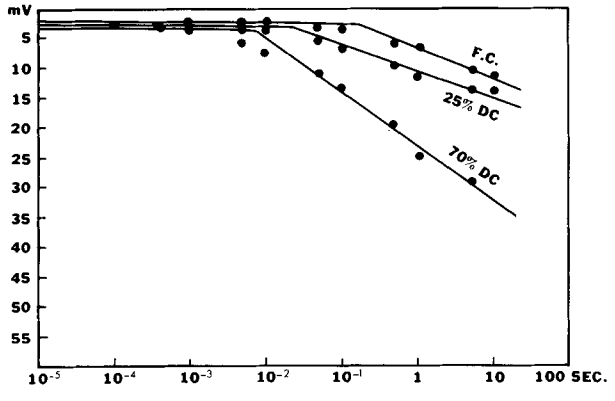

Fig. 3. Short-time overvoltage decay curves for an almost fully charged (FC), a 25% (25% d.c.) and a (70% d.c.) discharged electrode.

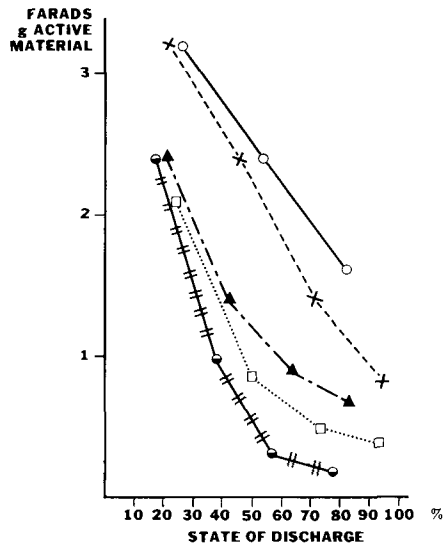

Fig. 4. Change of double layer capacitance during discharge of ——, 0.180g $Ni(OH_2)$/plaque d.c., 26 ma; — — —, 0.480g $Ni(OH)_2$/plaque d.c., 70 ma; — · —, 1.100g $Ni(OH)_2$/plaque d.c., 160 ma; . . . . ., 1.700g $Ni(OH)_2$/plaque d.c., 250 ma; —‖—‖—, 2.500g Ni $(OH)_2$/plaque d.c., 360 ma. Current density, 145 ma g $Ni(OH)_2 \sim 7.25 \cdot 10^{-7}$ amp/cm^2; based on a $Ni(OH)_2$ area of 20 m^2/g.

the pores is proportional to the weight, the curves should be identical.

For electrodes discharged up to 25%, the difference in capacitance between plates with 0.18g of $Ni(OH)_2$ and plates with 2.5g of $Ni(OH)_2$ is only approximately 20-25%. If we assume a double layer capacitance of 20 μf/cm^2 for the hydrated nickel oxide, the capacitance figures would suggest areas of the order of at least[1] 13-16 m^2/g of hydrated nickel oxide in reasonable agreement with reported surface areas for this oxide measured by the BET method (9, 10).

The capacitance and, therefore, the available surface area decreases with discharge, and the differences between lightly and heavily loaded electrodes become greater. It is suggested, however, that this might be due to interference of concentration polarization effects involving the electrolyte. Such effects would be considerably greater in heavily loaded cells since the current (and, therefore, mass transport) to pore volume ratio is approximately 25 times higher. The measurements with 75% charged plates are, therefore, considered more significant, and these indicate that the specific area does not drastically decrease with increased plate loading.

Figure 5 shows the long time overvoltage recovery of the same plates, again discharged at constant current per gram of active material, this time 200 ma/g, *i.e.*, 37 ma for the plate with one-third impregnation and 510 ma for the plate with 10 impregnations. The amount of time required to reach quasi-equilibrium is a function of the state-of-discharge. The fully charged cells, *i.e.*, cells which were approximately 4% discharged, attain equilibrium in approximately 20 min. The 50% discharged cells require approximately 16 hr, and the 80% discharged cells attain equilibrium only after a 24-hr stand.

The magnitude of recovery increases with the state-of-discharge and is 10 mv for a fully charged plate, 40 mv for 50% discharged cells, and 70 mv for 80% discharged cells.

Over long time periods, the curves are linear with the logarithm of time. At different states-of-charge the slopes are considerably different, indicating surface

[1] The curves suggest higher capacitance for fully charged nickel oxide electrodes.

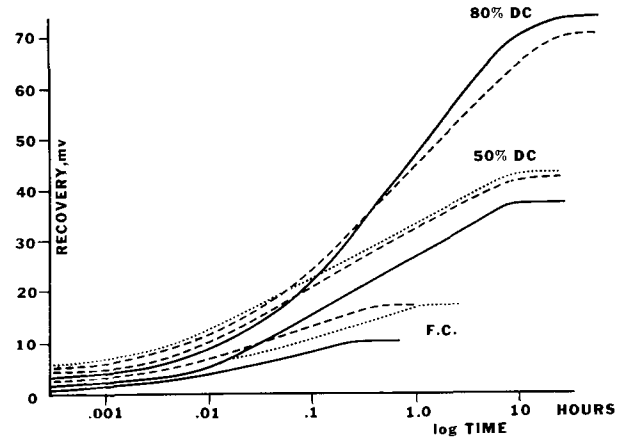

Fig. 5. Long-time overvoltage decay of positive plates for an almost fully charged, a 50% and an 80% discharged electrode. Discharge current 0.2 A/g active material. Active material per plaque: ——— 0.5g; — — — 1g, —.—. 1.5g.

changes as previously seen for the capacitance measurements.

For the same state-of-charge, however, the slopes of the recovery curves are very similar irrespective of active material loading if discharged at the same current per gram of active material. This behavior indicates similar current densities resulting from close to constant specific surfaces for these plaques containing various amounts of nickel oxide.

If the electrodes are discharged at the same current per gram of active material, *i.e.*, with 26 ma for the one-third impregnation and 360 ma for the 10-impregnation cells, the discharge curves are almost identical with respect to the voltage level as well as with respect to faradaic capacity.

If, however, a plate is discharged at various currents per gram of active material but within the same apparent current density limits as before, the difference is clearly visible in the reduced faradaic capacity delivered by the electrode at the higher current density (Fig. 6).

Discussion

These results indicate that the nickel hydroxide deposited in the pores in sequential impregnation cycles is deposited as a sponge of discrete particles. The available surface area is proportional to the $Ni(OH)_2$ weight, and cells discharged at the same current density per gram behave very similarly, although the apparent current density, *i.e.*, the current density per unit area of plaque, was varied 14-fold. If the current density per gram of active material is increased in the same limits, the effects are clearly discernible, mainly in the reduced faradaic capacity.

The long decay times and the slopes of the decay curves indicate solid-state diffusion or relaxation

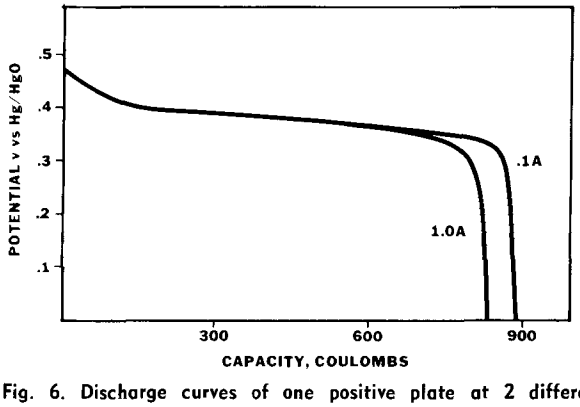

Fig. 6. Discharge curves of one positive plate at 2 different current densities.

phenomena, which again are very similar for plates of different loading if discharged at the same current per gram of active material.

The voltage decay measurements in the millisecond region indicate that KOH concentration overvoltage phenomena become important with increasing state-of-discharge of the electrode. These phenomena are not reflected in measurably decreased performance at room temperature, but they might be increasingly important at lower temperature.

The Heat-Treatment of Anodic Oxide Films on Tantalum

IV. Anodization in Phosphoric Acid Solutions

D. M. Smyth, T. B. Tripp, and G. A. Shirn

Research Laboratory, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Dielectric measurements have been made on tantalum which has been anodically oxidized in aqueous phosphoric acid of various concentrations and then heated in air. The resulting dielectric consists of a highly conducting portion adjacent to the tantalum and an outer, nonconducting portion. This structure is interpreted in terms of the distribution of phosphorus incorporated into the oxide and its effect on the diffusion of oxygen during heat-treatment.

The previous papers in this series have presented a model which explains the dielectric properties of heat-treated, anodized tantalum (1-3). It was proposed that the tantalum extracts oxygen from the oxide film at an appreciable rate during heat-treatment above 200°. When the heating is done in an oxygen atmosphere, a dynamic equilibrium is established with fixed compositions in the oxide at the Ta-Ta_2O_5 and Ta_2O_5-O_2 interfaces, and with an appropriate variation of composition across the film. On cooling, the compositional variation with position is quenched, and there is then an exponential gradient of conductivity across the oxide, decreasing from a maximum value at the Ta-Ta_2O_5 interface. The dielectric properties are consistent with such an exponential gradient of semiconduction with an activation energy of conduction of 0.6 ev.

The above analysis was based on experimental results obtained from samples anodized in dilute aqueous electrolytes, particularly 0.01M H_2SO_4. Small but reproducible differences noted for samples anodized in dilute H_3PO_4 led to a more detailed study of the role of the anodization electrolyte.

Experimental

The basic techniques have been described previously (1-3). Electroless nickel counter electrodes were deposited by a standard deposition technique (4). The entire surface of the anodized sample was covered with nickel. Small dots of acid-proof paint were painted on the nickel, and the exposed metal was dissolved in concentrated HNO_3. The paint was removed with successive toluene and alcohol rinses. This left small dots of electroless nickel on the Ta_2O_5 surface to which gold wires were affixed by means of a conducting epoxy resin. Measurements on these samples were made with a General Radio 716-C bridge.

In all cases, the dielectric measurements were made in the temperature range −70° to +100° after heat-treatment in the range 300°-500°.

Unless specified otherwise, all samples were anodized to 75v, and all measurements were made in 40% H_2SO_4 at 34° and 120 cps.

Results

It was observed that samples anodized in 0.001M H_3PO_4 differed in the following ways from those formed in 0.01M H_2SO_4:

1. The average equilibrium capacitance increase for heat-treatment at 400° in air was 24% for phosphate films, compared with 17% for sulfate films.
2. The equilibrium value was attained somewhat more slowly for phosphate films.
3. The rate of weight increase during heat-treatment (oxygen up-take) was 25% slower for phosphate films (0.040 $\mu g/cm^2$ min *vs.* 0.053 $\mu g/cm^2$ min) for samples anodized to 15v and heated at 400°.

The last two points are consistent with a lower oxygen mobility in phosphate films. Moreover, the fact that there are any observable differences indicates that allowance for an influence of the anodization electrolyte must be added to the simple mechanism previously proposed for the heat-treatment process.

These observations led to an investigation of the effects of heat-treatment on samples anodized in H_3PO_4 and H_2SO_4 solutions of various concentrations. Results are shown in Fig. 1 which demonstrates factors 1 and 2 enumerated above. The equilibrium increase of capacitance increases drastically with H_3PO_4 concentration up to 1M and then drops again for 14.6M (85% H_3PO_4). Detailed data for samples anodized in H_2SO_4 are shown only for a concentration of 0.1M. The vertical line which intersects the 0.1M H_2SO_4 line at 60 min, however, shows the spread of values obtained over the concentration range 0.01-1M. Compared with the phosphate samples, there is almost no effect of H_2SO_4 concentration on the dielectric properties.

The bias dependence of capacitance of heat-treated phosphate films increases with increasing H_3PO_4 concentration up to 1M. The equivalent series resistance

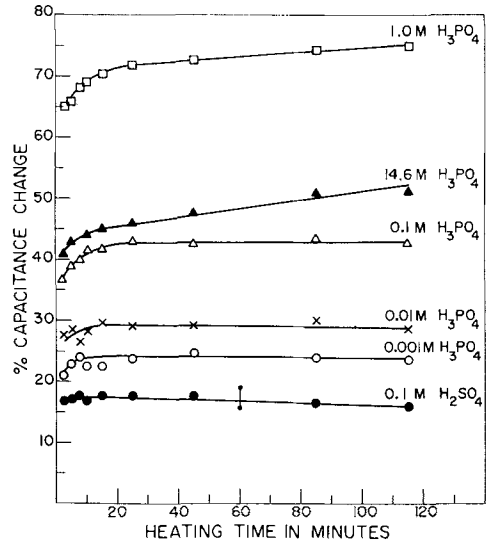

Fig. 1. Effect of anodization electrolyte on the capacitance increase due to heat-treatment of anodized tantalum at 400° in air.

increases up to a maximum at 0.1M and then decreases again. For the samples anodized in 14.6M H_3PO_4, even though the capacitance increased about 50% as a result of heat-treatment, the bias dependence of capacitance and the series resistance remained those of an unheated film. Characteristic data are shown in Table I. (Prior to heat-treatment, all of these samples had capacitances in the range 3.1-3.2 μf.)

Figures 2 and 3 show the temperature dependences of capacitance and dissipation factor for samples anodized in 1.0, 8.0, and 14.6M H_3PO_4 and then heated for 45 min at 400° in air. (The data for the 1M sample were obtained in two separate temperature runs. A different immersion depth probably accounts for the offset near 20°.) These results show that there is a smooth trend of properties with electrolyte concentration. The behavior shown in these figures is very similar to that reported earlier for heat-treated, partially reanodized samples (2). This similarity is shown clearly in Fig. 4 and 5, which show the frequency dependence of capacitance at several temperatures for a sample anodized in 14.6M H_3PO_4 and heat-treated in air; and for a sample anodized in 0.01M H_2SO_4, heat-treated in vacuum, and partially reanodized.

Another significant observation which is not related to heat-treament, is the effect of anodization in the more concentrated H_3PO_4 solutions on the interference color of the oxide film. Films anodized to the same voltages in solutions of increasing H_3PO_4 concentration appear optically to become progressively thinner. Thus a sample anodized to 75v in 14.6M H_3PO_4 has the same interference color as a sample anodized to about 55v in 0.01M H_2SO_4. For a given anodization voltage the capacitance of the unheated samples are essentially independent of electrolyte concentration, however. Similar observations have been made before (5, 6).

Discussion

As we have shown previously, the shape of the temperature dependence of capacitance is related directly

Table I. Dielectric properties of anodized tantalum after heat-treatment at 400° for 45 min in air, as a function of H_3PO_4 concentration in the anodization electrolyte

to the shape of the conductivity profile across the oxide film (1-3). In fact, the relative shape of the conductivity profile is obtained by rotation of capacitance-temperature curves, such as Fig. 2, 90° clockwise. This then has the same appearance as a plot of log σ (conductivity) *vs.* position in the film with the Ta-Ta_2O_5 interface on the left-hand side where all conduction has been effectively quenched at low temperatures. This transformation can be empirically understood from the fact that the conductivity is related to the temperature by an exponential expression, and the capacitance is inversely related to a thickness of film, and hence a position. A rigorous derivation is given in the Appendix.

The data shown in Fig. 2 are thus used to obtain the schematic depiction of the conductivity profiles in Fig. 6. The level of σ_o, whose intersection with a conductivity profile defines a dielectric thickness (3), is shown for a measuring frequency of 120 cps. It is seen that the conductivity profiles are made up of two

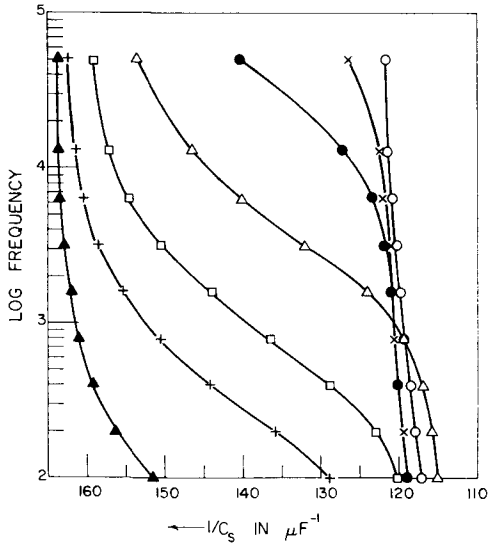

Fig. 5. Frequency dependence of capacitance of tantalum, anodized in 14.6M H_3PO_4, heat-treated in air at 400°. Counter electrode was 0.02 cm^2 electroless nickel. ○, 75.3°; X, 46.3; •, 26.4; △, —4.6; □, —23.8; +, —37.6; ▲, —59.8.

parts: a shallow, inner gradient which changes to a steeper gradient further out in the film. The distinction between the two slopes increases, and the transition between them moves closer to the tantalum with increasing concentration of H_3PO_4 in the anodization electrolyte. It is clear that these three samples represent a smooth trend, and that the apparent peculiarity of the 14.6M sample in Table I results from the particular choice of temperature and frequency of measurement. This resulted in the inner dielectric boundary (the intersection of the conductivity profile with σ_0) being on different characteristic parts of the profile. For the 1M sample the boundary is on the shallow, inner slope, and this very diffuse transition from dielectric to electrode results in high dielectric losses and large dependences of capacitance on bias, temperature, and frequency. For the 14.6M sample, on the other hand, the boundary is on the steep, outer slope which is so steep that it is as sharp a dielectric boundary as the Ta-Ta_2O_5 interface of an unheated sample (see Table I). When the frequency is increased or the

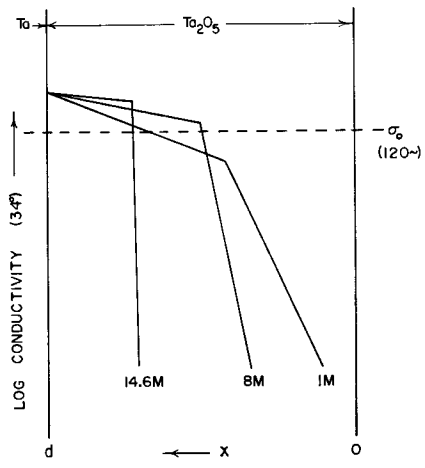

Fig. 6. Schematic representation of the conductivity profiles across oxide films on tantalum, anodized in various concentrations of H_3PO_4, and heat-treated at 400° in air.

temperature decreased enough to move the dielectric boundary up on the shallow, inner gradient, however, the dielectric properties of the 14.6M sample deteriorate as shown in Fig. 2, 3, and 5.

These samples have dielectric properties which are very similar to those of tantalum which has been anodized in dilute H_2SO_4, heat-treated in vacuum, and partially reanodized. Such treatment gives a similar conductivity profile, as seen in Fig. 4 and 5. In these figures log frequency, which is proportional to log conductivity (3), has been plotted against the reciprocal capacitance, which is proportional to the dielectric thickness. Thus these plots are equivalent to plots of log conductivity *vs.* position. These results at different temperatures could be normalized to a given temperature by use of the activation energy of conduction to give one continuous, overlapping curve which would represent the conductivity profile as shown in Fig. 6.

The obvious similarity between the samples represented by Fig. 4 and 5, and the fact that they yield identical activation energies of conduction both by the temperature dependence of conduction at a given position in the film, and by the frequency dependence of the maxima in the temperature dependence of tan δ (3), leads to the conclusion that the dissipative mechanism controlling the dielectric properties is the same for all of these samples, regardless of the anodization electrolyte. The problem of explaining the observations is thus reduced to an explanation of why the distribution of conductivity in the films which have been heat-treated in air is affected by the anodization electrolyte.

It has been proposed that, during the heat-treatment in air, a dynamic equilibrium is established whereby the compositions at both sides of the oxide film are fixed and oxygen is continuously flowing through the oxide from the air to the metal where it is held in solution. This flow is exemplified by a constant rate of weight increase during the heating. The flux of oxygen can be expressed as

$$J = D\frac{dn}{dx} \qquad [1]$$

where J is the flux density of oxygen at./sec cm^2, D is the diffusion constant, and dn/dx is the concentration gradient of the diffusing oxygen species. After equilibrium has been established, the flux must be the same across the entire film thickness. If these films consist of two layers, an inner layer where the diffusion constant of oxygen is high and an outer layer where it is low, then, to satisfy [1], the gradient of

oxygen content would be low across the inner layer and high across the outer layer. At this point it should be recalled that we have described two observations which indicate that oxygen has a lower rate of diffusion in phosphate films as compared with sulfate films: the longer time to reach the maximum capacitance increase during the heat-treatment, and the lower rate of weight increase.

Recent work by Randall, Bernard, and Wilkinson shows that anodic oxide films on tantalum are indeed composed of two layers with the outer layer containing material incorporated from the anodization electrolyte (7). They anodized tantalum in H_3PO_4 solutions containing P^{32} as a radiotracer. By measuring the residual radioactivity of the samples as thin layers of oxide were removed by dissolution in HF, these authors found that approximately the outer half of the oxide film contains a uniform distribution of phosphorus with the concentration increasing with the H_3PO_4 concentration in the anodization electrolyte. The boundary between the outer, phosphorus-containing layer and the inner, phosphorus-free layer was found to be quite sharp. Randall *et al.* concluded from this structure that the oxide film is formed by the migration of both tantalum and oxygen species with new oxide growth thus occurring at both the Ta-Ta_2O_5 and Ta_2O_5-electrolyte interfaces. Only the oxide which formed at the latter interface would contain material from the electrolyte. Samples which were anodized in 14.6M H_3PO_4 containing P^{32} and heat-treated in air were examined by this same technique. It was found that, as oxide was removed stepwise with HF, the reciprocal series capacitance, a measure of the effective dielectric thickness, and the residual P^{32} activity approached zero together at a point where significant oxide remained, as indicated by the interference color. Thus the effective dielectric thickness of the heat-treated oxide in this case corresponded precisely to that portion of the oxide which incorporated phosphorus from the electrolyte during anodization. If we can assume that the mobility of oxygen in the oxide during heat-treatment is reduced by the presence of phosphorus, the conductivity profiles shown in Fig. 6 follow logically: the phosphate films consist of an outer, phosphorus-containing layer in which the thermal diffusion of oxygen is low, and an inner, phosphorus-free layer in which the thermal diffusion of oxygen is "normal." The mobility of oxygen decreases with increasing phosphorus content. Thus when equilibrium is attained during heat-treatment, Eq. [1] requires that the compositional gradient be shallow in the inner, phosphorus-free layer, and steep in the outer phosphorus-containing layer. The conductivity profile is, of course, directly related to the composition profile. A combination of the phosphorus distribution and the conductivity profile in the oxide of the sample described above is shown schematically in Fig. 7.

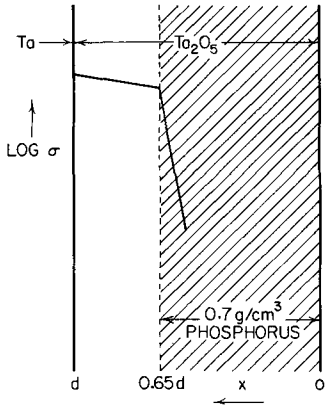

Fig. 7. Schematic representation of the correlation between the conductivity profile and the phosphorus distribution for tantalum, anodized in 14.6M H_3PO_4, and heat-treated in air.

Observations on other oxide systems indicate that the effect of incorporated phosphorus on oxygen mobility may be rather general. Bernard has reported that anodic oxides formed on aluminum in phosphate solutions are extremely resistant to hydration (8). It was found, for example, that films formed to 90v in 30% ammonium pentaborate in ethylene glycol and then continued to 100v in 0.1M NaH_2PO_4 were resistant to hydration, whereas borate films by themselves hydrated rapidly. The supposition is that a thin, outer layer of phosphorus-containing aluminum oxide was able to protect the underlying oxide. Since the hydration process presumably involves the migration of an oxygen-containing species, the effect of phosphorus on the mobility of such a species is reminiscent of the observations reported here. A related observation has been reported for the Si-SiO_2 system by Kerr, Logan, Burkhardt, and Pliskin (9). These authors have found that silicon field-effect transistors have greater stability if a layer of phosphosilicate glass, which is formed on the outer surface of the SiO_2 during processing, is left intact. If it is removed, a positive space charge forms in the oxide adjacent to the silicon. This space charge is attributed to oxygen vacancies which are introduced at the oxide-electrode interface and migrate across the oxide. Kerr *et al.* attribute the stabilizing effect of the phosphosilicate layer to the "oxidizing power" of the phosphorus which prevents the oxide from becoming oxygen-deficient. The mobility argument presented here seems more straightforward.

This investigation, and the radiotracer work of Randall, Bernard, and Wilkinson, also have significance with regard to the mechanism of the anodization process. Both works indicate that the interface between phosphorus-free and phosphorus-containing oxide moves toward the Ta-Ta_2O_5 interface as the concentration of H_3PO_4 increases in the anodization electrolyte. In other words, the amount of oxide formed as a result of oxide ion migration decreases as the amount of phosphorus in the oxide increases. Thus it appears that the presence of phosphorus in the oxide reduces not only the high-temperature mobility of oxygen in the oxide, but also the low-temperature field-driven mobility. Moreover, as the H_3PO_4 concentration in the anodization electrolyte increases, the interference colors of samples anodized under identical conditions correspond to thinner films. If this color difference is indeed related to a thickness difference rather than to changes in the optical properties, then the flow of both Ta ions and oxide ions must be retarded by the presence of phosphorus, although the earlier evidence indicates that the oxide ion current is restricted to the greater extent.

Thus in order to explain fully the kinetics of anodic oxidation, we must have expressions for the field dependence of ionic current for not only both tantalum ions and oxide ions, but for both of these ions in both regions of the oxide, with the expressions for the outer layer of oxide including allowance for the effect of electrolyte material incorporated into the oxide. This will necessitate terms for the identity of the electrolyte as well as for the current density and temperature of anodization. This means that a full understanding of the kinetics of anodization is much more complicated than hitherto appreciated. Of course the electrolyte effect can be minimized by the use of dilute solutions of relatively inert solutes such as H_2SO_4.

Although the explanation described here agrees with the observations in satisfactory detail, there are some basic inconsistencies which must be pointed out. The oxygen diffusion model which has been used to explain the origin of the gradient of oxygen content would normally lead to a linear distribution of the diffusing species across the film. The conductivity profile, how-

ever, has been found to be exponential, and the connection between this and the oxygen vacancy distribution has never been clarified. The treatment of mobility and concentration gradient exemplified by Eq. [1] and the subsequent discussion ignores this discrepancy. Moreover, the model assumes that all samples reach the same equilibrium compositions at the Ta-Ta_2O_5 and Ta_2O_5-air interfaces after equilibrium is attained during heat-treatment. As seen in Fig. 6, however, the outer, steep gradients will not extrapolate to a common conductivity at the oxide-air interface. The data are inconsistent with such a convergence. Possibly the phosphorus content of the oxide influences the Ta_2O_5-O_2 equilibrium. There is also evidence that the dielectric constant of the oxide depends on the phosphorus content (7). This may influence the ionization of oxygen vacancies in the outer portion of the film. These discrepancies are important and must not be overlooked, but they should not detract from the success of the original model in explaining these complex dielectric properties with the addition of only two observed facts: the nature of the distribution of phosphorus in the oxide, and the effect of phosphorus on the mobility of oxygen in the film.

Acknowledgment

The authors gratefully acknowledge the assistance of Dr. J. J. Randall, Jr., and Mr. Stanley Szpak, who carried out the radiotracer analysis, and the experimental assistance of Miss Marjorie Cutler.

Manuscript received Sept. 13, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

APPENDIX

Temperature Dependence of Capacitance Derived from an Exponential Gradient of Conduction

Let the spatial and temperature dependence of semiconduction across the Ta_2O_5 film be represented by

$$\sigma = Be^{ax}\, e^{-E/kT} \qquad [1a]$$

where a is the exponential slope, x is the position in the oxide measured from the Ta_2O_5-electrolyte interface, and E is the activation energy of conduction. The ratio of conductivity at the Ta-Ta_2O_5 interface ($\sigma = \sigma_d$ at $x = d$) to that at the Ta_2O_5-electrolyte interface ($\sigma = \sigma_1$ at $x = 0$) is

$$\frac{\sigma_d}{\sigma_1} = e^{ad} \qquad [2a]$$

Since $\sigma_d/\sigma_1 = 10^{21}$ by extrapolation of experimental observation, and $d = 1.5 \times 10^{-5}$ cm (20 Å/v for 75v film)

$$a = 3.2 \times 10^{6}\ \text{cm}^{-1} \qquad [3a]$$

Solving [1a] for B and using $E = 0.6$ ev, $T = 300°$K, $x = d = 1.5 \times 10^{-5}$ cm, and $\sigma_d = 3 \times 10^{-7}$ ohm^{-1} cm^{-1} (3) yields

$$\log B = -17.4 \qquad [4a]$$

$$B = 4 \times 10^{-18} \qquad [5a]$$

At the position, x, defined by

$$x = \frac{\epsilon\epsilon_o}{C_s} \qquad [6a]$$

$$\sigma_x = \sigma_o = \omega\epsilon\epsilon_o \qquad [7a]$$

so from [1a]

$$\frac{a\epsilon\epsilon_o}{2.3\, C_s} = \log \frac{\omega\epsilon\epsilon_o}{B} + \frac{E}{2.3\, kT} \qquad [8a]$$

Substituting and solving for C_s, the equivalent series capacitance, with $\epsilon = 27.6$, $\epsilon_o = 8.85 \times 10^{-14}$, and $\omega = 2\pi f$ gives

$$C_s = \frac{3.4\, T}{(6.6 + \log f)\, T + 3030}\ \mu\text{f/cm}^2 \qquad [9a]$$

The temperature dependence of capacitance is then

$$\frac{dC_s}{dT} = \frac{10{,}300}{(6.6\, T + T \log f + 3030)^2} \qquad [10a]$$

At 120 cps and 30°C

$$\frac{dC_s}{dT} = 3.22 \times 10^{-4}\ \mu\text{f/cm}^2\ °\text{C} \qquad [11a]$$

At 120 cps and −20°C

$$\frac{dC_s}{dT} = 3.77 \times 10^{-4}\ \mu\text{f/cm}^2\ °\text{C} \qquad [12a]$$

This represents a slope change of only 17% over our usual temperature range of measurement. Thus [9a] can be considered to be a quasi-linear relationship between C_s and T over this temperature range, in agreement with observation.

The Corrosion of Zirconium and Zircaloy-2 at Low Temperatures

R. Cigna, J. S. Llewelyn Leach, and A. Y. Nehru

Department of Metallurgy, Imperial College of Science and Technology, London, England

ABSTRACT

The aqueous corrosion of zirconium and Zircaloy-2 has been studied as a function of electrode potential, solution pH, and temperature below 100°C. The influence of these variables and of alloying is considered in terms of their effect on the rate and the temperature dependence of corrosion. The relation between the corrosion process and the electronic conduction in the oxide is discussed.

Some work on the low-temperature aqueous corrosion of zirconium has been briefly described in two previous publications (1, 2), which dealt chiefly with the corrosion of uranium. These early studies indicated the influence of a number of environmental and other factors on the corrosion behavior and showed that the results for both uranium and zirconium could be interpreted in the same general terms. Recently, further work on uranium has shown that changes in corrosion rate caused by altering the experimental conditions were associated with significant changes in the activation energy of the oxide growth process, and, in addition, suggested a relationship between the electronic and ionic conductivities of the oxides formed in aqueous electrolytes (3).

The present paper describes the results of a more detailed investigation of the corrosion behavior of zirconium with particular reference to the effect of cathodic polarization, solution pH, and alloying content. The temperature dependence of the corrosion process has been studied as a function of these variables. Changes in the corrosion rate have been shown to be accompanied in many instances by changes in the activation energy.

Experimental

The equipment developed for the estimation of corrosion rates has been adapted from a previous design (4) with some minor alterations and allows a study of the growth of oxide films without removal of the specimen from the test environment. The operating principle of the technique involves a continuous measurement of the intensity of light reflected from a metal corroding in an aqueous environment and calculation of film thickness by comparison with the intensity reflected from a clean surface. However, it is necessary to assume that the absorption coefficient of the oxide is not significantly influenced by its thickness.

The results reported in this paper are derived from measurements using an unfiltered high-pressure mercury lamp (Phillips HPK/125). The thickness of the oxide-film is given by

$$I = I_o e^{-2\theta x}$$

where I_o is the reflected intensity from the clean metal surface, I is the intensity at film thickness x, and θ is the absorption coefficient of the oxide. If x is some function of time (t), then

$$I = I_o e^{-2\theta f(t)}$$

and

$$\log_e I - \log_e I_o = -2\theta f(t)$$

A plot of ($\log I_o - \log I$) *vs.* t gives relative film thickness as a function of time.

Temperature control in the corrosion cell was achieved with an immersion heater and a temperature-controlling thermometer. The thermometer (Electromethods) which could be set to control to ±0.1°C at any temperature between 0° and 100°C was positioned near the specimen and activated a relay which switched the heater circuit.

The test solutions were prepared by dissolving Analar grade reagents in distilled water and were constituted as follows: pH 5.4 solution, 0.1*N* K_2SO_4; pH 13 solution, 0.1*N* KOH.

The materials examined were zirconium-10 and zirconium-20[1] (Zircaloy-2) supplied by Imperial Metal Industries (Kynoch) Ltd., in the form of 0.02 in. foil and 0.028 in. foil, respectively.

The average composition data are given in Table I.

The test electrodes were prepared in the form of strips and mounted in glass tubes with a cold-setting resin (Ciba Araldite) so that a rectangular working surface of about 4.5 cm^2 was exposed to the environment. Before testing, specimens were degreased in acetone and etched to a bright finish in a solution composed by volume of 1 part of 40% HF, 4 parts of 70% HNO_3, and 5 parts of water.

Tests were made in the temperature range 50°-90°C at values of cathodic potential maintained using a potentiostat (AERE type 1465A) and measured with a vacuum tube voltmeter (E.I.L. pH meter Model 23A).

Results

Figures 1 and 2 illustrate, respectively, the corrosion of zirconium and Zircaloy-2 in 90°C 0.1*N* K_2SO_4 solution at several values of cathodic potential. Assuming that the absorption coefficient of the oxide formed on zirconium is not significantly different from that of the film on the alloy, it is possible to attempt a direct comparison of the corrosion rates of the two metals. The following three observations may be made from the figures:

1. Protective kinetics appear to predominate for the corrosion of both metals within the present range of measurements. (Calculations show an approximation to the parabolic law except at the most negative potentials where the exponent of the growth law is about 1.5.)

[1] Zirconium-20 is the trade designation used by Imperial Metal Industries for Zircaloy-2.

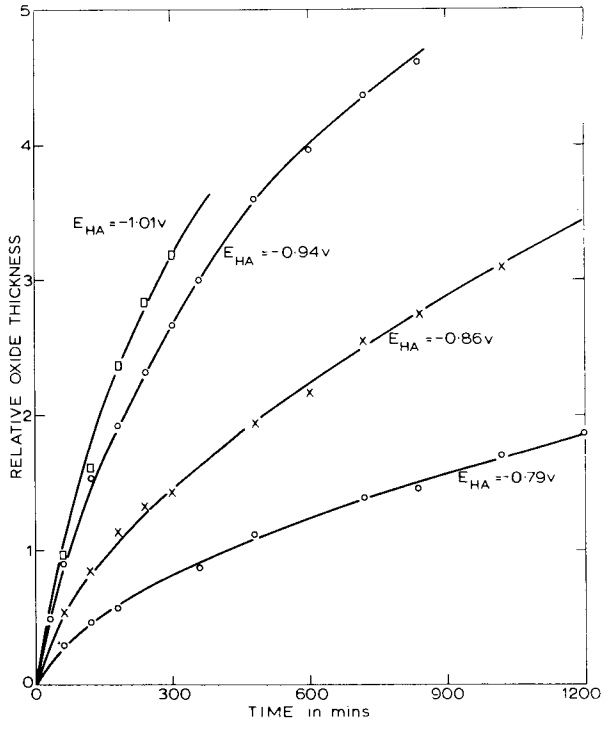

Fig. 1. Corrosion of zirconium as a function of cathodic polarization, 0.1*N* K_2SO_4, 90°C.

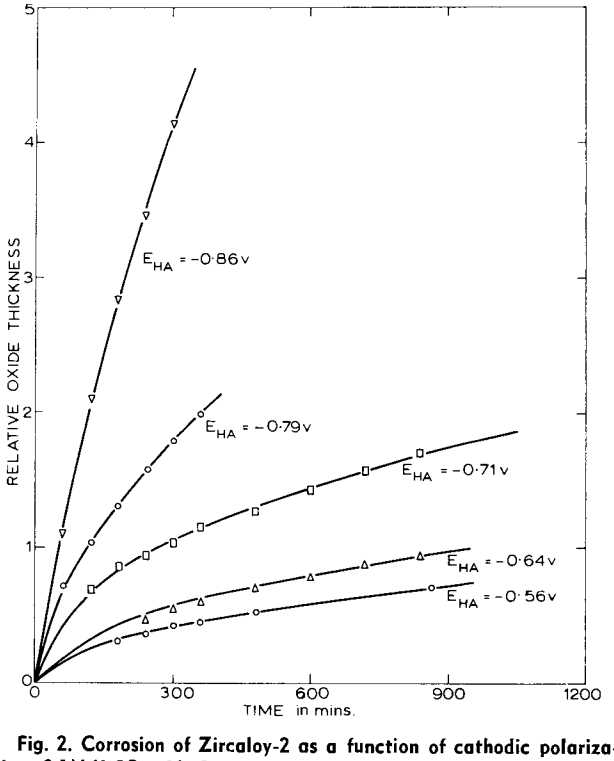

Fig. 2. Corrosion of Zircaloy-2 as a function of cathodic polarization, 0.1*N* K_2SO_4, 90°C.

2. The corrosion rate of both metals increases with increasing cathodic polarization.

3. The over-all corrosion rate of Zircaloy-2 is higher than that of zirconium for equivalent values of potential.[2]

Some examples of the corrosion of zirconium and Zircaloy-2 in 0.1*N* KOH are illustrated in Fig. 3. Comparison with Fig. 1 and 2 shows that over-all corrosion rates in the alkaline solution tend to be considerably higher than in acidic solution. Measurements at more negative potentials than those shown in Fig. 3 were not generally practical in 0.1*N* KOH due to irreproducibility of the corrosion kinetics.

Figures 4 and 5 show the temperature dependence of the arbitrary rate constant K for cathodically polarized zirconium and Zircaloy-2, respectively, in 0.1*N* KOH solution. (The kinetics of corrosion for each given value of cathodic potential being the same, K is taken as the reciprocal of the time required for the film to grow to a given thickness.) Activation energies were calculated by the standard method and were found to lie between 13.4 and 23 kcal/g mole for zirconium and 8.0 and 8.6 kcal/g mole for the alloy. Two values of potential are common to both sets of data.

It is clear from a comparison of Fig. 4 and 5 that alloying results in a considerable reduction of the activation energy for the corrosion of zirconium. Cathodic polarization appears to have a similar effect although this is too small to be significant in the case of the alloy.

It might be worth mentioning here that at a given temperature the measured increase in corrosion rate of zirconium due to cathodic polarization is considerably lower than the value expected from the associated decrease in experimental activation energy. Thus, for example, in Fig. 4 at temperature = 348°K, K changes

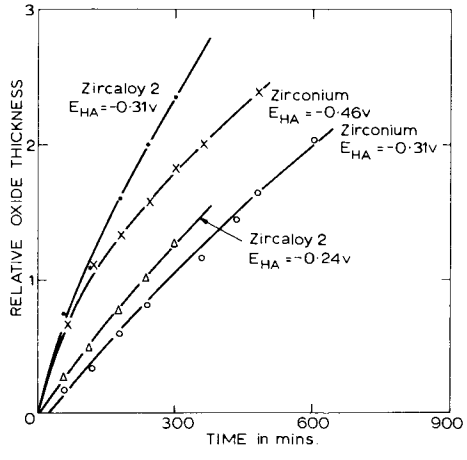

Fig. 3. Corrosion of zirconium and Zircaloy-2 as a function of a cathodic polarization, 0.1*N* KOH, 90°C.

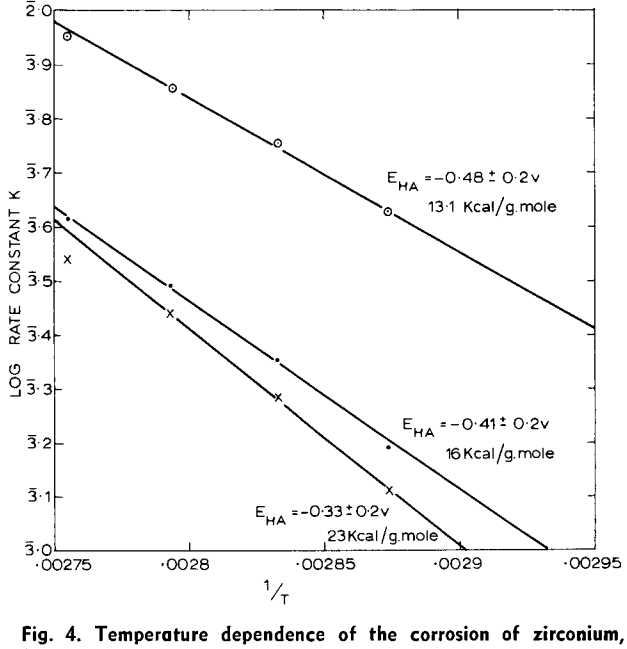

Fig. 4. Temperature dependence of the corrosion of zirconium, 0.1*N* KOH.

[2] $E_{HA} = E_H + 2.3RT/F$ pH, where E_H is the standard hydrogen potential.

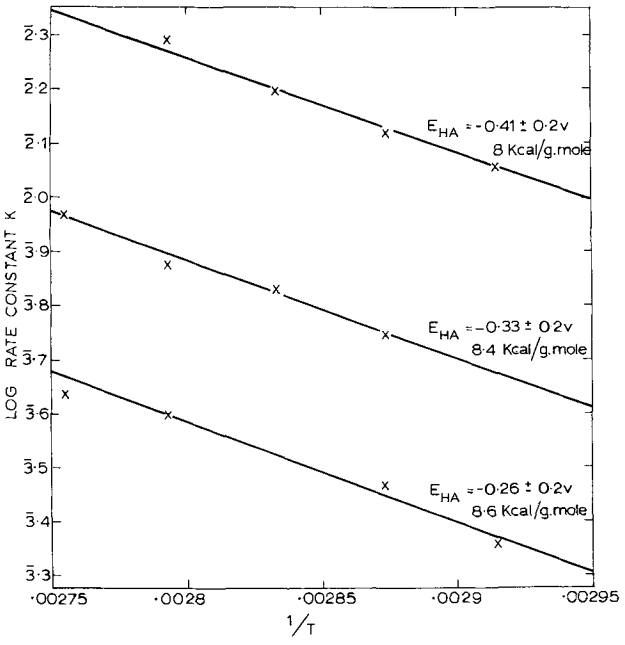

Fig. 5. Temperature dependence of the corrosion of Zircaloy-2, 0.1*N* KOH.

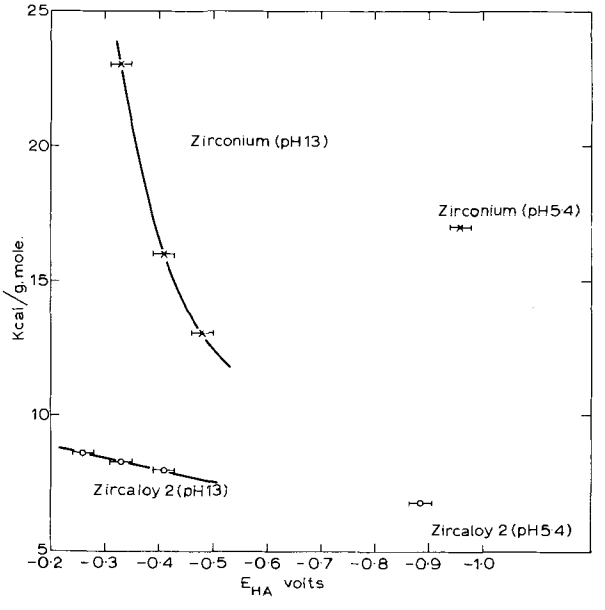

Fig. 6. Activation energy of corrosion as a function of potential, zirconium and Zircaloy-2, 0.1*N* K_2SO_4, 0.1*N* KOH.

from a value of 0.0013 for $E_{HA} = -0.33 \pm 0.02$v to 0.0016 for $E_{HA} = -0.41 \pm 0.02$v (same rate law applies at both potentials), an increase of 1.23 times, while, in fact, the change in rate caused by the observed reduction in activation energy from 23 to 16 kcal/g mole should amount to a factor of over two thousand times. This calculation suggests that decreases in the experimental activation energy E of the Arrhenius equation

$$K = A \exp -E/RT$$

are paralleled by decreases in the pre-exponential term A. Although in the present instance this does not appear to be true for Zircaloy-2, similar correlations between A and E have been found (5-7) for the corrosion of several other metals including uranium.

Figure 6 shows the simple relationships which appear to hold between the experimental activation energy and the impressed cathodic potential for the corrosion of both zirconium and the alloy in alkaline solution.

The temperature dependence of the corrosion rate in 0.1*N*/K_2SO_4 was not studied in detail, and only one value of activation energy was calculated for each metal (Fig. 6). These activation energies were obtained by measurement at very negative potentials due to the law rates of corrosion in the acidic solution. Although direct comparison is not possible, it would appear that higher activation energies prevail for the corrosion of both zirconium and the alloy in 0.1*N* K_2SO_4 than in alkaline solution.

Discussion

The present results, which were obtained under restricted and controlled experimental conditions, are not directly comparable with the results of the numerous detailed studies (8-11) of the high-temperature corrosion of zirconium and Zircaloy-2 available in the literature. The main contribution of a qualitative investigation such as this lies in the attempt made to determine which parameters involved in a given corrosion process are influenced by varying external factors.

Consider, then, the influence of cathodic polarization on the corrosion rate of the two metals studied (Fig. 1, 2, 3). It is clear that in all cases decreasing the electrode potential increases the rate without, in general, altering the mechanism. The corrosion kinetics for a given set of conditions remains constant over a wide range of potential.

Wanklyn and Hopkinson (12) also showed increases caused by cathodic polarization in the corrosion rate of zirconium in 325°C water. They rejected on two counts the cathodic reduction of the oxide formed as a possible explanation for this effect, but their observations did not permit a determination of the main sources of the rate increases, *e.g.*, it was not possible to distinguish between changes in the diffusion constants in the protective film and changes in its thickness. More recently, similar observations (1, 2) on the corrosion of both uranium and zirconium at lower temperatures have been interpreted in terms of higher ionic diffusion rates associated with increases in electronic conductivity of the corrosion-product oxide which follow the introduction of cathodically induced hydrogen ions.

The enhanced electronic conductivity can be discussed in the case of the n-type semiconducting oxide ZrO_{2-x} formed during the corrosion of zirconium (13, 14) in terms of the following equation

$$ZrO_{2-x} = Zr^{4+} + (2-x)O^{2-} + 2xe^-$$

where $2xe^-$ is the number of excess electrons required to maintain the charge balance. If the system is to remain electrostatically neutral, the addition of an H^+ ion will require the incorporation of an extra excess electron.

If the effect of this increase in electronic conductivity is now considered, it becomes clear that the potential gradients opposing ionic motion in the oxide are diminished and faster growth may take place. Similar relationships between the electronic conductivity and ionic diffusion coefficients have been demonstrated by Wagner (15) for the system Ag-Ag_2S-S and Jacobs (16) for anodic films on tantalum.

In discussing the reduction in activation energy associated with increasing cathodic polarization (Fig. 4, 6), it is relevant to compare the low values of activation energies calculated here and in other work with the values reported for self-diffusion in these oxides.

Oxide growth on zirconium in air or oxygen at high temperatures occurs by the inward diffusion of oxygen involving an activation energy of 30 to 40 kcal/g mole (17) very near the value of the activation energy

for the self-diffusion of oxygen in zirconia and undoubtedly much lower than the value for self-diffusion of the metal. It is known, however, that aqueous conditions can cause a significant change in the mechanism of oxide growth, and this applies over a wide range of temperature to several metals (3, 6, 18) including zirconium (19) and Zircaloy-2 (20). In the case of Zircaloy-2, an estimate from the data of Thomas and Forscher gave a value as low as 10 kcals/g mole for high-temperature aqueous corrosion. This is similar to the range of values found in this investigation but differs significantly from 28.6 kcal/g mole quoted (21) for the oxidation of the alloy in oxygen at high temperatures. Few explanations for the lowering of the activation energy due to the presence of water are generally available in the literature. One offered for the corrosion of magnesium (6) involves the assumption that hydrogen ions will convert O^{2-} ions in the lattice to OH^- ions, necessitating the introduction of vacancies at cation sites to maintain electrical neutrality. It is believed that the consequent distortion of the lattice reduces the activation energy for the diffusion of Mg^{2+}, but an explanation in these terms is unlikely for a system in which oxygen is the main diffusing species. Alternative arguments which invoke, for example, either the diffusion of both anions and cations in aqueous conditions or a lower energy barrier in opposition to hydroxyl ion diffusion than that opposing oxygen ion diffusion are so far unable to account for the lower activation energies. Decreases in activation energy due to diffusion via low-resistance short-circuit paths such as grain boundaries rather than entirely through the bulk by lattice vacancies are probably too small to account for the very low values obtained (22).

Values of activation energy calculated under the present experimental conditions are difficult to reconcile with the rate-controlling step during corrosion being oxygen diffusion either via low-resistance paths or through lattice vacancies. Nor do other simple explanations appear applicable. In a previous investigation on uranium (3) which yielded results of a similar nature, it was shown that activation energies for corrosion approximated closely to established values of activation energy for electronic semiconduction in uranium oxides. An extrapolation from the data of Johansen and Cleary (23) gives a value of about 15 kcal/g mole for the low-temperature dependence of n-type semiconduction in zirconia in reasonable agreement with two values obtained here for the corrosion of zirconium (Fig. 4).

It is difficult at the present stage of research to visualize a specific relationship between the electronic and ionic conductivities in corrosion-product oxides formed on metals such as uranium and zirconium. What does appear clear, however, is that those factors which alter the electronic conductivity appear to exert an influence on the rate and energetics of ionic diffusion. The increase in corrosion rate of both zirconium and the alloy caused by increasing the solution pH, shown in previous work (2), and illustrated here by comparison of Fig. 1 and 2 with Fig. 3, is associated with lower values of activation energy as was also the case for cathodic polarization. It is interesting, therefore, that, by treating the oxide as a solvent for hydrogen and hydroxyl ions, the effect of increasing alkalinity can be described in similar terms as the effect of potential. In alkaline solutions there will be a greater tendency for the oxide to contain hydroxyl ions arising from an attempt to achieve a balance between the OH^- activity in both the aqueous and the oxide solvent. These hydroxyl ions can also be produced in the film by the combination of a hydrogen ion and a lattice oxygen ion, and this is probably the most favored state for a proton in the lattice. Thus alkaline solutions should encourage the absorption of hydrogen into the oxide, which in turn leads to enhanced electronic conductivity. A recent study (24) of anodic films on zirconium has shown that oxides formed in alkaline solutions are better electronic conductors than their counterparts formed in more acidic solutions.

The increase in the corrosion rate associated with the alloying of zirconium (compare Fig. 1 and 2) may be interpreted in terms of faster ionic diffusion through a defective mixed oxide. However, it is necessary to reconcile this with the superior performance of Zircaloy-2 in high-temperature water. Earlier work on uranium (1) showed that, although initial diffusion rates were increased by alloying additions, the over-all corrosion resistance was improved by the greater thickness to which the protective film could grow before cracking. The present work gives no indication of a similar effect although the possibility cannot be excluded. An alternative explanation may, however, be tenable. It can be shown by extrapolation of the Arrhenius plots (Fig. 4 and 5) that the corrosion of zirconium cathodically polarized at $E_{HA} = -0.33 \pm 0.02$v and -0.41 ± 0.02v becomes more rapid than that of Zircaloy-2 at about 115° and 160°C, respectively. Hence, it is possible that the superior resistance of the alloy is apparent only at temperatures above the boiling point of water.

It has been suggested that the higher rate of corrosion observed for the alloy at low temperature might be due to the presence of oxygen in the solution. While this is not impossible, the solubility of oxygen in alkaline solution is much below that in pure water (25), and the effect of the higher temperatures will be to decrease this further. Moreover, it is believed that the effect of potentiostatic polarization will be to absorb any small amounts of oxygen present in a depolarizing reaction.

Conclusions

It is established from the results that the activation energy for the aqueous corrosion of zirconium is generally lower than the activation energies for either atmospheric oxidation or for the self-diffusion of oxygen in zirconia. Moreover, it has been shown that variables such as the formation potential of the oxide, the alloying content, and the pH of the environment which have a significant effect on the corrosion behavior also tend to influence the activation energy, and in this respect, the results appear to be closely related to the earlier observations (3) on the uranium-zirconium alloy system.

It is not clear at the present stage what mechanism permits corrosion to proceed with the low activation energies observed, but the results stress the suggestion previously made that the electronic conductivity is an important parameter in corrosion kinetics.

Acknowledgments

The authors wish to thank Professor J. G. Ball in whose department the work was carried out, the United Kingdom Atomic Energy Authority for financial support, and the Consiglio Nazionale delle Richerche, Italy, from whom one of the authors (R. C.) was seconded. The authors are indebted to the Imperial Metal Industries (Kynoch) Ltd. for supplying the materials examined.

Manuscript received Dec. 28, 1964; revised manuscript received Oct. 11, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Electrical and Structural Properties of Langmuir Films

Robert M. Handy and Luciano C. Scala

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Barium and calcium stearate Langmuir films from 1 to 10 monolayers in thickness (approximately 25-250Å) have been investigated for use as ultrathin insulating barriers between evaporated metal electrodes. These metal-insulator-metal sandwiches showed highly nonlinear and temperature dependent conduction characteristics, from which a thermal barrier height of 0.25-0.30 ev is calculated. Reproducibility of electrical properties however was poor, apparently due to voids and inhomogeneities in the organic insulating films. It is calculated that even in the best samples, 2 to 3 monolayers were required to eliminate voids penetrating completely through the organic films. A reactive and hence oxidized surface was found to be necessary for the formation and retention of low porosity layers, tin being the most successful substrate electrode material. Insulating behavior could not be obtained from films transferred onto gold electrodes. Film structure and adhesion was investigated by studying the layering process and the autoradiographs obtained from C^{14} tagged films. The autoradiographs did not reveal any significant defects in the layers down to the resolution of the negatives ($\sim 25\mu$). It was found that the physicochemical nature of the substrate surface affected the adhesion of more than the first monolayer, and that porosity alone was unlikely to account for the long-range effect. Positive ion adsorption, as described by Goranson and Zisman, is suggested as a possible alternative and shown to be consistent with some aspects of the electrical measurements.

Metal oxide layers have often been employed as thin insulating films, particularly for the observation of electron tunneling phenomena. Our aim in the present work was to investigate the feasibility of using organic layers for the same purpose, that is, as insulating barriers 10-100Å thick sandwiched between conductive electrodes. Such an organic layer must be thin, homogeneous, uniform in thickness, and an excellent insulator. Monomolecular layers appeared to satisfy most of these requirements and could be easily obtained using the classic process developed by Langmuir and Blodgett. It was known that Langmuir films of certain materials behaved as insulators, in the sense that after being charged by surface electrification to fields exceeding 10^6 v/cm they showed very slow rates of decay. It was not known, however, whether voids, defects, or inhomogeneities in the films could be reduced to such a level as to permit the construction of tunnel sandwiches of useful area, nor whether the electronic properties of the insulating monolayers were suitable for device applications. In pursuing the answer to these questions, we have obtained new information on the behavior of Langmuir multilayers of small total thickness.

The Langmuir-Blodgett (1-3) process consists typically of spreading a monolayer of amphipathic molecules (*e.g.*, stearic acid) onto an aqueous surface, squeezing the monolayer into a compact floating film, and transferring it to a solid substrate by passing the substrate through the water surface. The molecules stand approximately vertical to the water or substrate surface, so that the compressed monolayer may be said to resemble a dense carpet whose thickness is determined by the molecular length. The surface of this hypothetical rug is formed by the ends of the molecular chains, and its nature depends on which end of the molecule is attached to the solid substrate. A very large amount of data on the formation and orientation of fatty acid or fatty acid salt mono- and multilayers is available in the literature (1-13) and will not be repeated here.

The higher the lateral pressure applied to the floating monolayer the more compact it becomes until it finally collapses. If transfer is accomplished at a pressure significantly below the collapse pressure, then voids or holes in the monolayer are inevitable. This is shown directly by the beautiful electron micrographs of Ries *et al.* (14) and is reflected indirectly in the variability of electrical measurements made on the Langmuir films. Buchwald, Zahl, and co-workers (15) attempted to measure the insulating properties of stearate films of from 1 to 41 monolayers by immersing metal rods coated with the multilayers into conductive salt solutions. A decrease in capacity and an

increase in resistance was observed with increasing numbers of layers. However, there was at least a twofold variation in apparent dielectric constant and several orders of magnitude variation in resistivity, both of which were influenced by the choice and concentration of the electrolyte. Small area probe measurements using water or mercury droplets were more successful. The mercury droplets in particular tend to bridge small defects in the layers because of their high surface tension. Porter and Wyman (8), working in the range from 7 to 141 monolayers, obtained dielectric constant values ranging from 1.9 to 3.5, with an average value of ~2.5. Race and Reynolds (16) made similar measurements on somewhat thicker films using Hg droplets and obtained values of 2.50 for calcium stearate and 2.44-2.56 for barium stearate, virtually identical to the bulk values which we have measured. The dielectric constant was independent of frequency between 40 and 10^6 cps.

Several workers (8, 16) studied both the resistivity and the breakdown strength of multilayer films. In general, the breakdown strength was higher with films formed at a higher bath pH. Breakdown voltages were generally rather low, *e.g.*, $\leq$ 0.5v. Moreover, they were often independent of thickness over a wide range and depended on whether water or mercury droplets were used as the top contact. Conduction through the films was highly nonlinear with increasing voltage and slightly asymmetric. No attempt was made to explain these observations other than to suggest that the water may be able to penetrate the films despite the hydrophobic nature of their surface. The variations in resistivity and breakdown strength observed with the mercury dots were generally ascribed to inhomogeneities or voids in the films. Further interest in the electrical properties of Langmuir layers lagged until Miles and McMahon (17) reported the use of a stearate monolayer as an insulating barrier for electron tunneling between superconductors.

The existing electrical data on Langmuir films (8, 15-17) was obtained from layers deposited on metal surfaces such as chromium, stainless steel, lead, tin, etc., which had been exposed to the atmosphere. All of these metals oxidize readily so that the organic monolayer was actually being deposited on the surface oxide, rather than directly on the metal. One can expect that the thickness of this surface oxide is significant compared to a monolayer thickness. In fact a brief exposure to the atmosphere is one of the standard techniques (18) for producing thin insulating oxides for tunnel conduction studies. The surface oxide adds another semi-insulating region electrically in series with the organic film. For optical studies on multilayer films its presence can usually be ignored, but, for some electrical measurements, the surface oxide may dominate the behavior, particularly if the organic layer contains holes so that the oxide can come into intimate contact with the counter electrode. The contribution of the surface oxide has apparently been neglected by most previous workers. Much of the data presented by Porter and Wyman (8) or Miles and McMahon (17), for example, could be explained by assuming direct contact to semi-insulating oxide layers.[1] As will be shown, this is a likely occurrence.

We have investigated the electrical behavior of stearate multilayers. For the most part, evaporated electrodes were used rather than mercury dot probes, and the range from 1 to 10 monolayers in thickness (25-250Å) was explored. The evaporated electrodes lead to a higher incidence of shorts through defects in the films, but they also provide a realistic test of film uniformity and of the practical utility of Langmuir layers for use as ultrathin insulating films. In order to reduce the occurrence of voids to a minimum, film transfer was effected as close to the collapse pressure as possible, using special apparatus developed for this purpose. The layering process was examined in detail, and auto-radiographs were made using C^{14} tagged layers in order to study adhesion and the occurrence of gross defects in the film. Considerable attention was devoted to the problems presented by the surface oxide and the porosity of the organic layers.

The organization of the paper was dictated by the complex interrelation between the electrical and structural properties of the layers and the difficulties encountered in trying to discuss one aspect without already having said a great deal about the other. The "results" section begins with the electrical measurements and carries through to the structural observations. In the "discussion" section, however, the order has been inverted, since the electrical measurements can be best understood in the light of the discussion of the structure and physicochemical properties of the films.

Experimental

The experimental structure consisted of glass slides on which a number of parallel stripes of one or more metals had been evaporated. The organic film was then applied as described below, and finally the second electrode stripe was evaporated over the top at right angles to the first set. Each sample provided from 6 to 9 metal-organic-metal junctions approximately 1 mm^2. The capacity of these sandwiches was measured, usually at 1 kc. Current-voltage characteristics were obtained at d.c. and 60 cps by four terminal methods. For variable temperature measurements, the samples were clamped to a heavy copper block, enclosed in a heat shield, and cooled with liquid nitrogen.

The Langmuir film apparatus consisted of a modified Cenco Hydrophil balance of the Langmuir-Adam-Harkins type, housed in a double wall thermostated cabinet mounted on a heavy steel table. It is similar in design to that described by Ries (19). The table was suspended from the ceiling by shock cords to eliminate extraneous vibration. The cabinet was slightly pressurized with dry filtered nitrogen to minimize atmospheric dust during preparation of the layers. The aluminum trough and stainless steel compression barriers were Teflon coated. The stearic acid in these experiments (Eastman Kodak best grade, mp 69°-70°C) was dissolved in Fisher Spectranalyzed n-hexane (0.0274g of acid/100 cc of solution). A few drops of this solution were used to form the film on the aqueous subphase, which contained Ba or Ca acetate or carbonate and which was appropriately buffered (29). The water for these aqueous subphases was originally triple distilled and was subsequently purified by passing it through ion exchange resin columns (final resistivity of water 1-2 megohms). Small quantities of acetic acid or ammonium hydroxide were used to control pH, which was held at a value of 6.8-6.9 for Y layers and 9.0 for X layers.

After the monolayer was spread, it was allowed to rest for 10 min to allow for the complete evaporation of the solvent. Compression of the monolayer was carried out at a rate of 7 mm/min. Pressure readings were taken every 10 mm of barrier travel at the beginning, and every millimeter of barrier travel near the desired transfer pressure. The transfer pressure used throughout this work was 39 dynes/cm, and it was reproducible within 0.5 dynes/cm. On attaining the transfer pressure, the electrode bearing slides were dipped at a rate of 2 mm/min, compression barrier speed being adjusted to maintain constant film pressure.

The precautions observed to insure absence of impurities from the surface of the aqueous substrate are summarized below.

(*A*) Before each experiment the trough was washed with deionized water, CP acetone, Spectro Grade

[1] The authors are indebted to Dr. J. L. Miles, one of the authors of ref. (17), for suggesting this interpretation of their results.

benzene; it was then treated in a trichloroethylene vapor degreaser.

(*B*) Before the layer was spread, the surface of the aqueous subphase was swept in front of and behind the balance and the degree of cleanliness checked using the balance.

(*C*) Sample slides were cleaned with Alconox detergent and warm water, rinsed with running deionized water, blown dry in a clean nitrogen stream, and then placed in a liquid nitrogen trapped evaporator for depositing the lower electrodes.

(*D*) After electrode evaporation and before monolayer deposition, the slides were dipped in the aqueous substrate, and any impurity contributed by them was swept away as described in step (*B*).

(*E*) All the parts of the balance that came in contact with the aqueous substrate were thoroughly cleaned with Spectro Grade benzene or purified n-hexane, allowed to dry, and then coated with a thin petroleum ether solution of hard wax. After about 1 hr, these wax-coated pieces were rinsed abundantly with deionized water. This treatment tends to do away with loose pieces of wax which may, later on, interfere with the film formation and compression.

In general, clean room techniques were followed and every effort was made to prevent contamination of the monolayers and the substrate surfaces during preparation of the sandwiches. A detailed description of the apparatus, and some preliminary results were presented earlier (20).

Results

A large number of samples were prepared using noble metals (*e.g.*, Ag and Au) as the first electrode in order to minimize or avoid the presence of an oxide layer. On many of these samples, half of the first electrode stripes were tin. From one to ten layers of calcium or barium stearate were transferred to these samples using the techniques described previously. On each passage through the surface of the bath, the area of the floating monolayer was observed to decrease, providing direct evidence of the transfer of the monolayer to the surface of the slide. In every case, however, electrical tests of the finished samples showed a junction resistance of less than 1 ohm for the noble metal based junctions. By contrast, the tin-based junctions yielded significant numbers of insulating devices showing nonlinear current-voltage characteristics. It was not possible to obtain any insulating behavior on an oxide-free electrode, even when adjacent tin based structures showed uniform stable insulating properties. This suggests strongly that the oxide plays an essential role in determining the electrical properties of Langmuir film sandwiches.

Two explanations are possible: either the insulating behavior is derived directly from the oxide, or the oxide and the reactive metal ions which it contains contribute significantly to the adhesion of the organic film. As will be shown, both processes are important. The electrical data which follow were derived principally from tin based junctions with various metals (Sn, Ag, Au, Cu, Pb, etc.) serving for the upper electrodes. A few copper based samples were successfully prepared and have been included.

Capacity measurements.—Figure 1 shows the results of capacity measurements on some 75 samples.[2] The average electrical thickness, given in terms of the reciprocal capacity (1/C) is plotted as a function of the number of layers predicted from the transfer process (N_p). The apparent dielectric constant may be calculated using the stearate monolayer thickness of ~25Å. It is seen that the data fall essentially between the dotted lines given by $\epsilon = 2.1$ and $\epsilon = 4.2$. The heavy dashed line corresponds to the bulk value of

[2] On Fig. 1 many of the clusters represent points which would fall on top of each other, and, in order to show the density distribution of the data, they have been slightly misplotted to the left or right.

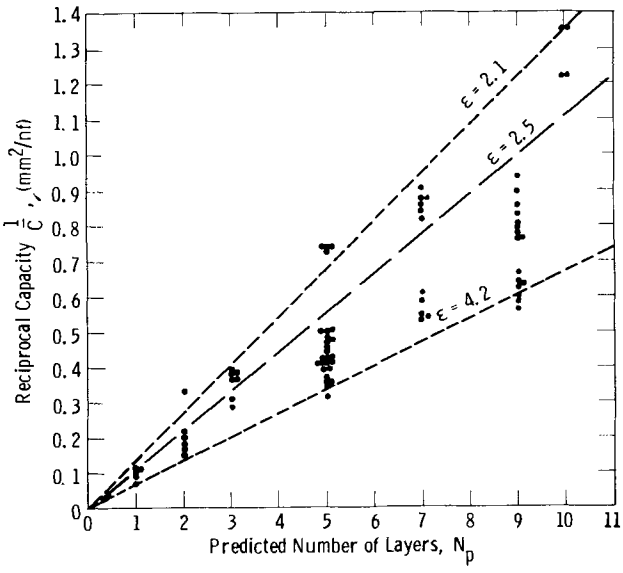

Fig. 1. Reciprocal capacity *vs.* predicted number of layers

$\epsilon = 2.5$. The spread in apparent dielectric constant values is of the same order as that obtained by others (8) working in a comparable thickness range, but using liquid contacts, *i.e.*, water or salt solution.

If the capacity is measured as a function of frequency, a slight change with frequency is observed, as shown in Fig. 2 for a typical sample. The upper curve gives C, and therefore ϵ *vs.* log *f*. Over the range from 100 cps to 20 kc, the dielectric constant drops by about 5%. The lower curve shows the variation with frequency of the imaginary part of the complex dielectric constant (proportional to *C* x *D*). It is noted that a slight maximum occurs near 700 cps, suggesting the presence of a weak polar adsorption mechanism with a characteristic relaxation time ($\frac{1}{2}\pi f_m$) of 0.23 msec. At higher frequencies (*i.e.*, $f > 10$ kc) the measurement uncertainty in the dissipation factor *D* becomes comparable with the observed values.

The contribution of the oxide region has been neglected in presenting the capacity measurements. To a first approximation this is reasonable, since, as will be shown in the next section, the resistivity of the oxide film is small compared to the resistivity of the organic layers. Calculation of the capacity of a composite oxide-organic multilayer structure shows that the porosity must exceed ~5% of the total area before a significant departure from the no-void value occurs. Under these circumstances, the sample resistance is usually so low that capacity values are not measurable.

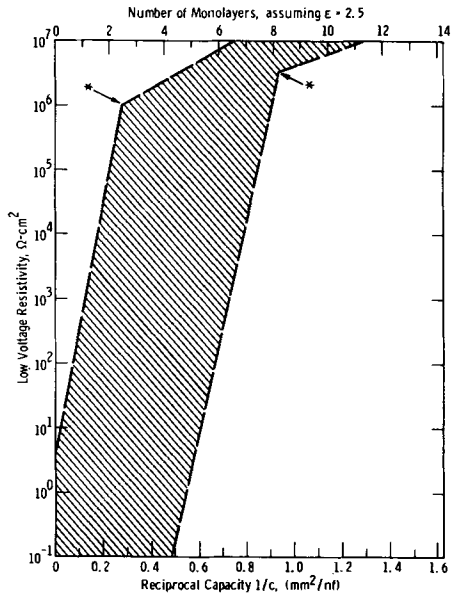

Fig. 3. Low voltage resistivity vs. reciprocal capacity (1/C) for barium stearate multilayers. Upper scale shows calculated number of monolayers assuming $\epsilon = 2.5$. * Indicates points of probably complete film coverage.

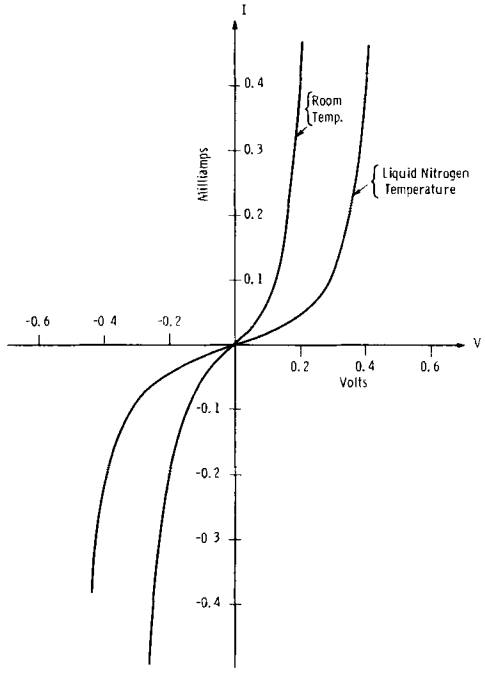

Fig. 4. Current-voltage characteristics at 0.1 cps of a Sn-3 layer calcium stearate-Sn sandwich of ~1 mm² area at two temperatures. Polarity is that of organic coated tin base layer.

Resistivity measurements.—The resistivity of the junctions was measured at low voltage (< 50 mv) where the current voltage characteristics are linear. If the values are plotted as a function of the measured thickness, as in Fig. 3, it is found that the points are approximately uniformly distributed within the shaded interval. The boundary lines denote the limits of the observed values. The points which define the upper limit of resistivity for a given thickness are generally those corresponding to the points on the upper limit line of Fig. 1, that is, the thickest layers obtained for a given number of transfer strokes. The wide range of resistivity values observed for the same measured thickness (1/C) supports the contention that the organic films are porous. It seems probable that, for small values of 1/C, the majority of the low-voltage resistivity values are characteristic of the oxide, and reflect the degree of coverage obtained, *i.e.*, the fractional area of the oxide in direct contact with the top electrode. The upper limit would correspond to those layers possessing the smallest fraction of voids.

The stearate films are necessarily transferred at a pressure slightly less than the collapse pressure, and hence the layers may well contain small open areas separated by comparatively large void-free regions of film. The collapse point corresponds to a fully compacted film of minimum area, which presumably no longer contains any voids. The pressure-area isotherm allows one to calculate the void area for pressures slightly less than the collapse pressure. We are interested in a worst-case estimate, hence we neglect changes in area due to elastic contraction or expansion of molecules and assume that for pressures less than the collapse pressure the deviation from the minimum area consists entirely of voids. Using the actual transfer pressure, and the measured pressure-area isotherm, we estimate the void area to be less than 2-3% of the total area. If the oxide is highly insulating, then one should be able to duplicate the electrical behavior of the organic coated samples by using an uncoated sample of sufficiently small area. To test this concept, the junction area was reduced from 1 to 0.02 mm² (*i.e.*, 2% of the usual value) and the junction resistance of coated and uncoated samples compared. Without exception, the uncoated samples gave resistivities of 10^{-4} to 10^{-5} ohm-cm², even when treated by a 1-hr exposure to a low-pressure oxygen glow discharge to promote oxide growth. By comparison, 1 mm² samples coated with a single monolayer gave low-voltage resistivities approaching 10^{3} ohm-cm², as can be seen from the upper limit line on Fig. 4. In order to account for the resistivity of the organic coated sample, the void area of this single monolayer would have to be less than 10^{-10} cm², or less than 10^{-6}% of the total area of a 1 mm² sample. Langmuir films are known to bridge small defects or voids (21), so that a multilayer sample corresponding to the upper limit line would have 10^{-14}% voids through two layers, 10^{-22}% voids through three layers, and so forth. The prospect of significant void area extending through more than about two layers is negligible under these conditions even if current flow is assumed to take place predominantly at the periphery of the junctions (27) rather than uniformly across the area. It can be seen in Fig. 3 that the upper limit line undergoes a significant change in slope at a calculated[3] thickness (N_o) between two and three monolayers, presumably corresponding to the onset of complete coverage. The resistance beyond this inflection point corresponds to an equivalent bulk resistivity of 10^{12} ohm-cm, which is comparable with the value for many bulk insulators. Most of the samples are not so compact as those falling near the upper limit line, and more than 2-3 monolayers are required to achieve total coverage of the surface. The lower limit line undergoes a change in slope at $N_o \approx 8$. Assuming that the low voltage resistivity (below the inflection point) provides a measure of the oxide area which remains exposed, then the average void area of the more porous films can also be estimated: *e.g.*, $R_o = 10^3$ ohm-cm² requires 10^{-6}% voids. The average void area per monolayer then should correspond to the N_o^{th} root of the void fraction. For the lower limit line, this gives an average void fraction per monolayer of the order of 6%, which is somewhat larger than the maximum value expected from the transfer conditions.

Conduction characteristics and temperature dependence.—Typical current-voltage characteristics of the metal-organic-metal sandwiches are shown in Fig.

[3] Calculated from capacity measurements assuming $\epsilon = 2.5$ and using the geometric area of the junction.

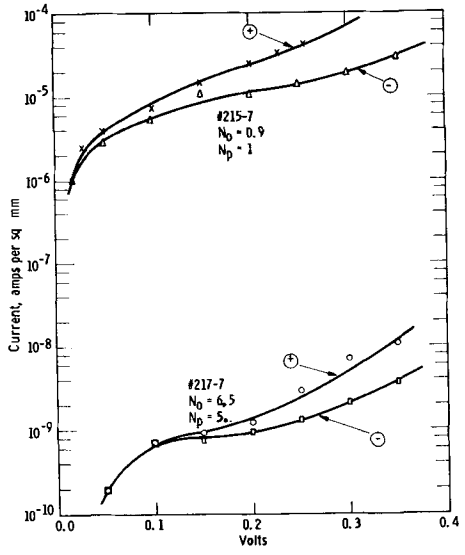

Fig. 5. Current-voltage characteristics of a one and a five-layer Sn-stearate-Sn sample. N_p = predicted number of monolayers; N_o = observed number of monolayers as calculated from measured capacity assuming $\epsilon = 2.5$. ⊕ and ⊖ indicate polarity of organic coated base layer.

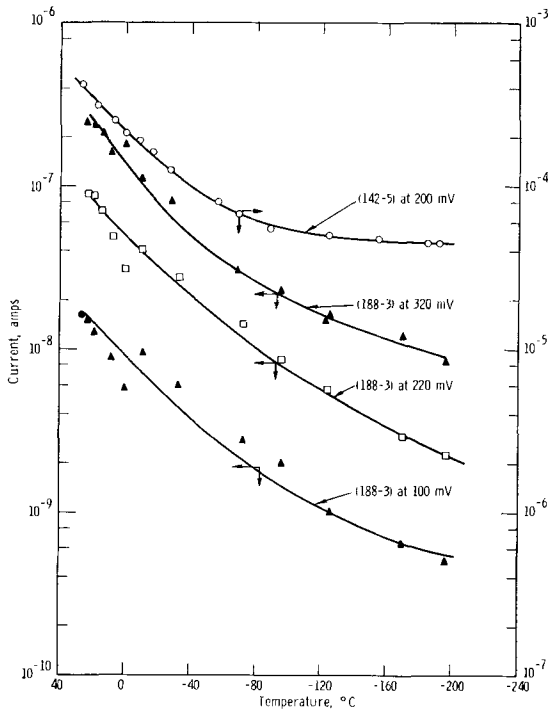

Fig. 6. Plot of current vs. temperature at constant voltage for two junctions. Junction (142-5), upper curve, is ~3 monolayers thick; junction (188-3), three lower curves, is ~5 monolayers thick. Polarity of test voltage is organic coated base electrode positive.

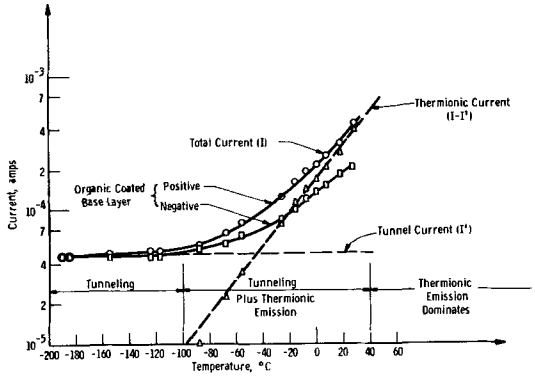

Fig. 7. Temperature dependence of current at constant voltage, 0.2 v.

4.[4] Near zero voltage the characteristic is linear and presumably controlled by the voids present in the organic films. As the voltage increases beyond 0.1-0.2v the current rises very rapidly with increasing voltage and, because of the current densities required, it must flow increasingly through the organic film. The voltage required for significant departure from linear conduction increased slightly with increasing layer thickness as would be expected, but in general was significantly less than the values typically observed for inorganic insulating films (*e.g.*, Al_2O_3) of comparable thickness. Figure 5 shows a semi-log plot of the I-V characteristics of a thin ($N_o \sim 0.9$) and a thick ($N_o \sim 6.5$) sample plotted on the same scale. The absolute current levels differ by about four orders of magnitude as would be expected from Fig. 3. The slope of the characteristics also differs slightly, the thicker film showing a more rapid increase in current than the thinner film. The thicker films are also more temperature sensitive. Figure 6 shows the variation of current with temperature at constant voltage for a ~3 layer film and a ~5 layer film. The slope at high temperature is approximately the same in both cases, indicating that the thermal activation energy for conduction is also comparable. At low temperatures, however, the slopes are quite different due to the different relative contribution of tunneling and thermionic currents through the sandwiches in the two cases.

The behavior of the 3 layer sandwich has been analyzed in detail as shown in Fig. 7. By subtracting the extrapolated zero temperature current value I', the thermionic contribution to the current (I-I') represented by the heavy dashed line, is obtained. This yields a straight line on a Schottky plot of log $[(I-I')/T^2)]$ *vs.* $1/T$ as shown in Fig. 8. From the slope and the measuring voltage, the zero voltage thermal activation energy ϕ_b is determined as $0.25 < \phi_b < 0.30$ ev. This analysis presumes that conduction is dominated by tunneling at low temperatures, and by thermionic emission over the insulating barrier of height ϕ_b presented by the composite oxide-organic film at high temperatures. Several attempts have been made to analyze the I-V characteristics using theoretical expressions derived by Stratton (22), Simmons (23), and others in order to obtain additional estimates of the various barrier parameters. However, a fit could not be obtained over any significant range of the variables. This was true even at low temperature and low thickness where we believe tunneling to be the predominant nonlinear conduction mechanism.

Layering and film structure.—In the present investigation considerable effort was expended to achieve reproducible results from the Langmuir-Blodgett monolayers. Extensive precautions were taken with regard to physical and chemical cleanliness of the materials and equipment, and film transfer was accomplished under much more carefully controlled conditions than were present during many of the earlier studies of electrical properties. Nevertheless, reproducibility of electrical properties was limited, and therefore some of the aspects of layering and film transfer onto solid substrates were examined by other means.

[4] In a few preliminary experiments in which the organic films were prepared by the classic piston oil and floating thread techniques but under very uncertain and crude layering conditions, some samples of remarkable electrical uniformity, stability, and voltage tolerance (*e.g.*, >1v) were obtained. They could not be duplicated once the experimental procedures were refined. It is possible that these may have represented nearly perfect layers; however, the high vibration levels and frequent leakage of piston oils during transfer made this unlikely. While the characteristics of Fig. 4 are not as attractive as these early results, they are more representative of the bulk of the samples.

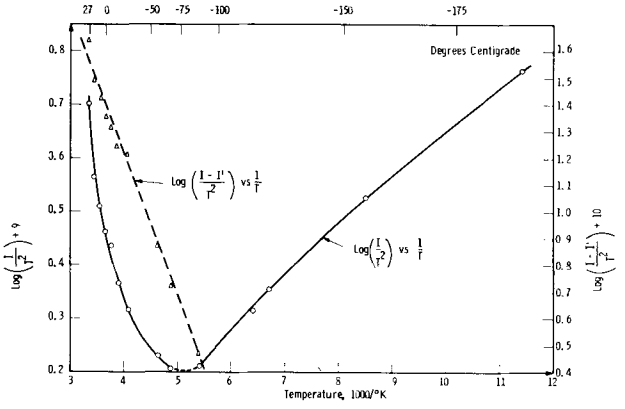

Fig. 8. Plot of log (I/T^2) vs. $(1/T)$ and log $[(I-I')/T^2]$ vs. $(1/T)$, where I = total current, I' = low-temperature current in amperes, and T = absolute temperature.

The uniformity and compactness of the monolayers used to build the insulating films are of paramount importance. These factors are most strongly influenced by the conditions during transfer, *e.g.*, film pressure, bath *p*H, etc. Pressure-area isotherms of barium and calcium stearates obtained during this study follow the course of the P/A curves of condensed monolayer films as discussed by Alexander (24), and indicate that the film forming techniques contained no gross defects. However, the area of monolayer swept off the bath by the compression bar during the actual transfer of layers was often different from the cumulative area of the sample being coated.[5] Using data from all of the samples prepared, it was found that on the average the barrier motion exceeded the predicted values by about 20%, which is considerably greater than the measurement uncertainty of our apparatus. This phenomenon may arise for example, from solution of a portion of the monolayer, or folding of the monolayer. It has been reported (30, 31) that stearic acid dissolves in the aqueous subphase under certain circumstances. In our case the rate of solution may have been increased because of the relatively high pressures employed throughout this work (30). Of these possibilities, only folding would be of serious consequence to the electrical measurements. This possibility was eliminated by autoradiograph studies described below.

Autoradiograph studies.—A visible demonstration of the effectiveness of transfer is provided by autoradiographs of mono- and multilayer Langmuir films containing C^{14} tagged barium stearate. The radioactive material was obtained as stearic acid in benzene solution from the Nuclear Chicago Corporation, with a total activity of 12.3 mc/millimole, and was diluted, spread, and transferred in the usual way, but at slightly lower pressures. Autoradiographs were taken by clamping a piece of Medical No-Screen x-ray film against the samples covered by the radioactive layer. Exposure time was approximately one day at 5°C. Results from four samples are shown in Fig. 9. It will be noted that the metallic stripes and circles evaporated onto the 1 x 3 in. glass slides and covered by the radioactive Langmuir films are visible. This is due to the difference between the back-scattering coefficient of the glass and that of the various metals. A number of small spots or scratches and a few large blemishes (*e.g.*, the dark region adjacent to the white clamp imprint at the top of Fig. 9a) can also be seen. With few exceptions these were traced to dust particles which settled on the surface after transfer, to imperfections in the film introduced during developing, or to artifacts of the reproduction and printing process. The general conclusion from the autoradiographs is that the organic layers are very uniform and cover the glass and metal stripes satisfactorily. There are no apparent gross defects. The resolution of the autoradiographs, however, is only 10-25μ depending on the film density,[6] so that uniformly distributed voids of the sizes discussed earlier would not be visible. Nevertheless, the large-scale uniformity over areas exceeding 3 in.^{2} is reassuring testimony as to the quality of the transfer procedures. None of the sample showed any evidence of "folded over" regions, such as reported by Roberts and Gaines (25).

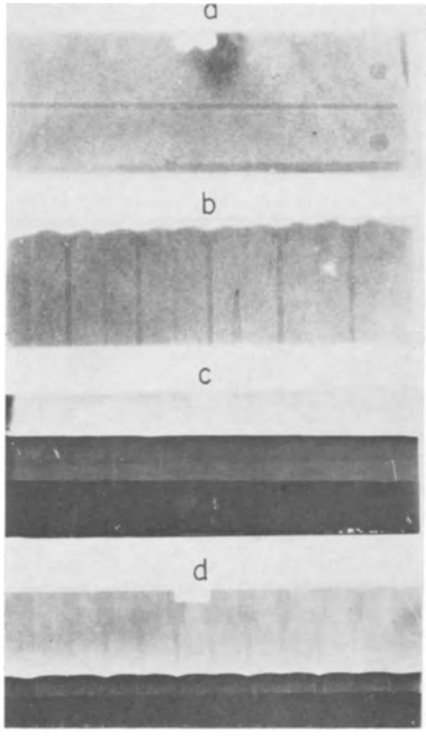

Fig. 9. Autoradiographs of radioactive Ba stearate and Ba stearate: PVB mixture mono- and multilayers. From the top: (a) one monolayer of Ba stearate over tin stripe on glass; (b) one monolayer of Ba stearate over tin and copper stripes on glass, showing different contact angles between aqueous subphase and glass or metal; (c) one, three, and five monolayer steps of Ba stearate; (d) one, three, and five monolayer steps of equiweight mixture of Ba stearate and PVB.

The four samples shown in Fig. 9 have been covered with varying numbers of monolayers as follows: (*a*) one monolayer over the whole slide, (*b*) one monolayer over part of the slide, the wavy edge showing the location of the meniscus at the beginning of the transfer stroke, (c) one monolayer over the whole slide, three monolayers and five monolayers over part of the slide as shown by the bands of increasing optical density, (*d*) steps of 1:3:5 monolayers similar to (c), but using an equiweight mixture of stearic acid and polyvinyl benzoate (PVB). The optical density of the exposures taken of the 1:3:5 stepped multilayer samples was measured and found to correspond to radioactive emission intensities also in the ratio 1:3:5, providing direct confirmation of the transfer of a single monolayer on each dipping stroke.

In those cases (Fig. 9b-d) where the slide was only partially immersed in the bath during some part of the transfer process, the optical density step gives an imprint of the meniscus where the floating monolayer met the surface of the slide. Over the different regions of the slide, *i.e.*, glass, copper, tin, the meniscus reached

[5] In most of the classical studies of Langmuir films a flexible floating thread was used as a barrier, and hence the accuracy of their area measurements is in some doubt.

[6] The resolution limit of these films was directly determined from the edge definition at the monolayer steps, (*e.g.*, 0 to 1, 1 to 3, 3 to 5, etc.), using a special instrument developed by Dr. A. Bennett of the Westinghouse Research Laboratories. We are indebted to Dr. Bennett for performing the measurements.

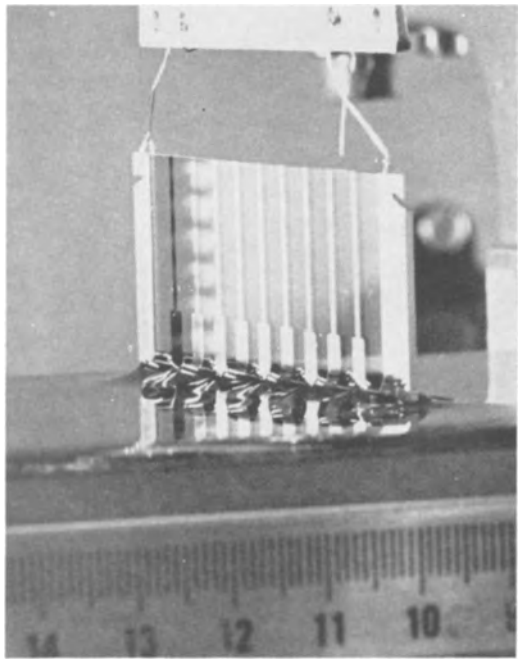

Fig. 10. Electrode arrangement on the sample and meniscus formed with the surface of the Langmuir bath content. There are 9 narrow electrodes and 2 wide end pads running parallel with the narrow dimensions of the slide. The 1st, 3rd, 5th, 7th, and 9th electrodes are gold. The remainder and the end pads are tin. Note the differences in the height of the meniscus over Sn, Au, and glass.

different heights, yielding a wavy pattern, corresponding to the different contact angles assumed by the meniscus. The higher the meniscus, the smaller the contact angle. The same effect can be seen visually during the actual transfer operation. Figure 10 shows a photograph of the meniscus drawn up on a slide as it is being pulled up out of the bath. (The slide is inverted with respect to those of Fig. 9.) The contact angle is small against the glass, and increases progressively against Sn, Cu, and Au surfaces in that order. The differences in contact angle reflect differences in the chemical nature of each surface, and to a first approximation one can expect that the binding forces, which tend to make the monolayer adhere, decrease as the contact angle increases. The first monolayer, understandably, should reflect these differences, as was seen in Fig. 10 and Fig. 9b. Once the first monolayer has been applied, however, the substrate surface is covered by a sheet of molecules 25Å thick, so that subsequent layers deposit on an organic base and are removed further and further from the substrate in 25Å steps. It is inconceivable that the interatomic binding forces responsible for the adhesion of the first layer could extend so far from the surface as to directly influence the adhesion of the second layer, much less the third and subsequent layers. The autoradiographs, however, show significant differences in contact angle to be present at the edge defining the third layer, and still perceptible differences to be present at the edge of the fifth layer. The effect was present on samples made with barium stearate as well as with the stearate-polyvinyl benzoate mixture. Clearly, the physicochemical nature of the substrate surface influences the contact angle and hence the adhesion of considerably more than the first monolayer.

We have observed that the contact angle against the glass surface increases as the number of dips increases. This corresponds to an over-all reduction in the adhesive forces tending to bind the floating monolayer to the solid surface, and to a gradual attenuation of the influence of the underlying substrate surface. Similarly, the difference in meniscus heights over the different regions of the slides, Fig. 10, becomes smaller as the number of dips increases. Equalization proceeds by means of the contact angle over the glass increasing more rapidly than the contact angle over the metal surfaces.

It was considered possible that this behavior might be explained on the basis of porous films, as were many of the electrical results discussed earlier. Inspection of the autoradiographs, however, places several conditions on this hypothesis: (i) the maximum hole size must be less than 25μ, (ii) the distribution of holes must be fairly uniform, and (iii) the percentage of holes must be approximately the same from layer to layer. Computing the porosity from the transfer pressure and the P/A isotherms, one finds that it can amount to only a small fraction of one per cent through the multilayers regions, and hence, by itself, porosity appears insufficient to account for the differences in wetting angle visible in the multilayer regions. Any tendency of the monolayers to bridge defects in the surface will further reduce the possibility that porosity has a significant bearing on the adhesion of subsequent layers. Some long-range force or ordering effect seems necessary.

Discussion

Germer and Storks (26) have observed that the azimuthal orientation of the molecules in the monolayers depends upon the physicochemical nature of the substrates. Films deposited on a hydrophobic surface (polystyrene resin) showed a high degree of hexagonal symmetry even in a single layer. On a metallic surface (chromium) the azimuthal orientation of the first monolayer was random, but a progressive increase in molecular order was observed in succeeding layers. This undoubtedly reflects the increased surface mobility of the molecules which are not in direct contact with the chemically active metal surface, or its oxide. Metal layers, however, may influence the adhesion of monolayers in another way. Goranson and Zisman (13) showed that excess divalent metal ions can become trapped in the films as they are withdrawn from the bath, so that the multilayer structure possesses a volume distribution of positive charge. The charges are distributed along the carboxyl group planes of the multilayer and, unless they are compensated, the net positive charge will increase with successive monolayers. The effect of this excess positive charge is to repel the positive ions adsorbed on carboxyl face of the floating monolayer. This is observed macroscopically as an increase in the contact angle with increasing numbers of layers. These authors also point out that the magnitude of the effect will depend on whether the substrate is conducting or insulating. The metallic regions on the substrate provide an equal negative image charge which reduces the repulsive force experienced by the floating monolayer. According to this hypothesis, the progressive increase in contact angles should be greatest over the insulating glass regions of the substrates, as we have observed. Unfortunately, we are not able to offer direct evidence of positive ion trapping in the multilayers. It is recognized that the arguments leading to this conclusion are largely circumstantial, being based on observations made during the transfer process and a study of the autoradiographs. However, no other mechanism has been discovered which can account for the long-range influence of the substrate surface through the multilayer films, and which is also consistent with all of the other experimental data.

If enough excess ions are being taken up by the films so as to perturb the layering process, then one can expect their presence to alter the electrical properties of the Langmuir films as compared with the bulk material. Figure 2 shows this to be the case in that the dielectric constant is slightly frequency dependent, and a weak maximum is observed in the loss factor. Neither

of these effects was present in bulk samples tested over the same frequency range.

The variable temperature measurements performed on the samples yielded a thermal barrier height ϕ_b of a few tenths of an electron volt. This is considerably smaller than the values (*e.g.*, 1-2 ev) reported (27) for metal-oxide-metal structures using materials such as Al_2O_3 for the insulating region. Not enough is known about the bulk electronic properties of the stearates to decide whether such low values are reasonable for a metal-stearate-metal barrier. We suspect, however, that the observed values of ϕ_b may be characteristic of the defects and impurities within the films, particularly in view of the evidence suggesting appreciable positive ion occlusion.

It was noted earlier that the I-V characteristics could not be satisfactorily fitted to the theoretical expression derived on the basis of simple homogeneous barriers. This is not surprising considering the complex nature of the composite Sn-SnO-stearate-metal barrier. Even for those multilayer samples in which we believe complete coverage of the lower electrode has been attained, there will still be significant local inhomogeneity in thickness. Small area variations in thickness will not have an important effect on the capacity measurements. However, both tunneling and field-assisted thermionic emission depend exponentially on thickness, so that the conduction characteristics will be strongly affected.

The results of the many attempts to form insulating multilayers on gold surfaces present an interesting problem. We have ample evidence to show that it is possible to seal off the surface of the tin electrodes. Given the same average porosity we would expect that at least some of the gold based samples would have been successful. None were successful, hence we conclude that the average porosity over the gold films must have been greater. The contact angle observations show that the adhesive forces between the floating monolayer and the gold surfaces were not as strong as in the case of glass or tin surfaces.

There is evidence in the literature (25, 28) to show that free stearic acid, which most of our films contain to some degree, is less strongly bound to noble surfaces, and furthermore can be pumped-off in vacuum. Thus, even though the porosity of the layers may initially have been no greater than that of the layers over the Sn or glass region of the samples, the layers on the gold surfaces will be less stable and are likely to develop significant voids extending through the entire multilayer.

Summary

A reactive, and in this case oxidized, electrode surface appears necessary for formation and retention of low porosity layers. The voids and inhomogeneities in the films strongly influence the electrical properties, giving rise to a 2 to 1 variation in capacity values and several orders of magnitude variation in low voltage resistivity for the same apparent thickness. Examination of the temperature dependence shows tunneling to be the dominant nonlinear conduction mechanism at low temperature and low thickness, while field assisted thermionic emission dominates at high temperature and greater thickness.

It was found that the physicochemical nature of the substrate surface affected the adhesion of more than the first monolayer, and that porosity alone was unlikely to account for the long range effect. Positive ion adsorption, as described by Goranson and Zisman, is suggested as a possible alternative and shown to be consistent with some aspects of the electrical measurements.

Surface Diffusion Processes and Dendritic Growth in the Electrodeposition of Silver from Molten Halides

Thomas B. Reddy*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Studies of the rise time of the cathodic overpotential during galvanostatic pulsing of silver electrodes in molten AgCl-LiCl-KCl mixtures at 450°C show that the mechanism of electrodeposition from fused salts includes a step for surface diffusion of adatoms from point of deposition to growth sites on the metal surface. The concentration of adatoms on the surface at equilibrium and the surface diffusion rate have been determined and are compared to those found in aqueous electrolyte solutions at 25°C. The formation of dendritic deposits of silver is found to occur only when a concentration gradient equivalent to 4 mv polarization is produced. Destruction of this gradient through the use of a high concentration of silver chloride and convection reduces the concentration polarization and leads to the formation of coherent deposits. Studies of the dendrites produced by electrodeposition show that they all contain two parallel twin planes and indicate that nucleation and growth in these dendrites occur by the twin plane re-entrant edge mechanism previously shown to occur in the growth of germanium dendrites from the supercooled liquid.

There has been much recent interest in the mechanism of electrodeposition from aqueous solution. Bockris (1-3) and Gerischer (4) have advanced convincing theoretical and experimental evidence that the mechanism of silver deposition involves a step following the charge-transfer reaction for the diffusion of adatoms from point of deposition to growth sites on the crystal surface. Concurrently, scientific interest in electrode processes in molten salt solvents has greatly increased.

There have been several previous studies of various aspects of silver deposition from molten salts. Aten, den Hertog, and Westenberg (5) found low cathode polarization during deposition of silver from a large number of salt mixtures. Microcrystalline deposits were obtained from mixtures of KCl, NaCl, and AgCl at 705°C. Drossbach (6) electrodeposited silver from mixtures of KCl-NaCl-AgCl at a current density of 0.20 ma/cm^2 and a cathode polarization of 2 mv. Drossbach and Petrick (7) determined the limiting current for silver deposition from dilute solutions of AgCl in the LiCl-KCl eutectic at 450°C. If the carbon anode was not isolated, considerable convection in the melt was produced by chlorine evolution. With an isolated anode, stirring was found to increase greatly the limiting current for silver deposition. The tendency for metals to form dendrites when deposited from fused salts is well known. Yang, Chien, and Hudson (8) studied the formation of silver dendrites grown from the LiCl-KCl eutectic at 500°C. The trunks of these dendrites grew in the <211> directions with branching in the <211> and <110> directions. Shams-El-Din and Wranglen (9) investigated the morphology of silver dendrites grown by electrodeposition from a molten LiCl-KCl eutectic with 10-40% added AgCl at temperatures of 413°-475°C and current densities of 30-200 ma/cm^2 and found results similar to those reported by Yang, Chien, and Hudson. The dendrites were shown to be planar and the addition of a number of inorganic salts to the melt was found to have little effect on the morphology of the dendrites. Faust and John (10) made metallographic examinations of the dendrites grown by Yang, Chien, and Hudson and found they contained two or more twin planes.

Barton and Bockris (11) studied the growth of silver dendrites at 308°C from molten equimolar sodium nitrate-potassium nitrate containing silver nitrate. These authors found that the growth of the dendrite tip at constant overpotential was linear with time after an induction period. Data on growth rate at varying overpotential were obtained for a large number of dendrites and data on growth rate, radius of curvature at the tip, and overpotential were obtained for three dendrites. Barton and Bockris have developed a theory of dendritic growth by metal deposition. Three factors are included in the theory to account for the observed overpotential: charge-transfer, diffusion, and surface energy. The resulting equation predicts the growth rate as a function of overpotential, concentration, surface energy, and exchange current. In an attempt to obtain a fit between experiment and theory, the exchange current, transfer coefficient, and surface energy are treated as adjustable parameters, but only fair agreement is obtained. This theory suffers from several defects. The diffusion is assumed to be a spherical tip rather than to the more physically reasonable paraboloid. The nature of diffusion to these surfaces is quite different. Diffusion controlled growth of a sphere varies as the square root of time, while that of a paraboloid is linear in time (12). In addition, Barton and Bockris have equated the thickness of the diffusion layer to the radius of curvature of the dendrite tip.

Hamilton (13) has adopted the theory of dendritic growth in a supercooled liquid metal developed by Ivantsov (12) and Temkin (14) to the case of electrodeposition. This development of the theory of electrochemical dendrite growth, based on the assumption that the rate is controlled by diffusion alone, shows remarkable accuracy in predicting the tip radii for the three specimens studied by Barton and Bockris without the use of any adjustable parameters. An expansion of the theory to include terms for the curvature of the tip and activation overpotential gives agreement between theory and experiment only if surface energy and exchange current are treated as adjustable parameters. The values of exchange current and surface energy required to fit the experimental curves of growth rate against overpotential are higher by an order of magnitude in the case of the exchange-current and lower by a similar factor in the case of the surface energy than those known to be physically reasonable for this system. These disparities throw considerable question on the validity of the extended theory and reinforce the conclusion that diffusion is the dominant factor in the electrochemical growth of dendrites. The contribution to the overpotential due to the curvature of the surface, given by

* Present address: American Cyanamid Co., Stamford Research Laboratories, Stamford, Connecticut, 06904.

the expression $2\gamma V/F\rho$, is of the order of 1 mv for the dendrite tips measured by Barton and Bockris. The effect is a secondary contribution to the total overpotential. The activation polarization under the condition employed by Barton and Bockris is only of the order of 20 μv at a current density of 10 ma/cm^2 and can be ignored.

Three distinct steps occur in the electrodeposition process. These are:

Mass transport:

$$Ag^+ \text{ (solution)} \rightleftarrows Ag^+ \text{ (interface)} \qquad (a)$$

Charge-transfer:

$$Ag^+ \text{ (interface)} + e \rightleftarrows Ag^o \text{ (surface)} \qquad (b)$$

Surface diffusion:

$$Ag^o \text{ (surface)} \rightleftarrows Ag^o \text{ (lattice)} \qquad (c)$$

Laitinen, Tischer, and Roe (15) have determined the exchange current and transfer coefficient for the charge-transfer reaction for silver deposition from the molten LiCl-KCl eutectic at 450°C. These parameters completely define the kinetics of the charge-transfer reaction. This paper describes experimental studies of the surface diffusion and mass transport reactions for silver deposition in a LiCl-KCl eutectic at 450°C. The rise time of the overpotential on application of galvanostatic pulses has been studied to determine if the mechanism of electrodeposition from fused salts involves a surface diffusion process in which adatoms migrate from point of deposition to growth sites on the crystal surface or if deposition occurs directly at such sites. Steady-state polarization measurements during the deposition of silver from the molten chloride eutectic have been made and the results correlated with the occurrence of dendrites. The mechanism of nucleation and growth of silver dendrites by fused salt deposition has been elucidated.

Theoretical.—The mechanism of crystal growth by electrodeposition has been the subject of much theoretical and experimental consideration recently. The surface diffusion of adatoms as an important step in the over-all deposition process has been derived largely from the theory of vapor deposition. Burton, Cabrera, and Frank (16) first emphasized the role of screw dislocations as sites for nucleation in crystal growth. Cabrera and Burton (17) showed that a model of crystal growth, based on uniform production of adsorbed atoms followed by diffusion of these atoms to steps on the surface and then along steps to kink sites, correctly predicted the growth rate of iodine crystals. Bockris and Mehl (1, 2) and Gerischer (4) showed almost concurrently that the adatom mechanism occurs in electrodeposition of metals from aqueous solutions at low overpotentials. Galvanostatic pulsing was employed under conditions where mass transport in the solution phase could be ignored, *i.e.*, at high concentrations of reducible species. A steady-state overpotential cannot be reached in a time faster than that allowed by the slowest step in the over-all process. For deposition from aqueous solutions, it has been established that surface diffusion is a slower step than charge-transfer because the rate at which a steady-state overpotential is approached is significantly less than predicted if charge transfer alone were controlling the rate of deposition.

The principal difference between the method of Bockris and co-workers and that of Gerischer lies in the nature of the model employed. Gerischer's approach involves a generalized diffusion rate from point of deposition to growth site, while Bockris has recourse to a specific model involving diffusion of adatoms on a plane between two parallel steps on a crystal face. In this study, the model first proposed by Bockris and Mehl will be tested. Although a more involved approach was later developed by Despic and Bockris (3), the simple model was chosen because measurements of overpotential-time curves in fused salts involve the observation of overpotentials smaller by a factor of ten to fifty and at times faster by a factor of 10^3 than those necessary in studies of deposition from aqueous solution. The refined theory of Bockris and Despic yields essentially the same results as that first advanced by Bockris and Mehl.

This study has concentrated on the determination of overpotential-time curves rather than the log current density-overpotential curves. This has been necessary again because the overpotentials observed in fused salt electrode reactions are small due to the large values of the exchange current. It would be fruitless to look for small variations in quantities which are already small. The overpotential-time curves are themselves still quite sensitive to a slow surface diffusion step. The Bockris-Mehl model (1, 2) is developed on the assumption that adatoms act as intermediates in essentially all deposition or dissolution processes occurring on a metal surface. The overpotential-time relation, assuming no depletion of ions at the electrode surface, may be written[1]

$$i = i_o\left[\exp\left(-\beta\frac{nF}{RT}\eta\right) - \frac{C(\eta,t)}{C_o}\exp\left((1-\beta)\frac{nF}{RT}\eta\right)\right] \qquad [1]$$

Expansion of the exponential for small values of η, neglecting the products of small variables and assuming $C(\eta,t)/C_o$ is not greatly different from [1] gives[2]

$$-\eta(t) = \frac{RT}{nF}\frac{i}{i_o} + \frac{RT}{nF}\frac{[C(\eta,t) - C_o]}{C_o} \qquad [2]$$

The rate of change of adatom concentration at any point on a surface is given by the difference between the rate at which the adatoms arrive by deposition and the rate at which they diffuse away

$$\frac{dC}{dt} = \frac{i}{nF} - \nu \qquad [3]$$

The diffusion rate is assumed proportional to the supersaturation with adatoms.

$$\nu = \nu_o\left[\frac{C(\eta,t) - C_o}{C_o}\right] \qquad [4]$$

Substituting [4] in [3] and solving the differential equation subject to the condition that $C(\eta,t) = C_o$ at $t = 0$ gives

$$\frac{[C(\eta,t) - C_o]}{C_o} = \frac{i}{nF\,\nu_o}\left[1 - \exp\left(\frac{-\nu_o}{C_o}t\right)\right] \qquad [5]$$

Substituting [5] in [2] gives

$$-\eta(t) = \frac{RT}{nF}\frac{i}{i_o} + \frac{RT}{(nF)^2}\frac{i}{\nu_o}\left[1 - \exp\left(\frac{-\nu_o}{C_o}t\right)\right] \qquad [6]$$

Equation [6] is the general expression for the overpotential-time curve, valid at small values of overpotential. At small values of t, the exponential term of Eq. [6] may be expanded giving

$$-\eta(t) = \frac{RT}{nF}\frac{i}{i_o} + \frac{RT}{(nF)^2}\frac{i}{C_o}t \qquad [7]$$

or

$$-\frac{d\eta}{dt} = \frac{RT}{(nF)^2}\frac{i}{C_o} \qquad [8]$$

Equation [8] allows evaluation of C_o from the linear portion of the η-t curve at small t. It should be em-

[1] A list of symbols used and their meaning is given at the end of this paper.

[2] It is necessary to assume that $\frac{C(\eta,t)}{C_o}\frac{nF}{RT} \sim \frac{nF}{RT}\eta t$ while assuming $\Delta C(\eta,t) \neq 0$. These two assumptions are not wholly compatible, but the fact that nF/RT is small means they are not seriously in error.

phasized that the linear portion does not correspond to double layer charging as is the usual case. Inman, Bockris, and Blomgren (18) have shown that it is necessary to make η-t observations in the nanosecond range in fused salt deposition studies to observe double layer charging in the presence of reducible ions. Calculation of the apparent capacitance from the linear portion of the η-t curves gives the pseudo-capacitance associated with the adatom layer. Now C_o can be evaluated from Eq. [8], and v_o may be calculated since

$$\eta - \eta_\infty = \frac{RT}{(nF)^2}\frac{i}{v_o}\exp\left(\frac{-v_o t}{C_o}\right) \quad [9]$$

or

$$\frac{d\ln(\eta-\eta_\infty)}{dt} = \frac{-v_o}{C_o} \quad [10]$$

In the steady-state, the overpotential observed in most fused salt electrode processes are controlled solely by mass transport in the electrolyte solution (6, 7, 30-43) since charge transfer reactions are orders of magnitude faster at 450° than they are in aqueous solutions (16, 18, 44-47), while diffusion coefficients and viscosities are comparable to those found with aqueous solutions (19, 20, 28). The fundamental equation for diffusion-controlled current density at a planar electrode under conditions of linear diffusion is

$$i = nF\,D\left(\frac{dC}{dx}\right)_{x=0} \quad [11]$$

If the concentration gradient is approximated by a linear gradient over a finite thickness

$$i = nF\,D\frac{C^o - C^*}{\delta} \quad [12]$$

If the exchange-current is very high, the overpotential in the steady-state will be due solely to concentration polarization

$$\eta = \frac{RT}{nF}\ln\frac{C^*}{C^o} \quad [13]$$

or

$$C^* = C^o\exp\left(\frac{nF}{RT}\eta\right) \quad [14]$$

At small overpotentials

$$C^* = C^o\left(1 + \frac{nF}{RT}\eta\right) \quad [15]$$

Then

$$i = \frac{-(nF)^2}{RT}\frac{DC^o}{\delta}\eta \quad [16]$$

This equation predicts linear current-overpotential curves in the steady-state at low overpotentials with slopes proportional to concentration. The diffusion layer thickness in fused salt deposition will be controlled by both diffusion and convection in the steady-state because a concentration gradient can be maintained only for a matter of a few seconds (19) at 450°C before convection occurs.

Starting from the assumptions that transport to a dendrite tip growing in the z direction is controlled by diffusion to the surface and growth of the tip into the solution and also that the electrode surface is at a uniform potential, Hamilton (13) has shown the concentration field about a parabolic tip is given in cylindrical coordinates by

$$C(r,z) = C^o + (C^* - C^o)\frac{Ei\left[-\frac{v\rho}{2D}\left(\frac{z}{\rho} + \sqrt{\frac{z^2+r^2}{\rho^2}}\right)\right]}{Ei\left(\frac{v\rho}{2D}\right)} \quad [17]$$

where $Ei(x)$ is the exponential integral. If the overpotential is due only to the concentration gradient, it is found that

$$\frac{C^oVF}{RT}\eta = -\frac{v\rho}{2D}e^{v\rho/2D}\,Ei\left(-\frac{v\rho}{2D}\right) \quad [18]$$

If terms for the exchange current and surface energy are included, the relation becomes

$$\frac{\frac{C^oVF}{RT}\eta}{1 + \frac{1.33\,FC^oD}{\rho i_o} + \frac{3.86\,C^o\gamma V^2D}{v\rho^2\,RT}} = -\frac{v\rho}{2D}e^{v\rho/2D}\,Ei\left(-\frac{v\rho}{2D}\right) \quad [19]$$

Experimental

Eutectic salt mixtures.—High-purity LiCl (59%)-KCl (41%) melts were obtained in glass ampoules containing a nitrogen atmosphere from the Anderson Physics Laboratory, Inc., Champaign, Illinois. These salt mixtures had been subjected to the rigorous purification procedures described by Laitinen, Tischer, and Roe (15). Residual currents measured at −2.0v against a Pt/Pt(II) reference electrode with a 0.020-in. diameter flush ground indicator electrode were of the order of 1 μa for all melts.

Silver chloride.—Fisher or Mallinckrodt reagent grade silver chloride was finely ground and dried in a desiccator over magnesium perchlorate for several days before use.

Electrodes.—Electrodes were fabricated from 0.020-in. diameter platinum wire sealed into a Corning 0120 lead glass tube by means of a Corning 0100 (G-164-EC) glass.[3] Flush ground microelectrodes were obtained by polishing the glass-to-metal seal first with 600 mesh silicon carbide, lapping with 1800 mesh silicon carbide abrasive, and polishing with Linde A (0.3μ alumina) on a polishing wheel. Macroelectrodes were prepared by spot welding 1 cm x 1 cm x 0.015 in. platinum foil to 0.020 in. diameter platinum wire projecting through the glass-to-metal seals described above. Platinum cathodes were plated with silver from the melt at low current density (0.5 ma/cm^2) before overpotential measurements were made. Laitinen *et al.* (15) have shown the roughness factor for polished platinum microelectrodes is about 2. A roughness factor of 3 has been taken for the silver plated microelectrodes used in the studies of the rise time of the overpotential, based on microscopic observations of the electrodes before and after plating.

Anodes were silver foil spot welded to silver wire. Ag/Ag(I) reference electrodes were silver wires dipped into the melt containing silver chloride. These wires were positioned about 1 cm away from the cathode. Closer placement is not required because of the high conductivity of the melt. Silver electrodes were cleaned and etched in 1:1 HNO_3, washed in distilled water, soaked in concentrated NH_3 solution, washed again, and dried.

Procedure.—Experiments were conducted in 15 x 2½ in. OD medium walled Pyrex test tubes flanged to fit No. 12 silicone rubber stoppers. These stoppers were frozen and drilled to fit electrode sheaths, thermocouple wells, etc. The test tubes were immersed in a three-zone Hevi-Duty furnace whose temperature was controlled at 450° ± 1°C by a Wheelco Model 404 temperature controller.

Cells and electrodes were cleaned in hot concentrated $HClO_4$ or cold chromic acid solution prior to use. These materials were then washed thoroughly and

[3] This glass has previously been described incorrectly as Corning 010 (15, 20). Corning 0010 is a common type of lead glass and is unsuitable for use at metal seals in fused salt electrochemistry because of its high conductivity and the resulting reduction of lead ions which occurs. Corning 0010 is similar to Corning 0120 in its properties.

dried prior to use. The procedure for evacuating and breaking the ampoule has previously been described (15).

Instrumentation.—A Teletronics Laboratory Model PS-110 constant current power supply was employed to supply currents in the range from 1 μa to 50 ma. A 16 μF oil capacitor was connected across the output terminals to remove residual a-c ripple. Currents were measured with a Sensitive Research ammeter. In measurements of the rise time of the overpotential, a Tektronix Type 565 dual beam oscilloscope with Type 2A63 plug-in units with rise-times of 1 μsec was utilized. A mercury-wetted relay system (Western Electric Type 276B) was used to switch the current from a dummy resistor (10 ohms) to the electrochemical cell. This was achieved by applying a pulse from a battery which activated the relay coil and triggered time base A of the dual beam oscilloscope simultaneously. Time base B was operated in the delayed mode after an interval of 3.75 msec which corresponds to the closure time of the reed in the mercury wetted relay. In this way, time base B was triggered a few microseconds before application of the constant current to the electrochemical cell and overpotential-time curves in the range of 0-100 μsec were obtained on the B channel and recorded with a Tektronix Type C-12 oscilloscope camera using Polaroid Type 47 film (ASA 3000).

Steady-state polarization measurements were made with a Sargent Model MR potentiometric recorder.

Convection.—Solutions were stirred with a paddle stirrer rotating in a Teflon gland and driven at 600 rpm by a Sargent synchronous rotator.

Results

In studies of the rise-time of the overpotential, current pulses from 2.5 to 500 ma/cm^2 were applied to a flush ground silver plated platinum electrode in a 0.101*M* AgCl solution. In the range of current densities from 2.5-100 ma/cm^2, the overpotential time curves are similar to those shown by Mehl and Bockris (1). A steady state is reached in times from 60-100 μsec over this range of current densities. If charge-transfer alone were rate controlling, a steady state should be reached in $\tau_{c.t.} \sim 5 \times (RT/nF)(C/i_o)$ (2). Using the known values of exchange current for 0.1*M* Ag^+ solutions and the double layer capacity which has been estimated from the known value for a Pt surface (21) in the same melt at 450°C, this calculation

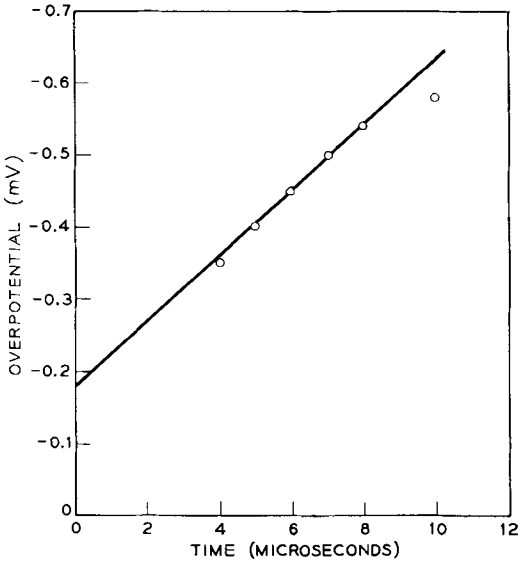

Fig. 1. Plot of overpotential against time for deposition of silver from 0.101M AgCl in molten LiCl-KCl at 450°. Current density, 98.7 ma/cm^2.

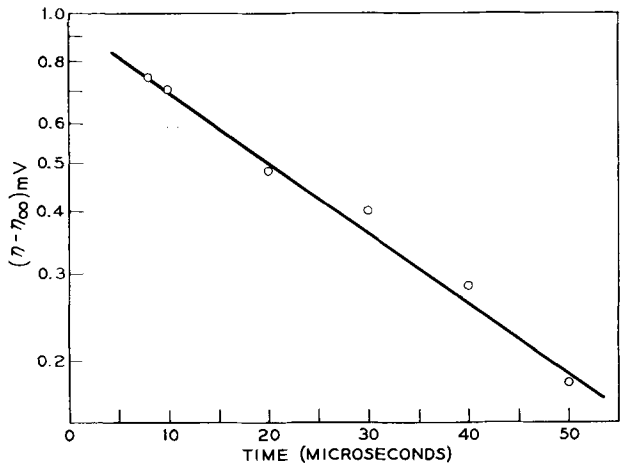

Fig. 2. Plot of log $(\eta-\eta_\infty)$ against time for the deposition of silver from 0.101M AgCl in molten LiCl-KCl at 450°C. Current density, 98.7 ma/cm^2.

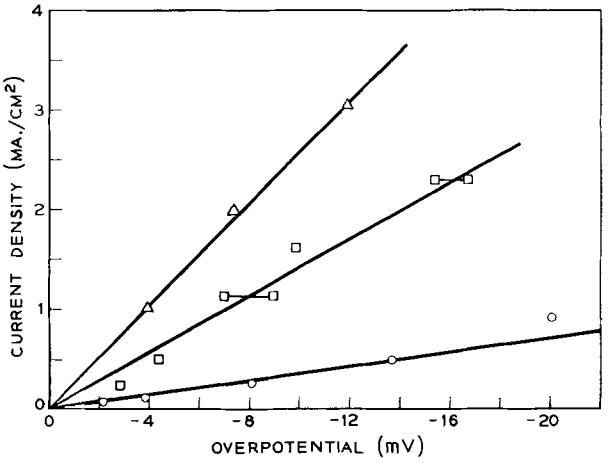

Fig. 3. Plot of steady-state overpotential against current density for the deposition of silver from AgCl in fused LiCl-KCl at 450°C. Concentrations: —○—, 0.48%; —□—, 1.36%; —△—, 3.33% AgCl.

gives $\tau_{c.t.} \sim 2$ μsec. At current densities above 100 ma/cm^2, the concentration overpotential, η_d, becomes significant before a steady state is reached. This may be calculated from

$$\eta_d = \frac{RT}{nF} \ln \left(\frac{\tau_d^{1/2} - t^{1/2}}{\tau_d^{1/2}} \right) \qquad [20]$$

where τ_d is the transition time for concentration polarization

$$\tau_d = \frac{\pi D}{4} \left(\frac{nFC^o}{i} \right)^2 \qquad [21]$$

Results are presented for a current density of 98.7 ma/cm^2; the highest current density employed before concentration overpotential becomes significant during the course of the measurement, since this affords the maximum accuracy of measurement. Figure 1 shows a plot of η against time for short times. The iR component has been subtracted from the observed overpotential to give the activation overpotential. Evaluation of C_o. the concentration of adatoms at the equilibrium potential, using Eq. [8], gives a value of 9×10^{-10} moles/cm^2. Calculation of the pseudocapacitance associated with the layer of adatoms from the linear $\eta - t$ curve gives a value of 700 μF/cm^2. Figure 2 shows the plot of log $(\eta - \eta_\infty)$ against time. Evaluation of the rate of surface diffusion using Eq. [10] and the C_o value obtained above gives $nF\ v_o = 3.3$ amp/

cm^2. The experimental data are seen to fit Eq. [8] and [10] well.

Figure 3 shows steady-state polarization curves observed at macroelectrodes for 0.48, 1.36, and 3.33 w/o (weight per cent) AgCl in the LiCl-KCl eutectic. The linear i-η curves predicted by Eq. [16] are observed showing that mass transfer is limiting the rate of electrodeposition. Linear i-η curves are also expected at low overpotentials when charge transfer is rate controlling. Calculations of the activation overpotential at current densities of 1-5 ma/cm^2 show that the observed values are far greater than the calculated ones. The linear i-η relation is thus due to mass transfer and not charge transfer. The slopes of the three lines shown in Fig. 3 are approximately proportional to concentration as Eq. [16] predicts. The scatter shown in Fig. 3 for the 1.36 w/o AgCl chloride solution is due to the difficulty of establishing a reproducible diffusion layer thickness. The diffusion layer thickness is controlled by both diffusion and convection. Since convection is difficult to reproduce, some scatter in the observed overpotential is expected. In all instances, the nature of the deposit was studied by observing the cathode in the molten bath with a 20-power eyepiece. At overpotentials of less than 4 mv, coherent deposits are always observed. The average thickness of the deposit was 1.6×10^{-4} cm. At overpotentials greater than 4 mv but less than 10 mv, a few well-developed dendrites grow at fairly rapid rates and are readily observable. The dendrite shown in Fig. 5 grew to a length of 6 mm in 1 hr at a current density of 2.28 $\mu a/cm^2$ and an overpotential of 5.3 mv from a 3 w/o AgCl solution. Above 10 mv polarization, a large number of small dendrites are formed. These results parallel those of Barton and Bockris (11) who found no dendrites at overpotentials less than 3 mv in their studies of silver deposition from a molten nitrate solution at 308°C. These studies were conducted with plating thicknesses of 2×10^{-3} cm and plating times up to 20 hr (current density of 0.25 $\mu a/cm^2$). These observations leave no doubt that dendrites do not form below the critical overpotential. Both 3 mv at 308°C and 4 mv at 450°C correspond to the same degree of concentration overpotential [$C^*/C^o = 0.94$] and indicate that dendritic growth occurs when ionic diffusion in the liquid phase controls the growth process. This suggests that destruction of the concentration gradient by convection would reduce the overpotential and the tendency for dendrite formation. Figure 4 shows the current-overpotential lines for stirred and unstirred 3.33 w/o AgCl solutions. At a given current density, simple stirring significantly reduces the overpotential and, thus, allows the use of higher current densities before the critical overpotential for the initiation of dendrites is reached. The critical overpotential was found to be 4 mv in both stirred and unstirred solutions.

Fig. 5. Typical silver dendrite grown from 3% AgCl solution in LiCl-KCl at 450°C. Current density, 2.28 ma/cm^2; overpotential, 5.3 mv.

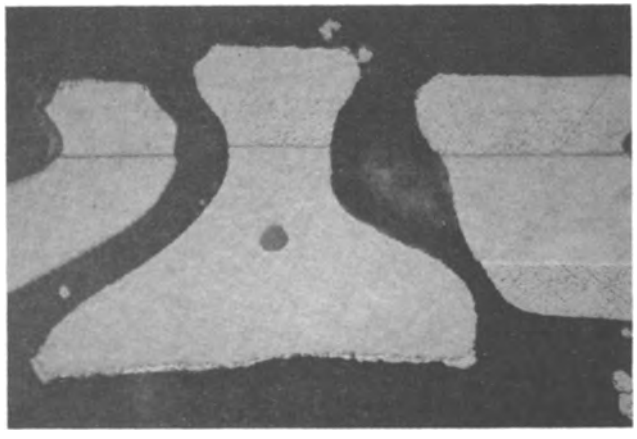

Fig. 6. Etched cross section of silver dendrite trunk showing closely spaced parallel twin planes at approximately 370X magnification.

Metallographic studies of the dendrites formed by electrodeposition of silver from the fused LiCl-KCl have been performed. Figure 5 shows a typical dendrite. The morphological studies of Yang, Chien, and Hudson indicate that this dendrite both grew and branched in the <211> direction. Figures 6 and 7 show cross sections of the trunks of two different dendrites at approximately 370X and 1470X, respectively. These dendrites were potted in CIBA Araldite epoxy polymer, polished and etched with a 5% KCN-5% $(NH_4)_2S_2O_8$ solution. In Fig. 6, two closely spaced parallel twin planes are seen. In Fig. 7, the twin planes are more prominent at approximately 1470X. Etching has apparently produced faceting of the surface between the planes. In Fig. 8. the cross section of a dendrite branch is shown. Here, the twin planes are considerably farther apart. All dendrite branches show at least two, and sometimes as many as seven, parallel twin planes.

Discussion

The fact that the rise time of the overpotential observed over a wide range of current densities is much slower than that predicted from simple theory for charge-transfer reactions constitutes proof that a proc-

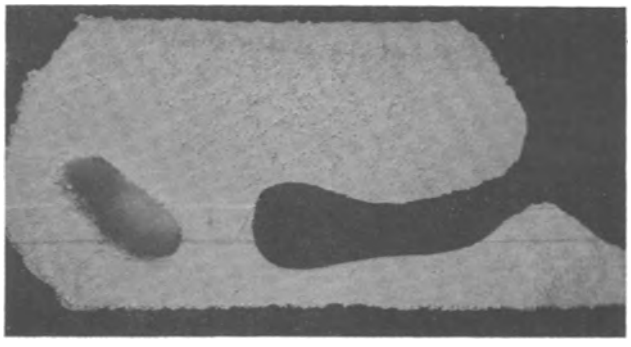

Fig. 8. Etched branch of silver dendrite containing parallel twin planes at approximately 370X magnification.

ess slower than charge-transfer must be rate controlling. Since these experiments were conducted over time scales and current densities where concentration changes at the electrode surface can be neglected, the slow step in the over-all process can only be surface diffusion. Good agreement is observed between the theory for the form of the overpotential-time curves and the experimental results. The adatom concentration found for the silver surface (9×10^{-10} moles/cm^2) at 450°C is approximately twice that found by Bockris and Mehl in aqueous solution at 25°C (4×10^{-10} moles/cm^2). This indicates that the adatom mechanism is relatively more important in deposition processes from fused salts than from aqueous solutions. This fact is understandable in terms of the relative rates of the charge-transfer and surface diffusion processes. The molar exchange current for silver deposition under the conditions employed in this study is 190 amp/cm^2, while that in aqueous solution at 25°C is 0.17 amp/cm^2 (2). The effect of temperature and change of medium gives an increase in rate by a factor of 1100. This is consistent with the activation energies for electrochemical charge-transfer reactions which are typically around 10 kcal/mole (48, 11, 27). The surface diffusion process, however, increases from 0.014 amp/cm^2 ($nF\,v_o$) at 25°C in an aqueous system to 3.3 amp/cm^2 at 450°C in the fused salt case. This represents an increase by a factor of 230 only, because of the relatively low activation energy for the surface diffusion process, estimated to be about 3 kcal/mole (4). Since the increase in rate of charge-transfer is several times greater than the increase in surface diffusion rate, the surface diffusion step is relatively more important in determining the rate of the over-all deposition process [see Eq. (b) and (c)]. The adatom concentration must be greater since adatoms are essential intermediates in the total process and the rate at which they are formed is increased more than the rate by which they are removed from the surface.

The results of the present study indicate that dendritic deposits may be expected when the electrode process is controlled primarily by ionic diffusion in the liquid phase. A calculation of the apparent diffusion layer thickness using Eq. [16] and the diffusion coefficient for Ag(I) in LiCl-KCl at 450°C as determined by Thalmayer, Bruckenstein, and Gruen (28) gives 0.071 and 0.026 cm as the apparent diffusion layer thicknesses for the unstirred and stirred 3.33 w/o AgCl solutions. The fact that a definite concentration gradient must be established before dendritic deposits occur has also been shown. To produce coherent deposits of silver by deposition from fused salts, it is necessary to work under conditions such that the critical overpotential for dendrite initiation, resulting from concentration polarization, is not exceeded. The results shown in Fig. 3 and 4 prove that this may be accomplished by two means: the employment of a high concentration of reducible ion, and the use of convection. Under these conditions, the extent of concentration overpotential will be minimized, and it will be possible to produce coherent deposits at higher current densities than would otherwise be the case. This conclusion is in contradiction of the statement of Yang, Chien, and Hudson (8) that dendritic deposits will occur at high concentration of reducible ions and high current density. These authors did not measure the overpotential during deposition, however, and were not cognizant of the fact that overpotential is the relevant parameter determining the morphology of the deposit. Undoubtedly, the use of a rotated cathode would provide the most efficient means of convection. A calculation of the current density necessary to produce 4 mv polarization at a disk electrode rotating at 600 rpm in a 1*M* AgCl solutions in LiCl-KCl at 450°C gives 56 ma/cm^2. Charge-transfer alone provides no limitation, since 12 amp/cm^2 are necessary to produce 4 mv of activation polarization under the same conditions. Although it has been proven only for silver, a critical overpotential for the initiation of dendritic growth may exist for other metals as well. The low value of the critical overpotential for silver is probably related to the low value of the stacking fault energy for silver of 25 ergs/cm^2 (29) which should be about half the energy necessary to form a twin plane.

The trunks and branches of all dendrites examined in this study were found to contain at least two parallel twin planes in agreement with the results of Faust and John (10). Since the morphological studies (8, 9) have shown that these dendrites grow in the <211> direction, the results suggest that nucleation and growth of these dendrites is occurring by the twin plane re-entrant edge mechanism similar to that known to occur in the growth of germanium dendrites (22-24).

The groove between two facets at the twin plane provides a site for low energy nucleation and two parallel planes provide a structure which growth cannot destroy (24). The recent reports of twin planes in electrodeposited dendrites (10, 22, 26) suggests that this is a general mechanism for their growth. Dendrite formation in electrodeposition must start with faceting of the planar surface (11). The idea that penetration of the diffusion layer by the facet leads directly to dendrite formation as suggested by Barton and Bockris (11) is incorrect, however. If this were the case, convection, which decreases the thickness of the diffusion layer, should lead to increased incidence of dendritic growth. This is not the case. In reality, faceting leads to increased mass transport to the faceted surface as opposed to the planar surface. Those facets containing two or more twin planes provide a site for low energy nucleation and rapid propagation. The closely spaced twin planes found in the trunk of the dendrites in this study help explain the rapid growth of electrolytically grown dendrites since Wagner (25) has shown that the growth rate of germanium dendrites is greater when the parallel twin planes are closer together.

Acknowledgments

The author wishes to thank Dr. K. A. Jackson for elucidating the process of dendritic growth. He is also indebted to Mr. A. A. Tartaglia for the expert performance of the metallography and to Mr. J. A. Gribbin for aid with some of the experiments.

Manuscript received Dec. 28, 1964; revised manuscript received June 24, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

SYMBOLS

i	Current density (positive for a cathodic process)
i_o	Exchange current density
β	Transfer coefficient ($0 < \beta < 1$)
n	Number of electrons in electrode process
η	Overpotential [E-E(equilibrium)]. Taken negative for a cathodic process
$C(\eta,t)$	Adatom concentration at any overpotential and time (moles cm^{-2})
C_o	Adatom concentration at the equilibrium potential (moles cm^{-2})
ν	Rate of surface diffusion (moles sec^{-1} cm^{-2})
ν_o	Intrinsic rate constant for surface diffusion (moles sec^{-1} cm^{-2})
D	Diffusion coefficient of reducible ion (cm^2 sec^{-1})
C^o	Bulk concentration of reducible ion
C^*	Concentration of reducible ion at electrode surface
δ	Apparent diffusion layer thickness (cm)
η_d	Concentration overpotential (polarization)
τ	Transition time for concentration overpotential ($C^* = 0$)
t	Time
C	Double layer capacitance
R	Gas constant
T	Absolute temperature
$\mathbf{F}$	The Faraday
V	Molar volume of metal
γ	Surface energy of metal (ergs/cm^2)
ρ	Radius of curvature of dendrite tip
v	Growth rate of dendrite tip (cm sec^{-1})

Preparation and Luminescent Properties of Ti-Activated Zirconia

J. F. Sarver

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

Very pure monoclinic ZrO_2 prepared from recrystallized zirconium oxychloride and activated with 0.08% Ti^{4+} responds well to 2537Å and cathode-ray excitation. A room temperature quantum efficiency of 70%, relative to $MgWO_4$, has been attained with 2537Å excitation. The emission band extends from below 4000 to above 6500Å, peaking at 4800Å. The phosphor has a broad excitation spectrum and responds almost equally well to wavelengths between 2100 and 2600Å. At 20°C the response to 2537Å excitation is about 82% of the maximum response which occurs at about −60°C. The initial decay is exponential with rate constant $\alpha = 1.5 \times 10^5$ sec^{-1}, but the visually detectable persistence lasts several minutes. The long persistence is associated with glow peaks which were found to exist above 20°C. Additional stronger glow peaks occur at lower temperatures.

Prior to this investigation it was observed by the author that several commercial sources of monoclinic zirconia responded to 2537Å and cathode-ray excitation, yielding a blue-white luminescence with a long persistence. ZrO_2 prepared from an experimental sample of hydrous zirconium carbonate, which is a relatively high purity zirconium compound manufactured by the Titanium Alloy Manufacturing Division of the National Lead Company, appeared to be only weakly luminescent. Similar observations have been mentioned previously in the literature (1, 2).

Further interest in this phenomenon was stimulated by a paper of Harrison, Melamed, and Subbarao (2) who prepared several compounds having the same generalized formula. Of special interest was a series of isostructural compounds having the generalized formula R_2^{2+} ZrR_2^{5+} O_9 where R^{2+} is Sr^{2+}, Ba^{2+}, or Pb^{2+}, and R^{5+} is P^{5+} or As^{5+}. These compounds responded to 2537Å excitation and exhibited broad emission bands with peak wavelengths between 4840 and 4920Å. They also found a similar emission for the monoclinic ZrO_2 used in the preparation of the ternary compounds. The marked similarity in the absorption, excitation, and emission spectra of these isotypic compounds and of ZrO_2 suggested to the authors that the phosphors were of the self-activated type, as are certain tungstate and molybdate compounds. They suggested the possibility that the luminescence is related to an asymmetric coordination of oxygens about the Zr^{4+} ions. The oxygen coordination of zirconium in monoclinic ZrO_2 is indeed asymmetric and unusual. According to McCullough and Trueblood (3), the zirconium ions are coordinated by seven oxygens and the Zr-O distances vary from 2.04 to 2.26Å. An idealized representation of the coordination polyhedron is shown in Fig. 1, in which the ZrO_7 group can be thought of as being derived from a cube. Four oxygens are at the base and one is located at one of the upper corners of the cube. Two additional oxygens are situated at the midpoints of the cube edges between the unoccupied corners. If the three oxygens on the top of the cube are moved as indicated by the arrows, their distances from the Zr^{4+} ion at the center of the cube are more nearly equalized but still average less than the Zr-O distances for the other four oxygens. The actual interionic distances determined by McCullough and Trueblood are given in Table I.

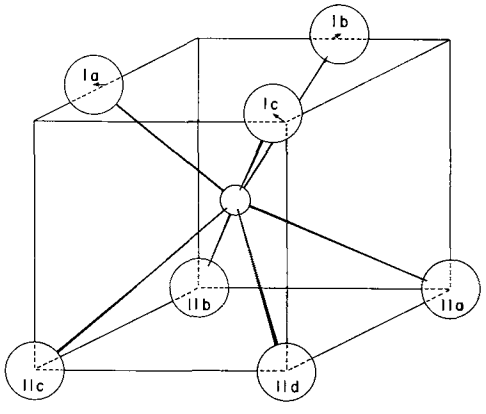

Fig. 1. Zr^{4+} coordination polyhedron in monoclinic ZrO_2 (McCullough and Trueblood).

The hypothesis of Harrison *et al.* regarding self-activation appears to be plausible if one considers their observations that certain zirconium compounds such as ZrP_2O_7, in which Zr^{4+} is symmetrically coordinated by six oxygens, are nonluminescent. On the other hand, a high-purity zirconia sample prepared by decomposing triply recrystallized zirconium oxychloride, $ZrOCl_2 \cdot 8H_2O$, did not respond to ultraviolet or cathode-ray excitation. The recrystallization procedure for purification of the oxychloride was developed by Hickok (4) in this laboratory, and was based on solubility data for the oxychloride compound in hydrochloric acid solutions cited by Blumenthal (5). These observations suggested that the luminescence observed in certain samples of ZrO_2 is due to the presence of some impurity which functions as a primary activator rather than to a self-activation mechanism. As discussed in subsequent sections, this impurity was shown to be Ti^{4+}.

Kröger and Overbeek (6) have prepared several Ti-activated phosphors including zirconia. In the case of ZrO_2, titanium was incorporated in amounts of 0.001 to 10 mole % by firing oxide mixtures at 1300°C. The phosphors yielded a greenish emission peaking at 4700Å when excited by wavelengths less than 3850Å, and the optimum activator concentration was found to be 0.1 mole %. The development of only weak emission can probably be attributed to the presence of other impurities such as iron which is quite detri-

Table I. Zr-O distances in monoclinic zirconia in Å (3)

		II_d	2.26

mental to the Ti^{4+} emission Besides hafnium, two of the major impurities in most commercial sources of monoclinic ZrO_2 are iron and titanium.

Phosphor Preparation

Purification of zirconium oxychloride.—According to Blumenthal, the room temperature solubility of $ZrOCl_2 \cdot 8H_2O$ in 8.72 NHCl solution is 0.0547 moles/liter and is highly temperature dependent in this solution. Based on this information a purification process by repeated recrystallization of the oxychloride was developed by Hickok. A description of his process follows.

Approximately 450g of TAM high-purity zirconium oxychloride is dissolved in 400 ml of deionized or distilled water and the solution is filtered to remove insoluble impurities. The solution is heated and added slowly with continuous heating to 800 ml of hot concentrated HCl so that the final solution is approximately 8*N* HCl. On cooling to room temperature, $ZrOCl_2 \cdot 8H_2O$ crystallizes and the yellow color of the supernatant liquid indicates that iron has been at least partially removed from the starting material. The supernatant liquid is vacuum-filtered from the crystals which are then washed several times with cold 8*N* HCl. The entire process of dissolving, recrystallization, etc., is repeated for further purification. The zirconium oxychloride is decomposed above 1000°C to form a white, fine-grained, polycrystalline monoclinic ZrO_2 which does not respond to either 2537Å or cathode ray excitation.

Spectrographic analyses.—In Table II, semiquantitative spectrographic analyses of two commercial zirconia samples (A and B) are compared with the analysis (C) of zirconia prepared from the purified oxychloride which was derived from oxychloride supplied by the TAM Division of the National Lead Company.

It is quite evident that the zirconia prepared from the recrystallized oxychloride is significantly purer than the other two samples. As far as possible activator impurities in the other two samples are concerned, the major differences occur for the elements Cu, Fe, Pb, Sn, and Ti. The blue-white luminescence observed in sample A suggested that the most likely activator should be Ti^{4+}. Titanium was not detected in the oxychloride sample whereas it was present in trace amounts in sample B and in greater amounts in sample A. Sample A exhibited a more intense emission with 2537Å excitation than did the sample B.

Phosphor synthesis.—Ti^{4+} as phosphor grade TiO_2 was substituted for Zr^{4+} in ZrO_2 in molar concentrations of from 0.06 to 0.6%. TiO_2-ZrO_2 mixtures were reacted in air in platinum crucibles at 1200°C for 1 hr and finally at 1300° for 2 hr after a second mixing. Firing in oxygen or mildly reducing conditions did not affect phosphor brightness. The latter atmosphere consisted of 0.5% forming gas passed through water at room temperature.

All of the preparations gave a blue-white emission with 2537Å excitation. Optimum plaque brightness for 2537Å excitation was observed for a Ti^{4+} concentration of 0.08 mole %. A plot of plaque brightness *vs.* titanium concentration is shown in Fig. 2. All of the subsequent discussions of optical properties will pertain to the optimized phosphor, *i.e.*, ZrO_2:0.0008Ti.

Optical Properties

Emission spectrum.—With 2537Å or cathode-ray excitation, Ti-activated zirconia exhibits a wide emission band extending from below 4000Å to above 6500Å with a peak emission at 4800Å as shown in Fig. 3. The absence of cathodoluminescence in unactivated high-purity zirconia suggests that the Ti^{4+} impurity ions function as a primary activator and not as a sensitizer for the observed emission.

The emission spectrum is very similar to that observed by Koelmans and Verhagen (7) for a similar concentration of Ti^{4+} in $Ca_2Ge_3O_8$. They noted that the emission is very much like that of Sb-activated calcium halophosphate with Cl/F = 1 and that the quantum efficiency was the same or slightly better than that of the halophosphate. Figure 3 also shows the emission spectrum of $MgWO_4$ which was used as a standard for quantum efficiency measurements.

Excitation spectrum.—It was not possible to record an accurate excitation spectrum for this phosphor continuously because of a slow build-up of the emission. With 2537Å excitation, the emission attained 90% of its maximum after 4 sec exposure but did not attain a nearly constant value until after 4 min of exposure (see Fig. 4). Therefore, it was necessary to determine the excitation spectrum point by point, allowing the

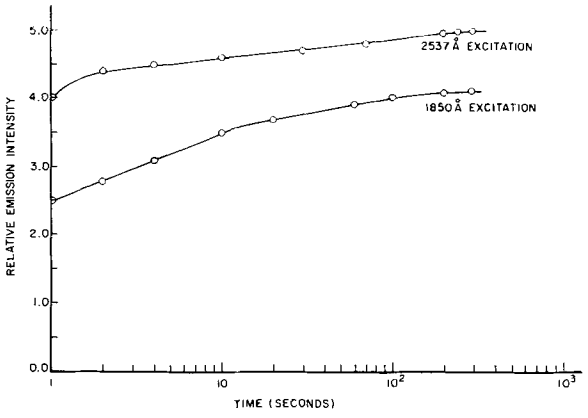

Fig. 4. Buildup of luminescence

emission to equilibrate at each wavelength of excitation.

The excitation spectrum shown in Fig. 5 was established using sodium salicylate as a standard for comparison at each wavelength. The spectrum is rather broad and the phosphor responds relatively well to 2537Å excitation.

Reflectance spectra.—In Fig. 6, the ultraviolet diffuse reflectance spectrum of purified unactivated ZrO_2, made from the recrystallized oxychloride, is compared with the reflectance spectra of the two commercial sources of zirconia mentioned previously. The spectrum for the activated sample clearly shows the effect of the Ti^{4+} impurity (800 ppm). Without quantitative spectrographic analyses, it would not be possible to explain the lower relative reflectance values for the two commercial samples. A reasonable approximation would be that both are considerably higher in iron content than either the purified sample or the phosphor made from it and that both contain Ti^{4+} as a major impurity since both are luminescent, although much weaker than the phosphor under discussion. According to a paper by Heffelfinger *et al.* (8), most commercial monoclinic zirconia samples have two major impurities in addition to hafnium; titanium and iron. These impurities will introduce absorption in the ultraviolet. Cr, Mn, Ni, Cu, etc., are generally present in only trace amounts or less.

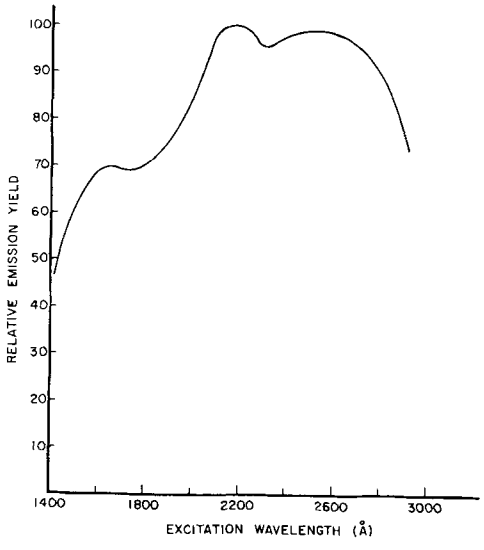

Fig. 5. Excitation spectrum

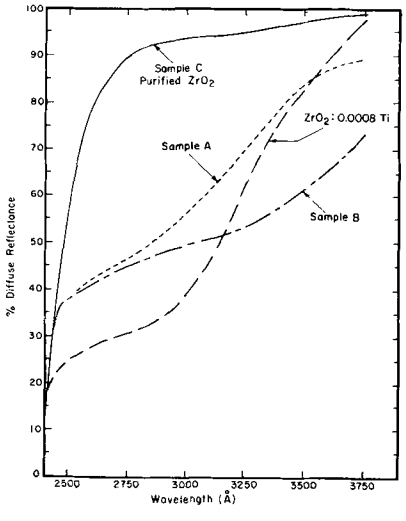

Fig. 6. Diffuse reflectance spectra for ZrO_2 and ZrO_2:Ti

Temperature dependence.—The dependence of the luminescence intensity on temperature is seen in Fig. 7. The shift of the emission to longer wavelengths (5100Å at 77°K) as reported by Harrison *et al.* for ZrO_2 was confirmed visually. At 20°C, the relative response to 2537Å excitation is about 82% of the response at −60°C as measured with a 1P21 photomultiplier tube and Corning UV filter. At 40°C, the approximate temperature at which ordinary 40 watt fluorescent lamps operate under normal ambient conditions, the relative brightness is 70%.

Decay and glow phenomena.—At room temperature the phosphor exhibits a very rapid initial exponential decay with rate constant $\alpha = 1.5 \times 10^5$ sec^{-1}, similar to $CaWO_4$ and $MgWO_4$ and some sulfide phosphors. Decay curves are shown in Fig. 8 and 9. Beyond about 20 μsec, the decay rate becomes much slower and the phosphorescence is visually detectable for a few minutes. It was found that the addition of certain mineralizers or fluxes, in particular 1 mole % LiF, besides leading to an expected increase in particle size during

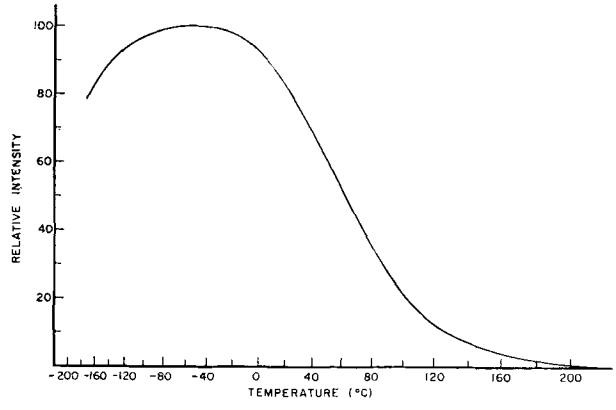

Fig. 7. Temperature dependence of emission

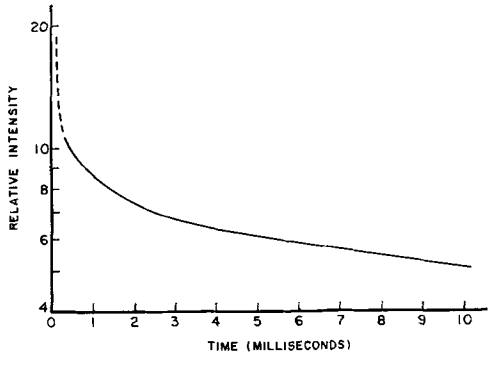

Fig. 8. Luminescence decay (2537Å excitation)

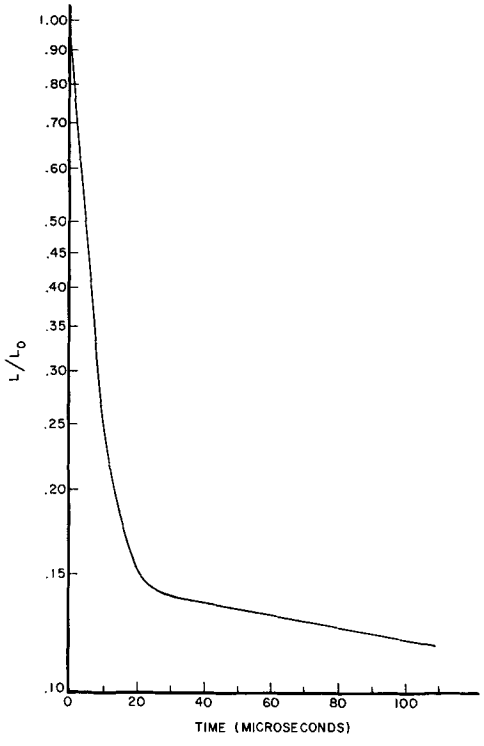

Fig. 9. Luminescence decay (cathode-ray excitation)

firing, also causes an increase in the intensity of the phosphorescence although the intensity of the fluorescence is virtually the same as ZrO_2:Ti phosphors synthesized without mineralizers. The effect of LiF on particle size development is shown in Fig. 10 and 11.

The long persistence of the phosphor is explained by the presence of trapped electrons which require heating above room temperature for release. The glow curve for this phosphor is shown in Fig. 12. In addition to the peaks above room temperature, there are several much stronger peaks at lower temperatures. There is apparently a very strong peak near liquid N_2 temperature. The phosphor was irradiated for 60 min at this temperature and allowed to decay 5 min before the heating was started at a rate of approximately 15°C/min.

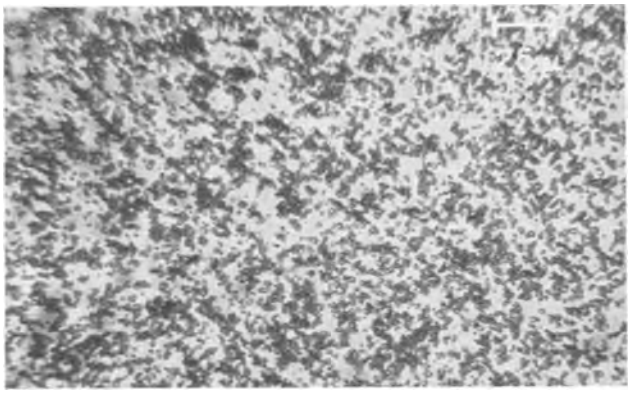

Fig. 10. Monoclinic ZrO_2 prepared from $ZrOCl_2 \cdot 8H_2O$

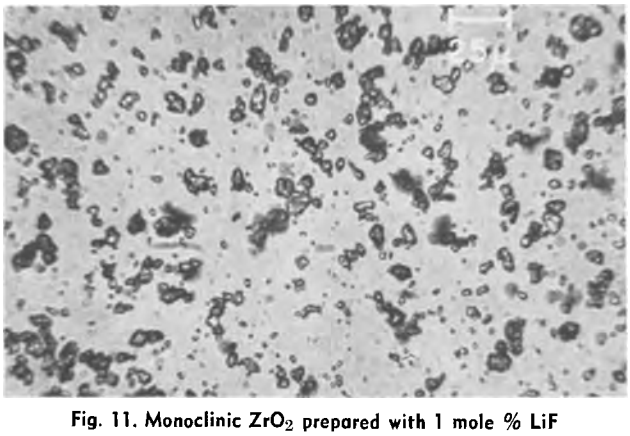

Fig. 11. Monoclinic ZrO_2 prepared with 1 mole % LiF

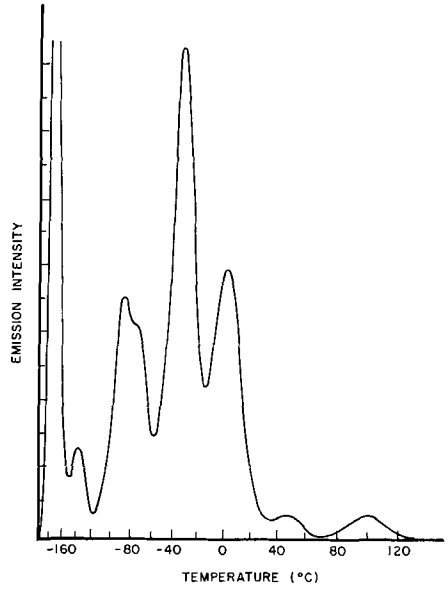

Fig. 12. Glow behavior above —196°C

Quantum efficiency.—Using a $MgWO_4$ phosphor as a standard for brightness comparison and $BaSO_4$ as a reflectance standard, relative quantum efficiency with 2537Å excitation was determined. $BaSO_4$ has a reflectance of 79% relative to MgO which is taken as 100% for 2537Å radiation, but the sulfate is much more stable under normal atmospheric conditions for longer periods according to Jones (9). Data used in the calculation of quantum efficiency are summarized in Table III.

An integration of the normalized photon plot, $\lambda^3 dE/d\lambda$ *vs.* λ(ev) for $MgWO_4$ and the zirconia phosphor yielded relative areas of 0.79 and 0.80, respectively. Both photon plots peak at 5000Å. The calculated relative quantum efficiency for the zirconia phosphor is 68 or 71%, depending upon whether that of $MgWO_4$ is taken as 95 or 100% (10).

Summary

The luminescence phenomenon associated with various commercial sources of zirconia and which has been cited in the literature has been shown to be attributable to the presence of titanium, a common impurity in commercial sources of ZrO_2. The intensity of the emission not only depends on the concentration of Ti^{4+} present but also is strongly dependent on the concentration of other impurities, in particular iron. It is therefore necessary to reduce the level of iron impurity to less than trace amounts before an efficient phosphor can be prepared. This undoubtedly serves to

Table III. 2537Å Reflectance and plaque brightness data

Sample	Reflectance, R Uncorrected	Reflectance, R Corrected	1-R	Plaque* brightness	Q.E.

$BaSO_4$	1.00	0.79	—	—	—

* At 5000Å.

reduce the amounts of other impurities also if the oxychloride recrystallization process is used. It is evident that commercial sources of zirconia, if used in the preparation of other zirconium compounds, will introduce the same undesirable impurities if luminescence phenomena involving other activator ions are being considered, for example, the rare earths. It is possible that these impurities may not have as pronounced a detrimental effect in such compounds as they do in ZrO_2 alone.

It is probable that Ti^{4+} replaces Zr^{4+} in monoclinic ZrO_2 substitutionally rather than interstitially. The usual coordination of Ti^{4+} in oxide compounds is octahedral. In monoclinic ZrO_2, however, the coordination of Ti^{4+} is likely the same unusual asymmetric sevenfold coordination discussed previously. This highly asymmetric environment may account for the strong emission which can be developed.

The slow build-up of steady-state luminescence and the long persistence of irradiated samples at room temperature is probably related to the filling and emptying of a relatively large number of traps which were shown to exist. Several strong glow peaks were detected above liquid nitrogen temperature. One of the peaks occurs between 0° and 20°C.

Acknowledgments

The author acknowledges the efforts of R. L. Brown in determining emission and excitation spectrum, of G. Schlotzer and F. Geraghty who measured decay rates, and to R. L. Hickok for his efforts in the preparation of high purity starting materials. R. Potter devoted considerable time in helping with the determinations of glow curves and quantum efficiency. The many discussions with J. S. Saby, E. F. Apple, and D. W. Magee during this investigation were most helpful.

Manuscript received Sept. 24, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Sb^{3+} and Mn^{2+} Activated Calcium Halophosphate Phosphors from Flux-Grown Apatites

A. Wachtel

Lamp Division, Advanced Development Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The crystallization of calcium chloro- and chloro-fluoroapatites from calcium halide fluxes was studied as a function of composition and heating schedules. Activation of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ was investigated by varying phosphor stoichiometry and firing methods. The results indicate that flux-grown apatites are slightly deficient in PO_4^{3-} and that for a particle size of predominantly 50-100μ, 72-hr firing at 1150°C causes only limited incorporation of Sb^{3+}, Cd^{2+}, and additional PO_4^{3-}. The incorporation of Mn^{2+} is more extensive and may be nearly uniform. The rate of migration of Mn and Sb toward the interior of the crystals increases with increasing PO_4^{3-} [as $(NH_4)_2HPO_4$] added prior to activation; however, maximum emission occurs at a calculated over-all metal/phosphorus ratio of exactly 5/3. High output of heterogeneously emitting crystals suggests that quantum efficiency is independent of activator concentration.

The present study consisted of preparation of Mn- and Sb-activated Ca-halophosphate phosphors, based on apatites crystallized in fused salt media. Morton (1) reported on the crystallization of Ca_2PO_4Cl and $Ca_5(PO_4)_3Cl$ in fused $CaCl_2$, and Klement and Harth (2) describe the preparation of Cl- and Br-apatites by fusion of $Ca_3(PO_4)_2$ with the respective Na halides. Nacken (3) reported on the system $Ca_3(PO_4)_2$-$CaCl_2$-CaF_2 in some detail, but included no observations on morphology of the products. In view of the present need to obtain luminescence-pure materials and the versatility with which apatites are known to incorporate or exchange foreign ions, the choice of fluxes was confined to the system $CaCl_2$-CaF_2. Melting points for this, in combination with the respective Li salts, are reported by Bukhalova and Bergman (4).

Johnson (5) prepared single crystals of Mn-activated apatite grown from a melt containing this element and reported that Mn- and Sb-activated Ca-halophosphates can be briefly fused while retaining the original luminescence properties. In the present case, the excess Ca halide (flux) results in a metal/phosphorus ratio much higher than 5/3 which would promote extensive oxidation of these activators. Therefore, the incorporation of Mn and Sb was effected by additional firings, conducted after removal of the flux, and suitable adjustment of stoichiometry of the crystallized apatites.

Experimental

Crystallizations were conducted in covered round bottom platinum dishes in a furnace kept at a constant temperature, followed by quenching in water so as to minimize formation of Ca_2PO_4Cl in the temperature range below about 1040°C. Experimental batches amounted to a total of 2×10^{-2}g atoms Ca^{2+} (apatite + flux), while for purposes of phosphor preparation, larger batches were crystallized, based on an expected yield of 0.5 moles $Ca_5(PO_4)_3X$. The reacted materials were soaked in water, carefully disintegrated, wet-

screened through 40 or 60 mesh, and freed of flux by several decantations, discarding all fines not settling in one minute. In this process, particles below about 10μ and almost all of the CaF_2 occurring in finely divided (gelatinous) form was also removed. After alcohol washing and drying, the apatites were analyzed by conventional chemical techniques.

Activators were added in the form of 2 w/o (weight per cent) $MnCO_3$, 4 w/o Sb_2O_3,[1] 1.0 w/o NH_4Cl, and varying amounts of $(NH_4)_2HPO_4$ in aqueous slurry and drying. The mixtures were fired in capped silica tubes at 1150°C for 1 hr to decompose volatile matter, screened through 60 or 80 mesh, mixed with 1% NH_4Cl, and refired for longer times. Refiring of small samples for long times (72 hr) posed problems with respect to losses and oxidation of activators. In this case, the refiring was done in sealed evacuated silica tubes, the quantity of NH_4Cl being limited to provide approximately 1 atm pressure at 1150°C. After firing, the phosphors were re-screened and washed in a solution of 0.5*M* ethylene-diamine tetraacetic acid (EDTA) (6, 7) in 4*M* NH_4OH at boiling temperature for 15 min, washed with water followed by alcohol, and dried.

Brightness readings were performed with a Spectra Brightness Spot Meter on samples prepared in aluminum plaques. Maintenance was determined by irradiating the plaques in close proximity to a quartz low-pressure mercury vapor lamp in a N_2 atmosphere for 100 hr, and repeating the brightness readings. Crystallographic data were obtained on a Philips x-ray diffractometer operated at 35 kv and 15 ma, using a Cu target and Ni filter.

Results

Calcium chloroapatite.—The molar proportion of apatite/flux was arbitrarily defined in terms of the ratio of Ca^{2+} present in either of the two components, so that a mixture of $1Ca_5(PO_4)_3Cl + 5CaCl_2$ is considered equimolar (1/1). Microscopic examination of material crystallized at 1150°C for 2 hr showed needles predominant at 30-50% apatite, and short hexagonal prisms at higher apatite concentrations. The largest prisms were obtained at 70-80% apatite. At 75% apatite and 1050°C and short firing times, the largest apatite crystals (50-80μ) resulted, but with numerous inclusions and surface imperfections. Higher or prolonged heating caused at first a considerable reduction in particle size (10-30μ) followed by a slight increase, while the general appearance of the crystals was continually improved. One-half mole batches with apatite/flux = 7/3, crystallized at 1050°C for 16 hr yielded well-crystallized $Ca_5(PO_4)_3Cl$ of considerably larger particle size. Figure 1 shows photomicrographs of this type, a crystal in the upper right hand corner illustrating the growth habit. The diamond-type platelet near top center occurs only rarely. At bottom center we note a crystal with a typical inclusion, often appearing in elliptical form. Focussing of the two crystals on the right was chosen to show typical surface defects appearing in the form of raised ridges, predominantly on larger particles.

Calcium chlorofluoroapatite.—Figure 2 shows the partition of F between apatite and flux as obtained by

[1] Based on a molecular weight of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ = 505.95, this corresponds to addition of 0.088 Mn^{2+} and 0.137 Sb^{3+}/5 Ca^{2+}. Based on 3 P, after adjustment of stoichiometry by $(NH_4)_2HPO_4$ addition, these figures are somewhat reduced.

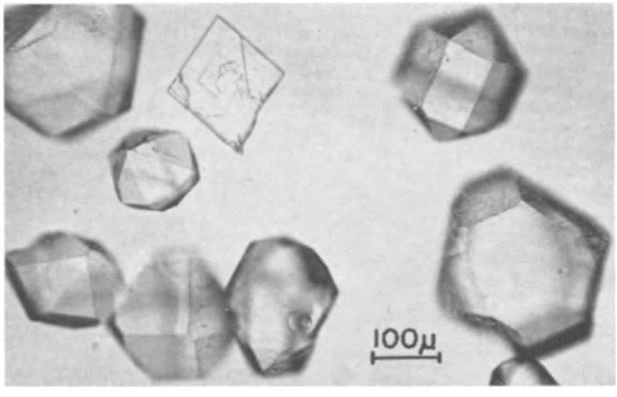

Fig. 1. $Ca_5(PO_4)_3Cl$ crystallized in 0.5 mole quantity from $CaCl_2$ at 1050°C, 16 hr, apatite/flux = 7/3 in terms of Ca^{2+} present in either phase.

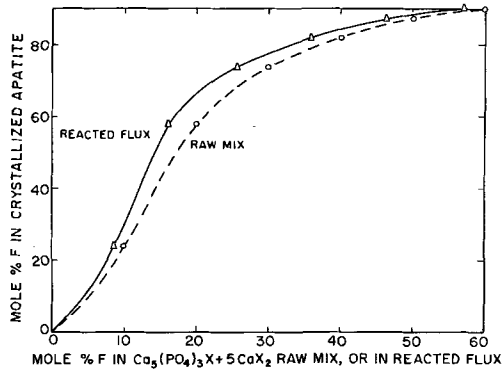

Fig. 2. Atom per cent F in crystallized apatite as a function of atom per cent F in raw materials with apatite/flux = 1/1 (dashed curve), and resulting in atom per cent F in reacted flux (drawn curve). The latter values are calculated from analyses of apatites and accounting for total Ca-halides present.

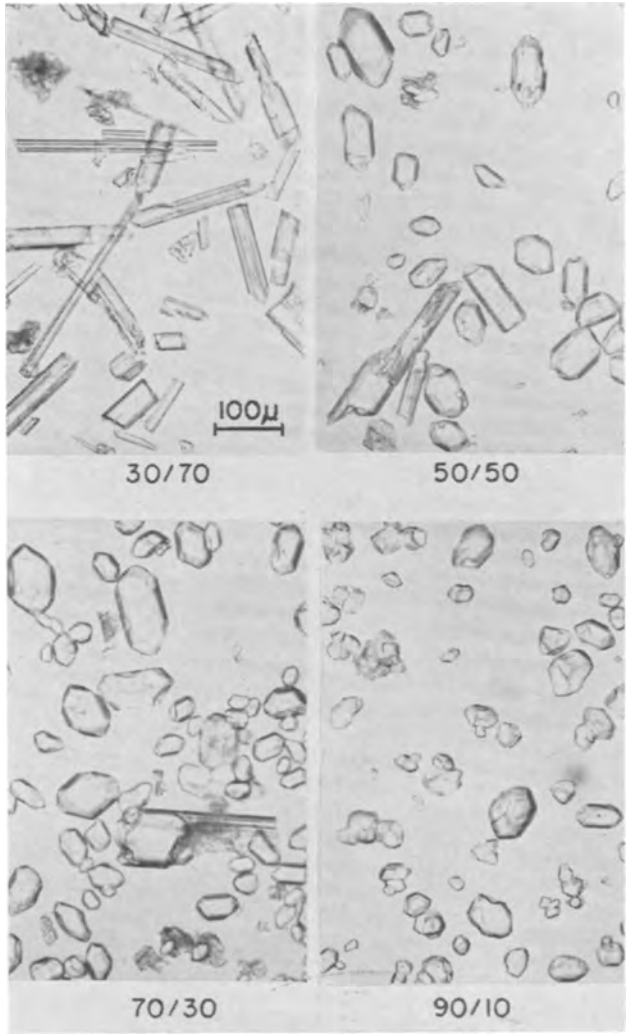

Fig. 3. Growth habit of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ crystallized from $0.57CaF_2 + 0.43CaCl_2$ as a function of apatite/flux ratio, expressed as per cent of total Ca^{2+} present in either phase.

crystallizing mixtures of [$Ca_5(PO_4)_3Cl$ + $5CaCl_2$] and [$Ca_5(PO_4)_3F$ + $5CaF_2$] in different ratios. The dashed curve is based on composition of the starting materials (apatite/flux = 1/1) while the drawn curve represents the composition of the reacted flux as obtained by difference and is therefore applicable for all apatite/flux ratios, assuming that the apatite "sees" only the composition of its immediate environment. For purposes of phosphor preparation, a F/Cl ratio of 9/1 was of particular interest, and we note this composition to be stable in equilibrium with $0.57CaF_2$ + $0.43CaCl_2$. The preferred incorporation of F into the apatite is fortunate inasmuch as leaching of the reacted melt depends on the solubility of the $CaCl_2$ and therefore becomes increasingly difficult with increasing CaF_2 concentration.

The influence of the apatite/flux ratio on the growth habit of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$, crystallized in different proportions of $0.57CaF_2$-$0.43CaCl_2$ flux is shown in Fig. 3 and closely resembles the effect observed for $Ca_5(PO_4)_3Cl$, except that in the present case, especially at low apatite concentrations, one also notes small aggregates of finely divided matter which are optically isotropic and probably consist of CaF_2. The prismatic form of apatite is slightly more elongated than that of $Ca_5(PO_4)_3Cl$. Toward higher apatite concentrations, the needle form diminishes in frequency, occasionally growing out of prismatic crystals as shown for two instances in the intermediate concentration ranges. At 90% apatite, needles are essentially absent and contamination by CaF_2 is noted only rarely. However, the particle size is reduced and the crystal faces appear more distorted, often resembling conchoidal fractures. At this point, owing to the preponderance of insoluble matter, the crystallized mass is also already more difficult to leach. For practical purposes, an apatite/flux ratio of 8/2, *i.e.*, $1.6Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ + $1.14CaF_2$ + $0.86CaCl_2$ was found to be a good compromise.

Preparation of larger batches was modified in accordance with the following observations: (*A*) Analyses of apatites often showed a considerable deficiency in P, *i.e.*, a high Ca/P ratio, possibly owing to CaF_2 contamination. Substitution of some of the raw material apatite by $Ca_2P_2O_7$ [2] helped to approach theoretical stoichiometry, as well as to promote crystal growth. (*B*) The 9F/1Cl apatite grows best at 1250°C [3] which during a 16-hr run, causes some loss of $CaCl_2$ by evaporation. The initial composition, therefore, has to be adjusted empirically. (*C*) Addition of $CaCl_2$ in the form of Ca_2PO_4Cl was found to be more convenient than $CaCl_2$ itself which is hygroscopic and often of questionable purity. Decomposition temperatures of Ca_2PO_4Cl of 945°C (1) and of 1040°C (3) have been reported. Present observation of Ca_2PO_4Cl formed at 1000°C support the latter figure.

Table I shows analytical data for a number of lots of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ prepared in this manner.[4] Analyses of the first two samples show high figures for Cl, F, and Ca; the remainder merely indicate high Ca and low P content. All of this suggests contamination by some Ca halide which is reasonable in view of the likelihood of residual flux occlusion.

Particle size increases primarily with firing temperature. The effect of batch size and firing time is much smaller. Increased firing time tends to decrease the amount of fines (10-20μ) as well as decreases the amount of visible crystal imperfections. Cooling was rapid in all cases and its contribution to crystal growth

[2] The reaction of $Ca_2P_2O_7$ and CaF_2 (forming apatite) has been described by Rabatin and Gillooly (8).

[3] This may also hold for $Ca_5(PO_4)_3Cl$, but was found unnecessary and inconvenient owing to extensive volatilization of $CaCl_2$. For this reason, temperatures above 1250°C were not employed.

[4] For a theoretical yield of 247.4g $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ (slightly less than 0.5 moles because of $Ca_2P_2O_7$ substitution), a suitable raw material composition consisted of 97.2g $Ca_5(PO_4)_3F$ + 26.7g $Ca_2P_2O_7$ + 150.3g Ca_2PO_4Cl + 37.9g CaF_2.

Table I. Analytical data on 0.5-mole batches of crystallized $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$

Batch No.	Yield		Analyses in w/o			
	Grams	%	Ca^{2+}	PO_4^{3-}	Cl^-	F^-
1	247.5	100	39.9	55.5	0.82	3.85
2	242.5	98	39.9	55.8	0.84	3.64
3	244.9	99	40.13	55.94	0.70	—
4	242.3	98	40.0	55.9	0.72	—

6	230.7	93	39.8	56.0	0.63	—
Theory	247.4	(100)	39.61	56.31	0.70	3.38

is questionable. Figure 4 shows the particle size distribution, as determined by screening, of typical 0.5 mole lots of $Ca_5(PO_4)_3Cl$ crystallized 16 hr at 1050°C (Fig. 1) and of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ crystallized 16 hr at 1250°C.

Phosphors.—Activation of $Ca_5(PO_4)_3Cl$ was limited to relatively short firing periods with fixed phosphate additions designed to adjust the stoichiometry of the phosphors to a metal/phosphorus (M/P) ratio of about 4.9/3. Emission colors ranged from relatively bluish-pink to orange, and close to the black body locus (9, 10), and brightness values ranged between 80 and 90% of N.B.S. standard No. 1031.

Activation of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ was performed with varying PO_4^{3-} additions and refiring times. With nominal additions, a minimum of 4 hr was generally found necessary to obtain good output. Losses of Sb^{3+} as well as oxidation of Mn^{2+} to Mn^{3+} (11, 12) (the latter noted to occur more readily at low M/P ratios) was avoided by conducting the prolonged (72 hr)

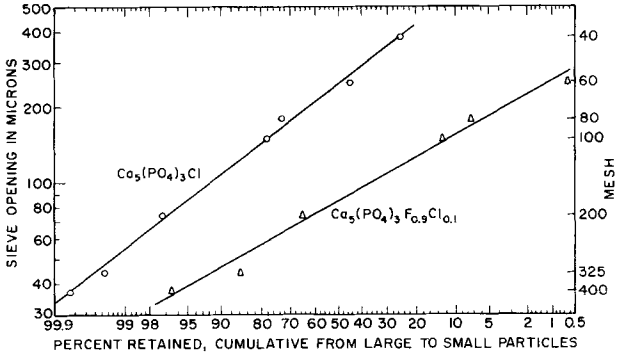

Fig. 4. Particle size distribution of $Ca_5(PO_4)_3Cl$ shown in Fig. 1 and of $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ crystallized in 0.5 mole quantity from $0.57CaF_2$ + $0.43CaCl_2$ (apatite/flux = 8/2) at 1250°C, 16 hr.

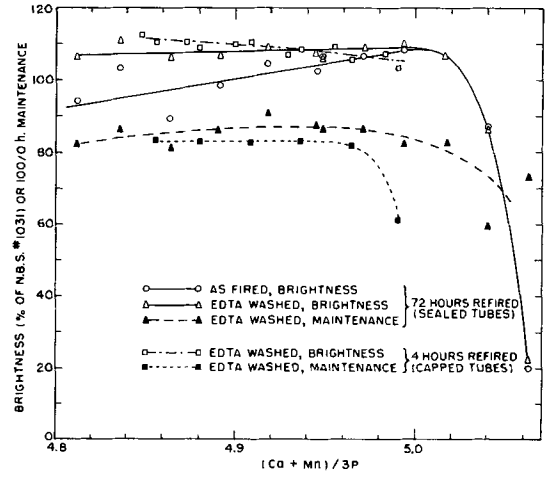

Fig. 5. Brightness and maintenance of phosphors as a function of stoichiometry. Under present conditions, the maintenance of NBS 1031 was 88%.

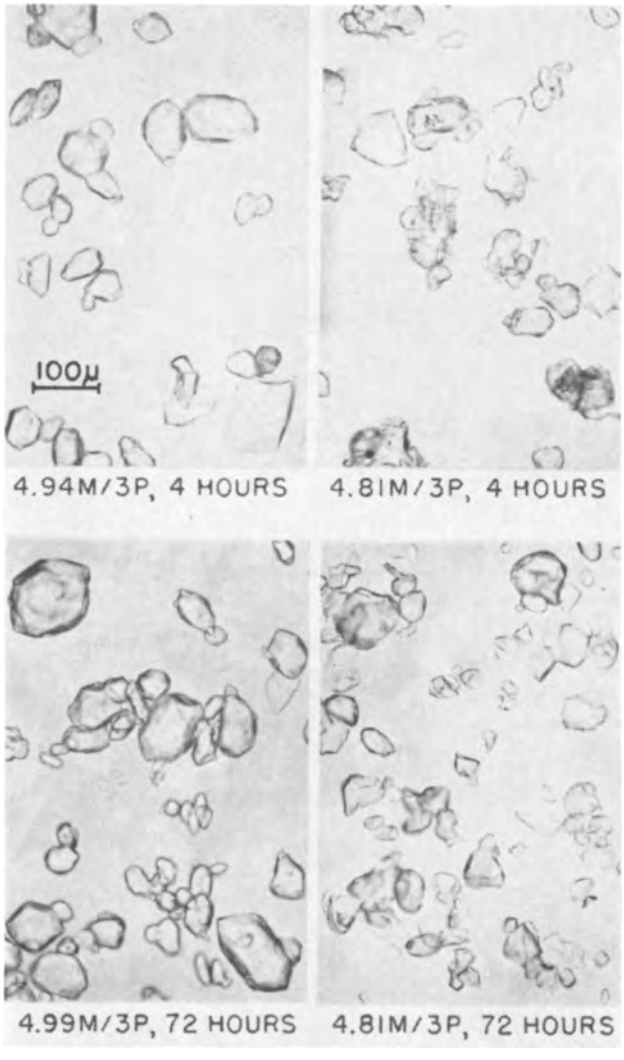

Fig. 6. Appearance of phosphors resulting from different $(NH_4)_2HPO_4$ additions (expressed as M/P ratio) and different firing times at 1150°C.

firing in sealed tubes as described. Figure 5 shows brightness and maintenance data on two series of phosphors (representing two firing times and methods) as a function of phosphor stoichiometry. We note that the output of phosphors activated by firing for 72 hr goes through a maximum at 5M/3P and is therefore in agreement with a theory to this effect proposed by Ouweltjes and Wanmaker (13) as well as calculations reported by Gillooly, Rabatin, and Vincent (14). On the other hand, phosphors activated for 4 hr improve at higher phosphate additions. We also note that differences due to EDTA washing decrease as the phosphor stoichiometry approaches the theoretical value and it therefore appears that this effect is connected with removal of an inert PO_4^{3-}-rich surface layer. Depreciation under ultraviolet irradiation was accompanied by development of yellow body color due to color center formation (15, 16) which decreased with M/P ratio (17). Depreciation of phosphors prior to EDTA washing (not shown) was severe and accompanied by black discoloration which increased with decreasing M/P ratio, *i.e.*, opposite to the observed dependence of the yellow discoloration. The maintenance of standard Ca-halophosphate phosphor N.B.S. No. 1031, under the same conditions, was 88%.

With increasing phosphate addition, sintering and attack of the apatite crystals increases. Attempts to circumvent this by using $SbPO_4$ and $Mn_2P_2O_7$ instead of $(NH_4)_2HPO_4$ (and the equivalent amounts of the respective oxide and carbonate) were of questionable value. Longer firing periods, however, did result in somewhat more friable products and also tended to eliminate small surface irregularities caused by high phosphate addition, but caused no actual re-crystallization. Figure 6 shows these effects on a group of typical phosphors representing short and long firing times as well as low and high excess phosphate additions. One of the photomicrographs (4.94M/3P, 4 hr) shows a rarely occurring plate-type crystal in the lower right-hand corner. It can be seen that at low M/P ratios, corrosion of the crystal surfaces is severe, while at high ratios (low phosphate additions), the original morphology is well preserved. In the latter case, it was also found that the particle size distribution remained the same as that shown for unactivated $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ in Fig. 4.

Incorporation of Cd (17, 18) was attempted during the growth of raw material apatite by replacing a portion of the CaF_2 by CdF_2 in varying amounts up to 10 a/o (atom per cent) substitution based on total Ca^{2+}. However, analyses showed that at the highest concentration, only about 0.1 a/o Cd entered the apatite. Cd added with activators had no effect on output, but slightly improved maintenance and eliminated discoloration of 72-hr fired phosphors. Four-hour (air) fired phosphors were severely degraded, probably owing to retention of an ultraviolet absorbing Cd-rich surface layer.

The extent of activator incorporation was investigated by etching phosphors in 3*N* HCl at room temperature. Details on the preparation of samples taken for this purpose are summarized in Table II. The depth of etching was calculated on a IBM 1401 computer on the basis of the weight loss of material assumed to be spheres with particle size distribution equal to that of the raw material apatite (Fig. 4). For sample 4 (from −400 mesh apatite) a particle size distribution corresponding to the same slope but including only the range of 10-37μ (400 mesh) was con-

sidered applicable.[5] The figures represent maxima because for real particles whose surface area is larger than that of spheres, the actual depth is correspondingly smaller. For larger phosphate additions (lower M/P ratios), corrosion of crystals was too severe to allow this approximation and no data of this nature were computed. Table III shows analyses which indicate the presence of concentration gradients of components added prior to the activation step. Analyses for total Sb in unetched phosphors ranged in the neighborhood of 1 w/o; however etching causes an apparent enrichment by (insoluble) Ca-antimonate, and therefore data on Sb analyses are confined to the trivalent (soluble) portion. With one exception (sample 3) the concentration gradient of Sb^{3+} is quite high, showing relatively small amounts in the interior of the particles. Comparison of samples 1 and 2 show that this is further increased for small sample sizes where contact with the atmosphere is more extensive, and samples 5 through 8 show that PO_4^{3-} appears to promote the migration of Sb to the interior. The incorporation of Mn is generally more rapid than that of Sb and is similarly promoted by PO_4^{3-} as well as by extended firing time (samples 2 and 3). The single instance in which Cd was determined indicates more limited incorporation compared to Mn; moreover this observation is supported by those previously mentioned concerning Cd. Ratios in PO_4^{3-} content are necessarily close to unity, since total phosphate greatly exceeds the portion subsequently added. Owing to activator content, the amount of phosphate present can be lower than that corresponding to stoichiometric $Ca_5(PO_4)_3F_{0.9}Cl_{0.1}$ (56.31%), but the analyses suffice to suggest the presence of a concentration gradient of this component as well.

[5] Owing to the large surface area of this phosphor, even the large phosphate addition employed resulted in little corrosion of the crystals.

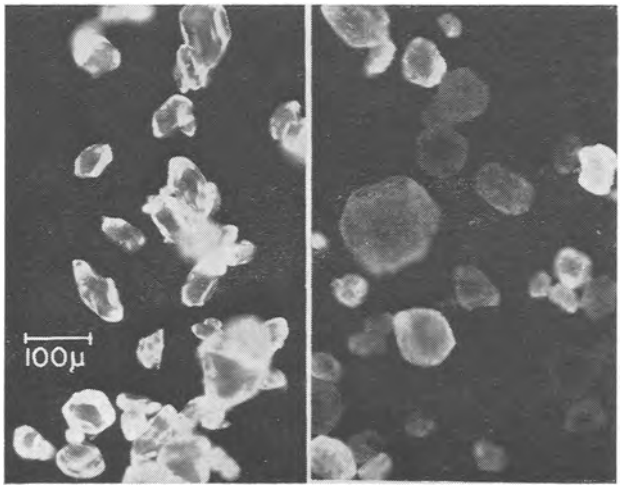

Fig. 7. Fluorescence of sample 10 (Table II) before and after etching in 3N HCl. The extent of etching was chosen so as to obtain an appreciable range of emission intensities; left, unetched; right, etched.

The process of etching is accompanied by a reduction in light output, more so in thin than in thick layers. Figure 7 shows the fluorescence of a thin layer of sample 10 prior to and after etching. Although these photomicrographs were difficult to obtain with all particles in sharp focus, the following observations can be made: (*A*) All of the unetched particles show about equal fluorescence which is principally noted at edges, corners, and surface irregularities. (*B*) The fluorescence of etched particles shows varying degrees of attenuation, ranging from occasional brightly emitting to completely nonluminescent crystals, the latter dimly outlined by illumination from the surrounding field. The roughened surfaces emit more or less uniformly and, in some cases, a fine structure, presumably an etch pattern, can be discerned. (*C*) There is no apparent relationship between size or shape and the luminescence intensity of etched particles. (*D*) Visually, it was noted that occasional crystals showed the characteristic green emission associated with compounds of Sb^{5+}, identified as fluoromeite (19), or Ca-antimonate or fluoroantimonate (11). It was interesting to note that etched crystals showing this effect appear uniformly green luminescent over the entire surface without being otherwise distinguishable (by shape or size) from neighboring white or nonluminescent crystals. Only after complete solution of the apatite does the Ca-antimonate appear in the form of small and irregularly shaped fragments. In the present materials, the effect of a high M/P ratio, oxygen, and limited firing schedule in promoting the formation of this phase (7, 20, 21) was very pronounced. Thus, in 4-hr air-fired phosphors with 4.94M/3P, green emitting crystals were abundant, a very small amount being visible even prior to etching, while in 72-hr sealed tube fired phosphors these were rare and revealed only on etching. Finally in both cases, the amount of green emitting matter rapidly diminished with increasing $(NH_4)_2HPO_4$ added prior to firing.

The spectral distribution of emission of etched phosphors, taken in 2 mm deep plaques, differs from that of the original phosphors by a reduction of the orange (Mn) band by about 10 to 20%, and a smaller reduction of the blue (Sb) band. The extent of reduction of crange emission increases with increasing relative orange emission of the unetched phosphor which, in turn, is a function of its previous history. Table IV illustrates this on a number of phosphors arranged in

decreasing relative intensity of the orange band. This correspondence indicates that these differences between samples arise mainly from differences in the concentration gradient of Mn. It can also be seen that longer firing times or smaller particle size causes a shift in emission color toward the blue, undoubtedly by promoting the migration of originally high surface concentrations of Mn toward the interior. Unfortunately, a quantitative correlation of relative peak heights and Mn content (Tables IV and III) is usually not very satisfactory by virtue of the appreciable influence of Sb content which, depending on firing conditions, could vary over a wide range.

Table V shows x-ray powder diffraction analyses of prism-type apatites and of a typical phosphor (sample 9), ground to pass 400 mesh. In order to enable direct comparison, the usual normalization to 100 for the strongest reflection in each sample was omitted. It can be seen that in spite of the extensive grinding, the reflection intensities of the unactivated apatites for the 100, 200, 300, and 400 planes were all very high, indicating a high degree of preferred orientation for these planes. A slight degree of orientation is still retained in the activated apatite when compared with the standard (N.B.S. 1031) Ca-halophosphate phosphor. Microscopic comparison of the unactivated and activated apatites (unground) under polarized light revealed no significant differences; the crystal planes in both samples show uniform extinction colors. This indicates that the activation step did not introduce random orientation within individual particles.

Discussion

Uniform incorporation of activators into a matrix whose average particle size is much larger than that of the conventional Ca-halophosphate phosphors is expected to proceed more slowly, and one also expects that under these conditions a greater proportion of Sb is lost through volatilization as halides or oxidation, even during the preliminary 1-hr prefiring step. Thus, we note the amount of Sb^{3+} incorporated in 72-hr sealed tube fired phosphors averaged 1 w/o in a surface layer not exceeding 10μ, and less than half of that for the cores. For the outer layer, the figure is in fair agreement with values of Sb^{3+} incorporation reported by Ouweltjes and Wanmaker (13). Inasmuch as the output of Ca-halophosphate phosphors does not decrease very sharply until the Sb concentration drops below about 0.25% (19), it is likely that the sharp concentration gradient of Sb^{3+} in the phosphors does not interfere with output for an appreciable portion of the crystal volume.

The presence of nonluminescent crystals in etched samples is related to the rate of migration of activators, particularly Sb^{3+} which, even during a 72-hr firing period is severely limited. This is evidenced by the generally low figures of Sb^{3+} in cores especially as the M/P ratio approaches 5/3 (Table III, samples 7, 9). While this condition is favored by high M/P ratios which causes oxidation to Sb^{5+} as mentioned, it has also been observed on etched phosphors prepared with large excess phosphate additions, although to a lesser extent.[6] The observation that reduction in luminescence intensity, as a result of etching, is less pronounced if the comparison is made on thick layers, suggests that the nonluminescent cores also have correspondingly low absorption in the ultraviolet. This is, of course, consistent with the analytical results for Sb^{3+} which is primarily responsible for absorption at 254 nm in this system (5).

Inspection of Fig. 5 shows that the output and maintenance of the present phosphors can approach values for modern conventional (powder) phosphors prepared with similar activator concentrations, although different with respect to particle size, homogeneity, crystal habit, as well as total Sb^{3+} content. For optical reasons however, this requires that they be viewed in layers which are considerably deeper, in fact which indicates that the absorption for 254 nm radiation of the luminescent portions is no higher (and, owing to low Sb^{3+} concentration, probably worse) than in powder phosphors. Moreover, the luminescent layer itself is heterogeneous with respect to relative height of the two emission bands. This means that high output (presently measurable only in plaques) has been brought about by viewing the summed light emitted by materials of which only a portion constitutes an efficient phosphor, while other portions contribute little or no radiation. From this, it may be concluded that at

[6] The mechanism whereby excess phosphate promotes the incorporation of activators is, of course, further aided by crystal corrosion (Fig. 6) which decreases the average particle size and greatly increases the surface area of the host material.

least within certain limits, the quantum efficiency of Ca-halophosphates is independent of Sb and Mn concentration.

The scope of the present study did not include x-ray diffraction analyses and activation of the needle-type form of apatite crystals, as prepared by present methods. Results of such further investigations will be reported separately.

Acknowledgments

The writer wishes to thank Miss I. Walinski for phosphor preparation and measurements, Mr. R. Farnum for chemical analyses, Dr. C. K. Lui Wei for x-ray powder diffraction analyses, Messrs. M. Barrick and C. Dawley for assistance in obtaining photomicrographs, and Mr. G. Hagen for computer programming. He is also grateful to Mr. R. C. Ropp and Dr. W. A. Thornton for valuable discussions.

Manuscript received Sept. 8, 1965; revised manuscript received November 9, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Preparation and Photoluminescence of Silicon Carbide Phosphors Doped with Group IIIa Elements and/or Nitrogen

Arrigo Addamiano

Lamp Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

ABSTRACT

Silicon carbide phosphors were prepared by firing in an atmosphere of argon containing a trace of nitrogen mixtures of semiconductor grade silicon and spectroscopically pure graphite to which a trace of group IIIa element was added. Room temperature photoluminescence was observed only with boron doping. Doping with other group IIIa elements resulted in low-temperature phosphors, whose brightness had not quite reached peak values at 77°K.

In the past few years and particularly since the advent of the Lely method for growing single crystals of silicon carbide (1), interest in the physical properties of silicon carbide has steadily grown (2). Recently attention was drawn on the luminescent properties of silicon carbide. Lely and Kröger (3) reported luminescence over all the visible spectrum at 77°K in single crystal α-SiC. The temperature dependence of the luminescence of commercial α-SiC crystals was investigated by Gorban' and Rud'ko (4). Yellow luminescence in natural α-SiC discovered in Bohemia was observed by Bauer, Fiala, and Hrichovà (5). The low-temperature photoluminescence of nitrogen-exciton complexes in high-purity single crystal SiC was investigated in detail for seven SiC polytypes by Choyke, Hamilton, and Patrick (6-10). Room temperature luminescence in α-SiC single crystals containing grown p-n junctions with B and N dopants was investigated by Addamiano, Potter, and Ozarow (11). More recently relationships between band gaps and luminescence in different SiC polytypes doped with boron were reported independently by Addamiano (12) and Kholuyanov (13). It seems likely that the mechanism of light emission in different B-doped SiC polytypes is very much the same. The nature of the luminescence center, however, is not yet known in detail. What is known from x-ray (1) and E.S.R. studies in α-SiC single crystals (14, 15) is that both B and N substitute for C in the lattice of SiC.

We thought that a comparison with other SiC phosphors containing group IIIa activators might help improve our understanding of SiC as a luminescent material. In this paper we describe their preparation and some of their properties.

Experimental

Because of the availability of "semiconductor grade" silicon and of "spectroscopically pure" graphite the preparation of SiC phosphors is a relatively simple one. The metal dopants (B,Al,Ga,In) were usually added to graphite powder in the form of a dilute solution, to make a paste, which was dried under i.r. heat. The doped graphite was then blended with a fine powder of silicon, usually in stoichiometric ratios. The mixture was transferred to a crucible of spectroscopically pure graphite and fired at the desired temperature in a graphite tube furnace in a controlled atmosphere, usually argon containing a trace of nitrogen. Temperatures of 2350°-2500°C were preferred for the synthesis of α-SiC phosphors, while temperatures around 2000°C were used for the preparation of β-SiC phosphors. Firing times ranged from 15 min to 2 hr follow-

ed by quenching.[1] With the furnace cool the charges were extracted, and excess unreacted graphite, mainly from the crucible walls, was eliminated by 900°C firing in air. The SiC so obtained was further treated with "white etch" (*i.e.*, $HF+HNO_3$) to remove oxide layers, if any. Finally it was washed and dried.

The products resulting from high temperature, *e.g.*, 2500°C, firing were coarse green powders. Firing at 2000°C resulted in relatively fine powders of yellow-green color. Luminescence depended on doping level. The best results were obtained with metal doping levels typical of ZnS-type phosphors, *e.g.*, 5 x 10^{-4} Al/SiC.

The metal doping had to be compensated or slightly more than compensated with nitrogen to produce materials with light body color and luminescence. Operating in a static atmosphere and using a charge of 10g, good results were obtained by exhausting the furnace (volume *circa* 10 liters), leaking in enough N_2 to establish a pressure of ~0.5 Torr then adding 99.999% pure argon to a final pressure of 5 psig at r.t. and firing. Similar results were obtained by flowing through the furnace a mixture of Ar + N_2 in the approximate ratio 1000:1. Preparations in the absence of nitrogen resulted in nonfluorescent materials with the dark color typical of p-type SiC. On the other hand a high partial pressure of nitrogen also resulted in materials of dark body color, with stabilization of the cubic, β-SiC, phase to very high temperatures (16). In some experiments BN was added to Si and C to supply the necessary doping, or B_4C + Si_3N_4 were used. The first outlined method, however, was preferred, insofar as more homogeneous products were obtained.

Optical measurements.—For the optical measurements a sample from each preparation was reduced to a very fine powder by vigorously shaking in a plastic vial containing a plastic sphere with the sample.[2] Contamination from the plastic were eliminated by 600°-700°C firing in air, followed by a short treatment with "white etch" washing and drying.

The emission spectra in the visible were measured using a grating monochromator in connection with a calibrated 1P22 phototube. The data were extended to 1.0μ using a Perkin-Elmer double pass monochromator with NaCl prism and a calibrated i.r. Du Mont 6911 photomultiplier.

With the exception of β-SiC:B,N, which has room temperature luminescence, all the powders were cooled to 77°K. Good thermal contact with the sample holder was insured by the use of a thin coating of Viscasil 10,000, a high viscosity, practically nonfluorescent silicone compound.[3] For the excitation we used a General Electric AH-6 high-pressure mercury lamp. The broad beam produced was confined to a region close to 3650Å by filtering through Corning 7-37 filters and through a solution of $CuSO_4$-$CoSO_4$ in water.

The photoluminescence spectra of the materials investigated are shown in Fig. 1.

Discussion

We summarize the results of our investigations on SiC phosphors in Table I, which includes some of the data published in a previous work (12).

As predicted in (12), β-SiC:B,N did show room temperature luminescence with a peak at 1.49 ev, in good agreement with the expected value, 1.48 ev. All the other SiC phosphors prepared in the course of the present investigation, both cubic and hexagonal, showed luminescence only at low temperature and in a region of the visible spectrum closer to the band edge than for SiC:B,N phosphors. The behavior is probably related to differences in the depth of the acceptor centers. The depth of the boron level in α-SiC as given by Lomakina (17) is $E_B = 0.39 - 5.5 \times 10^{-8} \sqrt[3]{N_D}$ ev. Of the other group IIIa elements only the depth of the aluminum level is known (3, 18, 19), with a value of 0.27 ev. From the shift in the position of the peak of luminescence in α-SiC:Al,N; α-SiC:Ga,N and α-SiC:In,N the depth of the Ga and In levels can be estimated to be ~0.23 and ~0.12 ev, respectively.

The α-SiC phosphors doped with group IIIa elements other than boron were brighter than the corresponding β-SiC phosphors. Measurements of brightness *vs.* temperature showed that their brightness has not yet reached peak values at 77°K.

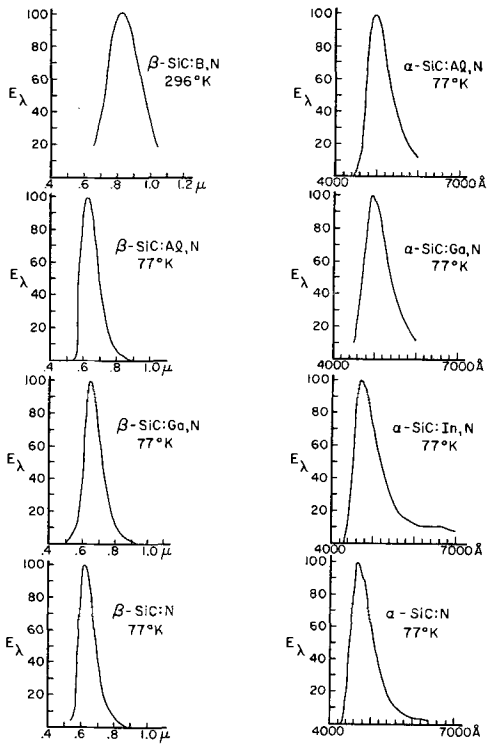

Fig. 1. Normalized emission curves for different SiC phosphors ($\lambda_{exc.}$ = 3650Å).

[1] The furnace used in our work (kindly loaned to us by Dr. G. A. Slack, General Electric Research Laboratory, Schenectady, New York) is described in ref. (2), p. 24-25. Because of the small heat capacity of such furnace it was possible effectively to quench the products of the high-temperature preparations. Thus the probability of forming layers of β-SiC on α-SiC grains or more complicated structures on cooling was very small.

[2] The apparatus used is known as Wig-L-Bug, a product of the Crescent Dental Manufacturing Company, Chicago, Illinois.

[3] A product of the General Electric Company.

Structural and Optical Properties of Thin Films of $Zn_xCd_{(1-x)}S$

Walter M. Kane, James P. Spratt, Lincoln W. Hershinger, and Imdad H. Khan[1]

Applied Research Laboratory, Philco Corporation, Blue Bell, Pennsylvania

ABSTRACT

Films of the solid solution system $Zn_xCd_{(1-x)}S$ have been produced by simultaneous evaporation from two separately controlled sources onto a single substrate. Films of uniform composition were made covering the full range from 0 to 100% ZnS concentration, and the dependence of energy gap, crystal habit, and lattice parameter on composition was investigated. Optical transmission edge measurements yielded a nearly linear dependence of gap width on composition between the values of 2.35 ev for pure cadmium sulfide and 3.35 ev for pure zinc sulfide. X-ray diffraction specimens were prepared by scraping the films from the substrates. The powder patterns obtained showed that a gradual transition from the wurtzite structure typical of CdS to the characteristic ZnS zinc-blende form takes place between 60 and 85% ZnS concentration. At compositions where both modifications are present, the basal plane spacing is the same for the hexagonal (002) and cubic (111). Equivalent hexagonal lattice parameters could therefore be defined for the cubic form, and a and c calculated for all compositions. The results show good agreement with data obtained by others on bulk material.

In certain device application (1), use is made of a semiconducting material whose energy gap is a controllable function of composition. The present paper deals with the properties of thin evaporated films of the solid solution system $Zn_xCd_{(1-x)}S$. Films of uniform composition were made covering the full range from 0 to 100% ZnS concentration. The following properties were studied as a function of composition: (*a*) energy gap; (*b*) crystal habit; (*c*) lattice parameter.

Experimental

Sample preparation.—The specimens were prepared by vacuum evaporation onto glass substrates (Corning cover glass No. 2) in an oil diffusion pumped system. All evaporations were made at pressures below 3×10^{-6} Torr, and the substrates were glow-discharge cleaned just prior to deposition of the film.

To evaporate the composite films, two molybdenum boats, one containing zinc sulfide powder and the other containing cadmium sulfide powder, were heated simultaneously, the heating currents controlled separately so that the evaporation rates were in the proper ratio to yield a film having the desired composition. Detectors in the vicinity of the substrate monitored the rate at which material was being deposited by each of the sources. This information was fed back into a control system which automatically adjusted the heater current to maintain the preset rates. The total film thickness was about 5000Å. All films were annealed in vacuum for 15 min at 450°C before any measurements were made.

Measurements.—Energy gap.—The optical-band gap was determined on 20 uniform composition sulfide films, covering the full composition range from pure cadmium sulfide to pure zinc sulfide. The measurement consisted of a transmission-edge determination, using a Cary recording spectrophotometer, Model 114R. Reflection was not taken into account.

Interference peaks in the transmission curves caused an apparent shift in the edge, but measurements on films of different thicknesses and films whose surfaces were treated to cut down internal reflection show that the transmission edge could be read to an accuracy of ±50Å.

The energy gap, determined from the transmission edge, is plotted as a function of composition in Fig. 1, and a nearly linear dependence is observed. Data on bulk material, collected by Curie (2), are shown for comparison. The deviation in the high ZnS range may represent a phase change from hexagonal to cubic structure (discussed further below).

Crystal habit.—Both zinc sulfide and cadmium sulfide are known (3) to exist in either the cubic (zinc blende) or hexagonal (wurtzite) crystal form, depending on the conditions of preparation of the material.

X-ray diffraction measurements made early in this study showed that thin films of zinc sulfide characteristically exhibit the cubic phase, while cadmium sulfide films appear to consist of the hexagonal form.

[1] Present address: General Telephone & Electronics Laboratories, Bayside, New York.

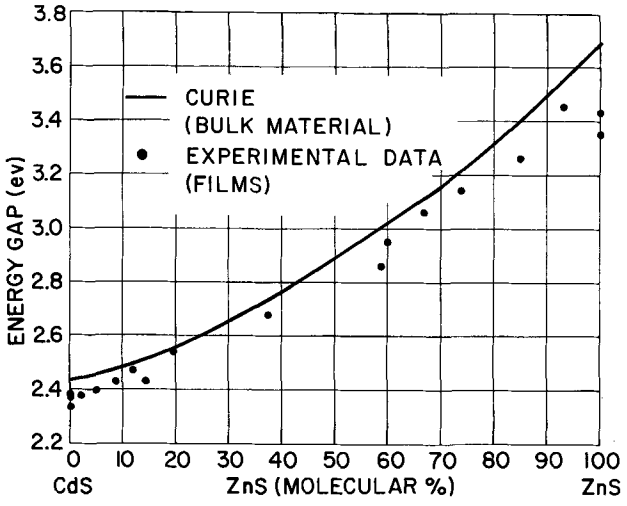

Fig. 1. Energy gap *vs.* per cent ZnS of $Zn_xCd_{(1-x)}S$ films

One of the objectives of the structural studies has been to evaluate the crystal habit of the composite films to determine the nature of the transition from cubic to hexagonal; in particular, to determine whether the transition is a gradual one with the intermediate compositions exhibiting both forms (polymorphism), or whether it is an abrupt one, the possibility of an abrupt change in crystal structure in a graded film in a device being an important consideration.

Measurements were made on 12 uniform composition films covering the full range of zinc sulfide concentration from 0 to 100%. The films, prepared as described above, were scraped from the substrates and glued to a quartz fiber with Canada balsam. The fiber was then mounted in a 36-cm circumference powder camera and exposed to Fe-filtered Co-Kα radiation.

Analysis of the x-ray powder patterns, although complicated by the close similarity between the face-centered cubic and the hexagonal close-packed crystal structures, showed that films containing less than about 60% ZnS are hexagonal in form, that films with

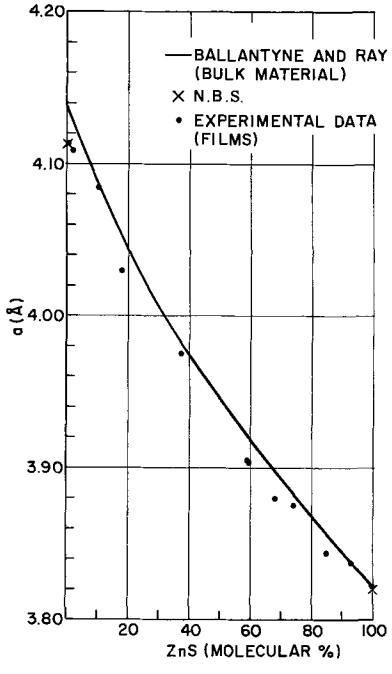

Fig. 2. Hexagonal lattice parameters *vs.* per cent ZnS of $Zn_xCd_{(1-x)}S$ films.

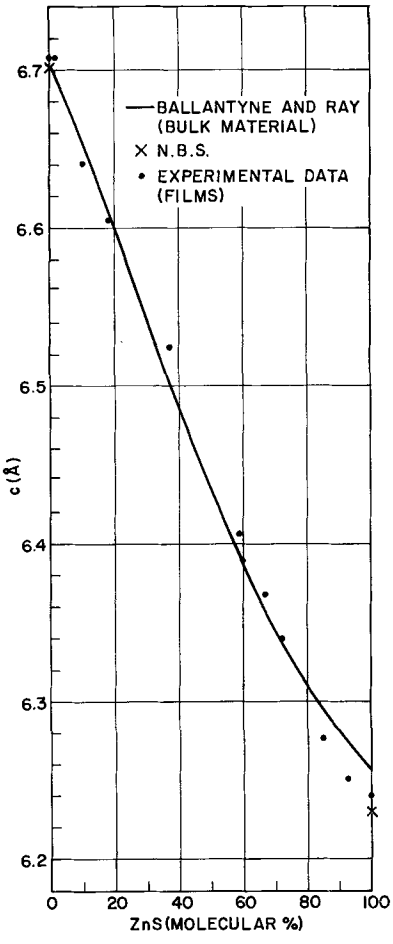

Fig. 3. Hexagonal lattice parameters *vs.* per cent ZnS of $Zn_xCd_{(1-x)}S$ films.

a ZnS concentration greater than about 85% are cubic, and that in the transition range both modifications are present, the relative quantities of the two polymorphs varying with composition.

Transmission and reflection electron diffraction patterns made on some of the films show that they are highly oriented with the basal plane parallel to the substrate.

Lattice parameters.—From the values of plane spacing d measured on the x-ray patterns, the lattice parameters were calculated for both the hexagonal and cubic forms. For convenience in presentation of the data we have made use of the equivalent planes and defined equivalent hexagonal lattice parameters a_H and c_H for the cubic modification. That is, since

$$d_{002} = d_{111}$$

we have $c_H = 2a_c/(3)^{1/2}$

and since $d_{110} = d_{220}$

we can write $a_H = a_c/(2)^{1/2}$

Because of the coincidence of the equivalent lines on the x-ray patterns, no error results from an assumption of the wrong crystal form in calculating lattice parameter.

In Fig. 2 and 3 we compare the lattice parameters of $Zn_xCd_{(1-x)}S$ films with bulk values given in the literature (4, 5), and find generally good agreement.

Discussion

From the well-behaved dependence of energy gap and lattice parameter on composition, we confirm that films prepared in the manner described are substitutional solid solutions in which solubility exists in all proportions.

A transition from the hexagonal to the cubic crystal form does apparently take place at high ZnS concentrations, but because of the close relationship between the two modifications, *i.e.*, having the same plane spacings, the transition is a gradual one and no discontinuity in the variation of composition dependent properties occurs.

Acknowledgments

The authors wish to thank Messrs. L. Altman and W. A. Hodorowski for their work in preparing the specimens, and Dr. M. H. Francombe for his help in interpreting the crystallographic data. This work was supported by the U.S. Army Electronics Command at Fort Monmouth, New Jersey.

Manuscript received Aug. 25, 1965; revised manuscript received Oct. 22, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Improved Properties of Silicon Dioxide Layers Grown Under Bias

A. Goetzberger

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Oxidation of silicon was carried out under the influence of an electric field which was applied by means of an electrode suspended close to the surface. Negative electrode potential resulted in a voltage dependent reduction of surface donor density during steam oxidation. Above several hundred volts surface donor density saturates at about 4 x 10^{11} states per cm^2. The results tend to suport the impurity ion model for channel and drift effects. No influence of field on dry oxidation was found. MOS-drift experiments gave indications of greatly improved stability of bias grown wet oxides.

Thermal oxidation of silicon usually results in an n-type inversion layer at the surface of p-type crystals. It is generally accepted that the inversion layer is caused by positively charged sites in the oxide close to the interface (1-3). Although these sites do not seem to be capable of exchanging charge with the silicon, they are commonly called slow surface states. Because it is more likely that they are fast levels located close to the conduction band, they will be referred to as surface donors in this paper. Surface donors with which this paper is mostly concerned, cause only a voltage shift of the capacitance voltage curve of an MOS (metal-oxide-semiconductor) capacitor without changing the curve shape. Fast surface states on the other hand are states which change their state of charge when the band bending is altered by an external field. These states produce a distortion of the MOS curve.

Various models have been suggested to account for the surface donors. Kuper and Nicollian (3) concluded that the channels associated with the surface donors result from hydration in wet ambients. Seraphim *et al.* (4) propose formation of positively charged oxygen vacancies in the oxide. Deal *et al.* (1), and Griffin *et al.* (2) recently presented evidence that the surface donors consist of alkali ions which are present as impurities in the oxide.

Drift effects that are observed in MOS structures during temperature-bias aging are closely related to the n-type channels. MOS aging is carried out by applying a voltage between field plate and semiconductor at slightly elevated temperatures (100°-300°C). Positive bias at the metal electrode enhances the channel, negative bias reduces it. This effect is caused by migration of charges through the oxide. Explanations of it depend on assumptions about the nature of the charges. In particular, migration of oxygen vacancies (5, 4) or alkali ions (1, 2) and electron trapping effects (6) have been suggested.

In the present investigation, oxide layers were grown under the influence of an electric field. Growth of SiO_2 in an electric field had previously been studied by Jorgensen (7); however, he was only interested in the growth kinetics of the oxide film. In the present investigation, the influence of the field on the density of surface donors was the main concern. The results obtained tend to support the alkali ion model.

Experimental Arrangement and Procedure

Oxide growth technique.—The equipment used for oxide growth is shown in Fig. 1. Bias is applied between the silicon sample and a Pt electrode. The electrode is suspended about 1 cm above a silicon pedestal which supports the sample. The pedestal is heated by RF in an arrangement very similar to an

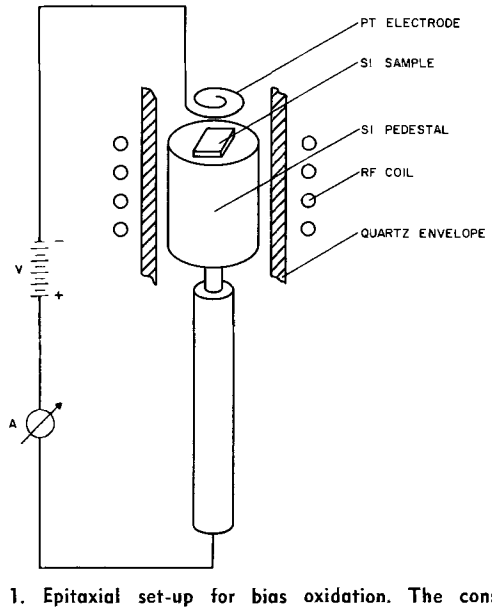

Fig. 1. Epitaxial set-up for bias oxidation. The constriction in the pedestal prevents excessive heat conduction from the hot zone. The oxidation chamber is enclosed in an oven that is kept at 100°C to prevent condensation of water vapor.

epitaxial grower. This technique differs from Jorgensen's in that the electrode is not in contact with the growing oxide. By this means the probability of contamination of the oxide from an evaporated electrode is eliminated.

In the arrangement used here, the potential drop is divided between the oxide layer and the gas phase. The situation is further complicated by the fact that not only the surface of the sample but also its rear side and the surface of the pedestal is being oxidized. Since no dependence of oxide growth rate on bias was observed, it can be concluded that most of the voltage drop occurred in the gas. According to Jorgensen's results, the drop across the oxide layer must have been below 2v. The electric field distribution during growth is presumably quite complex. In order to obtain detailed information about it a great deal of further experimentation would be necessary. This was not undertaken because the purpose of this work was the study of the influence of the growth techniques on interface properties.

In a typical oxidation run, a layer of 1000Å was grown at 1000°C. Growing time for this thickness was about 5 min in steam, 60 min in dry oxygen. Under these conditions, current flow at the beginning was between 10^{-7} and 10^{-6} amp, dropping during the run by about an order of magnitude. This applied to negative electrode voltages above 100v. Below this voltage, the system displayed an ohmic resistance of about 10^9 ohms.

Evaluation by MOS capacitance measurement.—Surface donor densities of the oxidized silicon were evaluated by the MOS capacitance technique. Metal dots were evaporated after oxidation. In most cases, evaporated Cr-Au contacts were used. No significant dependence of parameters on the contact metals was found with exception of the drift effects to be described below.

Capacitance *vs.* voltage curves of the MOS systems were measured at 100 kc. No significant hysteresis effect was noticed, indicating that all the surface states had come to equilibrium during the measurement. As pointed out above, oxidation in steam results in a channel on p-type silicon. The MOS capacitance curve of such a surface has a minimum at negative field plate voltage (Fig. 2). The correlation between this characteristic and channel properties is well known (8, 9). The voltage of the capacitance minimum is proportional to the density of surface charge. In the present paper, this voltage was converted to surface donor density with a relation given by Sah (10). This relation applies to the very low-frequency case where the electron concentration can follow the applied signal. It is also a good approximation for the present case where the increase of capacitance is caused by lateral current flow in the inversion layer. The surface charge measured this way comprises electrons in the inversion layer plus a small contribution from the charge in fast surface states. These states are located in the gap interval determined by the Fermi level at zero bias and at the capacitance minimum. The total surface charge is defined here as surface donor density, N_S. No correction for work functions was made.

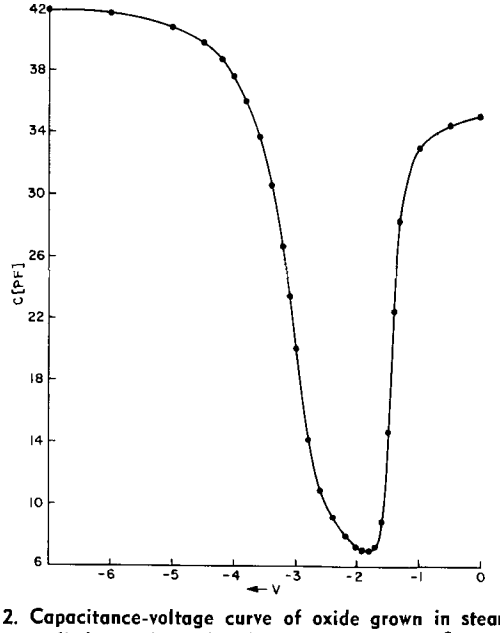

Fig. 2. Capacitance-voltage curve of oxide grown in steam with —1500v applied to electrode. Oxide thickness 900Å, frequency 100 kc; substrate p-type 50 ohm-cm.

Results

Influence of growth conditions.—Oxidations with different positive and negative biases were carried out in steam and dry oxygen. Substrate material was p-type silicon of 50 ohm-cm resistivity which had been electrochemically polished. The results can be summarized as follows:

Steam, zero and positive bias on electrode: Very high density of surface donors, large and uncontrollable fluctuations.

Steam, negative bias: Reduction of surface donor density. Reduction is bias dependent up to about 300v.

Dry oxygen, negative and positive and zero bias: No influence of bias on MOS characteristics.

The dependence of surface donor density on bias for steam oxidations with negative bias is shown in Fig. 3. MOS minimum voltages and the corresponding surface state densities are plotted.

It should be noted that the zero bias values are representative only of this particular run and can vary widely for different levels of contamination. The surface donor density saturates with voltage at an average of 3.9 x 10^{11} cm^{-2}. A typical MOS curve obtained at —1500v is given in Fig. 2. The saturation level at high bias, henceforth called residual surface donor density, varies only within narrow limits (3.2 x 10^{11} cm^{-2} to 6 x 10^{11} cm^{-2}). It does not depend noticeably on oxide thickness, growth temperature or crystal orientation. Ranges investigated were thicknesses from 500 to 6000Å and temperatures between 800° and 1100°C.

In another set of experiments, bias was applied only during part of the oxidation. The results (Fig. 4) indicate that no reduction of surface donor density occurs when the bias of 1500v is turned off after the first 1.4 min of a 5-min oxidation run. Turning off the bias during the last minute gives a low surface donor density. The same result is obtained when the bias is on only during the last 30 sec of the run.

The conditions under which a heavy channel could be removed were investigated. For this purpose steam oxide layers were grown without bias. An attempt was then made to reduce the channel by exposing the samples to 1500v at different temperatures. Results in-

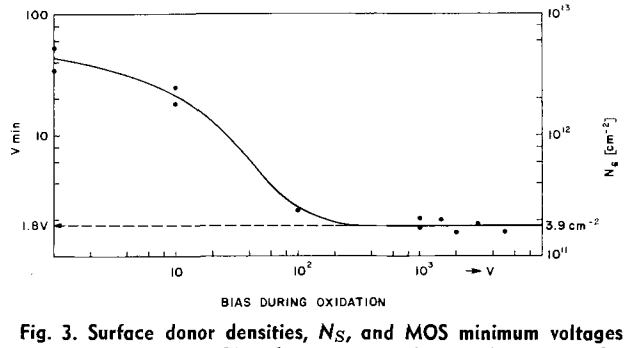

Fig. 3. Surface donor densities, N_S, and MOS minimum voltages *vs.* negative electrode bias for steam oxidation. All values for 1000Å oxide on 50 ohm-cm silicon.

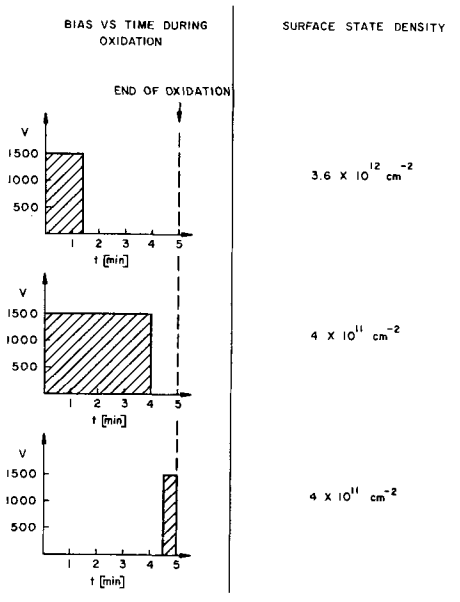

Fig. 4. Influence of interrupted bias during run. Oxidation time 5 min, bias —1500v.

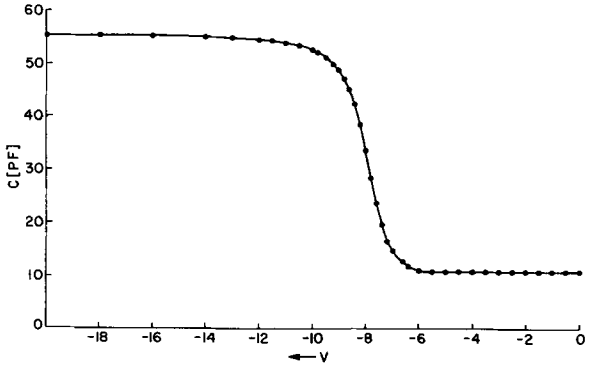

Fig. 5. Capacitance-voltage curve of oxide grown in dry oxygen

dicate that at 900° and 1000°C a 1-min exposure reduced the channel to its residual value. At 800°C, however, an increase in channel strength was observed. There is reason to believe that contamination of oxide surfaces and growing equipment has a major influence on these results. In another set of experiments, freshly grown oxides were contaminated by exposure to a NaCl solution. This contamination could be removed by a 1-min bias oxidation treatment. Control samples which did not receive the second oxidation treatment showed a very large MOS drift effect.

Oxidation in dry oxygen could not be influenced by biasing during growth. A typical MOS curve of a dry oxide is shown in Fig. 5. The capacitance rise at negative voltage indicates positive surface charge, but there is no inversion. If the surface were inverted, the capacitance would rise toward zero bias as in Fig. 2. In dry oxide, the Fermi level appears to enter a region of high density of fast surface states at the onset of inversion. The same type of curve is obtained when a wet oxide is dried thoroughly by heating in dry gas. Occasionally curves are obtained which are in between those shown in Fig. 2 and Fig. 5. The density of fast surface states in dry oxide is between 10^{12} and 10^{13} cm^{-2}. This is in striking contrast to oxides grown in steam or wet oxygen where fast surface state density is around 10^{11} cm^{-2} (11, 12).

Drift in MOS structures.—Drift experiments with positive bias during drift gave an increase of surface donor density by 3 x 10^{11} cm^{-2} within 60 min at 150°C. This is more than two orders of magnitude less than in steam oxide grown in the same equipment without bias. It was noticed that great care has to be exercised in applying the metal contacts to avoid contamination of the surface. Another effect interfering with drift measurements is in-diffusion of ions from the oxide air interface into the MOS structures during long runs at elevated temperature. For these reasons it is not certain that the figure quoted above is the limit of the bias oxidation technique.

Surface preparation.—For temperature bias aging experiments, surface cleaning in acids and solvents before oxidation was found not advisable. Oxide layers of less than 2000Å thickness had a tendency to develop shorts during aging. This effect could be avoided by oxidizing freshly grown epitaxial wafers.

Discussion

Wet oxide.—The results described here can best be explained by assuming that channels are caused by impurity ions. It is likely that, by oxidation under bias, ions are collected by the electrode from the gas phase. Ions within the SiO_2 are drawn to the surface and, if the vapor pressure of the ions or compounds formed by them is high enough, they evaporate. It is possible, of course, to carry out an oxidation in an exceedingly clean environment. Under these conditions, a very low surface donor density is expected even without an electric field.

The kinetics experiment (Fig. 4) can be interpreted as follows. Because short application of bias at the beginning of the run does not remove the channel, it can be concluded that the ions do not result only from surface contamination of the silicon. If this were the case, they would be removed by bias at the start only. Much of the contamination must therefore be introduced through the gas phase. Further conclusions can be drawn from the second experiment in Fig. 4, where the bias was turned off 1 min before the end of the oxidation, and a low surface donor density was observed. This shows that the channel cannot be due to the presence of water or oxygen vacancies because, in either case, equilibrium would have been established during the unbiased part of the run. The same is true for any polarization of the oxide that might have been introduced by the bias.

The reasons for the residual channel after bias oxidation are at present unknown. Possibly it is caused by the structure of the interface itself or by ions that are either immobile or unable to evaporate from the oxide surface.

Dry oxide.—No explanation exists at present for the difference of characteristics between dry oxides and wet oxides. If one accepts the fact that a dry oxide has a very high density of fast surface states, it is possible to speculate on a mechanism which might account for the independence of dry oxidation of bias. If a positive ion is located at an interface containing a high density of fast surface states, the probability that a surface state is close to the ion is high. The energy level of the fast surface state will then be modified by the coulomb field of the ion such that it becomes an electron trap. Thus the ion is bound to the surface state and cannot be removed by an external field. This model might also explain the fact that as a rule dry oxides exhibit only a small MOS drift effect.

MOS drift.—Since drift effects in MOS structures are closely related to mobile charges in the oxide, it can be expected that removal of the charges by growing under bias reduces drift. This is borne out by the results described above. The fact that no drift was ever observed with negative bias leads to the conclusion that there are no mobile negative charges in the oxide. This refers only to pure SiO_2. If the oxide is modified, for instance by incorporating P_2O_5, negative ions can be observed (13).

The experiments with positive bias during drift are still in a preliminary stage and more work has to be done. It can be stated, however, that the drift effect is not inherent in SiO_2 (1). Neither does it seem to depend on the contact metal. Some influence of the metal was found here, but most of it could be correlated with the difference of evaporation conditions.

Conclusions

The conclusions are:

1. N-type inversion in oxidized surfaces exceeding a density of about 4 x 10^{11} cm^{-2} is caused by positive impurity ions. It is not directly caused by the presence of water during oxidation. Most of the ions are highly mobile at elevated temperatures and can be removed by an electric field.
2. Of the different models proposed for MOS drift effects, alkali ion drift (1, 2) is the likeliest. Removal of these ions from SiO_2 layers will probably result in drift-free structures.
3. The bias oxidation technique described here is capable of reducing the density of surface donors after steam oxidation reproducibly to the range of 3.5-6 x 10^{11} cm^{-2}. Oxides produced this way exhibit greatly reduced drift effects.

The Substrate Orientation Effect on Impurity Profiles of Epitaxial GaAs Films

R. R. Moest

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Undoped n-type GaAs films have been grown epitaxially on heavily doped n-type GaAs substrates of various crystallographic orientations by the HCl/H_2 flow method. The thickness of the epitaxial films ranged from 0.5 to 20.5μ. The impurity profiles of undoped films on the (100) and (110) planes were strongly dependent on the film thickness but independent of the substrate dopants and their concentration. Impurity profiles of films grown on the (111) and ($\bar{1}\bar{1}\bar{1}$) planes were independent of the substrate dopants and their concentrations as well as of the film thickness. The steep impurity gradients at the substrate-film interface exclude the possibility of outdiffusion or autodoping of donors from the substrate. The minimum net donor concentrations obtained were in the low 10^{15} range. Reverse bias breakdown voltages vary from 5 to 60v for 0.5μ and 6μ thick films, respectively.

The epitaxial growth of GaAs films on GaAs substrates by the HCl/H_2 flow method has been described in detail by Williams and Ruehrwein (1) and by Weinstein, Bell, and Menna (2).

The objective of this communication is to report on a study made on the growth technique and evaluation of thin n-type epitaxial GaAs films of low carrier concentration on highly doped, n-type GaAs substrates.

Experimental

The system used in this work has been described previously by other authors (1, 2).

A mixture of HCl and H_2 gas is passed into a quartz reaction tube inside two coupled split-tube micro combustion furnaces. The schematic drawing of this arrangement and the temperature profile are shown in Fig. 1. Hydrogen gas is passed through a Deoxo Unit[1] and two glass-wool packed liquid nitrogen traps to condense any moisture. Lecture bottle HCl gas of 99.0% purity[2] is passed through an isopropanol-dry ice cold trap packed with Pyrex beads before the gas is admitted to the reaction tube. These purification

procedures for hydrogen and hydrogen chloride seem to be adequate for the system studied.

The source material used in this study was exclusively boat grown, undoped, n-type GaAs from Monsanto Chemical Company with a carrier concentration of 1.7 x 10^{16} at./cm^3, room temperature mobilities of 4000 to 5000 cm^{2}v^{-1} sec^{-1} and resistivities of approximately 0.1 ohm-cm.

The GaAs crystals used for substrates were either Bridgman or Czochralski grown ingots cut to various orientations with an accuracy of approximately 15 min. With the exception of one float-zoned GaAs crystal supplied by R. G. Sobers of this Laboratory, all substrate material was obtained from Monsanto Chemical Company.

Wafers 25 mil thick were cut from the oriented crystals. They were lapped with 12μ silicon carbide abrasive, mechanically polished with 0.1μ alumina, and chemically polished with Br_2-CH_3OH solution (3). The wafers were then thoroughly degreased in trichloroethylene and acetone, rinsed with deionized water, and etched in H_2SO_4-H_2O_2-H_2O solution (4). Weight measurements were made on a microbalance just prior to a run.

It has been observed that the substrate preparation immediately before the growth of a film is of greatest importance to at least the physical perfection of the epitaxial layers. Chemical polishing has frequently revealed surface imperfections in GaAs substrate wafers with carrier concentrations in excess of approximately 3 x 10^{18} (at./cm^3). In Czochralski grown material these imperfections display a pattern which might best be described as "phonograph record grooves" [see Fig. 2a (n_{Te} 4 x 10^{18})]. It is assumed that this pattern is caused by radial impurity segregation during the growth of the crystal. A similar but more randomly distributed impurity segregation might be responsible for the feathery type of imperfections observed on boat grown material, shown in Fig. 2b, (n_{Te} 3 x 10^{18}). In both boat grown and pulled crystals, randomly distributed solid particles in the GaAs have also been revealed by etching the material [see Fig. 2c (n_{Sn} 2 x 10^{18})]. These imperfections become more pronounced if the wafers are immersed and etched in a Br_2-CH_3OH solution for 5 to 10 min. The H_2SO_4-H_2O_2-H_2O etching solution, on the contrary, seems to smooth out these surface irregularities, and they may even disappear altogether after prolonged etching with H_2SO_4-H_2O_2-H_2O. It is apparent that these irregularities will be reflected in the visual perfection of epitaxial films grown on such substrate wafers.

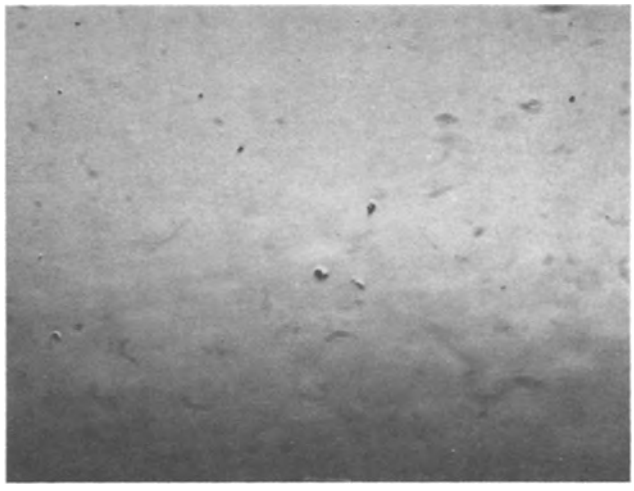

Fig. 2c. GaAs wafer, Czochralski grown; solid particles imbedded in the wafer, ($\bar{1}\bar{1}\bar{1}$). Magnification approximately 73X.

Five to ten GaAs source wafers of approximately 5 to 10 cm^2 total surface area were placed in a quartz boat. The substrate wafers, with a surface area of approximately 0.5 cm^2 each, were supported on a flat quartz plate. They were then positioned in the liner so that the source material was at the peak and the substrates were at the flat portion of the temperatube profile as shown in Fig. 1. The deposition zone is indicated by a shaded area in Fig. 1. Heavier GaAs deposition was experienced toward the lower temperature zone. The weight changes of substrate and source wafers were measured to an accuracy of ± 3 μg.

Since the objective of this work was primarily the growth and electrical evaluation of relatively thin films, no attempts were made to study growth variables such as hydrogen and hydrogen chloride flow rates, source and substrate temperature ranges, and various ΔT's in detail. The epitaxial films were all grown under the following conditions: H_2 flow, 300-500 cm^3/min; HCl flow, 1-3 cm^3/min; temperature source, 850°C; substrate, 750°C; reaction time, 15-30 min. At hydrogen flow rates of less than 100 cm^3/min, counterflow diffusion of arsenic has previously been observed resulting in arsenic condensation in the upstream portion of the reaction tube. Hydrogen flow rates in excess of 600 cm^3/min normally lead to etching of the substrate material due to undersaturation of the reacting gas at the source wafers. It appeared that the temperatures of source and substrate and their temperature differences were not critical within certain limits. It was, however, of greatest importance that the reactive H_2-HCl gas mixture passing over the substrates was supersaturated with source material. The conditions of saturation depend as well on temperature

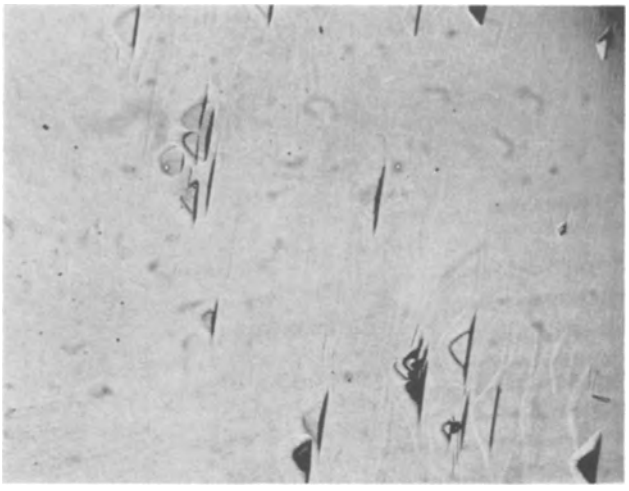

Fig. 3a. Epitaxial film on (110) oriented substrate. Magnification approximately 140X.

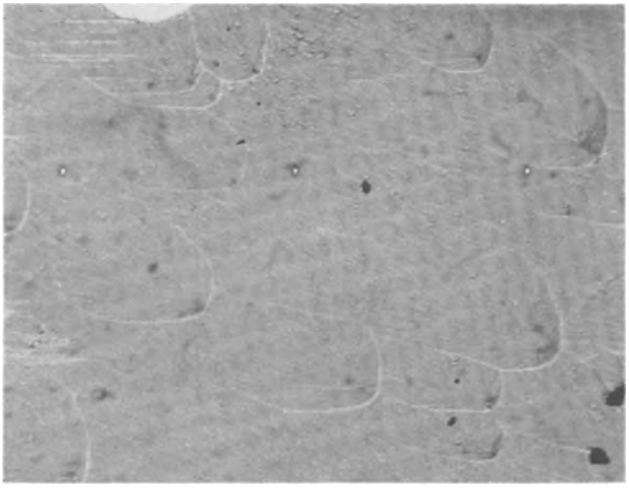

Fig. 3b. Epitaxial film on (111) oriented substrate. Magnification approximately 140X.

and flow rates as on the geometry of the system. No difference in the carrier concentration of the profiles of the films could be detected by using either fresh source material or the remainder of previously used source wafers.

Epitaxial films from 0.5 to 20.5μ thick have been grown on ($\bar{1}\bar{1}\bar{1}$), (111), (110), and (100) substrates. The surfaces of epitaxial films grown on the ($\bar{1}\bar{1}\bar{1}$) and (100) planes were visually and microscopically smooth and generally free of growth patterns, while films grown on (111) and (110) oriented substrates exhibited some surface texture (Fig. 3a and 3b). Growth rates were found to vary for different substrate orientations. The observed absolute growth rates were: 0.5-0.7 μ/min on (111) plane; 0.2-0.4 μ/min on (100) plane; 0.1-0.15 μ/min on (110) plane; 0.03-0.05 μ/min on ($\bar{1}\bar{1}\bar{1}$) plane.

The thickness of the epitaxial films was measured with a Beckman Infrared Spectrophotometer (Model IR-5, NaCl optics). Since the lower limit for measurements of film thicknesses with this technique is approximately 1μ, the thickness of films less than 1μ was calculated by area and weight gain measurements.

The carrier concentration profiles in the films have been determined by the differential capacitance-voltage method at 100 kc as described by Thomas *et. al.* (5). Schottky surface barrier diodes were used as rectifying contacts. Nominal 10 mil diodes were formed by evaporating gold at pressures of $\leq 10^{-6}$ Torr. Ohmic contacts were formed by spot-welding

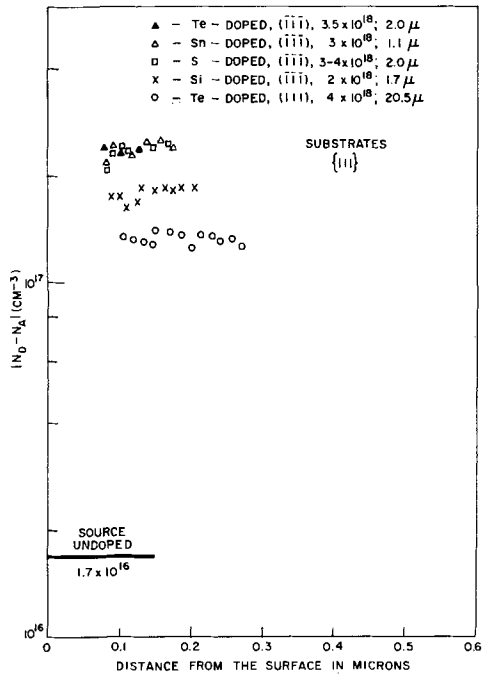

Fig. 4A. Several of the evaluated profiles

5% Sn-Au alloy wires to the bulk wafer. The ohmic behavior of these contacts and the characteristics of the diodes were checked on an I-V curve tracer. It was necessary to measure microscopically the diameter of the Au diode since variations from 9.3 to 12.5 mils diameter were encountered.

Results and Discussion

Epitaxial films with thicknesses from 0.5 to 20.5μ have been grown from "undoped," n-type GaAs source material on substrates doped with various impurities to a level of 2 to 4 x 10^{18}. The substrates were cut to different crystallographic orientations. Despite the fact that only one type of source material has been used, different results were obtained on films grown on different substrate orientations. The measurements were generally made without etching the units. It has been found that etching mesas frequently deteriorated the breakdown characteristics of the diodes to completely ohmic behavior. It seems appropriate to discuss the results on the basis of different substrate orientations.

Films grown on ($\bar{1}\bar{1}\bar{1}$) oriented substrates.—It has been observed that the ($\bar{1}\bar{1}\bar{1}$) plane is the slowest growing plane and yields the smoothest film surfaces. Epitaxial films grown on this plane also exhibit the lowest breakdown voltages, ranging from 2 to 8v. Films of various thicknesses have been grown on this plane using substrates doped with different impurities. Figure 4A shows several of the evaluated profiles together with the corresponding film thicknesses as determined by the infrared method. The different substrate dopants and their concentrations are included in this figure. The zero-bias space charge width extended only to 0.1μ with zero-bias capacitance values of 70 to 90 pf. This indicates an impurity concentration of 2 to 3 x 10^{17} at only 0.1μ from the surface. To assure that these relatively high carrier concentrations are not merely surface layer effects of the epitaxial films, several samples have been step-etched whereby part of the epitaxial film was etched off. A typical example is shown in Fig. 4B. In this case the total epitaxial film thickness was 1.0μ. Part of the sample was coated with Apiezon W wax and the sample etched in H_2SO_4-H_2O_2-H_2O solution to remove 0.75μ of the epitaxial film. After removal of the wax coating 10 mil

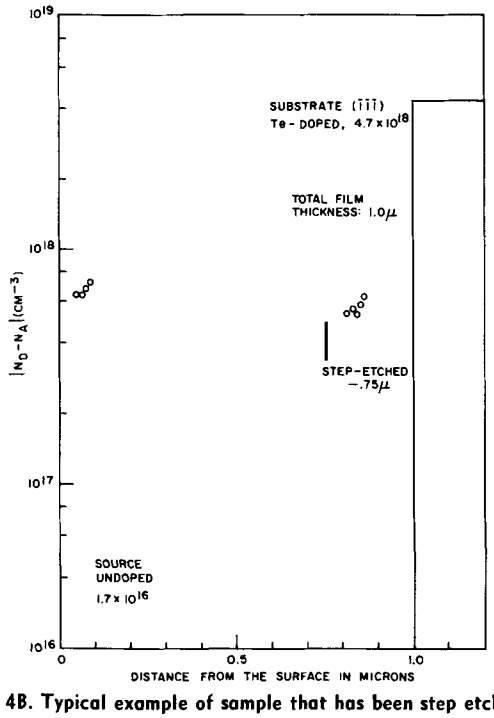

Fig. 4B. Typical example of sample that has been step etched

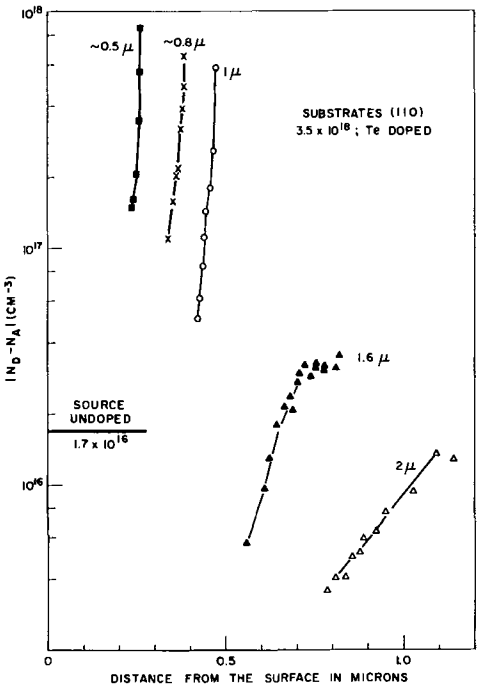

Fig. 5. Impurity profiles of several films

diameter gold dots were evaporated on the surface and the diodes were then evaluated as described earlier. The fact that the carrier concentration of the epitaxial film on the etched layer is identical with the one observed on the original surface indicates that the high carrier concentration is uniform throughout the epitaxial layer. These results seem to be completely independent of the film thickness and the type of substrate dopant.

Films grown on (111) oriented substrates.—The (111) plane proved to be the fastest growing plane, but the surface perfection of the films is very poor. The characteristics of the diodes on this plane are identical with the ones on the $(\bar{1}\bar{1}\bar{1})$ plane. The impurity profiles for the (111) films are the same as for the $(\bar{1}\bar{1}\bar{1})$ films (see Fig. 4A, B). Two films with thicknesses of 19 and 20.5μ have been grown showing the same film thickness independence of the impurity profile as observed on $(\bar{1}\bar{1}\bar{1})$ films.

Films grown on (110) oriented substrates.—Diodes of films grown on the (110) plane generally have V_{BS} ranging from 3 to 8v for films of less than 1μ thickness to approximately 20v for films 1-2μ thick. The impurity profiles are also remarkably different from those observed on (111) films. The space charge width at zero bias extends much farther into the film compared to {111} films. The impurity profiles of several films grown on the (110) plane are plotted together with the film thicknesses in Fig. 5. The space charge width at zero bias increases with the film thickness and the corresponding lowest carrier concentration at zero bias drops from the low 10^{17} range for 0.5μ thick films to the mid 10^{15} range for approximately 1.5μ thick films. The slope of the impurity profile at the apparent film-substrate interface is very steep, approximately 13-15 decades/μ. The discrepancy between the film-substrate interface as indicated by the impurity profile and determined by IR measurements can be explained by cummulative errors in the various measurements. This is particularly the case with the infrared thickness measurements where almost the entire width of the relatively small substrate wafer is exposed to the IR beam through a wide slit. The measurements therefore yield only an average film thickness of the sample.

Films grown on (100) oriented substrates.—The highest reverse bias breakdown voltages and the lowest carrier concentrations have been obtained with films grown on the (100) plane.

The Schottky surface barrier diodes had V_B values of 4-8v for approximately 0.5μ thick films and 40-60v for 3 to 6μ thick layers. The zero bias space charge width increases with the film thickness analogous to films grown on the (110) plane. The lowest carrier concentration at zero bias is about one order of magnitude lower than on (110) films of comparable thickness. The impurity profiles of (100) films thicker than 2μ exhibit some anomalous behavior at low bias (see Fig. 6). The carrier concentrations as determined by differential capacitance-voltage measurements at zero bias are in the low 10^{14} range, increasing rapidly with applied reverse bias to some peak value in the low or mid 10^{15} range and then decreasing slightly toward the substrate. Within a few tenths of a micron of the interface, the carrier concentrations increase very rapidly toward the substrate doping level. The same

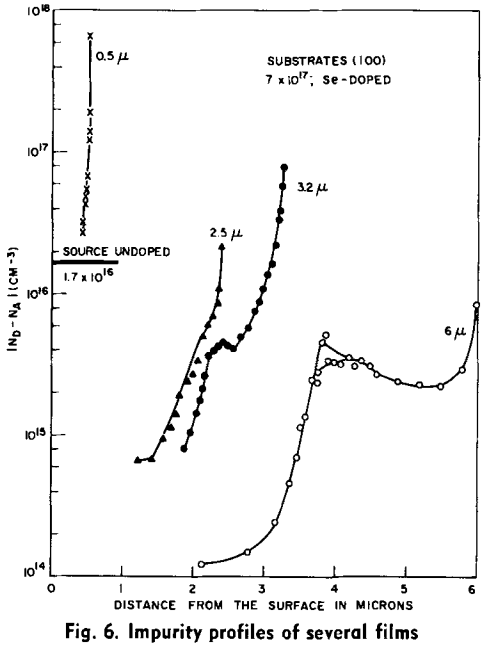

Fig. 6. Impurity profiles of several films

peculiar impurity profile was observed on a (100) film after etching. In this case the original gold dots were removed with a saturated aqueous solution of KI and I_2. The wafer was then etched with H_2SO_4-H_2O_2-H_2O and thus thinned down by removing part of the epitaxial film. New gold dots were then evaporated. The impurity profile, similar to the one shown in Fig. 6 for a 6μ thick film, remained essentially unchanged, except that the initial ascending slope and the peak shifted closer to the film-substrate interface, corresponding to the new film thickness. Lawley (6) has made similar observations on films grown with the water vapor system. He also conducted some experiments on bulk GaAs crystals with carrier concentrations of 2 to 3 x 10^{15} and observed the same anomalies (7).

The slope of the impurity profiles of (100) films at the film-substrate interface is practically infinite. This indicates that adverse reactions like outdiffusion of impurities from the substrate into the film or substrate autodoping as described by Thomas *et al.* (5) were not encountered in the experiments with films of this orientation.

The impurity profiles for epitaxial films grown by the HCl/H_2-method at substrate temperatures about 750°C are generally independent of the kind of substrate donors and their concentration up to 6 x 10^{18}. This conclusion is evident from the results obtained on (100) and (110) films. Not clearly explained, however, are the results on {111} films. It might be argued that some mechanism like substrate autodoping or outdiffusion of impurities from the substrate into the film is orientation dependent and is predominant on the {111} orientation. If this were the case one should be able to obtain {111} films of lower carrier concentration by using lightly or undoped {111} substrates. In Fig. 7 are depicted the results of such experiments. Two films were grown on {111} oriented substrates, Te-doped with a carrier concentration of 2 x 10^{16}. The films were 1. 3 and 1.2μ thick, and the impurity profiles were essentially identical to the ones observed on films grown on n^+-substrates. The impurity profiles of films grown on {111} oriented n^+-substrates with high carrier concentrations seem, therefore, to be independent of the kind and concentration of substrate donors. In view of the results obtained on (110) and (100) films it is improbable that the system itself could contribute to the high carrier concentration of these {111} films.

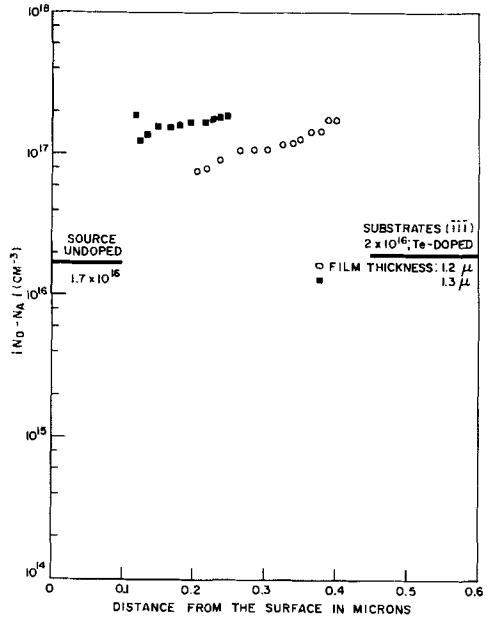

Fig. 7. Results of experiments

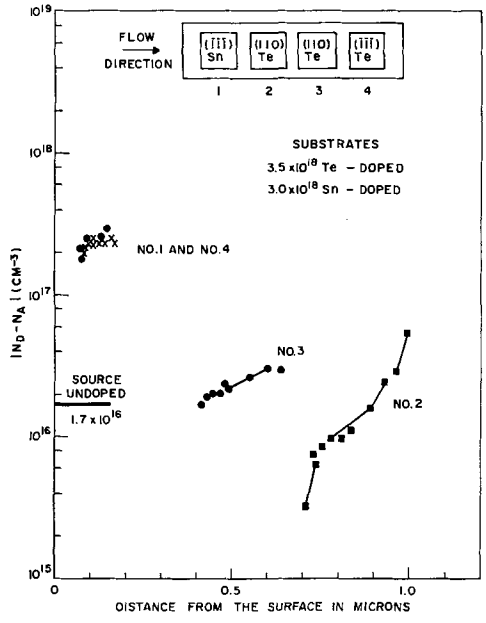

Fig. 8. Results of experiment

If we assume that no substrate-originating effects occur which adversely influence the properites of the epitaxial films, then it should be possible to place several substrates of various orientations on the quartz plate during one experiment and still observe the results shown in Fig. 4, 5, and 6 for the appropriate substrate orientations. The result of one such experiment is shown in Fig. 8. In this run four substrates of two different orientations, but approximately the same carrier concentration, were used. They were spaced close together on the quartz plate in the sequence indicated. The consistency of the results obtained on multiple substrate experiments with the results obtained on single substrate experiments indicates that no "downstream" impurity contamination occurs due to outdiffusion or autodoping from the substrates.

Conclusions

From the results obtained in this work we may conclude that thin GaAs films of approximately 0.5μ thickness can be grown by the HCl/H_2 system at substrate temperatures low enough to eliminate impurity diffusion from the substrates into the films. The impurity profiles of the films are strongly orientation dependent. Only the (110) and (100) orientations seem to yield low carrier concentrations in the films if source material of low carrier concentration is used. The slope of the impurity profiles at the film-substrate interface is very steep and indicative of an abrupt change in carrier concentrations. For {111} oriented films only relatively high carrier concentrations can be obtained, regardless of the substrate donor concentration and film thickness. For films of comparable thickness there appears to be a definite orientation dependent trend in carrier concentrations towards lower values in the order $(\bar{1}\bar{1}\bar{1}) = (111) >> (110) > (100)$.

The peculiar impurity profiles for {111} films are not explained in this work. It has been suggested by Williams (8) that anisotropic impurity segregation might occur in this vapor growth process similar to the one observed in the crystal growth from the melt.

Kinetics of the Reaction Hi-⟨111⟩Ge

A. Reisman and M. Berkenblit

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

ABSTRACT

Experiments are described which appear to differentiate between mass transport and surface reaction kinetics in the open tube reaction of gaseous hydrogen iodide with <111> germanium surfaces. Surface limiting reaction behavior is not observed until average linear gas stream velocities in the neighborhood of 800,000 cm/min are attained. The limiting reaction rate for the etching reaction is described by the equation $\log R_f = -3.64 \times 10^3/T^\circ K + \log p_{HI} + 5.42$, R_f having the dimensions mg/cm^2 hr. The reaction order was found to be unity which together with other information suggested that the desorption of germanium iodides constitutes the rate-limiting step. Autodoping phenomena are examined in view of the speed of the etching reaction, and calculated rate data for probable deposition reactions are presented.

The widespread usage of reversible vapor-solid chemical processes for the epitaxial growth of semiconductors has focused considerable attention on both the kinetic and equilibrium properties of the reactions involved (1-14). In general, kinetic studies conducted in open tube systems have not yielded reproducible data for either the forward, deposition, or the reverse, etching, processes. In the light of recent work by Sedgwick, in fact, it is not evident that open tube deposition processes as normally practiced should be treated kinetically, their behaviors more nearly approximating equilibrium states (1). Closed system investigations are frequently questionable on the grounds that experimental evidence demonstrating a differentiation between mass transport and surface limitations is lacking, a point applicable also to open tube work.

While a full understanding of the nature of the growth processes entails independent evaluations of both the forward and reverse reactions, the former represents a formidable problem in that deposition cannot be confined to the substrate alone. This suggests that investigations of the etching process are potentially more rewarding, information about the forward reaction then being inferred from relationships between etch rate and equilibrium constant information. Using this approach one may also obtain clues as to the extent of possible back etching reactions in depositions which lead to autodoping of the deposits by impurities initially present in the substrate, etched during the growth process, and then incorporated in the growing crystal via a gas phase segregation process.

One typical class of deposition reactions involves the hydrogen reduction of a polyhalide via the stoichiometry depicted in Eq. [1]. It is to be noted that a product of this reaction is the halogen

$$GeX_4 + 2H_2 \rightleftarrows 4HX + Ge \qquad [1]$$

acid, HX, and that the reverse reaction involving this acid occurs under conditions of an essentially constant, large H_2 ambient atmosphere, the tetrahalide usually being present in concentrations of less than a few mole per cent. The specific reaction of gaseous HI with solid Ge in an open tube system using an H_2 carrier gas has been discussed qualitatively by the authors with respect to the parameters affecting vapor polishing of Ge and Si (15). The present work was suggested by the results of the earlier etching study and is concerned with quantitative aspects of the surface limiting kinetics of the Ge(solid)-HI(gas) reaction. Concomitantly, techniques are described for separating surface and mass transport phenomena in solid-gas reactions.

Analysis of Open Tube Reactions

Parameters affecting an open tube process, that involving HI and Ge for example, Eq. [2], are the etchant concentration, etchant flux, temperature and reactor geometry. If

$$2(x+y)HI + xGe \rightleftarrows (x-y)GeI_2 + yGeI_4 + (x+y)H_2 \qquad [2]$$

surface kinetics alone are to be explored, effects due to the last named parameter must be obviated, the others being amenable to control. It is to be noted in Eq. [2] that two possible Ge-containing species may be formed in the general case by either parallel or sequential reaction paths. Conditions must be chosen to minimize one or the other of these reactions. A thermodynamic analysis of the type reported on earlier (12) can provide information on the temperature and concentration intervals in which one or the other of the over-all reactions specified in Eq. [3] and [4] prevails. While this represents a starting point, it is no guarantee

$$2HI + Ge \rightleftarrows GeI_2 + H_2 \qquad [3]$$

$$4HI + Ge \rightleftarrows GeI_4 + 2H_2 \qquad [4]$$

that the kinetics leading to the equilibrium states proceed via the gross mechanisms suggested by Eq. [3] and [4], and must be considered in the light of other evidence (13).[1] In an open tube system consisting of a source of HI and a reaction chamber of defined geometry, etchant flux may be varied simply by varying the input flow rate. In order to provide some crude normalization of the geometry factor, it is well to consider average linear gas stream velocity, l.g.s.v., rather than flow rate in the reaction chamber. The l.g.s.v. we will consider is simply the input carrier gas flow rate divided by the cross-sectional area of the reactor,

[1] K. Haq, for example, has suggested on the basis of spectrophotometric studies that, in the reduction of $GeCl_4$, the tetrahalide is reduced in the vapor to the dihalide from which point the reduction actually proceeds. If this is actually the case, then it follows that either free halogen or halogen acid is present prior to deposition.

correcting for the temperature of the reactor and the addition of etchant.

Two distinct types of mass transport limitations are associated with etchant flux into the reaction chamber. The first of these depends solely on the rate of introduction of gaseous reactant into the chamber. The second depends on the movement of this introduced mass to all portions of the chamber, particularly the reaction site. It is this second phenomenon which is a geometrically governed limitation, and it is the combination of both phenomena that establishes the mass transport limiting aspects of a reaction taking place in a given open tube apparatus. Boundary layers at the surface of the solid being etched need not be considered in our qualitative discussion since for all practical purposes it is the solid surface plus its inseparable boundary layer that must be together treated as the "surface".

In order to proceed, we will simplify our task subject to subsequent experimental verification by assuming that: (*a*) there exists a distinct slow step in the reaction; (*b*) the total pressure is to a first approximation constant with varying l.g.s.v.; and (c) pertinent vapor phase species are accounted for.

Low L.G.S.V. range-complete mixing-linear region.—At low linear gas stream velocities, the etchant introduced into the reaction chamber has sufficient residency time to come into equilibrium with the solid surface. In this l.g.s.v. interval nothing can be learned of the surface kinetics since the reaction is mass transport limited by the first mass transport process mentioned, *i.e.*, input rate of reactants into the reaction chamber. A plot of etch rate, R_t, *vs.* l.g.s.v. must be linear and it is a consequence of the situation specified that: (*a*) no species partial pressure gradients exist; (*b*) the partial pressures of reactant and products are the equilibrium values; and (c) the reaction efficiency, β, defined as the ratio of observed etch rate to that predicted thermodynamically is unity. These conditions, indeed, are those sought in a transpiration experiment of the type previously discussed by the authors (14), and coincide with a state of affairs in which complete mixing obtains.

Intermediate L.G.S.V.–incomplete mixing, sublinear region.—As the l.g.s.v. is increased, a critical value is reached where the residency time of etchant molecules introduced into the reactor becomes equal to, then less than the time required for complete equilibration to occur. Since this situation is concomitant with an increase of flux into the reactor, it represents the point at which mass transport into the reactor plays less of a role in limiting the reaction and where mass transport of etchant molecules from the walls of the reactor to the solid surface, for example, becomes a major rate-limiting step. Since not all of the introduced etchant molecules in the reactor are able to equilibrate with the solid surface being etched, the efficiency β, whose value may vary between 0 and 1, becomes less than unity and the etch rate-l.g.s.v. curve must become sublinear. The shape of the curve is dependent on the nature of some complicated function describing the relationship between β and l.g.s.v. where hydrodynamic aspects, not simply partial pressure differences, must be incorporated. If in the experiment being considered the surface of the solid is parallel to the gas drift velocity direction (the axial direction), it is evident that the partial pressure of etchant immediately above the solid surface where reaction is depleting its value will be less then at the walls radially removed from the surface (the radial direction).[2] Information relating to the surface limiting kinetics is not obtainable in the sublinear l.g.s.v. region because the radial and very probably axial partial pressure gradients make it impossible to define etchant partial pressure at the surface. In addition, the extent of the reverse reaction contribution to the etch rate is unknown. In the sublinear region, therefore, the case exists where the system tends from a state of complete mixing to one of zero mixing, and where the partial pressure gradients are not readily definable.

High L.G.S.V.-zero mixing, plateau region.—The observed etch rate, R_t, is assumed to represent the differences in rates between the etching and reverse reactions, Eq. [5], where k_f and k_r are the forward and reverse rate

$$R_t = k_f p_{HI}{}^x - k_r p_{GeI_2}{}^y \qquad [5]$$

constants, respectively, p_{HI} and p_{GeI_2} are the partial pressures of HI and GeI_2, respectively, at the surface, and x and y are the reaction orders for the forward and reverse reactions, respectively. With increasing l.g.s.v. we see that, because of the decreased depletion of etchant, the average partial pressure of HI at the surface will increase. This will increase the value of the forward reaction rate term, R_f, defined by Eq. [6]. Simultaneously,

$$R_f = k_f p_{HI}{}^x \qquad [6]$$

the increased l.g.s.v. will sweep away the reaction product(s) causing a diminution of its partial pressure and thereby decreasing the extent of the reverse reaction defined by Eq. [7]. When

$$R_r = k_r p_{GeI_2}{}^y \qquad [7]$$

the l.g.s.v. achieves a sufficiently high rate such that the depletion of etchant is experimentally insignificant, and the extent of the reverse reaction tends toward zero, mass transport effects are obviated, and the observed etch rate is directly that demanded by Eq. [6]. Since p_{HI} is effectively the input value at this point, further increase in l.g.s.v. does not result in a change in etch rate. It is in this l.g.s.v. range that the reaction is surface limited and reactor geometry independent for the first time. It is in this l.g.s.v. range also that zero mixing prevails for the first time.

During the sequence of events represented by the three l.g.s.v. regions, the difference p_{HI}(walls)-p_{HI}(solid) moves from a value approaching zero through a maximum, then back to a value approaching zero. At the two extremes, however, the values for the walls and solid approach $p_{equilibrium}$ in the linear region and p_{input} in the plateau region. In the intermediate sublinear region in which the wall-solid etchant partial pressure differential is not zero, the partial pressure at the wall or solid surface has a value less than the input value, but greater than the equilibrium one. Furthermore, the value of p_{HI} ranges closer to the equilibrium value over a wider l.g.s.v. interval at the solid surface than it does at the walls.

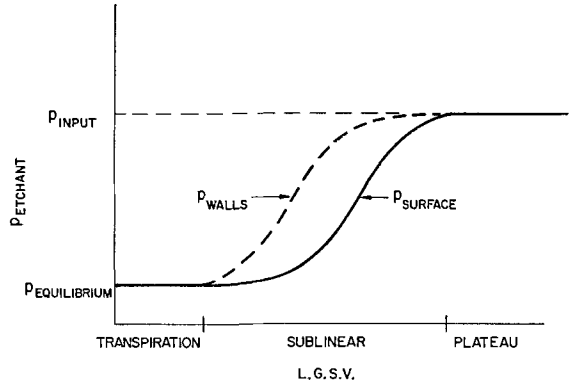

Fig. 1. Schematic representation of variation in partial pressure

[2] In ref. (15) experiments are described in which the existence of radial gradients was demonstrated. In essence, these experiments involved decreasing the diameter of the reaction chamber while maintaining the input etchant flux and temperature constant. Despite the increased l. g. s. v. (therefore, decreased residency time of HI molecules in the vicinity of the surface), the etch rate increased markedly. The effect is, of course, twofold, *i.e.*, bringing more of the HI to the surface and sweeping away reaction products at a faster rate.

Figure 1 schematically depicts the variation in partial pressure at both the walls of the reactor and at the solid surface over the entire l.g.s.v. range.

Based on the rationale, it is clear that experimental data must be acquired solely in plateau regions. These plateau regions can be defined by studying the etch rate-l.g.s.v. behavior, at each etchant concentration, at different temperatures, and for specific crystallographic surface orientations. Such an approach, while necessary in finding a suitable temperature and concentration range to examine, is very laborious, requiring the amassing of an enormous number of data points. A more palatable, but nonetheless laborious approach, involves testing each concentration and temperature interval at a few high l.g.s.v. values on each curve until a suitable region is found.

Experimental Procedure

A number of preliminary tests were applied by us before a region which appeared to represent a starting point for studying Ge surfaces was found. Experiments were conducted in a number of different reactors in which l.g.s.v. were continually increased, in which wafer dimensions were continually reduced to minimize axial direction effects, and temperatures were lowered to get to a reasonable reaction rate range. Having located a starting point, measurements were then made at the highest velocity attainable both below and above the test temperatures and at HI concentrations greater and lower than those used in the test. As long as surface kinetics prevailed, plots of log etch rate (ordinate) *vs.* $1/T$ (abscissa) were expected to provide linear graphs if a simple reaction process obtained. When mass transport conditions became significant, the curves were expected to bend downward indicating that a sublinear region had been entered. The starting crystallographic orientation for the final stages of the current study was the <111> surface which is reputed to be the slowest growing of the low indices planes and, therefore, presumably the slowest etching. It was felt consequently that <111> kinetics would be most amenable to resolution. Furthermore, to duplicate etching behavior in a deposition process, the etching was studied in a hydrogen ambient atmosphere. The hydrogen concentration as a consequence could be considered constant which approximates conditions in conventional deposition processes.

Figure 2 shows the results of a preliminary study conducted on <211> surfaces in a 0.13 cm^2 cross-sectional area rectangular chamber in which l.g.s.v. up to 60,000 cm/min were obtained. It is seen that plateaus were achieved only at the lowest temperatures. It is also observed in Fig. 2 that in a single wafer reactor in which only a small portion of the reactor volume is occupied by the wafer, equilibrium l.g.s.v. regions are obtainable. Here also it was demonstrated by etch rate *vs.* time studies that edge and damage effects were not important since the graphs were linear. It was also found that axial gradients were a potentially serious problem since the wafer leading edges were thinned preferentially.[3] Also there was some indication that the primary vapor phase species was GeI_2 since the quenched etch products were primarily GeI_2, little evidence for the red tetraiodide being observed.

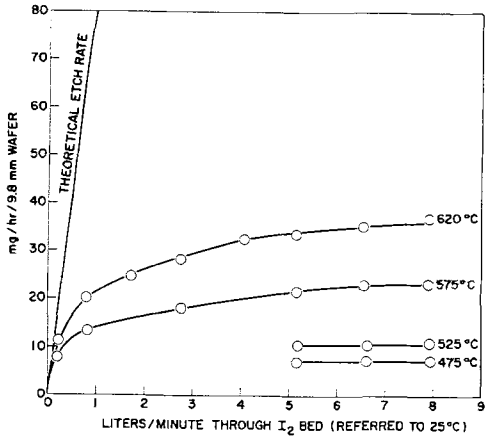

Fig. 2. Results of study on <211> surfaces. Reactor 4 13 x 1 mm; pHI = 3.8 Torr; <211> surfaces NaCl polished both sides; sample diameter *ca.* 9.8 mm.

Reagents.—HI was synthesized *in situ*, on demand, and with input flow rates up to 7.90 l/min at 25°C, using the modified generator design shown in Fig. 3 (15). The generator was constructed entirely of Pyrex and quartz and employed magnetically actuated, hand lapped ball joint members as valves. The leakage rate of the valves when closed was extremely small, since at 2-hr by-pass flow of 7.90 l/min over a Ge wafer at 910° failed to result in a measurable weight change or visually observable surface degradation. The platinum wool catalyst tower was maintained at 450°C and the generator temperature was controlled to ± 0.1°C in an oil bath. The vapor pressure of iodine in the temperature interval 43°-80°C was re-evaluated for purposes of the present study by a method to be reported on by the authors (16).

Matheson "ultra pure" H_2 was used as the carrier gas in all experiments without further purification.

Germanium wafers were prepared from Czochralski pulled single crystals doped with Ga to the 0.01-ohm-cm p-level. The crystals were sliced in the desired <111> or <211> orientation, then cut ultrasonically into circular wafers having a nominal diameter of 195 mils (*ca.* 5 mm) and a thickness of 30 mils. The slices were lapped planar with 3μ Al_2O_3 compound then polished on both sides by the NaOCl technique recently described (17). This provided a finished wafer size of 184-190 mils and a thickness of 19 mils. The dimensions, particularly the diameter, were checked before, and frequently after each run, each sample being used only once. After polishing, in which saw and lapping damage was apparently removed, the edges and one surface were coated with SiO_2 via the pyrolysis of tetraethoxy silane at 700°. The back side of the wafer and edges were protected with black wax, and the reaction side was treated with HF prior to use to remove any SiO_2 that may have deposited on it. Prior to conducting the etching experiment, the

[3] In the process of reducing the cross-sectional area of our reactors starting with the 7.77 cm^2 reactor described in ref. (15), we observed a sequence of events in which an axial gradient became pronounced as the wall surface to wafer surface distance was decreased with constant wafer size. In order to eliminate this effect it was necessary also to reduce wafer diameters. This effect is to be expected since surface etchant depletion at the leading edge of the wafer will be compensated for by diffusion from the walls if the wafer is large enough in a large diameter reactor. As the diameter of the reactor is reduced, however, this diffusion effect cannot overcome the depletion rate at the leading edge if the wafer axial dimensions are too large. Consequently, within limits imposed by experimental necessity, the axial extent of the wafer must be made of minimum dimension (a wire if feasible). With the reactor design to be described below, axial effects were not noticeable.

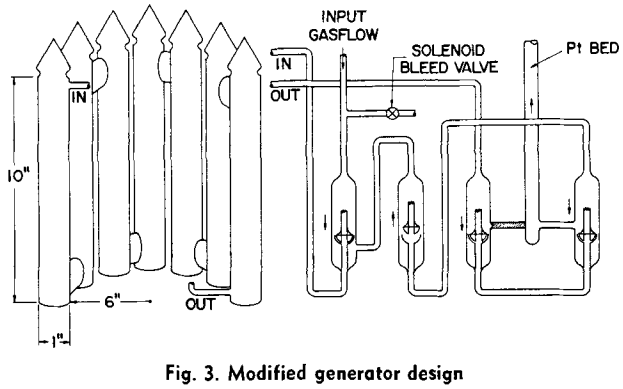

Fig. 3. Modified generator design

black wax was dissolved in trichlorethylene. The oxide coat minimized edge attack and completely eliminated attack of the under surface of the sample. The final weight of the samples was of the order of 40 mg. For each set of experimental conditions, etching times were varied so as to provide weight losses of *ca.* 10-15 mg. These run times varied between 20 min and 6 hr with the majority of experiments falling into the 1-2 hr range. In general, two to four determinations were made under each set of conditions. Etch time was varied to provide weight loss variation so that continued monitoring of possible edge and damage effects could be made. Generally, weight loss reproducibilities were within 2-3% of a mean with the worst case in one instance being 8%.

Apparatus.—Figures 4 to 6 show the design details of the high velocity reactor and reaction train used to acquire our final data. This reactor was capable of developing l.g.s.v. of approximately 800,000 cm/min at 760°C with input carrier gas flow rates at the 7.9 l/min level. The main portion of the reactor (the inner reactor) consists of precisely machined quartz parts having a rectangular cross section uniform over 2 in. to within a few square mils. The inner rectangle dimensions are 6.98 x 0.51 mm (275 x 20 mils) providing a cross-sectional area of 0.036 cm^2. Built into the center of the inner reactor is a 15-mil deep circular recess having a diameter of 105 mil. In the center of this recess, in which the wafer is positioned, is a 25-mil diameter hole connected to a vacuum line. This vacuum chuck is necessary to keep the wafer positioned at the high l.g.s.v. employed. The entire inner reactor and its associated vacuum chuck and effluent path are movable within a rubber sleeve attached to a female standard taper joint which in turn connects the inner reactor to the outer reactor into which etchant is first introduced.

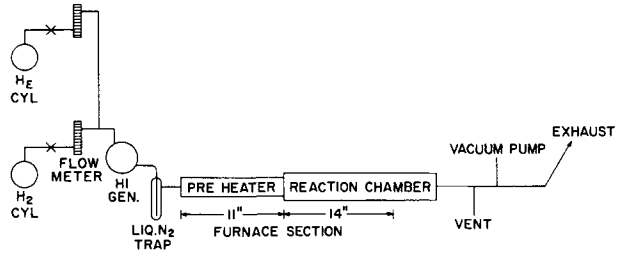

Fig. 4. Design details of high volecity reactor and reaction train

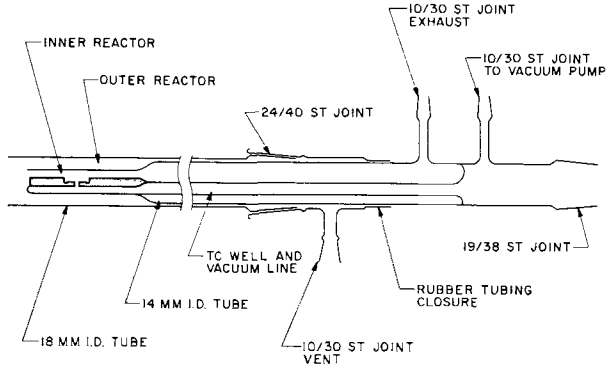

Fig. 5. Design details of high velocity reactor and reaction train

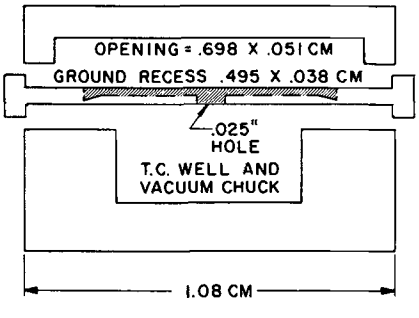

Fig. 6. Design details of high velocity reactor and reaction train

The combination of inner and outer reactor is resistance heated over a 14 in. length, and the sample temperature is monitored by a movable thermocouple located in the vacuum chuck portion of the apparatus which also functions as a thermocouple well. In order to assist the gas entering the outer reaction chamber in achieving the required temperature, the incoming gas was first preheated over an 11 in. length to the reaction temperature.

The experimental procedure followed was to load the wafer, then flush the system with the vent to the outer reactor open for 10 min at an input H_2 flow rate of 4 l/min. The system was then brought to temperature with the outer chamber vent closed and the experiment run. At the conclusion of the etching process, the system was flushed for 5 to 30 min at the experimental flow rate; the furnace was then turned off and allowed to cool while maintaining a flow rate of 4 l/min.

Some insignificant back streaming, as evidenced by the minute quantities of reaction product accumulating in the outer chamber, did occur. Over the course of several hundred runs, a thin Ge mirror formed in the colder regions of the outer reactor chamber.

Results

Figure 7 shows a plot of the log R_f *vs.* $1/T$ obtained on <111> surfaces with an input HI partial pressure of 3.8 Torr. The apparent temperature intervals for mass and surface-limiting reaction are delineated in the graph. The activation energy for the surface limited reaction was calculated to be 16.6 kcal, and the rate expression describing the data on this curve is given by Eq. [8].

$$\log R_f = \frac{-3.64}{T°K} + 5.99 \qquad [8]$$

where R_f is the etch rate in mg/cm^2 hr.

Figure 8 shows a number of such curves, each representative of a different input partial pressure of HI. Within experimental limits, the slopes of those curves defined by the greatest number of data points are identical, and those curves tested at only a few points clearly exhibit similar slopes. It is noteworthy that with increasing HI mole fraction the temperature

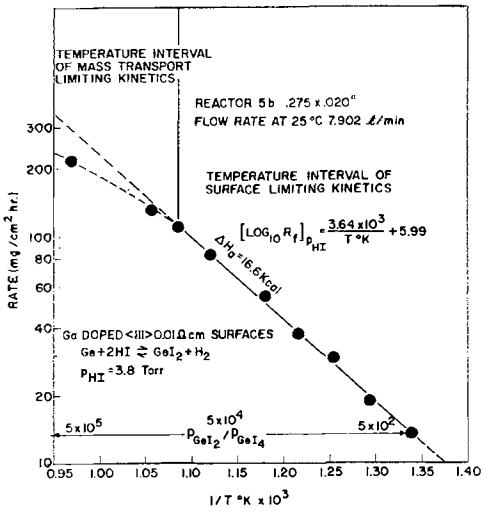

Fig. 7. Plot of log R_f *vs.* $1/T$ obtained on <111> surfaces

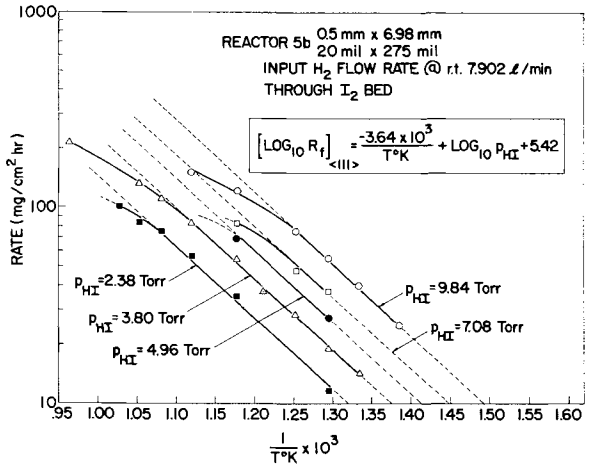

Fig. 8. Curves representing different input partial pressures of HI

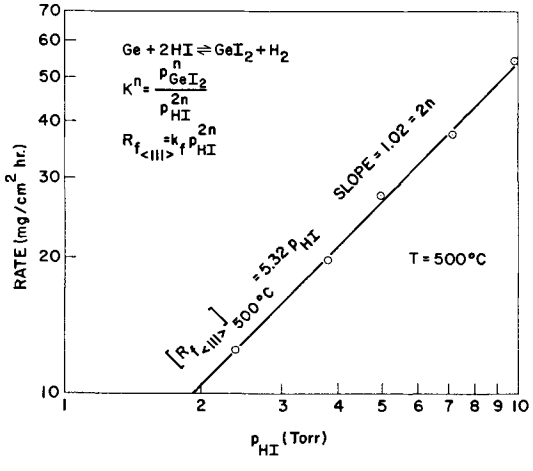

Fig. 9. Plot of log R_f vs. log pHI from 2.38 to 9.84 Torr at 500°C

at which mass transport conditions begin to prevail decreases.

Figure 9 is a plot of log R_f *vs.* log pHI, in the range 2.38-9.84 Torr at 500°C. These data provide an excellent straight line relationship having a slope very close to unity. The value of k_f was determined using Eq. [5], and its temperature dependency was determined from the Ahrennius relation, Eq. [9].

$$\log k_f = -3.64 \times 10^3/T°K + 5.42 \quad [9]$$

k_f has the dimensions mg/cm² hr Torr. From Eq. [6] and [9], the temperature dependency of the forward reaction rate was calculated and is given in Eq. [10].

$$\log R_f = -3.64 \times 10^3/T°K + \log p_{HI} + 5.42 \quad [10]$$

R_f has the dimensions mg/cm² hr, and p_{HI} is the input partial pressure of the halogen acid.

Discussion

Separation of mass transport and surface limiting phenomena.—From the results cited it appears that the qualitative description of open tube kinetic processes satisfactorily predicts the effect of l.g.s.v. in achieving a separation between the geometrically governed mass transport and the surface controlled reaction. In different systems and with different substrate orientations one would of course expect that the boundaries between the linear, sublinear, and plateau regions might vary greatly. No attempt to analyze the sublinear region analytically has been made because of the complicated nature of diffusion phenomena in nonstatic systems, static treatments such as applied by Lever and Mandel not being applicable (18-23). Furthermore, attempts on our part to computer analyze the sublinear region invoking a complete mixing assumption were completely unsuccessful as might have been anticipated.

Effect of etchant partial pressure increase at constant l.g.s.v. and temperature.—While it is the case, as can be seen from Eq. [3] and [4], that two or four molecules of HI must react at the surface in order that only one molecule of Ge containing product is generated, it is also evident that at constant temperature and l.g.s.v. the forward rate increases with an increase in etchant partial pressure as required by Eq. [6]. A consequence of this enhanced etch rate is the buildup of reaction product partial pressure at the surface and an increase in the rate of reverse reaction. Thus, what may be an adequate l.g.s.v. velocity to satisfy both conditions necessary for resolving the forward reaction kinetics at a low etchant partial pressure may become inadequate at higher values because of an increased reverse reaction rate.

Speculation on the reaction mechanism.—From the experimental results obtained we have seen that the forward rate is dependent on the HI partial pressure to the first power. In attempting to define a reasonable mechanism consistent with this, Eq. [11 a-e], a number of alternatives

$$\left.\begin{aligned} H_2(g) + Ge(s) &\rightleftarrows Ge \cdot H_2(a) \\ HI(g) + Ge(s) &\rightleftarrows Ge \cdot HI(a) \end{aligned}\right\} \text{Langmuir adsorptions} \quad [11a], [11b]$$

$$Ge \cdot HI(a) + HI(g) \rightleftarrows GeI_2(a) + H_2(a) \quad [11c]$$

$$GeI_2(a) \xrightarrow{\text{slow}} GeI_2(g) \quad [11d]$$

$$H_2(a) \rightleftarrows H_2(g) \quad [11e]$$

suggest themselves. The first involves a mechanism in which the adsorption of HI via Eq. [11b] represents the slow step. Such a rate-limiting step is not too probable, however, since initial surface coverage is likely to be rapid. In fact, with the large quantity of H_2 present it is likely that the HI absorption isotherm is so modified that even at very low HI pressures the surface rapidly achieves saturation with respect to HI. This leads to either Eq. [11c] or [11d] as representing the possible rate-limiting step. In attempting to assess the relative probability of each of these steps as rate limiting, some preliminary observations of <211> etching results are worthwhile mentioning. These data together with those of Fig. 7 are presented in Fig. 10 for comparison. It is to be noted that the etch rate on <211> surfaces is slower than on <111> surfaces. In order for the equilibrium constant describing the reaction to be constant, this observation indicates that the surface-controlled growth rate on <111> surfaces must be slower than on <211> surfaces. Also to be noted is the apparent similarity of

		600	5.8×10^3
		720	6.6×10^4
58.1	7.08	500	2.0×10^2
		600	2.6×10^3
		720	3.5×10^4
63.0	9.84	500	1.3×10^2
		600	1.8×10^3
		720	2.2×10^4

activation energies for both <111> and <211> surface rates, indicative of similar rate-controlling steps. Whether this is general for other low indices planes is yet to be explored, but it would tend to point more to the reaction product desorption step, Eq. [11d], rather than a bond breaking step, Eq. [11c], as rate limiting. The former is more likely to involve similar activation energies on different planes than is the latter.

Reverse reaction and autodoping phenomena.—In all of the experiments conducted, conditions were chosen in which the thermodynamic GeI_2/GeI_4 ratio was *ca.* 10^2 or greater, Table I (12). The data for the forward reaction, however, are independent of which product is predominant so long as the over-all reaction mechanism exhibits a distinct rate-limiting step and proceeds primarily by a sequential path. Assuming that the over-all reaction mechanism coincides with the thermodynamic relationship, Eq. [3], in which GeI_2 is formed, for which we have presented some indirect evidence, the equilibrium constant may be defined by Eq. [12]. In Eq. [12], the H_2 has been taken as a constant having a value of 755 Torr.

$$K = \frac{pGeI_2}{pHI^2} \qquad [12]$$

In order for the kinetics to be consistent in both the nonequilibrium and boundary equilibrium states, Eq. [12] may be rewritten as

$$K' = K^{1/2} = \frac{pGeI_2^{1/2}}{pHI} \qquad [13]$$

It will be noted that the pHI term is raised to the first power consistent with the reaction order determined. The temperature dependency of K' as determined from data in ref. (12) is given by

$$\log K' = -93.7/T°K - 0.631 \qquad [14]$$

The total rate expression for the reaction defined by Eq. [3] is given in Eq. [15].

$$R_t = k_f p_{HI} - k_r p_{GeI_2}^{1/2} \qquad [15]$$

A similar expression assuming GeI_4 as the end product is given by Eq. [16].

$$R_t' = k_f p_{HI} - k_r' p_{GeI_4}^{1/4} \qquad [16]$$

At equilibrium where the rates for the forward and reverse reactions are equal, it is a consequence that

$$k_f p_{HI} = k_r p_{GeI_2}^{1/2} \qquad [17]$$

or

$$k_f p_{HI} = k_r' p_{GeI_4}^{1/4} \qquad [18]$$

and

$$k_r = \frac{k_f}{K'} \text{ or } \frac{k_f}{K''} \qquad [19]$$

where K'' is the equilibrium constant for the reaction in which GeI_4 is the end product. The temperature dependency of $K''$is given by Eq. [20].

$$\log K'' = 1890/T°K - 3.771 \qquad [20]$$

Equations [14] and [20], together with the temperature dependency of k_f, Eq. [9], enable us to calculate the temperature dependency of the specific rate constant, k_r, for either of the assumed reverse reactions. These relationships are given in Eq. [21] and [22].

$$\log k_r = \frac{-3.55 \times 10^3}{T°K} + 6.05 \text{ where } GeI_2 \text{ is involved} \qquad [21]$$

$$\log k'_r = \frac{-5.53 \times 10^3}{T°K} + 9.19 \text{ where } GeI_4 \text{ is involved} \qquad [22]$$

Dimensionally k_f has the value mg/cm² hr Torr. k_r for the GeI_2 reaction has the dimensions mg/cm² hr Torr$^{1/2}$, and k_r' for the GeI_4 reaction has the dimensions mg/cm² hr Torr$^{1/4}$. The activation energies calculated for the reactions involving GeI_2 or GeI_4 are 16.2 and 25.3 kcal, respectively.

The above has considerable implications concerning the extent to which autodoping is likely to occur in a deposition reaction involving the reduction of GeI_2 or GeI_4. Since the etching kinetics of the HCl-Ge reaction are even faster than those we have determined for the Ge-HI system, the problem of autodoping is potentially more severe in the tetrachloride process.

In its simplest sense, as mentioned earlier, autodoping is a term used to describe an effect in a net deposition reaction in which a reaction product (here a halogen acid) reacts with the substrate and substrate dopants bringing both the semiconductor and the impurities into the vapor phase. These impurities then, either by a deposition or segregation process, become incorporated in the epitaxially grown layer. A drastic example of such an effect is observed in the growth of Ge on GaAs via the reduction of $GeCl_4$. Even though a net growth is observed, the GaAs is noticeably etched, and the deposited layer of Ge is doped almost to degenerate levels for some distance from the physical junction. Since the grown layer shields the substrate, once the former is thick enough, the autodoping decreases with increasing grown layer thickness.[4] The net effect is the formation of a nonabrupt impurity gradient around the grown junction. Alternately, workers in the field have attributed the observed impurity gradient characteristics to outdiffusion from the substrate or to the gas phase phenomena mentioned. The fact that our studies indicate such fast kinetics for the etching reaction is strong evidence to support the gas phase mechanism as the major factor in autodoping. If we consider further that the deposition reaction is dependent on either the ½ or ¼ power of the Ge halide while the etching is proportional to the first power of the halogen acid concentration, the gas phase mechanism becomes even more compelling. As we have pointed out earlier, the l.g.s.v. normally employed coincide with those in which the rates approach equilibrium values. This, of course, further favors a gas phase autodoping mechanism in view of our results. If these arguments are indeed representative of the state of affairs in open tube halide deposition reactions, it would appear that a means by which autodoping can be minimized is to increase l.g.s.v. to values many orders of magnitude greater than are normally employed at the start of the deposition to obtain initial surface coverage. When this has been achieved and the surface is protected, more normal conditions may then be employed.

As previously discussed, the temperature interval in which surface-limiting kinetics could be achieved in the reactor employed appeared to decrease with increased HI partial pressure. Since the faster l.g.s.v.

[4] In the initial growth stages, nucleation processes are occurring so that even though a net deposition occurs, most of the original surface is exposed to the attack of reaction products.

apparently needed to minimize autodoping would probably require proportionately decreased concentrations of reactants whose concentration effect behavior hopefully is similar in the deposition process to that observed in the etching process, both requirements for approaching surface-limiting kinetics and minimizing autodoping in a deposition would appear to be consistent.

Acknowledgment

The authors wish to acknowledge gratefully the assistance of R. L. Rohr in designing the reactor, and M. Sampogna in acquiring the data. They wish also to thank H. R. Leonhardt and T. O. Sedgwick for many stimulating discussions and critical evaluation of the manuscript, and R. F. Lever for evaluating it. The authors wish to acknowledge the assistance of S. A. Alyanakyan in providing needed thermodynamic information.

Manuscript received July 9, 1965; revised manuscript received Oct. 25, 1965. The work was supported in part by AFCRL Contract No. AF 19(628)-2468.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Kinetic Effects in Temperature Gradient Zone Melting

R. G. Seidensticker

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Experiments on the motion of liquid zones in the germanium-gold TGZM system indicate that kinetics characteristic of screw dislocations may play an important role. In many instances, dissolution rather than deposition appeared to be the rate-limiting mechanism. Finally, it was found that the motion of such zones was intrinsically unstable under some conditions.

Temperature gradient zone melting (TGZM), sometimes called the traveling solvent method of crystal growth (TSM), has been discussed in a number of papers (1-9). Migration of the zone occurs because a temperature gradient imposed on a solid-liquid-solid sandwich creates a concentration gradient, linear for most cases of interest, which provides a driving force for the diffusion of solvent across the zone. Since the solvent concentration may be equated to a temperature, T_{liquidus}, by the phase diagram liquidus curve, the concentration gradient may be equated to an "equilibrium temperature gradient," G^*. The migration velocity is proportional to the flux of solvent so that $v = \beta G^*$, where β includes the diffusivity of the liquid, and parameters relating to the phase diagram. A model frequently used for analyzing zone motion assumes that the liquid alloy is in equilibrium with the solid at both the high and low temperature interfaces so that $G^* = G$, the actual temperature gradient. On the other hand, Tiller (5) assumed that both interfaces depart from equilibrium due to kinetic effects and the resulting equations show an additional dependency on zone thickness and kinetic constant.

This effect of kinetics on zone migration can be easily seen from Fig. 1. Let δT_m and δT_s be the departures of the dissolving and solidifying interfaces from equilibrium at a given velocity, *i.e.*, $\delta T = T_{\text{liquidus}} - T_{\text{actual}}$. It is easily seen that

$$G^* = G - \frac{\delta T_s - \delta T_m}{l} \qquad [1]$$

where $\delta T_m \leq 0 \leq \delta T_s$, and l is the zone thickness. Since the migration velocity is proportional to G^*

$$v = \beta G^* = \beta G - \frac{\beta}{l}(\delta T_s - \delta T_m) \qquad [2]$$

If kinetics are neglected (the δT's $= 0$) or if l is very large, then Eq. [2] reduces to the usual form $v = G\beta$; when kinetic laws are specified, it reduces at once to Tiller's equations.

Zone stability has been discussed qualitatively for isotropic kinetics by Pfann (1), and by Tiller (5) who assert that the zone should be stable when moving in the direction of the temperature gradient. For the case of anisotropic interfacial energy [equivalent to aniso-

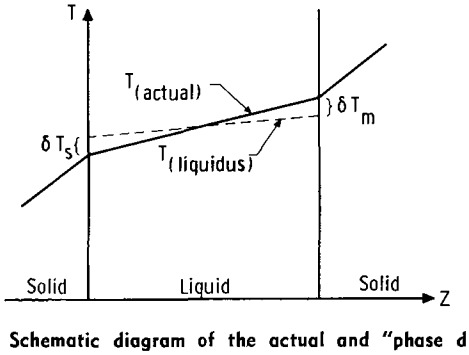

Fig. 1. Schematic diagram of the actual and "phase diagram" temperatures in a migrating zone with kinetics limitations.

tropic kinetics (5)] they conclude that stability depends on the orientation of both the zone and the temperature gradient.

As to the results of experiments, Wernick (4) reported that both gold and aluminum wire zones in germanium and silicon exhibited a dependence of velocity on zone size and a stability dependency on the orientation of both the zone and the gradient. Mlavsky and Weinstein (7), however, reported no indication of an orientation dependent velocity in the growth of GaAs from a Ga rich zone; indeed, they and their colleagues have asserted in several papers (7, 9) that if adequate wetting is obtained between the solid and liquid, then the zone moves uniformly through the sample. For the case of zone motion in GaAs, Mlavsky and Weinstein did report that the migration velocity depended on zone thickness, however, their analysis as well as Tiller's (6) indicates that this was due to a change in liquid composition rather than to kinetic effects. Wernick's interpretation of his data was based on undersaturation in the liquid combined with anisotropic dissolution at the hotter interface. Tiller, on the other hand, concluded that Wernick's data indicated that screw dislocation kinetics limited the zone velocity, but for lack of distinguishing criteria assigned equal weight to kinetics at both interfaces, *i.e.*, assumed $\delta T_m = \delta T_s$.

In this paper, various effects of kinetically limited mechanisms and of interfacial energy will be discussed. In many instances, dissolution was found to be the rate limiting process so that kinetics at the higher temperature interface do indeed limit the velocity. A quantitative evaluation of zone stability including kinetic effects is made, based on an extension of the stability analysis of Mullins and Sekerka (10). This treatment, derived in a later paper (11), shows that the migrating zone may be unstable even in the strictly isotropic case.

Experimental Apparatus and Procedures

Zone migration experiments were carried out using both flat or "slab" zone and wire zones. The germanium-gold system was chosen because the low eutectic temperature (12) permitted experiments to be done in a convenient temperature range, and the negligible solid solubility of gold in germanium (13) assured that the gold content of the zone was constant during a run.

The experimental apparatus is shown in Fig. 2. All the components are enclosed in a Vycor "T" tube to permit a choice of ambient. The furnaces were brought

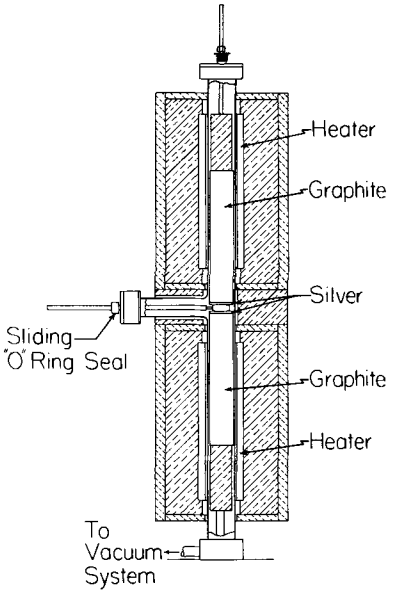

Fig. 2. Schematic diagram of the experimental apparatus

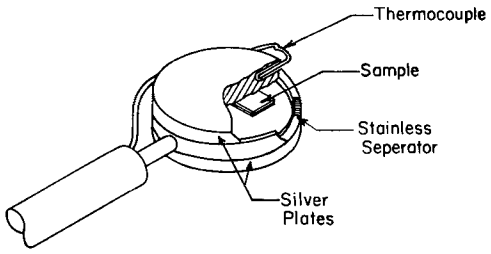

Fig. 3. Schematic diagram of the sample holder

up to temperature and outgassed at a pressure of 10^{-5} Torr. When the sample holder was inserted in the hot section to start a run, about 5 Torr of He was admitted to aid thermal transport. Heavy graphite pistons extending into the hot zones of the furnaces maintained the sample holder temperatures. A bellows at the top of the apparatus allowed the upper piston to be raised so that the sample holder could be easily moved, and yet provided a good pressure contact. Caps of 3/16 in. silver on the ends of the pistons reduced radial gradients at the sample holder.

The sample holder itself is shown in Fig. 3. Silver top and bottom plates separated by a stainless steel ring serve to further minimize radial temperature gradients. Temperature measurements at the plates were made using chromel-alumel thermocouples, protected by thin walled silica tubes, and inserted 1 cm into the plates. An additional 5 cm of the thermocouples were in the hot zone of the furnace to minimize immersion corrections. Since the difference in temperature between the two plates was much more important than the absolute temperature, some care was taken to insure that the couples had similar response. Both junctions were made from adjacent regions of the thermocouple wire; calibration of one pair of couples indicated an agreement of ¼°C or better, *i.e.*, about 1% of the temperature differences usually measured.

The temperature gradients in the sample were usually computed from the measured temperature difference across the sample holder. This technique required good thermal contact between the sample and the holder, and several methods were tried. The use of Aquadag as a cement was reasonably successful, however the use of a pressure contact with the sample separated from the holder plates by thin (75μ) graphite disks was more reproducible. When the disks were used, the sample had to be prepared so that there was a solid region around the liquid zone for support; the liquid was essentially enclosed. Calibration runs using samples with differential thermocouples embedded in them showed that the ratio of sample gradient to the temperature difference across the holder was constant to about 10%, especially when the pressure contact technique was used.

The samples themselves were prepared by first alloying gold plating or gold foil onto the individual germanium slices. If a plated deposit was used, additional gold foil was added to make up the final zone thickness. The alloying was done either in a hydrogen atmosphere or in forepump vacuum. Both techniques gave satisfactory results, however vacuum was preferred since gold-germanium eutectic has a small but important solubility for hydrogen. For some of the runs, an alloy of Au + ½ a/o (atomic per cent) Sb was used to enhance both the wetting of the germanium and the ease with which the redeposited material could be delineated. There was no significant improvement in wetting, so that in spite of the improved delineation, pure gold was used for most of the runs to reduce the number of parameters in the system. In the wire zone runs, the Ge slices were grooved lightly on one surface and pure gold wires fused into the grooves.

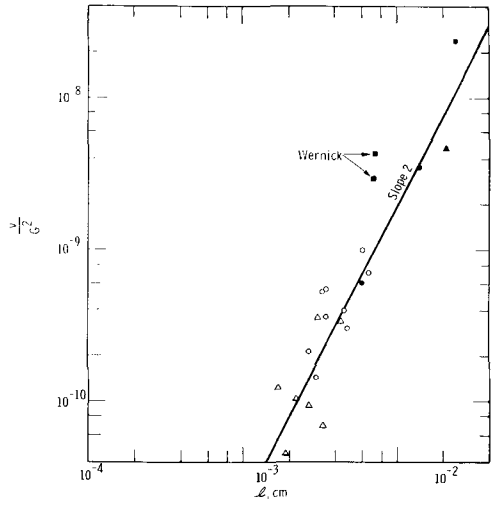

Fig. 4. Experimental data on the zone migration velocities. Zone velocity, v; temperature gradient in the liquid, G; zone thickness, l. ○ ●, ~ 525°C; △ ▲, ~ 625°C; solid points, wire zone.

The behavior of the zone was determined on the basis of one or more sections through the sample. Standard polishing and etching techniques were used to determine the zone travel, and hence the velocity.

Most of the flat zone runs were made using {111} wafers for both the source and the seed crystals. The axis of the wire zones was usually <110> and the temperature gradient in either <001> or <112>. The calculated gradients in the liquid zone ranged from 15° to 60°C/cm, and average zone temperatures of about 525° and 625°C were used.

Experimental Results

Although the flat zones frequently moved as segments rather than as a single slab, the segments were wide and thin enough to be considered as individual flat zones. Only those runs where the segment velocity was uniform over the sample were used for the evaluation of the kinetics. The experimental data on the migration velocity is shown in Fig. 4, where the function v/G^2 is plotted *vs.* the zone thickness. Data from the wire zone runs which showed uniform motion are also plotted in the same figure.

In some of the runs, the segments were the result of uneven wetting; in many cases, however, bubbles apparently formed in the liquid and forced some of it out of the zone. Fusion analysis in a mass spectrometer showed that samples that had been fused in hydrogen released sufficient gases to give such bubbling, even in the presence of the 5 Torr He ambient. Simple calculations indicated that when bubbling had forced droplets of liquid out of the zone, the free energy of the system was lowered and the configuration was stable. The use of samples fused in vacuum markedly reduced the size and number of voids.

The morphology of the zone was used to determine qualitatively at which interface the kinetics effects were most pronounced. If one interface but not the other showed faceting, then it is reasonable to assume that kinetic limitations were more important at that interface. In the case of flat zones bounded by {111} planes, the dissolving interface showed indications of faceting while the growing interface did not. The effect was more pronounced, however, with the wire zones. Figure 5 shows transverse and longitudinal sections of a <110> zone which has moved in a <001> gradient. The zone was dissolving in a faceted trough bounded by {111} planes, while the growing interface was highly curved. These observations confirm Wernick's conclusion that in wire zones, particularly, the rate limiting step was dissolution rather than solidification.

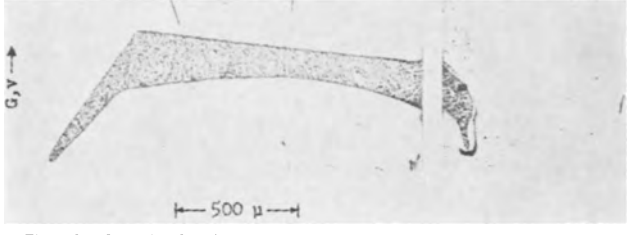

Fig. 5. Longitudinal and transverse section of a wire zone. Dissolving interface faceted and solidifying interface curved.

These observations were generally applicable to zone motion with moderate temperature gradients in the liquid, *e.g.*, $G < 60$°C/cm. Two runs were made using {111} flat zones with gradients above 100°C/cm. These runs, which apparently had good wetting and few if any voids, showed an instability characterized by the break up of the zone into small droplets. The possible cause of such instability will be considered later.

Discussion

In order to analyze the zone motion data, Eq. [2] must be modified by assuming a specific kinetic law. For example, if layer generation by a screw dislocation is the assumed mechanism, then $\delta T_s - \delta T_m = \Gamma v^{1/2}$, where $\Gamma = (1/\mu_s)^{1/2} + (1/\mu_m)^{1/2}$ and the μ's are the kinetic constants at the solidifying and melting interfaces. This assumption allows Eq. [2] to be solved for v giving

$$v = \frac{\beta^2\Gamma^2}{2l^2}\left\{1 + \frac{2l^2G}{\beta\Gamma^2} - \left[1 + \frac{4l^2G}{\beta\Gamma^2}\right]^{1/2}\right\} \qquad [3]$$

When kinetic effects are pronounced, $\beta\Gamma^2 >> 4Gl^2$ and Eq. [3] may be approximated by

$$v \approx \frac{G^2l^2}{\Gamma^2} \qquad [4]$$

For the case of linear kinetics ($\delta T = v/\mu$) a similar approximation leads to

$$v \simeq \frac{lG}{\Gamma'} \qquad [5]$$

and, for a two-dimensional nucleation process

$$v = \beta G - \frac{\beta A}{l}\left(\frac{1}{\ln \mu/v}\right) \qquad [6]$$

Hence, a plot of the experimental data as log (v/G^2) *vs.* log l should give a straight line of slope 2 if the screw dislocation law applies; log (v/G) *vs.* log l should yield a straight line of unity slope if linear kinetics obtain; and finally a plot of v/G *vs.* $1/lG$ should be reasonably straight if exponential kinetics fit the data. Only the plot appropriate to the screw dislocation kinetics gave a reasonable representation of the data (Fig. 4). The value of Γ computed from this plot is about 220 deg $(\text{sec/cm})^{1/2}$ giving a kinetic constant of $\mu = 2 \times 10^{-5}$ cm/sec-deg^2 if only the solution interface were kinetically limited, and twice this value if both interfaces were equally involved. Although this value is low for a kinetic constant, it is not implausible. (5).

With such sluggish kinetics, the effect on zone motion is very pronounced, and the migration velocity is much slower than is predicted by the simple theory which assumes that diffusion is the limiting mechanism. Thus the use of TGZM as a technique for the measurement of diffusivities is not straightforward, and diffusivities obtained in this manner can only be considered as lower limits.

One final point should be made with regard to the data in Fig. 4, namely that there does not appear to be any pronounced dependence on the average zone temperature; the gradient and zone thickness are the controlling parameters. Two of the points are taken

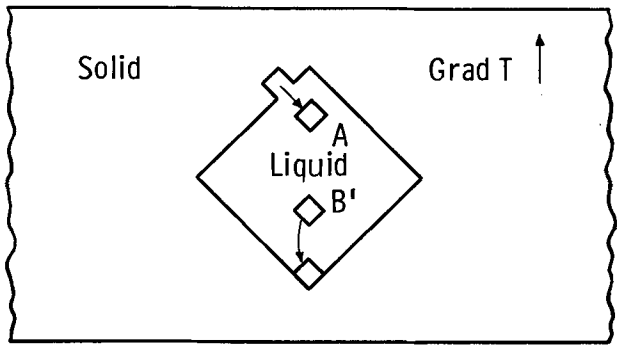

Fig. 6. Schematic diagram of a completely faceted <110> wire zone in a <001> temperature gradient.

from Wernick's paper (3) and are in reasonable agreement with the present results.

Derivation of the temperature gradient in the liquid, G, used in the analysis of the data, required several assumptions. First, the use of the relations between the gradients in the liquid and solid for static plane and wire zones is justified since the latent heat contribution is two to three orders less than the heat flux due to the temperature gradient and may be neglected. Second, when the flat zone consisted of isolated segments, it was assumed that the total heat flux passed through the liquid (conductivity through the voids being very small) and hence the liquid gradient was increased in inverse proportion to the liquid area. Differential thermocouple measurements confirmed that this assumption held to about 15%.

Some knowledge of the thermal conductivities is necessary, however the calculations are most sensitive to the value for solid germanium which fortunately is well known (14). The value used for the thermal conductivity of the liquid alloy was 0.5 watt/cm-deg and was based on a Wiedemann-Franz calculation. The electrical conductivity of the liquid alloy was taken to be proportional to the conductivities of pure liquid gold and germanium adjusted for temperature and weighted by the liquid composition.

The faceting at the solution interfaces of the zone may be interpreted using a simple layer source model. This model in its simplest form states that the addition or removal of an atom from a close packed plane (the {111} planes in germanium) is energetically less favorable and hence slower than at a step or corner. The application of such a model to zone motion may be most clearly illustrated by considering the fully faceted form of a <110> wire zone moving in a <001> temperature gradient, as shown in section in Fig. 6. Dissolution at the hotter interface would require an event of type "A," the removal of an atom or group of atoms from the close packed plane. Once this event occurred, subsequent dissolution could proceed by the removal of additional atoms from the edge so formed. Eventually, however, another "A" event would be required before additional dissolution could take place. At the colder interface, grooves or layer edges will always exist, and an event analogous to "A" will never be required. Atoms can always be added by the relatively easier events "B." Thus, a self-perpetuating step generated by a screw dislocation provides little advantage at the solidifying interface where steps are already plentiful but would greatly enhance the dissolution rate at the hotter interface.

Break up of several runs at high gradient, despite good wetting of the interface and freedom from voids, prompted an analysis of zone stability on a quantitative basis. The interfacial stability treatment of Mullins and Sekerka (10) was extended to include isotropic kinetics and specifically applied to the problem of TGZM. Details of the analysis will appear in a subsequent paper (11), however the central result is a stability function, S, which must be evaluated for both interfaces of the zone. Only when $S < 0$ is the interface stable, and both interfaces must be stable for stable migration of the zone as a whole. For systems with low solid solubility of the solute, S may be approximated by

$$S = -\frac{4\pi^2\gamma T_m}{\lambda^2 L} - \frac{Lv}{K_s + K_l} - \left(\frac{K_l - K_s}{K_l + K_s}\right)G + \frac{\delta T_2 - \delta T_1}{l} \quad [7]$$

where γ is the interfacial free energy, T_m the melting temperature of the pure solvent, L the latent heat per unit volume, λ the wavelength of the instability, K_s and K_l the thermal conductivities of the solid and liquid, v the average zone velocity, G the thermal gradient in the liquid, and l the zone thickness. δT_1 is the kinetic departure at the interface under consideration and δT_2 is the kinetic departure at the other interface. When the growing interface is being analyzed, $\delta T_2 < 0 < \delta T_1$ but when the dissolving interface is under consideration, $\delta T_1 < 0 < \delta T_2$. It should also be emphasized that because of the coordinate system used in the derivation (positive direction into the liquid), G and v are negative at a dissolving interface. Thus it can be seen that, for $K_l > K_s$, which is usually appropriate for semiconductors, the growing interface is always stable, but stability of the dissolving interface depends on λ, G and v. If the zone is stable for values of λ much larger than the total width of the interface, then the zone should be able to migrate considerable distances without appreciable distortion. It can be seen, however, that when the gradient is increased, the value of λ necessary for stability decreases. For most metallic systems, $K_l < K_s$ so that instability terms are present at both interfaces. Thus, the variation in thermal conductivities and interfacial energies for various systems may well account for the apparent conflict in experimental data reported for zone stability.

Summary

The experimental data for the motion of a gold-germanium liquid zone through solid germanium in a temperature gradient suggests that the motion is limited by kinetics characteristic of screw dislocations. The appearance of faceting on the dissolving interface but not on the growing interface indicates that for some experimental situations, it is dissolution and not deposition which limits the zone motion, especially in the case of wire zones.

Instability of the zone due to poor wetting and to bubbles in the liquid was found. In addition, an instability was observed in apparently flawless samples at high gradient. Analysis of interface stability following the technique of Mullins and Sekerka indicated that zone motion has regimes of intrinsic instability, particularly with high gradients and sluggish kinetics.

In Situ Etching of Silicon Substrates Prior to Epitaxial Growth

T. L. Chu, G. A. Gruber, and R. Stickler

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The cleanness of the substrate surface is important for the epitaxial growth of silicon. The *in situ* etching of substrates with commercial hydrogen chloride has been used successfully, and the resulting silicon films have been found to be generally of good crystal perfection by chemical etching and optical microscope techniques. However, transmission electron microscopy has revealed the presence of high concentrations of precipitates in the substrate-film interface region. Thermochemical considerations indicated that these precipitates were most likely silicon nitride. Most of these precipitates can be removed by using water vapor as an etchant.

The structural perfection of an epitaxial silicon film is an important factor determining its suitability for device applications. The most commonly observed imperfections in epitaxial silicon are dislocations, stacking faults, precipitates, hillocks, and inclusions of random orientations. With the exception of the dislocations propagated from the substrate, the majority of these imperfections were found to originate at the substrate-deposit interface and were attributed mainly to contaminants in the reactant mixture and foreign impurities on the substrate surface (1). The importance of cleanness of the substrate surface has been well-recognized, and *in situ* etching techniques have been developed. In these techniques, the substrates are chemically etched in the growth apparatus immediately prior to the deposition process, employing anhydrous hydrogen chloride (2, 3) or water vapor (4). Using the thermal reduction of silicon tetrachloride with hydrogen, epitaxial silicon films grown on substrate surfaces treated in this manner were found to have considerably improved structural perfection by chemical etching and optical microscope techniques. For example, the use of hydrogen chloride etchant has produced silicon films with stacking fault concentrations less than 200/cm^2 and dislocation densities no greater than those of the substrates (2). These results are indeed remarkable in view of the fact that the purity of commercial hydrogen chloride is not comparable to that of other reagents customarily used in epitaxial processes. On the other hand, imperfections of submicron dimensions cannot be readily revealed by optical microscope examinations, and submicroscopic imperfections in epitaxial silicon films, particularly in the substrate-film interface region, have not been extensively studied.

We have prepared a number of epitaxial silicon specimens using various *in situ* treatments of the substrates, including the thermal etching and the use of commercial hydrogen chloride and water vapor as etchants prior to the deposition process. The substrate-deposit interface regions in these specimens were examined by the transmission electron microscopy technique. The effects of various etchants on the structural perfection of the epitaxial silicon films are summarized in this communication.

Experimental

The epitaxial silicon specimens were prepared in the conventional manner, using the thermal reduction of silicon tetrachloride with hydrogen on heated substrate surfaces in a flow system (5). Electronic grade silicon tetrachloride, purchased from the Stauffer Chemical Company, was purified by fractional distillation through a quartz column and was found to yield n-type silicon with an electrical resistivity of 50 ohm-cm or higher. Commercial grade hydrogen was purified by diffusion through a palladium-silver alloy. The silicon substrates were of {111} orientation, n-type, 50 ohm-cm resistivity, and had dislocation densities less than 10^3 cm^{-2}. They were mechanically lapped with American Optical Company No. 305 abrasive, and chemically etched with CP_4 to remove at least 50μ of silicon from the surface. The substrates were supported on a susceptor in a quartz reaction tube, and the susceptor was heated externally by an rf generator. Hydrogen at a flow rate of 6 to 20 l/min was used for the thermal etching or as a diluent for the etchant, hydrogen chloride (HCl/H_2 = 0.01-0.05) or water vapor ($H_2O/H_2 = 2 \times 10^{-4}$ to 10^{-3}). The *in situ* etching was carried out at a substrate temperature of approximately 1270°C for 10-30 min. Subsequently, 0.3 to 0.5μ of silicon films were deposited, without intentional doping, on the substrates at 1200°C.

To provide adequate electron transmission for the electron microscope studies, the specimens must be reduced to 1μ or less in thickness. This was accomplished by removing the major part of the substrate from a portion of the specimen by jet chemical etching (6). The geometry of the resulting specimen is shown in Fig. 1. The specimen was mounted on a specimen stage and the substrate-film interface of the thin portions were examined in transmission in an electron microscope at 100 kv.

Results and Discussion

The thermal etching of the silicon substrate is related to the presence of an oxide film on the substrate

surface. The chemical etching of silicon with nitric acid and hydrofluoric acid mixtures usually leaves an oxide film of the order of 100Å depending on the resistivity of silicon (7). At high temperatures, this oxide film reacts with the silicon underneath to form volatile silicon monoxide according to the equation

$$Si(s) + SiO_2(s) = 2SiO(g) \quad [1]$$

Silicon monoxide has appreciable vapor pressures at temperatures above 1100°C. For example, the vapor pressure of silicon monoxide in equilibrium with silicon and silicon dioxide at 1300°C is approximately 2 Torr (8). In a flow system, this reaction approaches completion and an equivalent amount of silicon is removed from the substrate. The removal of silicon by this process is presumably more rapid than the evaporation of silicon because of its low vapor pressures in the temperature range under consideration. For example, the vapor pressure of silicon at 1510°K is 10^{-5} Torr (9), and the evaporation rate of silicon calculated on the basis of kinetic theory is approximately 10^{-2} μ/min. However, the presence of minute quantities of oxygen or water in hydrogen would increase the rate of removal of silicon as will be discussed later. When the substrates were subjected to the thermal etching prior to the deposition process, the substrate-film interface regions were found by transmission electron microscopy to be generally clean, indicating that the growth apparatus and the reactants did not introduce any appreciable amount of impurities.

Commercial hydrogen chloride used for the *in situ* etching of silicon substrates was analyzed by mass spectrography for impurities in the mass range 2 to 120. The principal impurities were found to be oxygen, nitrogen, and sulfur dioxide (Table I). When the hydrogen chloride containing these impurities was used as an etchant, the epitaxial silicon films were found to be generally of good crystal perfection by chemical etching and optical microscope techniques. However, the substrate-film interface regions were invariably found to have high concentrations of precipitates, a few hundred angstroms in dimensions. A typical example is shown in Fig. 2. These precipitates were not of sufficient concentration to be identified by electron diffraction or other methods. However, one could deduce the nature of these precipitates from the impurity contents of hydrogen chloride and the chemical behavior of silicon toward these impurities. It is assumed in the following discussion that the hydrogen-hydrogen chloride mixture used as the etchant contains oxygen, sulfur dioxide, and nitrogen at partial pressures of 2 x 10^{-5}, 3 x 10^{-5}, and 7 x 10^{-5} atm, respectively.

The reaction between silicon and oxygen at high temperatures yields silicon dioxide or silicon monoxide, depending on experimental conditions. Silicon monoxide is volatile at high temperatures. The free energy of formation of silicon dioxide at 1500°K (10) is

$$Si(s) + O_2(g) = SiO_2(s) \quad \Delta F^\circ_{1500^\circ K} = -146 \text{ kcal} \quad [2]$$

and the equilibrium partial pressure of oxygen over solid silicon and silicon dioxide is approximately 10^{-21} atm. Assuming that chemical equilibria are approached

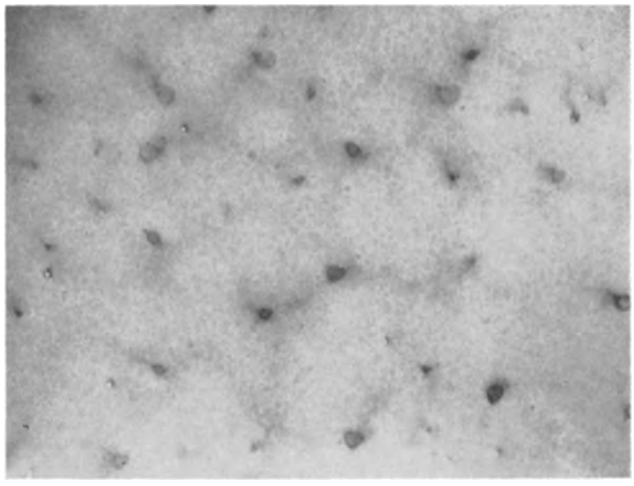

Fig. 2. Typical example showing a high concentration of precipitates in the substrate-film interface region of an epitaxial silicon specimen. The substrate was etched with commercial hydrogen chloride prior to the deposition process. Magnification approximately 36,000X.

at temperatures used in the etching process, the reaction of oxygen in the etchant with the silicon substrate is thus essentially complete. The silicon dioxide formed further reacts with the substrate according to Eq. [1] to yield silicon monoxide which has an equilibrium vapor pressure of approximately 10^{-3} atm at 1500°K. Since the partial pressure of oxygen in the etchant was considerably lower than this vapor pressure, it is unlikely that silicon dioxide would be deposited on the substrate surface during the *in situ* etching process.

The reaction between silicon and sulfur dioxide at high temperatures yields a mixture of oxides and sulfides. Silicon disulfide is similar to silicon dioxide in that the disulfide reacts with silicon at 850°C or above to form the volatile monosulfide (11). Thus, the monoxide and the monosulfide are the predominate products at low partial pressures of sulfur dioxide. The chemical reactions and the associated free energy changes at 1500°K (10) are

$$Si(s) + SiS_2(l) = 2SiS(g) \quad \Delta F^\circ_{1500^\circ K} = -45 \text{ kcal} \quad [3]$$

$$3Si(s) + SO_2(g) = SiS(g) + 2SiO(g)$$

$$\Delta F^\circ_{1500^\circ K} = -78 \text{ kcal} \quad [4]$$

The presence of minute quantities of sulfur dioxide in the etchant is not likely to cause the formation of precipitates on the substrate surface.

The reaction between silicon and nitrogen at high temperatures yields silicon nitride. The standard free energy of formation of alpha-silicon nitride at 1500°K (12) is

$$3Si(s) + 2N_2(g) = \alpha\text{-}Si_3N_4(s)$$

$$\Delta F^\circ_{1500^\circ K} = -60 \pm 6 \text{ kcal} \quad [5]$$

The equilibrium pressure of nitrogen over solid silicon and silicon nitride is of the order of 4.5 x 10^{-5} atm. Since the partial pressure of nitrogen in the etchant was higher than this equilibrium pressure, it is reasonable to assume that the precipitates shown in Fig. 2 were alpha-silicon nitride particles formed as a result of the nitridation of the silicon substrate by the nitrogen in the etchant. These particles could be epitaxial with respect to the substrate (12) and therefore had no appreciable influence on the epitaxial growth process. On the other hand, the presence of silicon nitride particles in the vicinity of p-n junctions is highly undesirable since dielectric precipitates may enhance the local electric resulting in reverse breakdown at low voltages (13).

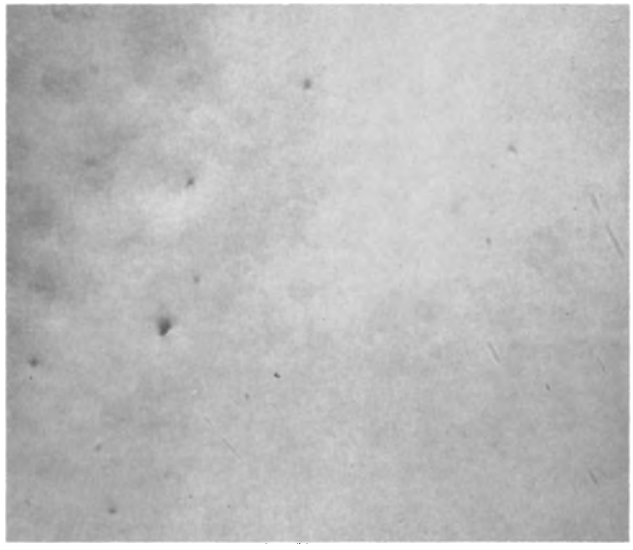

Fig. 3. Substrate-film interface region of an epitaxial silicon specimen having only a few small particles. The substrate was etched with water vapor subsequent to etching with commercial hydrogen chloride. Magnification approximately 36,000X.

Epitaxial growth experiments were also carried out in which the *in situ* etching of silicon substrates by a hydrogen-hydrogen chloride mixture was followed by using a hydrogen-water vapor mixture. The use of water etching was found to eliminate many of the precipitates in the interface region (Fig. 3) due presumably to the hydrolysis of silicon nitride.

$$Si_3N_4(s) + 3H_2O(g) = 3SiO(g) + 2N_2(g) + 3H_2(g)$$
$$\Delta F^\circ_{1500^\circ K} = 9.5 \text{ kcal} \quad [6]$$

The removal of silicon nitride is feasible because of the formation of volatile silicon monoxide. This result also verifies the previous assumption that the small concentration of oxygen in the etchant would not cause the formation of silicon dioxide on the substrate surface.

Conclusions

Epitaxial silicon films prepared by using commercial hydrogen chloride as an *in situ* etchant have been found to be generally of good crystal perfection by chemical etching and optical microscope techniques. However, transmission electron microscopy has revealed the presence of high concentration of precipitates, presumably silicon nitride, in the substrate-film interface region. Most of these precipitates can be removed by using water vapor as an etchant. These results illustrate the significance of using high purity reagents for the *in situ* etching of substrates in the epitaxial growth process.

A Raman Spectroscopic Study of the Molten Salt System $ZnCl_2$-KCl

J. R. Moyer, J. C. Evans, and G. Y-S. Lo

The Dow Chemical Company, Midland, Michigan

ABSTRACT

Using both polarized and normal incident radiation, spectra have been recorded over the temperature range 280°-500° for solutions with molar ratios of KCl:$ZnCl_2$ between 0 and 2. The results are interpreted in terms of polymeric zinc chloride and a single complex ion, $ZnCl_4^=$.

The structure of zinc chloride has been studied often and by many different techniques. Brehler (1) has determined that the solid is a three-dimensional network of $ZnCl_4$ tetrahedra with chlorine atoms disposed symmetrically between the Zn atoms. Considerable indirect evidence from viscosity measurements (2), conductivity (3), and self-diffusion (4), indicate that this polymeric structure is maintained in molten zinc chloride. Raman spectra of the solid (5, 6) and of the liquid (6-8) are virtually identical, indicating persistence of the network structure in the melt. Concentrated aqueous solutions of zinc chloride contain $(ZnCl_2)_n$ polynuclear aggregates (9).

There remains some uncertainty, however, about the structure of the melt. Gruber and Litovitz (2) have concluded that the network structure is lost about 20° above the melting point, whereas MacKenzie and Murphy (3) and Bockris and co-workers (4) find remnants of polymer up to, and probably beyond, 100° above the melting point. Irish and Young (8) found the anhydrous melt to be polymeric nearly 200° above the melting point. Discrete molecules ($ZnCl_2$ or

$ZnCl_n^{2-n}$) were postulated in addition to the dominant polymer.

Zinc chloride is known to form stable salts in the presence of excess chloride ions. The phase diagram of the system $ZnCl_2$-KCl shows the compound K_2ZnCl_4 (10). An x-ray crystallographic study of several solid compounds containing the $ZnCl_4^=$ anion shows it to have an almost perfect tetrahedral structure (11). The vibrational spectrum of this ion has been reported for the solid (12) and for aqueous solutions (13).

Planar MX_3^- ions have been reported in zinc halide systems as well as in cadmium and mercury halide systems, which also have the d^{10} electronic structure. Bues (6), in Raman studies of molten mixtures of $ZnCl_2$ and KCl, and of $CdCl_2$ and KCl, interpreted his spectra in terms of both MX_3^- and $MX_4^=$ ions. Morris, Short, and Waters (14) found $ZnCl_3^-$ and $ZnBr_3^-$ in nonaqueous solutions of zinc halides to which the corresponding hydrogen halide had been added.

In Raman studies of related systems, Janz and James (15) reported both HgX_3^- and $HgX_4^=$ ions in molten mixtures of HgX_2 and KX. Tanaka *et al.* (16) found $CdCl_3^-$ to be the only complex ion in the molten salt system $CdCl_2$-KCl. Bues (6) found both $CdCl_3^-$ and $CdCl_4^=$ in the same system.

Bredig and van Artsdalen (17) have criticized Bues' interpretation of his data in terms of a MX_3^- species and have questioned the existence of such ions in d^{10} systems on theoretical grounds.

Experimental

Reagent grade $ZnCl_2$ was fused to expel most of the water, then triply sublimed. The sublimer was 2 in. OD and 15 in. long with the outer portion, including the standard taper joint, made of fused silica. About 200g of fused zinc chloride was heated to 700° under vacuum while tap water circulated through the cold finger. About 100g deposited overnight in the form of transparent platelets. Accumulated sublimates were combined for a second sublimation. Since the residue of the second sublimation showed a faint yellow color, that product was sublimed a third time.

Reagent grade KCl was fused in platinum ware. All transfers of these materials were performed in a dry box.

Samples were prepared in the mixing-filtering apparatus shown in Fig. 1. The apparatus was cleaned, dried, and finally baked under vacuum at 500°C. Predetermined amounts of $ZnCl_2$ and KCl were then added.

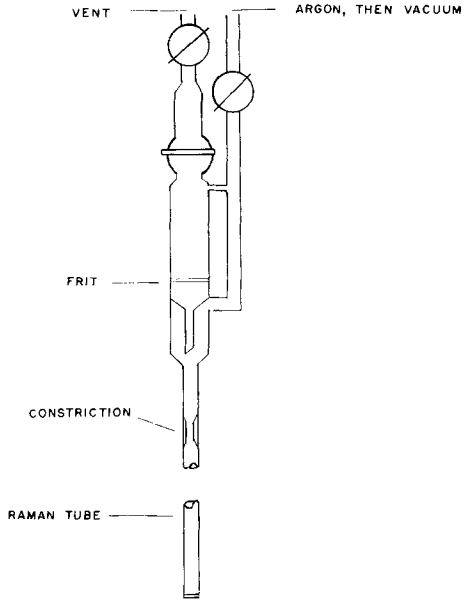

Fig. 1. Mixing filtering apparatus

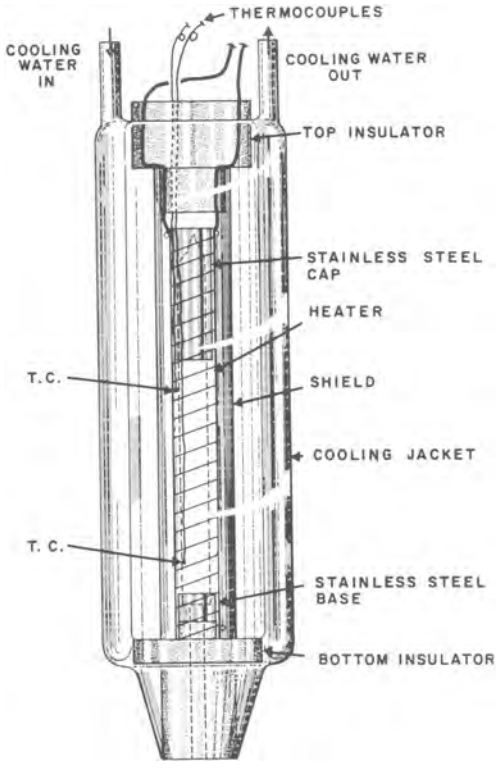

Fig. 2. High temperature Raman sample holder

The mixing-filtering apparatus was placed vertically in a tube furnace and heated about 100° above the melting point of the sample. During the melting, a stream of dry argon was passed through the frit from the underside. After melting, this purge served to mix the sample. After mixing, the argon flow was stopped and the apparatus was evacuated. The sample was filtered through the "fine" porosity fritted disk and dripped directly into the Raman tube. The Raman tube was sealed while the system remained under vacuum. The sample was allowed to freeze with the Raman tube lying in a horizontal position. This is necessary to avoid fracture of the Raman tube when the sample is remelted for the recording of its Raman spectrum.

The Raman spectra were recorded with the sample in the cell shown in Fig. 2. Stainless steel caps concealed the meniscus and the window and also centered the tube on the optical axis of the spectrometer. A vertical slot in the upper cap permitted the insertion of two thermocouples. This allowed measurement of the thermal gradient along the Raman tube. The spacing of windings of wire on the heater was adjusted until a gradient of 1° was obtained at 500°C.

The heater was a Vycor cylinder to which three binding posts were attached. A winding of 31 gauge Nichrome wire was anchored to these posts. Spacings were ⅛ in. for 1 in. at the bottom and ¼ in. above this. A second Vycor cylinder was placed around the heater to reduce heat losses by convection.

The sample and heating assembly were placed inside a doublewalled Vycor jacket. Circulating water through the jacket kept its outside surface near room temperature and permitted the use of Polaroid sleeves for polarization studies. Raman scattered light passed through the plane window at the bottom of the sample tube, through holes in the bottom cap and bottom insulator, and through a plane window on the bottom of the jacket.

Spectra were recorded over the temperature range 280° to 500°C with a Hilger Model E612 (f/5.7) Raman spectrometer having a reciprocal dispersion of 16 Å/mm. Preliminary runs were made using the Hilger source unit, but this proved unsatisfactory. Excessive background emission extended out to about 120 cm^{-1}

Table I. Raman frequencies of molten zinc chloride

vw = very weak; w = weak; s = strong; p = polarized.

from the exciting line. To overcome this a Toronto arc was constructed. Excitation by 4358 and 4047A Hg lines was employed; the latter was particularly useful in measuring the bands below 150 cm^{-1}. Unfortunately, it was not possible to use photoelectric recording and all spectra were recorded photographically.

Results and Discussion

Zinc chloride.—The Raman spectrum of molten zinc chloride shows five bands: an intense, polarized band at 226 cm^{-1}, an uncertain shoulder near 250 cm^{-1}, and weak bands near 75, 305, and 360 cm^{-1}. The results are compared with those of previous studies in Table I.

It was observed qualitatively that the weak features near 300 and 360 cm^{-1} were easier to discern on plates recorded with the sample at 425° compared with 290°C. The intensities of the bands at 226 and 250 cm^{-1} seem independent of temperature. Irish and Young (8) also observed that elevated temperatures increased the intensity of the 305 cm^{-1} band had no effect upon the 230 cm^{-1} band. On the other hand, they noted decreased intensity of the 266 cm^{-1} band on heating. A plausible interpretation is that these features arise from the depolymerization which is favored by the higher temperature. The higher frequencies are therefore assigned to terminal Zn-Cl stretching modes and the bands near 230 and 250 cm^{-1} to bridged Zn-Cl stretching modes.

These intensity changes are consistent with the observations of MacKenzie and Murphy (3), of Bockris, Richards, and Nanis (4) and of Irish and Young (8) that the network structure of the solid persists well above the melting point. Molten zinc chloride consists of polymeric $(ZnCl_2)_n$ species of various sizes. These species are made up of $ZnCl_4$ tetrahedra joined at corners to give a three dimensional array. At increasing temperatures the degree of polymerization is lowered, but even at 500°, the spectra show that the vast majority of Zn-Cl bonds are bridging rather than terminal bonds. Band assignments are given in Table I.

Chloride-rich solutions.—Addition of KCl has a significant effect on the Raman spectrum of molten zinc chloride. The results are given in Table II.

The bridging Zn-Cl stretching frequencies of polymeric $ZnCl_2$ are reduced in intensity: the weak band at 250 cm^{-1} disappears upon the first addition of KCl, the intense, polarized band at 226 cm^{-1} gradually fades. The terminal Zn-Cl stretching bands at 305 and 360 cm^{-1} in pure zinc chloride are shifted to lower frequencies and become at first more intense, then fade away. In the case of the 305 cm^{-1} band this pattern is obscured by the emerging spectrum of $ZnCl_4^=$, but careful scrutiny of the photographic plates indicates that the pattern of the 360 cm^{-1} band is followed.

The bands observed in mixtures containing 1.5 and 2 moles of KCl per mole of $ZnCl_2$ are readily identified from previous studies (12, 13) as those of the tetrahedral $ZnCl_4^=$ ion.

Increasing temperatures cause the bands in the 340-360 and 290-300 cm^{-1} regions to become more intense and the band at 226 cm^{-1} to grow weaker. These changes are consistent with the assignment of the higher frequencies to terminal ZnCl stretching modes and the 226 cm^{-1} band to a bridging ZnCl stretch.

A physical model consistent with the observed spectra is one of depolymerization and complex ion formation. According to this picture the initial process on addition of KCl to molten $ZnCl_2$ is the formation of smaller clusters of $ZnCl_4$ tetrahedra. The chloride ion added up to a molar ratio of KCl:$ZnCl_2$ of about 0.2 is consumed largely in the depolymerization reaction

$$(ZnCl_2)_n + Cl^- = (ZnCl_2)_{n-m} + (ZnCl_2)_m \cdot Cl^-$$

This process continues upon further addition of KCl but a second process predominates beyond the molar ratio KCl:$ZnCl_2$ of 0.2

$$(ZnCl_2)_m \cdot Cl^- + Cl^- = ZnCl_4^= + (ZnCl_2)_{m-1}$$

This model is consistent with the spectral observations and with the physical properties of these melts. It is reminiscent of the model proposed by Bloom and Bockris (18) to describe the break up of the structure of molten SiO_2 on the addition of a metal oxide. These authors describe a series of step-wise transitions from a three-dimensional network of SiO_2 tetrahedra through fused rings, planar rings, chains, and finally $SiO_4^=$ ions. The effect of adding MCl to molten $ZnCl_2$ seems to be roughly analogous, but with $ZnCl_4^=$ ions

Table II. Observed bands in Raman spectra of molten mixtures

p = polarized; w = weak; vw = very weak; m = medum; s = strong.
All bands are broad.

splitting out at all stages of the depolymerization.

The downward trend in several frequencies on addition of KCl is attributed to this change in the basic nature of the melt.

The data reported here do not eliminate the possibility of the formation of $ZnCl_2$ monomer or of the complex ion $ZnCl_3^-$. It does seem possible, however, to explain the data without invoking either species.

Manuscript received Sept. 13, 1965; revised manuscript received Oct. 21, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Determination of Resistance Factors of Porous Diaphragms and Electrodes

K. S. Spiegler

Sea Water Conversion Laboratory, University of California, Berkeley, California

ABSTRACT

Oxygen-argon interdiffusion measurements across two porous glass disks are compared to measurements of the electrical resistance of these disks when saturated with a dilute electrolyte solution. The resistance factors (also called formation factors) determined by the two methods agree within about 10%. The gas diffusion method of resistance factor measurement is applicable to conductive porous bodies, *e.g.*, sintered metal disks. Recording apparatus and method of interdiffusion measurement are described in detail. The same apparatus can be used for permeability measurements.

Porous diaphragms and electrodes used in electrochemical practice differ widely in accordance with their intended use. They can be classified according to their characteristic pore dimension which ranges from macroscopic size to submicroscopic; according to thickness, ranging from several millimeters to fractions of millimeters; according to matrix conductivity, which can be practically zero, to the considerable ionic conductivities of ion exchange membrane separators and the electronic conductivities of metallic electrodes; and according to many other factors.

This study deals with methods for the measurement of resistance factors of porous diaphragms, in particular with the gas diffusion method which is applicable to both conductive and nonconductive matrices.

The definition of the resistance factor, also called formation factor, of a nonconductive matrix is straightforward: it is simply the resistivity, ρ' (ohm cm), of the material when the pores are filled with a conductive liquid divided by the resistivity of the conductive liquid, ρ. It can be determined from two resistance measurements in a system consisting of two electrodes, each of area A (cm^2) immersed in an electrolyte solution of resistivity ρ. First, the resistance, R_1 (ohm), is measured without the separator in place, then with the separator of thickness l (cm) inserted between the electrodes and fully wetted with electrolyte. This yields the higher resistance R_2. The formation factor, F_E, is then

$$F_E \equiv \rho'/\rho = [A(R_2 - R_1)/(l\rho)] + 1 \qquad [1]$$

The difference $R_2 - R_1$ is often termed "separator resistance." Convenient methods for these measurements have been described and are in routine use in the battery industry (1, 2). Other types of apparatus have been used for the resistance measurement, including variants of the classical a-c methods using a Wheatstone bridge; one such method was developed in this study and is described in the experimental section. Formation factors are often interpreted in terms of the "spaghetti model" which describes the porous medium as bundles of n_τ tubes per unit volume, all of length τ. The radii n are not necessarily equal. The formation factor can then be expressed in terms of τ^2 and the porosity (= volume fraction of nonsolid space), by considering the passage of current under the influence of a potential gradient E (volt). In this model (Fig. 1), the porosity is

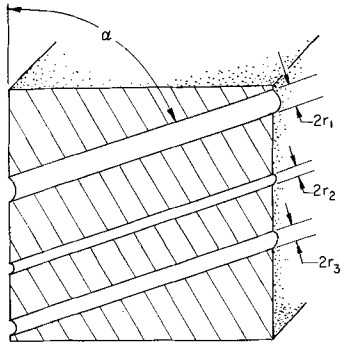

Fig. 1. Capillary bundle model ("Spaghetti model") of porous diaphragm. Cube of unit edge length is shown. r_1, r_2, and r_3 are pore radii.

$$\epsilon = \sum_r n_r r^2 \pi \tau \quad [2]$$

and the current density, i (amp cm^{-2})

i = cross section of pores x conductivity of electrolyte x potential drop

$$= \sum_r n_r r^2 \pi (1/\rho)(E/\tau) \quad [3]$$

Since

$$\rho' = E/i \quad [4]$$

it follows that

$$F_E = \rho'/\rho = \tau^2/\epsilon \quad [5]$$

The pore model can be generalized by assuming a distribution of pore radii as determined by porosimeter measurements (3, 4), but even so it is only of limited value for the description of flow phenomena in real porous media. Since porosity, ϵ, can be measured independently, τ^2, (the length of the fictional pore bundles per unit macroscopic thickness of the porous medium) can be calculated from the resistance factor. τ is called the "tortuosity" of the pore model, but some authors call τ^2 by this name.

When one deals with solid matrices which are themselves conductive, the determination of resistance factors by the electrical method is often inconclusive, because the solid can then act as a "short" with respect to the current path in solution. For instance, both a-c and d-c measurements of the conductance of a porous mass of ion exchanger grains in a solution reflect not only the conductance of the solution, but also that of the solid ion-exchange material; in a-c measurements of porous metal electrodes the current is carried primarily electronically through the metal matrix rather than through the pores which are filled with electrolyte, and this can even happen in d-c measurements, unless the conditions are properly chosen to prevent the current from following this path. Yet it is frequently important to know the formation factors (or tortuosities) of such conductive matrices. In this case one defines the formation factor of the conductive matrix as equal to the formation factor of a nonconductive matrix of the same geometry as the conductive one under consideration. Since the pore resistant factors of metal electrodes affect the operation of fuel cells, it was deemed important (*a*) to develop a method for formation factor measurement which is applicable to both conductive and nonconductive matrices, and (*b*) to compare the results for some nonconductive matrices with measurements by an a-c resistance method which is applicable only to nonconductive media.

The thought underlying the gas diffusion measurements is the following: When gases interdiffuse across a porous diaphragm, they follow the same tortuous path which ions follow when carrying the electric current through the same diaphragm. Hence the ratio of the interdiffusion coefficient of two gases in free space to their interdiffusion coefficient across the diaphragm is equal to the formation factor. In other words, it is assumed that ionic migration under the influence of an electrical potential gradient follows in a macroscopic sense the same path as the interdiffusion of gas molecules, caused by a chemical potential gradient. Although this thought is quite plausible, there is not much direct experimental verification in the literature, e.g., measurements of diffusion of water vapor through a synthetic porous rock (5) and through plugs of fine powders (6).

It will be shown that this simple hypothesis has to be modified somewhat because of the presence of "Knudsen" diffusion in gas interdiffusion measurements, and that, moreover, the choice of the gases has to be made judiciously, so that there is indeed only a single interdiffusion rather than two separate individual diffusion processes of the two gases proceeding at different rates.

Experimental

Gas diffusion measurements.—A schematic of the apparatus is shown in Fig. 2. The lower part is largely metal, the upper glass, connected to a conventional vacuum system. Flexible connections are made by vacuum rubber tubing. The electrode is held between two flanges, silver-soldered to the gas containers. A special gasket with "U" cross section (Irving B. Moore Corporation, Boston, Massachusetts) is used to prevent transport of gases through the edge of the electrode. The standard size of the electrode samples is a disk 2 in. in diameter. For samples yielding very high interdiffusion rates, part of the surface is masked on both sides with masking tape, care being taken that the two openings calender perfectly.

Vessels LI and RI are first evacuated and shut off from the vacuum system, Spheres LU and RU are filled with argon and oxygen, respectively, at about twice the pressure desired in the experiment. The solenoid valves (Circle Seal Products Corporation, Pasadena, California) are opened simultaneously for about 1 min and closed by a small programmer built for the purpose, thus admitting the gases to spheres LI and RI. The needle valve between spheres RU and RI has a micrometer head calibrated so that the pressure difference between LI and RI at the end of the filling process is as small as possible. To insure further that the experiment is started at equal pressure of the two gases, the top connection between spheres LI and RI is opened for about 15 sec immediately after the solenoid valves close.

The "peristaltic" pumps (Sigmamotor Pump Corporation, Middleport, New York) and paddle stirrers are now started, to circulate and mix the gases in spheres LI and RI. (Since pumping alone is not sufficient for perfect mixing in the spheres the paddle stirrers have been added.) The composition of the gases is determined from the continuous record of the thermal conductivity cells which have been calibrated before with mixtures of argon and oxygen of known composition.

The composition of the gases in spheres LI and RI is recorded until they contain 40 v/o oxygen and argon, respectively. The upper connection between the spheres is then opened and the composition equalized by vigorous gas recirculation through both spheres. This is done to verify that the final composition is 50% O_2-50% A. In general, some small deviation from this ideal condition is occasionally observed and suitable correction made.

The interdiffusion process is mathematically equivalent to heat flow between two identical good conduc-

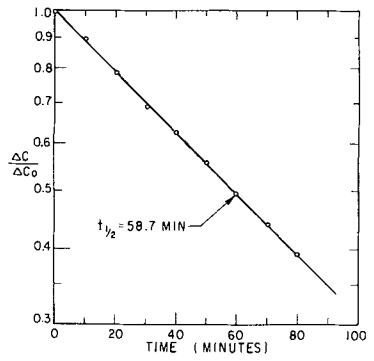

Fig. 3. Oxygen-argon interdiffusion across GS-I sintered glass disk. Exposed diameter 2r = 2.22 cm, thickness Δz = 0.549 cm, pressure 400 Torr, stirring rate 200 rpm.

tors connected by a poor conductor. Like the latter phenomenon it follows an exponential decay law

$$\frac{\Delta c}{\Delta c_o} = \exp\left[-2\bar{D}_{12}At/(V\Delta z)\right] \qquad [6]$$

where Δc and Δc_o are the oxygen concentration differences between the two spheres at time t (sec) and at zero time respectively, $\bar{D}_{12}$ the interdiffusion coefficient in the porous medium (cm^2 sec^{-1}), A(cm^2) and Δz (cm) the gross cross section and thickness of the disk, respectively, and V(cm^3) the sphere volume. Therefore a straight line is obtained when log $\Delta c/\Delta c_o$ is plotted against time. Figure 3 shows such a plot illustrating the graphical interpolation for finding the half-time, $t_{1/2}$(sec), from which the interdiffusion coefficient is calculated

$$\bar{D}_{12} = 0.347\ V\ \Delta z/(At_{1/2}) \qquad [7]$$

The area A is corrected for edge effects from a curve computed by Auslender *et al.* (7) shown in Fig. 4.

Because of the exponential nature of Eq. [6] the zero time can be arbitrarily set at any time after the start of the experiment. Although the experiments are started with pure gases, measurements at the very beginning of the experiment were disregarded because of some transient effects in the instrumentation and also because the assumption of a single interdiffusion coefficient for the gases, rather than separate individual coefficients, is weakest at the beginning when Δc is large. Zero time is usually taken at about 85 and 15 v/o oxygen in the two spheres, respectively.

The ideal gas pairs for interdiffusion measurements are para and ortho hydrogen, or isotopic pairs of very similar molecular weight and hence similar self-diffusion coefficients (7a). We used oxygen and argon (which do not quite meet the latter criterion) because

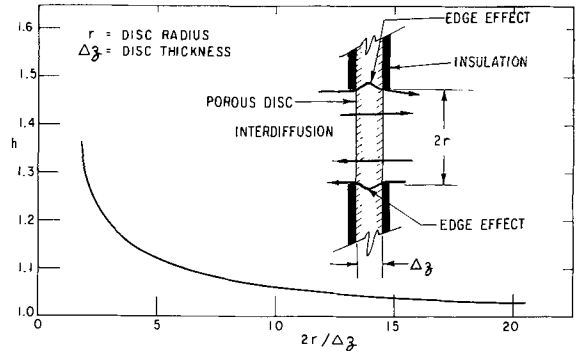

Fig. 4. Edge effect correction factors. h = (equivalent area of disk with no edge effect)/(true area of disk), r = disk radius, Δz = disk thickness.

their thermal conductivities are very different (thus simplifying the continuous monitoring of the gas compositions) while their self-diffusion coefficients are not too far apart. It should be realized, however, that the interdiffusion of different gases across a porous diaphragm proceeds at different rates, a phenomenon which becomes the more apparent, the lower the gas pressure and the smaller the characteristic pore dimension, i.e., the higher the ratio of gas-wall to gas-gas collisions. As a corollary, there should develop a transient pressure gradient between the two spheres (8). We measured this effect in a typical experiment with a V-shaped oil manometer and found the maximum pressure difference between the spheres to rise rapidly to about 0.1 Torr and then to decrease more or less exponentially as diffusion progressed. In this experiment, the sample was a porous disk of thickness 0.26 cm, exposed diameter 1.0 cm, porosity about 75% and characteristic pore dimension several microns. The volume of each sphere was about 4 liter.

Measurements were carried out at different pressures, thus enabling us to eliminate the Knudsen diffusion resistance term by use of the Bosanquet formula [8]

$$\frac{1}{\bar{D}_{12}} = \frac{F_G p}{[D_{12}]_{1\ atm}} + \frac{1}{\bar{D}_K} \qquad [8]$$

where $\bar{D}_{12}$ and $[D_{12}]_{1\ atm}$ are the measured interdiffusion coefficient across the medium and the oxygen-argon interdiffusion coefficient in free space at 1 atm, respectively, (cm^2 sec^{-1}), p the pressure (atm), $F_G(>1)$ the resistance factor for gas interdiffusion and $\bar{D}_K$ a positive, pressure-independent constant for a given porous medium and the oxygen-argon gas pair at 25°C. In other words, when plotting the measured $1/\bar{D}_{12}$ *vs.* pressure p, straight lines were obtained with positive ordinate intercepts. The slope of these lines is F_G/D_{12}. We used a recent literature value of D_{12} = 0.195 cm^2 sec^{-1} at 25° (9) and thus were able to calculate F_G from the slopes.

Equation [8] was originally derived from the kinetic theory of gases (8), but its main features can also be understood from the familiar friction model for linear transport processes in membranes and diaphragms (10, 11). According to this model, $1/\bar{D}_{12}$ represents a resistance to interdiffusion, which Eq. [8] splits into two additive terms *viz.*, (*a*) a term proportional to the pressure. This represents the resistance due to collisions between the interdiffusing gases; at 1 atm and in the absence of the porous medium this resistance equals $1/[D_{12}]_{1\ atm}$, but when the porous medium is present this resistance increases to $F_G/(D_{12})_{1\ atm}$, F_G expressing the decreased available cross section and increased tortuosity of the interdiffusion path. Thus F_G is considered identical with the electrical resistance factor (formation factor), F_E, which expresses the same steric factors. (*b*) A pressure-independent resistance term, $1/\bar{D}_K$, due to collisions between gas molecules and porous matrix, which becomes predominant at low pressures and is therefore identified with the reciprocal of the Knudsen interdiffusion coefficient, $\bar{D}_K$.

It is of interest that the apparatus shown in Fig. 2 can also be conveniently used for the rapid determination of permeability over the pressure range of about 100 to 800 Torr. In this case the spheres are first filled with the test gas at the desired pressure. A pressure differential of a few Torr is then created by opening one of the solenoid valves to the vacuum for about 1 sec by means of a programmed timer. The influx of air from the other sphere, which follows an exponential law similar to Eq. [6] is then determined from the gradual pressure increase by monitoring continuously the transducer output.

Electrical resistance factor measurement.—A schematic of the cell is shown in Fig. 5. In this apparatus

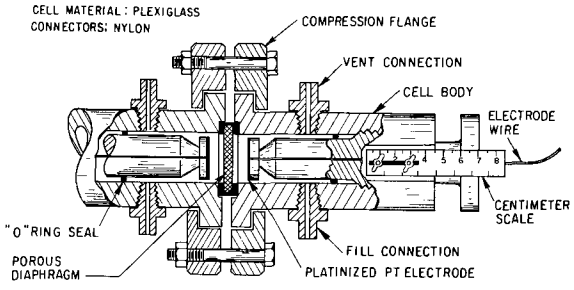

Fig. 5. Schematic of cell for electric resistance factor determination: material, plexiglas; connectors, nylon.

the electrical resistance is measured with alternating current. The electrodes never touch the diaphragm. The porous disk, contained in the gasket of U-shaped cross section is saturated with a dilute KCl solution and placed between the flanges of the two half-cells, which are filled with the same solution. Two platinized platinum electrodes of the same diameter as the porous sheet can be moved forward and backward in the cell by means of a screw drive so that the electrodes remain parallel to the plane of the sample. One electrode usually remains stationary close to the sample, but not in direct contact with it. The other is placed at different distances from the porous material, and the resistance between the electrodes measured with an a-c bridge (Industrial Instruments, Inc., Cedar Grove, New Jersey) at 60 cps. The position change can be measured to 0.005 cm by means of a ruler attached to the cell and subdivisions of the screw head.

When the measured resistance, R_1 (ohm) is plotted against the distance between the electrodes, a straight line is obtained which is described by Ohm's law

$$R_1 = \frac{1}{A}\left[\rho' \Delta z + \rho(z - \Delta z)\right] \qquad [9]$$

A is the effective cross section (cm^2), Δz the diaphragm thickness (cm), z the length coordinate (cm), ρ' and ρ the specific resistances of the solution-saturated diaphragm (ohm-cm) and of the solution, respectively. ρ can be taken from literature values, but it is preferable to determine it under the same conditions by repeating the measurements in the absence of the porous medium. This is done in order to guard against inaccuracies due to minor deviations from cylindrical geometry.

In this case, the resistance is

$$R_o = \frac{\rho z}{A} \qquad [10]$$

It is seen that both curves should have the same slope, ρ/A, and that the electrical resistance factor, (formation factor) F_E, is given by

$$F_E \equiv \frac{\rho'}{\rho} = (R_1)_{\Delta z}/(R_o)_{\Delta z} \qquad [11]$$

since, for $z = \Delta z$, Eq. [9] yields

$$\rho' = \frac{A}{\Delta z}(R_1)_{\Delta z} \qquad [12]$$

where $(R_1)_{\Delta z}$ and $(R_o)_{\Delta z}$ are the values of R_1 and R_o, respectively, at the electrode separation Δz.

In practice, resistances of diaphragm and pure electrolyte solution are measured in the same manner, except that for electrolyte measurement a dummy made up of circular plastic rings of similar thickness as the diaphragm is placed in the cell (small differences in thickness are allowed for by graphical correction).

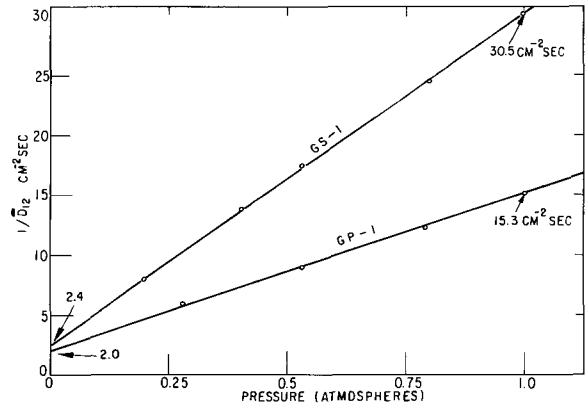

Fig. 6. Dependence of interdiffusion on pressure, Bosanquet plot shows reciprocal of oxygen-argon interdiffusion coefficient, D_{12} (cm^2 sec^{-1}) as function of pressure (atm). Porosities of sintered disks GS-1 and GP-1 are 30.2 and 65.0% respectively.

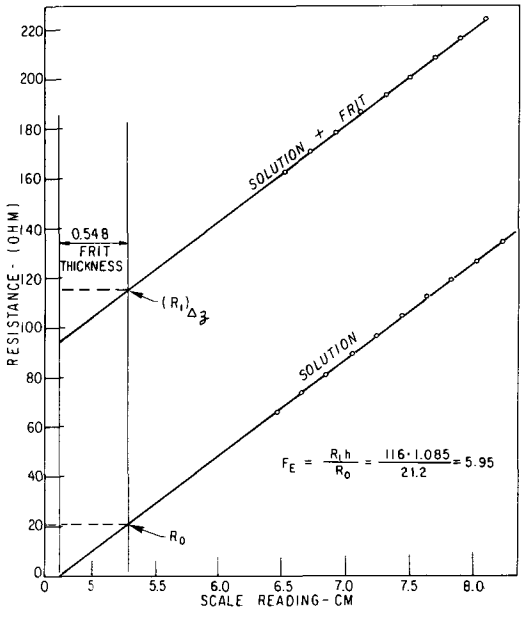

Fig. 7. Electrical resistance factor determination of sintered disk GS-1. Resistance between electrodes of measuring cell (Fig. 5) is shown as function of electrode distance. Upper line: dilute KCl solution and frit; lower line: solution only. Extrapolation of straight lines to distance Δz yields resistance of saturated disk, R_1 and solution (of same thickness), R_o, respectively. Electrical resistance factor, F_E, is $R_1 h/R_0$ = 116 x 1.085/21.2 = 5.95, where h is edge correction factor taken from Fig. 4.

Results and Discussion

Oxygen-argon interdiffusion measurements across two commercial glass frits, GS-1 and GP-1, respectively, (Ace Glass Company, Vineland, New Jersey), at different pressures are shown in Fig. 6 in terms of Bosanquet plots. From the slope of the straight lines the gas interdiffusion resistance factors F_G were calculated by the procedure described in the experimental section.

For comparison, the electrical resistance factor measurement of one of these glass frits, GS-1, is illustrated in Fig. 7. The electrical resistance factor for GP-1 was determined in the same manner.

The resistance factors (formation factors) calculated from the diffusion and from the resistance measurements are listed in Table I, along with some pertinent data on the glass frits.

It is seen that the resistance factors of the two frits are quite different, due mainly to the large difference

Table I. Properties of glass frits used in tests

Designation	GS-I	GP-I
Total diameter, cm	5.08	5.08

* Statement by manufacturer.

in porosity. The measurements by the gas diffusion and electrical method agree within about 10%.

In view of the results in Table I and the earlier findings of other investigations with radically different samples (5, 6) one can indeed assume that gas diffusion measurements can be used to determine the formation factors of the pores, irrespective of the conductivity of the matrix itself, provided (*a*) the geometry of the matrix in the dry and wet state is the same, and (*b*) due correction is made for Knudsen diffusion resistance.

Gas diffusion is not the only method for the measurement of the formation factors of conductive matrices. Instead, one can measure the diffusion of solutes or ionic self-diffusion across the porous body (12) and compare the measured diffusion coefficients to those in free solution. The appropriate ratios again yield the formation factor, provided the matrix have no surface conductivity due to the type of ions whose diffusion is being measured. For instance, for porous ion-exchange materials, the electrical and self-diffusion measurements do not yield the same formation factor unless elaborate corrections are made (10, 13). On the other hand, ionic self-diffusion measurements in metallic diaphragms should yield the correct formation factor. Yet another method is based on electrical potential drop measurements across polarized porous metal diaphragms. For instance, if a porous nickel disk is immersed in a solution of pure NaOH and a sufficiently small d-c potential difference applied to large electrodes on opposite sides of the disk, the current will pass only through the NaOH solution in the pores and not through the metal matrix, provided the potential difference is too small to maintain continuous electrode reactions at the nickel-solution boundary (14). The electrode resistance is calculated from the current and the potential difference across the porous disk, as measured between two small probe electrodes placed close to the diaphragm faces, (4-electrode method).

Acknowledgment

The author expresses thanks to Dr. J. G. Tschinkel, for many helpful discussions and suggestions, and to G. Grist and C. Osgood for their valuable assistance.

Manuscript received Oct. 11, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Differential Capacity Measurements at Carbon Electrodes

S. Evans

Research Department, Rocketdyne,
A Division of North American Aviation, Incorporated, Canoga Park, California

ABSTRACT

Voltammetry at continuously changing potentials has been used to determine the differential double-layer capacity of carbon materials. The total capacity of carbon microelectrodes was of sufficient magnitude to necessitate the use of slower scan rates than are normally used with the dropping mercury electrode. The differential double-layer capacities of Air-Spun graphite, acid-treated Air-Spun graphite, and MA-Norit graphite were 1.4, 1.8, and 60 farads per gram, respectively. At low applied potentials charging of the double layer was the major electrochemical process. In this potential range the magnitude of the double-layer capacity did not vary with potential.

Electrodes, formed by the impregnation of Dacron with chemically treated carbon paste, have been used for water demineralization (1). The determination of the double-layer capacity of various carbon pastes was part of a basic study of the mechanism of demineralization at carbon-type electrodes.

The theory and application of voltammetry at continuously changing potentials to the determination of the differential capacity of the double layer has been presented in detail by Loveland and Elving (2-5). At potentials where no reduction or oxidation occurs, the currents observed using this technique are the sole result of the charging and discharging of the double layer (6). The expression for differential capacity, C_d, is

$$C_d = dQ/dE \qquad [1]$$

where Q is the surface-charge density of the double layer, and E is the electrode potential. When the rate of change of potential across the double layer is equal to the rate of change of applied potential, this expression can be rearranged to

$$C_d = \frac{1}{v}\frac{dQ}{dt} \qquad [2]$$

where v is the scan rate in volt sec^{-1}, and dQ/dt is the differential capacity current (i_c). It will be seen that the limitations imposed by this condition ($dE/dt = v$) are more severe in the case of high surface-area carbon pastes than with the dropping mercury electrode. The differential capacity can be determined experimentally according to

$$C_d = \frac{i_c}{\text{scan rate}} \qquad [3]$$

The integration of the capacity current as a function of changing potential can also be used to evaluate the differential capacity in accordance with Eq. [1].

Experimental

The test electrode and the silver-silver chloride reference electrode were contained in the same compartment of the H-type cell (Fig. 1). The potential at the test electrode was detected through a Luggin capillary which contained a silver wire coated with silver chloride. This Ag-AgCl electrode was in contact with the electrolyte (*e.g.*, 10% NaCl). The potential of the test electrode was varied linearly with respect to the reference electrode. The cell current was measured as a function of the potential.

The test electrode (Fig. 2) consisted of a Teflon cup equipped with mating threads and a ¼-in. diameter graphite rod cemented to a Teflon plunger. The spectroscopic-grade graphite rod was wax impregnated and insulated on the sides so that a geometrical area of 0.3 cm^2 was exposed. A known amount of carbon material was supported on a disk of Whatman No. 42 filter paper.

The voltage-scanning instrument was constructed of commercial high-gain operational amplifiers. The basic potentiostat circuitry was similar to that described by

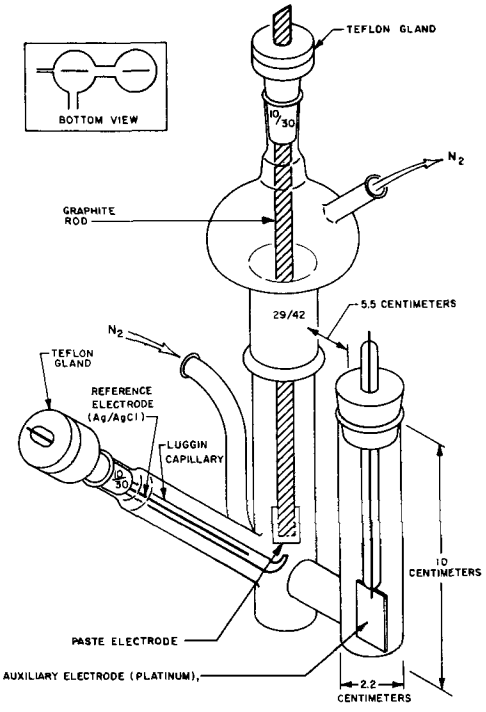

Fig. 1. H-cell

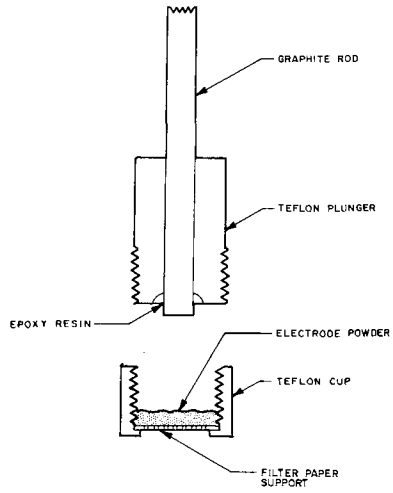

Fig. 2. Test electrode assembly

Lauer, Schlein, and Osteryoung (7). Current was recorded on the X-axis, and potential on the Y-axis of a Moseley X-Y recorder. At high-scan rates, the curves were photographed from the screen of a Dumont oscilloscope.

In other experiments the current was electronically integrated, and direct plots of charge *vs.* input voltage were obtained. In a typical experiment, the test electrode was maintained potentiostatically at a fixed potential for 10 min prior to scanning anodically or cathodically. Generally the scan range was 0.1 or 0.3v from the starting potential. The polarization curves were determined at varying scan rates in a 10% NaCl solution in the presence of air and with a nitrogen atmosphere.

The capacitative characteristics of Air-Spun graphite, mixed-acid treated Air-Spun graphite, "cation-responsive" paste, and the graphite support rod of the test electrode were studied. The cation-responsive paste has been used extensively in demineralization experiments and was prepared according to established procedures (1). Briefly, a 2:1 mixture of H_2SO_4 and HNO_3, washed, filtered, and dispersed with tannic acid. Twenty-four hours later the dispersion was stabilized by the addition of ammonium hydroxide. This is referred to as MA-Norit graphite (where MA means mixed-acid treatment).

Results

Air-spun graphite.—The characteristics of Air-Spun graphite (2.8 mg) were studied over a 0.3v range (*vs.* Ag-AgCl) at scan rates varying from 0.02 to 20 v/sec. At rates above 0.1 v/sec accurate results were not obtained. Double-layer capacitance values calculated from polarization data are given in Table I. Repre-

sentative curves obtained from cathodic scans (Fig. 3 and 4) were not significantly different from those determined anodically, and the presence of air had no noticeable effect on these determinations. The magnitude of the solution resistance between the test and reference electrodes was 35 ohms as established by a current-interrupter technique. The results of experiments on acid-treated Air-Spun graphite (1.7 mg) are shown in Table II.

MA-Norit graphite.—Linear current-potential curves were obtained with a 3-mg sample of the paste at 0.1 and 0.05 v/sec. A definite current plateau (0.55 ma) was observed at 0.0032 v/sec. This corresponds to a capacity of the order of 170 mf (57 mf/g of paste). Plots of dQ *vs.* dE yielded similar results.

To obtain more quantitative results, smaller samples of paste were required. Accordingly, 0.39 mg of paste was studied. The range studied was restricted to 0.1v from a potential which had been potentiostatically

fixed for 10 min. Anodic and cathodic polarization curves were determined from several starting potentials as a function of scan rate, and the results are shown in Table III. Representative anodic polarization curves determined are illustrated in Fig. 5.

A typical anodic polarization curve determined over a 0.3-v range (Fig. 6) exhibits a steady capacitance current over the entire range. This range was not useful for cathodic polarization, since the reduction of water commenced at approximately —0.4v with respect to the Ag-AgCl electrode. Anodic polarization curves, determined immediately after the test electrode was subjected to cathodic pretreatment below this voltage (*i.e.*, more negative), exhibited current waves presumably resulting from the oxidation of adsorbed hydrogen.

Graphite support rod.—Anodic and cathodic polarization curves were determined on the graphite support rod at scan rates of 1, 2, 10, 20, 40, and 80 v/sec. The

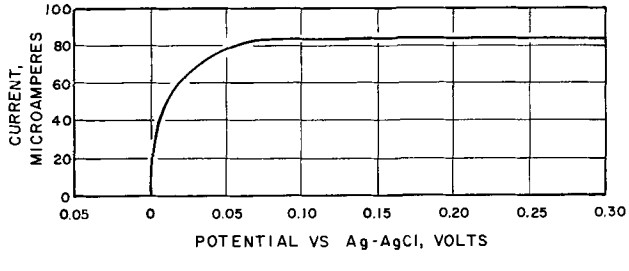

Fig. 6. Anodic polarization curve of MA-Norit graphite paste. (Range, 0.3v; rate: 0.0033 v/sec).

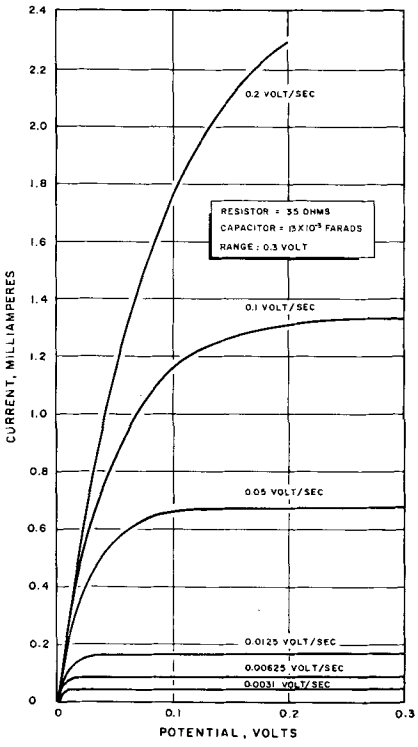

Fig. 7. Polarization of analog *RC* series circuit

resulting photographs of the oscilloscope trace revealed that dQ/dE was constant over the range of 10 to 80 v/sec. The double-layer capacitance was 30 ± 5 μf for this area of the rod. The purpose of this experiment was to assess the relative magnitude of contributions from the support rod in experiments where a sample was present. There was no significant difference in polarization characteristics when the filter paper was present.

Analog RC series circuit.—Polarization curves were determined on a series *RC* circuit as a function of scan rate, with R = 35 ohms and C = 13 mf (Fig. 7). The mean capacitance value determined at scan rates less than 0.1 v/sec, using the relationship $C = i/\text{scan rate}$, was 13.3 ± 0.3 mf.

Surface-area measurements.—The surface areas of Norit A, Air-Spun graphite, and the MA-Norit graphite paste were found to be 1200, 4, and 270 m^2/g, respectively. The Engelhard Isorpta Analyzer (BET method) was used. The samples were heated overnight in a slow stream of helium at 200°C. A mixture of 10% N_2 in helium was used in developing the nitrogen adsorption isotherm. From the lower portion of this isotherm (p/p_o = 0.15-0.25) the surface area was obtained by the application of the BET method.

Discussion and Conclusions

The determination of differential capacity, using voltammetric scanning techniques, is ideally undertaken when faradaic contributions can be ignored. Under such conditions (high faradaic impedance) the electrode equivalent circuit can be regarded as a series *RC* circuit, where *R* represents the solution resistance, and *C* is the capacity of the double layer. In an analog *RC* circuit the magnitude of the time constant (*RC* product), τ, limits the useful range of scan rates. Analysis of the time-variant voltage applied to such an *RC* circuit reveals that after a period to time, τ, has elapsed, the rate of change of potential across the capacitor is equal to the rate of change of applied voltage. Thus, for high time constants (R = 35 ohms, C = 13 mf) the experimental upper limit of scan rate for the 0.3-v range was 0.1 v/sec (Fig. 7). An analog *RC*-series circuit with R = 35 ohms and C = 25 μf was studied successfully in this laboratory from 0.02 to 40 v/sec.

The conditions under which such determinations are made on the dropping mercury electrode (2) cannot be extended to include electrodes of high surface area. Because of the large effective capacity of even small samples of carbon, slower scan rates must be used. The limit of scan rate is determined by the length of time required for the rate of change of the potential across the double layer to become equal to the scan rate (6). Thus, while the effective capacity of the graphite support rod (30 μf) was successfully determined at scan rates from 10 to 80 v/sec, slower scan rates and smaller samples were necessary with high surface-area carbons.

The double-layer capacity of Air-Spun graphite was found to be 1.4 f/g or 35 $\mu f/cm^2$ based on the measured surface area. Since the Isorpta Analyzer is better suited for larger surface areas, the value should be considered approximate. The double-layer capacity for mixed-acid-treated Air-Spun graphite was 1.8 f/g, and for the MA-Norit graphite paste it corresponded to 60 f/g, or 19 $\mu f/cm^2$. The latter value is based on the measured surface area.

It can be seen that over a small potential range and at several scanning speeds, typical capacitative behavior was obtained. Since the reduction of water begins at approximately —0.4v *vs.* the Ag-Ag-Cl electrode, it is desirable to limit the cathodic range to approximately 0.1v. Deviation from capacitative behavior was noted for Air-Spun graphite at approximately —0.1v *vs.* Ag-AgCl. Since the oxidation of water was found to occur at approximately 0.9v *vs.* the Ag-AgCl electrode, capacitative characteristics were observed over a wider range (Fig. 6).

It is concluded that at low applied potentials, charging of the double layer is the major electrochemical process. In this potential range the differential capacity did not vary with potential and did not depend on whether the polarization curve was determined anodically or cathodically.

There was no difference in polarization when air was present or excluded, indicating that oxygen was not reduced. Chronopotentiometric studies on carbon black electrodes indicated the absence of an air blank at cathodic potentials (8).

The Characterization of Anodic Aluminas

I. Composition of Films from Acidic Anodizing Electrolytes

G. A. Dorsey, Jr.

Department of Metallurgical Research, Kaiser Aluminum & Chemical Corporation, Spokane, Washington

ABSTRACT

High-purity aluminum sheet was anodized in eleven different acidic electrolytes: boric, chromic, phosphoric, sulfuric, oxalic, malonic, succinic, tartaric, fumaric, glutaric, and adipic acids. These anodic coatings were analyzed by infrared to determine the composition and nature of each. We found, aside from alumina differences particular to each electrolyte, that the anodic barrier layer can be distinguished from the porous layer by an absorption band in the 1000-900 wavenumber region. Background information for the interpretation of anodic coating infrared data was obtained from the infrared analysis of known mineral forms of alumina. A band correlation table was devised.

Anodic alumina films are generally prepared in acidic electrolytes, such as dilute sulfuric acid, and have properties attributable to the specific electrolyte, the anodizing conditions, and the aluminum substrate compositions. Films formed at temperatures near 0°C are hard, abrasion resistant, and are often dark-colored and semi-opaque. Films prepared near 25°C may be clear and colorless, as with high-purity aluminum alloys anodized in sulfuric acid electrolytes; however, these are softer than coatings prepared at lower temperatures.

Anodic coatings formed in room temperature electrolytes are often immersed, after anodizing, for short periods in hot water solutions; this process is referred to as sealing. Thick anodic coatings have been shown to have a porelike structure, and sealing is thought to close these pores at the outer surface of the coating; sealed films are more protective against corrosive environments than are unsealed films, and this is generally thought to be due to this pore-closure mechanism. Although the protectiveness of anodic films may be due, in part, to properties within the coating itself, much work has been done relating film properties to sealing conditions (1).

Attempts to obtain information about anodic films, using x-ray and electron diffraction techniques, have generally been unsuccessful owing to the coatings' amorphous or ill-defined state (2). Electron microscopy has contributed much information on the geometric structure, but not molecular structure, of anodic coatings (3, 4). Other means have been employed, such as film particle electrophoresis (5), resistivity measurements (6), and infrared analysis (7). Since we are concerned here with the molecular structure of these aluminas, infrared analysis has proven to be our most powerful tool for general use.

Infrared analysis has been widely used in the examination of mineralogical aluminas. Frederickson (8) characterized the Al-OH stretch and bend modes for most of the common monohydrates and proposed a hydrogen bonded structure for at least one alumina, the β-monohydrate diaspore. Others have used infrared in studies of thermally induced alumina phase transitions (9). Newsom has combined the various analytical and physical property data into an excellent review for mineralogical aluminas (10), as has Lippens (11).

Our purpose here is to combine the general knowledge of anodic alumina properties with the molecular structure and composition to better characterize anodizing mechanisms, film compositions, and structures.

Experimental

Reference aluminas.—A series of pure alumina phases was obtained from our Permanente Metals Division Laboratory. These alumina phases had been identified by x-ray diffraction and differential thermal analytical techniques. These samples, listed below, were taken as being representative of the alumina mineral system and were used as reference standards for our infrared analysis.

1. Alumina trihydrates: α, trihydrate (gibbsite); β, trihydrate (bayerite).
2. Alumina monohydrates: α, monohydrates (boehmite and pseudoboehmite); β, monohydrate (diaspore).
3. Anhydrous aluminas: α, γ, pseudo-γ, η, θ, χ.

Other aluminum compounds were also examined. Aluminum isopropoxide was used as an additional reference for the aluminum-oxygen linkage. In addition, much information was made available through the investigation of sodium aluminates; these were examined initially and after a series of bakings.

Infrared analysis—reference aluminas.—These were examined using the potassium bromide disk and nujol mull techniques. Nujol mulls were used as a supplement to the disk method since the latter occasionally altered the water content of the sample; disks are prepared in a vacuum press while mulls are simply oil dispersions of the sample. Both sampling methods were used over the 4000-600 cm^{-1} range of a Beckman IR-7, in double-beam operation. A blank disk was used as a reference with the potassium bromide method, while the mulls were spread on cleaned sodium chloride plates, and spectra were prepared using air as a reference.

Anodic aluminas.—Cleaned 99.99% aluminum sheet was used as the substrate material for the samples. Electrolytes were prepared from each of the following, using distilled water:

Inorganic electrolytes: Orthoboric acid, 2.2M; Chromium (VI) oxide, 0.3M; Phosphoric acid, 3.1M; Sulfuric acid, 1.5M.

Organic electrolytes: Oxalic acid, 0.6M; Malonic acid, 0.6M; Succinic acid, 0.6M; Tartaric acid, 0.6M; Fumaric acid, 0.6M; Glutaric acid, 0.6M; Adipic acid, 0.6M.

Current densities, electrolyte temperatures, and coating thicknesses are listed in the Results section, along with other pertinent data. When used, the sealing process was carried out in boiling distilled water adjusted to pH of 6.0 with sodium hydroxide.

Infrared analysis—anodic aluminas.—The samples were examined over the 4000-600 cm^{-1} range of the IR-7 operated in double-beam mode. The flat anodized sheets were mounted in the sample stage of a C.I.C. ATR-1 reflectance attachment at the 45° incidence angle, and spectra were prepared using a front-sur-

faced aluminized mirror as a reference; the latter was mounted in an identical fashion. The reflectance method eliminated the side effects common to other sampling techniques and preserved the integrity of the sample. The orthoboric acid samples were also examined in the 800-33 cm^{-1} region, using the Model IR-11 at the Beckman Fullerton Laboratories. As with the IR-7 spectra, these were prepared using 45° reflectance.

The attenuated total reflectance technique of Fahrenfort (12) was also used, in isolated instances, with the same attachments. To accomplish this, a thin silver chloride sheet was first pressed against the anodic coating surface; a flat chrome-surfaced plate was used to press against the opposite side of the silver chloride. The anodized specimen, with the silver chloride overlayer, was then clamped in place against a C.I.C. silver chloride ATR prism; this procedure gave far better sample-prism optical contact than could be achieved without the sample overlayer.

In each case, the instrument was operated with a slit program and gain setting yielding an unloaded SB/DB ratio of 1.5; speed and period were adjusted for each sample so that the instrument response was adequate.

Results and Discussion

Alumina-system correlation.—The objective here was to relate infrared absorptions with specific alumina-system chemical linkages. Four bond types were detected, or were previously reported: AlO-H stretching vibration, Al-OH bend, Al=O stretching vibration, and Al-OAl stretching vibration. The anhydrous alumina reference phases and aluminum isopropoxide spectral data yielded information about the Al-OAl region, while the hydrate phases were used to define the AlOH stretch and bend regions. The Al=O stretch region was determined from spectral data obtained with sodium aluminate samples and from pseudoboehmite samples.

Once each of the four infrared absorption regions had been located, the upper and lower wavenumber limits for each region were determined by using the following relation with appropriate reduced mass values for each limit

$$\bar{\nu} = 1307\sqrt{\frac{k}{\mu}}$$

where k is the binding constant expressed in dynes per centimeter and $\mu = \dfrac{M_1 \times M_2}{M_1 + M_2}$ = reduced mass.

If we consider the bond RO-H, then $M_1 = 1$ and M_2 becomes increasingly large for increasing mass increments within the remainder of the molecule; here $\text{Lim.}_{M_2 \to \infty}\ \mu = 1$. Similar considerations apply to the other bonds, leading to the following results:

Bond	M_1	Limiting value of reduced mass	
RO-H	1	1	
R_2Al-OH	17	17	R represents the remainder of the molecule
RAl=O	16	16	
R_2Al-OAlO	59	59	

(The Al-OAl bond has no limiting reduced mass value for the system R_2Al-OAlR_2, and R_2Al-OAlO was used as an approximation.)

Furthermore, it follows that the limits of variation of μ will determine the limits of variation of the absorption frequency. As the molecular weight increases, the reduced mass increases to a maximum, and the absorption frequency decreases to a minimum as indicated below.

This behavior was exploited to good advantage for our work. The lowest observed wavenumber of the band belonging to each bond type was considered as being associated with a large reduced mass; therefore, the lowest observed wavenumber for each bond type

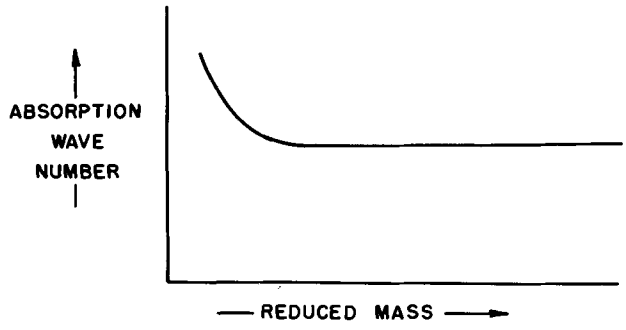

Fig. 1. Reduced mass *vs.* absorption wavenumber for relation $\bar{\nu} = 1307\sqrt{\frac{k}{\mu}}$

was taken to be an approximation to the lower absorption frequency limit for the bond type. From this, plus the limiting value of the reduced mass, binding constants were calculated for each of the bond types previously mentioned. The minimum limit of the reduced mass for each bond type was next calculated, and this, together with the binding constant, produced a value for the highest absorption frequency within each of the calculated frequency ranges for each type of bond, as is shown below:

Alumina-system chemical bond	Infrared absorption wavenumber range	Interpretation
AlO ⟷ H (stretch)	From 3660 to 2940 cm^{-1}	Bands in this region indicate the presence of water; either free, adsorbed, or combined as hydroxide
Al ⟷ O (stretch)	From 1696 to 1345 cm^{-1}	The presence of double bonds indicates an adsorptive or reactive material that probably does not have much crosslinking.
Al ⟷ OH (bend)	From 1162 to 900 cm^{-1}	Absorption here indicates the presence of aluminum hydroxides. Monohydrates are characterized by bands near 1070 cm^{-1}, while normal trihydrates show bands below 1025 cm^{-1}.
Al ⟷ OAl (stretch)	Below 900 cm^{-1}	Bands in this region indicate a high degree of crosslinking in the material; strong bands in this region are often associated with an absence of Al=O bonds. As the degree of crosslinking, i.e., molecular weight, increases, the bond absorption frequency will shift to lower values.

Infrared data for anodic aluminas.—Table I presents the infrared data that were obtained with the anodic aluminas; anodizing conditions and coating thicknesses are included in the table. The average anodic coating thicknesses were taken from metallographic cross-section determinations.

The anodic coating on aluminum may consist of one or more layers. The first layer to form, during anodizing, is termed the "barrier layer," further anodizing thickens this layer and may also cause a second layer to form on top of it. Unlike the barrier layer, this second layer is generally quite porous and is referred to as the "porous layer."

While the porous layer readily dissolves in acid solutions such as chromic-phosphoric mixtures, the barrier layer is less rapidly attacked. The barrier layer is also a better dielectric than the porous layer; the bulk of the voltage drop through an anodic coating, during anodizing, is thought to be due largely to the barrier layer. Many anodizing electrolytes can be used to produce the composite barrier and porous-layered coating; however, some yield only barrier layers. Orthoboric acid is commonly used when it is desired only to produce the barrier layer.

Table I. Infrared data for anodic aluminas

The following notations are used to describe the intensity of the infrared bands: S, strong; M, moderate; W, weak; b, broad; s, sharp; sh, shoulder on another band.

(1) This band may be due to aluminum phosphate. The 2.0μ film thickness contained 6%, by weight, PO_4^{-3} while the 5.3μ coating contained 8 w/o PO_4^{-3}.

(2) This band may be due to aluminum sulfate. The 1.8μ film thickness contained 13%, by weight, SO_4^{-2} while the 6.9μ coating contained 14 w/o SO_4^{-2}

The preceding table shows that the barrier layer electrolyte, orthoboric acid, yields an anodic coating having only one infrared absorption band in the 4000 to 33 cm^{-1} region: at 955 cm^{-1}. Similarly, each of the other electrolytes produce coatings with one infrared band in the 1000-900 wavenumber region. Often, the wavenumber placement of this band shifts to higher values as the thickness of the coating increases: example, orthophosphoric, sulfuric, and malonic acids.

The ATR spectra, which show only the surface composition, and bulk reflectance spectra of sulfuric anodic films are similar, however the 1000-900 cm^{-1} band is missing in the sulfuric anodic film ATR spectra. This indicates that the 1000-900 cm^{-1} band corresponds to an alumina composition not found on the sulfuric anodic coating surface. We conclude, therefore, that the anodic barrier layer is characterized by an infrared absorption band lying within the 1000 to 900 wavenumber region. The basis for this conclusion is reiterated below.

1. Orthoboric acid electrolytes produce only barrier layer oxide types. These anodic films have only one absorption band in the 4000 to 33 cm^{-1} region: between 1000 and 900 cm^{-1}.

2. The reflectance spectra of the entire group of coatings, from various electrolytes, have one common absorption region: 1000 to 900 cm^{-1}.

3. The surface composition of a porous coating is similar to the bulk composition (example, sulfuric anodic film); however the 1000 to 900 cm^{-1} region is blank.

Although the barrier layer alumina apparently can be identified with an infrared absorption in the 1000-900 wavenumber region, this presents an anomaly. The barrier layer infrared band is within the region ascribed to alumina hydrates; specifically, the band is in the trihydrate region. Alumina hydrates normally have a second band located in the higher frequency region near 3400 cm^{-1}; barrier layers normally do not have a band here. However, when there is a band in the 3400 region, the barrier layer band has usually shifted from a low to higher frequency (example: 25°C phosphoric coatings); this frequency shift normally corresponds to a breaking-up of a high molecular weight polymer to give a series of lesser polymers. We believe that our data show the barrier layer to be a hydrated alumina, specifically a trihydrate, which is altered in structure as anodizing progresses in a porous film-forming electrolyte.

Conclusions

Infrared analysis of anodic and nonanodic aluminas can reveal much about their composition and structure. The following correlation chart was derived from our preliminary work here.

Alumina bond type	Infrared absorption frequency range (wavenumbers)
AlO ⟷ H	3660-2940
Al <=> O	1696-1345
Al ⟷ OH	1162-900
(Barrier layer Al ⟷ OH	1000-900)
Al ⟷ OAl	Below 900

Infrared absorptions of composite anodic films may be used to distinguish the porous layer from the barrier layer; the barrier layer absorption is limited to the 1000-900 cm^{-1} region while the porous layer may show bands above 1000 cm^{-1} or below 900.

Acknowledgments

The author wishes to thank the Kaiser Aluminum & Chemical Corporation for its support of this work and for its permission to publish these results. Our thanks go also to Beckman Instrument's H. J. Sloane and K. W. Stein, who obtained the far infrared data for the orthoboric acid anodic films.

Manuscript received June 14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Characterization of Anodic Aluminas

II. Effect of Anodizing Temperature on Coatings from Aliphatic Dicarboxylic Electrolytes

G. A. Dorsey, Jr.

Department of Metallurgical Research, Kaiser Aluminum & Chemical Corporation, Spokane, Washington

ABSTRACT

High-purity aluminum sheet was anodized in eight dicarboxylic electrolytes: oxalic, malonic, succinic, and tartaric acids, ammonium tartrate, and fumaric, glutaric and adipic acids. The anodic coatings were quantitatively analyzed by infrared techniques to evaluate the amounts of porous and barrier layers in each. We found that the anodizing temperature influenced the amount of porous layer formed and appeared to be related to the dissolving tendency of the electrolyte. Furthermore, we found a shift in the absorption wavenumber of the barrier layer that correlates with the amount of porous layer. A mechanism for formation of porous layer from barrier layer is proposed.

A correlation chart, which we described previously, related alumina-system chemical linkages with absorption regions in the infrared (1). We were able to make a distinction between the infrared absorption of the anodic barrier layer and absorptions characteristic of the various porous layers. The composition of the porous layer varied with the anodizing electrolyte used. The purpose of this present work is to show the effect of anodizing temperature on the amounts of both barrier and porous layers within the same anodic film.

It is commonly accepted that the thickness of the barrier layer is defined by a relationship with the applied voltage: ~14 Å/v. However, as is pointed out by van Geel and Schelen (2), this relationship exists only under a certain set of conditions. When the peak anodizing voltage is reached, it must be held con-

stant until the anodizing current density has decayed to a low steady-state value. No further barrier layer should be formed at this fixed voltage. If the anodizing electrolyte and conditions are such that both porous and barrier layers form, the anodizing current will not correspondingly decay at fixed voltages and the 14 Å/v relation should not be applied to compute barrier layer thicknesses.

Since we are interested in the amounts of both porous and barrier layers which were formed at constant current density, the 14 Å/v relation could not be applied. Instead, we used the infrared absorbance of bands which could be identified with the porous and barrier layers, respectively. The absorbance of an infrared band is governed by two factors: (*i*) the absorbancy index, a relationship between refractive index and wavelength for a specific molecular absorption band, and (*ii*) the "amount" of absorbing material. The amount is determined by two factors: concentration of material per unit volume and thickness of the contained material.

As described earlier (1), our procedure for the infrared analysis of anodic aluminas is one of 45° incident angle reflectance. The readings for each anodized sample are made over equal areas so that only differences in coating density or coating thickness influence the quantitative reproducibility between samples of the same anodic material. The effective beam area is a fixed parameter and depends only on the angle of incidence for the sample and the optical geometry of the system.

We can make quantitative measurements on a relative basis without knowing the sample thickness or effective beam area but, to do this, we sacrifice the ability to express our data in terms of units. As a matter of expediency, our final data were obtained in unitless absorbance values that express the effects of coating thickness, density, and bond absorbancy indices. In this paper, therefore, we chose to refer to our quantitative results as amounts rather than in more normal concentration terms. A thin, dense coating could present the same amount of a particular molecular bond to the beam as would a thicker, but lighter, film.

Experimental

Anodic aluminas.—Cleaned 99.99% aluminum sheet was used as the substrate material for the samples. The following electrolytes were prepared, using distilled water: oxalic acid, 0.6M; malonic acid, 0.6M; succinic acid, 0.6M; tartaric acid, 0.6M; ammonium tartrate, 0.2M-solution of *p*H 6; fumaric acid, 0.6M; glutaric acid, 0.6M; adipic acid, 0.6M.

The aluminum panels were anodized at a constant current density of 1.08 amp/dm^2 or, where the current density could not be maintained, to a maximum of 400v. The samples were anodized for 5.0 and 10.0 min at temperatures ranging from near 0° through 100°C. At the lower temperatures, some solutes were not sufficiently soluble to obtain the desired concentration; at higher temperatures, the desired concentration was obtained. The samples were not sealed but were analyzed immediately after anodizing.

Infrared analysis.—The samples were examined, as before, over the 4000-600 cm^{-1} range of the Beckman IR-7. The flat anodized sheets were mounted in the sample stage of a C.I.C. ATR-1 reflectance attachment at a 45° angle of incidence. Double beam spectra were obtained *vs.* a front-surfaced aluminized mirror which was mounted in an identical fashion as the sample.

Quantitative determinations were made using a weight-method of graphical integration. Checks showed that the total precision, using this method, was within ± 1.3%.

Results and Discussion

Infrared absorption bands were assigned to porous or barrier layers according to the results of previous studies (1, 3, 4). A summary of these background data is given below:

Alumina bond type	Infrared absorption frequency range (wavenumbers)
AlO ⟷ H stretch	3660-2940
Al <=> O stretch	1696-1345
Al ⟷ OH bend	1162-900
(Barrier layer 1000-900)	
Al ⟷ OAl stretch	Below 900

The 1470 cm^{-1} Al=O band is used as a measure of the apparent amount of porous layer obtained from the dicarboxylic electrolytes. This band has been found only in the porous layer and is well defined, whereas the Al-OAl band is broad and often extends below the 600 cm^{-1} limit of our instrument. The 1570 Al=O band was not used, since this may be altered by the degree of sorbed water.

We recognize that a one-to-one correlation has not been established between the Al=O absorbance and the amount of porous layer. Further, the concentration of this bond group may vary with the thickness of a porous layer. Pending further work, we will refer only to the amount of porous layer Al=O, or to the apparent amount of porous layer, and not to the amount of porous layer itself.

A band in the 1000 to 900 cm^{-1} region is due to absorption by the anodic barrier layer (1). Accordingly, its absorbance is used as a measure of the amount of barrier layer.

The coating thicknesses were generally too small to be measured by metallographic cross-sectional techniques and are therefore not included here.

Figures 1 through 8 show the results that were obtained on coatings produced in each electrolyte and over a range of anodizing temperatures. Peak voltages are included with the barrier layer data.

It is well accepted that electrolytes which do not dissolve alumina produce only barrier layer coatings. Electrolytes which can dissolve alumina may produce both barrier and porous coatings. If the dissolving action of the electrolyte is weak, the anodic oxidation of aluminum may be less efficient at low anodizing temperatures; with such electrolytes, successively thicker coatings may be obtained as the temperature is increased under otherwise identical conditions of current and time. However, at higher temperatures, the dis-

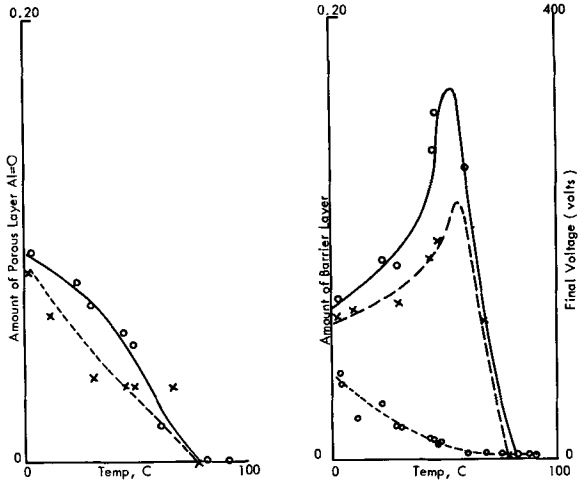

Fig. 1. Effect of anodizing temperatures on coating layers formed in oxalic acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, the amount of porous coating Al=O was greatest at low temperature. Increased anodizing time did not appear to change the amount obtained after 5 min of anodizing. The bond group did not form above 80°C. B (right), Barrier layer: Barrier layer trends; the barrier layer predominated at intermediate temperatures and reached a maximum amount near 60°C; above this temperature, it, too, ceased to form, and the metal then electropolished. —○—, 10-min anodize; — — ✕ — —, 5-min anodize; — — • — —, anodizing voltage.

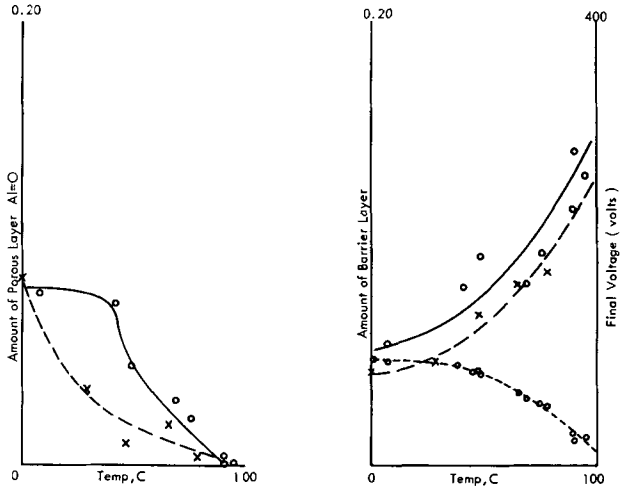

Fig. 2. Effect of anodizing temperatures on coating layers formed in malonic acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, the apparent amount of coating was greatest at low temperatures. The porous coating Al=O did not form above 90°C. (B) (right), Barrier layer: barrier layer trends, the barrier layer predominated and increased steadily in amount with increasing temperature. —⊖—, 10-min anodize; —✕—, 5-min anodize; — — ○ — —, anodizing voltage.

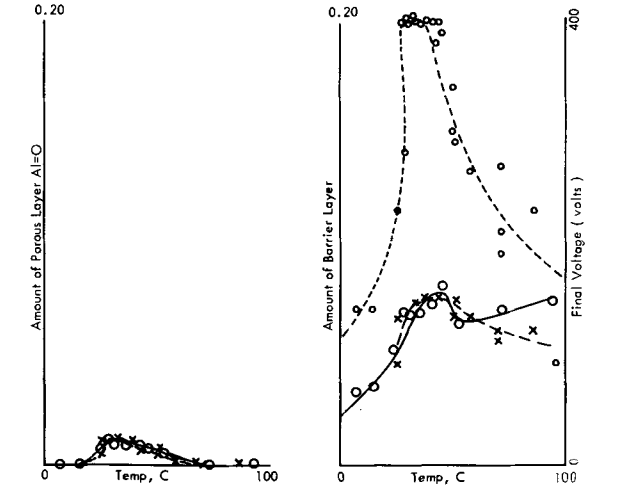

Fig. 3. Effect of anodizing temperatures on coating layers formed in succinic acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, the apparent coating formed only at mid-range temperatures and at high voltages. The coating did not form below 15°C nor above 60°C, and the amount of Al=O obtained did not change after the first 5 min of anodizing. B (right), Barrier layer: Barrier layer trends, the amounts of barrier layer showed maxima in the temperature region where a porous coating formed. —⊖—, 10-min anodize; —✕—, 5-min anodize; — — ○ — —, anodizing voltage.

solving action will predominate so that the porous layer is attacked (Fig. 1, 2, 3, 5, and 8). At still higher temperatures the porous layer, and thereafter the barrier layer, will dissolve; this sequence is demonstrated in Fig. 1 for the oxalic acid electrolyte.

Tartaric acid, Fig. 4, however appears to show two relationships between the dissolving rate and the formation rate of the coatings. We theorize that this behavior is due to the existence of two dissolving mechanisms with tartaric acid. Tartaric acid may form two distinct aluminum complexes: one which forms readily and a less-solubilizing complex that forms only at higher temperatures. The presence of such a dual complexing mechanism for tartaric and other polyhydroxy acids is well known (5).

Under such a system, thicker anodic coatings would be produced at successively higher anodizing temperatures until the dissolving action of the more readily

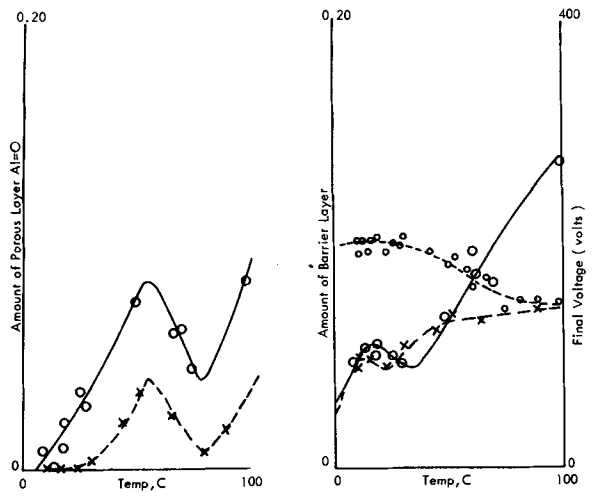

Fig. 4. Effect of anodizing temperatures on coating layers formed in tartaric acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, the amount of Al=O showed two temperature-dependent maxima: at 60°C and near 100°C. The amount obtained was also dependent on the anodizing time. B (right), Barrier layer: barrier layer trends, the barrier layer amount also exhibited two maxima that were temperature-dependent: at 20°C and near 100°C. An explanation for the occurrence of these dual maxima follows in this section. —⊖—, 10-min anodize; —✕—, 5-min anodize; — — ⊖ — —, anodizing voltage.

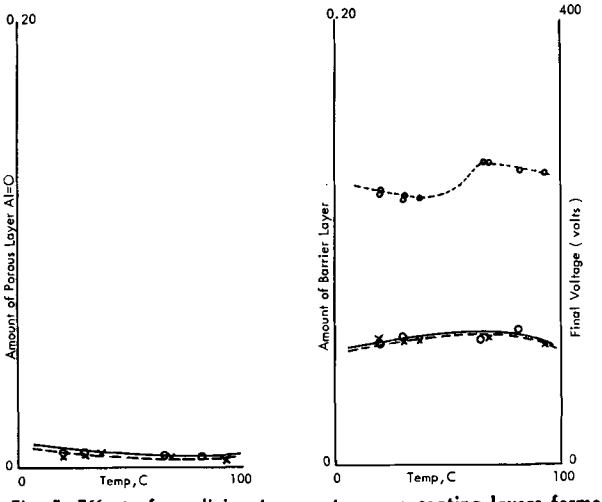

Fig. 5. Effect of anodizing temperatures on coating layers formed in ammonium tartrate; 0.2M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, a trace amount of Al=O was always present regardless of anodizing temperature or voltage. Anodizing beyond 5 min had no further effect on the total amount present. B (right), Barrier layer: barrier layer trends, the amount increased gradually with increasing temperature and went through a maximum of 80°C, afterwards decreasing slightly. —⊖—, 10-min anodize; —✕—, 5-min anodize; — — ⊖ — —, anodizing voltage.

formed aluminum tartrate complex approached the rate of aluminum oxidation. In this temperature region, thinner coatings would be formed. At still higher temperature, the first complex would revert to the weaker, less active form. This would result in a net decrease in the dissolving action of the solution, and the coating thickness would again increase with increasing temperature.

Further examination of these data revealed a peculiar trend for the anodic barrier layer. The trend was particularly well developed when the tartaric acid electrolyte was used; this electrolyte does not appear to exert a dissolving action on the barrier layer under the conditions employed here. Figure 9 shows that, when a porous coating was formed in conjunction with the barrier layer, the barrier layer infrared band tended to shift toward higher frequencies. A frequency

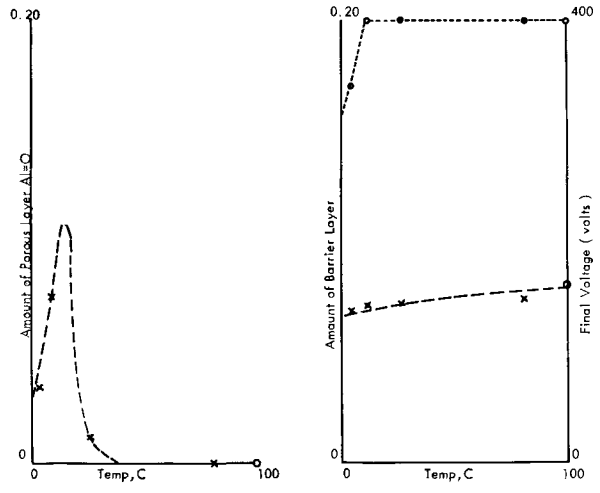

Fig. 6. Effect of anodizing temperatures on coating layers formed in fumaric acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, the apparent amount showed a sharp maximum near 15°C and rapidly decreased to an undetectable amount above 30°C; the porous coating Al=O did not form above 30°C. B (right), Barrier layer: barrier layer trends, the amount steadily increased with increasing temperature, from 0 to 100°C, the increase was uniform and without any apparent maximum. —⊖—, 10-min anodize; —✕—, 5-min anodize; ——⊖——, anodizing voltage.

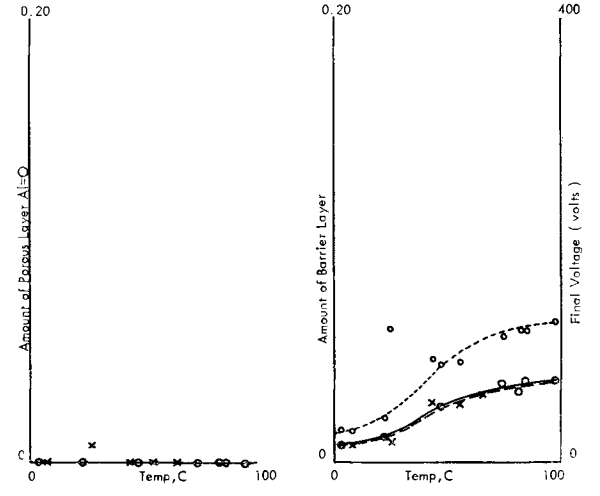

Fig. 7. Effect of anodizing temperatures on coating layers formed in glutaric acid; 0.6M at 1.08 amp/dm^2. A (left), Apparent porous layer: porous coating trends, no detectable Al=O formed during anodizing from 0 to 100°C. B (right), Barrier layer: barrier layer trends, the barrier layer amount increased with anodizing temperature; the increasing amount conformed well with increasing voltage increments. No change was detectable after the first 5 min of anodizing. —⊖—, 10-min anodize; —✕—, 5-min anodize; ——⊖——, anodizing voltage.

shift of this type normally corresponds to a reduction in polymer weight, indicating a breaking up of a high polymer to give a series of lesser polymers. This tendency appeared to be independent of the anodizing temperature and was influenced by increasing amounts of the porous layer Al=O bond.

We also found that coatings formed in chromic, oxalic, phosphoric, and sulfuric acids all show a similar relationship between porous layer Al=O absorbance and barrier layer wavenumber (1). Tartaric acid is the only example for which a complete set of data was available; previous data show the effect for the other acids, but the data are for two coating thicknesses and not for a uniformly increasing series of samples.

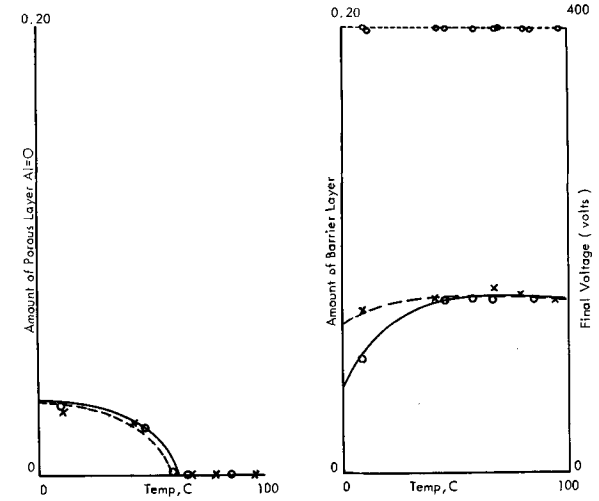

Fig. 8. Effect of anodizing temperatures on coating layers formed in adipic acid, 0.6M (current density could not be held constant at 1.08 amp/dm^2). A (left), Apparent porous layer: porous coating trends, the apparent amount decreased with increasing temperature and was not detectable above 60°C. B (right), Barrier layer: Barrier layer trends, the amount increased with increasing temperature and reached a plateau above 40°C. Effects of anodizing beyond the first 5 min were only apparent at temperatures below 40°C. —⊖—, 10-min anodize; —✕—, 5-min anodize; ——⊖——, anodizing voltage.

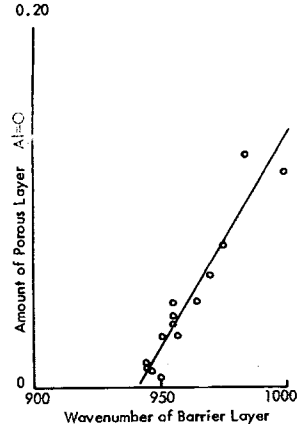

Fig. 9. Relationship between amount of porous layer and infrared positioning of barrier layer band: 0.6M tartaric acid; amount of porous layer *vs.* absorption wavenumber of barrier layer.

This effect was not evident if the amount of porous coating remained unchanged with increasingly higher temperatures or anodizing times. Moreover, coatings formed in barrier layer electrolytes did not show a shift in the wavenumber of the absorption band with increasing anodizing temperatures. We postulate from these observations that porous coatings are not formed from the barrier layer unless the surface of the barrier layer is first altered; this surface alteration appears to be a conversion of the barrier layer into a reactive hydrous alumina layer. Unless this surface layer, which we will call the "parent layer," is first formed, the barrier layer will apparently continue to grow without undergoing conversion to a porous overlayer.

This proposal of a two-phase barrier layer is consistent with earlier findings by Heine and Pryor (6), who found two regions of different high-frequency a-c resistance within an ammonium tartrate-anodized barrier layer. One such region lay next to the metal while the second region was about 90Å beyond the metal-oxide interface. Altenpohl, also, has reported two apparent sublayers within the anodic barrier layer (7); of the two, the innermost sublayer showed the least tendency to dissolve in chromic-phosphoric acid mixtures.

Conclusions

Quantitative infrared analyses of the barrier and porous layers, within the same anodic film, can be used to follow the effects of electrolyte temperature on the formation and dissolution of the coating. Acids which readily form stable complexes (here, oxalic or malonic) showed a high dissolving effect on the anodic film; the film was formed only at low temperatures, and it dissolved in the electrolyte at higher temperatures. Tartaric acid, a weaker complexing agent, required a higher temperature to produce a similar dissolving action; two dissolving mechanisms were apparent here. Other acids, which were not complexing agents under these conditions, produced only barrier layers.

We found, too, that the barrier layer apparently undergoes a change as the porous overlayer forms. The apparent polymer weight of the barrier layer decreases as the apparent amount of porous overlayer is increased.

Theory of Potentiostatic and Galvanostatic Charging of the Double Layer in Porous Electrodes[1]

F. A. Posey and T. Morozumi[2]

The Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

A theory of potentiostatic and galvanostatic transients which occur during charging of the double layer in porous electrodes is developed. Solutions are presented for transients due to charging processes in the interior of idealized, one-dimensional porous and tubular electrodes of finite length. In addition, the effect of IR drop which occurs in solution between the tip of the reference electrode capillary and the front surface of the porous electrode is calculated. The effect of the external surface of the electrode on the charging transients is also assessed. Solutions for charging transients are presented for the case of potentiostatic and galvanostatic single pulse methods, for measurements made with square waves of current or voltage, and for triangular current or voltage sweeps. The effect of the conductivity of the metallic phase on the observable transients is considered. Graphical solutions of the theoretical equations are presented.

Double layer capacity measurements provide an important means for the study of electrode systems. The capacity of the double layer is a function of the nature of the metallic phase, electrode potential, temperature, and composition of the solution. Double layer capacities reflect the presence of adsorbed substances at the interface, and for this reason capacity measurements may be useful for the study of processes occurring in porous electrodes of large surface area in which adsorption plays a significant role. This paper presents equations which may be used for analysis of potentiostatic and galvanostatic transients which occur during charging of the double layer in porous or tubular electrodes of finite length.

Galvanostatic charging transients of semi-infinite porous electrodes were first considered by Ksenzhek and Stender (1, 2) for the case of combined double layer charging and Faradaic reaction which was assumed to follow a linear polarization relation. These authors later used their formulas in studies on the properties of graphitized anodes in the electrolysis of aqueous chloride solutions (3, 4). Further treatments of Ksenzhek and Stender considered galvanostatic charging transients for combined double layer charging and Faradaic reaction for electrodes of finite length, as well as effects of the external surface of the electrode and of concentration polarization (5, 6). De Levie (7) derived potentiostatic and galvanostatic charging transients for semi-infinite porous electrodes in the absence of any Faradaic reaction. Similar relations and some other special cases of galvanostatic charging were developed by Bonnemay, Bronoël, Levart, Pilla, and d'Orsay (8). Various cases of the response of porous electrodes to alternating current were investigated by Ksenzhek and Stender (1-6), Winsel (9), DeLevie (7, 11), Feuillade (10), Coffre and Feuillade (12), and Vergnolle (13).

Equations are presented below for potentiostatic and galvanostatic charging transients of porous and tubular electrodes of finite length in the absence of appreciable Faradaic currents. Solutions are also given for potentiostatic and galvanostatic single pulse methods, for measurements made with square waves of current or voltage, and for triangular current or voltage sweeps. Complications due to the effect of IR drop in solution between the tip of the reference electrode capillary and the front surface of the electrode are considered. Effects of the external surfaces of the electrode and of the conductivity of the metallic phase upon the observable transients are also discussed. Graphical solutions of the theoretical equations, obtained by use of a high-speed digital computer, are presented.

Fundamental Relations

A schematic diagram of an idealized, one-dimensional porous or tubular electrode is shown in Fig. 1. The current density of the non-Faradaic process for charging of the double layer, $j(x,t)$, is related to the rate of change of interfacial potential difference by Eq. [1].

$$j(x,t) = C\frac{\partial\Delta\phi(x,t)}{\partial t} = C\frac{\partial\eta(x,t)}{\partial t} \qquad [1]$$

[2] Present address: Faculty of Engineering, Hokkaido University, Sapporo, Japan.

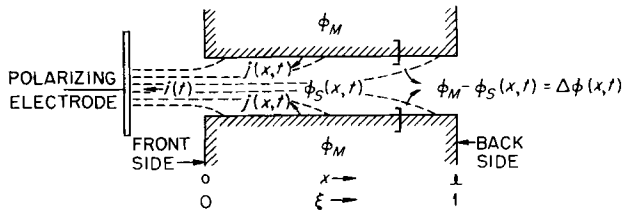

Fig. 1. Schematic diagram of idealized, one-dimensional porous electrode.

Here, C is the differential capacity (Farads/cm^2), $\Delta\phi(x,t) = \phi_M - \phi_S(x,t)$ is the potential difference between metal and solution phases, and $\eta(x,t)$ is the overpotential or change in interfacial potential difference [we assume in the usual case that $\eta(x,0) = 0$].

Because of the finite conductivity of the solution phase,[3] the passage of current introduces a gradient of $\eta(x,t)$ throughout the length of the pores. The fundamental differential equation governing the distribution of potential in porous electrodes was derived by Daniel'-Bek (14). This relation is given by Eq. [2] for the one-dimensional case, where x is the

$$\frac{\partial^2\eta(x,t)}{\partial x^2} = \frac{S}{\sigma A} j(x,t) \qquad [2]$$

length coordinate (cm), S is the internal surface area of the porous electrode per unit length (cm^2/cm), σ is the specific conductance of the solution (ohm^{-1} cm^{-1}), and A is the average cross-sectional area of the electrolyte in the electrode (cm^2).[4]

Combination of Eq. [1] and [2] and introduction of a dimensionless length, $\xi = x/l$, and of the time constant $\tau = SCl^2/\sigma A$ (sec), lead to Eq. [3]

$$\frac{\partial^2\eta(\xi,t)}{\partial\xi^2} = \tau\frac{\partial\eta(\xi,t)}{\partial t} \qquad [3]$$

which is the fundamental relation for charging of the double layer in one-dimensional porous electrodes.[3] The time constant may be expressed as the product of the resistance of the solution in the pores of the electrode, $R_o = l/\sigma A$, times the total differential capacity of the electrode, $C_T = SCl$; thus $\tau = R_oC_T$.

Solutions of Eq. [3] for a number of boundary conditions corresponding to potentiostatic and galvanostatic charging modes are presented below. These relations were obtained by use of the method of Laplace transforms (16, 17), and graphical solutions were computed by use of a high-speed digital computer.[5]

Galvanostatic Transients

Basic solution.—Boundary conditions for the solution of Eq. [3] when a constant current, $i(t) = i$ = constant, is applied to the electrode are given by

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=0} = -iR_o\,;\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = 0$$

The initial condition is simply $\eta(\xi,0) = 0$. Equation [4] gives the potential distribution in the electrode as a function of time.

$$\frac{\eta(\xi,t)}{iR_o} = \frac{t}{\tau} + \frac{2}{\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k^2}\cos[\pi k(1-\xi)]\,[1-\exp(-\pi^2k^2t/\tau)] \qquad [4]$$

Potential transients at various positions in the electrode, calculated from Eq. [4], are shown in Fig. 2. The directly observable potentials are $\eta(0,t)$ and $\eta(1,t)$, the potentials of the front and back sides of the electrode. The slope of the linear portion of the transients in Fig. 2 is given by $d\eta(0,t)/dt = d\eta(1,t)/dt = iR_o/\tau = i/C_T$. Relations for the intercepts (extrapolated) of the linear portions are shown in Fig. 2. The parameters R_o and C_T may be estimated from experimental transients by use of these relations. During the first moments after application of the current, $\eta(0,t)$ follows Eq. [5], a relation valid for semi-infinite

$$\frac{\eta(0,t)}{iR_o} = 2\,(t/\pi\tau)^{1/2} \qquad [5]$$

electrodes which was derived earlier by Ksenzhek and Stender (1, 2), Ksenzhek (5), de Levie (7), and Bonnemay *et al.* (8). The transient predicted by Eq. [5] is shown as the dotted line in Fig. 2; it holds well for finite electrodes for times less than about $t = \tau/3$.

Charging of the electrode occurs in a "wave," and a certain delay time is required for the charging current to penetrate to the back side of the electrode. This delay time may be obtained by extrapolation of the $\eta(1,t)$ transient back to its intersection with the time axis. Use of Eq. [4] then leads to t (delay) = $\tau/6$;

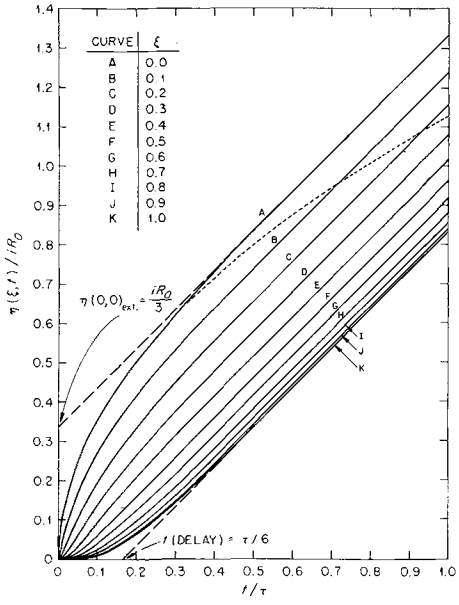

Fig. 2. Variation of potential with time during galvanostatic charging of finite porous electrode as a function of position.

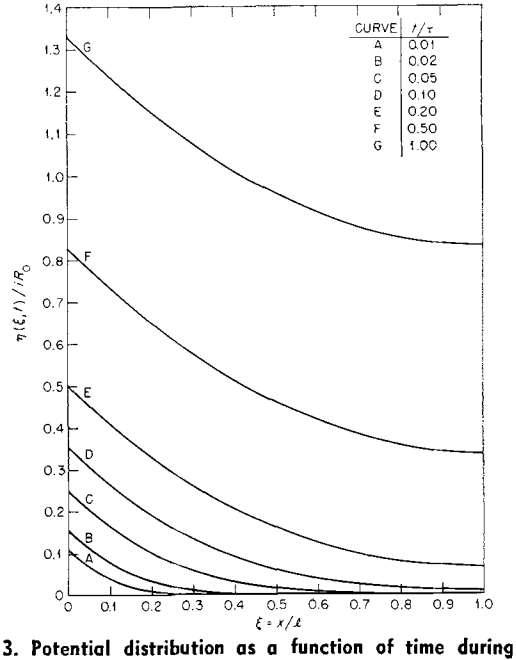

Fig. 3. Potential distribution as a function of time during galvanostatic charging of finite porous electrode.

[3] We assume for the most part that the resistivity of the metallic phase is essentially zero so that ϕ_M = constant. This restriction is relaxed below in considering cases where the conductivities of metallic and solution phases are comparable. We assume also that the differential capacity is independent of the potential. This assumption may limit strict applicability of the equations to small potential excursions in some cases.

[4] Equation [2] has been integrated for a number of important cases occurring in the operation of porous electrodes [see, for example, ref. (15)].

[5] Control Data Corporation Model 1604-A.

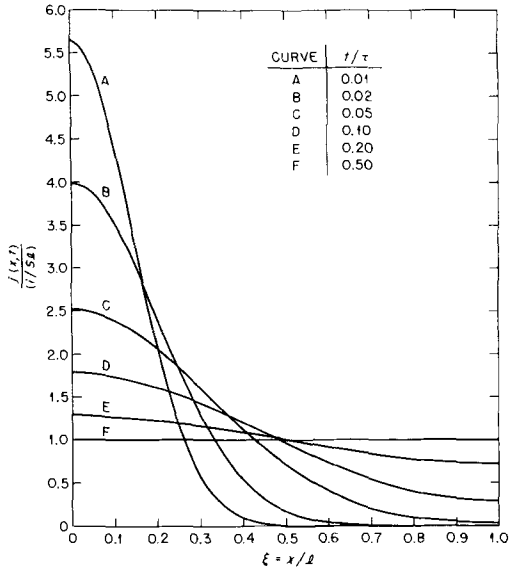

Fig. 4. Current density distribution as a function of time during galvanostatic charging of finite porous electrode.

the delay time is directly proportional to the differential capacity and to the square of the pore length since $\tau = SCl^2/\sigma A$. Figure 3 shows the potential distribution as a function of time; at the delay time the potential of the back side of the electrode [$\eta(1,t)$] begins to change significantly.

The current density distribution during the charging transient may be calculated by differentiation of Eq. [4] and use of Eq. [1]. Figure 4 shows how the current density distribution changes with time. For times greater than about $\tau/3$, the current density is constant throughout the length of the pores and all parts of the electrode change potential at the same rate (cf. Fig. 2). In this region of constant current density, the potential profile is parabolic and obeys Eq. [6]. It follows that the potential

$$\frac{\eta(0,t) - \eta(\xi,t)}{iR_o} = \xi(1 - \xi/2) \qquad [6]$$

difference between the front and back sides of the electrode for $t > \tau/3$ is simply related to the resistance of the electrolyte in the pores by the expression $[\eta(0,t) - \eta(1,t)]/i = R_o/2$. Both of the parameters R_o and C_T of the simple one-dimensional model may be estimated from experimental data by use of these relations, whereas only the ratio R_o/C_T may be obtained by use of Eq. [5] alone.

Effect of IR drop.—In the case where the tip of the reference electrode capillary is located between the front side of the porous electrode and the polarizing electrode (cf. Fig. 1), some IR drop is included in the measurement of the $\eta(0,t)$ transient. The measurable transient is then given by the relation $\eta_T(0,t) = \eta(0,t) + iR_{REF}$, where $\eta_T(0,t)$ is the potential transient measured with respect to the reference electrode, R_{REF} is the solution resistance between the tip of the reference capillary and the front side of the electrode ($\xi = 0$), and $\eta(0,t)$ is obtained from Eq. [4]. In the case of a reference electrode located at the back side of the electrode ($\xi = 1$), the $\eta(1,t)$ transient and the delay time are unchanged.

Single pulse.—For the case where a single galvanostatic pulse of current, i, is applied to the finite electrode for a time, t_o, the potential distribution during the pulse up to the time t_o is given by Eq. [4]. After the current is switched off, a type of relaxation process occurs and the potential of the electrode becomes uniform throughout the length of the pores. The initial condition for the relaxation transient is given by Eq. [4] with $t = t_o$. Appropriate boundary conditions are

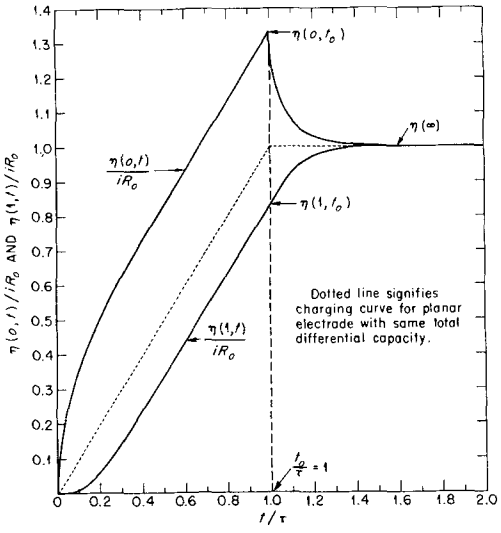

Fig. 5. Variation of potential with time during galvanostatic charging of finite porous electrode with single pulse.

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\substack{\xi=0\\ t>t_o}} = \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\substack{\xi=1\\ t>t_o}} = 0$$

The corresponding solution of Eq. [3] for the potential distribution during the relaxation transient is given by Eq. [7]. The current density distribution

$$\frac{\eta(\xi,t)}{iR_o} = \frac{t_o}{\tau} + \frac{2}{\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k^2}\cos[\pi k(1-\xi)][\exp(\pi^2k^2t_o/\tau)-1]\exp(-\pi^2k^2t/\tau) \qquad [7]$$

may be calculated from Eq. [1] and [7]. Figure 5 shows a graph of the charging transient for the case, $t_o = \tau$. The dotted line is the charging curve of a planar electrode having the same total differential capacity as the porous electrode. Up to $t = t_o$, the $\eta(0,t)$ and $\eta(1,t)$ transients are the same as those shown in Fig. 2; for $t > t_o$, the relaxation transients are described by the appropriate cases of Eq. [7].

The single pulse galvanostatic method provides a very simple way of determining C_T for finite porous electrodes when Faradaic currents are negligible. For $t >> t_o$, Eq. [7] approaches the limit t_o/τ, so that C_T is easily calculable from the relation, $C_T = i\,t_o/\eta(\infty)$, where $\eta(\infty)$ is the final change in potential produced by the current pulse. For t_o greater than about $\tau/3$, the final potential, $\eta(\infty) = \eta(0,\infty) = \eta(1,\infty)$, bears a definite relation to the potentials exhibited by the electrode at t_o [$\eta(0,t_o)$ and $\eta(1,t_o)$]; this relation is given by Eq. [8]. For t_o less than about $\tau/3$, Eq. [8]

$$\frac{\eta(\infty)-\eta(1,t_o)}{\eta(0,t_o)-\eta(1,t_o)} = 1/3 \qquad [8]$$

is no longer valid, and the value of the ratio lies between 0 and 1/3.

Square wave.—Application of a symmetrical square wave of current to a finite porous electrode produces a symmetrical potential wave which may conveniently be displayed on an oscilloscope or other recording device. The square wave of current may be expressed as

$$i(t) = (-1)^{(n-1)}\,i$$

where

$$\frac{(n-1)}{2}T \leqq t < \frac{n}{2}T$$

where T is the period of the square wave and n the number of half cycles applied at time t ($n = 1, 2, 3, \ldots$). The value of the current $i(t)$ therefore alternates between $+\,i$ and $-\,i$. Initial and boundary conditions are the same as those for the basic solution, and the expression for the potential transient is the same as Eq. [4] when the right-hand side of this

equation is multiplied by the factor, $(-1)^{(n-1)}$. The amplitudes of the potential excursions are given by Eq. [9] and [10]. When $T << \tau$,

$$\frac{\eta(0,T/2) - \eta(0,T)}{iR_o} = \frac{T}{\tau} + \frac{2}{3} - \frac{4}{\pi^2}\sum_{k=1}^{\infty}\frac{1}{k^2}\exp(-\pi^2k^2T/2\tau) \quad [9]$$

$$\frac{\eta(1,T/2) - \eta(1,T)}{iR_o} = \frac{T}{\tau} - \frac{1}{3} - \frac{4}{\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k^2}\exp(-\pi^2k^2T/2\tau) \quad [10]$$

the amplitude of the potential wave is related to the time constant (τ) by Eq. [11]. Since $\tau = R_oC_T$, measurements with frequencies much higher than

$$\frac{\eta(0,T/2) - \eta(0,T)}{iR_o} = [\sqrt{2}\,(1+\sqrt{2})](T/\pi\tau)^{1/2} \quad [11]$$

$1/\tau$ yield information only about the ratio, R_o/C_T. When $T >> \tau$, the summed terms in Eq. [9] and [10] approach zero, so that C_T could be estimated from measurements at frequencies considerably lower than $1/\tau$.

Triangular wave.—Solution of Eq. [3] for the case of application of a triangular wave of current to the finite porous electrode makes use of the same initial and boundary conditions as those for the basic solution. The current wave may be expressed as:

$$i(t) = \mu t \qquad (0 \leqq t < T/2)$$
$$i(t) = \mu(T-t) \qquad (T/2 \leqq t < T)$$

where μ (amp/sec) is the constant rate of change of applied current and T is the period of the triangular current wave. As in the case of the square wave, the low- and high-frequency solutions are of most immediate applicability. For $T << \tau$, the maximum potential excursion of the front side of the electrode is given by Eq. [12], and only the ratio R_o/C_T

$$\frac{\eta(0,T/2)}{i(T/2)R_o} = (2/3)(2T/\pi\tau)^{1/2} \quad [12]$$

can be determined at high frequencies. For low frequencies ($T >> \tau$) of the triangular wave, Eq. [13]

$$\frac{\eta(0,T/2)}{i(T/2)R_o} = T/4\tau \quad [13]$$

gives the maximum potential excursion. Low-frequency triangular waves therefore permit a direct estimation of C_T, the total differential capacity of the porous electrode.

Effect of external surface.—The galvanostatic charging transient of a finite porous electrode may be affected considerably by the external surfaces of the electrode provided the external surface area is comparable to the internal surface area.[6] Part of the total current (i) applied to an electrode is used to charge the front surface, part is involved in charging the interior surface of the electrode, and part charges the back surface. The fraction of the total current involved in each charging process depends on the electrode parameters and on the time. The total current may be divided into three parts, $i = i_F(t) + i_I(t) + i_B(t)$, where $i_F(t)$ is the current used in charging the front surface, $i_I(t)$ is the current involved in charging the interior surface, and $i_B(t)$ is the current which charges the back surface of the electrode. If $\alpha = A_M/Sl$ is the ratio of the front (or back) surface area (A_M) to the interior surface area of the electrode (Sl), the rates of change of $\eta(0,t)$ and $\eta(1,t)$ may be expressed by Eq. [14] and [15]. Equation [3] may be solved subject to the constraints imposed

$$\frac{\partial\eta(0,t)}{\partial t} = \frac{i_F(t)}{A_MC} = \frac{i_F(t)R_o}{\alpha\tau} \quad [14]$$

[6] Internal surface areas of most real porous electrodes are very large compared to their external surface areas. However, the relations derived in this section and in a later section on the potentiostatic charging transient may be useful in analysis of charging curves of very thin porous electrodes or of finely perforated planar electrodes.

$$\frac{\partial\eta(1,t)}{\partial t} = \frac{i_B(t)}{A_MC} = \frac{i_B(t)R_o}{\alpha\tau} \quad [15]$$

by Eq. [14] and [15] by use of the initial condition, $\eta(\xi,0) = 0$, and the boundary conditions

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=0} = -[i_1(t) + i_B(t)]R_o;$$
$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = -i_B(t)R_o$$

The potential distribution in the electrode is given as a function of time and of the area ratio (α) by Eq. [16]. Values of the index m

$$\frac{\eta(\xi,t)}{iR_o} = \frac{t/\tau}{(1+2\alpha)} + 2\sum_m \frac{\alpha m\sin[m(1-\xi)] - \cos[m(1-\xi)]}{m^2\Delta(m)}[1-\exp(-m^2t/\tau)] \quad [16]$$

where

$$\Delta(m) = 2m\,\alpha(1+\alpha)\sin(m) - (1+2\,\alpha-\alpha^2m^2)\cos(m)$$

are the positive roots of the auxiliary equation $\tan(m) = 2\,\alpha m/(\alpha^2m^2-1)$. Equation [16] reduces to Eq. [4] for $\alpha = 0$. An increase of the area ratio α reduces the slope of the transients in the region where $\eta(0,t)$ and $\eta(1,t)$ change linearly with time; this slope is simply equal to $1/(1+2\alpha)$ according to Eq. [16]. The intercept obtained by extrapolation of the linear part of the $\eta(0,t)$ curve back to $t = 0$ decreases with increasing α, and the delay time increases with increasing α. Figure 6 shows how the $\eta(0,t)/iR_o$ intercept and the delay time change with the value of α. For small external areas, the $\eta(0,t)/iR_o$ intercept is equal to 1/3 and the delay time is given by t (delay) $= \tau/6$. For large external areas (α greater than about 10), the $\eta(0,t)/iR_o$ intercept approaches the value ¼, and the delay time becomes proportional to α according to the relation t (delay) $= \alpha\tau/2$.

Essentially all the current is concerned with charging of the front surface of the electrode during the initial part of the transient. During the first moments $\eta(0,t)$ changes linearly with time according to $\eta(0,t)/iR_o = t/\alpha\tau$ as implied by Eq. [14]. With time, the interior of the electrode is charged and $\eta(0,t)$ may vary according to Eq. [5]. Finally the current begins to penetrate to the back side of the electrode. For $t >> t$ (delay), the current is distributed according to the ratio of areas.

Effect of conductivity of metallic phase.—Galvanostatic charging transients of finite porous electrodes differ from the predictions of Eq. [4] if the conductivity of the metallic phase is comparable to that of the liquid phase. The expected charging transient for this case may be derived by use of a modification of the basic model shown in Fig. 1. The potential of the metallic phase, $\phi_M(\xi,t)$, is no longer constant in the x direction, so that the interfacial potential difference is given by

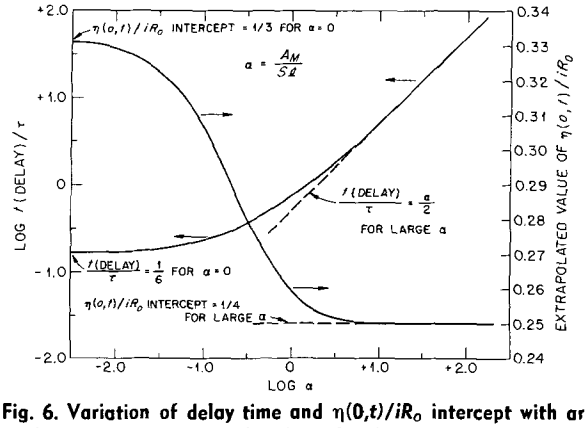

Fig. 6. Variation of delay time and $\eta(0,t)/iR_o$ intercept with area ratio (α) for galvanostatic charging of finite porous electrode.

$\Delta\phi(\xi,t) = \phi_M(\xi,t) - \phi_S(\xi,t)$. If A_T is the total cross-sectional area of the electrode, A_M is the cross-sectional area of the metallic phase, A is the cross-sectional area of electrolyte as before, κ is the specific conductance of the metallic phase, and σ is the specific conductance of the electrolyte phase as before, then the porosity (f) is given by $f = A/A_T$ and Eq. [3] becomes Eq. [17]. the new

$$\frac{\partial^2\eta(\xi,t)}{\partial\xi^2} = \tau'\frac{\partial\eta(\xi,t)}{\partial t} \qquad [17]$$

where:

$$\tau' = \frac{SCl^2}{A_T}\left[\frac{\sigma f + \kappa(1-f)}{\sigma\kappa f(1-f)}\right]$$

time constant, τ', can be set equal to $C_T(R_M + R_o)$, where $C_T = SCl$ and $R_o = l/\sigma A_T$ have the same significance as before and $R_M = l/\kappa A_T(1-f)$ is the resistance of the metallic phase in the x direction. When R_M approaches zero, τ' approaches τ of the basic solution.

The electrical lead to the porous electrode is assumed to be attached at $x = l$ (or $\xi = 1$), so that ϕ_M varies only in the x direction. Boundary conditions for this case are:

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=0} = -i\,R_o; \quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = +i\,R_M$$

Solution of Eq. [17] with these boundary conditions and the initial condition $\eta(\xi,0) = 0$ leads to the potential distribution of Eq. [18],

$$\frac{\eta(\xi,t)}{i\,R_o} = (1+\gamma)\frac{t}{\tau'} + \frac{2}{\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k^2}\{\gamma\cos[\pi k\xi] + \cos[\pi k(1-\xi)]\}[1-\exp(-\pi^2k^2t/\tau')] \qquad [18]$$

where γ is the ratio of the resistance of the metallic phase to that of the solution phase ($\gamma = R_M/R_o$). For $\gamma = 0$, Eq. [18] reduces to Eq. [4].

The potential-time characteristics, $\eta(0,t)/i\,R_o$ and $\eta(1,t)/i\,R_o$, are similar in form to those shown in Fig. 2, except that the slopes and intercepts of the linear regions of the transients depend on the value of γ. The $\eta(0,t)/i\,R_o$ intercept is given by $1/3 - \gamma/6$, and the delay time for propagation of the current to $\xi = 1$ is given by

$$\frac{t(\text{delay})}{\tau'} = \frac{1}{(1+\gamma)}\left(\frac{1}{6} - \frac{\gamma}{3}\right)$$

For sufficiently large values of $\gamma = R_M/R_o$, the back side of the electrode is charged up before the front side. This fact accounts for the negative delay times predicted for the $\eta(1,t)$ transient for large γ. On the basis of Eq. [18], one can derive the symmetry relation, $\eta(\xi,t,\gamma) = \gamma\cdot\eta(1-\xi,t,1/\gamma)$. This expression may be useful for visualizing the effect of γ on the observable transients. The difference between the front side and back side potentials in the linear region of the charging transient is also affected by the resistance ratio γ. Use of Eq. [18] for this region leads to $[\eta(0,t) - \eta(1,t)]/i = R_o(1-\gamma)/2$. Therefore γ may be calculated provided R_o is known. For sufficiently large γ, this potential difference is given by $[\eta(1,t) - \eta(0,t)]/i = R_M/2$. Under the same conditions, the potential of the back side changes in the initial moments according to $\eta(1,t)/i\,R_o = 2\gamma(t/\pi\tau')^{1/2}$.

Potentiostatic Transients

Basic solution.—Boundary conditions for the solution of Eq. [3] when the potential of the front side of a finite porous electrode is suddenly changed to the value η_o are

$$\eta(0,t) = \eta_o; \quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = 0$$

As before, the initial condition is $\eta(\xi,0) = 0$. The resulting potential distribution is given by Eq. [19], where all quantities have their previously

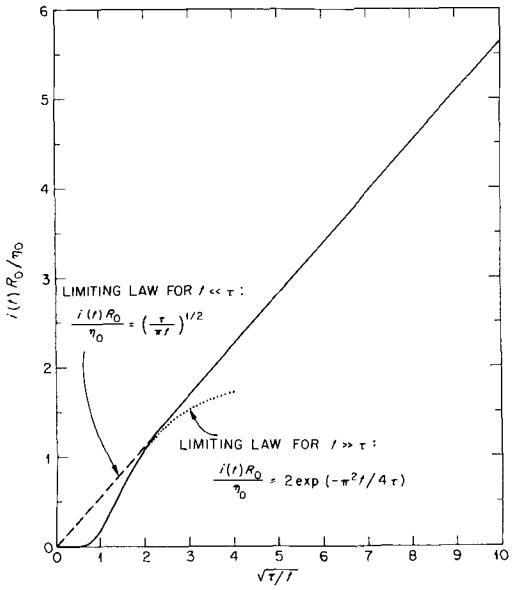

Fig. 7. Variation of current with time during potentiostatic charging of finite porous electrode.

$$\frac{\eta(\xi,t)}{\eta_o} = 1 - \frac{2}{\pi}\sum_{k=0}^{\infty}\frac{(-1)^k}{(k+\frac{1}{2})}\cos[(k+\tfrac{1}{2})\pi(1-\xi)]\exp[-(k+\tfrac{1}{2})^2\pi^2t/\tau] \qquad [19]$$

defined significance. The observable current transient may be obtained by differentiation of Eq. [19] with use of the relation

$$i(t) = -\frac{1}{R_o}\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=0}$$

This result is given in Eq. [20]. Figure 7 shows the current transient

$$\frac{i(t)R_o}{\eta_o} = 2\sum_{k=0}^{\infty}\exp[-(k+\tfrac{1}{2})^2\pi^2t/\tau] \qquad [20]$$

plotted against reciprocal square root of time. For $t << \tau$, this type of plot is linear. Equation [21] gives the relation followed during this period

$$\frac{i(t)R_o}{\eta_o} = (\tau/\pi t)^{1/2} \qquad [21]$$

(cf. dashed line in Fig. 7); it was derived previously by de Levie (7) for the case of potentiostatic charging of semi-infinite electrodes. For $t >> \tau$, the current decreases according to $i(t)R_o/\eta_o = 2\exp(-\pi^2t/4\tau)$; this limiting law is shown as the dotted line in Fig. 7.

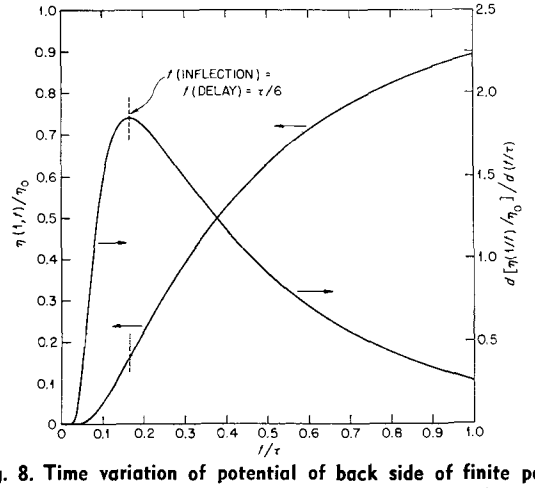

Fig. 8. Time variation of potential of back side of finite porous electrode and its time derivative during potentiostatic charging of the double layer.

The slope of such a plot of current against reciprocal square root of time enables one to estimate the value of the ratio C_T/R_o by use of Eq. [21].

Charging of the electrode occurs in a "wave," just as in the case of galvanostatic charging. The current density distribution may be obtained by differentiation of Eq. [19] with use of Eq. [1]. As in the case of galvanostatic charging, a certain delay time is required for the current to penetrate to the back side of the electrode. Figure 8 shows how $\eta(1,t)$, the potential of the back side, varies with time. The delay time may be identified with the inflection in this curve. Figure 8 also shows how the time derivative of $\eta(1,t)$, which has a maximum at the time of inflection or the delay time, changes with time. The delay time is given by $t(\text{delay}) = t(\text{inflection}) = \tau/6$, just as for galvanostatic charging. The delay time may be determined experimentally by use of a differentiating circuit for the measurement of $\eta(1,t)$. A knowledge of the delay time, together with the slope of the plot of current against reciprocal square root of time (cf. Fig. 7), allows estimates to be made of both R_o and C_T from an experimental transient.

Effect of IR drop.—When the resistance between the tip of the reference electrode and the front surface of the porous electrode (R_{REF}) is considered, boundary conditions for the solution of Eq. [3] become

$$\eta(0,t) = \eta_o - i(t)R_o; \quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = 0$$

The potential distribution in this case is given by Eq. [22], where values

$$\frac{\eta(\xi,t)}{\eta_o} = 1 - 2\sum_m \frac{\cos[m(1-\xi)]\exp(-m^2t/\tau)}{m[(1+\rho)\sin(m) + \rho m\cos(m)]} \quad [22]$$

of the index m are the positive roots of $m\tan(m) = 1/\rho$. The resistance ratio ρ is equal to R_{REF}/R_o. When $\rho = 0$, Eq. [22] reduces to Eq. [19]. The observable current transient is given by Eq. [23]; this equation was used

$$\frac{i(t)\,R_o}{\eta_o} = 2\sum_m \frac{\sin(m)\exp(-m^2t/\tau)}{(1+\rho)\sin(m) + \rho m\cos(m)} \quad [23]$$

to calculate the results in Fig. 9, which depicts the effect of ρ on potentiostatic charging transients. For large values of ρ, a long time may be required for

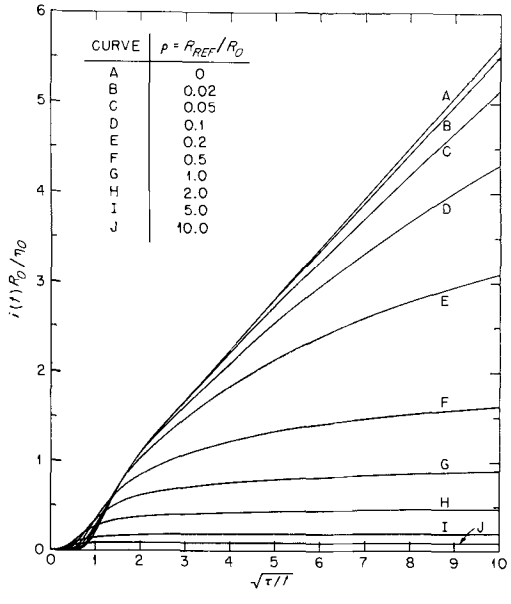

Fig. 9. Effect of R_{REF} on variation of current with time during potentiostatic charging of finite porous electrode.

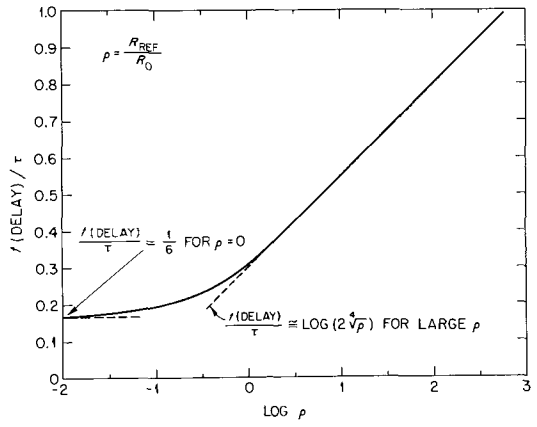

Fig. 10. Effect of R_{REF} on delay time for potentiostatic charging of finite porous electrode.

$\eta(0,t)$ to reach the value η_o; during this time charging of the electrode occurs essentially at constant current. For intermediate values of ρ, nonlinear plots of current against reciprocal square root of time will be obtained. Potentiostatic charging transients are therefore most easily interpreted if R_{REF} is kept small compared to R_o.

The current limitation imposed on the potentiostatic charging transient by large values of ρ affects the delay time for propagation of the charging "wave" through the electrode. Figure 10 shows how the delay time varies with ρ and gives limiting expressions for the delay time. If ρ can be estimated, then τ can be obtained from the curve in Fig. 10 if transients of the form shown in Fig. 9 are observed experimentally.

Single pulse.—If a potentiostatic pulse of magnitude η_o is applied to the front side of a porous electrode for a time t_o, then the current transient up to the time t_o is given by Eq. [20]. Equation [3] may be solved for the transient in the region $t > t_o$ by use of the following boundary conditions

$$\eta(0,t) = 0; \quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = 0$$

At the time t_o the potential distribution is given by Eq. [19] with $t = t_o$. Equation [24] gives the current transient for $t \geqq t_o$. If η_o is positive, the

$$\frac{i(t)\,R_o}{\eta_o} = 2\sum_{k=0}^{\infty}\exp[-(k+\tfrac{1}{2})^2\pi^2t/\tau] - 2\sum_{k=0}^{\infty}\exp[-(k+\tfrac{1}{2})^2\pi^2(t-t_o)/\tau] \quad [24]$$

current of Eq. [24] is negative for $t > t_o$. For $t_o << \tau$, the value of the current at the time t_o, $i(t_o)$, is given approximately by Eq. [21] with $t = t_o$. This relation may be used to estimate the ratio C_T/R_o from potentiostatic measurements with short single pulses.

Square wave.—If the potential of the front side of a porous electrode is forced to alternate between the values $+\eta_o$ and $-\eta_o$ by use of a potentiostat which supplies a symmetrical square wave of potential to the electrode, the boundary conditions for the solution of Eq. [3] are

$$\eta(0,t) = (-1)^{(n-1)}\eta_o; \quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = 0$$

where $(n-1)T/2 \leqq t < nT/2$ and T is the period of the square wave ($n = 1, 2, 3, \ldots$). The corresponding current transient is given by Eq. [20] when the right-hand side of the equation is multiplied by the

factor, $(-1)^{(n-1)}$. For $T << \tau$, the difference between the amplitudes of the current transient at $t = T/2$ and at $t = T$ is given by Eq. [25]. This relation may be used to

$$\frac{[i(T/2) - i(T)]\,R_o}{\eta_o} = (1 + \sqrt{2})\,(\tau/\pi T)^{1/2} \quad [25]$$

estimate the parameter τ from potentiostatic measurements with square waves of frequency higher than $1/\tau$.

Triangular wave.—For the case where the potential of the front side of a porous electrode is forced to follow a triangular wave, the potential excursion may be expressed by

$$\eta(0,t) = \frac{2\Delta\eta}{T}\,t \qquad (0 \leqq t < T/2)$$

$$\eta(0,t) = \frac{2\Delta\eta}{T}\,(T - t) \qquad (t/2 \leqq t < T)$$

where $\Delta\eta$ is the amplitude, and T is the period of the triangular potential wave. The initial condition and the boundary condition at $\xi = 1$ are the same as those used above. Equation [26] gives the resulting current transient

$$\frac{i(t)R_o}{\Delta\eta} = (-1)^{(n-1)}\frac{2\tau}{T}$$

$$\left[1 - \frac{2}{\pi^2}\sum_{k=0}^{\infty}\frac{1}{(k+1/2)^2}\exp\{-\pi^2(k+1/2)^2 t/\tau\}\right] \quad [26]$$

where $(n-1)T/2 \leqq t < nT/2$ with $n = 1, 2, 3, \ldots$. For $T << \tau$, the amplitude of the current transient is given by Eq. [27], which may be used

$$\frac{i(T/2)R_o}{\Delta\eta} = (\tau/\pi T)^{1/2} \quad [27]$$

to estimate τ when triangular waves of frequency higher than $1/\tau$ are used. For $T >> \tau$, the electrode is charged very slowly and the summed terms in Eq. [26] may be neglected at large T. The current amplitude in this case is given simply by $i(T/2)\,R_o/\Delta\eta = 2\tau/T$, and C_T may be estimated directly from this relation.

Effect of external surface.—Potentiostatic charging transients of porous electrodes may be affected by the external surfaces of the electrode.[6] Although the front surface of the electrode is charged very quickly by the potentiostat, time is required before the interior and back surfaces of the electrode are charged up to the potential of the front side ($\eta(0,t) = \eta_o$). The total current during the transient may be divided into two parts, $i(t) = i_I(t) + i_B(t)$, where $i_I(t)$ is the current used for charging the interior surface, and $i_B(t)$ charges the back surface of the electrode. If $\alpha = A_M/Sl$ is the ratio of the back (or front) surface area (A_M) to the interior area of the electrode (Sl), the rate of change of $\eta(1,t)$ is the same as that in Eq. [15] for the case of galvanostatic charging. The current transient may be obtained by integration of Eq. [3] together with the constraint of Eq. [15] and the following boundary condition

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = -\,i_B(t)\,R_o$$

Integration leads to the current transient of Eq. [28], where values of

$$\frac{i(t)R_o}{\eta_o} = 2\sum_m \frac{\sin(m) + \alpha m\cos(m)}{(1+\alpha)\sin(m) + \alpha m\cos(m)}\exp(-m^2 t/\tau) \quad [28]$$

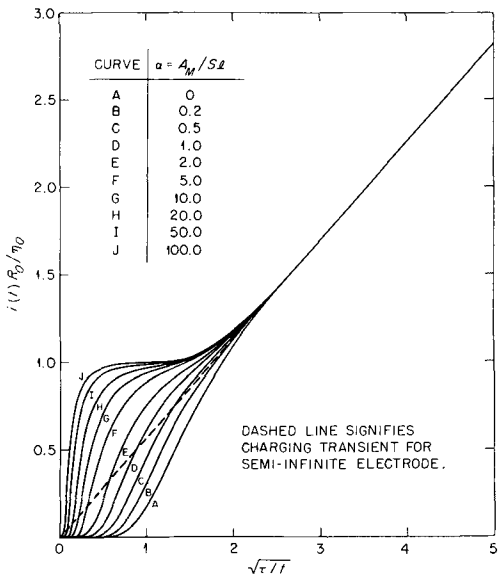

Fig. 11. Effect of external surface of the electrode on the variation of current with time during potentiostatic charging of finite porous electrode.

the index m are the positive roots of $m\tan(m) = 1/\alpha$. For $\alpha = 0$, Eq. [28] reduces to Eq. [20].

Current transients corresponding to Eq. [28] are plotted in Fig. 11 as a function of the area ratio α. Additional current is required to charge the back side of the electrode compared to the basic potentiostatic charging transient (cf. Fig. 7). For large values of α, a limiting current is observed. In this region, $i(t)/\eta_o \cong R_o$ and considerable time may be required before $\eta(1,t)$ begins to change significantly. Therefore, potentiostatic charging of the back side of an electrode with a large external surface takes place by essentially a galvanostatic process; the current available for charging the back side is determined by the potential change on the front side (η_o) and by the properties of the pore system expressed by the quantity R_o. For times less than about $\tau/10$, essentially all the current is used in charging the interior of the electrode. For times greater than about $\tau/2$, the current ratio $i_I(t)/i_B(t)$ is essentially constant with time and depends on the value of the area ratio α.

Effect of conductivity of metallic phase.—The model used above to derive the galvanostatic charging transient of a porous electrode when the conductivity of both the metallic and the electrolyte phases are comparable may also be used to derive the corresponding potentiostatic charging transient. In this case, Eq. [17] is solved subject to the constraint, $\eta(0,t) = \eta_o$, and the following boundary conditions

$$\left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=0} = -\,i(t)\,R_o\,;\quad \left(\frac{\partial\eta(\xi,t)}{\partial\xi}\right)_{\xi=1} = +\,i(t)\,R_M$$

The potential distribution is given by Eq. [29], where values of the index

$$\frac{\eta(\xi,t)}{\eta_o} = 1 - 2\sum_m \frac{\gamma\cos(m\xi) + \cos[m(1-\xi)]}{m\sin(m)}\exp(-m^2 t/\tau') \quad [29]$$

m are the positive roots of $m = \cos^{-1}(-\gamma)$. As before, $\gamma = R_M/R_o = \sigma f/\kappa(1-f)$ is the ratio of the resistance of the metallic phase [$R_M = l/\kappa A_T\,(1-f)$] to the resistance of the solution phase ($R_o = l/\sigma A_T f$). Equation [29] reduces to Eq. [19] when $\gamma = 0$. The value of γ can be determined quite simply by measuring the sudden change in the potential of the back side of the electrode when the potential of the front

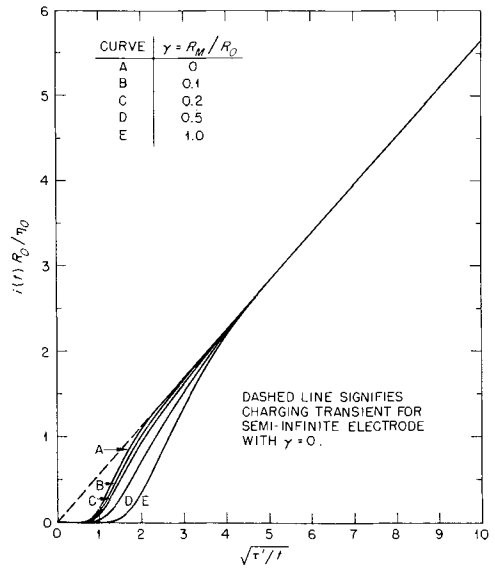

Fig. 12. Effect of resistance of metallic phase on variation of current with time during potentiostatic charging of finite porous electrode.

side is changed potentiostatically by the amount η_o. Thus $\gamma = \eta(1,0)/\eta_o$.

Differentiation of Eq. [29] and use of the boundary conditions at $\xi = 0$ lead to Eq. [30] for the observable current transient. Equation [30]

$$\frac{i(t)R_o}{\eta_o} = 2\sum_m \exp(-m^2t/\tau') \qquad [30]$$

reduces to Eq. [20] for $\gamma = 0$. Figure 12 shows the effect of the resistance ratio γ on the observable current transient. Solutions of Eq. [29] and [30] exist only when the resistance ratio lies in the range $0 \leqq \gamma \leqq 1$. In the limiting case when $\gamma = 1$, the potentials of both front and back sides of the electrode immediately attain the value η_o at the start of the charging transient. For values of γ greater than unity, the potentiostatic constraint $\eta(0,t) = \eta_o$ cannot be fulfilled; in this case most of the charging current crosses the interface near $\xi = 1$, and the potential of the front side of the electrode cannot be polarized to η_o by use of a normal potentiostatic configuration.

Summary

Solutions to a number of boundary value problems occurring in the theory of potentiostatic and galvanostatic charging of porous or tubular electrodes of finite length are presented above. Charging of the double layer is assumed to be the only interfacial process of significance; Faradaic reactions are not considered. Experimental transients obtained on systems which reasonably satisfy these stipulations may be analyzed by use of the appropriate relations to yield values of R_o and C_T, the resistance of the electrolyte phase and the total differential capacity of the electrode. Complications may arise in the interpretation of the charging transients because of IR drop in solution between the front surface of the electrode and the tip of the reference electrode capillary, because of charging processes on the external surfaces of the electrode, and because of a limited conductivity of the metallic phase. The forms of the charging transients in these cases are sufficiently different from the basic charging transients so that in favorable instances some information may also be obtained about the complicating parameters. Real porous electrodes have intricate geometries and the parameters of the simple, one-dimensional model used here should be regarded as averages which may nevertheless be useful for the study of porous electrodes.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

SYMBOLS

A	Cross-sectional area of electrolyte in porous or tubular electrode, cm^2
A_M	Cross-sectional area of metallic phase (also area of front or back surface of electrode), cm^2
A_T	$A_T = A + A_M$; total cross-sectional area of porous electrode, cm^2
C	Differential capacity, Farad/cm^2
C_T	$C_T = SCl$; total differential capacity of electrode, Farad.
f	$f = A/A_T$; porosity of porous electrode
$i, i(t)$	Total current applied to porous electrode, amp
$i_F(t)$	Current used to charge front surface of electrode, amp
$i_I(t)$	Current used to charge interior surface of electrode, amp
$i_B(t)$	Current used to charge back surface of electrode, amp
$j(x,t)$, $j(\xi,t)$	Current density used to charge double layer (non-Faradaic), amp
k	Summation index
l	Pore length, cm
m	Positive roots of auxiliary equations (cf. Eq. [16], [22], [28], and [29].
n	Number of half-cycles of square wave of current or voltage applied to electrode or of transients observed at time t.
R_M	$R_M = l/\kappa A_M = l/\kappa A_T(1-f)$, resistance of metallic phase, ohms
R_o	$R_o = l/\sigma A = l/\sigma A_T f$; resistance of electrolyte phase, ohms
R_{REF}	Resistance of electrolyte between front surface of porous electrode and tip of reference electrode capillary, ohms
S	Interior surface area of porous electrode per unit length, cm
t	Time, sec
t_o	Time of application of single current or voltage pulse, sec
T	Period of square or triangular wave of current or voltage, sec
x	Distance coordinate, cm
α	$\alpha = A_M/Sl$; ratio of area of metallic phase (also area of front or back surface) to total interior surface area of electrode
γ	$\gamma = R_M/R_o$; ratio of resistance of metallic phase to resistance of solution phase
$\eta(x,t)$, $\eta(\xi,t)$	Change of interfacial potential difference during potentiostatic or galvanostatic charging transient volts.
η_o	Change of potential of front side of electrode by potentiostat, volts
$\eta(\infty)$	Final potential change exhibited by porous electrode after application of single galvanostatic pulse, volts
$\eta_T(0,t)$	Total potential change of front side of porous electrode including effect of R_{REF}, volts
$\Delta\eta$	Amplitude of triangular potential wave, volts
κ	Specific conductance of metallic phase, ohm^{-1}cm^{-1}
μ	Rate of change of current with time during application of triangular current wave to electrode, amp/sec
ξ	$\xi = x/l$; dimensionless distance coordinate
ρ	$\rho = R_{REF}/R_o$; ratio of electrolyte resistance between front surface of porous electrode and tip of reference electrode capillary to resistance of solution in pores of electrode.
σ	Specific conductance of solution phase, ohm^{-1}cm^{-1}

τ	$\tau = R_oC_T = SCl^2/\sigma A$; time constant for propagation of charging current through porous electrode, sec
τ'	$\tau' = (R_o + R_M)C_T$; time constant for propagation of charging current through porous electrode taking into account resistance of metallic phase, sec
ϕ_M, $\phi_M(\xi,t)$	Potential of metallic phase of porous electrode, volts
$\phi_S(x,t)$, $\phi_S(\xi,t)$	Potential of solution phase of porous electrode, volts
$\Delta\phi(x,t)$, $\Delta\phi(\xi,t)$	Interfacial potential difference of porous electrode, volts

Electrochemical Studies of Single Crystals of Lithiated Nickel Oxide

1. Distribution of Charge and Potential at Oxide Electrolyte Interface

T. O. Rouse and J. L. Weininger

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Lithiated nickel oxide is a p-type semiconductor. Electrodes were made from single crystals of this material and their d-c and a-c behavior was studied in acid electrolytes. These electrodes are nearly ideally polarizable over an appreciable potential range. At 0.5-1.0v, with respect to a hydrogen electrode in the same solution, there is observed a capacitive impedance, which is associated with the charging of a space charge region due to the exhaustion of holes near the NiO surface. The experimentally determined flat-band potential for NiO is pH-dependent, which indicates the existence of an adsorbed surface layer in equilibrium with protons in the electrolyte. Near zero potential hydrogen evolution is observed, and above 1v faradaic processes occur.

Electrochemical processes at metallic electrodes are often influenced by the reactivity of a semiconducting surface oxide. A fundamental description of these processes should reflect the interaction of the semiconducting properties and the surface reactivity of the oxide. A necessary first step in arriving at such a description is the determination of the relationship between surface charge and the potential at the oxide-electrolyte interface in the absence of any reaction.

Lithiated nickel oxide is one of the few transition metal oxides with well-characterized semiconducting properties. This report describes a study of the distribution of charge and potential across the interface of the lithiated NiO single crystal electrode in an acid electrolyte. This distribution of charge and potential depends on the degree of doping of the semiconductor bulk, the pH of the solution, and the applied potential across the interface.

The energy band structure of oxides of the 3d-transition metals are discussed in detail by Morin (1). Among these oxides, NiO has been studied most extensively. It has a very wide band gap and, therefore, is an insulator in the pure state. When doped with lithium ions ($Li_xNi^{+2}{}_{1-2x}Ni^{+3}{}_xO$) it becomes a p-type semiconductor. Verwey *et al.* first suggested (2) that this conduction arises because the addition of Li^+ generates an equal number of Ni(III) ions. The mechanism of conduction is then thought to consist of the exchange of holes between Ni(II) and Ni(III) ions in the cation lattice and is termed a "hole-hopping" mechanism. The exchange takes place over an energy barrier (3); hence the drift mobility of the holes is very small and increases with temperature. This mechanism, which may also occur in other 3d-transition metal oxides, *e.g.*, Fe_3O_4, is quite unlike that usually described by the band theory of semiconduction.

The electrochemical behavior of zinc oxide single crystals has been studied by Dewald (4). ZnO is an n-type semiconductor which conducts through bands no comparable investigation for oxide electrodes which conduct by the hole-hopping process has been made Lithiated NiO was chosen for this study because it is the best characterized of this class of oxides. Second, large crystals of NiO can be grown, and these crystals can be doped with lithium under controlled conditions. Third, preliminary d-c measurements indicated that there were no appreciable faradaic processes, including dissolution, at the single crystal surface in nondepolarizing acid solutions.

There are important differences between the semiconduction process found in nickel oxide and that found in oxidic or elemental semiconductors to which the band theory of conduction applies (5). In common with all semiconductor electrodes, however, on applying a potential to the nickel oxide electrode in solution, the potential difference from the interior of the semiconductor to the bulk of the electrolytic solution will consist of two individual contributions. There will be a potential difference across a region of accumulated electronic charge in the oxide, the space charge region, and another across a region of accumulated ionic charge in the electrolyte. The characteristics of

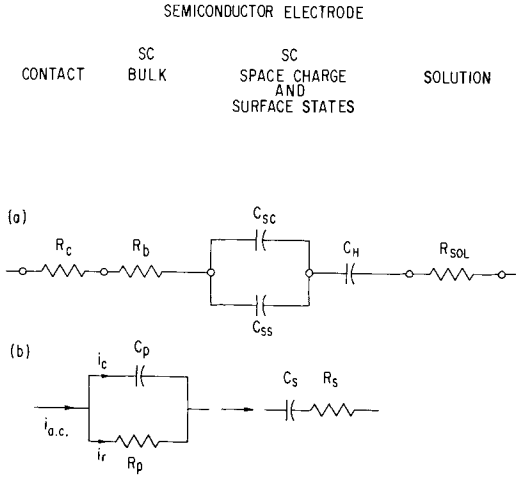

Fig. 1. Equivalent circuits. (a) Representation of system-semiconductor/electrolytic solution. (b) Experimentally measured quantities, C_p, R_p, and their series equivalents.

the space charge portion of this double layer are determined by the bulk properties of the semiconductor; the solution side of this double layer is determined by the properties of the electrolyte and by the interaction of the electrolyte with the oxide surface.

The potential difference, U, of the galvanic cell

$$\underset{\text{I}}{M_1}/\underset{\text{II}}{\text{Semiconductor}}/\underset{\text{III}}{\text{Solution}}/\underset{\text{IV}}{\text{Reference Electrode}}/\underset{\text{V}}{M_2}$$

can be given by

$$U = \Delta\phi_{\text{I, III}} + \Delta\phi_{\text{III, V}}$$

where the subscripts refer to the appropriate phases and interfaces. Thus, ϕ_N would be the inner potential associated with phase N. $\Delta\phi_{\text{III, V}}$ is defined as zero for the normal hydrogen reference electrode.

The potential difference $\Delta\phi_{\text{I, III}}$ is frequently represented by the voltage drop across an equivalent circuit such as that shown in Fig. 1a. Usually, the solution resistance is considered separately, and another solution layer, the Gouy layer (not shown), is assumed to be absent at high concentrations of the electrolyte.

In practice, at a given frequency one measures a resistance and capacitance in a simple series or parallel connection as shown in Fig. 1b. For example, the impedance of the elements in series, Z, is given by

$$Z = R_S + 1/(j \cdot \omega \cdot C_S)$$

R_S and C_S are the measured quantities. Therefore, the central problem in interpreting experimental results is the correlation of impedance measurements, at several frequencies and applied potentials, with the individual components of the circuit in Fig. 1a. Two of these components, the bulk resistance, R_b, and the space charge capacitance, C_{sc}, are related to the bulk properties of the semiconductor.

The theory of the space charge layer at a semiconductor-electrolyte interface has been developed by several workers (4-8). In lithiated NiO holes and electrons are distributed among energy levels localized about nickel cations and isolated acceptors (Li^+ ions). The levels will be altered by a change in potential $\Delta\phi(x)$, hence, the local distribution of holes and electrons will be altered.

The relation between space charge capacitance and potential is derived from Poisson's equation for the distribution of space charge and potential. This distribution must follow semiconductor statistics in the same way as the more usual band-type semiconductors. The behavior of the space charge in lithiated NiO can simply be considered that of a p-type semiconductor with acceptor exhaustion.

$$C = \pm\left(\frac{e_o^2\,\epsilon N_{Li}}{8\pi kT}\right)^{1/2} \frac{\exp\left[e_o(\phi_B - \phi_S)/kT\right] - 1}{\{\exp\left[e_o(\phi_B - \phi_S)/kT\right] - e_o(\phi_B - \phi_S)/kT - 1\}^{1/2}} \quad [1]$$

$\phi_B - \phi_S$ is the potential difference between the bulk and surface, and is zero for the isolated semiconductor. We use the usual electrochemical notation, having $\phi_B - \phi_S$ larger than zero for an anodic surface. The positive sign in [1] is used for positive values of $\phi_B - \phi_S$; the negative sign for negative values of $\phi_B - \phi_S$. N_{Li} is the concentration of Li^+; ϵ, the dielectric constant of NiO; e_o, the charge of the electron; k and T have their usual significance.

Two approximations are applicable to Eq. [1].

At large positive values of $\phi_B - \phi_S$ the surface is enriched with holes and

$$C \sim \left(\frac{e_o^2\,\epsilon N_{Li}}{8\pi kT}\right)^{1/2} \cdot \{\exp\left[e_o(\phi_B - \phi_S)/kT\right]\}^{1/2} \quad [2]$$

For large negative values of $\phi_B - \phi_S$ the surface is depleted of holes and the space charge is due to uncompensated occupied acceptors.

$$C \sim \left(\frac{e_o^2\,\epsilon N_{Li}}{8\pi kT}\right)^{1/2} \cdot \frac{1}{[-e_o(\phi_B - \phi_S)/kT - 1]^{1/2}} \quad [3]$$

This is the well-known Mott-Schottky approximation.

The total applied potential, U, across the interface is

$$U = (\phi_B - \phi_S) + (\phi_S - \phi_{Soln}) + (\phi_{M_1} - \phi_B)$$

ϕ_{Soln} and ϕ_{M_1} are inner potentials of the solution and of the contacting metal, respectively. Equation [3] can be rewritten

$$U = U_{FB} - \frac{kT}{e_o}\left[1 + \left(\frac{\epsilon e_o^2 N_{Li}}{8\pi kT}\right)/C^2\right] \quad [4]$$

where U and U_{FB} are referred to the normal hydrogen electrode.

Although in NiO there is no conduction in bands we retain the definition of a "flat-band potential," U_{FB}, as that value of the applied potential at which the potential at the surface and in the bulk of the semiconductor are equal. At that value, the entire potential difference in the cell (*vs.* NHE) is concentrated across the metal-semiconductor contact and the solution side of the double layer, the Helmholtz layer. This is illustrated in Fig. 2. It is tacitly assumed in obtaining Eq. [4] that $(\phi_S - \phi_{Soln})$ is not altered by a change in U. This assumption is usually valid in the case of semiconductors whose carrier and surface state concentrations are low compared to the electrolyte concentration in the solution (5). Its validity in the present case will be discussed in connection with the experimental results. $(\phi_{M_1} - \phi_B)$ is not a function of U for an ohmic contact.

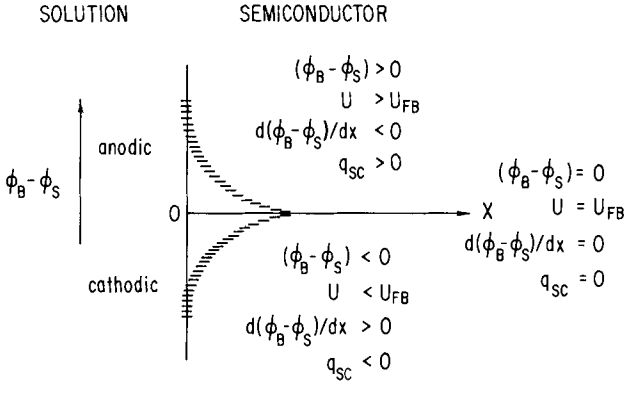

Fig. 2. Distribution of potential in the electrode

The space charge region is treated as if its impedance were purely capacitive. This capacity is in series with the resistive impedance beyond the space charge layer (R_b in Fig. 1a). At the flat-band potential, the space charge region has been compressed to zero thickness, and the charge carrier distribution is uniform throughout the bulk of the semiconductor. The capacitive impedance then is associated only with the surface charge distribution, and the resistive impedance is a measure of the bulk resistivity of the entire crystal. The conductivity, σ, of the crystal, and the bulk resistance R_b, respectively, are given by

$$\sigma = N_A e_o \mu$$

and

$$R_b = \frac{d}{N_A e_o \mu A} \qquad [5]$$

where d is the thickness of the crystal; A, its area; and μ, the drift mobility of the hole.

Experimental

Single crystals of NiO were grown by the method of Cech and Alessandrini (9); this method produces very pure crystals, with a (100) orientation, and a geometry suitable for flat, large, and thin electrode structures. In this method $NiBr_2$ vapor is hydrolyzed at 640°C and at a water vapor pressure of 25 mm in a flowing system. NiO deposits epitaxially on the {100} surface of an MgO single crystal substrate. Subsequently, the crystals are separated by dissolving the MgO substrate in boiling 1*N* H_2SO_4 or 1*N* H_3PO_4. This acid treatment does not affect the NiO crystals adversely. The size of the crystals depends only on the availability of large MgO substrate crystals and surface areas of one square inch can be achieved. Maximum thickness is about 400μ, but thinner crystals are used for electrodes in order to reduce the time required for uniform doping. The purity of the crystals can be judged by their conductivities which were determined to be of the order of 10^{-13} ohm^{-1}-cm^{-1}. Any extraneous cations or cation vacancies would increase this value to about 10^{-6} ohm^{-1}-cm^{-1}, depending on the impurity concentration.

Cooling from the formation temperature introduces some strain into these crystals. The degree of strain is, however, much lower than that found in crystals grown by other methods, *e.g.*, the flame-fusion technique.

The crystals were doped by heating (1600°-1800°C) in air for various times (3-50 hr) with a powdered mixture of NiO and Li_2O. The latter serves as the source of Li^+ ions, and the former presents a means of maintaining a lithium oxide atmosphere over the NiO single crystals for a longer period of time than would be possible using Li_2O alone at these high temperatures. The time and temperature of doping is calculated from the diffusion coefficient of Li in NiO, $D = 2.0 \exp(-3.55 \text{ ev}/kT)$, in cm^2/sec, which has been determined by Garfinkel (10).

With this method NiO crystals were doped with Li up to a concentration of 0.48 a/o (atom per cent). The conductivity of the highest doped crystals is of the order of 10^{-2} ohm^{-1}-cm^{-1}. Lithium concentrations were determined by flame-photometric analyses.

NiO crystals were mounted in Pyrex electrode holders. Ag was chosen as the contact material, but Ni, Pt, and a Ga-Al alloy were also tried. Such electrodes were used in a conventional cell containing a hydrogen reference electrode and a large platinized Pt counter electrode. The reference electrode dipped into the same solution, but was separated from the bulk of the solution by a porous diaphragm. This permitted stirring the solution with Ar gas while measuring the test electrode directly with respect to the hydrogen reference. Unless otherwise noted, potentials are referred to the hydrogen electrode in the same solution as the test electrode.

The following solutions were used: 1*N* H_2SO_4, 1*N* $HClO_4$, and 1*N* $NaClO_4$ adjusted to pH 4 with $HClO_4$.

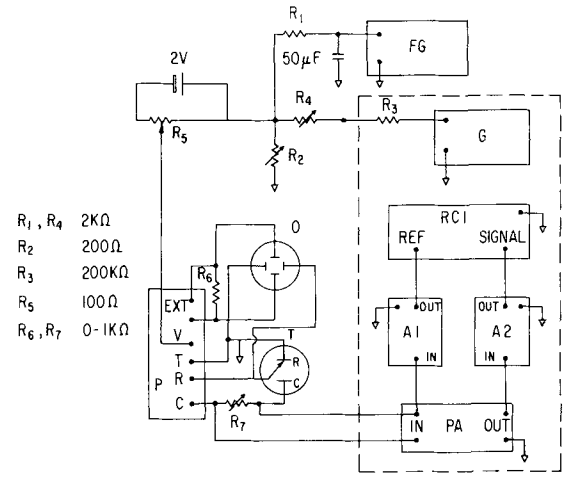

Fig. 3. Schematic circuit diagram: A_1, A_2, Ballantine decade amplifiers; PA, Tektronix type D plug-in unit in power supply used as preamplifier; RCI, Solartron-resolved component indicator, Model VP 250; G, Hewlett-Packard oscillator, type 200CD; O, Tektronix 502 double beam oscilloscope; FG, Exact Electronics function generator, type 250; P, Wenking potentiostat with connections for V, applied voltage; T, test electrode; R, reference electrode; C, counter electrode; and EXT, output. Dashed box: a-c instrumentation.

The circuit used in this study is shown in Fig. 3. It is a modification of an earlier circuit which combined instrumentation for d-c potentiostatic and a-c impedance measurements (11). Because the previous circuit introduced a phase shift between the reference and test signals above 3000 cps the circuit was altered by taking the a-c reference signal from R_7 (Fig. 3) instead of the previously used R_6. This placed the comparison of reference and test signals on adjacent components without introducing the phase shift due to the potentiostat. The high-frequency limit now became that of the resolved component indicator, namely 20 kcps.

A-c impedances were measured in a d-c potential range from 0 to 1.5v (with respect to the hydrogen electrode) at 200 cps, 1, 2, 5, 10, and 20 kcps, with the resolved component indicator. This instrument gives directly the in-phase and out-of-phase currents, i_r and i_c, of Fig. 1b. The electrolytic solution resistance, $R_{sol.}$ of Fig. 1a, was determined separately. From the experimental currents i_r and i_c, the parallel impedance R_p and C_p were calculated. The parallel circuit of Fig. 1b was converted into the equivalent series circuit, and the experimentally determined electrolytic resistance was subtracted from the calculated series resistance. Final corrected values were then computed for tan δ (tan $\delta = 1/\omega R_s' C_s$), R_s', and C_s. R_s' is the equivalent series resistance after elimination of the electrolytic resistance between the working electrode and the reference electrode. All computations were performed on a G.E. 225 computer, which also plotted the data against applied potential.

D-c measurements were performed galvanostatically, potentiostatically at steady state, and potentiostatically with a transient triangular voltage sweep method with rates up to 1 v/sec.

Galvanostatic measurements were made with a conventional constant current circuit. Potentials were measured by a Keithley Model 610A electrometer, with an input impedance of 10^{14} ohms, which in turn drove an X-Y recorder.

Results

A schematic comparison of the experimental results obtained by the four methods mentioned above is shown in Fig. 4. In this figure the potential scale is drawn accurately to indicate the different regions of potential where electrochemical processes may be occurring. Only the magnitude of the dependent varia-

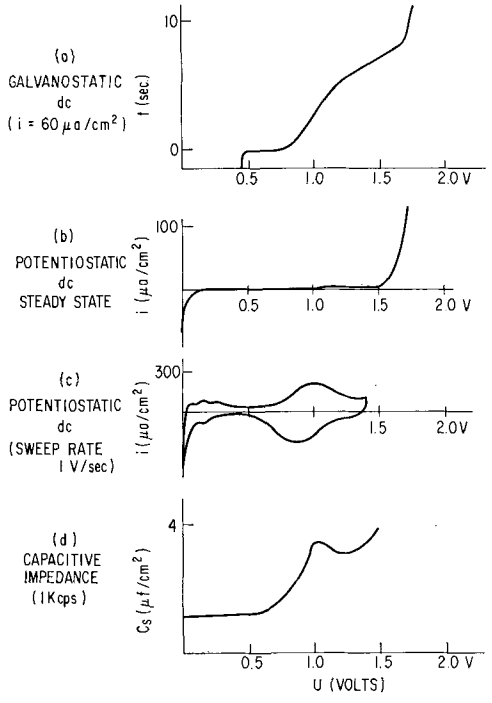

Fig. 4. Schematic curves of time, current, and capacitance vs. applied potential for Li-doped NiO single crystal electrodes.

bles are noted because their actual values depend on doping.

Figure 4a shows the galvanostatic curve obtained on passing a current of 60 μa/cm^2. A charging step is observed beginning at about 0.75v. This step is followed by a slow rise in potential above 1.20v. Oxygen evolution becomes appreciable at 1.7v. The i·t product for the potential step is independent of current, and for this crystal it has a value of 0.18 mC/cm^2.

In the steady-state potentiostatic measurements (Fig. 4b) only a small anodic current (1-5 μa/cm^2) is observed above 1.1v. At higher potentials oxygen is evolved, and at low potentials a cathodic reaction, possibly hydrogen reduction, is observed.

In the transient method (Fig. 4c) a triangular voltage sweep is applied to the electrode under potentiostatic conditions at a high sweep rate of approximately 1 v/sec. Transient phenomena appear. The close correspondence of anodic and cathodic current peaks at such a high sweep rate demonstrate the reversibility of the process beginning at potentials above 0.75v. The very small transients below 0.5v, are not observed at slower sweep rates.

Figure 4d shows a characteristic maximum of C_s for a crystal with 0.48 a/o Li in a solution of *p*H 4.

It should be pointed out that after the crystals are subjected to a high current density other phenomena appear. Under these circumstances crystals frequently develop cracks. Results reported here refer only to crystals which were not subjected to high current density.

Figure 5 through 11 show the a-c behavior of a NiO electrode doped with 0.48 a/o Li, in 1*N* $NaClO_4$ solutions adjusted with $HClO_4$, respectively, to *p*H 1 and 4.

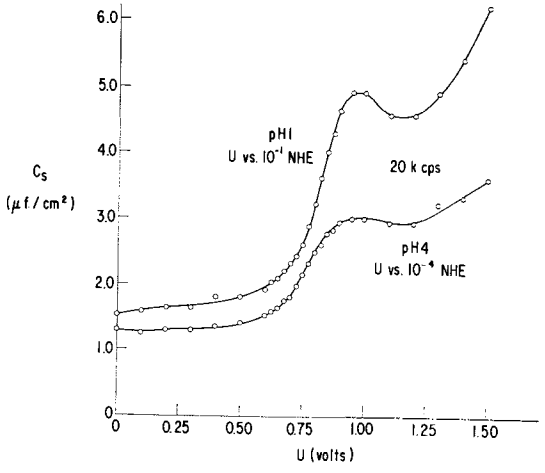

Fig. 10. Comparison of C_s function vs. applied d-c potentials at pH 1 and 4. Potential scales: pH 1 vs. 0.1 NHE; pH 4 vs. 10^{-4} NHE.

The series capacitance and resistance are shown, respectively, in Fig. 5 and 6 as a function of applied potential at several frequencies, and in Fig. 7 and 8 as functions of frequency for several potentials. At the lower frequencies, both resistance and capacitance show pronounced frequency dependence. At 10 and 20 kcps the resistance is independent of frequency and the capacitance is only slightly dependent on it.

The values of the series resistance and capacitance did not change on adding detergent or N-methyl-2-pyrrolidone to the solution.

Although the crystals represented by these figures belonged to the most highly doped group of NiO crystals, the data obtained with crystals having lower lithium concentrations differ only in magnitude from those shown in these figures.

The variation of the phase shift, tan δ, with reciprocal frequency at several values of applied potential is shown in Fig. 9. It is apparent that, at lower frequencies, the simple equivalent circuit of Fig. 1b does not describe the semiconductor-electrolyte interface adequately. No peaks are observed in the tan δ curve which can be associated with relaxation processes. At 10 and 20 kcps tan δ approaches a straight line with an intercept at zero (dashed line, Fig. 9). From this we conclude that the simple equivalent circuit of Fig. 1b describes the interface adequately at 20 kcps. The capacitance *vs.* potential curves of Fig. 10 were obtained for the same NiO electrode in *p*H 1 and *p*H 4 solutions. In the experimental setup the hydrogen reference electrode dipped into the same electrolyte in which the NiO was immersed. Thus, in Fig. 10 the

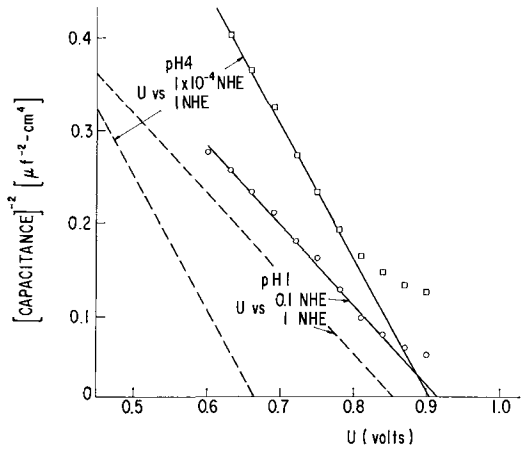

Fig. 11. Mott-Schottky plot for lithium-doped NiO crystals at pH 1 and 4. Dashed curves, reference potential 1 NHE; solid curves, experimental.

potentials for the *p*H 1 curve refer to a 0.1 NHE and those for the *p*H 4 curve refer to a 10^{-4} NHE. The C_s — U curves are then shifted by nearly 180 mv *vs.* the NHE for a *p*H change of three. Furthermore, the capacitance values were always lower in the more alkaline electrolyte.

The resistivities of several of these crystals were obtained after the impedance measurements had been made. The outer face of the crystal was coated with silver while still in the electrode assembly. The resistances were then determined from the slope of the current-voltage curve for this two-contact, dry, Ag-NiO-Ag system. The linearity of the curve indicates that Ag forms an ohmic contact with NiO, a conclusion in agreement with the findings of Thistlethwaite *et al.* (12).

Figure 11 shows a typical plot of $1/C^2$ *vs.* U for a given crystal in the two electrolytes in the range 0.50-1.00v. The Mott-Schottky plots in this potential region are linear for all crystals at all frequencies. The inverse slope decreases with increasing frequency; the intercept is independent of frequency. The results obtained at 20 kcps for several crystals are given in Table I, in which the slopes S_{exptl} and S_{calcd} are compared. S_{exptl} is the inverse slope of Fig. 11, $dU/d(1/C^2)$, and S_{calcd} is the value calculated from Eq. [4]. In the latter calculation a value of 12 was assumed for the dielectric constant for NiO (13). Crystals 1 and 2 were cut from the same original crystal after doping; crystals 3 and 4 were from the same doping run. Crystal 3 was rather small, its analysis should obviously be viewed with caution.

The measured resistive component of the impedance at U_{FB} was used to calculate the conductivity of the crystals. Drift mobilities were calculated from Eq. [6], using the resistances obtained electrochemically and those obtained from the solid-state measurements (Ag-NiO-Ag). These are shown in Table II.

Discussion

The general trend of the experimental results by all methods, shown in Fig. 4, indicates that a reversible process occurs in the potential range 0.5-1.0v. This process is not diffusion controlled; it is not affected by surfactants; and it is associated with an increasing equivalent series capacitance. At potentials above and below this range, small d-c currents indicate the presence of other minor reactions.

The mobilities reported in Table II are in good agreement with those found by van Houten (14) on polycrystalline samples of Li-doped NiO and with those estimated by Koide (15) for single crystals similar to those used in the present work.

are diagnostic for a space charge region in a semiconductor with charge exhaustion. The Mott-Schottky plots found here were invariably linear over a potential range of about 250 mv. These plots began to deviate from linearity only at potentials less than 0.55v (with respect to the hydrogen electrode in the same solution), where fast potential sweeps (Fig. 4c) show the occurrence of another process. The observed values of the slopes at a given frequency are fairly reproducible. They show clearly the predicted dependence on lithium content.

The discrepancy between observed and predicted values of the slopes will be discussed later.

The existence of a surface dipole due to a specific interaction of the surface with protons is shown by the pH dependence of the flat-band potential

$$U_{FB} = 0.94 - 0.050\ \text{pH} \quad (U\ vs.\ \text{NHE})$$

At the flat-band potential, the entire potential difference between bulk oxide and solution is concentrated across the Helmholtz layer. Ideally, for the case of ions specifically adsorbed on a surface in equilibrium with protons in solution, the potential difference is given by

$$\Delta\phi_H = \frac{\bar{\mu}_{H^+} - \bar{\mu}_{surface}}{F} - 0.059\ \text{pH}$$

This pH-dependent Helmholtz potential difference has been found for germanium (6, 16), where the effect was attributed to the presence of an acidic surface oxide. It has also been observed for the Ta_2O_5-electrolyte system (17). In that case, the effect is attributed to protons adsorbed on the oxide surface.

The discrepancy between prediction and experiment at 20 kcps is manifested in two ways: the observed Mott-Schottky slope is about half a decade low, and the observed capacities are low by a factor of about two to three. This discrepancy cannot be due to the presence of slow surface states. Because surface states store charge in parallel to the space charged layer, their presence would result in capacitances higher than predicted and slopes higher than predicted. Furthermore, although surface states could conceivably be distributed in such a way as to give a linear Mott-Schottky slope over a limited range of applied potential, it is unlikely that any such single distribution could apply to crystals of different bulk doping (4). Slow surface states do not appear to contribute to the capacitance at 20 kcps; they may contribute at the lower frequencies where the tan $\delta - 1/f$ curve (Fig. 9) indicates the simple series circuit is not applicable.

It does not appear that incomplete dissociation of Li(1)-Ni(III) ion pairs can account for this discrepancy. MacDonald (18) has treated the case of incompletely ionized donors in local equilibrium with charge carriers. This treatment is applicable here and results in an equation of the form

$$C \sim \left(\frac{e_o^2 \epsilon N_{Li}}{8\pi kT}\right)^{1/2} \frac{1}{[-e_o(\phi_B - \phi_S)/kT - f + \ln f]^{1/2}}$$

for an exhaustion space charge region, *i.e.*, for large negative valves of $(\phi_B - \phi_S)$.[1] f is the fraction of ion pairs dissociated to form free carriers, and N_{Li} is the total number of Li ions. The slope of the Mott-Schottky plot is not a function of the degree of ionization, but the intercept is a function of f. The reproducibility of the flat band potentials found for the dopings used here is too low to give any information on the degree of ionization.

The discrepancy cannot be attributed to the Helmholtz capacitance in the case of simple specific adsorption of protons; although in this case C_H should be dependent on pH and applied potential, it should not be less than that of the double layer in the absence of specific adsorption, *i.e.*, 20-40 μf/cm^2. The magnitude of the discrepancy then is too large to be accounted for in this way.

The Helmholtz portion of the double layer may, however, have a more subtle influence in the charge-potential relationship. In deriving Eq. [4] it was assumed that $(\phi_S - \phi_{Soln})$ was independent of applied potential. If this is not the case, it can be shown simply that the observed slope, $\delta U/\delta(1/C^2)$, is given by

$$\frac{\delta U}{\delta(1/C^2)} = \frac{-kT}{e}\left(\frac{e_o^2 \epsilon N_{Li}}{8\pi kT}\right)\left[1 + \frac{\delta(\phi_S - \phi_{Soln})}{\delta(\phi_B - \phi_S)}\right]$$

The discrepancy between theory and prediction can be resolved if $\delta(\phi_S - \phi_{Soln})/\delta(\phi_B - \phi_S)$ is independent of capacitance and if its magnitude is somewhat greater than unity. A definitive consideration of this point cannot be given at this time; however, some tentative estimates of the magnitude of this ratio can be made. Verwey and Niessen (20) have considered the potential distribution across a double layer, both sides of which are diffuse. We have given preliminary consideration to the case more nearly applicable here, *i.e.*, a diffuse layer in the semiconductor and a layer in solution bounded by a Helmholtz plane. In both cases, because of the high doping concentrations available in nickel oxide, the magnitude of the ratio appears to be of the order of unity.

A final consequence of the high carrier concentration is that the thickness of the space charge layer is quite small. For the potential range over which the Mott-Schottky approximation holds for NiO and for the doping concentrations used in this study, most of the space charge is due to uncompensated lithium ions in the first two or three lattice layers. The quantitative discrepancy may conceivably be attributed to nonhomogeneous acceptors near the surface.

At potentials more positive than U_{FB} the behavior of the capacitance is also complex. Equation [4] predicts that the space charge capacitance should increase

[1] Dewald (19) has arrived at a similar limiting solution to this problem.

exponentially as (ϕ_B — ϕ_S) increases. As ϕ_S approaches a value corresponding to the Fermi level, the Boltzman distribution is not applicable, and the surface becomes degenerate. Charge should then accumulate more slowly than predicted by the Boltzman approximation. In the case of the hole-hopping mechanism of conductance a density-of-states function is not known, and the exact dependence of the space charge capacitance on the potential in the degenerate region cannot be derived. However, in the degenerate region the capacitance should increase only slowly with potential and should become independent of doping. The predicted rapid rise in capacitance of U_{FB} and the subsequent slower increase in capacitance is not observed. This finding is in general agreement with Dewald's observations (4) of the enrichment region in n-type ZnO. It appears likely that for NiO at potentials greater than U_{FB} the complex dependence of the capacitance on applied d-c potential is due to faradaic or adsorptive processes which give rise to a small d-c current above 1v in the steady-state potentiostatic measurements (see Fig. 4b). At these high anodic potentials the space charge capacitance will have become sufficiently large that the measured capacitance is primarily due to the charge distribution in the Helmholtz layer.

Conclusions

In summary, it is concluded that:

1. Single crystals of NiO, doped with lithium, are nearly ideally polarizable electrodes over an appreciable potential range. Near zero potential (with respect to the normal hydrogen reference) there is some evolution of hydrogen and above 1v, on the same scale, there is evidence for faradaic processes.

2. A space charge region due to the exhaustion of holes near the surface of the NiO is observed at weakly anodic potentials (*vs.* NHE).

3. The flat-band potential for NiO is given by

$$U_{FB} = 0.94 - 0.050\ p\mathrm{H}$$

At the flat-band potential, the potential drop in the Helmholtz region is controlled by an adsorbed layer on the oxide in equilibrium with protons in solution.

4. The resistive component at the flat-band potential is determined by the crystal resistance.

5. The measured capacitance at potentials more anodic than U_{FB} is not controlled by the semiconductor. The behavior is complex and is probably related to the faradaic processes at the electrode surface.

Technical Notes

Comparison of Platinum and its Group VIII Nearest Neighbors as Anode Electrocatalysts in Propane-Phosphoric Acid Fuel Cells

W. T. Grubb

Research and Development Center, General Electric Company, Schenectady, New York

Low-temperature survey experiments have indicated that platinum black is the best simple electrocatalyst for the anodic oxidation of hydrocarbons near room temperature (1). More recently, high performance platinum black hydrocarbon anodes operating in phosphoric acid fuel cells at 110°-200°C (2,3) have been reported. It was therefore of interest to re-examine the question of whether platinum is still superior to other group VIII noble metals under such conditions. A limited series of experiments was carried out to help provide an answer to this question.

Experimental

Teflon-bonded fuel cell electrodes were prepared by techniques previously described (4). Commercial blacks of platinum,[1] palladium,[2] rhodium,[1] and iridium[1] were used. Their areas as measured by a BET method were respectively, 20, 28, 0.6, and 82 m^2/g. Electrocatalytic ability was compared by observing the performance of these electrodes as propane anodes in complete fuel cells at 150°C using the same Teflon-bonded platinum black cathode and 85% H_3PO_4 as electrolyte. Anode overvoltage *vs.* an unpolarized hydrogen reference electrode in the same electrolyte was also obtained. All of the anodes performed well with hydrogen as fuel indicating that effective gas electrode structures had been achieved in each case.

Results

A comparison of propane current densities at an anode overvoltage *vs.* reversible hydrogen of 0.5v are presented in Table I. The superiority of platinum is clearly indicated. The performance comparison between platinum and iridium is particularly striking as Fig. 1 shows. The current density *vs.* voltage is plotted for hydrogen-oxygen and propane-oxygen cells under the same conditions. Both platinum and iridium black electrodes gave extremely high performance on hydrogen as fuel and in fact supported current densities in excess of 800 ma/cm^2 in both cases. By contrast, a very strong difference in activity with propane was observed. Platinum black supported more than three orders of magnitude higher current density than iridium in spite of its being of somewhat lower specific surface area.

Pd	0.7
Rh	0.05 ± 0.05
Ir	0.05 ± 0.05

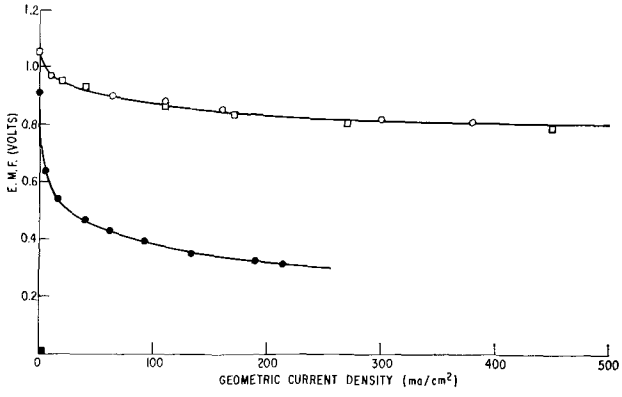

Fig. 1. Comparison of Pt and Ir as anode electrocatalysts in 85% H_3PO_4 at 150°C; cathode *vs.* anode voltage as a function of current density; anodes: ○, H_2-Pt; □, H_2-Ir; •, C_3H_8-Pt; and ■, C_3H_8-Ir; cathode: O_2-Pt (the ordinate is the iR-free cell voltage).

Discussion and Conclusions

The data support the conclusion that platinum is the best simple electrocatalyst for the direct oxidation of hydrocarbon fuels under conditions where, in the case of platinum, high hydrocarbon reactivity is observed. It appears to be orders of magnitude better than its nearest neighbors in the periodic table.

This result is the more surprising in view of the many similarities among these metals. Taking platinum and iridium as an example: both have partially filled d electron orbitals, both are of face-centered cubic crystal structure, the lattice parameters (a_o) differ by less than 3%, and both are known to be excellent catalysts for many nonelectrochemical reactions involving hydrocarbons (5). Apparently some very specific property or set of properties is required for catalyzing the direct electrooxidation of hydrocarbons in the moderate temperature region. It is hoped that further study of the electrooxidation mechanisms will shed light on this point.

The results described here do not of course preclude the possibility of improving the electrocatalytic activity of platinum by various means such as alloying. Considerable literature exists (6-8) indicative of the possibility that such measures may result in increased activity in fuel cell electrodes. However, the nature of the fuel and electrolyte are expected to have an important bearing on the detailed requirements for a suitable electrocatalyst.

Acknowledgment

Hydrogen Plasma Transport of Se, As, and Te

S. W. Ing, Jr., and Y. S. Chiang

Fundamental Research Laboratory, Xerox Corporation, Webster, New York

We have transported Se, As, and Te from either a vapor source or a solid source to substrates located some distance away from the source by using a low-pressure hydrogen plasma. It is suggested that energetic species of hydrogen react with these elements to form hydrides. The gaseous hydrides formed are thermodynamically unstable in the absence of the plasma and decompose rapidly when these hydrides have been transported out of the plasma region. The element, Se, As, or Te is then deposited out.

A continuous flow system was employed in which hydrogen gas was continuously fed into and pumped out of the reaction chamber. The hydrogen discharge was ignited and sustained by using an external inductively coupled excitation source. The generator consisted of a water-cooled copper coil wound around a section of the Pyrex reaction tube near the hydrogen inlet. This coil was connected to a 30 Mc r.f. source. It was found that under a pressure of 20 to 100μ the plasma could be easily sustained using such an excitation source. The visible light intensity of the plasma appeared to be highest at the r.f. coil region, gradually decreased downstream of the coil and finally terminated at the end of the tube.

When a solid source was used, it was usually placed inside the tube in the region of the r.f. coil. The plasma was terminated by using a grounded electrode, strapped to the outside of the tube wall, a short distance downstream of the r.f. coil. It was seen that the element began to deposit out in a thin film form along the tube wall, downstream of the plasma front, which was distinguishable by its glow color. No deposition occurred on the section of the tube wall where the glow color extended very close to the wall. This suggests that any Se deposited in this region was quickly removed by the plasma and returned to the gas phase. All three elements, Se, As, and Te, have been transported and deposited in this manner.

In order to demonstrate the effectiveness of the hydrogen plasma transport of Se, for example, an argon plasma has been tried under otherwise identical conditions. No significant amount of Se transport took place. Only a slight amount of deposition was observed in the immediate vicinity of the solid source.

We have also shown that this transport process is not merely a localized heating and evaporating process. We have applied heat to the solid selenium exposed to a flowing stream of normal hydrogen under a reduced pressure. The selenium vapor simply condensed out on a narrow section of the tube wall adjacent to the heated zone, without being transported along the tube to any appreciable length.

The over-all chemical reactions that possibly are occurring in this plasma transport process can be visualized as follows. The first step is the formation of active hydrogen species, such as atomic hydrogen and energetic molecular hydrogen, by electron bombardment of the hydrogen molecule. These active hydrogen species, on collision with the elements, in either the solid or the gaseous phases, can form metastable gaseous hydrides. Radford (1) has, for example, observed an appreciable amount of hydride radicals of Se and Te in the gas phase when he exposed these solid elements to a reduced pressure hydrogen plasma formed by a d.c. discharge. The ratio of hydrogen to Se, Te, and As in these hydrides is not known. Presumably, this ratio could vary over a wide range. The hydride species formed are likely to decompose on collision with the wall surface to deposit out the elements.

The rate of deposition can be increased substantially by pumping these elements into the plasma in a vapor form. This technique has been applied to transporting Se. The solid source was placed in a small closed end tubular side arm. This side arm was situated close to the hydrogen gas inlet to the reaction chamber, hence on the up-stream side of r.f. coil. Heat was applied to the solid source causing it to evaporate rapidly, and Se

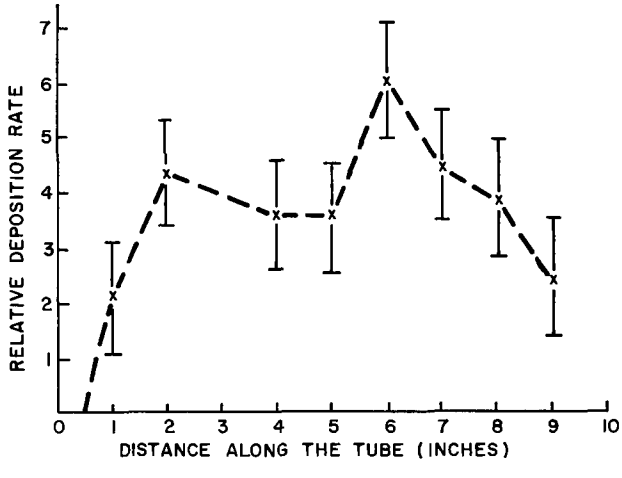

Fig. 1. Relative deposition rate vs. distance along the reaction tube

vapor was thus injected into the plasma. The high-frequency coil used to generate the plasma was water-cooled. and, being in contact with the reaction tube, it also served the purpose of cooling the reaction tube wall. No Se deposition was observed on the tube wall closest to the r.f. coil. The plasma was allowed to extend approximately 12 in. down stream of the coil, *i.e.*, near the grounded electrode. The glow intensity appeared to diminish only very gradually from the r.f. coil, to the region where the plasma was terminated. The plasma was seen to break away from the tube wall outside of the coil region; in this region deposition primarily took place.

Thin Pyrex glass slides were placed along the length of the plasma for monitoring the amount of Se deposited. Relative rates of deposition were obtained by measuring the weight increase of these glass slides at various locations following a certain time length of operation. These results are shown in Fig. 1. The zero distance on the abscissa indicates the region where the r.f. coil ends. The deposition rate is seen to rise rapidly and reaches a broad plateau. This broad peak extends over a distance of 6-7 in. The rate then decreases as the glass slides are further removed from the source. This suggests that the deposition process itself is limiting the net deposition rate. It is likely that the deposited Se is being removed constantly by the hydrogen plasma, and the net deposition rate is therefore strongly dependent on the removal rate. Since the plasma intensity and the removal rate are highest in the region of the r.f. coil, there is no net deposition in this area. The glow intensity gradually decreases down stream of the coil primarily due to the recombination of active species at the tube wall, which allows deposition to occur. The deposition rate is then dependent on the concentration of the gaseous Se species and the active hydrogen; both quantities are expected to decrease simultaneously down the reaction tube. This effect could give rise to the observed deposition rate distributed along the tube wall.

The hydrogen plasma deposited Se films have been studied under an electronmicroscope. The film, with a mean thickness of a few hundred angstroms, is constructed of close packed nodules of around a thousand angstroms in diameter. Electron diffraction measurements show that these films are amorphous. The substrate surface where Se deposition occurred is apparently less than 60° or 70°C. Above these temperatures Se crystallizes very rapidly. Electrical resistivity measurements of the deposited Se films in the dark have been made using evaporated gold electrodes as the contacts. Because of carrier trapping effects no quantitative measurements could be made, however, the film resistivity is estimated to be of the order of 10^{13} ohm-cm.

Diffusion of Transition Metal Ions into Rutile (TiO_2)

James P. Wittke

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

Although the diffusion of hydrogen (1), boron (2), and lithium (3) into single crystal rutile has been previously reported, we have not found any reference to diffusion of the larger, heavier transition metals into this material. This Note reports the observation of the diffusion of Cr, Fe, Co, and Ni into rutile. These observations are important for at least two reasons. In the past, measurements of the electrical and other properties of rutile have led to somewhat conflicting conclusions (4, 5) We believe that the observed discrepancies reflect different states of purity of the crystals on which the measurements were made, and the observation that many metals readily diffuse into rutile offers an explanation of why this may be so. Second, rutile doped with chromium or with iron is perhaps the most important material yet found for use in microwave masers (6, 7). For masers, uniformity of doping and accurate control of paramagnetic ion concentration are very important. The techniques reported below for introducing paramagnetic impurities by diffusion offer promise of better maser materials than can be achieved by introducing them during crystal growth.

When transition metal ions are introduced into rutile, the absorption edge at about 4100Å that gives pure rutile its yellowish cast is shifted further toward the red. This results in an orange-brown coloration by means of which the presence of these ions can be monitored. [The color of rutile depends strongly on the treatment of the sample as well as on the doping; *e.g.*, if chromium-doped rutile (brown) is reduced by heating in a vacuum, the absorption at about 1.2μ that gives "reduced" (nonstoichiometric) pure rutile its blue appearance also appears in the doped sample, resulting in a green crystal.] The brown coloration associated with fully oxidized rutile doped with transition metal ions was used to monitor the diffusion of these ions into the crystal.

Rutile has the cassiterite structure; its tetragonal unit cell contains two TiO_2 molecules. The structure can be considered as composed of titanium ions in a body-centered sublattice, with pairs of oxygen ions placed between the titanium ions in alternative face-diagonal directed pairs normal to the c-axis. The titanium ions lie in rows directed along the c-axis, the rows forming a square array when viewed along this axis. The rutile lattice has "channels" of low electron density, lying along the centers of these squares (8). These channels lead to greatly enhanced interstitial diffusion of impurity ions, compared to diffusion via substitutional lattice sites (8).

As in the cases of boron (2) and lithium (3), the diffusion of transition metal ions is exceedingly anisotropic, proceeding along the c-axis (as evidenced by the coloration) faster by orders of magnitude than perpendicular to this axis. This is strong evidence that transition metal ions diffuse into rutile by means of the same interstitial mechanism found for lithium and boron. That this is plausible can be seen from an argument based on lattice geometry. From the electronegativity of titanium and oxygen (9), we estimate the Ti-O bond to be about 60% ionic. Using Pauling's values (9) for ionic and covalent radii for Ti and O, and interpolating linearly with degree of ionicity gives radii of R (Ti) = 0.90Å and R (O) = 1.06Å. Using these values and the lattice parameters a_o = 4.593Å and c_o = 2.959Å determined by Cromer and Herrington (10), we find the interstitial diffusion channels

Table I. Ionic radii

Ion	Radius (9), Å
Cr^{3+}	0.69
Fe^{3+}	0.64
Co^{2+}	0.74
Ni^{2+}	0.72
Ni^{3+}	0.62

(8) to consist of chains of "voids" of approximately 0.77Å radius, joined by deformed regions of comparable cross-sectional area. Thus, the observed rather rapid interstitial diffusion of the transition metal ions(ionic radii given in Table I) is understandable. The much larger rare earth ions [R (Yb^{3+}) = 0.94Å to R (Ce^{3+}) = 1.11Å (9)] do not give measurable diffusion even at a temperature (1200°K) well above those required to make the transition metal ions mobile.

An interesting aspect of rutile is that all of the paramagnetic ions we have diffused into it, with the notable exception of Ni, are preferentially found on substitutional sites, as shown by our paramagnetic resonance studies. This is in agreement with the results reported by Gerritsen (11) for rutile with impurities incorporated during crystal growth. [In the case of Fe^{3+} incorporated at growth, paramagnetic resonance studies (12) indicated that over 70% of all the iron was in a substitutional site.] The fact that the bulk of the ions are found on substitutional sites argues strongly for rapid, energetically preferred reactions in the crystal in which interstitial transition metal ions (except Ni) are captured at vacant Ti sites. Whether there is a valence change accompanying these reactions is at present unknown.

The transition metal ions can be applied to the surface of the crystal prior to diffusion in any of a number of ways. We have used metallic evaporation in a vacuum successfully; alternatively, we have coated the surface of the crystal with an alcohol solution of the transition metal nitrate or acetate, which we subsequently evaporated to remove the solvent. Upon heating to diffusion temperatures, the nitrate or acetate decomposed, leaving an oxide residue that acted as the dopant source for the diffusion. We have also immersed the rutile crystal, at the diffusion temperature, in a vapor of $FeCl_3$ or $CrCl_3$, both of which react at the crystal surface to yield $TiCl_4$, which comes off as a vapor.

Based on visual examination of the coloration induced by diffusion, all transition metal ions have approximately the same diffusion rate, although nickel diffuses perhaps twice as fast as iron; chromium also diffuses somewhat faster than iron. While accurate diffusion constants have not been measured, we estimate $D \approx 10^{-6}$ cm²/sec for temperatures of about 1000°C Chemical analysis indicated that we were able to incorporate over 0.04% Fe (by weight) by diffusion, and much higher concentrations can presumably be achieved (13). At our highest doping levels of Fe we observed paramagnetic resonances that could not be associated with simple substitutional sites. These might be due to interstitial ions or to substitutional sites with associated lattice defects (other impurity ions on adjacent sites, oxygen vacancies, interstitial Ti^{3+} ions, etc.). We have prevented loss of oxygen ions during diffusion, with attendant nonstoichiometry (14), by carrying out the diffusion in an atmosphere of flowing oxygen.

By controlling the amount of transition metal ion applied to the surface of a rutile crystal, a predetermined amount of dopant can be introduced into the crystal in a few hours by holding it at readily attainable temperatures. Since it apparently is very difficult to control closely the doping level when the transition metals are introduced during crystal growth, this technique makes possible many experiments requiring a controlled doping concentration that otherwise would be difficult to do.

The Phase Diagram of the BI_3-SiI_4 System and Its Relationship to Zone Refining

A. F. Armington

Air Force Cambridge Research Laboratories, Office of Aerospace Research, Bedford, Massachusetts

and E. O. Fisk

Wentworth Institute, Boston, Massachusetts

Experiments with zone refining have indicated unfavorable effective segregation coefficients[1] for silicon tetraiodide (SiI_4) in boron triiodide (BI_3) and for boron triiodide in silicon tetraiodide (1, 2). In order to determine whether these segregation coefficients were due to experimental problems or to a high equilibrium segregation coefficient, the authors have constructed the phase diagram for the system BI_3-SiI_4. A rough curve for the liquidus portion of this diagram was published previously (3), but the solidus portion needed for zone refining evaluation was not reported.

Two methods were used in this study. Usually the phase transitions were determined by thermal analysis

[1] The segregation coefficient is $K = C_S/C_L$ where C_S is the impurity concentration of solid after zone refining and C_L is the impurity concentration in the liquid zone.

using the cell shown in Fig. 1. With this apparatus, melting of the samples could be examined prior to placement of the cell into a Dewar flask. Measurements were made using a bare copper constantan thermocouple immersed into the sample through the hollow paddle-type stirrer. This was found to be more sensitive than the use of a thermocouple inserted in a well. The thermocouple output voltage was monitored on a 0-400 μv potentiometric recorder (L&N Speedomax G). A potentiometer (Rubicon model No. 2748) was used to compensate part of the thermocouple voltage with a precisely known voltage. This "bucking" voltage was changed each time the pen reached the edge of the chart; thus the cooling curve consisted of a number of successive curves on the chart. Repeated runs on the same mixture were within ± 0.5°C. Variations in the cooling rate provide a small time lag (particularly near the ends of the diagram) so that in general the liquidus temperature is accurate to ± 0.6°C and the solidus to ± 1.2°C.

A potential source of error tending to give lower transformation temperature is the possible presence of hydrolysis products. To test the magnitude of this effect the following checks were made: pure BI_3 containing 0.47% each of I_2 and B_2O_3 showed a melting point lowering of 1.47°C; a BI_3-SiI_4 mixture (59.27% SiI_4) containing 0.34% I_2 showed the liquidus temperature to be lowered by 0.60°C and the solidus temperature to be lowered by 0.72°C.

For dilatometer measurements a simple volume apparatus consisting of a tubular container (of about 10 ml volume) with a capillary tube attached by means of a tapered joint was used. The capillary tube had an internal diameter of approximately 0.7 mm and was approximately 60 cm long. The sample was placed in the container and covered with Dow Corning 704 fluid as a inert liquid. By proper adjustment of the amount of fluid a plot could be made of temperature *vs.* volume (cm of fluid height in the capillary tube). The dilatometer was contained in a water bath in a Dewar flask along with a thermometer, immersion heater, and stirrer. Using the dilatometer it was not possible to obtain eutectic temperature indications for mixed compositions as close to the edges of the diagram as it was with the cooling curves. However, with the dilatometer it was possible to approach the eutectic temperatures from both sides and obtain a more accurate temperature by slowing down the heating and cooling rates, thus narrowing down the distance between the lags in temperature.

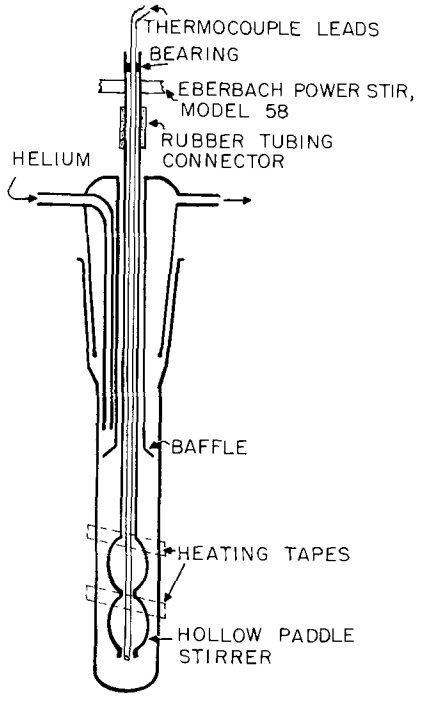

Fig. 1. Sketch of thermal analysis apparatus used for solidus and liquidus temperatures.

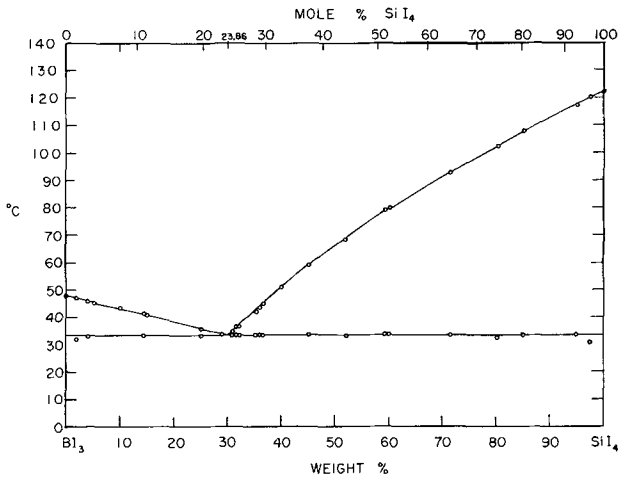

Fig. 2. Phase diagram of the system BI_3-SiI_4

The boron triiodide was distilled from a 30 plate Oldershaw column and was approximately 99.99% pure. The silicon tetraiodide was purified by recrystallizing from toluene and was approximately 99.9% pure; some points were determined using sublimed SiI_4. No difference in results could be detected with this material however.

Since both materials hydrolize readily in the presence of water vapor, they were stored in sealed containers; the weighings were done as rapidly as possible into the thermal analysis cell in air and immediately covered by a flow of dry helium.

The results of the experimental work on the phase diagram are shown in Fig. 2. From this, it can be seen that the phase diagram consists of a simple eutectic system with no evidence of compound formation. The eutectic appears at 30% by weight of SiI_4 and a temperature of 33.8°$\pm$ 1°C. Since Niselson and Chernyaev did not accurately determine the eutectic, but based it on a single point near the eutectic, it is difficult to compare their value with the eutectic reported here. However, their eutectic appears to be in the 23-25 mole % SiI_4 region rather than at the 30 mole % SiI_4 value found in this study. Using the equipment discussed in the previous section, the authors were not able to detect the solidus points below 2% or above 97.5% SiI_4.

Thus the maximum equilibrium segregation coefficients would be 0.028 for BI_3 in SiI_4 and 0.067 for SiI_4 in BI_3. Since these values are markedly lower than the experimental values of 0.42 for the former and about one for the latter, it is evident that the failure of zone purification in these cases is not due to high equilibrium segregation coefficients, but is due to experimental conditions. In both cases cited here, considerable fracture of the solid was observed at the freezing interface and the authors believe the filling of the cracks with impure liquid could be responsible for the failure of the zone purification of these materials.

Tetragonal Germanium Dioxide Layers on Germanium

W. A. Albers, Jr., E. W. Valyocsik, and P. V. Mohan

Research Laboratories, General Motors Corporation, Warren Michigan

The desirability of exploiting as-grown oxide layers of germanium and silicon for diffusion masking and electronic surface passivation in semiconductor device technology has been recognized for some time. In recent years this concept has been unambiguously successful in the fabrication of silicon devices. A similar development for germanium devices has not been forthcoming because the oxide that naturally forms on a germanium surface is chemically very reactive. Naturally occurring GeO_2 invariably assumes either an amorphous or an hexagonal (hex) crystalline state. Germanium dioxide can also occur in a tetragonal (tet) crystallographic modification (1, 2). An examination of the chemical and physical properties of the tet GeO_2, as listed in Table I, suggests that it might provide the same advantages for germanium devices as SiO_2 does for silicon devices. In order to test this conjecture, a means of preparing germanium specimens with tet oxide layers had to be developed. The purpose of this note is (*a*) to report a method which we have employed for obtaining tet oxide layers on germanium and (*b*) to describe preliminary observations on the semiconductor surface properties as influenced by the oxide.

Our approach to the preparation of tet oxide layers on germanium centered on the fact that the hex form can be completely converted to tet by a solid-solid phase transformation at relatively low temperatures (2-4). This transformation can be effected either by heating hex powders in the presence of small quantities of a mineralizer, such as an alkali-metal salt, to temperatures in the 800°-1000°C range at atmospheric pressure, or by heating to temperatures in the 300°-600°C range under several hundred atmospheres of pressure (hydrothermally). We confined our attention to the first of these. The hydrothermal conversion of GeO_2 layers has been investigated in another laboratory (5).

The experimental program consisted of two parts: (*a*) a detailed study of the transformation kinetics of bulk powders employing 1% by weight Li_2CO_3 as the mineralizer, and (*b*) an investigation of the direct conversion of as-grown crystalline oxide layers on germanium employing lithium carbonate to promote the phase transformation. The study of bulk powders was carried out in the hope that it would provide a description of the transformation mechanism which could be applied to the conversion of as-grown hex oxide layers. Only the pertinent aspects of the bulk conversion work are reported here; a detailed report will be published elsewhere (6).

Table I. Properties of germanium and its crystalline oxides

Property	Germanium	Hexagonal	Tetragonal
Coordination	Tetrahedral	Tetrahedral	Octahedral
Crystal type	Diamond	Quartz	Rutile
Density @ 25°C, g/ml	5.35	4.228	6.239
Molar volume, cc	13.57	22.24	16.77
Melting point, °C	937	1116 ± 4	1086 ± 5
Transition point, °C	—	1033 ± 10	1033 ± 10
Index of refraction	4.0	1.735	2.05-2.10
Thermal coefficient of expansion	61 × 10^{-7}	95 × 10^{-7}	~60 × 10^{-7}*
Solubility in H_2O @ 25°C, g/liter	Insoluble	4.53	<0.005
Action of HF	None	Reacts very rapidly	None
Action of HCl	None	Reacts rapidly	None
Action of 5*N* NaOH @ 100°C	None	Dissolves rapidly	Dissolves very slowly

* Approximate average of several crystallographic directions [see J. F. Sarver, *J. Amer. Ceram. Soc.*, 46, 195 (1963)].

The experimental procedure for the bulk powder transformation studies involved baking commercially available hex GeO_2 (obtained from K & K Laboratories, Plainview, New Jersey), to which had been added 1% by weight Li_2CO_3, at temperatures in the range 800° to 1000°C. Small portions of the powder were extracted at certain intervals and analyzed for relative weight percentages of hex and tet GeO_2 by x-ray diffraction techniques (4). This procedure was repeated for several different temperatures in the above range. The resulting data are summarized in Fig. 1 where the fraction, *f*, of hex material transformed is plotted *vs.* the temperature, *T*, with reaction time as a parameter.

The samples for investigating the conversion of as-grown oxide layers were prepared from oriented (111) single crystal germanium slices. After lapping and etching by standard methods, they were oxidized in several ways. One of these was direct oxidation in wet oxygen at 500°C. A second method consisted of anodic oxidation in a 0.25*N* solution of sodium acetate in glacial acetic acid and a third involved chemical oxidation in concentrated (15*N*) nitric acid. X-ray and electron diffraction observations of the resulting oxide layers revealed that the thermally grown oxide was amorphous while those prepared anodically were either amorphous or hexagonal depending on a number of factors. The samples that were oxidized in concentrated HNO_3 were invariably the hex crystalline form.

Attempts to convert these oxide layers were carried out by placing a specimen in a ceramic crucible along

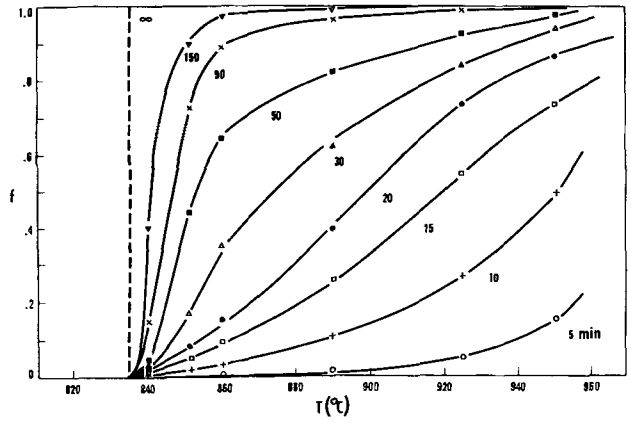

Fig. 1. Fraction of material transformed, *f*, as a function of temperature, *T*, for the hexagonal-to-tetragonal phase transformation of germanium dioxide, with time as a parameter.

with either pure Li_2CO_3 or hex GeO_2 powder containing 1% by weight Li_2CO_3. The crucible was covered with a loosely fitting lid and heated to temperatures in the 700°-900°C range for periods varying between several hours and a day. The crystalline form of the oxide layer was then determined by electron diffraction or by chemical techniques based on the relative reactivity of the two forms as listed in Table I. The samples were weighed before and after the above processing and any weight change noted. All experiments were conducted in a room atmosphere of about 40% relative humidity.

An analysis of data for the bulk powder transformation presented in Fig. 1 suggests the following description of the hex-to-tet conversion (6). The tet phase is nucleated through the formation of alkali-metal oxide groups in the host hex crystallites. These oxide groups promote a local octahedral coordination of germanium atoms consistent with the structure of the tet GeO_2 phase. Since the tet phase is the more stable phase below temperatures of about 1000°C (2), some of these nuclei grow at the expense of the host hex phase. The macroscopic features of this growth are adequately described by the phenomenological theory of diffusion-like phase transformations (7, 8), which takes into consideration the influence of strain in the host and transformed lattices. We believe that strain energies play an important role in the GeO_2 phase transformation in view of the large specific volume difference between the hex and tet phases (see Table I).

The results of the conversion of as-grown oxide layers can be summarized as follows:

(*a*) In all cases in which pure Li_2CO_3 was employed, the oxidized specimens were destroyed, presumably because of a reaction of the Li_2CO_3 with germanium;

(*b*) Systems employing the 1% Li_2CO_3-99%GeO_2 mixture also resulted in the destruction of the samples when the conversion was attempted above 800°C;

(*c*) Between 700° and 800°C the crystalline oxide layers were completely converted to the tet form when the Li_2CO_3-GeO_2 mixtures were used and reaction times were about 16 hr. No change of weight was observed. Under the same conditions, the samples with amorphous oxide layers remained unchanged.

Several features of the successful oxide-layer conversions are worth noting. For example, the complete conversion of the layer was accomplished at temperatures well below those necessary for conversion of the bulk powders; indeed, Fig. 1 indicates that the bulk transformation rates are essentially zero below about 830°C. Also, the GeO_2 hex powder, which was included in the oxide-layer transformation systems, was not converted to the tet form, consistent with the results of the bulk powder studies.

It appears reasonable that the oxide layers grown on germanium are more highly strained than the bulk powders and that this strain could be responsible for the lower conversion temperature of the oxide layers. As already noted, strain is an important feature of the transformation mechanism and therefore could also account for the differences observed in the conversion kinetics.

The fact that GeO_2 powders had to be included in the systems which resulted in successful oxide layer conversions suggests that GeO plays an important role. It is well established that the vapor of GeO_2 is predominantly GeO at the temperatures of interest (9). Also, considering the reaction $Ge^{(s)} + GeO_2^{(s)} \rightleftharpoons 2GeO^{(g)}$, which we feel is dominant in the destruction of samples in the unsuccessful conversion, the importance of the GeO can be appreciated. Below 800°C the GeO vapor pressure associated with the GeO_2 powder is sufficient to inhibit this reaction from proceeding to the right. On the other hand, above 800°C the reaction apparently proceeds to the right at a rate large enough to etch the germanium sample.

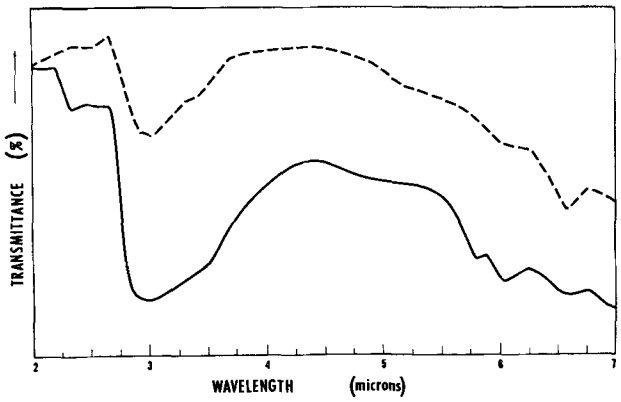

Fig. 2. Infrared spectra of hexagonal (——) and tetragonal (- - -) oxide layers on single crystal germanium. Note the difference in transmittance associated with the O-H stretching frequency near 3μ.

A final remark about the oxide-layer conversion studies pertains to the unsuccessful conversion of amorphous oxide layers under any of the conditions described. We conclude that the crystallinity of the oxide is an important feature of the conversion process. Evidently, a stage of recrystallization is necessary before thermal oxides can be converted.

The successful preparation of tet oxide layers on germanium led us to a consideration of the influence of such layers on the surface properties of germanium. To this end, several single-crystal, p-type specimens of germanium were oxidized in 15*N* nitric acid, and the following experiments were set up:

(*a*) The oxide was converted to tet and checked as a potential diffusion mask by exposing the sample to arsenic vapor for 2 hr at 750°C.

(*b*) Sheet resistivity of the germanium surface was measured before and after conversion to determine the possible effect of the expected diffusion of lithium into the germanium substrate.

(*c*) Infrared absorption of the oxide layers before and after conversion was observed.

(*d*) Field-effect measurements were carried out on samples before and after conversion to characterize the surface electronic properties by a method previously developed (10). All of the oxides in these experiments were converted by heating at 750°C for 16 hr in the presence of the Li_2CO_3-GeO_2 mixture as described earlier.

The results of the diffusion mask experiments were negative. The entire sample was invariably converted to an n-type semiconductor which is characteristic of arsenic doping. We attribute this result to the polycrystalline nature of the oxide layer since large voids between grains were observed by electron microscopy subsequent to the diffusion studies. The sheet resistivity measurements indicated that lithium was not a problem; the resistivity was the same before and after conversion to tet.

A typical set of infrared spectra for an oxide layer, before and after conversion, is presented in Fig. 2. The relatively strong absorption in the 3.0μ wavelength region is associated with the O-H stretching frequency. It is evident that the density of O-H groups is larger for hex than for tet. The field-effect studies revealed that, although both germanium surfaces were n-type, the surface bearing the tet oxide layer was invariably less n-type than the surface covered by a hex oxide. Since the O-H of the oxides can be associated with adsorbed water, known to cause germanium surfaces to exhibit n-type properties (11), the above results support the conjecture that water vapor in the atmosphere will not influence germanium specimens protected by tet oxide as seriously as those bearing hex oxide layers.

Growth and Preferential Doping of Zircon and Thorite

A. B. Chase and Judith A. Osmer

Aerospace Corporation, El Segundo, California

Single crystals of stable, transparent metal oxides that can incorporate rare earth ions are of research interest and may also be of value for electronic applications. Zircon ($ZrSiO_4$) and thorite ($ThSiO_4$), an isomorph of zircon, meet these basic requirements. Zircon and thorite are tetragonal crystals and belong to the space group $I4_1/amd$ (1, 2). Naturally occurring zircon has been reported to have Y_2O_3 and U_2O_3 as impurities (3). In the present work, synthetic crystals of both $ThSiO_4$ and $ZrSiO_4$ were readily doped with various lanthanides and UO_2.

Espig has grown crystallites of zircon from Li_2MoO_4 by the use of mass transport techniques for both nucleation and growth of crystals (4). Using similar techniques, Finch *et al.* (5) have grown thorite with $Li_20.2MoO_3$, $Li_20.2WO_3$, or $Na_20.2WO_3$ as solvents. These techniques normally involve placing the solute in a hot zone and rely on either diffusion or diffusion and convection in the solvent to carry the solute to a cooler region to nucleate and grow crystals. Ballman and Laudise have grown crystals of zircon by slow cooling of $Li_20.3MoO_3$ melts (6).

In the present work, crystals as large as 7 mm across have been grown from molten Li_2MoO_4-MoO_3 and doped with UO_2 and various lanthanide ions. The method of crystal growth is similar to that used by Ballman and Laudise. It involves mixing the solute and solvent and relies on programmed cooling for crystal nucleation and growth. Crystal growth runs of 3 to 5 days' duration generally produce crystals large enough for crystal growth and spectroscopic studies.

The melts from which the largest zircons were grown consisted of 3 mole % ZrO_2, 3 mole % Li_2SiO_3, 5-10 mole % Li_2MoO_4, and 84-89 mole % MoO_3. The materials used were 99.7% pure ZrO_2 obtained from the Zirconium Corporation, high-purity grades of Li_2SiO_3 and Li_2MoO_4 (Lithium Corporation and Chemical Procurement Laboratories, respectively), and an analytical reagent grade of MoO_3 (Allied Chemical Corporation). Appropriate amounts of the powders were mechanically mixed and placed in tightly covered 50 to 100 ml standard form platinum crucibles. The crucibles were heated to 1250°C in Super-Kanthal muffle furnaces that have vertical temperature gradients of no more than 0.5°C/in. The crucibles were held at 1250°C for 2 to 8 hr and program cooled at 2° or 4°C/hr to 1000°C. At this temperature the crucibles were removed from the furnaces and allowed to cool to room temperature. The crystals were separated from the contents of the crucibles by leaching with hot 25% ammonia solutions. The weight loss of a standard run was between 25-35 w/o (weight per cent).

The procedure used to grow thorite was similar to that used for zircon. The ThO_2 was 99.9% pure (purchased from the Lindsay Company). Silicon dioxide was used instead of Li_2SiO_3 in these runs. All other materials were the same as those used for the zircon.

The primary differences in the procedure were that a lower soaking temperature and a different flux composition were necessary for the growth of thorite. Finch (3) indicated that only thorite could be grown below 1225° ± 10°C, and only huttonite could be grown above this temperature.[1] Having substantiated this conclusion, we used a soak temperature of 1220°C with cooling rates of 2°-4°C/hr. The crucibles were removed from the furnaces at 900°C.

The melts used for thorite contained 3 mole % ThO_2, 3 mole % SiO_2, 74 mole % Li_2MoO_4, and 20 mole % MoO_3. Huttonite was obtained from a melt consisting

[1] Huttonite ($ThSiO_4$), the high-temperature polymorph of thorite, is a monoclinic crystal belonging to space group $P2_1/n$ (7) and is retained metastably at room temperature when grown from this system.

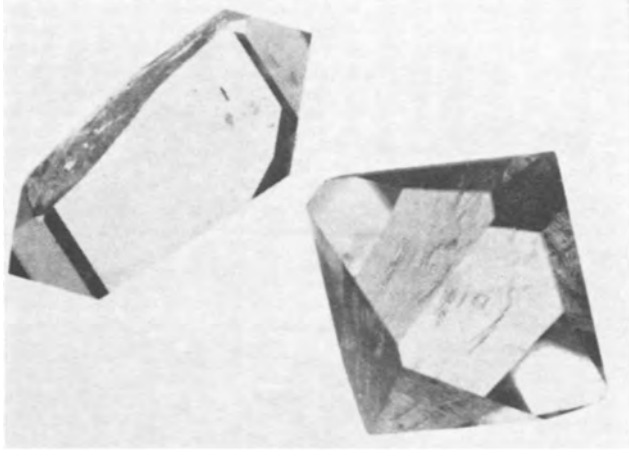

Fig. 1. Zircon crystals showing the change in habit due to rare-earth doping. The crystal on the right is from a doped run, the one on the left from an undoped run. Magnification approximately 8X.

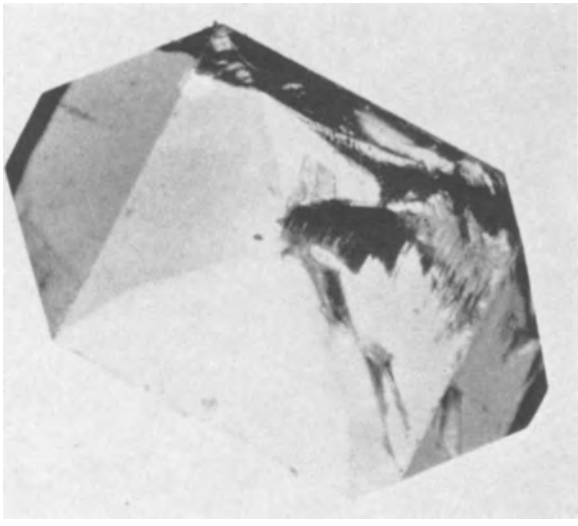

Fig. 2. A UO_2-doped zircon crystal with the dark areas more heavily doped with UO_2 than the light areas. Magnification 12X.

of 5 mole % ThO_2, 5 mole % SiO_2, 70 mole % Li_2MoO_4, and 20 mole % MoO_3 with a maximum temperature of 1250°C. Because the solubility of $ThSiO_4$ in Li_2Mo_4-MoO_3 fluxes increases with increasing MoO_3, it was necessary to use 10% ThO_2 and 10% SiO_2 to produce thorite with a MoO_3-to-Li_2MoO_4 ratio of 1 to 1.

Utilization of the above mixtures for both thorite and zircon provided between 5 and 20 single crystals of good optical quality per run. The crystal sizes in a run varied from 2 to 7 mm long, and the yield for a normal run was 60 to 80% of the starting material. Most of the crystals grew on the bottom of the crucible with a few attached to the sides of the crucible below the melt surface. The largest crystals trapped small amounts of solvent in layers parallel to the major growth planes, during early growth. The normal habit of the crystals from an undoped melt was that of a {110} rod with {111} terminating pyramids.

The habits of the crystals changed when the mixtures were doped with the lanthanide ions. The {111} faces became larger as the lanthanide doping was increased, until, at about a 1 to 3 ratio of the lanthanide sesquioxide to ZrO_2 in the melt, the {110} faces disappeared completely. Figure 1 is a photograph of a crystal from an undoped run and one from a doped run. With up to 0.8 mole % lanthanide ions in the melt, the resultant crystals were clear. Above this level of doping the crystals were cloudy with what appeared to be an unidentified exsolved phase. The experimental evidence implies that the disappearing {110} faces are relatively uncontaminated and grow out of existence as the growth rates of the {111} faces decrease owing to contamination. The particular mechanism of habit change is similar to that described by Frank (9) when an impurity ion is adsorbed onto a face, thereby retarding the propagation of steps on that face and decreasing the growth rate of that face.

While the lanthanide ion changed the habit of zircon, UO_2 contamination had no appreciable effect on the habit. However, the amounts of UO_2 that were incorporated in the crystal varied in direct relationship to the different faces on the crystal. The differences are readily apparent by the color of the crystal. The volume of the material below the {111} faces is a dark green and that below the {110} faces is light green. Figure 2 is a photograph of such a crystal. Spectroscopic analysis of the absorption spectra of the crystals indicated that the color was due to differences in the concentration of the U^{4+} ion. Spectrographic analysis showed 0.08 mole % UO_2 incorporated in a crystal obtained from a run where the UO_2-to-ZrO_2 ratio in the melt was 1 to 2. The U^{4+} ion is much larger than the Zr^{4+} ion and presents a fairly difficult size fit problem for replacement of a Zr^{4+} ion in the lattice.[2] This may account for the relatively small amount of U^{4+} incorporated in the lattice.

Acknowledgment

The authors wish to express appreciation to P. Kisliuk who identified U^{4+} by analysis of the absorption spectra of the crystals. This work was supported by the United States Air Force under Contract No. AF 04(695)-469.

Manuscript received Sept. 2, 1965.

Incorporation of Zinc into Epitaxial GaAs Using Diethyl Zinc

R. W. Conrad and R. W. Haisty

Texas Instruments Incorporated, Dallas, Texas

Generally two approaches have been taken in incorporating acceptor impurities into epitaxially grown III-V semiconductors (*A*) doped source material, and (*B*) a separate reservoir of the dopant inside the deposition system, heated to provide an appreciable vapor pressure.

Method (*A*) has been applied to zinc-doping of epitaxial GaAs (1) and $GaAs_xP_{1-x}$ (2) and found to be unsatisfactory. Reproducible doping levels could not be obtained, apparently because of rapid depletion of the dopant in the source material, perhaps by outdiffusion.

Method (*B*) has been employed with some success to the doping of epitaxial GaAs (3) and $GaAs_xP_{1-x}$ (2) with elemental cadmium. This method, however, has several disadvantages, *viz.*, very accurate temperature control of the dopant is required, the dopant cannot easily be turned on and off abruptly, and nonconstant doping profiles cannot easily be produced except by using elaborate temperature-programming equipment.

Recent work in our laboratories with the volatile organometallic diethyl zinc (bp 118°C) shows this

material to be very promising for the controlled introduction of zinc into epitaxial GaAs.

Epitaxial GaAs was prepared on chromium-doped, semi-insulating (100) oriented GaAs substrates in an open-tube deposition system. Undoped, pulled-crystal GaAs was used as source material and $AsCl_3$ in hydrogen as the transport agent. Source and deposition temperatures were 840° and 735°C, respectively. The background excess donor concentration of undoped epitaxial GaAs prepared in this system was typically 1-2 x $10^{16}cm^{-3}$. Diethyl zinc from the Gallard-Schlesinger Chemical Company was used without further purification.[1] Figure 1 illustrates the deposition and doping systems.

A very small flow of purified hydrogen is metered into the diethyl zinc reservoir where it is saturated with diethyl zinc vapor, then swept by a dilution hydrogen flow (35 cc/min) into the deposition zone of the reactor. Initial experiments in which the hydrogen was introduced through a capillary tip below the surface of the diethyl zinc were unsuccessful because of persistent clogging of the tip by a white solid. This solid, although not positively identified, was probably zinc oxide produced by the reaction of diethyl zinc with traces of oxygen known to be present in the helium used as a flush gas. The ultrafine quartz frit situated at the exit end of the dope tube serves to restrict the passage of particulate matter such as zinc oxide or carbonaceous material. After several doping experiments the quartz frit would become discolored, but the material causing the discoloration was present in only trace amounts and could not be identified.

A series of GaAs depositions was made with various rates of flow through the diethyl zinc system maintained either at room temperature or 0°C. Figure 2 shows the variation of hole concentration in the deposits (from room temperature Hall measurements) as a function of dopant flow rate. In general, the surface quality of the deposits was very good at doping levels $< 10^{19}$ cm^{-3}. Scanning reflection x-ray topographic examination (4) of several of these samples did not reveal any macroscopic inclusions. At $> 10^{19}$ cm^{-3}, however, several samples exhibited what appeared to be small inclusions, when examined with transmitted infrared light. Also, at these high doping levels, deposition rates were substantially reduced, and surface quality degraded. Figure 3 shows the variation of room temperature hole Hall mobility with hole concentration. Included for comparison are the data of Meyerhofer (5) for zinc- and cadmium-doped bulk GaAs.

Two possible explanations for the decrease in deposition rate and surface quality at high dopant flow rates are (*a*) a dilution effect, in which the depositing species are literally swept away from the vicinity of the substrate by the high gas flow issuing from the dope tube outlet and, (*b*) an inhibition of deposition by the high concentration of zinc and/or carbonaceous material smaller than the pore size of the quartz frit. To clarify this, epitaxial GaAs was deposited with a high flow of hydrogen only issuing from the dope outlet tube (20 cc/min plus the usual dilution flow of 35 cc/min). The rate of deposition was drastically reduced and the surface quality seriously degraded, indicating that the dilution effect is a contributing factor in the production of poor quality deposits. To evaluate more fully the role of dopant concentration, it will be necessary to employ a more volatile zinc compound such as dimethyl zinc.

The room temperature hole mobilities in diethyl zinc-doped epitaxial GaAs compare favorably with the published values for zinc- and cadmium-doped bulk GaAs, implying that carbon, if incorporated, is not seriously affecting the electrical properties. An improvement in the hole mobilities in diethyl zinc-doped epitaxial GaAs should be realized by reducing the background donor impurity concentration.

Experiments are presently being conducted in these laboratories on the doping of various epitaxial III-V

[1] Caution should be used in handling this material, since it is spontaneously flammable in air and highly toxic.

Purification of Lithium Metal by High-Vacuum Fractional Distillation

Paul H. Schmidt

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Lithium, the lightest of all metals, has a high thermal conductivity, low melting point, and small thermal neutron cross section. It is, therefore, of interest to nuclear scientists as a heat transfer fluid. Its advantages as compared to other alkali metals are, however, limited in part by the presence of impurities both gaseous and metallic which greatly accelerate the corrosion process of lithium with its container material. High purity is also a requirement for the investigation of the electronic band structure of a metal, this being the primary motivation for the present study.

The purest commercially available lithium produced today approaches 99.99% purity (Table I) and is prepared chiefly by the electrolytic reduction of a fused eutectic mixture of lithium chloride and potassium chloride (1). Purification beyond this level either by zone refining (2) or by distillation (3-7) has not been achieved. Attempts to purify lithium by vacuum distillation have generally been ineffective because of the small differential vapor pressures between lithium and its contaminants at high temperatures. Furthermore, the improper choice of suitable container materials for still construction and marginal design and operation has led to the belief that the purification of lithium metal by vacuum distillation was not feasible. Lithium metal of 99.9999% purity,[1] however, has been prepared in this laboratory by high-vacuum fractional distillation.

Apparatus

Distillations were carried out in a 2½ in. diameter 16½ in. long stainless steel column (Fig. 1). All seams were helium arc welded during fabrication of the retort. A 0.010 in. thick rolled molybdenum sheet with a ¼ in. overlapping seam was used as the liner. It extended from the top to the bottom of the chamber. A molybdenum crucible was used to contain the raw material. Ten perforated molybdenum sieve plates served as the rectifying portion of the column producing approximately a ten to one reflux ratio and a very low holdup at operating temperatures. Each plate, 0.010 in. thick, contained four ⅜ in. diameter holes and was rotated from the adjacent plates by 45° to prevent vapor channeling. The plates were held together with three molybdenum rods and separated with molybdenum tube spacers 0.292 in. long. The entire assembly fit snugly into the chamber for positive thermal contact with the wall and rested on the

crucible. A ¾ in. diameter stainless steel tube, closed and pointed at one end, was welded to the inside of the top flange. It projected downward into the column and served as the solid-state condenser. The temperature of the condenser could be maintained at any desired temperature in the interval from —196° to 800°C by cooling liquid nitrogen, gas, or water or by heating with an electric heater.

The column was heated with a nichrome wound resistance furnace. A temperature gradient of 2°-5°C was maintained from plate to plate of the rectifying column by shunting windings on the furnace. The temperature during distillation was controlled to ± 0.5°C using a digital set point proportional controller and continuously monitored using seven thermocouples spaced along the column's length. The upper portion of the still, not in the furnace, was water-cooled.

A 15 l/sec diode-type getter-ion pumping system employing 1½ in. diameter tubing and copper O-ring seals was used in conjunction with the distillation chamber. The pumping system incorporated a viewing window to permit observation of the light fraction as it condensed in the water cooled section of the still. A valve between the ion-pump and the chamber permitted removal of the still, under vacuum, to a dry box for sample removal.

Container Materials

Choice of suitable container materials both for distillation and sampling procedures was essential for the success of these experiments. Since most metals are severely corroded by liquid lithium and lithium hydroxide the choice of a container material is difficult. The metals modybdenum,[2] tantalum, and tungsten are perhaps the most resistant to corrosion by liquid lithium (8, 9). Unfortunately, these metals are difficult to weld and fabricate and furthermore become embrittled on exposure to the atmosphere at distillation temperatures. The use of these metals was restricted to structures within the distillation chamber (liners, crucibles, and baffles). Stainless steel types 304 and 321 were the materials selected for structures exposed to the atmosphere. The use of a molybdenum liner in the distillation chamber prevented, for the most part, excessive contact of liquid lithium with the stainless steel shell. Failures due to corrosion were not experienced even after 2000 hr at 500°C using the molybdenum liner.

Experimental Procedure

Careful chemical cleaning of the still and all its associated components preceded each distillation. The still was then assembled and attached to the pumping system. The column was then baked overnight at 700°C in vacuum. The bakeout served the twofold purpose of reducing to a minimum those volatile contaminants not previously chemically removed and insured that no leaks had occurred either during the chemical cleaning procedures or through corrosion from a previous distillation. The molybdenum crucible was filled with lithium metal, allowed to cool, and then loaded into the still along with the rectifying column. Following the initial pumpdown to 1×10^{-9} Torr, the column temperature was slowly increased to 400°-550°C. Typical vacuum conditions at distillation temperatures ranged from 5×10^{-6} to 4×10^{-8} Torr measured at the ion pump. During this phase of the distillation those impurities having a high vapor pressure were separated from the bulk charge, enriched in the rectifying baffles, and driven up the column. The collector was maintained at a high temperature preventing condensation at this time. Approximately 10-25% of the charge was driven to the top of the column and later discarded, the amount being determined by the volatile impurity content in the raw material. The collector temperature was then decreased and lithium allowed to condense. By controlling the vapor density through the rectifying baffles and the temperature of the collector, the grain size of the distillate could be varied from finely polycrystalline to very coarsely polycrystalline. Once the desired fraction was collected on the condenser, the still was shut down and allowed to cool under vacuum. Enriched low-vapor-pressure contaminants were thus contained in the balance of the lithium remaining in the crucible and on the baffles. The valve isolating the vacuum system was then closed and the still moved to an argon-filled dry box. Samples were removed from the distillate with molybdenum knives and stored in degassed and prereacted mineral oil.

[2] Solubility ~1 ppm at 950°C.

Discussion

Analysis for residual metallic impurities indicated that group II elements, especially calcium, were the most difficult to remove (Table II). Distillation effects with uranium metal and boric oxide additives to the charge were studied in an effort to change the differential vapor pressures between lithium and its metallic contaminants. Additive amounts were controlled to compensate for the known impurity concentration in the raw material. The results indicate that the addition of uranium metal as an additive to the charge did not affect the purity of the distillate. It was observed, however, that addition of a small amount of boric oxide to the charge improved the purity considerably (Table II) (Fig. 2). Only trace amounts of impurities were detectable. In distillations carried out under similar conditions, but in the absence of boric oxide, 14-31 ppm metallic impurities remained in the distillate. The mechanism believed to be responsible

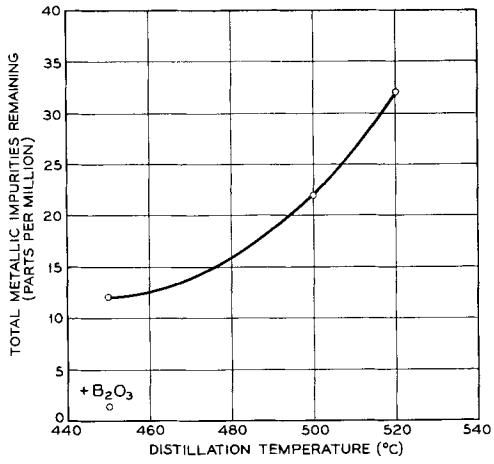

Fig. 2. Total metallic impurities *vs.* distillation temperature. The distillate purity approaches an apparent asymptotic level of approximately 10 ppm at temperatures near 450°C.

for the purity reduction is the formation of a stable oxide.

$$6Li + B_2O_3 \xrightarrow{\text{vacuum}} 3Li_2O + 2B \qquad [1]$$

$$Li_2O + \text{Ca impurities} \xrightarrow{\leftarrow} CaO + 2Li \qquad [2]$$

Reaction [2] favors the formation of calcium oxide which is more stable thermodynamically than lithium oxide. Calcium oxide would be stable at distillation temperatures and not decompose. Separation based on the differential vapor pressures of calcium oxide and lithium would now apply. The stable compound would therefore remain in the "bottoms" on distillation of the lithium charge.

A direct correlation of temperature *vs.* purity is observed during distillation, lower distillation temperatures being associated with higher purities (Fig. 2). This is not surprising in view of the increasing relative volatility α, as temperatures are reduced. Variation of vacuum conditions from 4×10^{-8} to 5×10^{-4} Torr did not seem to affect the distillate purity. Distillation below 450°C did not seem practical, even though greater purity might ultimately be achieved (Fig. 2), since distillation rates are very low (0.005 g/hr at 400°C and 0.042 g/hr at 450°C). At the lowest temperature of the present series of experiments (450°C), the total distillation time was 21 days. Cleaning and bakeout of the chamber and vacuum system required another six days.

Analysis.—The eddy current decay method of measuring resistivity ratios (10) was used as a rapid means of ascertaining the electronic quality and "purity" of lithium samples. Resistivity ratios $\rho_{300°K}/\rho_{4.2°K}$ of the purest commercially available lithium, 99.9-99.99% purity, ranged from 500 [3] to approximately 1000 [4] while ratios as high as 4000 were recorded on samples taken from the distillate of the run using the boric oxide additive. Resistivity ratios measured on samples taken from the distillates of other runs never exceeded 1100. Even though spectrographic analyses indicated a reduction in the total metallic impurity level, the resistivity ratios were not greatly affected. Calcium impurities were thought to affect the resistivity ratios more than any other impurities in these samples.

[4] Lithium Corporation of America, Bessemer City, North Carolina.

Samples of lithium metal from different sections in the still as well as the raw material were analyzed for metallic impurities (Table II, Table III). Bulk specimens of lithium metal were used for x-ray fluorescent analyses while lithium carbonate samples were used for analysis by emission spectroscopy. Specimens of metallic lithium were converted to lithium carbonate by reacting the metal with water and carbon dioxide gas. Polypropylene containers were used for the reduction process and platinum containers for drying. Fused silica containers were found to contaminate the samples with 5-30 ppm of silicon. Excellent correlation was obtained for potassium and calcium impurities using the two methods of analysis. The usefulness of x-ray fluorescence was, however, limited by the dilute nature of the other metallic impurities.

A study of the electron spin resonance of bulk metallic lithium specimens (11) at 12 kMc frequency has further substantiated the above analytical data. Using our 4000 residual resistivity ratio lithium metal, the spin resonance line is approximately 0.2 gauss wide, the narrowest line width thus far observed in bulk lithium. Line widths of the raw material are at least a factor of four broader.

Conclusion

Distillations carried out using an additive of boric oxide in the charge yielded a higher purity distillate than distillations without the additive. Distillations carried out at lower temperatures yielded higher purity distillates. Group II elements, especially calcium, were the most difficult impurities to remove by distillation techniques.

Acknowledgments

The author wishes to thank C. C. Grimes for his assistance and constructive criticism regarding still design, K. B. Jefferts for his guidance in vacuum system design and technology, and G. Adams for resistivity ratio measurements. He would also like to thank D. Nash for spectrographic analyses.

Hydrogen Oxidation on Platinum

M. P. Makowski,[1] Ewald Heitz,[2] and Ernest Yeager

Western Reserve University, Cleveland, Ohio

The anodic reaction of hydrogen on platinum has been studied by a number of authors in both acid (1-14, 16) and basic (1, 6, 11-13, 17) media, but some questions continue to exist as to the nature of the results and in particular the kinetics of the reaction. Of particular interest is the work of Frumkin and Aikazyan (5, 6, 17) who found a zero or near zero-order dependence of the anodic limiting current for hydrogen oxidation on the hydrogen concentration in the solution adjacent to the electrode in acid media. These authors used slow sweep voltammetry in con-

junction with the rotating disk method to obtain these results.

In a relatively recent review (17) Frumkin has cited the work of other electrochemists which indicates first order dependence on hydrogen concentration for the oxidation of hydrogen in acid media. Included in this other work is reference to preliminary studies conducted in our laboratories in 1961 under conditions similar to those employed by Frumkin and Aikazyan with the added feature of variable pressure. These data have never been submitted for publication. Subsequently, additional more extensive data supporting the earlier unpublished results have been obtained. The purpose of this note is to present these data.

Slow sweep voltammetry (20-95 mv/min) has been used to study the anodic hydrogen reaction on platinum in conjunction with the rotating disk technique at pressures from 1 to 60 atm and disk velocities up to 20,000 rpm. Several experiments also have been conducted by varying the disk velocity while holding the potential constant in the range of the limiting currents. The platinum anodes had an apparent area of 0.283 cm^2 and were machined from reference grade platinum supplied by Englehard Industries with a purity of 99.999%. The electrolytic cell was made of Teflon and was mounted in a high-pressure stainless steel enclosure together with the drive system used in conjunction with the rotating disk technique. The whole system was located in a thermostated bath maintained at 26°C. Details of the apparatus and experimental procedures are given elsewhere (16). The solutions used in the present work included 1*N* H_2SO_4, 1*N* HBr, and 1*N* $HClO_4$. Considerable effort was directed to the purification of the solutions and the hydrogen gas used to saturate the solutions. All polarization runs were preceded by a pre-electrolysis treatment extending for 48 hr with a reversible hydrogen cathode (smooth or platinized platinum) and a polarized smooth platinum anode of at least several square centimeters apparent area unless otherwise noted.

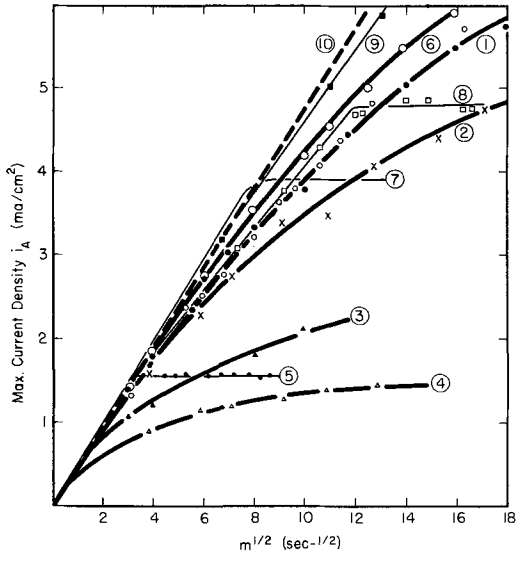

Fig. 2. Anodic current density (i_A) for hydrogen oxidation on a smooth platinum disk in 1*N* acids as a function of angular velocity (m); 1 atm; T = 25°C. 1, solid points, maximum current density, permanganic acid pretreatment, electrochemical activation, 1*N* HBr; open circles, current density at +100 mv from Fig. 1; other conditions same as curve 1; 2, HBr pretreatment; other conditions same as open circles for curve 1; 3, maximum current density, chromic acid pretreatment, electrochemical activation, 1*N* HBr; 4, current density at +100 mv from Fig. 1; HBr pretreatment, no electrochemical activation, 1*N* HBr; 5, maximum current density in 1*N* HBr according to Frumkin and Aikazyan; 6, maximum current density, permanganic acid pretreatment, electrochemical activation, 1*N* H_2SO_4; 7, maximum current density in 1*N* H_2SO_4 according to Frumkin and Aikazyan; 8, same as curve 6 except no distillation of acids or pre-electrolysis; 9, same as curve 6 except in 1*N* $HClO_4$; 10, limiting current density for pure diffusion control.

Prior to the introduction of the solution into the cell, both the cell and the electrodes were given a pretreatment with either chromic acid or an acid permanganate solution at room temperature for a few minutes. The cell and electrodes were then washed profusely with distilled water and the solution to be used in the subsequent measurements prior to commencing final preparations for the experiment.

Before obtaining the anodic polarization curve, the disk electrode was polarized usually at a potential of −0.40v (re. reversible hydrogen electrode) for a period of 1 min. This activation procedure is to be compared with the cyclic procedure used by Frumkin and Aikazyan, in which they polarized their platinum alternately anodically and cathodically in sulfuric acid at unspecified potentials.

In Fig. 1 are presented typical potential-current density curves obtained at various angular velocities. The current maximum was observed for the oxidation of hydrogen in all instances where the voltammetry sweep was extended to sufficiently anodic potentials. In instances where the upper limit on the current density was imposed by the kinetics of the electrode reaction rather than transport in the solution, the maximum was observed at relatively low anodic potentials. In instances where combined reaction and diffusion control are involved, the maximum is very broad and difficult to see from the curves shown in Fig. 1 (*e.g.*, HBr, 1 atm, permanganic acid pretreatment) because of the limited range of the anodic sweep. The shape of the curve and in particular the position of the maximum were critically dependent on the nature of the electrolyte, the type of pretreatment given to the electrode, the rate of voltage scan, and the rotation rate.

The least active electrodes (lowest current density maximum) were found in experiments with electrodes pretreated with chromic acid solution. The permanganic acid treatment resulted in much more active electrodes, using the maximum current density as a criterion of activity. A comparison of the results obtained in the present work and those reported earlier by Frumkin and Aikazyan shows that their electrodes had activities comparable to the electrodes pretreated with chromic acid solution and considerably less than those prepared with the permanganic acid pretreatment.

Two or more runs were made to check each of the curves given in Fig. 1. The agreement of all the curves

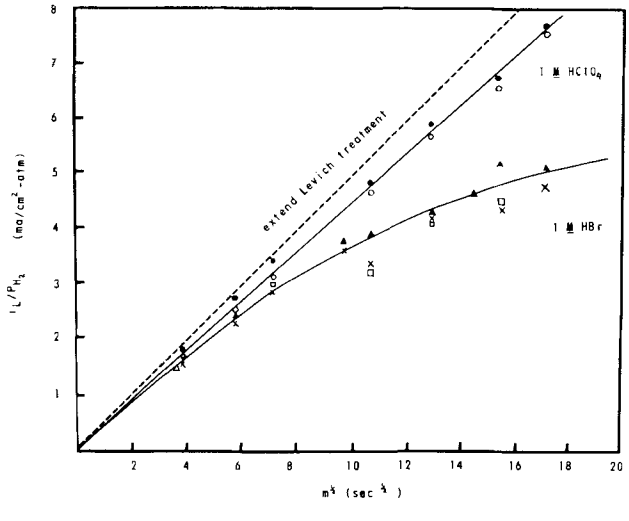

Fig. 3. Anodic maximum current densities in HBr and $HClO_4$ as a function of rotation rate. ○, 1*M* $HClO_4$, 1 atm; ●, 1*M* $HClO_4$, 20 atm; ×, 1*M* HBr, 1 atm; ▲, 1*M* HBr, 10 atm; □, 1*M*, HBr, 60 atm; T = 25°C.

reported was within a few per cent. Hysteresis was also checked in some instances by recording currents with decreasingly anodic potentials. While some hysteresis was observed, in general the magnitude was not sufficient to modify the over-all shape of the curve. The relatively small hysteresis effects observed are what one would anticipate for a system in which large anodic Faradaic currents are involved. The currents associated with the adsorption and desorption of anions during the course of the slow sweep voltammetry would be very small compared to the anodic Faradaic current associated with hydrogen oxidation.

In Fig. 2 are plotted maximum current densities as a function of the square root of the angular velocity. Superimposed on these curves is the curve of Frumkin and Aikazyan for hydrobromic acid and the curve expected from the Levich equation for a purely diffusion-controlled process. The sharp break in the curve of Frumkin and Aikazyan is evidence for zero order or very low fractional order dependence of the limiting current on the hydrogen concentration in the solution adjacent to the electrode.

The only instance in the present work under which the zero or near zero order dependence of the limiting current on hydrogen concentration has been observed is that represented by curve 8 in Fig. 2. The data corresponding to this curve were obtained in 1*N* H_2SO_4 which had not been subjected to any special purification procedures.

Figure 2 includes data for electrodes prepared without either chromic acid or permanganate pretreatment and also electrodes not subjected to cathodic polarization prior to the anodic run. The differences in the activities of the electrodes given these various pretreatments are self-evident from the figure. Electrodes given the acid permanganate treatment and cathodic polarization prior to the anodic run were the most reproducible.

In Fig. 3 are graphed the anodic maximum current densities in HBr and $HClO_4$ as a function of the square root of the angular velocity for various partial pressures of hydrogen gas. While there is some scatter of the data, these results generally support the conclusion that the limiting current has a first order dependence on concentration of hydrogen dissolved in the HBr solutions.

No kinetic control has been found in 1*N* $HClO_4$ (see curve 9, Fig. 2) over the range of potentials investigated in the present work. A plot of the overpotential *vs.* the function log $(i_L - i)/i_L$ has a slope of approximately 30 mv/decade as would be expected for pure diffusion control.

Attempts have been made by the authors to explain the curves in Fig. 1 quantitatively on the basis of combined kinetic and diffusion control with hydrogen dissociative adsorption and hydrogen ionization together responsible for the kinetic control. Temkin-type adsorption kinetics for hydrogen adsorption and ionization and double layer behavior in the vicinity of the point of zero charge have been considered. A quantitative correlation with theory, however, has not been accomplished. Perhaps the difficulty is associated with inadequate quantitative consideration of the competitive adsorption of anions and hydrogen in the presence of water dipoles, particularly near the point of zero charge.

Theory of the Performance of Porous Fuel Cell Electrodes

John A. Rockett and Ralph Brown

Pratt & Whitney Aircraft, Division of United Aircraft Corporation, East Hartford, Connecticut

ABSTRACT

A theoretical analysis of the polarization mechanisms in a porous fuel cell electrode was made employing a model consisting of a single pore coated by a thin film of electrolyte. The analysis accounted for those polarizations associated with transport of electrolyte species, transport of dissolved gas, chemical reaction at the solid-liquid interface, and ohmic losses in the electrolyte. The theory was compared with data from biporous nickel electrodes operating on oxygen in 80% KOH at temperatures ranging from 300° to 500°F.

An important adjunct to the development of a high performance fuel cell electrode is the development of a satisfactory theoretical description of the electrode. We have devoted a good deal of effort in the last five years to the development of biporous, sintered, metal electrodes and to the development of a theory for them.

The criterion for judging any theoretical description is its ability to match accurately the measured performance of practical electrodes. Some of our previous attempts, one of which considered only the polarizations associated with diffusional transport processes, and one which considered only the chemical reaction, gave no satisfactory agreement with any of our porous electrode data. The foundations of the theory which is presented here were first suggested in an unpublished paper by Wagner (1). His paper presented a good, comprehensive theoretical study. It contained no data. Wagner had combined aspects of both the transport and chemical reaction in his theory. A similar fusion of these processes is the heart of this theory. This theoretical approach has also been discussed by other authors (2, 3). In the work presented here, however, particular care had to be exercised in the description of the transport processes in the electrolyte. The compositions of the electrolytes in our applications are considerably different from the low solute concentrations often discussed in the published literature. Molar ratios of solute to solvent of over one are common. A satisfactory description of the transport in these highly concentrated electrolytes is often a formidable problem.

This theory represents an attempt to make a comprehensive analysis of the processes taking place in a porous gas-diffusion electrode. After making a basic assumption regarding the geometry of the gas-liquid-solid interface, the theory accounts for those polarizations associated with transport of electrolyte species, transport of dissolved gas, chemical reaction at the solid-liquid interface, and ohmic losses in the electrolyte.

Theoretical Model

The first and one of the most dramatic of the assumptions which must be made is the selection of a geometrical model for the porous structure. Figure 1 shows a cross section of a typical biporous sintered electrode and a cross section of the analytical model adopted. The sinter particles which are seen in cross section are interconnected below the focal plane of the microscope to form a coherent mass; the walls of the analytical model are connected below the section plane of the drawing to form a circular cylinder. Better representations of the sinter can be readily proposed, and a few of these are being developed. The model presented here is the simplest which has proved quantitatively useful. The bulk electrolyte completely fills the fine pore layer represented in the model by an array of small diameter tubes, and coats the entire surface of the coarse layer with a thin liquid meniscus. The variable thickness meniscus is thickest at the fine pore-coarse pore interface and thinnest at the gas side. The reactant gas occupies the volume to the right of the coarse pore and also fills the central portion of the tubular meniscus coated coarse pore.

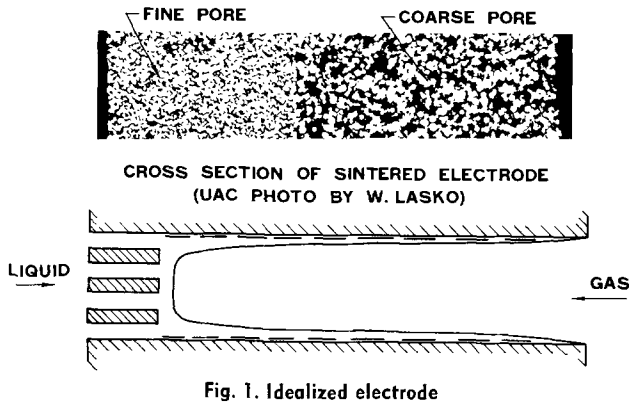

Fig. 1. Idealized electrode

The second assumption deals with the half-cell electrode reactions. The theory, as presented here, applies to the cathode of a hydrogen-oxygen fuel cell. These arguments, with minor variations, could equally well be phrased for the anode or other gas diffusion electrodes. The over-all reaction for the complete reduction of oxygen in alkaline electrolyte is as follows

$$O_2 + 2H_2O + 4e^- \rightleftharpoons 4\,OH^- \qquad [1]$$

At the relatively high temperatures and concentrations which have been of specific interest to us, the experimental open-circuit potentials are very close to those calculated from the free energy change of the H_2-O_2 reaction as shown in Fig. 2.

The fact that the experimental open-circuit values are not below their theoretical values suggests that any competing reactions that could lower the open-circuit potential are of relatively little importance. Reaction [1], therefore, substantially represents the

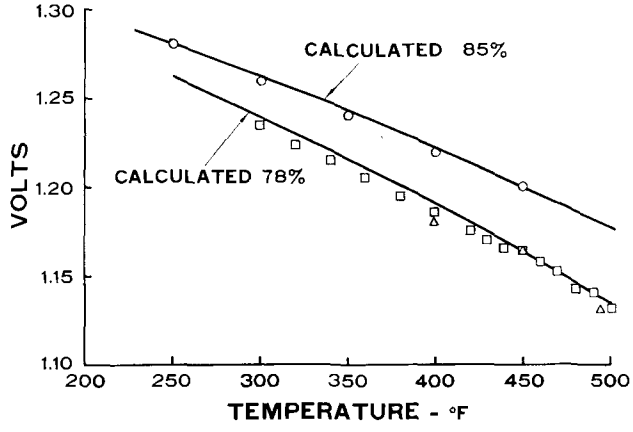

Fig. 2. Open-circuit voltage. ○, Measured 85% KOH; □, △, measured 78% KOH.

net cathode reaction. In order to write a precise kinetic expression for the net half-cell reaction, however, the sequence and relative rate constants for each reaction step must be known. To illustrate the problem, suppose the over-all reaction can be divided into two steps

$$2M + O_2 + 2e^- \rightleftharpoons 2MO^- \qquad [2]$$

$$MO^- + H_2O + e^- \rightleftharpoons M + 2\,OH^- \qquad [3]$$

where the first of these is presumed to be the rate-limiting step. The kinetic expression for reaction [1] is

$$i = i_1 \left[\frac{\alpha_{O_2}}{\alpha_{O_2}^{\circ}} \left(\frac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{\frac{2F}{RT}\eta} - \left(\frac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^4 e^{-\frac{2F}{RT}\eta} \right] \qquad [4]$$

where α_i is the local activity of species i, α_i° is the reference activity for the bulk electrolyte, i_1 is the exchange current, and η is the local metal-solution potential difference.

On the other hand, the kinetic expression for the sequence of reactions [2] and [3] is

$$i = i_2 \frac{\dfrac{\alpha_{O_2}}{\alpha_{O_2}^{\circ}} \left(\dfrac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{\frac{2F}{RT}\eta} - \left(\dfrac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^4 e^{-\frac{2F}{RT}\eta}}{\left[(1-\theta_o) \left(\dfrac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right) e^{\frac{F}{RT}\eta} + \theta_o \left(\dfrac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^2 e^{-\frac{F}{RT}\eta} \right]^2} \qquad [5]$$

where θ_o is the equilibrium fractional coverage of adsorbed oxygen.

Note that the numerator of Eq. [5] is identical to Eq. [4]. The important addition in Eq. [5] is the denominator which changes the exponentials and alters the functional dependence of the water activity term. In spite of the apparent differences in the specific expressions for various hypothetical reaction sequences, it is a practical fact that the complete electrode theory is a synthesis of many interacting parts and is not highly sensitive to the detailed reaction mechanism. After trying a variety of possible reaction sequences, the insensitivity of the results became apparent. Considering this fact, and considering the conjectural basis for choosing any particular reaction sequence, we decided to employ Eq. [4] because of its relative simplicity. This choice does impose certain assumptions on the nature of the reaction sequence, the principal one being that the controlling step involves diatomic oxygen species, and does not take place after the O-O bond is broken. This is a good assumption because the strength of the O-O bond suggests that O-O dissociation is likely to be the controlling step. This assumption also yields the important result that the exchange current is directly proportional to oxygen partial pressure.

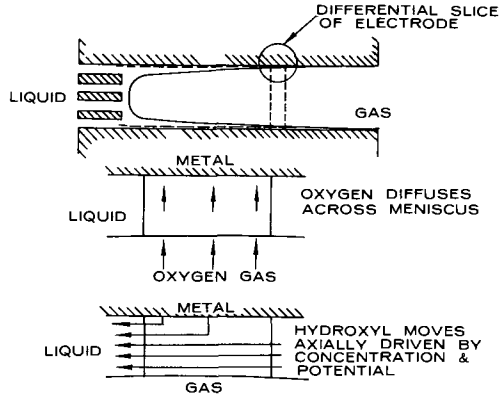

Fig. 3. Meniscus model

Mathematical Formulation

The analysis considers a differential slice cut from the meniscus portion of the electrode as shown in Fig. 3. The local current density on the metal surface is given by the kinetic expression. The potential, E, of the electrode is measured relative to a reference probe located in the bulk liquid to the left of the electrode fine pore. The potential of the electrolyte is chosen as zero at the left edge of the fine pore and chosen to have increasingly positive values in the positive X direction. The local metal-solution potential difference at any point in the meniscus is given by the difference between the electrode potential and the solution potential. The kinetic expression in Eq. [4] can then be written with the driving potentials in terms of the solution potential.

$$i = i_1 \left[\frac{\alpha_{O_2}}{\alpha_{O_2}^{\circ}} \left(\frac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{\frac{2F}{RT}(E-\phi)} - \left(\frac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^4 e^{-\frac{2F}{RT}(E-\phi)} \right] \qquad [6]$$

The gas consumed in the differential portion is assumed to diffuse directly across the meniscus. For most practical geometries the partial pressure of the reactant gas is constant all along its length. This being the case, the local current density in the differential element can be expressed in terms of the Fick's law diffusion expression for the diffusion of the reactant gas across the meniscus.

$$i = \frac{4FD_{O_2}\alpha_{O_2}^{\circ}}{\delta} \left(1 - \frac{\alpha_{O_2}}{\alpha_{O_2}^{\circ}} \right) \qquad [7]$$

where δ is the meniscus thickness.

Simultaneous solution of Eq. [6] and [7] allows the elimination of the gas activity ratio from the expression for local current density.

$$i = i_1 \left[\frac{\left(\dfrac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{\frac{2F}{RT}(E-\phi)} - \left(\dfrac{\alpha_{KOH}}{\alpha_{KOH}^{\circ}} \right)^4 e^{-\frac{2F}{RT}(E-\phi)}}{1 + \dfrac{i_1\delta}{4FD_{O_2}\alpha_{O_2}^{\circ}} \left(\dfrac{\alpha_{H_2O}}{\alpha_{H_2O}^{\circ}} \right)^2 e^{\frac{2F}{RT}(E-\phi)}} \right] \qquad [8]$$

The local current density is related to the current in the axial direction of the meniscus by making a current balance on the differential element.

$$i = \frac{1}{2\pi R} \frac{dJ}{dx} \qquad [9]$$

The current in the axial direction of the meniscus is related to the ohmic potential in the electrolyte by Ohm's law.

$$-J = 2\pi R\delta\sigma \frac{d\phi}{dx} \qquad [10]$$

where σ is the conductivity of the electrolyte.

Substitution of Eq. [10] into Eq. [9] relates the ohmic potential in the electrolyte to the local current density. In making this substitution, the meniscus thickness will be assumed constant with X. This assumption is justified by the fact that only a fraction of the total meniscus length is utilized.

$$i = -\delta\sigma \frac{d^2\phi}{dx^2} \qquad [11]$$

Equation [11] represents the second order differential equation which is to be solved in order to obtain the total current produced in the pore. If we can obtain the water and KOH activity ratios as a function of electrolyte potential, the local current density can then be expressed solely as a function of this potential. The total current produced by the pore is given by the axial current (Eq. [10]) evaluated at the fine pore-coarse pore interface. Although some current is produced in the fine pore as gas diffuses into it, this is assumed to be negligible because of the low diffusion rate of the gas into this flooded portion of the electrode. The total current is then given by

$$-J = 2\pi R\delta\sigma \frac{d\phi}{dx} \Bigg/ \text{evaluated at fine pore-coarse pore interface} \qquad [12]$$

The ohmic gradient at the fine pore-coarse pore interface is obtained by one integration of Eq. [11] over the active length of the meniscus. Equation [11] is multiplied by $d\phi/dx$ and the following differential identity is applied

$$\frac{d}{dx}\left(\frac{d\phi}{dx}\right)^2 = 2\frac{d\phi}{dx}\frac{d^2\phi}{dx^2} \qquad [13]$$

Equation [11] can then be written.

$$d\left(\frac{d\phi}{dx}\right)^2 = -\frac{2i}{\delta\sigma}\, d\phi \qquad [14]$$

This form of Eq. [11] can then be directly integrated to obtain $d\phi/dx$. Substitution of the result into Eq. [12] yields an expression for the pore current as a function of a definite integral in ϕ.

$$-J = \pi R\left[8\sigma\delta\int_{\phi_1}^{\phi_o} i(\phi)\, d\phi\right]^{1/2} \qquad [15]$$

The lower limit of integration is the potential, ϕ_1, at the fine pore-coarse pore interface. This must be obtained by simultaneous solution of Eq. [15] and an Ohm's law expression which describes the proportionality between the axial current through the fine pore and this potential. The expression is corrected for the number of fine pores associated with each coarse pore.

$$-J = \pi R^2 \frac{P_{FP}\tau_{CP}\sigma}{P_{CP}\tau_{FP}^2 t}\phi_1 \qquad [16]$$

where P_{FP} is the fine pore porosity, P_{CP} is the coarse pore porosity, τ is the tortuosity, and t is the fine pore thickness.

The upper limit of the integration is that potential at which the local current density becomes zero. Inspection of the numerator of Eq. [8] shows that as the ohmic potential increases along the meniscus, the forward reaction driving potential decreases, the water activity ratio decreases, and the KOH activity ratio increases.

The result is that the forward and reverse reaction rates approach each other, and the local current becomes zero. It was pointed out earlier that a variety of reaction sequences are described by expressions that differ only in the denominator. Whereas the numerator specifies the upper limit of integration, the value of the upper limit is common to these various mechanisms. This is the reason that the final result is fairly insensitive to the choice of the reaction mechanism. The upper limit of integration, which is related to the working length of the meniscus, is a far more important factor than the functionality of the denominator of the rate expression. In most practical cases, the working length of the meniscus is just a fraction of its total length.

The requirements for computing the current from one pore have been indicated. The solution is given as a function of definite integral in Eq. [15], but a numerical integration is required for even the most simple reaction mechanism. In order to include the resistance of the fine pore, this solution must be solved simultaneously with the linear expression of Eq. [16] to find the lower limit of integration. A numerical approach is also required to solve for the root of a transcendental equation to find the upper limit. The pore radius is chosen to correspond to an average pore size of the structure. Using a "spaghetti" model, the number of pores in a given area of electrode is

$$\frac{N}{A} = \frac{P_{CP}}{\tau_{CP}}\frac{1}{\pi R^2} \qquad [17]$$

The electrode current density is found by multiplying the current for each pore by the number of pores per unit area.

$$I = \frac{-JP_{CP}}{\pi R^2\tau_{CP}} \qquad [18]$$

The discussion to this point has been predicated on the assumption that a means of obtaining the water and KOH activities as a function of solution potential is available. This problem is discussed below.

Transport of Electrolyte Species

The hydroxyl ion that is produced in the reaction must diffuse axially through the meniscus from the reaction surface to the bulk electrolyte. If ideal solutions are assumed and bulk transport is neglected, the transport equations for both potassium and hydroxyl ions show a term proportional to KOH concentration gradient and a term proportional to ohmic potential.

$$J = \pi R^2\left[-FD_{OH}\frac{dC_{OH}}{dx} - \lambda_{OH}C_{KOH}\frac{d\phi}{dx}\right] \qquad [19]$$

$$O = \pi R^2\left[-FD_K\frac{dC_{KOH}}{dx} + \lambda_K C_{KOH}\frac{d\phi}{dx}\right] \qquad [20]$$

Equation [20] can be integrated using a reference concentration, C_{KOH}^o, as that in the bulk electrolyte where the reference electrolyte potential is zero. The variation of the diffusivity and ion equivalent conductance with concentration are neglected.

$$\frac{C_{KOH}}{C_{KOH}^o} = e^{\frac{\lambda_K}{FD_K}\phi} \qquad [21]$$

In extremely dilute solutions, the Nernst-Einstein relation could be applied to the coefficient of ϕ in Eq. [21] and the concentration variation as a function of ϕ would be known. In a nonideal electrolyte, however, the correct driving force for the diffusive transport is not the concentration gradient, but the gradient of chemical potential. Equation [21] can be corrected to the proper diffusive drive force by a simple adjustment to the diffusivity.

$$D_K = D_K^o\frac{\partial(\ln a_{KOH})}{\partial(\ln C_{KOH})} \qquad [22]$$

Application of the correction in Eq. [21] assumes the correction factor does not vary strongly with concentration. There are other correction factors for the diffusivity which are functions of the electrolyte fluid properties such as viscosity and density. These same corrections apply to the equivalent ion conductance so that the conductance to diffusivity ratio is assumed constant. With these assumptions, the Nernst-Einstein relation can be applied.

$$\frac{\lambda_K}{FD_K^o} = \frac{F}{RT} \qquad [23]$$

The KOH concentration variation as a function of potential can now be written by substituting Eq. [22] and [23] into Eq. [21]

$$\frac{C_{KOH}}{C_{KOH}^{o}} = e^{\frac{F\phi}{RT\frac{\partial(\ln a_{KOH})}{\partial(\ln C_{KOH})}}} \quad [24]$$

It is necessary to relate the concentration changes to activity changes as are required in the kinetic equation. Activity coefficients for KOH have been measured but only to 50 w/o (5). Water vapor pressures have been measured over highly concentrated KOH over a wide range of temperature (6). The solvent activity is defined as the ratio of electrolyte vapor pressure to pure solvent vapor pressure. The water vapor pressure data gives us the water activity as a function of the solvent concentration. Specifically, the water vapor pressure data was related to the water concentration by the following empirical expression

$$\ln p_{H_2O} = AF_{H_2O}^2 + BF_{H_2O} + C \quad [25]$$

where F_{H_2O} is the weight fraction water; $A = -34.135$; $B = 45.110 - 0.024055\ T$; $C = 0.021597\text{-}14.01648\ T$; T = temperature °F.

In order to calculate the water activity, the above expression is divided by the pure water vapor pressure which can be related to temperature by the Clausius-Clapeyron equation. The water activity is then known as a function of the water molar density or the KOH molar density from the following expressions

$$F_{H_2O} = C_{H_2O} M_{H_2O}/\rho \quad [26]$$

$$1 - F_{H_2O} = C_{KOH} M_{KOH}/\rho \quad [27]$$

The water activity ratio corresponding to the KOH molar density ratio of Eq. [24] is then given by substitution of Eq. [27] into Eq. [25] and taking water vapor pressure ratios

$$\ln \frac{a_{H_2O}}{a_{H_2O}^{o}} = A\left[\left(1 - \frac{C_{KOH}M_{KOH}}{\rho}\right)^2 - \left(1 - \frac{C_{KOH}^{o}M_{KOH}}{\rho}\right)^2\right] + B\frac{M_{KOH}}{\rho}(C_{KOH}^{o} - C_{KOH}) \quad [28]$$

The KOH activity ratio is related to the water activities by application of the Gibbs-Duhem expression

$$\ln \frac{a_{KOH}}{a_{KOH}^{o}} = -\int_{\ln a_{H_2O}^{o}}^{\ln a_{H_2O}} \frac{C_{H_2O}}{C_{KOH}}\, d(\ln a_{H_2O}) \quad [29]$$

Application of the Gibbs-Duhem relation can also be employed to obtain the Onsager-Fuoss correction employed in Eq. [24]. Equation [29] is simply differentiated with respect to $\ln C_{KOH}$.

$$\frac{\partial(\ln a_{KOH})}{\partial(\ln C_{KOH})} = -C_{H_2O}\frac{\partial(\ln a_{H_2O})}{\partial(\ln C_{KOH})} \quad [30]$$

The above relation is computed at the reference KOH concentration since, as previously indicated, it varies slightly with concentration.

It was assumed initially that bulk transport properties would be neglected. This is only precisely correct in a pore where the axial water diffusion molal flux is equal and opposite to the hydroxyl ion flux. If, for example, the product water of the total cell is allowed to evaporate into the hydrogen gas, the axial water diffusion flux does not balance the hydroxyl ion flux. It was found experimentally, however, that the cathode polarization was unaffected by wide variations in the flow rates of pure oxygen over the electrode. These flow variations affect the water vapor pressure in the gas and so control the amounts of water transported through the working electrode. This experimental result indicates that the assumption of no bulk flow is a good one.

Comparison with Experiment

Oxygen electrode half-cell data were measured for KOH concentrations ranging from 60 to 85 w/o and temperatures from 300° to 500°F. The current-potential measurements had been made on electrodes having essentially the same properties. A set of polarization curves for various temperatures and 80% KOH is chosen as an example to describe the theory-data fits. Equations [15] and [16] are rearranged into a convenient form.

$$I = \frac{1}{R}\left[\frac{P_{CP}}{\tau_{CP}}(32FD_{O_2}a_{O_2}^{o}\sigma)^{1/2}\right]_{\{1\}}\left[\frac{i_1\delta}{4FD_{O_2}a_{O_2}^{o}}\right]_{\{2\}}^{1/2}\left[\int_{\phi_1}^{\phi_o}\frac{i}{i_1}d\phi\right]_{\{3\}}^{1/2} \quad [31]$$

$$\phi_1 = \left[\frac{t_{FP}\tau_{FP}^2}{P_{CP}\sigma}\right]_{\{4\}} I \quad [32]$$

Various terms are bracketed and subscripted for reference. In Eq. [31], the coarse pore radius is chosen to correspond to a mean for the structure as obtained by porosimeter measurements. This radius was 3μ for the electrodes employed in this study. The bracketed term {4}, which is a function only of the conductivity and fine pore properties is calculated. This term specifies the magnitude of the polarization losses resulting from the ohmic and concentration polarization in the fine pore. The bracketed term {1} can act as a scale factor to obtain the correct magnitude of current and was determined in this manner during the experimental-theoretical fitting. Rough estimations of this factor are possible, and comparison of the estimation with the empirically determined quantity provides a basis for checking the validity of the theoretical model. The bracketed term {3} is the integration of the local current density over the active portion of the meniscus. The activity ratios in the local current density expression are predicted by the methods previously indicated, and the exchange current is factored out of the integrand. The remaining unknown is that which appears in the denominator of Eq. [8] and is in the bracketed term {2}. This term is proportional to the product of the exchange current and meniscus thickness. There is no accurate way to estimate either of these quantities so the term has been applied strictly as an empirical parameter. Physically, this term is the ratio of the exchange current and a characteristic oxygen diffusion current. The value of the exchange current, which controls the degree of activation polarization, has a strong influence on the shape of the current-polarization characteristic. In summary, one term is applied as an adjustable parameter, another is also adjustable but must have a value reasonably comparable with prediction, and all other quantities are predicted.

The theoretical curves and their corresponding data points are shown in Fig. 4. Values of the three param-

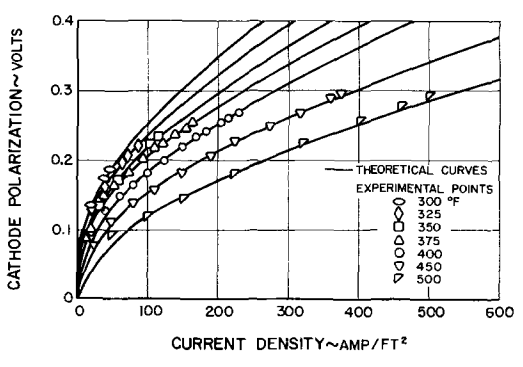

Fig. 4. Comparison of data and theory, 80% KOH

T, °F	Calculated geometric factor, ohms-cm² $\left(\frac{t_{CP}\tau_{FP}^2}{P_{FP}\sigma}\right)$	Fitted exchange current to oxygen diffusion current $\left(\frac{i_0\delta}{4FD_{O_2}a_{O_2}^0}\right)$	Scale factor (amp/cm) $\frac{P_{CP}}{\tau_{CP}}(32FD_{O_2}a_{O_2}^0\sigma)^{1/2}$
300	0.23	6.7×10^{-8}	9.32×10^{-3}
325	0.20	1.8×10^{-7}	8.42×10^{-3}
350	0.18	4.6×10^{-7}	7.49×10^{-3}
375	0.16	1.2×10^{-6}	6.51×10^{-3}
400	0.14	4.0×10^{-6}	5.95×10^{-3}
425	0.13	8.0×10^{-6}	5.22×10^{-3}
450	0.12	2.0×10^{-5}	4.37×10^{-3}
500	0.10	1.4×10^{-4}	3.51×10^{-3}

eters required for the theoretical line in Fig. 4 are shown in Table I. The logarithm of the ratio of exchange current to characteristic oxygen diffusion current, which is the adjustable parameter, is plotted *vs.* reciprocal temperature in Fig. 5. The straight line is indicative of an Arrhenius law dependence on temperature as should be expected of a quantity proportional to the ratio of a kinetic rate constant and a liquid-phase diffusivity.

In order to estimate the bracketed term {1}, the diffusivity-solubility product must be known. Rotating electrode data obtained in our laboratories in 85% KOH and at 450° indicate that $D_{O_2}^{2/3}a_{O_2}^0 = 2.3 \times 10^{-12}$. The diffusivity of oxygen was estimated from that in pure water (7) by applying viscosity data and the Stokes-Einstein relation. The resulting diffusivity-solubility product for 80% KOH and 450°F is 4×10^{-12}. Applying values of the other constants

$$\frac{P_{CP}}{\tau_{CP}}(32\,FD_{O_2}a_{O_2}^0\sigma)^{1/2} = \frac{0.6}{2}(32 \times 96{,}500 \times 4 \times 10^{-12} \times 2.16)^{1/2} = 1.55 \times 10^{-3}\ \text{amp/cm}$$

In the 80% KOH and 450°F case, the empirical value of this quantity required to obtain a theory-data fit was 4.37×10^{-3} amp/cm. It can be shown that the correspondence between the empirical and estimated quantities is satisfactory by considering the uncertainty in the choice of just one parameter. Note that a coarse pore tortuosity factor of two was assumed. Measurements of the tortuosity factor by comparison of gas diffusion rates through porous structures and free gas diffusivities have shown a range of values between one and two. So if the lower limit of the measured range was applied, the calculated value would have been 3.1×10^{-3} amp/cm. Furthermore, a factor of two was also assumed in the fine pore tortuosity. The ohmic drop through the fine pore, being proportional to the square of this factor, would have been considerably less if a smaller tortuosity was assumed. This would decrease the lower limit of integration in the bracketed term {3}. This term would then have been greater, and so a smaller value of the scaling factor could have been applied to obtain the experimental-theoretical fit.

Considering the inexactness of the choice of a tortuosity factor, the comparison of the theoretically calculated scale factor with that empirically determined is well within the inherent limitations of the model. Similar comparisons could be shown for data at other concentrations, but this comparison is sufficient to illustrate the point.

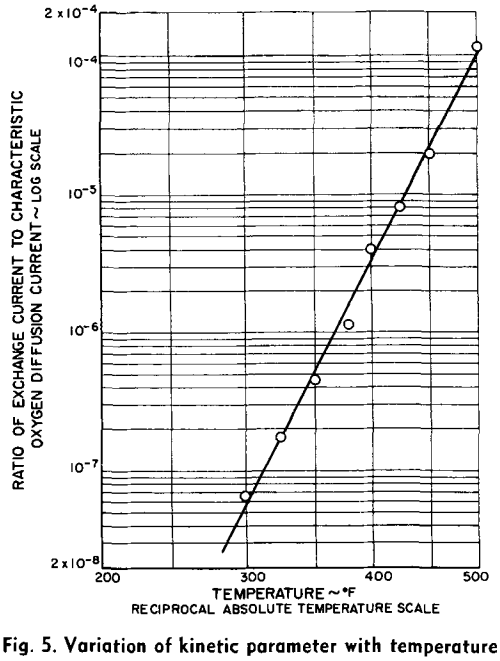

Fig. 5. Variation of kinetic parameter with temperature

Discussion

What does the theory tell us about how a porous electrode behaves? Inspection of the equations giving the current in a pore (Eq. [15] or [31]) will show that the current is proportional to a geometric mean of two kinetic or transport properties. At low electrode potentials, where the local current density near the base of the meniscus is activation controlled, the pore current is proportional to a geometric mean of electrolyte conductivity and exchange current. At intermediate electrode potentials, where the local current density near the base of the meniscus is gas diffusion controlled, the current is proportional to a geometric mean of electrolyte conductivity and a characteristic oxygen diffusion rate across the meniscus. At potentials approaching the limiting current regime, the current is proportional to a geometric mean of a characteristic oxygen diffusion rate and a characteristic electrolyte species diffusion rate. It is this electrolyte species diffusion rate from which the existence of a limiting current is derived, as this diffusion limits the length of active meniscus. In each potential region, the net current is determined by the geometric mean of a local current characteristic (exchange current or oxygen diffusion current) and an electrolyte property from the integration along the meniscus (conductivity or electrolyte diffusion). The fact that the pore current is proportional to the geometric mean of two properties illustrates a general feature of gas diffusion electrodes; their performance is not limited by one effect but by an interplay of several. In fact, the coupling of effects is so important that approximations which eliminate one or another of the transport processes, although pedagogically useful since they lead to analytic solutions, often turn out to be unacceptable for data analysis. The characteristic rate constant for the local current density is directly proportional to the gas partial pressure, whether it is represented by the exchange current or a gas diffusion rate. This rate constant is contained in a geometric mean with either the conductivity or electrolyte species diffusion rate, which are electrolyte properties and independent of reactant gas partial pressure. Thus the mean, being the root of the product, varies with the square root of partial pressure. This effect is illustrated in Fig. 6. The currents with dilute gases are scaled to those at 100% oxygen by dividing them by the square root of the mole fraction oxygen. Let us examine this effect more closely to better understand its origin. Consider the region close to the base of the meniscus where most of the current is generated. The reactant gas is then diluted to below its original partial pressure keeping the total pressure and electrode potential constant. At this reduced pressure, less gas is available to react in the active region. This means that less current will be generated at every point along the pore, and there will be less accumulated ohmic and concentration potential in this region. The active region of the meniscus is then extended. Although the local currents at

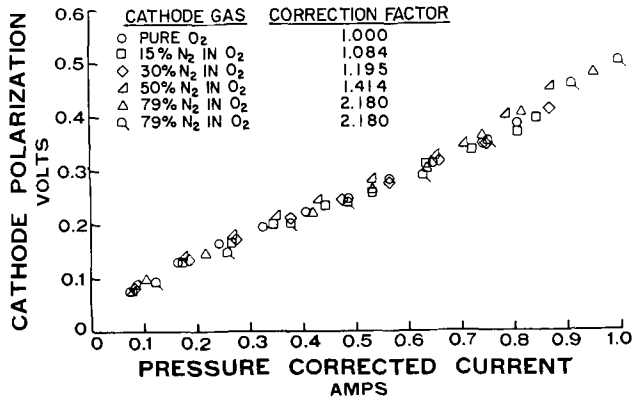

Fig. 6. Effect of oxygen pressure on cathode performance, verification of square root pressure law.

each point along the meniscus have decreased proportionally to the partial pressure reduction, the useful active area of the electrode has increased. The net quantitative result is the square-root proportionality of current on the reactant gas partial pressure.

The useful length of the electrode depends not only on the gas partial pressure but also on the catalytic activity of the electrode. Had we introduced a catalytic poison into our electrolyte, the current would again have decreased all along the pore and again the active area would have increased. Conversely, a more active electrode would have a smaller useful area. If the electrode potential were decreased, this too would increase the useful, working electrode area until very close to open circuit, where the entire wetted area of metal would become active.

The local current density can be computed along the meniscus by a second integration of Eq. [11]. This was done by employing a Runge-Kutta technique. The location along the meniscus where the local current equals zero is plotted *vs.* electrode potential in Fig. 7 for the 400° and 500°F case. This illustrates some of the arguments in the preceding paragraphs. At low potentials, the zero-current location decreases with potential and has values of 10^4-10^5. As soon as the potential is high enough so that electrolyte freezes at the zero-current point on the meniscus, the length to thickness ratio drops very rapidly with increasing potential. The length to thickness ratio at zero current then becomes constant with polarization at limiting current density. The potential region beyond that at which electrolyte freezes is only of theoretical interest, this potential region being well above that at which the electrodes operate. The theoretical freezing takes place at current densities very close to the calculated limiting current. Figure 7 shows how the less active electrode at 400°F has a longer working area except in the limiting current range. At limiting current, where current is affected only by diffusion processes, the active length decreases with temperature reduction because of the smaller diffusivities. In order to give some suggestion of the shape of the local current *vs.* location characteristic, the location from the base of the meniscus to where a local of 95% of the pore current is produced is shown on Fig. 7 for 500°F. This shows that 95% of the current is produced in about 30% the length of the active meniscus at the operating potentials, 0.1-0.3v. Apparently, the ohmic and electrolyte concentration polarizations along the rest of the meniscus make the local current densities relatively small. At potentials approaching that of limiting current density, however, the shape of the local current-location characteristic changes drastically as the 95% pore current point is almost coincident with the 100% pore current point.

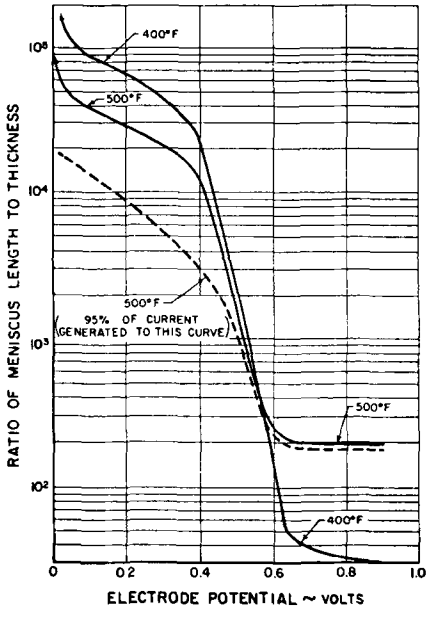

Fig. 7. Active lengths of meniscus, 80% KOH

The length of the electrode required to give enough active meniscus is, of course, dependent on the meniscus thickness. If we use the 0.5μ thickness from light interference measurements (8), this means that the length of the active meniscus is about 0.5 cm. The electrodes in this study were 0.25 cm thick, but the meniscus lengths are no doubt a few factors longer due to their tortuous shapes. It is also possible that the meniscus thicknesses in a porous structure are less than the reported values in which a flat is plate partially immersed in 3.5*N* KOH at room temperature. We have found that the thickness of electrodes having the same properties of those in this study could be reduced by a factor of two with no change in performance.

The comparison of the porous electrode theory with experiment has suggested that the model does give a good representation of the polarization mechanisms in porous electrodes. This means that in addition to providing a systematic scheme for data correlation, the theory gives useful quantitative estimations for the design of fuel cell electrodes and fuel cell systems. For example, it shows how much polarization is associated with the fine pore and how variations in fine pore porosity or thickness will affect performance. By variation of the exchange current, it shows what fraction of this electrode polarization is activation polarization. This tells what gains are possible by improved catalysis. The theory also provides a quantitative prediction of the effect of reactant gas partial pressure on performance.

Having a theory that seems to work leads us to a better understanding of the behavior of porous gas diffusion electrodes. There are, however, certain limitations. Since certain empirical values of inestimable physical quantities are required in the fitting, the proof of the theory is, in part, circumstantial. Furthermore, the results of the theory, being fairly insensitive to the details of the reaction mechanism, can tell us little about this mechanism. Finally, the assumption of cylindrical pores of one size eliminates the possibility of estimating the effects of both pore-size distribution and the relative gas-filled to liquid-filled volumes in the electrode. In spite of these limitations, we have a beginning and can go on from here to refine and better define the model.

A Comparison of the Passivity of Iron in Acid and Neutral Electrolytes

J. L. Ord

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

The results of similar sets of measurements on a passive iron electrode in acid and neutral electrolyte indicate that a high-field conduction process, limited by an activation barrier of fixed energy, is operating in both systems. The exchange current density across the activation barrier is not constant in either system and depends on the applied current density. Changes in the exchange current density require appreciable charge transfer, and overshoot is observed when the applied current density is changed. Differences in the conduction mechanism reported in previous work are attributed to the techniques of data analysis used.

Recent work on the passivity of iron indicates that the conduction mechanism through the passive layer in acid electrolyte is quite different from the mechanism in neutral electrolyte. Ord and Bartlett (1), working in $2N$ H_2SO_4, conclude that the current is controlled by the electric field at an activation barrier. They find the activation energy to be constant and the electric field to vary inversely with the layer thickness. Sato and Cohen (2), working in a buffered neutral electrolyte, also find an activation-controlled process, but conclude that the activation energy is proportional to the layer thickness and that the conduction process is independent of the electric field in the layer.

A recent study (3) of the experimental determination of overpotential parameters on passive electrodes finds that the values obtained for the parameters depend strongly on the measuring technique. The conclusions described above concerning the conduction mechanism are based on different types of measurement in the two electrolytes. The work described below consists of a set of similar measurements performed on a passive iron electrode in acid and neutral electrolyte. The aim of the work is to determine whether the reported differences in the conduction mechanism are genuine, or are due to the difference in measuring technique.

Experimental

The experimental equipment is a modification of that used in previous work. The simple battery and Helipot combination used previously acts as a potentiostat only if the cathode is stabilized either by working in hydrogen-saturated electrolyte or by using a two-component cathode (4). This potentiostat is not satisfactory for work in argon-saturated neutral electrolyte, and it has been replaced by an electronic potentiostat. The development of small solid-state differential operational amplifiers (Philbrick SP2A) has simplified the design of electronic potentiostats. A schematic diagram of the circuit used is shown in Fig. 1. One operational amplifier is used as a potentiostat, the other as an electrometer follower to drive a fast recorder. A galvanostat can be designed using an operational amplifier, but in this work a galvanostat consisting of resistors in series with a 200v battery bank is used to simplify switching problems. The switch shown in Fig. 1 connects the cell to either the potentiostat or the galvanostat. This switch is a lever switch with open contacts which can be bent for proper phasing. Current is measured using a battery-operated electrometer VTVM with shunt (Keithley 200B with 2008 shunt) operated off ground. The potentiostat automatically compensates for the voltage drop across the VTVM. A mercurous sulfate electrode

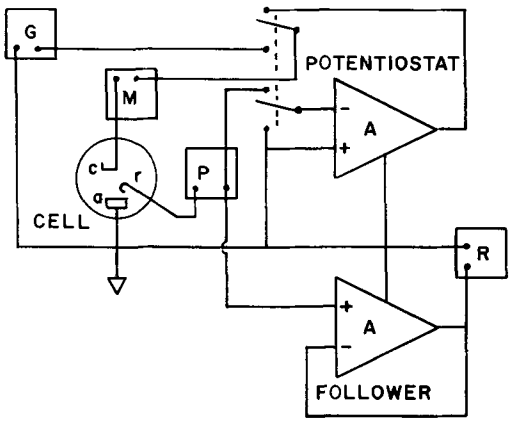

Fig. 1. Circuit schematic: A, operational amplifier; G, galvanostat; M, electrometer VTVM with shunt; P, potentiometer; R, recorder; c, cathode; r, reference electrode; a, anode.

with a 0.1N K_2SO_4 salt bridge is used as a reference for potential measurements, and all potentials are expressed relative to the potential of this electrode.

Jacketed five-neck flasks with ground glass joints are used as cells. The electrolyte is saturated with Linde argon. The impurity specifications of this gas make further purification unnecessary. The argon leaves the cell through a water trap which maintains a slight excess pressure within the cell. Quantitative results on the effect of the dissolved oxygen in the electrolyte are reported below. Twelve hours of bubbling with argon were found to be sufficient to remove dissolved oxygen from the 500 ml of electrolyte used in the cell. The acid electrolyte used is 1N H_2SO_4, and the neutral electrolyte is the 0.15N sodium borate-boric acid buffer (pH 8.4) used by Sato and Cohen (2). Iron electrodes of 0.2 cm^2 area are prepared by coating iron single crystals with epoxy. The electrodes are mounted in the cell with the exposed surface vertical.

Results and Discussion

Studies of the passivity of iron all indicate that the current density, i, depends exponentially on the overpotential, V, above the Flade potential. This dependence can be written in the simple form

$$i = i_o \exp(V/V_o) \qquad [1]$$

where the parameters i_o and V_o have the same units as the measured quantities i and V. The observation that the steady-state current density in 1N H_2SO_4 is independent of potential is consistent with the exponential dependence expressed in Eq. [1], for the parameter V_o is found to be proportional to the steady-state passivating potential (1, 3). The differential equation of a general transient is

$$C\,dV/dt + i_o \exp(V/V_o) = i_1 \qquad [2]$$

where C is the layer capacitance and i_1 is the total current flowing in the circuit. Most measurements involve one or the other of two special cases of the general transient. One can define a fast (or capacitive) transient as one for which dV/dt is large enough to require that the first term in Eq. [2] be retained. (The layer thickness does not change appreciably over a fast transient, and hence it is often assumed that i_o and V_o also remain constant over the transient.) A slow (or oxidation) transient is one for which dV/dt is small and the first term in Eq. [2] can be neglected. For such a transient the current going into layer formation far exceeds the current charging the layer capacitance. According to these definitions, all potentiostatic transients are classed as slow, whereas galvanostatic transients have fast and slow regions. These regions are usually quite distinct, and are characterized by dV/dt's which differ by orders of magnitude.

In a typical experiment one determines the dependence of the parameters i_o, V_o, and $1/C$ on the experimentally controllable variables such as temperature, pH, accumulated charge, etc. The experimental data obtained are then used in conjunction with the equation relating current density to overpotential across an activation barrier

$$i = \kappa\lambda e \frac{kT}{h} a_1 \exp(-U/kT)\,[\exp(\beta\lambda e\eta/kT) - \exp(-(1-\beta)\lambda e\eta/kT)] \qquad [3]$$

to deduce basic features of the conduction mechanism and oxidation reaction. In Eq. [3], κ is the transmission coefficient, λ is the valence of the charge carriers, a_1 is the activity of the carriers moving in the forward direction across the barrier, U is the activation energy in the forward direction at the reversible potential, and β is the fraction of η, the overpotential, aiding motion in the forward direction; the other symbols have their standard meanings. In most experiments η is sufficiently large that the second term on the right of Eq. [3] (which represents the reverse current across the barrier) can be neglected.

Fast galvanostatic transients have been used to study the passivity of iron in acid electrolyte (1, 3). In the simplest set of experiments, the electrode is held at a constant passivating potential until the current shows no further time dependence. In this steady state the rate at which the layer is being formed is balanced by the rate at which it dissolves in the acid. Once a steady state is reached, the circuit is opened, and the resulting fast transient is analyzed (3) to determine V_o and $1/C$. When the circuit is opened, the current across the metal-layer and layer-electrolyte interfaces is reduced to zero, but the current through the layer decreases gradually to zero as it discharges the layer capacitance. The region over which the transient is fitted involves a change in the current density by a factor of about 20. Beyond this region the reverse current across the activation barrier (the second term on the right of Eq. [3]) cannot be neglected. In Fig. 2, V_o and $1/C$ are plotted $vs.$ steady-state passivating potential for an iron electrode in argon-saturated 1N H_2SO_4 at 25°C. The steady-state current density is 5.5 $\mu a/cm^2$. If the zero of overpotential is taken to be —0.16v on this potential scale, i_o is found to be constant and equals 0.06 $\mu a/cm^2$. The data plotted in Fig. 2 were taken in an increasing sequence of passivating potentials. The electrode was allowed to stabilize for 1 hr and 20 min after each 0.1v increment in passivating potential. The value of V_o shows little further time dependence after this

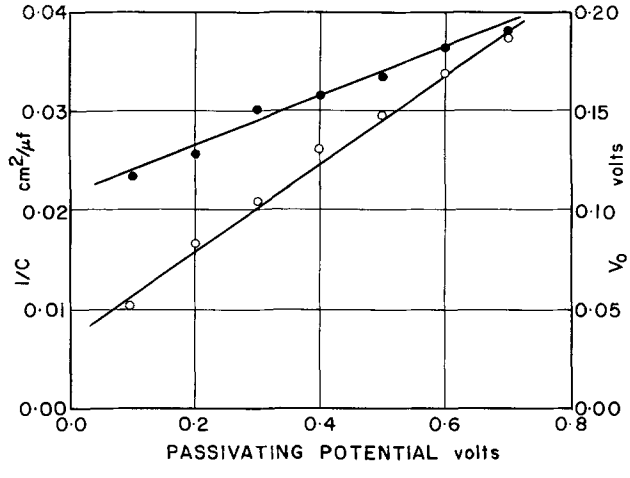

Fig. 2. Dependence of V_o and $1/C$ on steady-state passivating potential in 1N H_2SO_4 at 25°C. The open circles represent V_o, the solid circles, $1/C$.

interval, but the reciprocal capacitance continues to change with time for at least a week (5), and hence the state is not truly steady. This time dependence complicates the interpretation of capacitance measurements, and hence it is simpler to use only the parameters i_o and V_o to compare the behavior in acid and neutral electrolyte.

The interpretation of the acid-electrolyte data is carried out by direct comparison with Eq. [3]. Since i_o is constant, both U, the activation energy, and a_1, the activity of ions crossing the barrier, must be constant. The overpotential in the steady state, V_p, is the passivating potential used as abscissa in Fig. 2 plus 0.16v. Figure 2 shows that V_p/V_o is constant, and hence the overpotential across the barrier, η, must also be constant, independent of the overpotential above the Flade potential, V_p. Therefore the electric field at the activation barrier must be independent of V_p. This will be the case if V_p appears across a layer of thickness D which is proportional to V_p. Using this model V_o is proportional to D through the equation

$$V_o = (kT/ea)\, D \qquad [4]$$

where a is the half-jump distance of the activation barrier. The two main features of the conduction mechanism which emerge from these considerations are: (*i*) the ionic current through the layer is controlled by the high electric field (V/D) within the layer, and (*ii*) the activity of the charge carriers is constant at a limiting activation barrier of fixed energy. It must be emphasized that in the experiments on which these conclusions are based, V_p, the initial steady-state passivating overpotential, is a parameter describing the initial state of the electrode. The points plotted in Fig. 2 were obtained from transients in which V sweeps out a range of values from V_p to zero. The V_o and $1/C$ values in Fig. 2 essentially are plotted *vs.* layer thickness.

In neutral electrolyte the passive layer is insoluble, and hence it is not generally possible to achieve a steady state in which the current and potential are independent of time. The simplest transients in such a system are slow galvanostatic and potentiostatic transients. Sato and Cohen (2) found that, except for the initial stages, potential increases linearly with time for slow galvanostatic transients. The slope of these transients is proportional to the oxidation current, and hence dV/dQ, where Q is the charge accumulated at the electrode, is independent of the oxidation current. The displacement between transients starting from the same layer thickness is proportional only to the logarithm of the current ratio. They found in addition that, for potentiostatic transients, the logarithm of the current density decreases linearly with Q, and that the slope of this decrease is independent of the passivating potential.

These experimental results can be summarized in two equations

$$\left(\frac{\partial V}{\partial Q}\right)_i = \frac{\beta}{B} \qquad [5]$$

$$\left(\frac{\partial \ln i}{\partial Q}\right)_V = -\frac{1}{B} \qquad [6]$$

where β and B are constants determined from the experimental data. These equations can be integrated to give an equation between i and V

$$i = k' \exp(\beta V - Q/B) \qquad [7]$$

where k' is an additional constant. This equation can be compared to Eq. [3] to deduce a conduction mechanism in the same way as the conduction mechanism is deduced in acid electrolyte. A comparison of the potential dependent factors shows that η, the activation overpotential, is proportional to V and independent of Q. A comparison of the other exponential factors indicates that U, the activation energy, is proportional to Q which is, in turn, assumed proportional to layer thickness. Since k' is constant, the activity of ions in the initial state, a_1, must be constant. Sato and Cohen conclude that a suitable conduction mechanism consistent with these observations is one in which ions move through the layer by a correlated flipping of ion pairs. This mechanism has an activation energy which is proportional to the length of the chain of ion pairs (in this case the thickness of the layer), and the activation overpotential appears across the entire passive layer. The features of this proposed mechanism to be compared with the mechanism proposed for acid electrolyte are (*i*) the ionic current through the layer is controlled by the overpotential across the layer and not by the field within the layer, and (*ii*) the activity of the charge carriers is constant, but the energy of the activation barrier is proportional to the layer thickness.

Both proposed conduction mechanisms require the activity of the charge carriers to be constant, but in all other features they differ markedly. There is little doubt as to the validity of the experimental data, but it is important to note that the acid-electrolyte data were obtained using fast transients whereas the neutral-electrolyte data were obtained using slow transients. A recent study (3) of the experimental determination of overpotential parameters on passive electrodes, with iron in acid electrolyte as the system under study, shows that the values obtained for these parameters depend strongly on the measuring technique used. Hence it is possible that the reported difference in the conduction mechanism is due to the measuring technique and not to the electrolyte. This possibility can be explored by making similar measurements in the two systems.

The selection of an experiment to be performed in both acid and neutral electrolyte requires some care. In neutral electrolyte it is not possible to perform steady-state measurements similar to those used to obtain the data plotted in Fig. 2 for acid electrolyte. The slow galvanostatic transients used by Sato and Cohen can be used in acid electrolyte (3, 6), but the analysis is complicated by the fact that the rate of dissolution of the layer under these conditions is not necessarily the same as it is in the steady state (7). The layer dissolution in sulphuric acid electrolytes is governed by an activation energy of approximately 0.7 ev, and hence the effects of this process can be reduced by a factor of 10 by working near 0°C rather than at 25°C. For this reason the electrolytes were held at 0.3°C for the experiment. The experiment chosen, consisting of galvanostatic oxidation transients interrupted by brief open-circuit transients, combines the techniques used by Ord and Bartlett in acid electrolyte and Sato and Cohen in neutral electrolyte. During galvanostatic oxidation, the layer thickens at a uniform rate. When the circuit is opened, the capacitance discharges through the layer, and the overpotential across the layer and current through the layer decay together to zero over the transient. This process increases the layer thickness only slightly, and hence the open-circuit transient can be used to determine the dependence of the current through the layer on the overpotential across the layer at a fixed value of the layer thickness. Analysis of the open-circuit transients determines the overpotential parameters at a series of potentials along the oxidation transient. The overpotential parameters chosen are i_o and V_o from Eq. [1]; they are related to the parameters used in Eq. [7] through $V_o = 1/\beta$ and $i_o = k' \exp(-Q/B)$. These parameters can be plotted *vs.* either the charge accumulated at the electrode or the potential of the electrode just before the circuit is opened. In this work, the potential at which the circuit is opened, designated the passivating potential, is chosen as abscissa for plots of experimental data. The data are expected to depend also on the oxidation current density. The oxidation current densities used

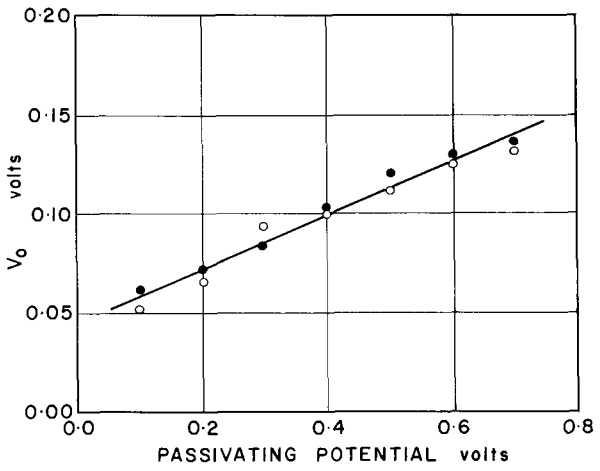

Fig. 3. Dependence of V_o on passivating potential in 1*N* H_2SO_4 at 0.3°C. The oxidation current density is 25 μa/cm^2 for the data represented by open circles, 5 μa/cm^2 for the solid circles.

in acid electrolyte are at least an order of magnitude greater than the steady-state current density at 0.3°C.

The results of this experiment performed in 1*N* H_2SO_4 are plotted in Fig. 3 for oxidation current densities of 5 and 25 μa/cm^2. The linear increase of V_o with passivating potential is similar to the plot in Fig. 2, although the slope is somewhat lower. The straight line in the figure is fitted to the average of the data at the two current densities. If the data are fitted to two straight lines, one for each current density, their slopes differ only slightly. The conduction mechanism proposed above for acid electrolyte, for which a_1 and hence i_o are constant, predicts that the reciprocals of the slopes differ by the natural logarithm of the ratio of the oxidation current densities. For these data, this amounts to a difference of 22% in the slopes themselves. (This effect shows up more clearly in neutral electrolyte where the absence of layer dissolution permits the use of a wider range of oxidation current densities.) The conduction mechanism proposed for acid electrolytes can be made consistent with the data plotted in Fig. 3 if the requirement that a_1 be constant is relaxed. Variations of i_o with current density in acid electrolyte have been reported previously (1).

Results of a similar experiment performed in neutral electrolyte are plotted in Fig. 4 for oxidation current densities of 2.5 and 25 μa/cm^2. Figure 4 shows

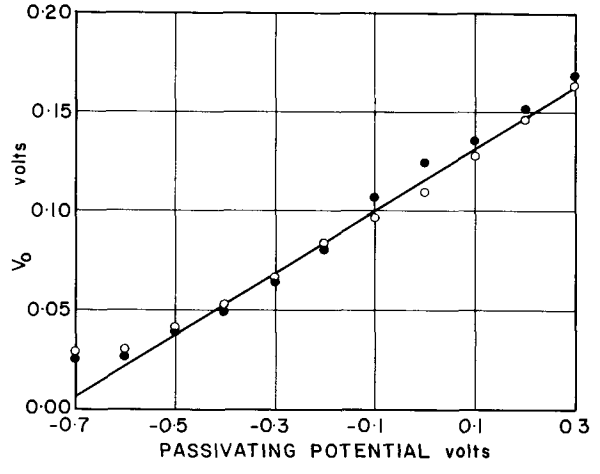

Fig. 4. Dependence of V_o on passivating potential in 0.15*N* sodium borate-boric acid buffer at 0.3°C. The oxidation current density is 25 μa/cm^2 for the data represented by open circles, 2.5 μa/cm^2 for the solid circles.

that V_o increases linearly with passivating potential, varying by a factor of 6 over the passive region. Results plotted in Fig. 4 are similar to the results plotted in Fig. 3 for acid electrolyte. The slopes of the least-squares lines differ by only 14%. [The deviation of the V_o value at −0.7v in Fig. 4 is similar to the deviation observed in acid electrolyte (1) where it is attributed to the existence of a minimum thickness for a continuous passive layer.] There can be little doubt that the same conduction mechanism is operating in both electrolytes. The sixfold variation in V_o ($1/\beta$) is not consistent with Eq. [7] (in which β is constant) nor the conduction mechanism based on it. It is consistent with the high-field conduction process proposed for acid electrolyte. The V_o values fall on a straight line which intersects the passivating potential axis at or near the Flade potential. Since $V/V_o = \ln (i/i_o)$, this result requires $\ln (i/i_o)$ to be independent of film thickness, and hence the activation energy cannot be proportional to film thickness.

The discrepancy between the V_o values plotted in Fig. 4 and the $1/\beta$ value determined from slow transients is related to the fact that both sets of data in Fig. 4 fall approximately on the same straight line. If two lines are used to fit the data, their slopes differ by 10%, increasing with decreasing current density. This result can be checked over a wide range of current densities by interrupting a potentiostatic transient with brief open-circuit transients. The data obtained confirm the galvanostatic result, i.e., an increase of approximately 10% in V_o is associated with a tenfold decrease in current density. If i_o is independent of the oxidation current density, Eq. [1] requires a 36% increase in V_o for a tenfold decrease in the oxidation current density. Since only a 10% increase is observed experimentally, i_o must be a function of the oxidation current density. A tenfold decrease in the oxidation current density is associated with a 10% increase in V_o and a fivefold decrease in i_o. There are two factors in Eq. [3] which can produce changes in i_o: the activity factor and the activation energy factor. Because i_o is independent of layer thickness for a fixed value of the oxidation current density, it is assumed by this author that the variations in i_o are directly proportional to changes in the activity of charge carriers in the initial state. (Other explanations, based on different assumptions, are possible also.) Under this assumption, the activation energy is constant, but it is extremely difficult to measure experimentally. Data obtained at 25°C are almost indistinguishable from the data plotted in Fig. 4 which were obtained at 0.3°C. A direct proportionality between i_o and the oxidation current density, considered in conjunction with Eq. [1] and the data in Fig. 4, results in a constant slope, dV/dQ, for slow galvanostatic transients. If, as the experiments indicate, i_o varies somewhat more slowly than a direct proportionality requires, dV/dQ should increase slightly with oxidation current density. Sato and Cohen (2) find a small deviation in this direction.

The dependence of i_o on the oxidation current density raises a question concerning the validity of the analysis of open-circuit transients. Over the course of such a transient the current density through the layer decreases to zero. The analysis requires, and in fact indicates, that i_o is constant over the transient. This is consistent with evidence from overshoot experiments which indicates that changes in i_o require charge transfer across the layer interfaces. Figure 5 shows a slow galvanostatic transient in which oxidation current density is switched from 11 to 25 μa/cm^2 and then back to 11 μa/cm^2. On the slow time base used in the figure, the capacitive switching transients appear as vertical lines. After each switching transient there is an overshoot, and appreciable time is required before the transient again becomes linear. This delay indicates the changes in i_o require charge transfer since i_o cannot follow rapid changes in the

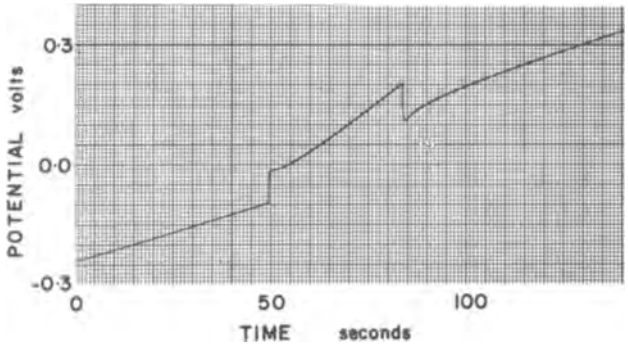

Fig. 5. Recorder trace of potential *vs.* time for an oxidation transient in which the current density is switched from 11 $\mu a/cm^2$ to 25 $\mu a/cm^2$ and then back to 11 $\mu a/cm^2$. The electrolyte is 0.15*N* sodium borate-boric acid buffer at 25°C.

oxidation current density. For a discussion of Fig. 5 it is convenient to differentiate Eq. [1] with respect to Q

$$dV/dQ = \ln (i/i_o)\ dV_o/dQ - V_o/i_o\ di_o/dQ \qquad [8]$$

The positive term on the right is the steady-growth term; the negative term arises from changes in i_o. dV_o/dQ is a constant proportional to the rate of change of thickness of the layer with accumulated charge. When the oxidation current density is increased, there is first a capacitive transient, then i_o begins to increase. The increase in i_o decreases the magnitude of the positive term, and introduces the negative term, thus decreasing dV/dQ (and perhaps making it initially negative). Similarly when the oxidation current density is decreased, i_o begins to decrease, increasing the first term and making the second term positive, thus increasing dV/dQ. It is important to note that no overshoot is observed when the circuit is reclosed after an open-circuit transient. This result is expected if i_o is unchanged over the course of such a transient as is asserted above.

It has been reported (2) that trace amounts of oxygen dissolved in neutral electrolyte affect the electrical behavior strongly. This is true of the measurements used in this investigation. Figure 6 shows a plot of potential *vs.* time for an iron electrode immersed in oxygen-saturated neutral electrolyte under open-circuit conditions. One can calculate the potential dependence of the oxidation current density required to produce a transient of the form shown in Fig. 6 for an oxygen-free electrolyte. This equivalent oxidation current density is very high at low potentials, but falls off rapidly as the potential increases (actually as the layer thickness increases) and becomes insignificant over the upper two-thirds of the passive region. Galvanostatic oxidation in oxygen-saturated electrolyte is masked by this effect at low potentials. A sensitive test for traces of dissolved oxygen in the electrolyte is provided by an open-circuit transient at a passivating potential of —0.7v. In oxygen-free electrolyte the decrease of potential with time is monotonic. If a small amount of oxygen is present in

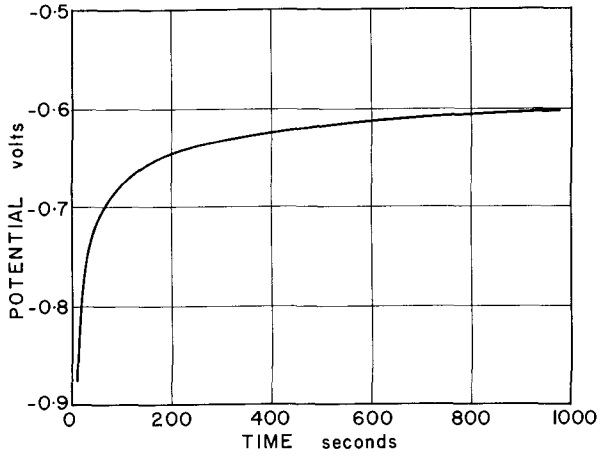

Fig. 6. Plot of potential *vs.* time for an iron electrode immersed in oxygen-saturated 0.15*N* sodium borate-boric acid buffer at 25°C.

the electrolyte, the potential initially decreases, but then begins to increase slowly. This test indicates that bubbling argon through the electrolyte for a 12-hr period is sufficient to remove traces of oxygen from the electrolyte.

Conclusions

This comparison of the passivity of iron in acid and neutral electrolytes leads to three main conclusions:

1. The conduction mechanism through the passive layer is the same in the two electrolytes.
2. The differences in the conduction mechanism reported in other investigations are due to the technique of data analysis and are not due to the data themselves.
3. A high-field conduction mechanism, limited by an activation barrier of fixed energy, operates through the passive layer, and the activity of the charge carriers depends on the oxidation current density.

Infrared Study of Adsorbed Corrosion Inhibitors: Butyl Nitrite and Nitric Oxide on Iron-Iron Oxide

G. W. Poling and R. P. Eischens

Texaco Research Center, Beacon, New York

ABSTRACT

Infrared techniques for observing spectra of adsorbed molecules were used to study the mechanism of corrosion inhibition. Attempts were made to study the chemisorption of butyl nitrite and nitric oxide on reduced iron and on iron oxide surfaces. It was possible to detect differences between nitric oxide chemisorption on iron oxide and on reduced iron even though the latter became oxidized by reaction with nitric oxide. On a preoxidized surface, nitric oxide produces a band at 1820 cm^{-1} which is attributed to $Fe^{++}:N{=}O^{+}$. Oxidative chemisorption on initially reduced iron produces a band at 1750 cm^{-1} which is attributed to Fe—O—N=O. Butyl nitrite decomposes during chemisorption to give chemisorbed hydrocarbon and chemisorbed nitrogen oxides. Neither oxygen nor water vapor displaces the observed chemisorbed species from oxide surfaces. The results suggest that the corrosion inhibitor properties involve both the oxidizing action of nitrogen oxides and the strong chemisorption of neutral or cationic inhibitor species on the oxide surface.

Corrosion of iron and steel can sometimes be retarded by inhibitors which have nitrogen oxide functional groups. Many investigators attribute the inhibitive properties of these groups to their ability to promote the development of protective oxide films (1-3). Other workers believe that the protective mechanism involves chemisorption of oxygen-containing inhibitor on the metal surface (4, 5). In a study of amine inhibitors, Yu Yao emphasized the importance of chemisorption of inhibitor on the oxide film rather than chemisorption on the metal (6). She suggests that chemisorbed inhibitor renders the oxide barrier more effective by decreasing the electric field gradient across the oxide and thereby slowing the transport of metal ions through the oxide. The work to be presented here shows that strong chemisorption of nitrogen oxide inhibitor also occurs on the oxide film and thus, to some extent, supports the Yu Yao mechanism.

This paper is mainly concerned with the infrared spectra of butyl nitrite and nitric oxide adsorbed on samples which consist of small particles of iron or iron oxide dispersed on high area silica. In transmission through this type of sample, the infrared beam traverses sufficient adsorbent surface to provide monolayer detecting sensitivity. The butyl nitrite and nitric oxide are related because butyl nitrite dissociates during chemisorption, and one of the fragments appears to be nitric oxide.

The techniques for observing these spectra of molecules adsorbed on small particles were developed in studies of chemisorption systems related to catalysis (7). It will be seen that the small particle samples introduce factors which are not pertinent to corrosion research. However, the important aspects of the observed chemistry at iron/iron oxide/inhibitor interfaces appear to be widely applicable to corrosion studies.

Experimental Procedure

Recording spectra.—The spectra (of the 4000-1300 cm^{-1} region) were obtained using a CaF_2 prism in a Perkin-Elmer Model 12C spectrometer which had been modified to allow the beam to pass vertically through a 10 in. long sample cell (8). The cell, shown in Fig. 1, was made from Pyrex tubing 45 mm in diameter. Infrared transmitting CaF_2 end windows were sealed to the body of the cell with glyptal resin. These windows were cooled with air jets when the cell was heated. The cell could be evacuated to 10^{-6} mm Hg by means of a conventional mechanical pump-oil diffusion pump-cold trap system.

The sample powder was pressed at 12,000 psi into a self-supporting disk and then placed on a glass ring stand (ring not shown in Fig. 1). The sample disks were 26 mm in diameter and weighed about 0.15g. The composition of the samples is described later.

The infrared spectral data were supplemented by mass spectral analysis of the gas phase. A Consolidated Vacuum Corporation Model 21-611 mass spectrometer was connected to the cell through a variable leak valve.

Sample preparation.—Samples were prepared by impregnating Cabosil type silica with an aqueous solution of $Fe(NO_3)_3$, drying, and then reducing with flowing hydrogen at 350°-400°C for 50 hr. On the basis of experience with a similar preparation of nickel and platinum samples, it was expected that this method would produce small particles of iron (~50Å diameter) dispersed on silica. Sufficient $Fe(NO_3)_3$ was used to yield a sample which would contain 12 w/o iron after complete reduction.

In practice it was found to be impossible to reduce all of the iron to the metallic state. This difficulty is attributed to a type of dispersion (perhaps as individually adsorbed ferric nitrate molecules) which prevented sufficient aggregation of impregnated ma-

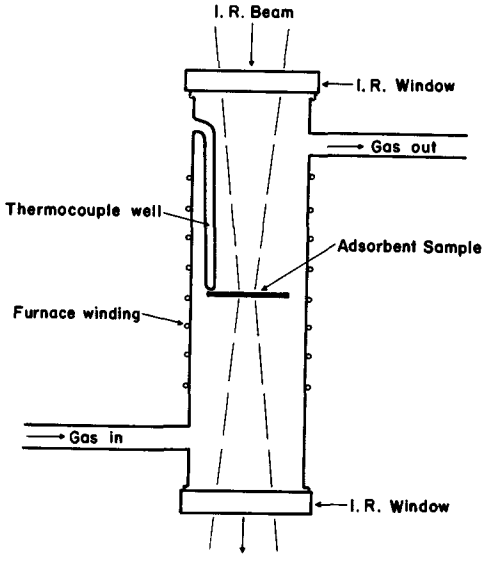

Fig. 1. Cell for infrared study of chemisorbed molecules

terial for subsequent reduction to the metallic state. Using the concept that formation of discrete ferric nitrate crystallites is likely to facilitate reduction to metal, efforts were made to determine the most satisfactory method of preparing iron on silica samples. This problem was not completely solved, but it was possible to prepare samples having sufficient reduced iron to allow a comparative study of reduced and oxidized iron. In the most satisfactory samples, reduction was carried to the state where about 20% of the exposed iron was in the reduced state and 80% was unreducible and remained in an oxidized state. Determination of the relative amounts of surface iron in the reduced and oxidized states was based on the concept that carbon monoxide adsorbs only on reduced iron while nitric oxide adsorbs on both reduced and oxidized iron. Details of this determination will be given later.

The specific procedure found to be the most satisfactory in attempts to prepare reduced iron samples involved addition of the amount of $Fe(NO_3)_3$ solution needed to form a thick paste with the silica, rapid drying of the paste under vacuum at 30°C, pressing the sample disk, installation of the disk in the cell with minimal loss of time, further vacuum drying at 105°C, and finally reduction with hydrogen at 350°-400°C. Palladium diffused hydrogen was used at a flow rate of 40 ml/min. After reduction, the hydrogen was evacuated from the cell at 400°C, and the sample was then cooled to room temperature. Satisfactory samples were used in several different experiments with intermediate reductions at 400°C for 16 hr. Unless stated otherwise, all spectra discussed in this paper were recorded at room temperature.

Determination of reduced iron surface area.—Studies of the spectrum of carbon monoxide chemisorbed on silica-supported iron have been reported (7,9) so the interpretation of these spectra will not be discussed here. It now appears that not more than 10% of the surface iron was in the reduced state in the previous studies.

As indicated, the extent of reduction was determined from the ratio of the volumes of carbon monoxide and nitric oxide which were adsorbed. This determination involved only surface atoms so statements regarding extent of reduction apply to the fraction of the surface which was reduced. The ratio of the total atoms in the reduced or oxidized state can be different from the surface ratios if particle size is a factor in ease of reduction (as it probably is with larger particles being the more easily reduced).

The measurements of the amounts of carbon monoxide and nitric oxide chemisorbed were obtained by dosing in measured volumes of gas until the infrared bands attributable to the chemisorbed species reached maximum intensity. The volume of gas retained in the gaseous phase was subtracted from the total added. The method for determining the end point for carbon monoxide chemisorption is discussed below while the end point for nitric oxide will be discussed later in connection with the studies of nitric oxide chemisorption.

Chemisorbed carbon monoxide produced strong bands in the 1900-1990 cm^{-1} region. As carbon monoxide was dosed into the cell, the intensity of the bands increased until a terminal point was reached. Further addition of carbon monoxide produced a band at 2020 cm^{-1} which was attributed to iron carbonyl formation. The carbonyl band was removed by evacuation at 30°C without affecting the bands of chemisorbed carbon monoxide. The best samples were capable of chemisorbing 0.16 cc (0.15g sample). This would correspond to about 2000 cm^2 of reduced iron surface.

All gas volumes reported in this paper (including vapors of water and butyl nitrite) are given as cc s.t.p.

The silica did not adsorb either carbon monoxide or nitric oxide under the experimental conditions used in the chemisorption determinations.

Purification of adsorbates.—Commercial tank nitric oxide (Matheson-99% purity) contains nitrous oxide and nitrogen dioxide. These impurities were removed by distillation through cold traps (10). The satisfactory purity of butyl nitrite vapor (Eastman Kodak white label grade) was established by observing the infrared spectrum at 13 mm pressure in a 9 cm path length gas cell (11). The carbon monoxide (Airco, spectra assayed grade) and the commercial tank oxygen were used as-received.

Bulk iron oxides.—Iron oxide (Cabot's E-7) was obtained in the form of γ-Fe_2O_3. This material had a specific surface area of 35 m^2/g. Because the infrared transmission was poor, only about 0.0075 g/cm^2 of the γ-Fe_2O_3 could be tolerated in the beam path. This thickness did not allow preparation of a self-supporting disk so it was diluted with about three times as much silica in order to make the disk for infrared examination.

Adsorbents of Fe_3O_4 and α-Fe_2O_3 were produced by conversion of the γ-Fe_2O_3. Evacuation at 250°C for several hours removed any adsorbed water and also produced an Fe_3O_4 adsorbent (12, 13). The same sample was converted to an α-Fe_2O_3 adsorbent by heating at 350°C in 1 atm of oxygen for 16 hr followed by rapid cooling to room temperature in the pure oxygen atmosphere (14).

Results and Discussion

Nitric oxide on oxidized iron.—Since it was not possible to obtain completely reduced iron samples, studies of nitric oxide chemisorption were limited to completely oxidized samples and samples which were only partially reduced. The completely oxidized samples are considered first because they provide the simpler system.

Samples, having completely oxidized iron surfaces, may be obtained either by starting with bulk iron oxide or by taking a silica-supported sample through the preparative sequence previously described, and then exposing the partially reduced sample to oxygen (2 mm Hg) at 30°C. Exposure to oxygen under these conditions was expected to form 15-20Å thick films of Fe_3O_4, or mixtures of Fe_3O_4 and γ-Fe_2O_3, on the iron which had been reduced (13, 14). Oxidized iron samples prepared by this method were more amenable to infrared study than the bulk iron oxides. This advantage was due to the smaller particle size of the silica-supported iron oxide. The smaller particle size gave better infrared transmission and higher adsorptive capacity per unit weight of oxide.

Samples which were studied directly after reduction with hydrogen will be referred to as "reduced" even though it is understood that the reduction was only partially successful. Samples prepared by exposing reduced iron to oxygen will be referred to as "pre-oxidized" to differentiate them from "bulk" iron oxide and from samples in which the iron became oxidized during chemisorption.

Spectrum A of Fig. 2 shows the 1900-1700 cm^{-1} region for a pre-oxidized sample and spectrum B shows this region after chemisorption of 0.095 cc of nitric oxide. The chemisorption of nitric oxide produced a strong band at 1824 cm^{-1}. No other bands were observed in the 4000-1300 cm^{-1} region which was scanned in the present work.

Chemisorption of nitric oxide on bulk Fe_3O_4 produced a spectrum similar to B with a single band near 1830 cm^{-1}. No band attributable to chemisorbed nitric oxide was detected when α-Fe_2O_3 was exposed to nitric oxide.

The band observed after chemisorption of nitric oxide on either pre-oxidized iron or on bulk Fe_3O_4 is attributed to the nitrogen-oxygen stretching frequency of an adsorbed nitrogen-oxide species which was

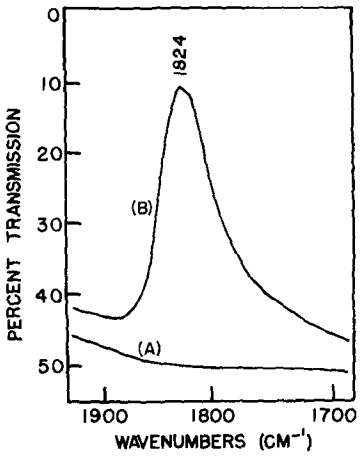

Fig. 2. Nitric oxide chemisorbed on pre-oxidized iron. A, background after exposure to oxygen at 30°C; B, after chemisorption of nitric oxide.

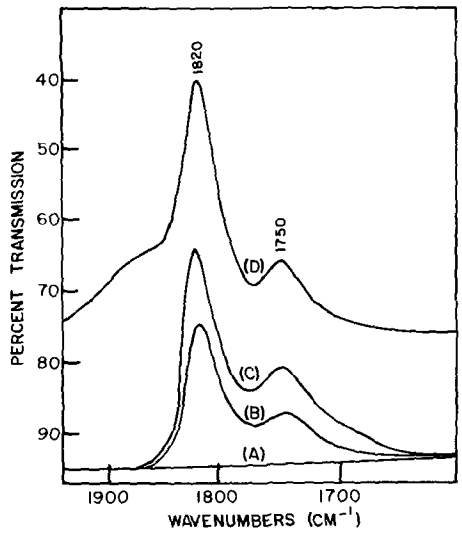

Fig. 3. Nitric oxide chemisorbed on reduced and oxidized iron: A, background of freshly reduced sample; B to D, after chemisorption of: B, 0.08 cc; C, 0.14 cc and D, 0.41 cc of nitric oxide.

bonded to the surface through the nitrogen. More specifically, the nitrogen is thought to be bonded to Fe^{++} sites on the oxidized iron surfaces as $Fe^{++}:N{=}O^{+}$.

The conclusion regarding the Fe^{++} sites is indicated by the detection of chemisorption on Fe_3O_4 but not on α-Fe_2O_3. Partial support for this conclusion comes from the reported observation of a similar band near 1850 cm^{-1} when nitric oxide was adsorbed on Fe^{++} sites of $FeSO_4$ (15).

The positive charge associated with the adsorbed nitric oxide represents a formal charge which is indicated because a coordinate covalent adsorption bond is visualized with both bonding electrons donated by the nitric oxide (15).

A general decrease in transmission over the entire 4000-1300 cm^{-1} region was observed when a reduced sample was exposed to oxygen to produce a pre-oxidized sample. The effect was frequency dependent with the transmission loss being greater in the higher wavenumber regions of the spectrum. In the case of the sample used for spectrum A of Fig. 2, the transmission was 90-100% prior to exposure to oxygen. It can be seen that exposure to oxygen decreased the transmission of this sample by about one half in the 1900-1700 cm^{-1} region. The observed decrease in transmission poses an interesting solid-state problem because at first thought it would be expected that conversion of metal to oxide would increase the infrared transmission.

An understanding of the mechanism of the observed decrease in transmission is not vital to the present work, and at this time it is not possible to put forth a nonspeculative explanation of this phenomenon. However, it is reasonable to expect that the quantitative explanation will be related to the small diameter of the metal particles. The diameter of the particles (~50Å) is less than the normal mean free path of electrons in metals, and it is reasonable that this factor accounts for the relatively high transmission of the reduced samples (16). The iron oxide obtained after exposure to oxygen probably had semiconductor properties and could have been a better conductor, and correspondingly a poorer transmitter, than the small metal particles. Another possibility is that the transmission loss was primarily due to increased scattering loss as indicated by the observed frequency dependence. This demands that growth of oxide film on the metal particles increased light scattering losses due to increased particle sizes more than it decreased their absorptivities due to conversion of metal to oxide.

Nitric oxide on reduced iron.—Figure 3 shows typical spectra observed when a reduced sample was exposed to nitric oxide. Spectra A, B, C, and D correspond to nitric oxide adsorptions of 0, 0.08, 0.14, and 0.41 cc, respectively. The band at 1820 cm^{-1} is attributed to nitric oxide chemisorbed on oxidized iron, $Fe^{++}:NO^{+}$, as discussed for Fig. 2.

The 1750 cm^{-1} band is related to chemisorption of nitric oxide on portions of the sample which were in the reduced metallic state prior to chemisorption. This is not equivalent to chemisorption of nitric oxide on reduced metal since the chemisorption process appears to involve an oxidation.

The sample used for Fig. 3 had chemisorbed 0.050 cc of carbon monoxide in the test for reduced iron surface. Prior to nitric oxide adsorption the sample was re-reduced for 2 hr at 350°C to remove the chemisorbed carbon monoxide.

During the addition of nitric oxide, the residual gas was analyzed by a mass spectrometer. A total of 0.026 cc of nitrogen was evolved during the sequence of spectra shown in Fig. 3. On the basis of the approximately 2/1 ratio for the volumes of nitrogen evolved and carbon monoxide previously chemisorbed it appears that the nitric oxide was involved in an oxidative chemisorption on the reduced iron. The oxidative phase of this reaction can be expressed as

$$2NO + 2Fe_{red.} \rightarrow 2FeO_{ads.} + N_2\uparrow \qquad [1]$$

Equation [1] indicates that each molecule of nitrogen corresponds to loss of two reduced metallic surface sites. This is therefore consistent with the observation that the number of evolved nitrogen molecules is one half the number of carbon monoxide molecules which could be chemisorbed.

In Eq. [1] the oxygen attached to the iron is indicated as being adsorbed. This designation is used to emphasize the difference between the surface oxide formed by the oxidative chemisorption of nitric oxide and the bulk or pre-oxidized type of iron oxide which were discussed previously. This differentiation is necessary because chemisorption of nitric oxide on the Eq. [1] oxide produced a band at 1750 cm^{-1} while chemisorption of nitric oxide on the bulk or pre-oxidized iron oxide produced a band above 1820 cm^{-1}.

The band observed at 1750 cm^{-1} is attributed to the nitrogen-oxygen stretching frequency in a species formed by chemisorption of nitric oxide on FeO_{ads}

$$NO + FeO_{ads} \rightarrow Fe{-}O{-}N = O_{ads} \qquad [2]$$

Partial support for this assignment comes from the observation of bands near 1700 cm^{-1} in organic nitrites of the type RONO (11).

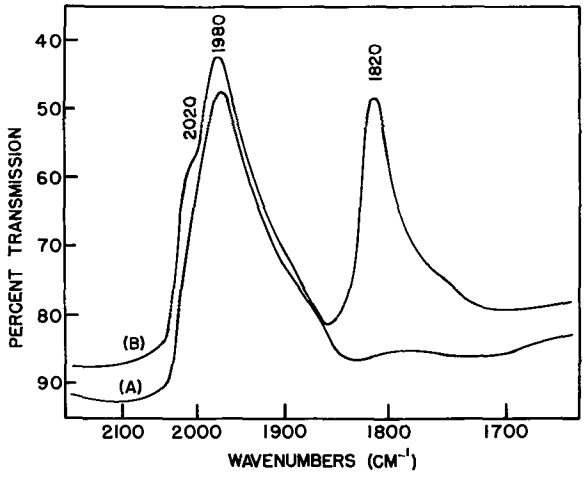

Fig. 4. Co-adsorbed carbon monoxide and nitric oxide on iron: A, carbon monoxide chemisorbed on the reduced iron; B, after co-adsorbing nitric oxide on the unreducible iron phase.

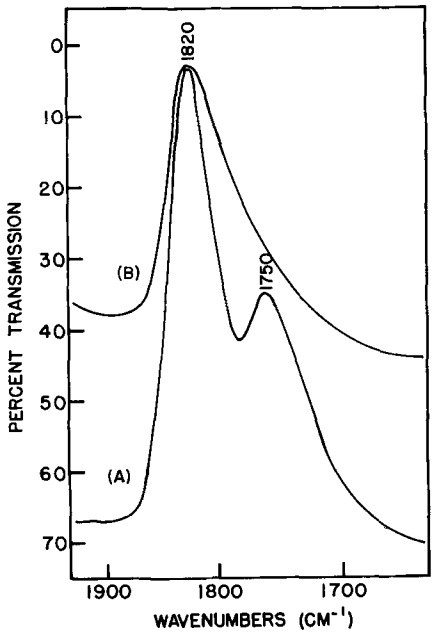

Fig. 5. Effect of oxygen on chemisorbed nitric oxide: A, nitric oxide chemisorbed on both oxidized and initially reduced iron phases; B, after adding oxygen at 30°C.

The present work indicates that it is not possible to preserve iron surfaces in the reduced state after exposure to nitric oxide at room temperature. For this reason the 1750 cm^{-1} band is attributed to nitric oxide chemisorbed on iron which was in the reduced state prior to exposure to nitric oxide and is not referred to as nitric oxide on reduced iron. There is a discrepancy between this concept and the conclusions of Terenin and Roev (15). These workers observed a band at 2008 cm^{-1} which they attribute to nitric oxide chemisorbed on reduced iron as Fe—N≡O^+. In this case the iron atom is considered as a constituent of a reduced metallic particle. Thus it is significantly different from the iron in our Fe^{++}:NO^+ structure because here the Fe^{++} refers to an iron cation in an oxide. The 2008 cm^{-1} band has not been observed in the present work even though it shows up strongly in the Terenin and Roev spectrum. Moreover, if the 2008 cm^{-1} band were observed, it would not be possible to attribute it to nitric oxide on reduced iron without abandoning the concept of the oxidative nature of nitric oxide chemisorption.

Co-adsorption of carbon monoxide and nitric oxide.—The above discussion implies that the 1750 cm^{-1} band is produced by an oxidative chemisorption of nitric oxide on the reduced iron sites which were initially capable of chemisorbing carbon monoxide. This conclusion is supported by observations made when nitric oxide is added to reduced samples on which carbon monoxide is chemisorbed. Spectrum A of Fig. 4 was recorded after chemisorbing 0.09 cc of carbon monoxide on a reduced iron sample. The strong band at 1980 cm^{-1} is attributed to the carbon-oxygen stretching frequency in Fe—C≡O. Spectrum B of Fig. 4 was observed after dosing in small quantities of nitric oxide until a total of 0.12 cc of nitric oxide had been added. Even though a slight perturbation of the carbon monoxide band caused a shoulder to appear at 2020 cm^{-1}, the conclusion is that the band at 1820 cm^{-1} (characteristic of nitric oxide on oxidized iron) grew without profoundly affecting the chemisorbed carbon monoxide. A small band is observed at 1750 cm^{-1} in spectrum B. However, this band is small compared to the 1750 cm^{-1} band in spectrum C of Fig. 3. Thus, it appears that the chemisorbed carbon monoxide is effective in protecting the underlying iron surface from oxidation by nitric oxide. This protection is not complete because an additional 1.0 cc of nitric oxide caused the disappearance of the chemisorbed carbon monoxide band and the 1750 cm^{-1} band increased to the levels expected on the basis of spectrum C of Fig. 3.

Effect of oxygen and water on chemisorbed nitric oxide.—If a chemisorbed nitrogen-oxygen species is to be regarded as a significant factor in corrosion inhibition, it is reasonable to expect that these species would resist displacement by oxygen or water. The effect of exposing chemisorbed nitric oxide to oxygen is shown in Fig. 5. Spectrum A was observed after adding 0.75 cc of nitric oxide to a reduced iron sample. This spectrum shows the 1820 cm^{-1} and 1750 cm^{-1} bands which have been discussed for Fig. 3.

Spectrum B of Fig. 5 was observed after adding 1.15 cc of oxygen. The oxygen caused complete removal of the 1750 cm^{-1} band. The 1820 cm^{-1} band has been decreased but a large portion remains. The disappearance of the 1750 cm^{-1} band indicates that the Fe—O—N=O species, which is thought to be responsible for this band, is not a significant factor in corrosion inhibition. The retention of the 1820 cm^{-1} band suggests that any inhibitive properties of adsorbed nitrogen-oxygen species would be associated with the Fe^{++}:NO^+ structure.

The decrease in transmission, which is observed in going to spectrum B of Fig. 5, suggests that further oxidation of the particles on which the —O—N=O species (1750 cm^{-1}) were adsorbed may have been a factor in the displacement of this species.

Exposure of a sample, equivalent to that which gives spectrum A of Fig. 5, to water vapor did not cause displacement of either the 1820 cm^{-1} or the 1750 cm^{-1} bands. If a reduced sample was exposed to water vapor prior to adsorption of nitric oxide, the spectrum of the chemisorbed nitric oxide showed only a single band at 1820 cm^{-1}. Prior exposure to water vapor would result in formation of a thin oxide film on the iron. Results presented in Fig. 2 indicate that nitric oxide adsorption would then produce only the one nitrogen oxide band at 1820 cm^{-1} as was observed. Preadsorption of nitrogen oxide species on the reduced iron (as O—N=O groups) was apparently able to prevent this oxide film formation.

Effect of excess nitric oxide.—In Fig. 3 a decrease in transmission is observed in going from spectrum C to spectrum D. This decrease proceeded further as more nitric oxide was added until a transmission level of about 50% was reached after addition of 0.95 cc of nitric oxide. This decrease in transmission is evidence for a change in the nature of the reaction since there was no decrease in transmission in going from spectrum A to spectrum C. Other evidence for the changing character of the reaction of nitric oxide with the

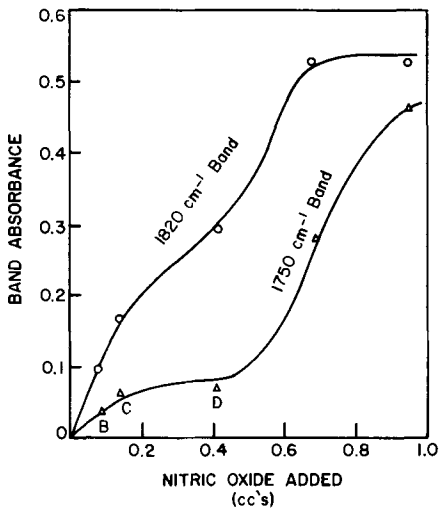

Fig. 6. Growth behavior of chemisorbed nitric oxide bands

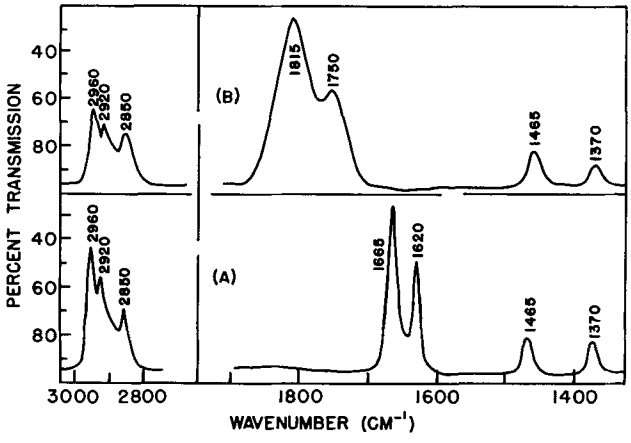

Fig. 7. Chemisorption of butyl nitrite on iron: A, butyl nitrite vapor (adsorbate); B, chemisorbed butyl nitrite on iron.

iron sample was also noted. When more nitric oxide was added, after the stage represented by spectrum D, nitrous oxide and nitric oxide were detected in the gaseous phase while the evolution of nitrogen ceased.

The most puzzling aspect of the changing character of the reaction lies in the observation of a further increase in the intensity of the 1750 cm^{-1} band. This increase cannot be explained on the basis that the 1750 cm^{-1} band is due solely to a monolayer of Fe—O—N=O on the initially reduced iron surface.

Figure 6 shows a plot of the absorbances of the 1820 cm^{-1} and 1750 cm^{-1} bands as a function of the amount of nitric oxide added. Up to the region of 0.8-0.9 cc the amount of nitric oxide added is equivalent to the amount chemisorbed since no residual nitric oxide could be detected. The residual pressure of nitric oxide after addition of 0.95 cc was ~0.01 mm. The absorbance is the log I_o/I where I is the transmission at the band peak and I_o is the base line background transmission at the peak frequency.

The specific extinction coefficient of the species responsible for the 1750 cm^{-1} band was calculated from the intensity of this band in previous spectra using the assumption that the adsorbed species is formed as indicated by Eq. [1] and [2]. This extinction coefficient is 0.1 x 10^{-17} cm^2/molecule (where extinction coefficient k is defined by: 2.3 log $I_o/I = kC$; C is concentration in molecules per square centimeter of beam path). This value is about one half that of the extinction coefficient of carbon monoxide chemisorbed on reduced iron. For the sample used to provide the data of Fig. 6, the absorbance due to chemisorbed carbon monoxide was 0.22. This would predict a maximum intensity of about 0.11 for the 1750 cm^{-1} band if this band is due solely to Fe—O—N=O groups on the portion of the surface which was initially capable of chemisorbing carbon monoxide. The flat portion for the 1750 cm^{-1} absorbance curve in Fig. 6 is slightly lower than this, but the agreement is acceptable.

The change to the evolution of nitrous oxide rather than nitrogen suggests that nitrogen evolution was related to the presence of reduced iron surface. When this type of surface was no longer available, the stoichiometry of the oxidative reaction suggests that it involved reaction of a molecule of nitric oxide from the gaseous phase with a molecule of nitric oxide which was previously chemisorbed.

A bulk oxidation could explain the decrease in transmission, but it cannot explain the additional growth of the 1750 cm^{-1} band. On the basis of present evidence, it is most reasonable to assume that the increase in the 1750 cm^{-1} band and at least some of the increase in the 1820 cm^{-1} band, which is observed above the plateau region (0.5 cc) of Fig. 6, was due to the formation of iron nitrosyl, $Fe(NO)_4$. Iron nitrosyl has bands at 1810 cm^{-1} and 1730 cm^{-1} (17). A single monolayer of iron nitrosyl could give the absorbance values shown in Fig. 6. However, the possibility of the formation of some bulk iron nitrosyl cannot be excluded.

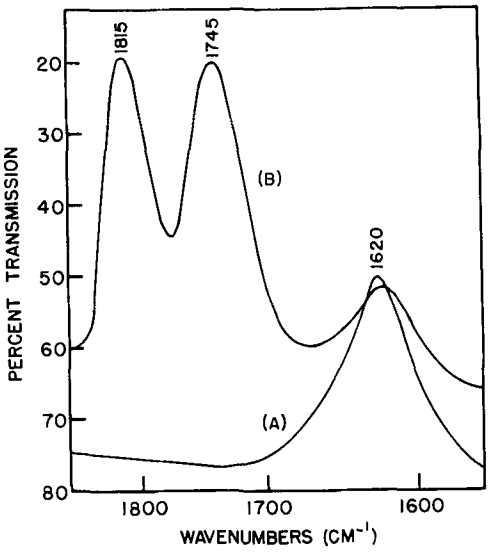
Adsorption of butyl nitrite on reduced iron.—The vapor pressure of n-butyl nitrite is about 13 mm at room temperature. This vapor pressure permits it to be used as a vapor phase corrosion inhibitor. It also permits convenient handling in the gas transfer procedures which are associated with the infrared method. However, there is some likelihood of its condensing on the silica portions of the sample. The spectrum of butyl nitrite physically adsorbed on silica is similar to that of butyl nitrite vapor. The physically adsorbed butyl nitrite can be easily removed from silica by evacuation at room temperature.

The spectrum of butyl nitrite vapor is shown as spectrum A of Fig. 7. This spectrum was observed with 13 mm of butyl nitrite in a gas cell which had a path length of 9.5 cm. The bands at 2960 cm^{-1}, 2920 cm^{-1}, and 2850 cm^{-1} are carbon-hydrogen stretching bands, and the 1465 cm^{-1} and 1370 cm^{-1} bands are due to carbon-hydrogen bending vibrations of the butyl group. The bands at 1665 and 1620 cm^{-1} have been attributed (11) to the stretching vibrations of the nitrogen-oxygen double bond in the trans, R—O, N=O, and cis, R—O, N, O, isomers, respectively.

Spectrum B of Fig. 7 was observed after adding 0.28 cc of butyl nitrite vapor to a reduced iron sample. This spectrum shows bands at 1815 and 1750 cm^{-1} which are similar to the bands observed after adding nitric oxide to reduced samples. It appears that there was no butyl nitrite physically adsorbed on the silica because bands are not observed at 1665 and 1620 cm^{-1}.

The hydrocarbon bands of spectrum B are similar to those of spectrum A. This similarity indicates that the majority of the adsorbed butyl hydrocarbon radicals remained intact.

Evacuation at room temperature had no effect on any of the bands in spectrum B. However, after evacuation at 100°-150°C it was observed that the 1815 cm^{-1} and 1750 cm^{-1} nitrogen-oxygen bands disappeared while the hydrocarbon bands remained unaffected. The hydrocarbon bands became smaller after the temperature was increased to 200°C, but did not completely disappear until the temperature was increased to 380°C.



Fib. 8. Chemisorption of butyl nitrite on iron covered by an adsorbed water film: A, adsorbed water; B, after adding butyl nitrite vapor.

At temperatures above 200°C, bands attributed to carboxylate ions were observed near 1550 and 1420 cm^{-1}. These bands indicate that the hydrocarbon fragments on the surface were being partially oxidized. This oxidation is thought to have involved oxygen furnished by the iron oxide.

The difference in the ease of removal of the nitrogen-oxygen and hydrocarbon bands shows that the butyl nitrite had dissociated. However, there is a question as to whether the dissociation occurred during the evacuation above 100°C or whether the dissociation occurred during the initial chemisorption of room temperature. The nitrogen-oxygen bands at 1850 and 1750 cm^{-1} are similar to those observed when nitric oxide was chemisorbed. This is taken as an indication that the dissociation of butyl nitrite occurred during the chemisorption at room temperature. It is difficult to account for the 1815 and 1750 cm^{-1} bands on the basis of structures in which the nitrogen-oxygen functional groups remain attached to butyl groups.

Butyl nitrite might dissociate by rupture of the carbon-oxygen bond, RONO → R— + ONO, or by rupture of the oxygen-nitrogen bond, RONO → RO— + NO. The spectra of the residual hydrocarbon fragments are not useful in clarifying which type of dissociation occurs. It is difficult to distinguish between the spectra of adsorbed butyl radicals, C_4H_{11}–, and adsorbed butoxy radicals, $C_4H_{11}O$—. Moreover, rupture to initially give butyl radicals might result in butoxy radicals if the butyl radical were adsorbed on an oxygen.

Nitrogen was evolved during the initial phases of the chemisorption of butyl nitrite on the reduced iron sample. This nitrogen was probably produced by the oxidative chemisorption of nitric oxide formed during decomposition of butyl nitrite. The decrease in transmission, which has been associated with oxidation of the iron, was also observed during the chemisorption of butyl nitrite.

Chemisorption of butyl nitrite on pre-oxidized iron.—Chemisorption of butyl nitrite on pre-oxidized samples produced spectra similar to that of spectrum B of Fig. 7. Nitrogen-oxygen bands were observed at 1815 and 1750 cm^{-1}. As in the case of butyl nitrite on reduced iron, the 1815 and 1750 cm^{-1} bands were removed by evacuation at 150°C while the hydrocarbon bands were retained.

If the butyl nitrite had dissociated to butoxy radicals and nitric oxide, observation of the 1750 cm^{-1} would not be expected since nitric oxide did not produce this band when adsorbed on a pre-oxidized sample. Thus, the observation of the 1750 cm^{-1} band in this case presents a question which is difficult to resolve. Tentatively, the 1750 cm^{-1} band of butyl nitrite on a pre-oxidized sample is ascribed to Fe—O—N=O produced by adsorption of —O—N=O fragments. These result from the rupture of the carbon-oxygen bonds RONO → R— + O—N=O. Attempts have been made to support this explanation by adsorbing nitrogen dioxide on iron and iron oxide samples, but no chemisorbed O—N=O species were detected.

Effect of water on butyl nitrite chemisorption.—In many practical situations if butyl nitrite were to be an effective corrosion inhibitor, it would necessarily adsorb on a surface which was initially covered with a layer of water. In order to determine whether preadsorbed water would retard chemisorption of butyl nitrite, a reduced iron sample was exposed to 6 cc of water vapor prior to admission of butyl nitrite. This quantity of water was sufficient to cover all of the surface of the sample including the silica.

Spectrum A of Fig. 8 was observed after adsorption of the water and prior to adsorption of the butyl nitrite. It shows a strong band at 1620 cm^{-1} which is due to the hydrogen-oxygen-hydrogen bending mode of physically adsorbed water. Spectrum B of Fig. 8 was observed after adding 0.65 cc of butyl nitrite vapor. The observed nitrogen-oxygen bands are similar to those of Fig. 5. This shows that the preadsorbed water did not retard the chemisorption of butyl nitrite.

Significance of results to corrosion inhibition.—The work presented in this paper shows that both nitric oxide and butyl nitrite cause oxidation of the surface of reduced iron and that chemisorption of these molecules produces strongly held nitrogen-oxygen species on oxide surfaces; with butyl nitrite, strongly adsorbed hydrocarbon fragments are also detected. On the basis of the specific examples studied, it is reasonable to conclude that chemisorption on reduced iron is not likely to be a significant factor in corrosion inhibition by nitrites.

The role of the chemisorbed hydrocarbon fragments, produced by dissociation of butyl nitrite, cannot be evaluated on the basis of present results. It is reasonable to assume that the chemisorbed hydrocarbons would render the surface partially hydrophobic and would thereby provide some protective action. However, the many examples of the inhibitive properties of sodium nitrite show that a hydrocarbon constituent is not essential to the corrosion inhibitive properties of inorganic nitrites.

The evidence presented here shows that nitrogen-oxygen species adsorb strongly on iron oxide and also resist displacement by water and oxygen. Extension of these observations to a conclusion regarding the role of the adsorbed species in corrosion inhibition is admittedly speculative. However, it is reasonable to consider that the nitrogen-oxygen species, which is thought to adsorb as $Fe^{++}:NO^{+}$, creates surface conditions which are significantly different from those which prevail in the absence of the inhibitor. In the latter case the surface is probably covered with species such as $O^{=}$, OH^{-}, or Cl^{-}. Replacement of these anions by the NO^{+} could be expected to decrease the potential drop across the oxide layer and thereby reduce the field assisted migration of metal ions through the oxide barrier.

Present plans call for a continuation of the infrared study of adsorbed corrosion inhibitors with emphasis on the development of techniques which preclude the necessity of using silica supported samples. Hopefully, an application of infrared methods to samples which are suitable for simultaneous testing of the efficiency of corrosion inhibition will provide additional worthwhile information.

Acknowledgment

The authors wish to express appreciation to D. Bauer and B. Clark for help with the experimental work, to L. C. Roess and A. N. Webb for stimulating discus-

sions, and to the management of Texaco, Inc. for support of this work.

Manuscript received Sept. 9, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Gallium-Phosphorus-Zinc Ternary Phase Diagram

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The data obtained from a series of differential thermal analysis studies have been used, along with several x-ray studies, information from the literature, and a regular solution computation to construct a portion of the condensed ternary phase diagram for the gallium-phosphorus-zinc system. The phase diagram consists principally of the primary phase fields of GaP and Zn_3P_2.

The major interest in the Ga-P-Zn ternary phase diagram is the result of the current interest in electroluminescence in gallium phosphide p-n junctions made by the diffusion of zinc into n-type GaP. Since the ternary phase diagram defines the stability conditions for GaP in the presence of a third component, it is of importance in the selection of diffusion source compositions and for the definition of crystal growth conditions.

Thurmond's (1) binary liquidus data for the gallium-phosphorus system, and Hultgren's (2) tabulated data for the gallium-zinc system have been used, along with experimental data obtained from a series of differential thermal analysis studies, and a regular solution extrapolation procedure, to construct a portion of the ternary phase diagram for the gallium-phosphorus-zinc system.

The Binary Phase Systems

GaP.—Gallium and phosphorus form a single congruently melting compound, GaP, with a melting point of 1465°C (3). Thurmond (1) has utilized the solubility data of Rubenstein (3) and Hall (4) along with an adaptation of the regular solution treatment of Vieland (5) to construct the binary phase diagram.

Ga-Zn.—Gallium and zinc form a simple eutectic system with a eutectic temperature of 25.5°C at a zinc concentration of 3.7 a/o (atom per cent). Hultgren, Orr, Anderson, and Kelley (2) have constructed the phase diagram on the basis of measurements by Heuman and Predel (6).

P-Zn.—There is not enough data available in the literature for the construction of the P-Zn binary phase diagram. Hansen (7) reports the existence of two zinc phosphides, Zn_3P_2 and ZnP_2. For the purposes of the work reported here it has been assumed that the shape of the binary phase diagram is similar to that reported for the Zn-As system (7).

Experimental

Semiconductor grade phosphorus and zinc with purities better than 99.99% were used in this work. The gallium in some runs was 99.9999% pure, but for some runs in which large amounts of gallium were required, reclaimed gallium with purity better than 99.99% was utilized.

Fused silica capsules with a volume of about 13 cc which were about 2/3 filled with melt were used for the differential thermal analysis experiments. The experimental details are very similar to those which have already been described for the study of the Ga-As-Zn system (8).

In order to obtain x-ray data for the phases present during cooling process, several of the DTA cells were removed from the cooling apparatus before they had cooled enough to go through all the expected phase transitions. These cells were then air or water quenched in an attempt to freeze in the phases of interest.

Results and Discussion

The temperature at which thermal effects were observed when melts of various compositions were cooled are given in Table I. T_1 represents the temperature at which the surface of primary crystallization is reached. T_2 is the temperature of appearance of a second solid phase. T_3 and T_4 are temperatures at which there are apparently solid phase transitions in Zn_3P_2. T_5 is the temperature at which a ternary peritectic is reached and the reaction

$$Zn_3P_2 + 2Ga \rightarrow 2GaP + 3Zn \qquad [1]$$

occurs. T_6 is the temperature at which a zinc-gallium phosphide mixture precipitates. Figure 1 is a plot of the temperature at which most of the thermal effects described above were observed in melts whose over-all compositions were along the GaP-Zn pseudobinary.

As can be seen from Table I and Fig. 1, experimental thermal effect data were obtained only in the region of the ternary system in which the over-all phosphorus composition was less than about 19 a/o. The restriction of experimental work to this part of the phase diagram was necessary because of the high equilibrium phosphorus pressures which would have been encountered had experiments been done at higher phosphorus composition.

Construction of the ternary diagram.—The Ga-P binary diagram of Thurmond (1) and the Zn-Ga binary diagram of Hultgren (2) were used as boundaries for the ternary without modification. It was assumed that the P-Zn phase diagram is similar in shape to the As-Zn phase diagram; however, no effort has been made to show details of the ternary diagram in the region of the Zn-P axis.

The ternary Ga-P-Zn phase diagram is shown in Fig. 2. The position of the ternary eutectic valley was obtained from the T_1-T_2 thermal effect intersection on the GaP-Zn pseudobinary (Fig. 1), from the T_2 thermal position for a point on cut C (Fig. 2 and 3), and from the position of the ternary peritectic point. The ternary eutectic valley was extrapolated towards the Zn-P axis of the diagram, by assuming that the

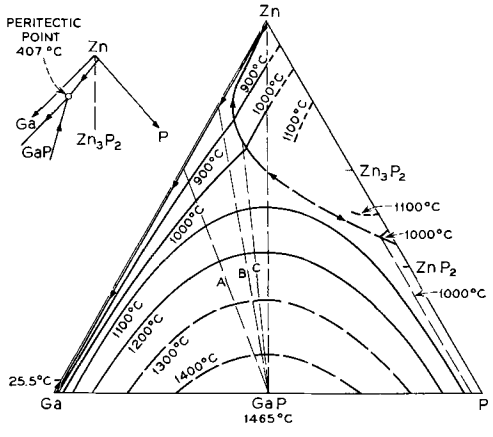

Fig. 2. The Ga-P-Zn ternary phase diagram

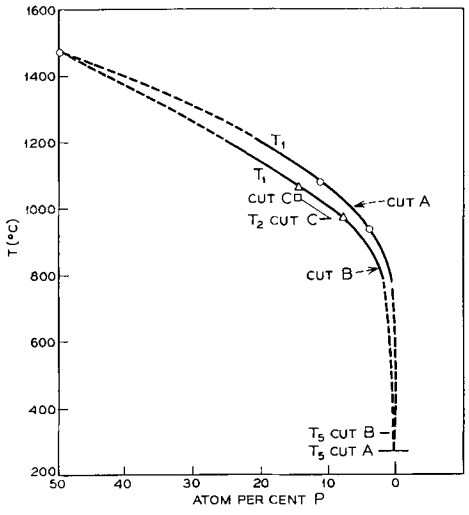

Fig. 3. Thermal effects for mixtures along several cuts in the Ga-P-Zn ternary system.

Ga-P-Zn system behaves in a manner similar to that already shown for the Ga-As-Zn system (8).

The composition at which the ternary peritectic occurs was obtained by assuming that this composition is very close to the Ga-Zn axis and therefore is essentially on the Ga-Zn binary at a composition corresponding to the liquid-solid equilibrium composition at the observed peritectic temperature. This assumption is supported by the fact that in the Zn-P system the liquidus has been reported to rise steeply from the melting point of pure Zn (9). The binary eutectic temperature is thus very close to the melting point of pure zinc and there is very little phosphorus in the liquid binary at the eutectic temperature.

X-ray analysis of samples quenched after formation of the first solid phase were found to contain only zinc, gallium, and GaP when the initial over-all composition was along cuts A and B. When the initial over-all composition was along the Zn-GaP pseudobinary or in the indicated Zn_3P_2 primary phase field, the slow cooled or quenched solid was found to contain zinc, gallium, GaP, Zn_3P_2 (occasionally), and an unidentified phase. The unidentified phase was present in all these samples, even in cases in which the sample was allowed to slow cool through the peritectic transformation temperature. The x-ray data are consistent with the phase diagram if it is supposed that the peritectic transformation is incomplete and that the unidentified phase is a modification of Zn_3P_2.

The latter assumption is substantiated by electron beam microprobe analyses which demonstrated the presence of a phase containing only zinc and phosphorus when the unidentified phase was observed by x-ray analysis. The thermal effects designated T_3 and T_4 in Fig. 1 are consistent with the suggested existence of one or more solid phase transitions in Zn_3P_2. A similar thermal effect which has been interpreted as a solid state transition has been observed in the Zn-As system (7) and the Ga-As-Zn system (8).

The regular solution procedure for interpolation of ternary isotherms which was recently suggested by Furukawa and Thurmond (10), and which has been applied by them to the Ga-As-Cu system, and by this author to the Ga-As-Zn system (8), was used for estimation of the isotherms in the GaP primary phase field. For this procedure the equation

$$RT \ln \left[\frac{k}{x_1 x_2}\right] = \{(a_{12}x_2 + a_{13}x_3)(x_2 + x_3) + (a_{12}x_1 + a_{23}x_3)(x_1 + x_3) - a_{23}x_2x_3 - a_{13}x_1x_3\} \quad [2]$$

was used. The symbols a_{12}, a_{13}, and a_{23} represent the interaction energies for components 1, 2 and 3; x_1, x_2,

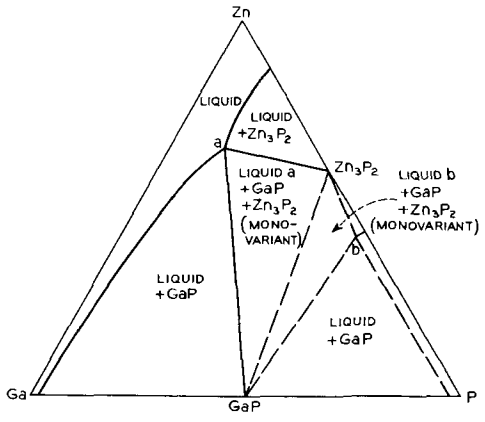

Fig. 4. The 1000°C isotherm in the Ga-P-Zn system.

and x_3 are atom fractions of the constituents, and K is the equilibrium constant for the reaction

$$GaP \rightleftarrows Ga_{(l)} + P_{(l)} \quad [3]$$

which was obtained from Thurmond's (1) binary data. Isotherms at 900°, 1000°, 1100°, and 1200°C were computed with data from Thurmond's Ga-P binary diagram and from several points along cuts A and B (Fig. 2 and 3). The 1300° and 1400°C isotherms were drawn to be consistent with the extrapolations of the various cuts, the Ga-P binary and the shape of the curves at lower temperatures. It should be noted that because of the limited region in which data was obtained the isotherms should be considered to be preliminary estimations.

Two isotherms in the Zn_3P_2 primary phase region were drawn by connecting the isotherm composition on the GaP-Zn pseudobinary with the intersection point of the isotherm in the GaP primary phase region with the ternary eutectic valley. Several other isotherms were roughly estimated by comparison with the Ga-As-Zn system.

Conclusions

The ternary phase diagram of the gallium-phosphorus-zinc system consists principally of two primary phase fields due to GaP and Zn_3P_2, respectively. The Zn_3P_2 phase field exists over part of the GaP-Zn pseudobinary, and there is a ternary peritectic point near the zinc corner of the diagram. These facts have several interesting implications for electronic device work done with gallium phosphide.

The existence of the Zn_3P_2 primary phase field over a large region of the ternary diagram indicates that it will be difficult to produce zinc alloyed electrical contacts to gallium phosphide without interference from Zn_3P_2 unless zinc-gallium "solders" are used. The presence of the additional phase will, however, be useful in diffusion studies. On any isotherm below about 1050°C there are extensive composition regions in which two solid phases and a liquid phase coexist. See, for example, Fig. 4. These regions are monovariant, the partial pressures of the equilibrium gaseous species being a function only of the temperature within the region. Highly reproducible diffusion sources may therefore be produced from mixtures with over-all compositions within the monovariant regions specified by the phase diagram.

A more detailed discussion of the implication of the ternary condensed phase diagram to diffusion studies and solid solubility in a system such as that discussed here has been given elsewhere (8).

Acknowledgments

The author is indebted to C. D. Thurmond for his helpful suggestions during the course of this work. The aid of Mr. S. Sumski with some of the experimental work, of Mrs. V. Compton for the x-ray analysis, and of H. Schreiber for the electron beam microprobe analyses is gratefully acknowledged.

Manuscript received Oct. 18, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Luminescence in Mg_2SiO_4:Tb,Li Phosphors

W. A. McAllister

Lamp Division, Advanced Development Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Magnesium orthosilicate (Mg_2SiO_4) can be activated by terbium, when lithium is used as a flux, to give the characteristic green line emission of Tb^{+3} ion. The emission is modified without loss in 254 nm-excited efficiency on addition of manganese, to give a supplementary orange band. The incorporation of high concentrations of activator terbium, a cation much larger than any other species present, without significant distortion of the olivine structure is probably related to known features of this lattice. The good brightness at such high activator levels suggests better coupling of the emitting rare earth to the ultraviolet absorbing host.

The emission characteristics of rare earths have been studied for the free ions (1, 2) and when present as constituents in various host lattices such as oxides (3), tungstates, and molybdates (4, 5). Where the rare earth is part of a crystal matrix its spectral properties are largely those of the free ion, characterized by a series of lines indicative of the shielding of the f-orbital energy levels involved in optical processes. Accommodation of the rare earths is usually by replacement of other cations of similar size,

with compensation of any charge differences if necessary. This is doubtless true in the europium-activated alkaline earth silicate phosphors described by Jenkins and McKeag (6), in which calcium, strontium, or barium were the cations involved. On the other hand, substitution of lanthanides (r = 1.1Å) for magnesium (r = 0.78Å) in a lattice is not likely since the differences in ionic radii are over twice the 15% value considered to be the limit of miscibility for mixed crystal formation (7). It has been found possible, however, to introduce rare earths into hosts having magnesium as the largest cation, by using a compensating alkali metal ion (lithium). The work described herein represents a portion of the effort devoted chiefly to magnesium silicate activated by terbium or terbium and manganese.

Experimental

Phosphors were prepared by firing mixtures of carbonates of magnesium and lithium, silica, and terbium oxide (Tb_4O_7) at 1300°C for several hours. The carbonates were SL grade and the terbium oxide was 99.9% pure with respect to rare earth ions. Although luminescent materials were produced by air firing, those prepared in a stream of nitrogen, containing a few per cent hydrogen, were superior.

Optical properties of the phosphors were examined using equipment described by Thornton (8) elsewhere. Briefly, the appropriate wavelength from the radiation in a lamp is isolated by a Bausch and Lomb monochromator and focussed on the sample plaque. The emission spectrum for a given exciting wavelength is then determined by focussing the emitted radiation on the entrance slit of a second (analyzing) monochromator and scanning with an EMI 9558B photomultiplier. Excitation spectra were determined by setting the analyzing monochromator on the desired emission peak and scanning the first monochromator in the region 200-400 nm. The intensity of the uv radiation incident on the phosphor was found by repeating this operation with sodium salicylate as the standard. Excitability is taken as the ratio of photomultiplier signals for phosphor and standard. Reflectance characteristics were compared using calibrated magnesium oxide as the standard with source and sample at the usual positions and the drive mechanisms of the two monochromator gratings coupled during scanning. Plaque brightness data were collected on thick samples with other equipment including a 400w mercury vapor arc tube, appropriate filters and a 1P28 photomultiplier.

Quantum efficiency was determined relative to magnesium tungstate by measurements of relative emission spectra coupled with reflectance data. Color coordinates and luminosity factor were computed from spectral emission curves. Correction of raw data and calculations of important parameters of this type were accomplished by use of computer programs.

Results

Phosphors were made with terbium concentrations ranging from 0.01 to 0.48 moles of terbium for a constant 2 moles of $MgCO_3$ and 1 mole of silica. Lithium additions up to 0.30 mole were also used. In the absence of lithium only a faint blue-green luminescence (line spectrum) was noted for any terbium concentration. Addition of even small quantities of lithium shifted the color to yellow-green and increased brightness markedly, best output being at 0.12 mole of terbium and 0.14 of lithium (Table I). At this level, the changes in color with activator concentration are associated with the suppression of some of the blue peaks and concurrent enhancement of those in the green-yellow region (Fig. 1). Especially pronounced is the increased height of the lines peaking at 543 and 553 nm, in the region of maximum eye sensitivity.

Introduction of lithium also favorably alters the excitability of the phosphor by shortwave uv radiation (Fig. 2). In fact said response is more sensitive to lithium than to terbium concentration, as shown by the plaque brightness data of Table I. The same increment in 254 nm excited emission results when lithium is increased from 0.10 to 0.14 at 0.04 Tb as is produced by increasing terbium from 0.04 to 0.12 at 0.10 lithium. Another feature of the excitation spectra is the appearance, or perhaps better resolution, of a peak at 300 nm with addition of lithium.

Absorption of uv radiation is also dependent on the presence of lithium (Fig. 3). In the absence of this alkali metal oxide only half the incident 254 nm radiation was absorbed while 80-85% absorption, measured by diffuse reflectance, could be attained in the best samples. From Table II it is evident that the raw

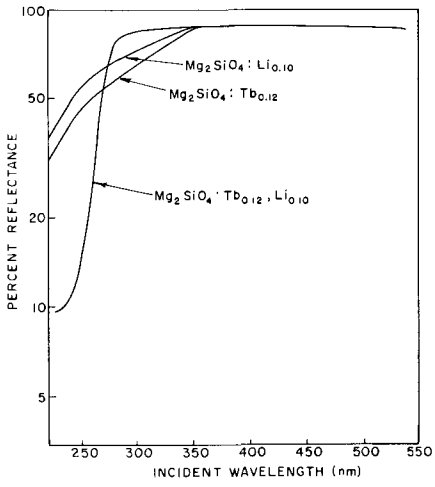

Fig. 3. Diffuse reflectance of magnesium silicate activated by terbium or lithium or both.

mix with only terbium results in a mixture of products, while addition of lithium gives a single phase. Thus the comparisons made in Fig. 3 are not, strictly speaking, justified, since the reflectance of the sample without lithium could be ascribed to the other product (MgO, SiO_2). The Mg_2SiO_4:Li, on the other hand, is a single material with the characteristics of that noted with terbium and lithium as activators.

With these reservations in mind, the absorption properties described do highlight the fact that good phosphors are noted only when lithium is used, along with the terbium which is responsible for the emission found. When this restriction is observed, the x-ray diffraction patterns are those of the mineral olivine, Mg_2SiO_4. The lattice constants of several luminescent materials were compared with published values for olivine. From the data of Table III it is apparent that only the b-dimension is perceptibly different from that of Mg_2SiO_4. The disparity is not of sufficient magnitude to change the structure.

While phosphors with terbium emission are promising, addition of radiation other than the characteristic green luminescence is attractive. Transfer of energy between rare earths, *e.g.*, $Tb^{+3} \rightarrow Eu^{+3}$(9) has been noted, and simultaneous uv absorption by several activators, each with its own characteristic emission color, is another useful process for alteration of the spectrum. Of the activators considered only manganese was found to be effective. Figure 4 shows the change in spectral properties with addition of manganese to the silicate. The green peaks are suppressed and a new orange band appears. Excitation spectra for the emission at 650 nm (manganese) and 550 nm (terbium) were determined and found to be quite similar (Fig. 5), with the manganese containing phosphor being more responsive to uv wavelengths below 200 and above 350 nm. The color of phosphors with varying amounts of manganese was determined along with quantum efficiency. Despite the marked change in the former (Fig. 6), the quantum efficiency remains essentially constant at the 0.5 level. These quantum efficiency figures, along with luminosity factors and color are presented in Table IV.

Finally the temperature dependence of brightness was determined using a quartz arc tube as source and

taking measurements in transmission on thin samples. The results in Fig. 7 show that the phosphors retain a significant portion of their room temperature output at elevated temperatures.

Discussion

The crystallographic data show that, in the presence of lithium, the terbium is included in the olivine host without structurally significant distortion of the latter. While the lithium can substitute at magnesium sites, their ionic radii both being 0.78Å, the terbium ion would be expected to modify the structure if sub-

Table IV. Color and efficiency of Mg_2SiO_4:Tb,Li,Mn phosphors (λ_{exc} = 256 nm)

Phosphor	x	y	Quantum efficiency	Luminosity factor, η
$Mg_2SiO_4:Tb_{0.12}Li_{0.10}$	0.321	0.516	0.43	0.62
$Mg_2SiO_4:Tb_{0.12}Li_{0.10}Mn_{0.01}$	0.418	0.476	0.51	0.52
$Mg_2SiO_4:Tb_{0.12}Li_{0.10}Mn_{0.03}$	0.486	0.430	0.50	0.41
$MgWO_4$	0.222	0.312	0.84	0.38

stituting for either cation present in the olivine matrix. The reason such lattice changes are not evident may be associated with known features of the olivine structure. The latter may be regarded as an assembly of hexagonal close-packed oxygen ions in which half the octahedral and an eighth of the tetrahedral sites are occupied (8). This fact accounts for the occurrence of materials like Li_3PO_4 in the olivine structure, at the same time suggesting that the framework has some freedom to accommodate additional ions, even of disparate size, under favorable conditions.

When trivalent cations substitute for divalent species some type of charge compensation is required. Since luminescence depends on the presence of lithium, substitution of one Tb^{+3} and one Li^{+1} for two Mg^{+2} would provide the necessary compensation. The oxygen added with the first two is most likely in substitutional locations and is probably compensated by defects on the cation lattice. In a structure such as that of magnesium silicate, the effect of a few more unoccupied cation sites on lattice parameters should be infinitesimal. The slight, measured change in the b dimension (Table III) can be accounted for by the space requirements of the large added terbium ion.

Although the replacement described

$$Tb^{+3} + Li^{+1} \rightarrow 2Mg^{+2}$$

satisfies the arithmetic of charge compensation it avoids some possible symmetry problems. The effect of replacing divalent cations about a common SiO_4^{2-} anion radical is a difference in unshielded nuclear charge as seen by the silicate grouping. An anticipated consequence would be polarization of the radical toward terbium, rather than lithium, *i.e.*, a decrease in volume about the rare earth and better coupling to the absorbing lattice. Both the presence of alkali with rare earths (Tb^{+3}, Eu^{+3}) and the volume occupied by the latter have been found to alter emission characteristics of tungstates and molybdates in which host cations, but not structure, have been varied (10). The increase in brightness of Mg_2SiO_4 with terbium concentration and its dependence on concomitant lithium addition indicate the importance of such rare earth-lattice coupling here also.

High-Temperature Resistivity of the Chalcopyritic Compound $CuInTe_2$

Stojan M. Zalar[1]

Research Division, Raytheon Company, Waltham, Massachusetts

ABSTRACT

To investigate extrinsic and intrinsic behavior of the semiconductor $CuInTe_2$, high-temperature electrical resistivity experiments were carried out, using the technique of porcelain "cocoons." $CuInTe_2$ was considered as part of the pseudobinary system Cu_2Te-In_2Te_3. Inspection of the plots ln ρ *vs.* $1000/T$ for samples with 44 to 56 molar % Cu_2Te revealed the existence of two extrinsic regions: room temperature to 200°C and 200°-710°C. The latter was found complex and exhibited in general two different slopes. The intrinsic region in these samples existed in a narrow temperature interval between 710° and 779.8°C (the melting point of $CuInTe_2$), and was well defined and reproducible. Assuming a $T^{-3/2}$ dependence of carrier mobility, the "thermal" energy gap of $CuInTe_2$ could be calculated from the intrinsic slopes in the plots ln ρ *vs.* $1000/T$, and was found to be 1.04 ev. Observed deviations from this value were ±0.02 ev. Prolonged annealing of various samples of $CuInTe_2$ at 400°C promoted disappearance of extrinsic differences among them, while their intrinsic slopes remained the same.

$CuInTe_2$ is a semiconductor belonging to the broad family of ternary chalcopyritic compounds I-III-VI_2, which in turn are generally regarded as cross-substitutional derivatives of II-VI binary compounds, such as CdTe and ZnSe. We have previously studied the crystal growth (1), thermoelectric power, and electrical resistivity (2) at room temperature. In this paper we report studies of the high-temperature behavior of the chalcopyritic compound $CuInTe_2$.

In a previous work on semiconducting solid solutions $Cu_xAg_{1-x}InTe_2$ (3) we found it convenient to consider them as a linear part of the ternary system Ag_2Te-Cu_2Te-In_2Te_3, as illustrated in Fig. 1. In a similar way Mason and Cook (4) investigated the peritectic compound $CdIn_2Te_4$ as part of CdTe-In_2Te_3, while O'Kane and Mason (5) studied $AgIn_3Te_4$ as part of the Ag_2Te-In_2Te_3 system. Figure 1 shows stoichiometric composition of $CuInTe_2$ as $(Cu_2Te)_{50}$-$(In_2Te_3)_{50}$. Since our prime interest was in studying physical phenomena in slightly off-stoichiometric $CuInTe_2$, it was decided to investigate compositions in the range between $(Cu_2Te)_{44}$-$(In_2Te_3)_{56}$ and $(Cu_2Te)_{56}$-$(In_2Te_3)_{44}$ and to explore changes in electrical resistivity up to their melting point. To our knowledge a "thermal" energy gap of $CuInTe_2$ has not yet been determined.

[1] Present address: Westinghouse Research Laboratories, Pittsburgh, Pennsylvania.

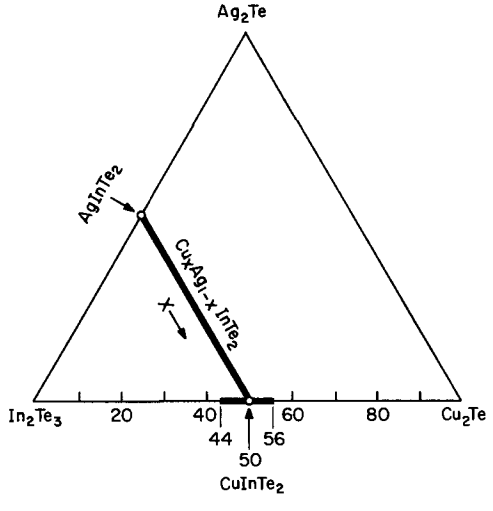

Fig. 1. $Cu_xAg_{1-x}InTe_2$ as part of the pseudoternary system Ag_2Te-Cu_2Te-In_2Te_3, and $CuInTe_2$ as part of the pseudobinary system Cu_2Te-In_2Te_3.

Experimental Method

The work on $CuInTe_2$ at high temperature (up to 800°C) required a method which would suppress evaporation of tellurium, thus maintaining the original composition. Of several different techniques, from pressurized capsules to immersions into ceramic powders, the method of porcelain "cocoons" proved to be the most successful.

There are three main techniques for single crystal growth of solids: Czochralski crystal pulling, Bridgman method, and zone melting. The last two were applied to $CuInTe_2$ in these laboratories. In both cases the material was placed in evacuated and sealed quartz capsules, hence preventing the nonequilibrium evaporation of volatile tellurium. This is why in principle the Czochralski method of pulling crystals out of the melt, which otherwise produces essentially stressfree ingots, is not very suitable for chalcopyrites containing tellurium with its relatively high partial vapor pressure. For resistivity studies, as reported here, only Bridgman specimens were used, while zone melting of $CuInTe_2$ was employed in the thermoelectric investigations (2).

For the initial preparation of specimens $CuInTe_2$, the method of direct melting of elements, weighed separately on a microbalance with an accuracy of ±0.0001g, was utilized. Because of the critical effect of impurities in semiconductor investigations, the purest available materials were used: copper: spectroscopically pure, +99.999% (ASARCO); indium: special high purity, +99.999% (ASARCO); tellurium: semiconductor grade, +99.999% (ASARCO).

The first phase, which consists of melting and reacting the elements, was done in relatively large batches (100g or more). The quartz capsule containing the elements was first evacuated (typical vacuum: 1×10^{-5} Torr) and then sealed with a hydrogen-oxygen torch. The capsule was then placed in the center of a tiltable furnace with temperature controlled at 850°C or more. During the melting operation, the furnace was vigorously tilted upside-down many times in order to enhance the thorough mixing of the elements and to remove the surface bubbles. The melt was first held at temperatures about 100° above the melting point of $CuInTe_2$ (779.8°C) for several hours, then its temperature was lowered to 800°C for about

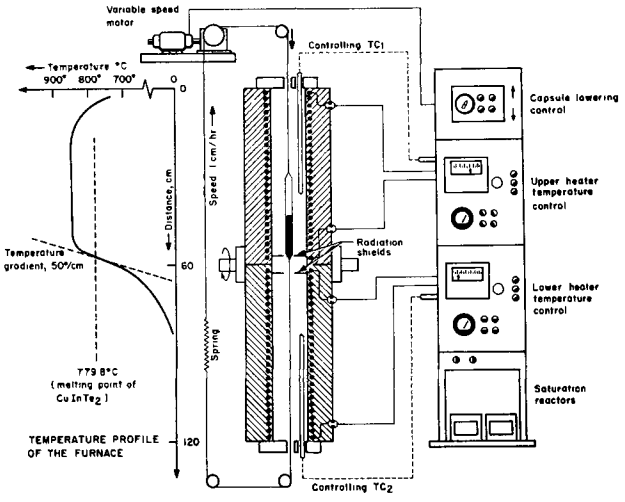

Fig. 2. Vertical Bridgman furnace experimental set-up for the crystal growth of $CuInTe_2$.

half an hour, after which the capsule was quenched in ice water.

In the second phase (crystal growing), the capsule from the first phase was cautiously crushed and the brittle $CuInTe_2$ broken into small pieces. All the powder was thrown away. Small pieces of $CuInTe_2$ were placed into clear, carefully pointed quartz tubes (7 mm OD, 5 mm ID). These were in turn evacuated to a pressure of 1×10^{-5} Torr, and subsequently hooked to the Bridgman lowering mechanism.

The Bridgman furnace, as shown in Fig. 2, consisted of two kanthal wound sections, separately temperature controlled to an accuracy of $\pm 0.5°C$ by saturable reactors. A sharp temperature gradient of about 50°C/cm, produced by two platinum radiation shields, was needed for the successful crystal growth of $CuInTe_2$. The lowering speed of the capsule was regulated very accurately by a variable speed motor. The best speed was between 5 and 20 mm/hr. It was held at 7 mm/hr for the most part.

The resulting ingots, of 5 mm diameter, were coarsely polycrystalline, containing an average 3-7 grains and mostly with no bubbles on the surface. They were cut into lengths of 15-20 mm and carefully sandblasted.

One of the most stubborn experimental problems in the Bridgman method of crystal growing $CuInTe_2$ was the formation of surface bubbles. These bubbles, believed to be primarily caused by the evaporation of dissolved gases, were difficult to remove during the slow motion of the Bridgman ingot. Several experimental measures were tried in order to solve the problem. First it was noticed that a steeper temperature gradient partially removed the surface bubbles, mostly in the upper portion of the ingot. The temperature gradient was hence increased from 17° to 53°C/cm by inserting two platinum radiation shields in the central portion of the furnace.

A second improvement was achieved by using refrasil (quartz) sleeving, placed tightly against the inner walls of the quartz tubing (13 mm in diameter). In one typical run the temperature in the upper portion of the furnace was held at 880°C, and the capsule was lowered at the high speed of 35 mm/hr for 6 hr. Results were positive: no bubbles appeared on the surface of the ingot. While this method was successful in eliminating bubbles, large single crystals could not be grown by this technique, presumably because the sleeving with its interwoven structure induced the formation of crystal nuclei.

A third substantial improvement in the reduction of surface bubbles in $CuInTe_2$ was accomplished by using a carbon coated quartz tube. The carbonizing of the inner walls of the quartz tube was done by thermal decomposition of pentane: $C_5H_{12} \rightarrow 5C + 6H_2$. First the tube was evacuated. Then the vapors of pentane were introduced (pentane is a liquid with a high vapor pressure) and decomposed by the heat of a gas-oxygen torch. This procedure was repeated several times; each time a very thin layer of carbon was deposited on the inner wall of the tube. The results were good; ingots of $CuInTe_2$ were bubble-free.

In order to prepare specimens for resistivity experiments four thin platinum wires of 0.005 in. in diameter were electrically welded onto the surface of the ingot at even distances from each other. The distances between these potential probes were measured with an accuracy of 0.001 cm using an optical microscope and were typically of the order of 0.15 cm. Four-point electrical resistivity was calculated from the Valdes' formula (6).

A direct current of 10-50 ma was applied, automatically and successively in both directions, thus eliminating thermoelectric end effects by simple subtraction of voltage readings.

A thin chromel-alumel thermocouple (No. 30 wire) was also welded on the surface of the ingot, close to the four electric leads, allowing an on-the-spot temperature reading with an accuracy of $\pm 0.2°C$.

The schematic wiring of $CuInTe_2$ specimens for high-temperature resistivity investigations is shown in Fig. 3. The "cocoon" itself was made by repeated dipping of the specimen into a pot of diluted liquid porcelain (Sauereisen No. 1). After each dip, thin porcelain layers were left to dry under infrared illumination. Typically from five to eight coatings were applied. A finished cocoon ready for measurement is shown on the right of Fig. 3. These porcelain coatings proved to be very dense and prevented tellurium from evaporation at temperatures above 400°C. A certain amount of contamination of $CuInTe_2$ by impurities in Sauereisen coatings during high-temperature runs could have occurred thus influencing its extrinsic behavior. No systematic study was performed on this question. Intrinsic properties, however, were not affected by the porcelain encapsulation.

On several occasions the resistivity measurements could be extended well into the molten phase of $CuInTe_2$, some 50° above the melting point. The four platinum probes, rigidly set in solid porcelain, maintained their position in the molten $CuInTe_2$ within the cocoon. A sharp drop of electrical resistivity at the melting point of $CuInTe_2$ was observed, but no further work has been done on this possibly useful method of studying the resistivity behavior in the vicinity of the melting point of compounds.

The thoroughly dried cocoon, with six wires protected by Refrasil sleevings was lowered into a quartz tube filled with washed Alundum bubbles. The tube

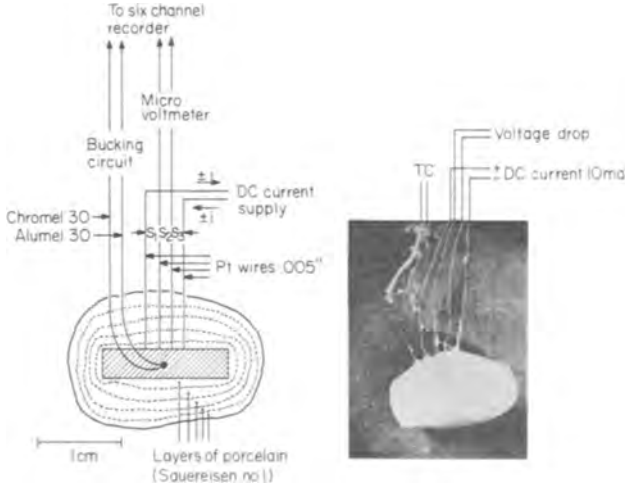

Fig. 3. Schematic wiring of experimental "cocoons" of $CuInTe_2$ for high-temperature resistivity investigations.

was in turn placed into a vertical resistance furnace. A slow stream of clean argon flowed through the furnace during the duration of the entire experiment to prevent any oxidation of the specimen. The temperature of the furnace was increased manually.

All electrical signals, $+\rho$, $-\rho$, and TC were automatically printed on a six-channel L&N recorder at 4-sec intervals. The measuring ranges were adjusted manually by the bucking circuit for the thermocouple case and by the Keithley microvoltmeter amplifier for the resistivity case.

Results and Interpretation

Microstructure of specimens.—The samples had the following compositions: $(Cu_2Te)_x$ $(In_2Te_3)_{100-x}$, x = 44, 45, 46, 47, 48, 49, 50, 52, 53, 54, and 56. Metallographic inspection showed that all quenched specimens were coarsely polycrystalline and mostly monophase, as revealed by etching with CP4 (without bromine).

The microstructure of some samples exhibited a small amount of a secondary phase in the form of little "chicken-pox" like islands. In previous work (3) we found that $CuInTe_2$ undergoes a metastable transition near 650°C. This was determined by thermal analysis in which a slight thermal arrest occurred at that temperature. On the basis of this evidence, it was proposed that $CuInTe_2$ is a supersaturated solid solution. To test this idea, several Bridgman-grown and several quenched polycrystalline ingots of stoichiometric $CuInTe_2$ were annealed at 650°C for 15 hr. Their microstructure was examined before and after annealing. Results are shown in Fig. 4. It is seen that after annealing at high temperatures some secondary phase or phases precipitate out of the chalcopyrite matrix of $CuInTe_2$, thus supporting the hypothesis of a supersaturated solid solution.

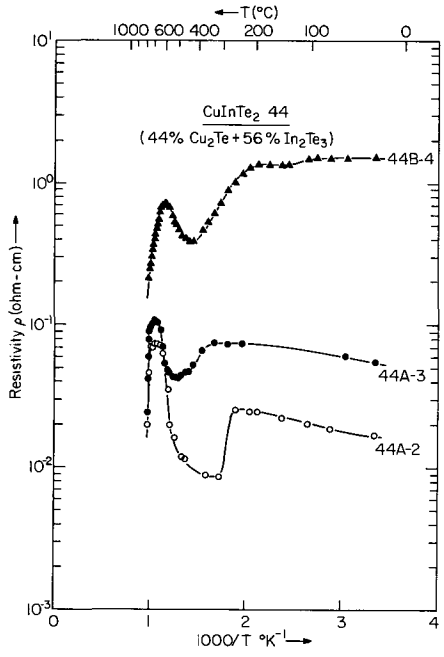

Fig. 5. Electrical resistivity vs. 1000/T in $CuInTe_2$ 44

To check this assumption still further, x-ray diffraction data were taken of samples with 44, 50, and 56% Cu_2Te in quenched and in annealed form. In all cases only the lines of the chalcopyrite structure occurred. These somewhat unexpected results were explained by the inherent limitation of x-ray diffraction technique. In the case of $CuInTe_2$ secondary phases could be detected only if they were present in the amount of more than 4%.

As in a previous x-ray study (3) very weak fixed count peak intensities of InTe (ASTM card 7-112) could be detected in annealed samples of $CuInTe_2$ (44, 50, and 56% Cu_2Te, rest In_2Te_3). InTe is the most prominent, congruently melting compound of the binary system indium-tellurium. Its relatively high melting point (696°C) suggests a stable compound with the lowest potential energy of any compound in the system. It is probable that after a prolonged annealing at elevated temperatures the structure of $CuInTe_2$ or of compounds (Cu_2Te)-(In_2Te_3) close to the ratio 50/50 becomes unstable and the compound InTe forms locally and precipitates out of the chalcopyritic matrix.

Resistivity at elevated temperatures.—By using the "cocoon" technique it was possible to measure and record electrical resistivity of specimens $CuInTe_2$ from room temperature up to their melting point, 779.8°C. Figures 5, 6, and 7 show typical plots of ln ρ *vs.* 1000/T for the compositions: 44, 50, and 56 molar % Cu_2Te. These plots and others for intermediate compositions not included in this paper, have several common features:

1. There are three distinct temperature ranges; the first an extrinsic region, from room temperature up to about 200°C; the second, an extrinsic region, from 200° up to 710°C; and the third, an intrinsic region, from 710°C up to the melting point at 779.8°C.
2. The extrinsic region 200°-710°C is complex and shows in general two linear slopes: one in the temperature range 200°-500°C and one in the range 500°-710°C. They could be explained by the presence of shallow and deep impurity levels.
3. Well-defined, reproducible "resistivity pockets," sandwiched between two extrinsic slopes appear in the stoichiometric $CuInTe_2$ in the temperature interval 455°-600°C. Similar, although distorted pockets could also be detected in other compositions.
4. The intrinsic region (710°-779.8°C) is nearly the same in all samples.

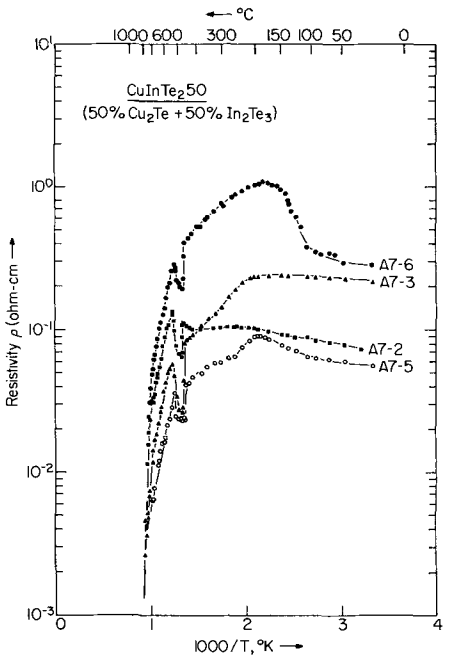

Fig. 6. Electrical resistivity vs. 1000/T in $CuInTe_2$ 50

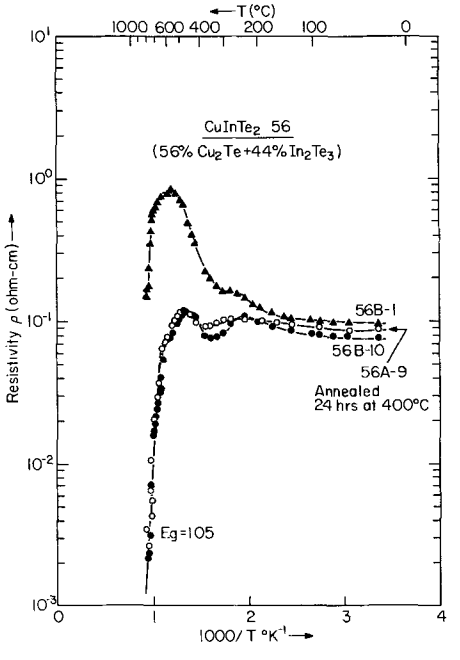

Fig. 7. Electrical resistivity vs. 1000/T in $CuInTe_2$ 56

Thermoelectric measurements at room temperatures have shown (2) that in the extrinsic region $CuInTe_2$ and all compositions from 44 to 56 molar % Cu_2Te are p-type semiconductors. From the linear relation between $\ln \rho$ and $1000/T$ in the high-temperature intrinsic region, the intrinsic "thermal" energy gap of $CuInTe_2$ was calculated with certain assumptions as follows:

For the effective mass of the carriers independent of temperature the resistivity in the intrinsic range is given by

$$1/\rho = en_i(\mu_n + \mu_p) = (\text{constant})\,T^{3/2}\,(\mu_n + \mu_p)\,e^{-E_g/2kT} \qquad [1]$$

where n_i is the concentration of intrinsic carriers, μ_n and μ_p are mobilities of electrons and holes respectively, T is the absolute temperature, E_g is the intrinsic energy gap at temperature T and k is the Boltzmann constant: 8.62×10^{-5} ev/°K.

If we now assume that $\mu \sim T^{-3/2}$, Eq. [1] simplifies to

$$1/\rho = (\text{const})\,e^{-E_g/2kT} \qquad [2]$$

We further assume that in the narrow intrinsic region (710°-779.8°C) the energy gap E_g changes linearly with temperature

$$E_g = E_{go} + \alpha T \qquad [3]$$

Here E_{go} is the intrinsic energy gap at 0°K, and α is the temperature dependence coefficient of the energy gap. Then for two different temperatures we may write

$$\ln \rho_1 - \ln \rho_2 = \frac{E_{go}}{2kT_1} - \frac{E_{go}}{2kT_2} \qquad [4]$$

solving for E_{go}, we obtain

$$E_{go} = \frac{2k \ln \rho_1/\rho_2}{(1/T_1 - 1/T_2)} = \frac{3.965 \times 10^{-4} \log_{10} \rho_1/\rho_2}{(1/T_1 - 1/T_2)} \qquad [5]$$

The intrinsic energy gaps E_{go} of samples $(Cu_2Te)_x(In_2Te_3)_{100-x}$ for $44 < x < 56$, calculated from Eq. [5] on the basis of experimental linear slopes of $\ln \rho$ *vs.* $1000/T$, are 1.04 ev. Variations observed were in the range ±0.02 ev, which corresponds to an experimental accuracy of approximately ±2%. If some other temperature dependence of mobility were assumed, say $\mu \sim T^{-5/2}$ or $\mu \sim T^{-1/2}$, it was calculated that the value for energy gap E_{go} of $CuInTe_2$ would change by less than +2 or −2%, respectively, because the intrinsic temperature interval is so small. Austin *et al.* (7) measured the energy gap of $CuInTe_2$ optically and found the value 0.95 ev.

The origin of distinct "resistivity pockets," as seen in Fig. 6 for the specimens of stoichiometric $CuInTe_2$, is not yet completely understood. One explanation may be that the first sharp drop of resistivity above 455°C is due to precipitation of a more conductive secondary phase, such as InTe. At higher temperatures the carrier mobility in this secondary phase decreases and the resistivity climbs again until it joins the original curve. The usual explanation of a resistivity drop as the temperature increases, based on the degeneracy of charge carriers (8), cannot be applied here since the change of resistivity is much too sudden and much too sharp on the low-temperature side

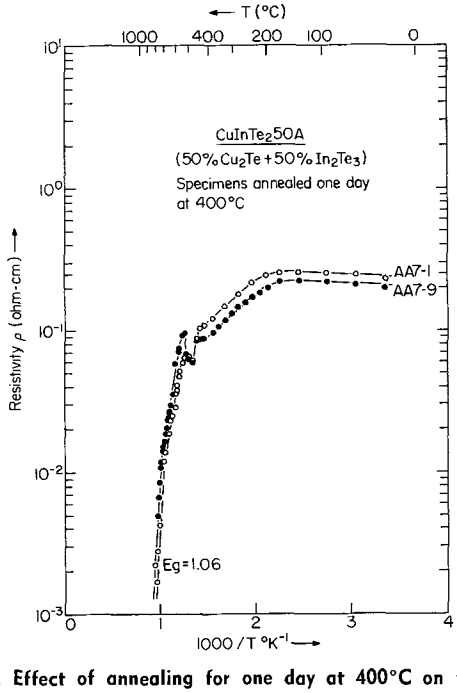

Fig. 8. Effect of annealing for one day at 400°C on the high-temperature resistivity of stoichiometric $CuInTe_2$. Compare with Fig. 6.

of the pocket, as compared with the smooth changes in germanium and silicon.

In order to see if the observed extrinsic and intrinsic effects in $CuInTe_2$ were reversible upon annealing, specimens were heat-treated 24 hr at 400°C in argon. The results shown in Fig. 8 for the compositions with 50% Cu_2Te and in Fig. 7 for the composition with 56% Cu_2Te indicate that impurity dominated extrinsic differences mostly disappear, "resistivity pockets" largely shrink, while intrinsic slopes remain unchanged. These changes during annealing are due to an equilibrium redistribution and relaxation of atoms within the basic chalcopyritic matric of $CuInTe_2$.

Conclusions

$CuInTe_2$ was treated as part of the pseudobinary system $(Cu_2Te)_x(In_2Te_3)_{100-x}$ for $44 < x < 56$ molar % of Cu_2Te. Coarsely polycrystalline specimens with these compositions were prepared by a vertical Bridgman growth technique. After long annealing at 650°C specimens of $CuInTe_2$ show a tendency to precipitate a small amount (below 4%) of a secondary phase, probably InTe.

High-temperature (up to the melting point 779.8°C) electrical resistivity measurements were performed, using the method of porcelain "cocoons." Inspection of the plots of ln ρ *vs.* $1000/T$ for samples with 44 to 56 molar % Cu_2Te revealed the existence of two extrinsic temperature regions (room temperature-200°C, 200°-710°C) and one well-defined and reproducible intrinsic temperature region from 710° to the melting point. Stoichiometric $CuInTe_2$ specimens in particular, show sharp, well-defined "resistivity pockets," sandwiched between two extrinsic slopes in the temperature interval 455°-600°C. The origin of these pockets is not yet clear, but is believed to be due to a high-temperature precipitation of a more conductive secondary phase, such as InTe.

The "thermal" band gap in all investigated samples of $CuInTe_2$ (in the composition range from 44 to 56 molar % Cu_2Te), calculated from the experimental intrinsic slopes of ln ρ *vs.* $1000/T$ with the assumption that $\mu \sim T^{-3/2}$, was 1.04 ev. Observed variation of the energy gap in samples with different compositions was ± 0.02 ev. This value compares with the "optical" energy band gap in $CuInTe_2$ of 0.95 ev, measured by Austin *et al.*

Acknowledgments

Experimental assistance of Robert P. Whelan, Harold E. LaBelle, Jr., and Neal I. Obert in the preparation of specimens and resistivity measurements is gratefully acknowledged. Ruth Brown and Marylin Harrison helped ably with numerical computations.

The author also wishes to thank Dr. R. Mazelsky, Dr. D. J. Page and particularly Dr. R. W. Ure, Jr. of Westinghouse Research Laboratories for critical reading of the revised manuscript.

Manuscript received Oct. 10, 1963; revised manuscript received *ca.* Nov. 29, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

High Conductivity Transparent Contacts to ZnS

V. A. Williams

Department of Physics and Applied Physics, University of Ife, Ibadan Branch, Ibadan, Nigeria

ABSTRACT

Two methods of producing high conductivity transparent contacts on ZnS single crystals are investigated. It is found that sputtering of In_2O_3:Sn onto the crystal followed by suitable heat-treatments gave much better results than a straightforward attempt at diffusion of compensated donor systems into the crystal lattice.

The nature of an ohmic metal-semiconductor contact has been discussed by Kroger and co-workers (1) who proposed a model for a metal-CdS contact. Ohmic contacts on semiconductors are now achieved through $n\text{-}n^+$, otherwise called L-H junctions. L-H stands for low-high, implying a junction arising from a change in impurity concentration from low to high between two adjacent regions of a crystal, which gives a corresponding change in conductivity value, but not type, across the junction.

At an L-H (or $n\text{-}n^+$), unlike the p-n junction, there is no high field barrier region and no minority carrier injection, the current across such a junction being carried entirely by majority carriers, with no rectification. The discontinuity in impurity concentration across the L-H junction can be brought about by controlled diffusion of donor impurities into the crystal, or by forming a heterojunction on the crystal surface. The heterojunction in this case would be between the host crystal and another crystal of similar structure, but of the same conductivity type. The latter crystal could for example be epitaxially grown on the host crystal, or deposited thereon by a variety of other means.

ZnS is a wide bandgap material (3.7 ev), normally of very low intrinsic conductivity. A variety of suitable doping materials exist however which could in principle give it n- or p-type conductivity. Table I (2) shows such a range of suitable dopants and some of their characteristics. The last two columns of Table I show,

Table I. Suitable donor and acceptor impurity materials for ZnS

Impurity material	Group	Substituting in ZnS for:	Acceptor or donor	$E_c - E_i$ (ev)	$E_i - E_v$ (ev)
Chlorine, Bromine	VII B	S	D	0.25	—
Aluminum	III B	Zn	D	0.25	—
Scandium	III B	Zn	D	0.35	—
Gallium	III B	Zn	D	0.42	—
Indium	III B	Zn	D	0.5	—
Copper	I B	Zn	A	—	0.95
Silver	I B	Zn	A	—	0.55

respectively, depth or height of the impurity level E_i, below or above the conduction or valence band edges E_c or E_v.

In attempting to diffuse impurities into zinc sulfide it is often necessary to balance (3) the charge created by the partial replacement of the S^{2-} ion by the halide ions ($Cl^-Br^-I^-$) or the replacement of the Zn^{2+} ion by, say, trivalent ions (Al^{3+}, Ga^{3+}, In^{3+}) or monovalent ions (Cu^+Ag^+, Au^+). Charge compensation normally requires the presence of an anion vacancy whether ionized or not, *i.e.*, $V_A{}^+$ or V_A. If the energy involved in replacing a lattice ion by one of these foreign ions is less than that required to form a cation vacancy, then the introduction of a second type of foreign atom may be necessary to incorporate the former ions in the lattice in sufficient quantities. However, the formation of $V_A{}^+$ or V_A centers may be enhanced if the activation energy for the formation of these centers is supplied externally (*e.g.*, thermally), in which case, the incorporation of the donor ions is self-compensated.

With the process involving the formation of a heterojunction as for example between tin-doped indium oxide and ZnS the use of indium as the donor impurity in the ZnS could be effected by diffusing it into the lattice via the same process as is necessary to form the indium oxide semiconductor. Note that the word heterojunction used here to describe the junction between ZnS and indium oxide is not strictly correct as indium oxide has a different lattice structure from ZnS. However only thin films of indium oxide are here involved.

Diffusion of Donor Impurities into ZnS *from the Vapor*

The experimental arrangement for the diffusion of donor impurities into ZnS is illustrated in Fig. 1. The materials tried are listed in Table II below. (All materials were of analar quality.) The ZnS pieces are cut from larger crystals supplied by the Eagle Picher Company, Joplin, Missouri.

The material to be diffused into the ZnS crystal is placed at one end of a sealed evacuated quartz tube while the ZnS is placed at the other, the two materials being separated by clean quartz wool. The separation between the two substances depends on the temperature at which the impurity material is desired to be kept relative to that of the ZnS.

The temperature of the ZnS is so chosen that its vapor partial pressure is negligible relative to that of the vapor of the doping material, while the temperature for the latter depends on its melting point or the vapor pressure.

The sealed tube is then in turn placed in a fused silica furnace tube, toward the cool end of the furnace where a desired temperature gradient can be obtained at the desired hot-end temperature. Figure 2 illustrates typical temperature gradients when the center temperatures of the furnace are 700° and 900°C, respectively.

A standard diffusion time of 1 hr was used for all experiments. Cooling after the run is effected fairly rapidly by withdrawing the tube completely into the cool zone of the furnace where the temperature is only slightly above room temperature.

The average diffusion depth (based on the depth at which the sheet resistance is $1/e$ of its surface value) obtained is about 50μ and the resistivities calculated

Table II. Temperature characteristics of some doping materials

Material	Melting point, °C	Temperature, °C at which the V.P. = 1 Torr
Zinc chloride ($ZnCl_2$) (anhydrous)	365	428
Copper chloride ($CuCl_2$) (anhydrous)	422	546
Aluminum chloride ($AlCl_3$) (anhydrous)	192	100 (sublines)

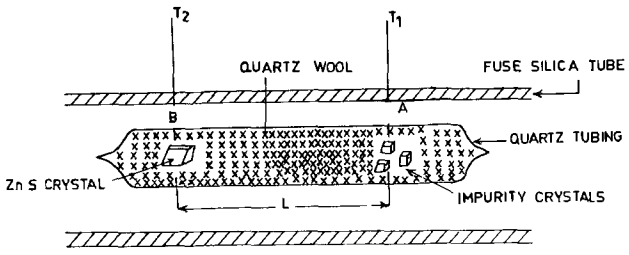

Fig. 1. Arrangement for diffusing impurities from the vapor phase into zinc sulfide crystals.

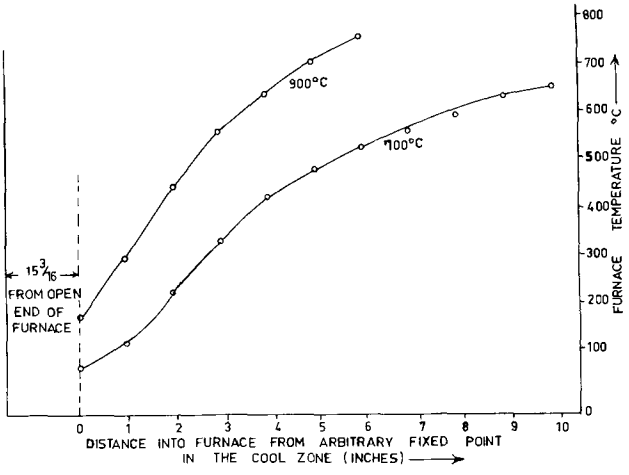

Fig. 2. Typical temperature profile at the cool end of diffusion furnace.

on this mean thickness of 50μ varies from 5 x 10^3 ohm-cm for copper chloride to 5 ohm-cm for aluminum chloride.

It was further found that, using aluminum chloride (which gave the lowest observed resistivity), a lowering of the resistivity resulted from further heating for about 5 min at 700°C in an inert atmosphere, the resistivity being approximately halved.

The treated crystals were however very dark in appearance, indicating strong absorption in the visible; the lower the resistivity, the darker the crystal. It is thought that, although this effect might be due to free carrier absorption, it may perhaps also be due to colloidal aggregation of the impurity material. In any case this darkening is of course a great disadvantage because any luminescence arising from the crystal interior would be strongly absorbed.

Deposition of Another Semiconductor on the ZnS *Surface*

This involves the deposition on the ZnS of a thin layer of oxygen-deficient indium oxide doped with tin, by a sputtering process. The process is only partially chemically reactive in that, although chemical combination of oxygen is effected during the process, yet the deposited layer has a very high concentration of the free metal and it is opaque. This is an important difference from the method employed by Shivonen and Boyd (4) for making transparent indium oxide contacts on CdS.

Details of the sputtering apparatus are shown in Fig. 3. Aluminum head pieces are used for the electrodes as this material is strongly resistant to sputtering. Provision for water cooling is made to prevent excessive rises in temperature of the electrodes and of the glass-to-metal seals.

Spectroscopically pure indium and tin are evaporated together in the ratio 4:1 in high vacuum (10^{-6} Torr) onto the aluminum cathode to obtain a very thick coating, such evaporation being carried to completion to maintain the composition of 4:1 ratio.

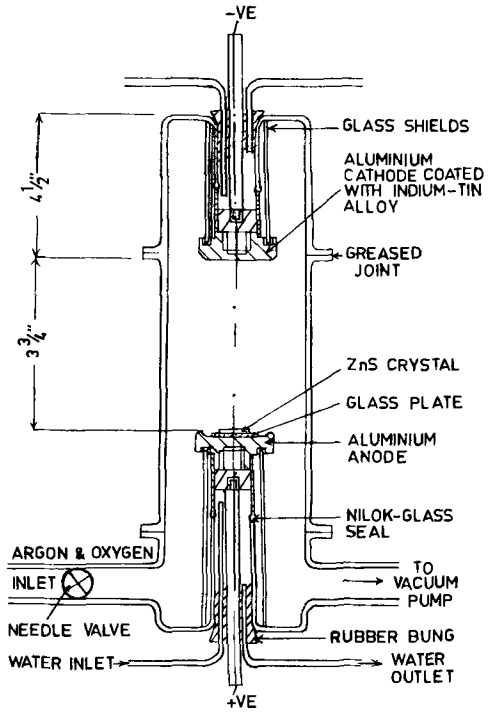

Fig. 3. Details of the sputtering apparatus

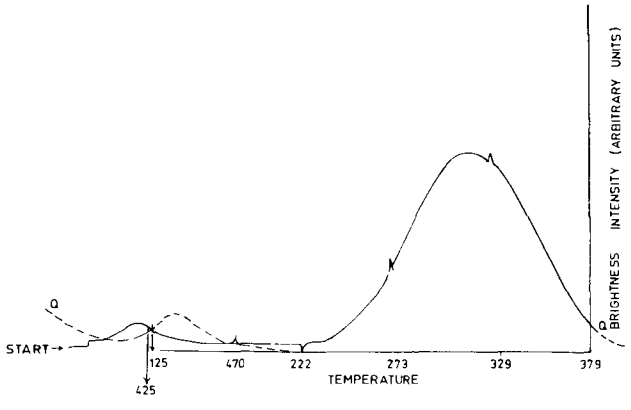

Fig. 4. Thermal glow curve of a ZnS crystal equipped with an In_2O_3:Sn contact.

For sputtering, ZnS crystals, in the form of 7 x 5 x 1 mm plates cut and polished from larger crystals of reasonable perfection, are masked to expose surfaces of 3 x 5 mm on each flat face and then mounted on a glass disk placed in turn on the anode as shown in Fig. 3. Thermal resistances between the pieces are reduced by use of thin films of silicone grease.

Sputtering is then carried out at 0.1 Torr in an atmosphere consisting approximately of 5 parts of argon (99.999%) to two parts of pure oxygen (supplied by BOC), for 7-10 min. The anode is maintained during this time at 2.2-2.5 kv relative to the cathode with 60-70 ma discharge current.

The resulting sputtered layer has a rather opaque metallic appearance: after removing the silicone grease from the crystal by cleaning in a mixture of acetone and toluene it is then heated for about 5 min at 700°C in argon at 2 atm pressure in order to diffuse some indium into the ZnS. The crystal is then subsequently fired in air at 375°-400°C to give a completely transparent layer. Crystals used for measurements had contacts approximately 3 x 5 mm placed on the two flat faces fairly accurately located opposite one another. For the electrical measurements aluminum foil electrodes were attached on the edges of the transparent layers using a hard setting silver conducting paste (from Johnson Mathey Company).

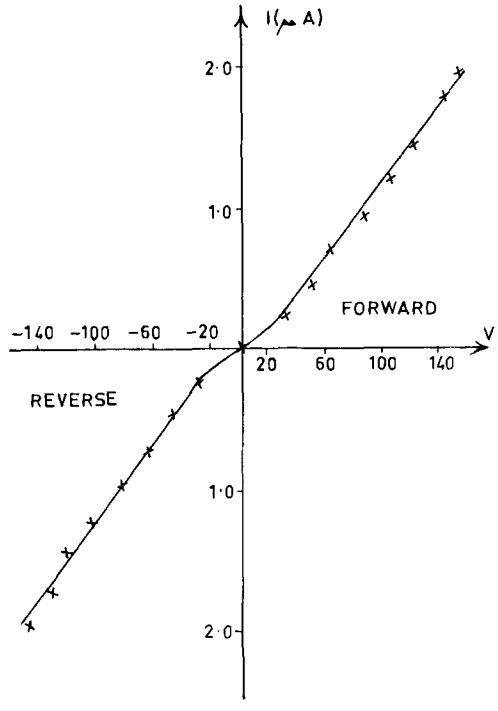

Fig. 5. Current-voltage characteristics of a crystal equipped with In_2O_3:Sn contacts.

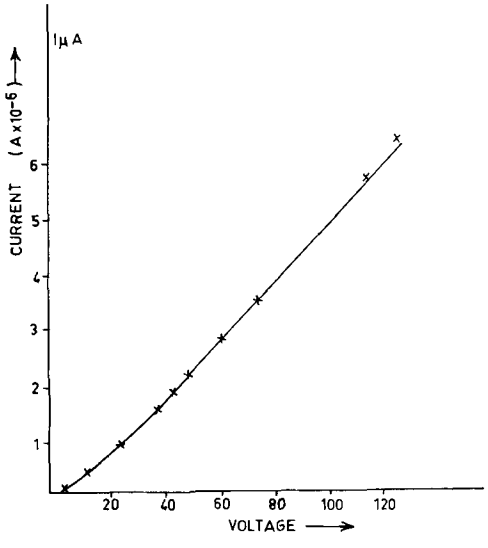

Fig. 6. Current-voltage characteristics under 3650Å uv irradiation.

Irradiation of the crystal by 3650Å uv light gave luminescence characteristic of indium centers. Figure 4 gives the typical glow curve obtained from a crystal doped with indium in the manner described (after previous light body doping with aluminum and chlorine).

The resistivities of the indium oxide layers obtained were of the order of 10^{-1} ohm-cm (assuming a 50μ thickness). The current-voltage characteristics of the contacts are shown in Fig. 5. Photoconductivity measurements for undoped crystals equipped with the indium oxide contacts were made, and the resulting current-voltage characteristic for 3650Å excitation is shown in Fig. 6. The conducting properties of the In_2O_3:Sn layer itself appears to be unaffected by low temperatures as the conductivity did not appear to change from room temperature down to 77°K.

Discussion

It is evident from the foregoing that diffusion of donor impurities into ZnS could lead to an increase

in surface conductivity. Two problems are attendant with this method of achieving high conductivity however; the first is the problem of diffusion of impurities into ZnS owing to the effects of charge or vacancy compensation (5). This makes it easier for deeper centers to be incorporated than shallower ones. The second problem arises from the first. The shallowest centers are 0.25 ev for donor levels, and 0.5 ev for acceptor centers, so that, both because of the depth of levels, and because of charge compensation, very high impurity concentrations ($\approx 10^{20}/cm^3$) are required to give adequate conductivities. Such high concentrations of impurities frequently lead to discoloration of the crystals, and self-absorption of luminescence (6), this appears to be confirmed by the experiment. This discoloration is objectionable since transparency is of prime importance.

On the other hand, the formation of In_2O_3:Sn-ZnS contact is easier to achieve and appears to be more straight forward. To a rough approximation the junction between the two materials could be treated as H-I heterojunction which in many ways agrees with the proposals of Kroger *et al.* as to the nature of an ohmic semiconductor contact. The required region of relatively high conductivity in the ZnS would arise from the diffusion of indium into the crystal as would be expected from the heat-treatment immediately following after the sputtering process, and as it is known that indium has a high diffusion rate in ZnS single crystals.

Acknowledgment

This work was carried out while the author was in the Department of Electrical Engineering, Manchester University (U.K.). Thanks are thus due to Professor F. C. Williams, for facilities provided, and further to Dr. C. N. W. Litting and Dr. D. E. Mason, for helpful discussions and to Ferranti Ltd. who constructed the sputtering apparatus and the diffusion furnace.

Manuscript received July 7, 1965; revised manuscript received Nov. 3, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Detection of Thermal Reaction in Mixed Oxide Powders by Electrical Resistance Measurements

A. N. Copp, M. Nakahira, and G. W. Brindley

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Resistivity measurements are made on 1:1M mixtures of MgO-Cr_2O_3, NiO-Cr_2O_3, ZnO-Cr_2O_3, and CoO-Cr_2O_3 powders heated in oxygen, and in nitrogen atmospheres at 2.5°C/min. Sharp inflections are found in the log ρ *vs.* $1/T$ curves; two inflections are found for MgO-Cr_2O_3 and ZnO-Cr_2O_3 heated in oxygen. X-ray diffraction measurements are made of similar powders heated under identical conditions and quenched from various temperatures, and curves are obtained of α (fraction reacted) *vs.* T, maximum heating temperature. The temperatures of the inflections in the log ρ *vs.* $1/T$ curves (the lower inflection when two are observed) correspond with reasonable extrapolations of the α *vs.* T curves to $\alpha = 0$, *i.e.*, these inflections appear to correspond with, or to be closely related to, the onset of reaction in the powder mixtures. The method has potential application for studying the onset of reactions under conditions where more bulky equipment cannot be used and particularly in closed systems.

The present paper is concerned with the possibility of detecting the onset of thermal reaction in intimately mixed oxide powders under conditions of progressively rising temperature by following the change of electrical resistance of compacted powder samples. The more commonly used methods, such as x-ray diffraction and differential thermal analysis, tend to be insensitive to the onset of these reactions. Electrical resistance measurements for this purpose have hitherto received rather little attention, but several studies indicate that the question is worth examination. Garn and Flaschen (1) showed that polymorphic transformations in quartz, barium titanate, and several other materials gave rise to a change in slope of resistance *vs.* temperature curves. Bielanski and Deren (2) studied 1:1M mixtures of ZnO-Cr_2O_3, MgO-Cr_2O_3, and ZnO-Fe_2O_3, and Bielanski, Deren, Haber, and Polaczkawa (3) made a further study of the ZnO-Cr_2O_3 1:1 mixture. They observed well-defined breaks in the log σ *vs.* $1/T$ plots (σ = electrical conductivity). In the earlier study, the breaks were attributed to an interaction involving the migration of one oxide over the surface of the other beginning at about 400°, 400°, and 700°-800°C for the respective oxide mixtures given above. In the later study, it was emphasized that the conductivity depends on the surface states of the particles and on the formation of a reaction product. The ZnO-Cr_2O_3 mixture was shown to give two inflections, the first of which at around 415°C was associated with surface migration of one oxide over the other, and the second at around 650°C with formation of a spinel product. Szabó and Solymosi (4) studied 1:1 MgO-Cr_2O_3 mixtures and considered that the beginning of spinel formation, about 600°-700°C, changes the electrical properties of the mixed oxides markedly by the formation of a product with good defect state conductivity.

In the present work, attention has been given to the behavior of intimately mixed oxide powders in 1:1M proportions of MgO, NiO, ZnO, and CoO with Cr_2O_3. In all cases the resulting product is a spinel. Under dynamic conditions of progressively rising temperature, solid-state reactions between mixed powders depend greatly on the particle sizes of the components, on the rate of heating, and in many cases (as will be shown) on the ambient atmosphere. It is scarcely possible,

therefore, to make detailed comparisons between results obtained by different investigators using different experimental conditions. Likewise a comparison between results obtained by electrical resistance measurements and by other techniques, such as x-ray diffraction, will be significant only if identical conditions are employed during the reactions. Particular attention has been given to this aspect of the study.

Experimental

Raw materials and sample preparation.—Reagent grade powders from Fisher Scientific Company of MgO, ZnO, NiO, Cr_2O_3, and a CoO-Co_3O_4 mixture were used. The CoO-Cr_3O_4 mixture was heated in air at 1000°C for 12 hr to convert it wholly to CoO. The MgO powder was preheated in air at 1300°C for 2 hr to obtain an oxide of coarser particle size. Following these treatments, the MgO and CoO samples were finely ground in an agate mortar. Microscopic examination showed that the resulting MgO and CoO powders had particle diameters of the order 1-10μ, and all other powders were somewhat finer than 1μ. It was considered unnecessary for the immediate purpose to prepare well-sized fractions.

The 1:1M mixtures were hand-ground in an agate mortar with acetone for approximately 2 hr. They were dried in air, finely pulverized, and stored in a desiccator over P_2O_5. Cylindrical pellets, 1.27 cm diameter and about 1.5 cm in length, were formed in a hardened steel pellet mold without use of a binding material under a pressure of about 50 kg/cm^2.

Heat-treatment.—For the resistance-temperature measurements, a horizontal mullite tube furnace with silicon carbide heating elements was used. The temperature was uniform over a 1-in. section up to 1100°C. A cam-type program controller gave a temperature increase of about 2.5°C/min. This rate is a compromise between slow running to obtain resistance measurements at sufficiently well-defined temperatures and a uniform temperature in the sample, and fast running to obtain the desired range of temperature in a convenient working time.

Samples for x-ray analysis were prepared in a vertical tube furnace wound with Kanthal, type A-1, wire with identical arrangements for temperature control. The samples were suspended in platinum containers in the hot zone of the furnace and were quenched by fusing the suspending wires when desired temperatures were reached.

Because solid-state reactions between oxides frequently depend on the ambient atmosphere, the present tests were carried out under two conditions, with a slow flow of either dry oxygen or dry nitrogen through the furnace tubes. After flushing the system at room temperature with the gas to be used, a small excess pressure was maintained as shown by an outlet "bubbler." The investigation was not concerned with the specific role of the gas atmosphere in the reactions considered.

Resistance measurements.—These were made using a four-terminal measuring technique with a 10v potential drop across the sample. The sample was held in a specially constructed silica framework, with two platinum foil electrodes pressed against the end faces by means of spring-loaded silica rods, with the springs mounted outside the hot zone of the furnace. The potential probes, also spring loaded, consisted of platinum wires pressed into finely drilled holes penetrating about 0.5-1 mm into the cylindrical surfaces of the sample, and about 5 mm apart. Two thermocouples, Pt, Pt-Pt/10% Rh, were pressed against the opposite side of the sample. Resistances were measured up to temperatures of about 1000°C, higher temperatures being avoided because of possible deformation of the silica framework.

D.C. power was applied only during measurements and was supplied by a Kepco 5M-160-12MK regulated power supply. Current and potential measurements were made with a Keithley 410-R electrometer.

Resistivities were calculated using sample dimensions prior to heating. Compaction (sintering) of the powders occurred during the heating process resulting in changes of about 10-15% in linear dimensions. Since the resistivity is expressed in ohm-cm units, the resistivity values obtained will be influenced to the same extent. Changes of this magnitude, however, are small compared with the over-all resistivity changes recorded.

X-ray measurements.—The quenched samples were ground in an agate mortar to a particle size estimated to be of the order of 5μ. A standard weight of material, 0.160g, was packed from the rear into a rectangular opening in a glass slide, with no smoothing of the front surface exposed to the x-ray beam. The sample thickness was effectively infinite for the CuKα radiation employed. Integrated intensity measurements were made on reflections from the initial components and from the resulting spinels. Three measurements were made for each reflection involved, using independently prepared samples. The fraction of material reacted, α, was determined by comparing the reflected intensity from a quenched sample with that from a fully reacted sample, heated at 1400°C for 48 hr. This procedure is legitimate because the mass absorption coefficient of the powder sample for the x-rays employed is not changed by the reaction; the reflected intensity, therefore, is proportional to the amount of reflecting material (initial material or product) in the sample.

Results

Resistivity data.—Values of log ρ *vs.* $1/T$, where ρ is the resistivity of the powder compact and T the absolute temperature, for the four oxide mixtures are shown on Fig. 1 where arrows on the curves indicate the direction of temperature change. Solid and open symbols indicate, respectively, results obtained for mixtures heated in oxygen and in nitrogen. For NiO-Cr_2O_3 heated in oxygen, circles and squares denote observations on different samples and illustrate the good reproducibility of the data. The curves on Fig. 1 are seen to consist of nearly straight portions with sharp inflections. In six of the eight sets of data shown, there are sharp deflections downward of the log ρ *vs.* $1/T$ curves with rising temperature, but in two sets

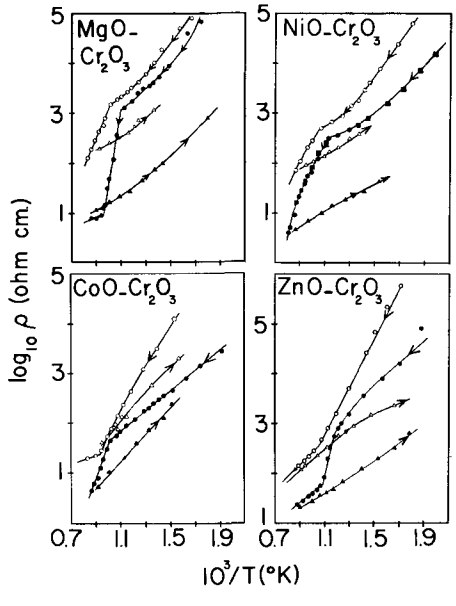

Fig. 1. Log ρ (resistivity) *vs.* $1/T$ (degrees absolute) for 1:1M mixtures of oxides heated in oxygen (solid symbols) and in nitrogen (open symbols). For NiO-Cr_2O_3 in oxygen, closed circles and squares denote observations on different samples.

Table I. Temperatures in °C of inflections in log ρ vs. $1/T$ curves

1:1 Mixture	In oxygen, °C	In nitrogen, °C
$MgO-Cr_2O_3$	635, 770	713
$NiO-Cr_2O_3$	615	660
$CoO-Cr_2O_3$	707	795
$ZnO-Cr_2O_3$	575, 645	674

($CoO-Cr_2O_3$ and $ZnO-Cr_2O_3$) the deflections give lines of lesser slope. In two sets of data, $MgO-Cr_2O_3$ and $ZnO-Cr_2O_3$ both heated in nitrogen, a second deflection also appears. The temperatures, in °C, at which the deflections occur are listed in Table I and are considered to be accurate to about ±5°C.

X-ray data.—The results obtained for the fraction α of material reacted are plotted in Fig. 2 against the temperature T, in °C, from which the samples were quenched. Solid and open circles refer, respectively, to reactions in oxygen and in nitrogen. In all cases, the reactions proceed at lower temperatures in oxygen than in nitrogen, and the α *vs.* T curves are of sigmoidal shape. In nitrogen, two and, possibly, three of the reactions are represented by curves which may be sigmoidal, but only the initial, acceleratory region is achieved; the fourth reaction, $ZnO-Cr_2O_3$ in nitrogen, yielded an almost linear relation. The smallest values of α which could be determined were of the order of 0.05-0.10.

Discussion

The temperatures listed in Table I of the inflections in the log ρ *vs.* $1/T$ curves are shown by arrows in Fig. 2. In all cases, these inflection points (the lower temperatures where two inflections are found) correspond with reasonable extrapolations of the α *vs.* T curves to $\alpha = 0$. These extrapolations are shown by dashed lines in Fig. 2. It is concluded that the inflection points (lower temperatures where two are found) are coincident with, or are closely related to, the temperatures of initial reaction under the experimental conditions employed.

When second inflections are found in the log ρ *vs.* $1/T$ curves, in $MgO-Cr_2O_3$ and $ZnO-Cr_2O_3$ reactions in oxygen, there is a possible coincidence between these inflections and a rapid change in slope $d\alpha/dT$ in the α *vs.* T curves, but on the basis of these two results alone, no firm conclusion can be drawn. For the $ZnO-Cr_2O_3$ reaction, there is a qualitative agreement with the results of Bielanski *et al.* in that they also observed two inflections, but these occurred at about 415° and 650°C as compared with 575° and 645°C in the present work. It is probably not surprising that previous authors associated the second and higher inflection temperature with the formation of a spinel product if this inflection corresponds to a maximum of $d\alpha/dT$, especially if conditions were not identical in the two methods of study (x-ray and resistance measurements).

The present experimental data do not justify making comments either for or against the previous suggestions that the first inflection corresponds to a surface migration, beyond the observation that such a migration may constitute the first step toward a solid-state reaction.

Whether resistivity measurements have any worthwhile merit for detecting the onset of solid-state reactions under rising temperature conditions is a valid question. When the experimental equipment is available, it is easy and relatively quick to determine a log ρ *vs.* $1/T$ curve, and if many tests are required, the method could be automated. The method is quicker than x-ray diffraction using quenched specimens; with a heated stage, x-ray diffraction would take no longer than the resistivity measurements, but there would remain the difficulty that the method is insensitive to small amounts of product. The resistivity change appears to occur sharply at a temperature corresponding to the earliest stage of the reaction, what previous workers have described as a surface migration of one reactant over the other. A possible advantage of the resistivity method is that it may be applicable under circumstances where more bulky equipment cannot be used, for example, in closed systems.

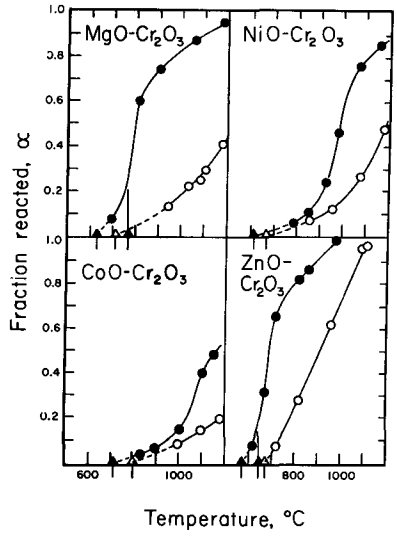

Fig. 2. Fraction reacted, α, vs. T (°C) for 1:1M mixtures of oxides heated in oxygen (solid circles) and in nitrogen (open circles). Temperatures of inflections in log ρ vs. $1/T$ curves (see Table I) are shown by arrows. Solid lines are curves through points obtained from x-ray diffraction measurements; dashed lines are extrapolations joining the solid lines to the resistivity inflection temperatures.

Acknowledgments

This investigation forms part of a program sponsored by the United States Atomic Energy Commission under Contract AT(30-1)-2581. The authors thank Dr. L. E. Cross and Dr. M. E. Bell, of The Pennsylvania State University, for valuable discussions.

Vapor Growth Parameters and Impurity Profiles on N-Type GaAs Films Grown on N^+-GaAs by the Hydrogen-Water Vapor Process

K. L. Lawley

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Controlled growth of very smooth n-type films of GaAs on n^+-GaAs substrates has been achieved with the hydrogen-water vapor transport process. These films are grown at 1000° and 1050°C at growth rates from 0.080 to 1.5 μ min^{-1} with partial pressures of water vapor of 0.30 x 10^{-3} to 6.0 x 10^{-3} atm and total flow rates from 300 to 600 cc min^{-1}. The impurity profiles of these films have been determined from differential capacitance-voltage measurements on gold surface barrier diodes. These profiles show that films grown on Si-doped substrates have much steeper impurity gradients at the substrate-film interface than those grown on Te-doped substrates. Films grown on Te-doped substrates at low flow rates become graded with a slope of about one decade per micron. These results suggest that outdiffusion from the substrate controls the profiles of thin films. The minimum net donor concentration in the films is 4 to 5 x 10^{15} cm^{-3}. Reverse bias breakdown voltages of the gold diodes range from > 200 to 5-7v for 11μ and 1μ thick films, respectively.

The synthesis of monocrystalline films of GaAs on GaAs substrates in a H_2-H_2O transport system has been demonstrated by Frosch (1), Sirtl (2), and Gottlieb and Corboy (3). The present investigation is designed to establish the growth parameters and substrate preparation by which controlled growth of smooth, thin films may be achieved in an open-tube system similar to that of Frosch and to explore the effects of these parameters on the resulting impurity profiles of n-type films grown on n^+-substrates.

Apparatus and Experimental Procedure

The apparatus in which the films were grown is shown schematically in Fig. 1. It consists of a fused silica reaction tube (26 mm ID, 140 cm long) into which is inserted a fused silica liner (22 mm ID, 46 cm long) which holds the single crystal source and substrate. The source and substrate are positioned in the liner so that the source is at the maximum furnace temperature and the substrate is at a position downstream from the source within the zone of deposition shown as a shaded area in Fig. 1. The source slices of about 10 cm^2 surface area are held normal to the gas flow in a quartz holder. The substrate is placed on a thin quartz plate to minimize growth on the back of the substrate. The furnace profile as measured in the tube is achieved by shunting the windings on a one-zone tube furnace. In this way the entire profile may be raised or lowered by changing the control temperature. The maximum temperature is controlled to ±1°C by a Pt-Pt/10% Rh thermocouple adjacent to the furnace windings at the midpoint of the furnace.

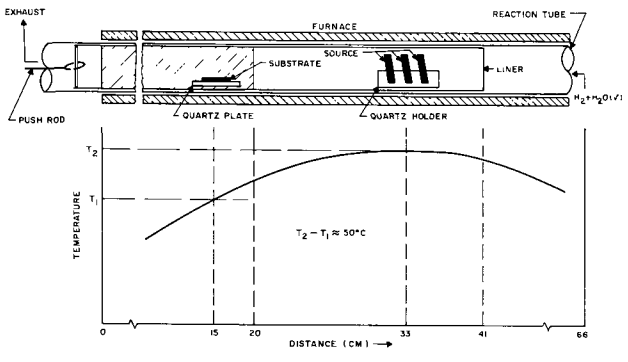

Fig. 1. Schematic drawing of the apparatus and furnace temperature profile.

The substrate temperature for the growth of films is 1000° or 1050°C with the source material being 50°C hotter than the substrate. The temperature gradient at the substrate is about 10°C cm^{-1}.

The water content of the reactant gas is maintained by mixing hydrogen passed through a Pd-Ag tube purifier with purified hydrogen which had been bubbled through a water saturator immersed in an ice-water bath. The dew point of the water-saturated gas was found to be the temperature of the ice-water bath and was independent of the hydrogen flow rate. The dew points of the mixtures of pure and water-saturated hydrogen agreed with those calculated from the volume ratios of the gases. Dry nitrogen is used to purge the apparatus of hydrogen prior to insertion or removal of the liner.

The $(\bar{1}\bar{1}\bar{1})$, B or As faces of the substrates have been used almost exclusively for this investigation, because growth on substrates oriented <110> or <100> is about twice as rapid as on the $(\bar{1}\bar{1}\bar{1})$ planes and smoother films also result from growth on the $(\bar{1}\bar{1}\bar{1})$ planes.

An important factor which contributes to the perfection of these films is the substrate preparation immediately before the growth of the film. Initially the substrate is mechanically lapped and polished with 1800 grit alumina and with Linde B and then chemically polished with a dilute solution of bromine in methanol (4). Immediately before loading the substrate into the liner, the substrate is boiled in acetone, washed in deionized water in an ultrasonic agitator, etched in 70 H_2SO_4/15 H_2O_2 (30%)/15 H_2O, washed in deionized water ultrasonically, and blown dry with line nitrogen. Approximately 10μ of substrate are removed with the sulfuric acid etch.

Films grown on $(\bar{1}\bar{1}\bar{1})$ substrates prepared in this way are very smooth. Under bright field illumination at 50X, the films appear flawless. Examination of the films with an interference contrast microscope shows the presence of parallel growth steps concentrated mostly near the edges of the wafer. Films grown on the other major planes have rough textures due to irregularities such as square patterns on the (100) planes and tilted pyramids on the (110) planes.

The impurity distributions in the films have been determined by the differential capacitance-voltage method at 100 kc as outlined by Thomas *et al.* (5) using gold surface barrier diodes (10 mil diameter) as the rectifying contacts. The diodes are formed by evaporating gold in an oil-pumped evaporator at pres-

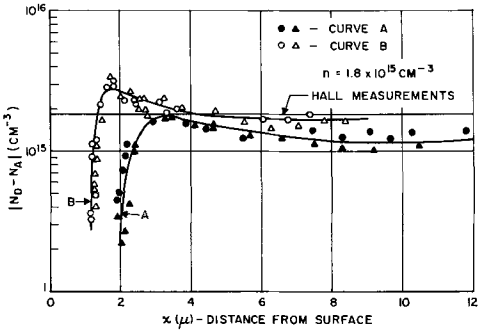

Fig. 2. Impurity profile obtained from Au surface barrier diodes on bulk GaAs (n = 1.8 x 10^{15} cm^{-3}). Curve A, H_2SO_4-H_2O_2-H_2O etch; curve B, Br_4-CH_3OH etch. Different symbols are used for different diodes.

sures of less than 10^{-6} mm Hg. Mesas are formed by etching off the film around the gold diodes with 1 H_3PO_4/1 H_2O_2 (30%)/3 CH_3OH. Alloyed tin balls on the n^+-surface served as the ohmic contact. All units were checked on an I-V curve tracer to determine the ohmic behavior of the tin balls and the rectification characteristics of the diodes.

Kahng (6) has shown that Au-n-type surface barriers are non-injecting majority carrier rectifiers on bulk GaAs having a net donor concentration of 5-9 x 10^{16} cm^{-3}. In this range, the inverse square of the capacitance varies linearly with the applied reverse bias.

Most of the films grown in this system have net donor concentrations in the low-10^{15} cm^{-3} range; therefore, it was necessary to examine the diode behavior on bulk material of this donor concentration. Gold diodes were fabricated on bulk GaAs with a net donor concentration of 1.8 x 10^{15} cm^{-3}. One slice (A) was prepared by the technique used for preparing substrates using the $H_2SO_4/H_2O_2/H_2O$ etch. A second slice (B) was prepared using only bromine in methanol as the etch. The net donor concentration variation shown in Fig. 2 as computed from differential capacitance-voltage measurements does not always approximate the net donor concentration obtained from Hall measurements. All four diodes show a rapid rise in the calculated net donor concentration of about 1 decade of carrier concentration per micron over the first micron of the depletion width. The depletion width of 1μ corresponds to reverse bias voltages of 1v or less. Reverse bias breakdown voltages were about 130v on A and about 100v on B. For biases greater than 1v, the carrier concentration appears to decrease slightly. In this region, diodes on slice B approximate the donor concentration as obtained from Hall measurements better than those on A. Curves from diodes on slice A are displaced about 1μ into the film from those obtained from slice B. This fact suggests that the surface treatment prior to the evaporation of the gold has changed the nature of the surface. These results are consistent with the existence of surface states at the Au-GaAs interface. A comparison of these curves with the results of Kahng (6) suggests that at the higher dopant concentration the effects of the surface may be masked by the higher bulk donor concentration. The objective here is not to give a detailed description of the physics of these surface barriers, but rather to give a basis for comparison of the results on bulk material in which the carrier concentration is well-established with those in films grown by this process. It is concluded that differential capacitance-voltage measurements at greater than 1v reverse bias on gold diodes may be used to determine the net donor concentration of films grown by this process.

The thickness of the n-type films grown on n^+-substrates are measured with a Beckman Infrared Spectrophotometer (Model IR-5, NaCl optics). The lower limit of film thickness which may be determined by this instrument is about 1μ. In the range of thicknesses of 1-3μ the accuracy of indexing the reflectance patterns is about $\pm$0.15μ. For thicker films, the accuracy is greater because of the increased number of reflectance maxima. Also, greater accuracy is achieved when there exists an abrupt change in the carrier concentration at the film-substrate interface. Some films were angle-lapped on a 3° block and stained with 5 HCl/5 H_2O_2 (30%)/3 HF/30 H_2O (7) to delineate the n-n^+ structure. Generally, the film thicknesses obtained in this manner are 0.2 to 0.3μ thinner than those obtained from IR measurements, probably because the etch attacked the film surface and reduced its thickness.

Materials.—The single crystals of GaAs used in these experiments were obtained from the Monsanto Chemical Company except for one semi-insulating crystal of float-zone GaAs used as source material. The electrical characteristics of these crystals are included in Table I which gives the pertinent growth data for each of the films under discussion. Substrates are about 15 mm in diameter.

Experimental Results and Discussion

Films have been grown at 1000° and 1050°C with total flow rates of 20-600 cc min^{-1} and partial pressure of water vapor of 0.30-6.0 x 10^{-3} atm. Growth rates do not differ significantly at these two temperatures. Frosch (8) has shown for the GaP-H_2O-H_2 system that the theoretical growth rate for a constant temperature difference of 50°C between the source and substrate does not differ greatly for substrate temperatures of 1000° and 1050°C. The difference in growth rates at

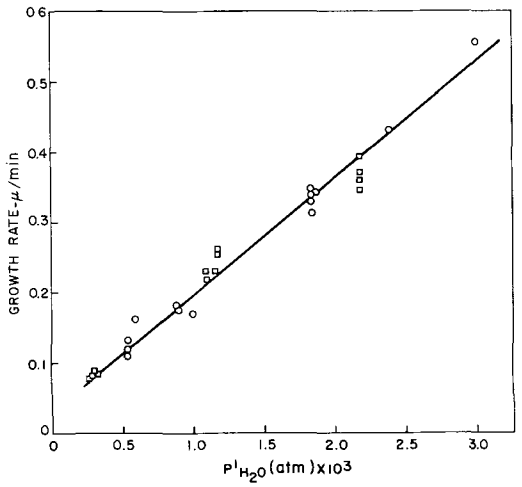

Fig. 3. Dependency of the growth rate on P_{H_2O} at a total flow rate of 600 cc min^{-1} and substrate temperatures of 1000° and 1050°C. ○, 1050°C; □, 1000°C.

these two temperatures also decreases as the partial pressure of water vapor decreases. The same conclusions would be anticipated for the GaAs-H_2O-H_2 system. Films with the smoothest surfaces are grown at 1000°C or higher.

The growth rate varies with the partial pressure of water vapor. Gottlieb and Corboy (3) demonstrated a square-root dependence of growth rate with the partial pressure of water vapor. This result has been confirmed for this system at flow rates of less than 70 cc min^{-1}.

Figure 3 shows the linear variation of growth rates with the partial pressures of water vapor for films grown at 1000° and 1050°C and with total flow rates of 600 cc min^{-1}. At low flow rates the only observable reaction product is GaAs; whereas, at high flow rates, arsenic deposits outside the furnace, and gallium forms on the source.

These observations suggest that the controlling reaction at low flow rates is

$$2\,GaAs(s) + H_2O(g) = Ga_2O(g) + As_2(g) + H_2(g) \quad [1]$$

At high flow rates, the GaAs dissociates and the water vapor reacts directly with the liquid gallium as given in the following reaction

$$2\,Ga(l) + H_2O(g) = Ga_2O(g) + H_2(g) \quad [2]$$

The particular growth conditions of partial pressures of water vapor of 0.30-6.0 x 10^{-3} atm and a total flow rate of 600 cc min^{-1} result in growth rates of 0.080-1.5 μ min^{-1}, respectively. Most of the films to be discussed were grown at 300 or 600 cc min^{-1} because the films show less taper and steeper gradients at the interface than those grown at lower flow rates. The thicknesses of films grown at these flow rates decrease in the direction of the gas flow about 10-20%.

The net donor concentration of films grown by a vapor deposition process is the cumulative effect of numerous sources: dopant transfer from the source, system doping (contamination from the reaction tubes, from reactant gases, from the back of the substrate, etc.), autodoping, or a counter-current deposition as described by Thomas *et al.* (5), and outdiffusions during growth as formulated by Rice (9). Because the profiles of films grown at high flow rates have been in reasonable agreement with the results of this outdiffusion model, all the profiles will be discussed from this standpoint. Under some conditions it appears that other dopant sources are involved in establishing the profiles.

In order to apply Rice's model of outdiffusion, the diffusion constants of the substrate donors (Te and Si) are required; however, these quantities have not been measured. The apparent diffusion constants have been calculated from the value of bV/D[1] which gives the best fit of Rice's numerical tabulations to the profiles. The bV/D values are redefined as α in order to simplify the discussion.

The net donor concentration profiles are plotted as the log of the net donor concentration *vs.* the distance from the substrate-film interface. Different symbols are used to identify different diodes on each film. The curve corresponding to an α which gives the best fit to these data is shown. In some cases, no α could be determined. The donor concentration from the vapor phase which is assumed to be the minimum donor concentration in the film is added to the donors from the outdiffusion to give the final profile labelled Σ. Pertinent growth data are given in Table I, and the film profiles are shown in Fig. 4 through 9.

The impurity profile of film A grown on an n^+-Si-doped substrate is shown in Fig. 4. The effect of outdiffusion of Te may be seen in Fig. 5, which is an impurity profile of another thin film, B, grown on a Te-doped substrate. Both films, A and B, were grown at 1050°C, at a total flow rate of 600 cc min^{-1} and a partial pressure of water vapor of 0.60 x 10^{-3} atm. The values of D calculated from α are 2.9 x 10^{-13} and 1.2 x 10^{-12} cm^2 sec^{-1} for the Si and Te-doped substrate, respectively. The consequence of this difference in diffusion constants is that the net donor concentration in the film grown on the Si-doped substrate is

[1] b is the film thickness (cm), V the growth rate (cm-sec^{-1}), and D the diffusion constant (cm^2-sec^{-1}).

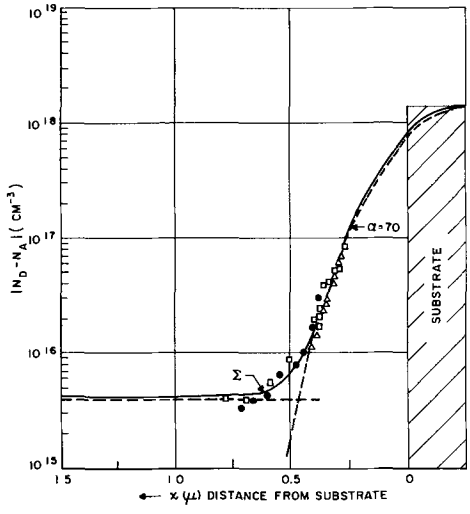

Fig. 4. Impurity profile for film A on Si-doped substrate

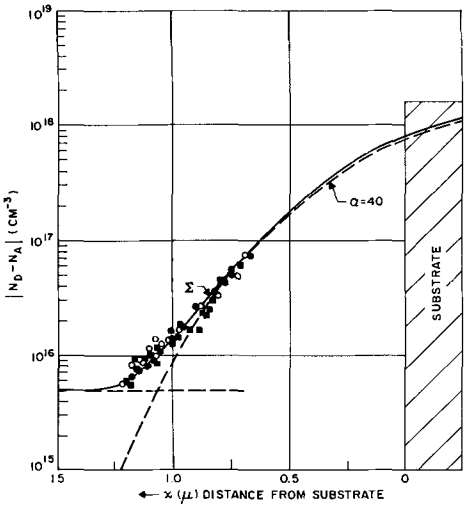

Fig. 5. Impurity profile for film B on Te-doped substrate

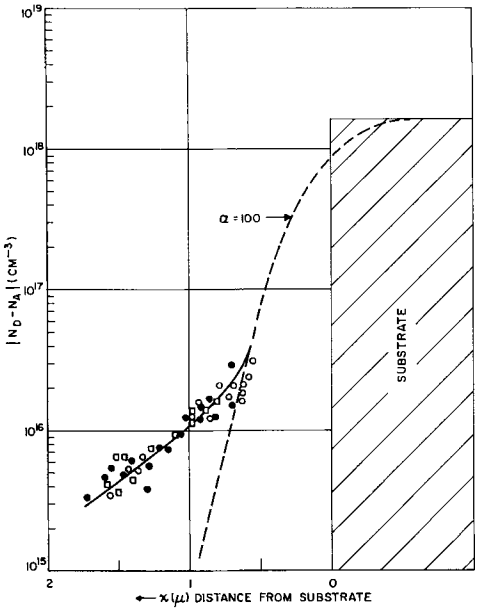

Fig. 6. Impurity profile for film C on Te-doped substrate

lower near the substrate-film interface than when Te-doped substrates are used. For film A and film B, a net donor concentration of 10^{16} cm^{-3} is reached at $\sim 0.4\mu$ and $\sim 1.10\mu$, respectively. In both cases it appears that the donor concentration levels off at about 4-5 x 10^{15} cm^{-3}.

The profile of film C grown at 1000°C on a Te-doped substrate is shown in Fig. 6. The value of α is approximately 100; therefore, D is approximately 4.9 x 10^{-13} cm^2 sec^{-1}. Again the minimum donor concentration in the film is about 3-5 x 10^{15} cm^{-3}. Comparing D values for films B and C (1.20 x 10^{-12} and 4.9 x 10^{-13} cm^2 sec^{-1}), it is apparent that the diffusion constant is lower at 1000°C than at 1050°C as expected. The activation energy for diffusion of group VI donors is roughly about 4.1 ev as has been reported for Se and S diffusions (10). From these values of D for films B and C, the calculated activation energy is roughly 3 ev, a somewhat surprising agreement in light of the method of calculation of D. The diffusion constant for Te in GaAs has not been reported. These results suggest that the effective diffusion constant lies between those of S and Se. Because Te has a greater atomic radius than S and Se, it might be expected to have a lower diffusion constant than S or Se. The higher value may be due to the intermediate electron affinity and electron density of Te with respect to S and Se or due to a more rapid diffusion in a film which undoubtedly has a higher imperfection density than does bulk material. A contribution from some additional dopant would also increase the apparent diffusion constant.

It has been shown that films grown at 600 cc min^{-1} total flow have impurity profiles which may be approximated by the impurity distribution equation given by Rice. Films C and D, however, were grown at 300 and 61 cc min^{-1}, respectively. In both cases, the datum points suggest a linear log concentration *vs.* distance variation of about one decade per micron. It appears that an additional dopant source may be operative under these conditions. A plausible explanation would be that the dopant, in this case Te, could be coming from the back side of the substrate. At high flow rates this dopant would be swept away; whereas, at low flow rates, the Te vapor could envelop the substrate until enough GaAs is deposited on the back to cut off the vapor supply. Eventually the net donor concentration would then arrive at some constant value. A countercurrent, autodoping model (5) could also account for this behavior.

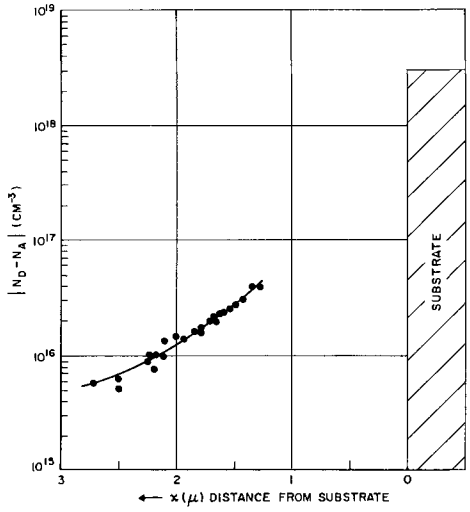

Fig. 7. Impurity for film D on Te-doped substrate

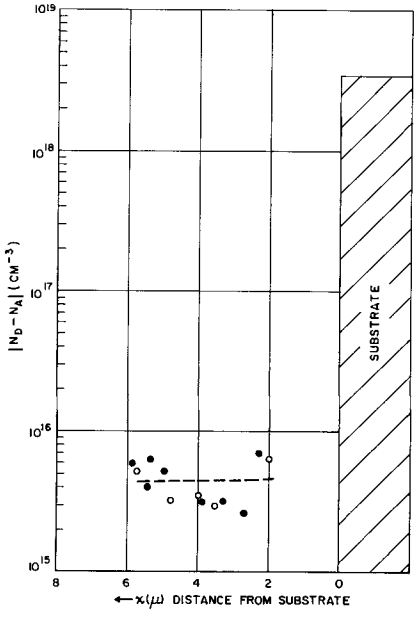

Fig. 8. Impurity profile for film E on Te-doped substrate

The profile of film D in Fig. 7 grown at 61 cc min^{-1} shows this effect even more markedly than does film C in Fig. 6. In the former film, the net donor concentration does not drop to 10^{16} cm^{-3} until 2μ of film have been deposited. This conclusion may be exaggerated in part because the donor concentration in the substrate for film D is higher than in the other films discussed.

In order to conclude the analysis of films grown on Te-doped substrates, a thick film (11.1μ) was grown. The profile of this film (E) is shown in Fig. 8. Here the profile is reasonably flat at a net donor concentration of about 5 x 10^{15} cm^{-3}. The diffusion tail could not be obtained because of the very small capacitance variation with voltage when the depletion layer approached the substrate.

The difference between the profiles of thin films grown on Si- and Te-doped substrates was illustrated in Fig. 4 and 5. This difference was attributed to the different apparent rates of diffusion of the substrate donors into the films during growth. The effect of Si on the film profile of a thicker film may be seen in Fig. 9, which is the profile of film F. This film was also grown at 1050°C. The value of D calculated from α is 2.9 x 10^{-13} cm^2 sec^{-1}, which is in agreement with 2.9 x 10^{-13} cm^2 sec^{-1} for film A. Figure 9 shows that the profile changes abruptly at about 0.5μ from the

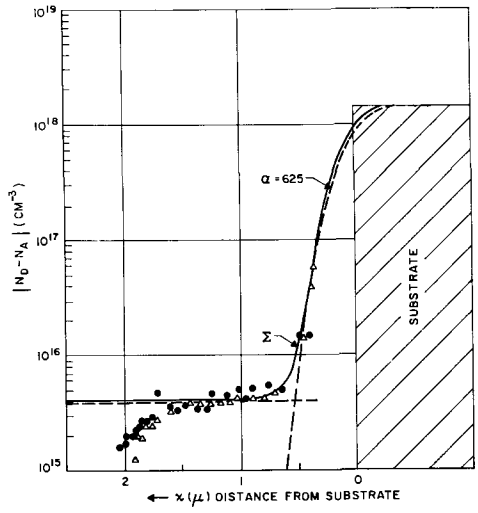

Fig. 9. Impurity profile for film F on Si-doped substrate

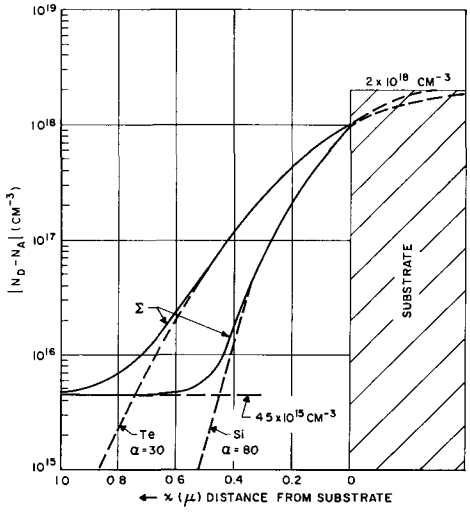

Fig. 10. Proposed impurity profiles for 1μ films grown on Te-and Si-doped substrates.

film-substrate interface. Most of the film is doped to a net donor concentration of ~5 x 10^{15} cm^{-3}. Although not shown here, films grown at 1000°C on Si-doped substrates have a slightly steeper gradient at the interface. The calculated D value for these films is about 2 x 10^{-13} cm^2 sec^{-1}. The apparent diffusion constant for Si does not vary greatly with temperature and, at both 1000° and 1050°C, it is lower than that of Te. The diffusion of Si into GaAs would be expected to be more rapid than the diffusion of a group VI element because Si may replace both gallium and arsenic (11). This fact and the apparently low activation energy associated with the lack of variation in D values suggests that the Si which comes from the substrate may not be in an electrically active state. It is altogether conceivable that the oxygen atoms from the oxide vapor species have effectively neutralized the electrical contribution of Si in the films by pairing of the oxygen with the Si atoms.

From the observations of the apparent diffusion of substrate donors, it appears that the growth of films of thicknesses of 1μ or less with an abrupt rise in the donor concentration at the film-substrate interface is not feasible. At 1000°C the only way of increasing the abruptness is to increase the growth rate. In this system, the maximum growth rate compatible with the growth of a 1μ film is about 0.1 μ min^{-1}. The corresponding α calculated from the apparent diffusion constants for Si- and Te-doped substrate are α (Te, 1000°C) ≈ 30 and α (Si, 1000°C) ≈ 80. The minimum system doping is assumed to be 4.5 x 10^{16} cm^{-3}. From these data, the calculated impurity profiles of 1μ films grown on substrates of net donor concentrations of 2 x 10^{18} cm^{-3} are shown in Fig. 10. For the case of Si-doped substrates, about half the film is influenced by the substrate. For Te-doped substrates, the influence of the substrate is observed almost throughout this film.

An alternate approach to the problem of increasing the steepness of the concentration gradient at the interface is to grow thicker films so that the growth rate may be increased, and then, by controlled etching, remove the film to the desired thickness. In this manner, a steeper gradient at the interface could be achieved so that the influence of the substrate dopant would be decreased.

The investigation of the gold surface barrier diodes on these films was performed to provide a method of determining the variation of impurity profiles with process variables. A complete characterization of these diodes has not been undertaken. It is interesting to note, however, the reverse bias breakdown voltages (reverse voltage at which the diode draws 1 μa of current). These voltages are listed for diodes on each film in Table I. The breakdown voltage is limited by the accumulation of charge as the depletion zone is pushed toward the substrate interface. This is illustrated in films D and F which are of identical thickness. Film F as shown in Fig. 9 is reasonably flat up to 0.5μ from the interface with an abrupt increase in the donor concentration near the substrate. The reverse bias breakdown voltages are between 50 and 60v. Film D as shown in Fig. 7 has a graded profile, so that breakdown occurs at smaller voltages, 20 to 22v. Film E has a very high breakdown of slightly greater than 200v because of the low doping in the film and because the space charge region may extend for such a long distance into the film. For this film the maximum electric field strength is approximately 4 x 10^5 v cm^{-1}.

Conclusions

The growth of n-type films of GaAs on n$^+$-GaAs by the H_2-H_2O transfer process has been investigated. The surface preparation of the substrate immediately before deposition has been determined to be an important factor in obtaining smooth films. The best films have been grown at 1000°C or higher. The slowest growth rate and smoothest films result when growth occurs on the $(\bar{1}\bar{1}\bar{1})$ planes. At low flow rates (≤70 cc min^{-1}), the growth rate is proportional to the square root of the partial pressure of water vapor, however, at high flow rates (≈600 cc min^{-1}) the growth rate is directly proportional to the partial pressure of water vapor. The variation of the partial pressure of water vapor and the total flow rates may be used to vary the growth rate from 0.080 to 1.5μ min^{-1}.

Examination of the impurity profiles of the resulting films suggests that outdiffusion of substrate dopants near the substrate-film interface may be controlling the profiles. This effect may be minimized if Si-doped substrates are used. The net donor concentration in the remainder of the film appears to be about 4 x 5 x 10^{15} cm^{-3}. Growth at 600 cc min^{-1} results in a flattening of the profile in the section of the film not affected by outdiffusion by reducing the effect of other dopant sources. High flow rates also yield flatter films.

Profiles obtained on bulk GaAs (n = 1.8 x 10^{15} cm^{-3}) suggest that the gold surface barrier diodes do not show classical diode behavior. The interpretation of the impurity profiles of these films, although based on these diode measurements, has been tempered to reflect these peculiarities.

Acknowledgments

The author is indebted to R. G. Sobers for the semi-insulating GaAs used in some of these experiments, to

Dr. J. M. Whelan, R. R. Moest, and C. J. Frosch for their sustained interests in this work and for their valuable suggestions, and to D. F. Raver who made many of the electrical measurements.

Preparation of Ge/Si and Ge/GaAs Heterojunctions

A. R. Riben,[1] D. L. Feucht, and W. G. Oldham[2]

Electrical Engineering Department, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

ABSTRACT

The effect of various substrate preparation techniques is investigated in the vapor growth of germanium on Ge, Si, and GaAs substrates. Important differences are noted for substrates which are iodine etched *in situ*, chemically etched, and cleaved *in situ;* namely, the appearance and crystal perfection of the overgrowth as well as epitaxial junction properties, all improve in the order of the above procedures. Flat, structureless overgrowths on cleaved GaAs substrates and growths with negligible stacking fault densities and dislocation densities of approximately 10^6 cm^{-2} on cleaved germanium substrates are obtained. However, strain and cracking of the overgrowth, in addition to higher defect densities occur in germanium grown on cleaved silicon substrates.

Considerable interest has been aroused in recent years in the study of heterojunction devices, especially structures made from various combinations of group IV and III-V compounds. Poorly defined interfacial conditions arising from contamination and defect states have confused efforts to relate heterojunction device characteristics to material bulk properties (1-4). In the interest of improving the knowledge of interfacially derived effects, as well as achieving better device consistency, a variety of device preparation techniques have been examined and compared. Heterojunction structures have been prepared by the open tube vapor growth of germanium on gallium arsenide and silicon substrates at relatively low temperatures using the germanium di-iodide disproportionation reaction. A comparison of growth features and final device behavior has been made for various substrate preparation techniques including water and solvent washing, aqueous etching, iodine etching, and cleaving. It has been found that surface conditions alter both the physical growth features and the final device electrical properties. The most consistent device behavior as well as the sharpest reverse breakdown has been obtained by cleaving the substrates *in situ* during deposition.

Experimental

The germanium vapor deposition system employed here has been described briefly in a previous publication (5) and is quite similar to the original systems devised by Ruth *et al.* (6) and Marinace (7). The furnace arrangement used and the corresponding temperature profile are shown in Fig. 1. After Marinace (7), the furnace consists of "Nichrome" ribbon wound on quartz, allowing observation of the growth process through the furnace walls. The hydrogen carrier gas is passed through a "De-Oxo" purifier and a liquid nitrogen cold trap before entering the reaction tube which contains three zones: an iodine zone, a source, and a seed zone. At the exit end of the reaction tube the exhaust gases are passed through a bubbler to maintain positive pressure within the system.

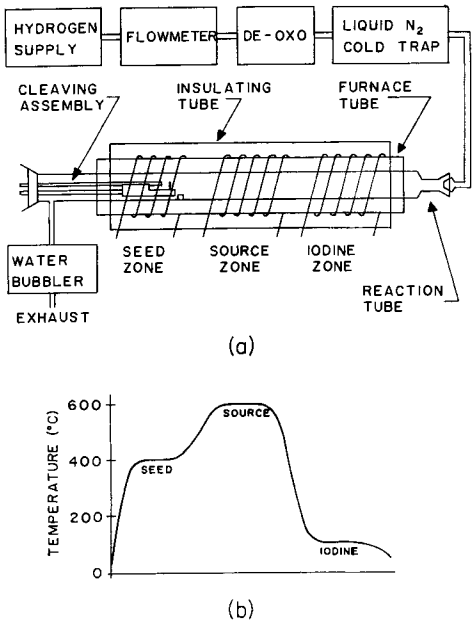

Fig. 1. Germanium vapor growth system: (a) experimental arrangement; (b) temperature profile during growth.

High-purity hydrogen,[3] ultrahigh-purity I_2,[4] and appropriately doped germanium ingots are used as starting materials. Before operation, the system is flushed with hydrogen for 12-18 hr to purge any traces of water or oxygen. If gas etching of the seed is not required, the iodine, seed, and source temperatures are

raised to 110°, 400°, and 600°C, respectively, and deposition proceeds. Gas etching is accomplished by first adjusting the iodine temperature to 50°C and both the seed and source temperatures to 400°C for approximately 1 hr. This gas etching causes the chemically polished surface to become dull gray in appearance. The various methods of seed preparation include: chemical etching[5] followed by a de-ionized water rinse, chemical etching with a water rinse followed by iodine etching, cleaving in air, cleaving in air followed by chemical etching and a water rinse, cleaving in air followed by an organic solvent rinse, and cleaving in the growth stream.

The latter operation, cleaving of the substrate to expose a fresh surface during steady-state deposition, requires a special quartz cleaving apparatus depicted in Fig. 2. The samples are prepared by cutting them into L bars which when cleaved yield several square millimeters of flat surface (8). Figure 3 illustrates a typical cleavage surface obtained for silicon. In general, the germanium cleaved surfaces are similar, but the cleaved GaAs surfaces are much flatter. While the Ge and Si surfaces are not of the perfection reported by Gobeli and Allen (8), due to the lack of rigidity of the quartz sample holder, they are adequate for the studies described here.

Results

Growth rates.—Single crystal growth of germanium has been achieved on all surfaces attempted, *i.e.*, on the three major planes of Ge, on the (111) ($\bar{1}\bar{1}\bar{1}$) and (110) planes of GaAs and on the (111) plane of Si. In the case of silicon, growth has been possible only on the (111) plane, because cleavage was necessary to produce an oxide-free surface at these low growth temperatures. Growth rates range from 0.5 to 10 μ/hr and are dependent on seed orientation. In Fig. 4 the growth rate is plotted as a function of the I_2 partial pressure for growth on the ($\bar{1}\bar{1}\bar{1}$) plane (As plane) of GaAs for source and seed temperatures of 600° and 400°C, respectively. No quantitative measurement of

[5] The chemical etches used were 1:1:10 H_2O:H_2O_2:H_2SO_4 for GaAs seeds and 1:5 HF:HNO_3 for Ge seeds.

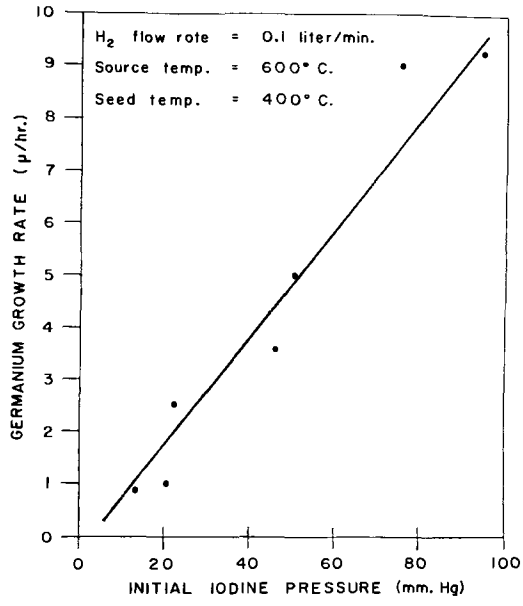

Fig. 4. Growth rate of Ge on (111) plane GaAs substrates as a function of iodine partial pressure.

growth rates on other surfaces has been made. It has been noted that growth on cleaved (110) plane GaAs surfaces proceeds considerably slower than on corresponding uncleaved surfaces. A possible explanation is that the number of growth steps is reduced on a cleaved surface due to near atomic flatness and perfect orientation.

Control of resistivity.—Four-point probe and Hall measurements have been made on test samples to determine doping control. Germanium films grown from intrinsic sources are invariably n-type with carrier concentrations greater than 10^{16} cm^{-3}. However, if the source doping is raised above this value, n-type films may be grown with controlled doping in the range 10^{17}-10^{20} cm^{-3}. A modification of the system, described in another publication (9), has permitted the growth of higher resistivity n-type films. Previously, a troublesome donor has prevented the growth of controlled resistivity n-type Ge films having a doping concentration less than 10^{17} cm^{-3}. P-type films grown in this manner normally have a very thin intermediate n-type layer similar to that reported by Marinace (10).

Crystalline perfection.—The appearance of the overgrowths is in general similar to the films reported by Marinace (7). However, some qualitative differences may be noted between growths on differently prepared surfaces. In one experiment a comparison was made of the overgrowth of four (110) plane GaAs seeds prepared in the following manner and grown simultaneously under the same conditions: (*a*) cleaved in air, chemically etched, and rinsed in de-ionized water; (*b*) cleaved in air and rinsed in organic solvents (semiconductor grade); (*c*) cleaved in air; and (*d*) cleaved *in situ* during steady-state Ge deposition.

Treatments (*a*) and (*b*) resulted in similar heavily faceted overgrowths, Fig. 5(a), whereas the treatment (*c*) produced a nearly flat structureless overgrowth, Fig. 5(b). The overgrowth on surfaces prepared by treatment (*d*) was similar in nature to that of (*c*) but possessed some additional structure. This experiment indicates that contamination left on the surface from wash treatments is primarily responsible for the heavily faceted overgrowth usually observed for (110) plane seed orientations with the Ge-I_2 system (7). Extensive gas etching of the substrate prior to growth forms a dull gray surface which also results in heavily faceted overgrowth. In the absence of high-temperature seed treatments in hydrogen the overgrowth of Ge on Si substrates has been possible only for freshly cleaved surfaces, that is cleaved as the Ge is deposit-

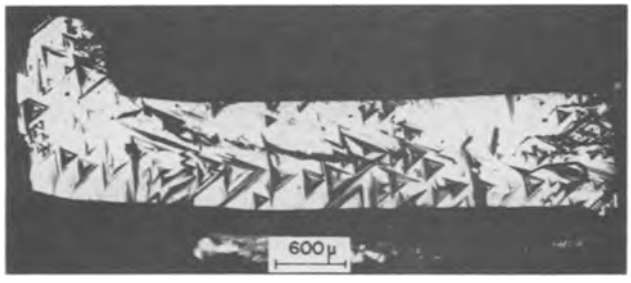

Fig. 6. Appearance of a Ge overgrowth on a cleaved Si substrate

ing. The germanium films thus obtained are not so featureless as the (110) plane growths on cleaved GaAs substrates, but resemble the usual (111) plane Ge films grown on cleaved Ge susbtrates. A photograph of a complete overgrowth of Ge on Si is shown in Fig. 6. In addition to variations in growth appearance, surface treatment also plays a role (to be discussed) in determining the electrical properties of both heterojunctions and homojunctions.

A defect present in germanium layers grown on silicon but not present in layers grown on germanium or gallium arsenide is a cracking of the overgrowth. Some of the cracks can be observed directly, while a brief etch serves to enlarge those not immediately observable. The crack lines are almost entirely in the [110] direction, suggesting that, as the germanium overgrowth cools from the growth temperature, it cleaves on those (111) planes intersecting the surface. The mean distance between cracks has been as low as 40μ, *i.e.*, the crack density is 1/40 μ^{-1} for layers thinner than 10μ. On thick layers the mean distance between cracks has been up to 230μ. Crack density correlated with crack width as well as growth thickness. The very dense cracks on the thinner growths cannot be observed without etching, whereas cracks became easily observable as the thickness of the growths increased and crack density decreased. The cracks cannot be associated with specific defects on the silicon substrate. However, the very thin growths ($<10\mu$) on areas with dense cleavage defects have a high crack density, and more perfect areas have a lesser density. Figure 7 shows a 4μ thick Ge overgrowth; (a) as grown and (b) following a 9-sec etch. The corresponding region of the cleaved silicon substrate[6] is shown in Fig. 7 (c). In Fig. 7(b), the crack free regions correspond to the more perfect cleavage areas [see Fig. 7(c)]. The crack density varies in (b) from $1/50\mu^{-1}$ to zero. The thicker growths have both a different appearance and a lower density of cracks.

[6] As a result of the cleaving process a section of the silicon L bar is pushed upstream into a region where no deposition occurs. Thus it may later be removed and examined to determine the cleavage perfection.

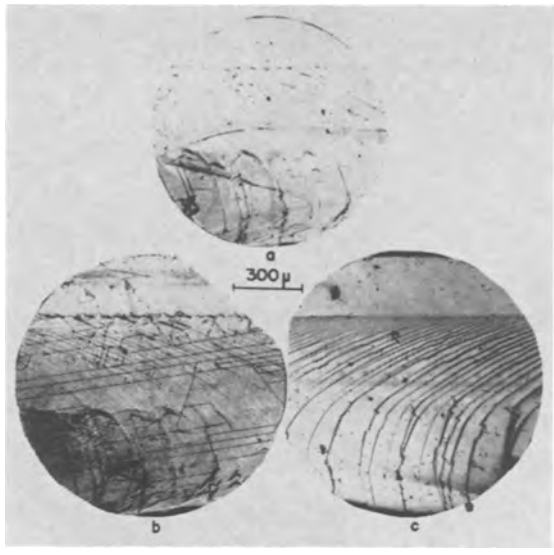

Fig. 7. A 4μ-thick Ge overgrowth on a cleaved Si substrate: (a) as grown (b) after a 9-sec WAg etch showing cracks in the overgrowth; (c) corresponding Si cleavage surface (see text).

Growth pyramids on thicker growths (see Fig. 6) have triangular bases whereas pyramids on thinner growths [see Fig. 7(b)] have more circular bases. The areas of very low crack density on the more perfect substrate regions suggest that improved cleavage quality and growth uniformity can mitigate the cracking difficulties. In any case, it has been possible to fabricate devices by etching mesas which do not include cracks.

X-ray analysis.—Laue back reflection photographs and diffractometer studies have confirmed the single crystal, epitaxial nature of the overgrowths. Studies of Ge/GaAs structures indicate no distortion of the Ge film or GaAs substrate. However, Laue photographs of Ge/Si structures show considerable distortion in the form of elongated Laue spots with striations as previously reported by Ruth *et al* (6). The latter attributed the distortion to the lattice mismatch between Ge and Si; however, such distortion in the Laue photographs has not been found to be present in other heterojunction pairs with equally large lattice mismatches (11) (InP-GaAs and InAs-GaAs), nor in heavily dislocated Ge layers grown on any Ge or GaAs substrates. In addition, it has been observed that in Laue photographs taken at 350°C, some of the distortion disappears, suggesting that the greater shrinkage of the Ge overgrowth during cooling from the growth temperature is responsible for the distortion. The striations in the spots are concluded to be reflections from the various slightly misoriented facets separated by cracks. This has been further confirmed by an experiment in which the x-ray beam diameter was increased and the striations became more pronounced.

Etching studies.—Germanium layers grown on Ge, GaAs, and Si have been treated with an etchant sensitive to crystalline defects. For the Ge-Ge and Ge-GaAs structures a comparison of the number of dislocations and stacking faults in the epitaxial layer as a function of the original surface preparation of the seed has been made. The etchant used to bring out both the stacking faults and the dislocations was the Westinghouse silver etch (12), (25 ml H_2O, 10 ml HF, 15 ml HNO_3, 0.2g $AgNO_3$). The optimum procedure was found to be a 5-sec etch, followed by a water rinse, and then removal of excess silver by wiping. The procedure is repeated until the imperfections are visible. Normally, after a total of 15 sec the stacking faults are visible, and after 30 sec the dislocation pits appear.

A comparison of dislocation pits in germanium grown on three (111) plane germanium substrates having different surface preparations is shown in Fig.

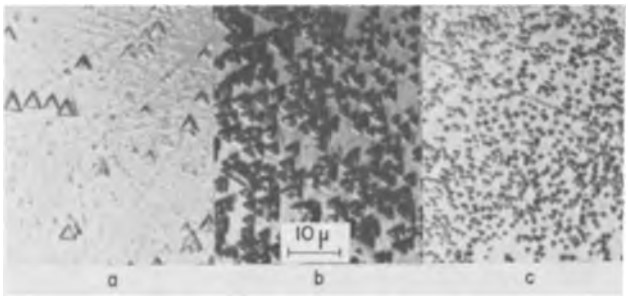

Fig. 8. Etch pits in the Ge overgrowth on (111) Ge substrates for various substrate preparation techniques. (The etch pits were developed with a 30-sec WAg etch): (a) substrate cleaved *in situ;* (b) substrate chemically etched; (c) substrate iodine etched *in situ.*

8. The growths on the cleaved and chemically etched substrates, shown in Fig. 8(a) and 8(b), were deposited simultaneously. The lowest dislocation density (less than $10^6/cm^2$) occurs in growths on substrates cleaved *in situ.* Dislocation counts on chemically etched seeds indicate approximately 10^7 dislocations cm^{-2} whereas the number of dislocations in the overgrowth on a typical iodine etched substrate [Fig. 8(c)] is greater than 3 x 10^7 cm^{-2}. The substrates themselves have an average dislocation count of approximately 10^4 cm^{-2} and a maximum count of 10^5 cm^{-2}. Cross sections of the cleaved growths show a smooth transition from substrate to overgrowth whereas for cross sections of the chemically or iodine etched seeds a dark line occurs at the interface which appears to be a region of very high dislocation density. Germanium layers grown on the (111) and ($\bar{1}\bar{1}\bar{1}$) planes of gallium arsenide show dislocation densities approximately a factor of two higher than those grown on correspondingly prepared germanium substrates. It has not been possible, however, to decorate the dislocations for overgrowths on (110) plane cleaved gallium arsenide substrates.

The stacking fault densities follow a similar pattern; the density is higher for germanium overgrowths on gallium arsenide than on germanium, and they increase as the substrate preparation is changed from cleaving to chemical etching to iodine etching. No stacking faults are observed on cleaved Ge substrates, occasional isolated stacking faults are observed in layers grown on chemically etched germanium substrates and up to 100 faults cm^{-2} occur on I_2 etched substrates. In comparison, clusters of stacking faults with a density of 3 x 10^4 cm^{-2} appear relatively uniformly spaced across the germanium layer grown on a chemically etched gallium arsenide seed.

A striking difference is noted for germanium grown on cleaved silicon substrates. Both the dislocation density (greater than 5 x 10^7 cm^{-2}) and the number of stacking faults (approximately 10^6 cm^{-2}) are much higher than for germanium grown on any germanium substrates.

These etching studies confirm the importance of substrate imperfections in initiating stacking faults and dislocations in the overgrowth (13-15). Cleaved substrates should initially be oxide and contaminant free leading to the lowest fault density as observed. Iodine-etched substrates apparently are left with a film of contaminants which nucleate both stacking faults and dislocations. The higher defect density in germanium grown on silicon is expected in light of the defect nucleation at microscratches (13) and local stresses (14) for silicon grown on silicon. In addition, oxides which rapidly form on the cleaved silicon surface would be expected to cause defect nucleation, by analogy to the growth of silicon on silicon (15).

Electrical properties.—The electrical properties of these junctions have also been studied and correlated with the surface preparation. Capacitance as a function of voltage shows a square law dependence which

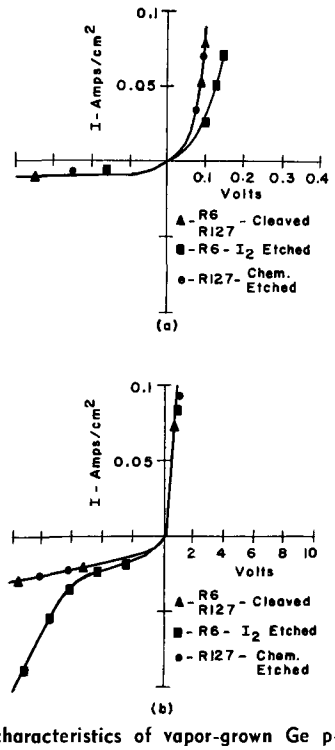

Fig. 9. V-I characteristics of vapor-grown Ge p-n junctions for cleaved, iodine-etched, and chemically etched substrates: (a) low voltage region; (b) high voltage region.

indicates the existence of an abrupt junction. In Fig. 9 the V-I characteristics of junctions fabricated from Ge grown on Ge substrates having different surface preparations are shown. In Fig. 9(a) the forward characteristics are shown for cleaved, chemically etched, and iodine etched substrates. At the same voltage, the forward current density is approximately the same for devices grown on cleaved and chemically etched substrates whereas devices on iodine etched substrates have a smaller current density. At low reverse voltages (less than 0.5v) the reverse current densities are presumably determined by the doping in the seed ma-

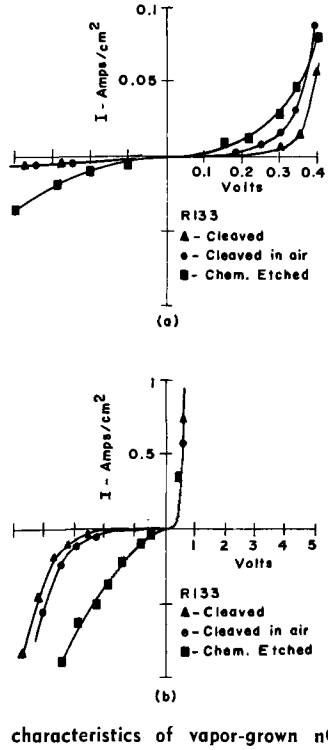

Fig. 10. V-I characteristics of vapor-grown nGe-pGaAs junctions for cleaved, iodine-etched and chemically etched GaAs substrates: (a) low voltage region; (b) high voltage region.

terial and are therefore identical. For higher reverse voltages, shown in Fig. 9(b), the diode on the iodine-etched substrate has a much larger reverse current density at a given voltage than those on the cleaved or chemically etched substrates. The devices fabricated on iodine-etched substrates vary widely but always exhibit a larger current density.

The forward and reverse V-I characteristics of nGe-pGaAs heterodiodes having various GaAs substrate preparations are shown in Fig. 10. The forward current density at constant voltage increases as we proceed from cleaved to cleaved in air to chemically etched substrates, Fig. 10(a). A similar dependence of the current density on surface preparation is noted in the reverse direction, for the same diodes as shown in Fig. 10(b). The reverse current increases with voltage as a power law prior to breakdown ($I \sim V^m$ where $m > 3$) (16) due to tunneling via interface states. The forward electrical characteristics of Ge-GaAs diodes are also controlled by tunneling via interface states. Both of these mechanisms will be discussed in detail in a future publication (17). Avalanche breakdown would normally occur in these diodes at approximately 9v.

Conclusions

A correlation of crystal defects in vapor-grown germanium layers with substrate surface preparation is established. The electrical properties of epitaxial heterojunctions and homojunctions also show a similar correlation with substrate preparation. The most perfect overgrowths and the best device characteristics (*i.e.*, highest rectification ratio) are obtained for growths on substrates which have been cleaved *in situ* during vapor deposition.

Preparation and Properties of AlAs-GaAs Mixed Crystals

J. F. Black and S. M. Ku

General Telephone & Electronics Laboratories, Incorporated, Bayside, New York

ABSTRACT

AlAs-GaAs mixed crystals of composition varying throughout the solid-solution range 0-40 mole % AlAs and 60-100 mole % AlAs have been prepared by halide-vapor disproportionation and by melt-growth techniques, respectively. Electron-beam-probe data and optical data showed that the epitaxially grown mixed crystals were of graded composition, while the melt-grown crystals were homogeneous in composition (within ±1 mole %). Measurements of the optical energy gap, the x-ray lattice parameter, the density, and the electrical properties of these crystals are described. The variation of the optical energy gap with composition is discussed in relation to an ideal mixed crystal model of the energy band structure.

Direct-band-gap III-V compounds are of considerable interest for opto-electronic devices, especially since the advent of high-frequency high-efficiency light-emitting and laser diodes in 1962 (1). The value of the energy gap of a semiconductor is very important in opto-electronic devices, where, for example, it is often necessary to "tailor" the optical properties for acceptable performance. It has long been known that by combining appropriate III-V compounds a number of mixed crystal systems can be formed which make it possible to produce direct-band-gap semiconductors over a continuous range of energy gaps (2-4). These direct-band-gap mixed crystal systems can be divided into two groups according to the type of band structure of the terminal compounds: (*i*) direct-direct and (*ii*) direct-indirect, where the indirect gap compound usually possesses the higher energy gap. The direct-indirect combinations are of particular interest because they offer higher energy gap ranges than the direct-direct combinations.

Only one direct-indirect III-V system, GaAs-GaP, has been thoroughly examined to date (5-7). Previous work by Stambaugh *et al.* (8) in 1960 established that another of these systems, AlAs-GaAs, was potentially useful for its high energy gap range. The results of Stambaugh and co-workers indicated that AlAs possessed the same type of band structure as GaAs, *i.e.*, direct. However, later measurements on pure AlAs conducted by Mead and Spitzer (9) provided strong evidence that AlAs had an indirect band structure. The present paper describes a more detailed investigation of the AlAs-GaAs system with results which confirm the conclusions of the latter investigators. A description of the methods of preparation and the properties of mixed crystals of AlAs-GaAs is given herein. A succeeding paper (10) will deal with

the fabrication and measurements of light-emitting diodes made from some of these mixed crystals.

Synthesis Studies Experimental Approach

Epitaxial AlAs-GaAs.—*Preparation.*—Single-crystal layers of AlAs-GaAs of a composition extending to about 40 mole % AlAs were grown epitaxially on GaAs substrates by an iodide-disproportionation-type closed-tube vapor-transport process similar to that used for GaAs-GaP (11). The essential details of the technique are shown in Fig. 1. The GaAs substrates were suspended from quartz hooks by loops of rhodium wire. Rhodium was chosen because it did not contaminate the epitaxial layers, *i.e.*, rhodium was not detectable by spectroscopic analysis of layers grown in preliminary experiments. The substrates were <110> oriented single crystal wafers of high purity ($n < 5 \times 10^{16}/cm^2$) with faces which had been ground flat and parallel, lapped with No. 1800 grit and then chemically polished in 1% bromine-methanol solution.

The source material was either a mixture of presynthesized AlAs powder and GaAs powder or a mixture of powdered GaAs and granules of pure Al. The AlAs powder was prepared by reacting pure aluminum with arsenic vapor in the presence of iodine (12). When the pure aluminum was used to charge the epitaxial growth capsule, care was taken to ensure that there was a layer of GaAs powder between the aluminum and the capsule wall to avoid contact of the quartz with molten aluminum. The iodide vapor phase was established by introducing pure iodine into the capsule in evacuated breakseal ampoules which were broken after the capsule had been sealed from the vacuum system. Enough iodine was used to yield 1 mg of free iodine per cubic centimeter of capsule volume. In a few instances small chunks of SnI_4 were used instead of pure iodine to produce a dopant-iodide vapor phase. Just prior to seal off, the capsule was backfilled with ½ atm of H_2 purified by passage through a palladium diffusor. It was found that by sealing ½ atm H_2 in the capsule better epitaxy and more uniform growth resulted than if the capsule were sealed under vacuum. Mixed crystal growth was initiated by quickly inserting the capsule into the preheated furnace. When sufficiently thick layers had been grown the run was terminated by removing the capsule from the furnace and cooling in the air.

Results.—Most samples of epitaxially grown AlAs-GaAs displayed a dull matte finish on their surfaces, but some, especially those with high aluminum content toward the surface, had smooth mirrorlike surfaces. Figure 2 shows an example of one of these mirrorlike surfaces. Surfaces of this type were sufficiently good for optical measurements, but the matte-finish surfaces required lapping and polishing to prepare the epitaxial layer for measurement of optical transmission. All of the epitaxial layers were "dished," especially near the edges of the sample; therefore, only the central regions of the grown layers, where the epitaxial film was of uniform thickness, were used for measurements. Figure 3 shows the uniformity of layer thickness that was generally obtained in the central regions of the layers.

Many of the epitaxial layers which were prepared in this investigation were not only quite thin—as thin as 3 mils—but they proved to have composition gradients through the thickness of the layer. By use of the electron beam probe, it was possible not only to identify and recover those films of uniform composition, but also to gather useful information from those films of a graded composition.

Figure 4 shows the composition profiles of several samples as determined by the electron-beam-probe technique. Lateral variations of composition, *i.e.*, in a plane parallel to the epitaxy substrate interface, were not more than 1 mole % AlAs in any epitaxially grown layer. This was consistent with the results of measurements of injection electroluminescence of diodes made from these layers (10).

Samples were also analyzed by x-ray fluorescence analysis using conventional x-ray equipment and grinding thin increments from the layer between successive analyses. In this case the irradiated region was several millimeters square, and the sampling depth about 1.5 mils. Where sample uniformity and size was such as to allow comparison, for example in slices cut from polycrystalline ingots, good agreement was obtained between x-ray fluorescence analysis (including electron-beam-probe results) and other means

Table I. Epitaxial growth parameters

Sample	Transporting agent	Source composition, g	Duration of growth, hr	Thickness of epitaxy, mils	Epitaxial composition max. AlAs mole %	Epitaxial composition profile
104	I_2	AlAs—2.1 GaAs—3.0	48	6.0	40	Graded increasing AlAs toward surface
105	I_2	Al—0.1 GaAs—3.4	64	10.5	16	Graded increasing AlAs toward surface
109	I_2	Al—0.5 GaAs—4.0	64	4.5	37	Graded increasing AlAs toward surface
113	SnI_4	AlAs—1.7 GaAs—2.3	141	4.0	40	See Fig. 5
116	SnI_4	AlAs—1.6 GaAs—2.3	231	6.0	40	Graded decreasing AlAs toward surface

of composition determination. By comparison with chemical analysis, with density determinations, and with precision x-ray lattice parameter measurements, the analytical accuracy was determined to be ±1 mole % AlAs.

The time required for growth of AlAs-GaAs layers and the composition of the layers were strongly dependent on the source material as may be seen from the data in Table I. Epitaxial layers with graded composition (continuous increase in Al content from interface to surface) were consistently formed from Al + GaAs source material. When AlAs was used in the source instead of aluminum, the grown layers sometimes showed regions of nearly constant composition (sample No. 113). The use of SnI_4 rather than pure iodine as transport agent resulted in Sn doping of the grown layers and also resulted in greatly reduced growth rates, presumably because the SnI_4 did not decompose sufficiently to provide the proper concentration of iodide vapor phase for rapid material transport. Epitaxial layers with greater than 40 mole % AlAs grew very slowly and were heavily contaminated with silicon. Suitable mixed crystal material with composition in excess of 40 mole % AlAs was best prepared by slow freezing of AlAs-GaAs melts.

Melt-grown AlAs-GaAs.—*Preparation.*—Mixed crystals with greater than 50 mole % AlAs composition were prepared by directional solidification (*i.e.*, normal freezing) of AlAs-GaAs melts in sealed evacuated quartz tubes, because of the difficulties that were encountered in growing suitable epitaxial crystals in this composition range. Previous work by Stambaugh *et al.* (13) had demonstrated that melt techniques could be used to good advantage for preparing crystals of AlAs-GaAs. The multiple zone furnace arrangement employed was essentially as described by Stambaugh (14) except that an aluminum oxide sleeve was placed around the graphite susceptor to keep the inside walls of the quartz tube cool enough to prevent softening and to minimize reaction of the quartz with aluminum vapors. To prepare mixed crystal ingots, the boat was charged either with a mixture of presynthesized AlAs powder and powdered GaAs or with a sandwichlike arrangement of slices of pure aluminum and high-purity GaAs. When the latter procedure was used, severe attack of the quartz tube occurred in the region of the hot zone, presumably by aluminum vapors, during the process of melting and reacting the charge. The use of the presynthesized AlAs powder rather than aluminum in the charge kept the aluminum vapor density at a minimum at all times and reduced the degradation of the quartz tube to tolerable levels. Boron nitride boats were found to be most suitable for crystallizing molten AlAs-GaAs. The ingots could not be easily removed from the boats without cracking, and most of the ingots were recovered by filing and sandblasting the boats away.

Results.—All of the ingots prepared were polycrystalline with a relatively fine (about 0.5 mm) grain size. To produce ingots with sections of reasonably good lateral homogeneity (*i.e.*, with no more than ±1 mole % variation from the mean value as determined by electron beam probing), it was necessary to crystallize at a speed of no more than 2 mm/hr. Even so it was not possible to produce homogeneous material of less than about 50 mole % AlAs. The composition at the first-to-freeze end was always considerably higher than the initial melt composition, indicating a wide gap between the liquidus and solidus lines in the AlAs-GaAs temperature-composition phase diagram. For example, in an ingot of initial composition of 33 mole % the first-to-freeze end had a composition of 78 mole % AlAs, Similar observations were reported previously for this system (13).

A section of one of the melt-grown ingots which was polished for optical measurements is shown in Fig. 5. The composition of this piece was 72 mole % AlAs, and it was a clear red-orange color by transmitted light. Black spots which are barely visible in the sample are inclusions of an unidentified foreign material. Since the total amount of these inclusions was less than 1% of the total volume of the sample, their presence was neglected in correlating optical measurements with composition.

Precision lattice parameter measurements made on a sample of 58 mole % AlAs yielded a value of 5.6581 ±0.0003Å. A comparison of this value with values for GaAs (5.6534 ± 0.0002Å) and AlAs (5.662 ± 0.001Å) (15) is made in Fig. 6 which indicates that the lattice

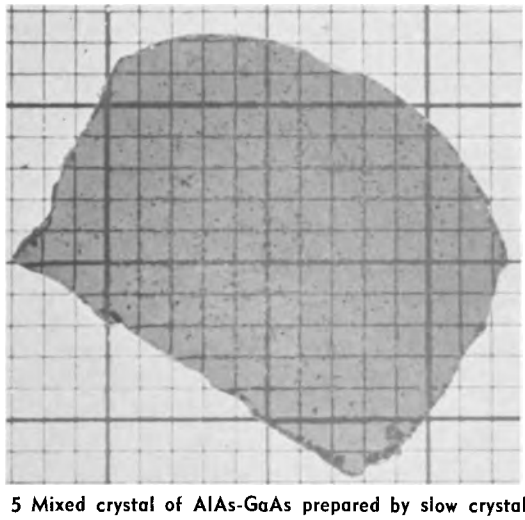

Fig. 5 Mixed crystal of AlAs-GaAs prepared by slow crystallization from the melt. The actual size of the section shown is 5/16 x 1/4-in. and it is 0.015-in. thick.

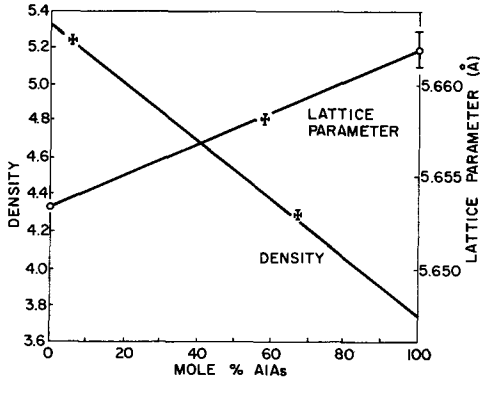

Fig. 6. Variation of lattice parameter and density with composition in the AlAs-GaAs system. The horizontal and vertical bars at each data point represent the limits of experimental error. The solid lines represent the behavior expected if Vegard's law is followed.

parameter-composition variation (mole per cent) may be linear (Vegard's law). Once it was established that there was no serious deviation from Vegard's law, it was a simple matter to calculate the density-composition variation. For the purpose of a density calculation even as large a mid-range deviation from Vegard's law as $a_o = 5.600$Å or $a_o = 5.700$Å would not have been serious since it would have introduced an error of only ±½% in the calculated mid-range density. A density measurement is capable of very good precision in determining the AlAs-GaAs composition since the density change is quite large. For example with a measurement accuracy of ±½% (which is easily achieved in measurements of density), the composition determined by the density measurements was within 2 mole % of the analysis values for samples of either high or low aluminum content. These results are shown in Fig. 6.

Optical and Electrical Studies

Measurement methods.—Optical measurements.— Optical transmission measurements were performed on a model 350 Perkin-Elmer spectrometer using a beam condenser attachment for small samples. Measurements on epitaxial layers of graded composition were made as follows. Samples 3-4 mm long x 2-3 mm wide were mounted on separate quartz plates with a transparent wax, and the GaAs substrate was ground off. By careful grinding and polishing, successive layers were removed from the epitaxial layer and the optical absorption edge was correlated with the mixed crystal composition determined by electron beam probe analysis of the polished surface. The optical absorption edge was defined as the intercept of the transmission curve with the zero transmission abscissa, neglecting the short-wavelength tail caused by the spectrometer band pass. In this way the region of the polished sample face which defined the absorption edge (or the optical energy gap) was the first several microns that the spectrometer beam traversed in passing through the sample. This is equivalent to defining the optical energy gap as that energy corresponding to an absorption coefficient of about 10^4 cm^{-1}. Since the region of the film sampled by the electron beam probe was essentially the same as that determining the absorption edge, good correlation could be expected between the two kinds of information. Strictly speaking, good correlation could be expected only for compositions where the (lowest energy) band-to-band transitions were still direct. Band-to-band optical transitions in the indirect III-V compounds are generally characterized by absorption coefficients no higher than 10^3 cm^{-1}. Thus for AlAs-GaAs compositions where the band gap transitions were indirect, the region determining the optical energy gap would no longer be comparable to the region sampled by electron probe analysis.

By the technique described above it was possible to investigate (optical) energy gap-composition variations over a moderate range of composition in a single graded composition epitaxial layer. The correlation was best accomplished in layers possessing a monotonic increase in AlAs content from the substrate-epitaxy interface to the surface of the epitaxial layer. For sharp composition gradients, *i.e.*, more than a few mole per cent over several microns, the correlation was made less reliable because of the difficulty experienced in keeping the plane of polish exactly parallel to the epitaxial surface. In effect this limited our optical measurements on the epitaxial mixed crystals to the composition range 0-25 mole per cent AlAs (see Fig. 4). Only those melt-grown samples which were of uniform (within ±1 mole per cent) mixed crystal composition were used for the correlation of optical energy gap with composition. Furthermore, only samples with minimal amounts of foreign inclusions, such as in Fig. 5, were used. The optical transmission measurements were made on mechanically polished samples 5-20 mils in thickness, and the optical energy gap was calculated at the shoulder of the absorption edge. This is a common method of determining the optical band edge of a semiconductor, and it is a more accurate definition of the energy gap than the point of intercept with the zero-transmission abscissa, especially for an indirect semiconductor. [Previous measurements of pure AlAs by Mead and Spitzer (9) indicated that high AlAs composition mixed crystals would be of an indirect band structure.] In addition, the energy gap of the AlAs-GaAs mixed crystals could then be better compared with pure AlAs since the values that have been reported for the optical energy gap of pure AlAs are essentially equivalent to the shoulder of the absorption edge.

Electrical measurements and impurity analysis.—Electrical measurements were made in much the same way as the optical measurements, *i.e.*, by mounting the samples on flat quartz plates and grinding off the substrate. Undoped epitaxial mixed-crystal layers were n-type. P-type material was produced by in-diffusing zinc from the vapor phase at 800°C in small evacuated quartz ampoules. For the most part, electrical measurements were confined to four-point probe resistivity measurements using a co-linear probe arrangement, and to hot-point probe thermoelectric measurements to determine the sign of the charge carriers. The making of low-resistance alloyed contacts was very difficult due to the rapid formation of tenacious oxide films even on samples of low AlAs content. However, this difficulty was partially overcome by forming spring-loaded point contacts with a spark discharge from a Tesla coil of the kind used for vacuum leak detection. Because of the difficulties involved in the handling of these thin samples and in making suitable ohmic contacts, Hall effect measurements were successful in only a few instances. The impurity content was obtained by quantitative emission spectroscopy of pieces of the epitaxial layers recovered after grinding off the substrate material.

Electrical measurements were not made on polycrystalline material because of the severe effects that grain boundaries often have on the measured electrical properties of semiconductors.

Results and discussion.—Electrical measurements and impurity analysis.—The results of electrical measurements of AlAs-GaAs layers are listed in Table II, and the results of spectroscopic analysis are found in Table III. No other impurity elements besides those

[a] By quantitative emission spectroscopy, concentrations given in ppm by weight.

listed were detected. The high level of Si contamination in the layers was consistent with a noticeable etching of the quartz capsule by the aluminum iodide vapors. The attack was continuous, and therefore longer term runs contained high Si-contamination. Note that there is a significant amount of Cu contamination also. It is believed that the quartz is the source of Cu contamination too. It is encouraging that despite the heavy contamination of these mixed crystals, the electron mobilities measured are still reasonably high. In addition, the resistivities observed in the zinc-diffused layers are comparable to the resistivities one would obtain for diffusion of zinc into GaAs under similar conditions.

The melt-grown AlAs-GaAs material showed much lower Si content than the epitaxially grown crystals even though the processing temperature was much higher (1700°C) than for the epitaxial material (700°C). This points up the critical role of iodine in promoting the attack of quartz by aluminum vapor at low temperature. For example, spectroscopic analysis of the polycrystalline ingots typically showed 30-50 ppm Si compared to 100-2000 ppm Si in epitaxially grown material. Other trace impurities present in the melt grown AlAs-GaAs were Ag (1-2 ppm), Cu (5-10 ppm), and Mg (5 ppm). Boron was detected in the ingots, but in relatively low concentrations, less than 100 ppm, indicating very little dissolution of the boron nitride boats in AlAs-GaAs melts.

Optical measurements.—In Fig. 7 is shown the variation in optical transmission of a graded composition layer as the layer was successively ground and polished toward the region of high aluminum content. The first measurement included the region of the film near the epitaxy-substrate interface. This region was low in aluminum content, and the transmission curve is nearly identical to that of pure GaAs. The decrease in transmission beyond the absorption edge as the sample was made thinner was probably caused by the difficulty experienced in getting a high polish in regions of high Al content. There appeared to be an increase in the hardness of AlAs-GaAs mixed crystals at high AlAs compositions.

The optical energy gap-composition variation determined for both epitaxially prepared AlAs-GaAs and melt-grown AlAs-GaAs is shown in Fig. 8. Included are the results of the measurements of two homogeneous polycrystalline melt grown samples of low AlAs composition.[1] The energy gap for these samples was defined in the same way as for the graded composition samples, and the composition-energy gap data are in good agreement with the data obtained on epitaxial material.

The solid circles are values of the optical energy gap measured by Stambaugh *et al.* (8) for polycrystalline melt-grown material. The value for the optical energy gap of GaAs corresponds to an absorption coefficient $\alpha = 10^4$ cm^{-1} and was determined at the intercept of the absorption edge with the zero-transmission abscissa in order to be consistent with the data on the low-Al-content mixed-crystal material.

The dashed lines are extrapolations of the experimental data. The [000] energy value for AlAs is from ref. (9) while the lower conduction band energy of AlAs is from ref. (9) and (16). |—|, this investigation; |—△—|, polycrystalline samples from Battelle; •, Stambaugh *et al.*

The fact that the energy gap composition data differ widely from a linear relationship between the conduction band energy of GaAs and the conduction band energy of AlAs is evidence for the indirect nature of the AlAs band structure (3, 4) confirming the conclusions of Mead and Spitzer (9). The data suggest a marked change of slope at 2.0 ev and 50 mole % AlAs, the approximate values of the energy gap and composition, respectively, at which the energy separating the direct and indirect band edges in AlAs-GaAs mixed crystals would approach zero.

The composition-energy gap relation in the Al-rich end of the composition range is in good agreement with the band-gap value of AlAs obtained by measurements of the photoresponse of n-type AlAs-Au surface barrier layers (9). It is also in good agreement with reported values of the optical energy gap of pure AlAs (16).

A virtual crystal model of the energy band structure of an ideal mixed crystal predicts to a first approximation a linear relationship between energy transitions of like kind and molar composition. Woolley (17) has recently discussed the merits of this theoretical approach in interpreting the properties of mixed crystal semiconductors. As he has pointed out, this kind of application of a virtual crystal model leaves something to be desired, but we believe it to be a useful framework for the following discussion. Actually, ideal behavior has been observed for energy transitions of like kind (band-gap) in InAs-InP mixed crystals and more recently for several like-kind energy transitions (above band-gap) in GaAs-GaP mixed crystals (18). If ideal behavior is assumed to apply to the AlAs-GaAs system, then a linear extrapolation of the data in the high AlAs composition range will intercept the GaAs ordinate at the energy of the indirect minimum in GaAs which corresponds to the indirect minimum forming the conduction band in AlAs. The estimated energies of the indirect minima in GaAs at room temperature are 1.75-1.80 ev for the [100] minimum (19, 20) and 1.90-1.95 ev for the [111] minimum (19). An extrapolation of our data intercepts the GaAs ordinate at about 1.90 ev which is closer to the energy gap associated with [111] transitions than to that associated with [100] transitions. This is contrary to a theoretical postulate of a [100] type of minimum for the conduction band of AlAs made by Paul (20). However, the uncertainty in the intercept on the GaAs ordinate is about ±0.05 ev and prevents a definitive conclusion from our data as to whether the [111] or [100] transition establishes the energy gap in AlAs.

The measurements of Mead and Spitzer (9) indicate a direct-band-gap energy of 2.9 ev in AlAs. Thus, if the data in the Ga-rich range of the AlAs-GaAs energy gap-composition diagram follow fairly closely the line interpolated between the direct-band-gap energy of GaAs and 2.9 ev for AlAs, this would provide good evidence for ideal behavior in the system. The data obtained in this part of the composition range, however, differ widely from this line. The data of Stambaugh *et al.* (8) determined for polycrystalline melt grown material fall well below the extrapolated data of this investigation at mid-range compositions. It is significant that their data points toward mid-range compositions fall furthest below our data line since the results of a number of recent investigations of mixed crystal III-V compounds have shown that it is particularly difficult to achieve a high degree of homogeneity in melt-grown crystals of mid-range composition (21). Inhomogeneous material typically gives optical energy gap values which are lower than those obtained for (more) homogeneous material of the same average composition (5). A polycrystalline melt-grown sample produced in this investigation with an average composition of 13 mole % AlAs was shown to be inhomogeneous (composition range 7 to 20 mole %) by electron beam probe analysis and gave a value of 1.47 ev ($\alpha = 10^4$ cm^{-1}) for the optical energy gap, whereas a value of 1.65 ev was obtained for 13 mole % AlAs determined to be homogeneous by electron beam probing. Unfortunately, the usually reliable method of determining the homogeneity of a mixed crystal by measuring the sharpness of high angle x-ray diffraction lines is not applicable to AlAs-GaAs mixed crystals because of the nearly identical values of the lattice parameters of AlAs and GaAs. Thus, we suggest that the early data of Stambaugh *et al.* fall below the present data because their samples were less homogeneous. With respect to the present samples, the results of electron-beam-probe analysis show that any inhomogeneity present cannot exceed ±1 mole % (and this has already been taken into account in plotting the data) or else the inhomogeneity must exist on a scale which is near the resolution capability of the electron beam probe, *i.e.*, a few microns. Even if there were inhomogeneity on such a microscale, measurements of the near-band-edge recombination radiation in diodes made from this material indicated that the range of inhomogeneity could not be more than 2 mole % (10). Therefore, unless the energy gap in AlAs-GaAs mixed crystals is very sensitive to small degrees of inhomogeneity, we conclude that the energy gap in this system does not follow a linear interpolation between the direct transition minima of the terminal compounds, and hence the system does not behave as an ideal solid solution. It appears that such nonideal behavior of the band structure is the rule in most III-V mixed crystal systems whether they be of the direct-indirect or the direct-direct types. Of six systems where sufficient energy gap-composition data are available for an evaluation (InAs-InP, InAs-GaAs, InSb-InAs, InSb-GaSb, GaAs-GaP, and GaSb-AlSb) (4, 5, 9, 22) only one, the direct-direct system of InAs-InP, has been positively identified as having an energy gap-composition relation compatible with an ideal system. It is interesting to note that, of the five remaining systems that are nonideal, three are substituted on the group III sublattice, the same sublattice which is substituted in AlAs-GaAs.

Acknowledgment

It is a pleasure to acknowledge the aid rendered by many colleagues. In particular, the electron-beam-probe, x-ray fluorescence, and spectroscopic analysis of our samples, which have been quite indispensible for this study were made by W. Sutkowski, P. Lublin, J. Cosgrove, and S. Weisberger. Thanks are also due to Dr. E. Stambaugh of Battelle Memorial Institute for supplying several samples of melt-grown AlAs-GaAs mixed crystals. The technical assistance of A. Marx and J. Hurley during the course of this work are also gratefully acknowledged. The authors are especially indebted to Dr. S. Mayburg and Dr. B. Smith without whose support and encouragement this work could not have been carried out.

Manuscript received Sept. 20, 1965; revised manuscript received Nov. 12, 1965. This paper was presented in part at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

A Spreading Resistance Technique for Resistivity Measurements on Silicon

R. G. Mazur and D. H. Dickey[1]

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A technique for determining local silicon resistivity from the measured spreading resistance associated with a metal to semiconductor, small-area pressure contact is described. The major problems encountered in earlier attempts to derive quantitative resistivity data from small area pressure contacts on silicon have been circumvented by making the measurements at bias levels of a few millivolts and by using a particular osmium-tipped probe arrangement to provide contact reproducibility. The method provides a three-dimensional spatial resolution in resistivity measurements on silicon on the order of 1μ, and, using a calibration curve determined for a particular silicon surface finish, yields an experimental reproducibility $\leq 15\%$ for sample resistivities in the range 10^{-3} ohm-cm $\leq \rho \leq 500$ ohm-cm. Several examples of the application of the technique to problems of current interest in silicon technology are given.

One of the most important control parameters in semiconductor technology is that of material resistivity. If the carrier mobility in the material is known, a simple measurement of the semiconductor resistivity then gives direct quantitative data on the net concentration of majority carriers. For silicon, the requirement of known carrier mobility has been obviated through the publication of empirical data relating impurity concentration directly to material resistivity (1). These data are widely used in conjunction with resistivity measurements, both to assure known impurity concentrations in starting material and to maintain control of desired impurities introduced during device manufacture.

The resistivity measurements needed are normally made by one of several well-known potential probe techniques (2-4). A variety of other resistivity techniques have been advanced for special purposes (5), but the potential probe methods have remained standard because of their directness and relative ease in operation.

One aspect of the standard potential probe measurements that has become increasingly frustrating is the limited spatial resolution normally obtained. Generally speaking, the spatial resolution of these techniques is measured in millimeters. For instance, the most commonly used small four-point probe spacing is about 0.5 mm. As the current flow in a region of two or three probe spacings around the central pair of probes contributes significantly to the potential between the voltage probes, the quantitative resolution of this technique is 1 or 2 mm. The standard techniques may be used for high resolution resistivity measurements under certain conditions, *e.g.*, the four-point probe technique has been used with a sectioning procedure (such as boiling water or anodic oxidation of the silicon and subsequent dissolution of the silicon dioxide layer with HF) to measure resistivity in diffused layers with a resolution (normal to the plane of the section) measured in some tens of Angstrom units (6). However, this requires a one-dimensional geometry in that the material measured must still be homogeneous over millimeter distances in the plane of the section.

Some specific problems in which spatial resolution is of importance are: resistivity measurements of lightly doped epitaxial layers grown on heavily doped substrates of the same conductivity type; measurements on internal layers in multi-layer epitaxial or diffused structures; and the rapid evaluation of actual resistivity, (or concentration) profiles of diffused layers. Less frequent but equally troublesome problems involve initial resistivity measurements on certain materials as-grown, such as whiskers or dendrites, which are either physically too small for the use of standard resistivity techniques or are normally inhomogeneous.

In response to these problems, a variety of techniques for high spatial-resolution resistivity measurements have been reported in recent literature. One of the most well-known is the "three-point probe" technique (7, 8), based on a measurement of the breakdown voltage of a metal semiconductor point contact and using an empirically established relationship between the measured breakdown voltage and the resistivity of the silicon. Several of the available quantitative techniques for measuring epitaxial silicon have been compared (9); the methods covered included a modification of the three-point probe technique involving the use of d-c methods and a two-point probe "constriction resistance" method (10) which, while less developed, is quite similar to the technique discussed in this paper, both being based on a point contact resistance measurement. More recently, the details of a technique which employs a four-point probe of a special configuration have been published (11).

In the course of our attempts to find a suitable resistivity technique with high spatial resolution, we investigated the possibilities of metal-semiconductor point contacts. It is well known that certain features of the I-V characteristics of such contacts can be used to obtain information about the basic electrical properties of the semiconductor material (12). In particular, at least semiquantitative measurements of semiconductor resistivity have been made by measuring the "spreading resistance" or "constriction resistance" of such contacts (12, 13).

This paper presents details of some developments introduced into the use of the "spreading resistance" technique, allowing local resistivity measurements on silicon with a sampling volume of about 10^{-10} cm^3 and an estimated maximum probable error of $\pm 15\%$ on bulk samples, with a somewhat larger error on highly inhomogeneous silicon. This is followed by a description of both the apparatus used and the calibration procedure found to be of primary importance in obtaining accurate data. Results of typical measurements on several inhomogeneous silicon structures are then given to illustrate the use of the technique.

Background

Some of the phenomena involved in current flow through small area contacts are quite familiar in semi-

[1] Present address: Physics Department, Montana State University, Bozeman, Montana.

conductor technology. A more extensive background to small-area current flow exists in the study of metal-to-metal contacts (14-16). It has been shown (14) that, for the case of a perfectly conducting hemisphere embedded in a homogeneous semi-infinite solid of resistivity ρ, the spreading resistance (or equivalently, the constriction resistance) in the semi-infinite solid is given by

$$R_s = \frac{\rho}{2\pi r} \quad [1]$$

in which r is the radius of the embedded hemisphere. This relationship has been widely used in making rough estimates of spreading-resistance effects in current-flow in solids. Reference (16) has indicated that a more realistic geometry for the contact interface between a hemispherically surfaced member and a flat solid is a circular disk of radius a, which is given by the Hertzian formula

$$a = 1.1\{(Fr/2)[(1/E_1) + (1/E_2)]\}^{1/3} \quad [2]$$

in which F is the force applied to the contact, r is the radius of curvature of the spherically surfaced member, and E_1 and E_2 are the Young's moduli of the materials involved in the contact. The spreading resistance on either side of such a flat circular contact between two members of bulk resistivity, ρ, has been shown (15) to be

$$R_s = \frac{\rho}{4a} \quad [3]$$

These relationships have been used extensively in research on electrical contacts and in work on the frictional behavior of solids, primarily as a means of determining the true electrical contact area between contact members whose bulk resistivities are known (14-16). The spreading resistance resistivity technique inverts this process to determine local material resistivity from a measurement of the spreading resistance associated with a contact-spot of known dimensions. Furthermore, for a metal-semiconductor contact, the spreading resistance in the metal is negligible compared to that in the semiconductor because of the order-of-magnitude or more difference in bulk resistivity between metal and semiconductor. Therefore, the total contact resistance at a single-spot circular contact between a metal and a semiconductor should be given by

$$R_s = \rho/4a \quad [4]$$

where ρ now refers specifically to the resistivity of the semiconductor and a is the radius of the circular contact spot. The derivation of Eq. [3] and [4] involves the assumption that ρ is homogeneous in the contact members, at least in the region surrounding the contact. The general problem of inhomogeneous ρ has not been treated in the literature, but particular cases of interest are discussed later in connection with the spatial resolution of the spreading resistance technique on silicon. Also, the value of R_s as given by Eq. [4] will be the total measured contact resistance only if experimental conditions are such that the bulk resistances involved, the resistance of surface insulating layers (if present), and other contact resistances in the ciricuit are all much smaller than $\rho/4a$, or are otherwise accounted for.

The use of a spreading resistance technique for semiconductor resistivity measurement has been reviewed (12) with the conclusion that, at best, only semiquantitative results are possible. This failure to achieve good quantitative results was due to a number of effects peculiar to the metal-to-semiconductor contact system. These are (17)

(*i*) In general, metal-semiconductor contacts are nonohmic; there is either a reverse-biased barrier in series with the spreading resistance; or, with bias applied in the forward direction, excess carriers are injected into the semiconductor, reducing the local resistivity.

(*ii*) Due to the small size of the contact, the electric field in the spreading resistance region may be high enough to alter the carrier mobility, again resulting in a modification of local resistivity.

(*iii*) Also because of the small contact area, significant Joule heating in the spreading resistance region can occur at moderate currents. The heat generated may cause an appreciable thermoelectric voltage, which will be added to the resistive voltage drop, or, the temperature rise in the contact-region may alter the carrier concentration or carrier mobility in the semiconductor.

(*iv*) The actual contact area of a metal-semiconductor pair is difficult to determine, primarily due to deformation of the metal probes used in such point contacts.

Despite these problems, initial measurements produced results in approximate agreement with Eq. [4]. The results achieved could be rationalized as follows.

(*A*) For voltages appreciably $<\beta kT/q(\beta > 1)$ (17), the injected carrier density for contacts such as those used in our work is small relative to the equilibrium carrier density, producing a nearly linear V-I region near the origin where a reasonable spreading resistance measurement may be made. The maximum expected temperature rise at the point contacts used in this work has been calculated from a relationship given by Holm (14) as $<0.1°C$ for applied voltages <15 mv. Furthermore, the maximum electric field in the spreading resistance region of the contacts used for applied voltages ≤ 15 mv is about 10^3 v/cm, a value somewhat less than that which has been found to appreciably affect carrier mobility in silicon. Thus, the measurement difficulties mentioned above in (*i*), (*ii*), and (*iii*) may apparently be eliminated by making the contact resistance measurement at a sufficiently low voltage level.

(*B*) It appears that previous difficulties in obtaining reproducible contacts and in determining the area involved in metal-semiconductor point contacts may have been due as much to the over-all mechanical construction as to the inherent limitations imposed by the contact materials. Most metal-semiconductor point contact studies have been carried out with metal wires of very small diameter; the often-observed deformation of these probably then is due more to the lack of structural rigidity rather than plastic deformation of the metal itself. Some additional remarks on the point-contacts themselves are included below in the section on measurements on inhomogeneous silicon structures.

While the problems expected on the basis of effects indicated in (*i*), (*ii*), and (*iii*) were thus experimentally resolved by our initial measurements as outlined above, the lack of complete agreement between the experimental data and Eq. [4] and especially the consistent differences observed between p- and n-type material pointed to the presence of a less commonly appreciated problem due to the metal-semiconductor barrier other than those listed above. This is a resistive voltage drop measured across the barrier at any bias level, *i.e.*, the "zero-bias barrier resistance" (18), which is then always in series with the geometrical spreading resistance itself. By definition, the zero-bias barrier resistance obviously cannot be eliminated by the approach used in our measurements to eliminate carrier injection, etc.; the zero-bias barrier resistance is present at any voltage level used. While, in theory, the zero-bias barrier resistance of a particular contact may be calculated for a given barrier height (18), real metal-semiconductor interfaces are complicated by semiconductor surface states, geometry, and the generally unclean nature of real surfaces, precluding an analytical allowance for zero bias barrier resistance in a spreading resistance measurement.

However, in order to make practical use of the spreading resistance technique, we have constructed

a calibration curve, established under conditions such that the metal-semiconductor barrier height is, at least, reproducible. Further remarks on the observed zero-bias barrier resistance are included in the discussion of the calibration data.

Experimental

Homogeneous Resistivity Silicon

Apparatus.—The apparatus used in this work consisted of one or two probes (Jensen A-70LP phonograph needles) supported in such a manner that they could be carefully placed with a known, fixed force on a sample surface without dragging. The total resistance between a pair of probes or between one probe and a low resistance base contact was measured with a Keithley 610A electrometer-ohmmeter. For the calibration procedure discussed in detail in this paper, an arrangement of two identical probes was used.

The probes themselves had an osmium tip of 2.5 x 10^{-3} cm radius of curvature (checked with an optical comparator to within 10%) and were mounted on separate booms, which were loaded with calibrated 50g weights.

Calibration procedure and results.—Slices of both n- and p-type silicon with resistivities from 10^{-3} ohm-cm to several hundred ohm-cm were obtained from commercial sources. The slices were hand-lapped with a slurry of 5μ particle size aluminum oxide and water on a glass plate. The resistivity of each sample was checked with an A. & M. Fell four-point probe, obtaining values which are considered reproducible within ±10%. The spreading resistance measurement was then made at least ten times on the surface of each sample in the region where the four-point probe measurement had been made. Measurements were made under both forward and reverse bias to establish experimentally the validity of the use of ultralow power in avoiding the "normal" effects involved in a metal-semiconductor point contact. In addition, the current was changed in decade steps to insure that the V-I characteristics of the contacts used was linear (to within the accuracy of the meter) well beyond the typical applied voltage of 10-15 mv. The average of the measurements on each sample was divided by two to normalize the data to a single probe, and the result plotted as R_s on the ordinate of Fig. 1 (with the four-point probe value plotted on the abscissa as "true" resistivity). The main features of the data in Fig. 1. are: (*A*) The measured spreading resistance is proportional to sample resistivity, as predicted by Eq. [4], over a resistivity range from 10^{-3} to about 10^3 ohm-cm. (*B*) The exact relationship between contact spreading resistance and bulk resistivity is obviously more complicated than would be expected on the basis of Eq. [4], with an observed deviation from the theoretical linear relationship of as much as 300%.

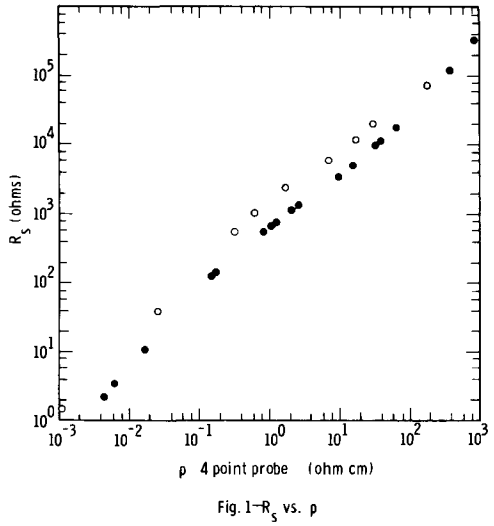

Fig. 1. Spreading resistance vs. true (four-point probe) resistivity for lapped surfaces of p (•) and n (○) silicon.

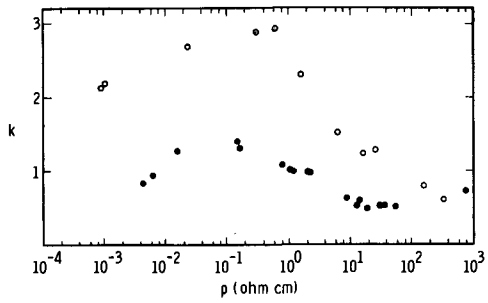

Fig. 2. Proportionality constant "k" between spreading resistance and resistivity for p (•) and n (○) silicon.

One way of characterizing the variation of the experimental data from that expected on the basis of Eq. [4] is to introduce an empirical parameter as

$$R_s \text{ (actual)} = \frac{k\rho}{4a} \qquad [5]$$

With $a = 4 \times 10^{-4}$ cm, k may be then evaluated from the actual sample resistivity. This has been done for the data of Fig. 1 and is plotted in Fig. 2. No attempt will be made at the present time to explain the detailed variation of k with resistivity and conductivity type; however, the existence of a higher k value for n-type silicon of a given resistivity is consistent with the zero-bias barrier resistance concept in that the published (19) values of work-function indicate that a contact between osmium and n-silicon should be rectifying and that between osmium and p-silicon should be ohmic; since $\phi m > \phi_s$ in this case. A further treatment of this aspect of the spreading resistance technique is in progress.

Considering the individual measurements of spreading resistance in the data shown in Fig. 1, the fractional standard deviation of the group of measurements made on a particular sample varied from 0.04 to 0.25, depending on the sample, with more than 90% of the samples having fractional standard deviations in the range 0.04-0.15. The existence of a specific, reproducible fractional standard deviation for each particular sample used in the calibration work indicates that much of the scatter of individual data points is probably due to inhomogeneities in resistivity in samples used. The existence of specific samples with spreading resistance fractional standard deviations on the low end of the range (0.04-0.06) clearly shows that the inherent reproducibility of the measurement technique itself must be consistent with a fractional standard deviation of about 0.05 Therefore, it is highly unlikely that a single measured R_s value will be in error by more than ±15%, at least on bulk silicon.

Inhomogeneous Resistivity Material

After establishing calibration data and the reliability of the spreading resistance measurements on bulk "homogeneous" silicon samples, experimental attention was turned to the investigation of inhomogeneous samples. In this regard, the size of the contacts used is of paramount importance as the spatial resolution of the measurements made depends directly on the size of the spreading resistance contact.

An initial calculation of the contact radius under the conditions used in this work was made on the basis of the Hertz formula, Eq. [2], assuming elastic deformation of the materials involved. The values of Young's modulus for silicon and osmium were taken as (20) Silicon, $E = 1.884 \times 10^{12}$ dynes/cm^2; Osmium, $E = 5.4 \times 10^{12}$ dynes/cm^2. The other parameters used were:

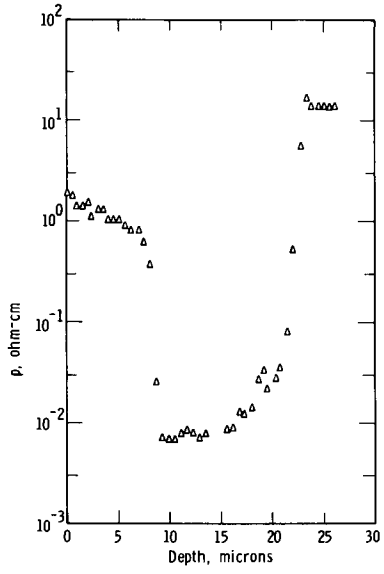

Fig. 3. Resistivity profile of an n-n$^+$ epitaxial silicon layer as determined with a spreading resistance probe.

$r = 0.001$ in. $= 2.54 \times 10^{-3}$ cm; $F = 4.9 \times 10^4$ dynes (a load of 50g). The calculation leads to a value $a \cong 4 \times 10^{-4}$ cm.

The validity of this calculation is admittedly open to question in that, although the stress applied is well within the elastic range of osmium, the silicon surface is visibly damaged by what appears to be local microcracking. However, experimental measurements of the average diameter of these microcracked regions agree well with the value $a = 4 \times 10^{-4}$ cm. We thus assume that the contact radius of our spreading resistance contacts is 4×10^{-4} cm.

On the basis of the above and the known (14) spatial distribution of the equipotentials around circular flat contacts, it is apparent that useful quantitative data may be derived from spreading resistance measurements with a resolution of 1-2μ. In addition, for silicon giving a relatively large zero-bias barrier resistance, the spatial resolution may be better, as the zero-bias barrier-resistance depends essentially on the surface layer of the silicon only. An illustration of the resolution obtained experimentally is given in Fig. 3, which is a plot of the local resistivity of an epitaxially produced n on n$^+$ on p silicon wafer. These data were taken by beveling the wafer at a nominal three-degree angle and probing down the bevel with the pair of spreading resistance probes arranged parallel to the intersection of the bevel surface and the upper surface, the "edge" of the bevel. Measured values of spreading resistance were related to material resistivity through the use of Fig. 1 and the resistivity values plotted against the depth below the surface. The resolution of the technique may be seen in the delineation of the nn$^+$ boundary at a depth of 8μ, where the resistivity is seen to change by about two orders of magnitude in a depth increment less than 2μ.

As previously mentioned, the original derivation of spreading resistance magnitude assumed homogeneity in the material concerned. Thus, the presence of low-high or pn junctions near the spreading resistance contacts on silicon will affect the measurements. It is obvious, for instance, that a transition from high resistivity to low resistivity occurring within the spreading resistance region will shunt the resistance associated with a probe placed on the high resistivity material, and that an insulating boundary (or a pn junction) nearby would have the opposite effect. One of the authors (21) has provided the necessary correction to the measured R_s for the case of approach to an insulating boundary, which can be important in the study of diffused layers. Our results indicate that for layers less than several contact radii thickness, the corrections may be significant, depending on the actual resistivity profile. Because of the extent of these calculations the problem of these immediately adjacent inhomogeneities will not be covered completely in this paper.

Multilayer epitaxial structure.—Figure 4 is a plot of local resistivity *vs.* depth beneath the surface of an angle-lapped sample with an epitaxially produced n$^+$n n$^+$n configuration on a p$^+$ substrate. The resistivity values were derived from the measured spreading resistance of a single probe (using as base contact an ultrasonically soldered strip along one edge of the beveled surface in order to obtain a low-resistance contact to all conductivity regions) traversing the beveled surface from the original outer surface of the sample (all the points to the left of the vertical dashed line) over the edge of the bevel (indicated by the vertical dashed line) and down the bevel into the substrate region. The thickness of material plotted in the figure represents only the epitaxially grown layers, with the substrate material continuing to the right. The horizontal dashed line on the right is drawn to

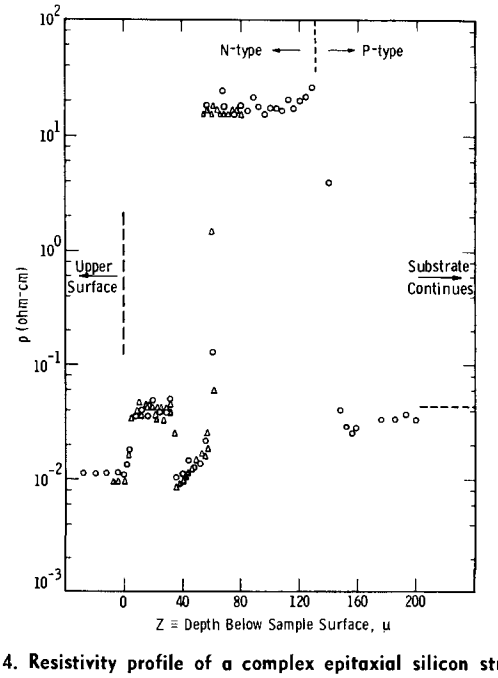

Fig. 4. Resistivity profile of a complex epitaxial silicon structure containing an n-p junction.

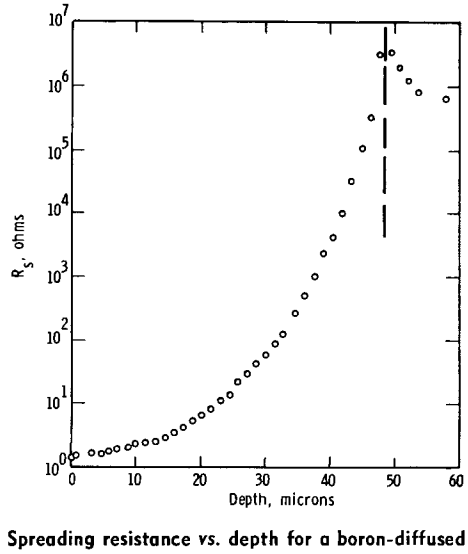

Fig. 5. Spreading resistance *vs.* depth for a boron-diffused sample

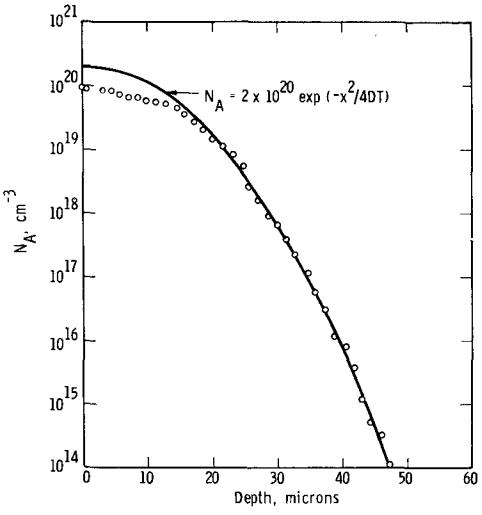

Fig. 6. Boron concentration *vs.* depth derived from spreading resistance measurements.

indicate the continuing substrate material and is positioned so as to correspond to the substrate wafer's resistivity according to its manufacturer (0.043 ohm-cm). The circles and triangles refer to two separate runs down the angle-lapped surface, separated horizontally by 20-30μ (to avoid overlap of residual-damage regions) and indicate the over-all reproducibility of the measurements on this type of material. The run plotted as triangles was not carried all the way through the p-n junction. The scatter seen in the points of a particular resistivity region is thought to be real inasmuch as some epitaxially grown silicon (not deliberately doped), measured under identical conditions as used in obtaining the data shown in Fig. 4, gave as many as 30 points with a scatter less than 2%.

The data of Fig. 4 near the p-n junction or one of the low-high junctions are not to be considered accurate to the $\pm 15\%$ estimated for points in regions several contact diameters away from inhomogeneities as the formula on which these measurements are based have been derived on the assumption of homogeneous resistivities.

Diffused pn *junctions.*—An example of a spreading resistance determination of a concentration profile resulting from a boron diffusion is given in Fig. 5 and 6. Figure 5 is the measured spreading resistance on a beveled surface of the diffused sample. Figure 6 shows the actual boron concentration as a function of depth, derived from the spreading resistance data as outlined in reference (21). This figure shows the good agreement obtained between the measured concentration profile and the theoretical Gaussian distribution expected for this diffusion. The poor agreement near the surface of the sample may be due to precipitation or other electrical inactivation of the diffused dopant at the high concentrations found there, or to a depletion of boron as the result of thermal oxidation of the sample.

While the present publication does not claim to have thoroughly covered all aspects of the spreading resistance resistivity measurement technique, the data does indicate a wide range of application to practical measurement problems; with the hope of further work leading to a solution of the remaining problems.

Acknowledgments

The authors would like to thank T. L. Chu who supplied both continual stimulation and much of the material studied in this work. Appreciation is also extended to H. F. John and O. C. Wells for critical readings of the manuscript and to J. Morris and R. Pfeil, who assisted in the experimental work.

Manuscript received Oct. 4, 1965. This paper was presented at the Pittsburgh Meeting, April 15-18, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Optical Study of the $GeCl_4$/Ge System

K. E. Haq and W. von Muench[1]

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

ABSTRACT

The optical absorption characteristics of $GeCl_4$, both with and without free germanium present in the system, have been studied for the wavelength region between 2300Å and 2μ. Pure $GeCl_4$ was found to have a dissociation continuum with the long wavelength edge beginning at 2700Å at a temperature of 150°C. When free germanium was added to the system, $GeCl_4$ was found to react with it to give rise to one or more species, depending on whether or not the molar quantity of free germanium was greater than that of $GeCl_4$. It has also been observed that $GeCl_2$ has a strong absorption band with a peak at 3150Å.

To understand the phenomenon of germanium film growth in vapor transport processes, it is important to know the species present in the vapor phase at various temperatures and equilibrium conditions. One obvious method is to study the vapor pressure of the gas at different temperatures. However, such a measurement permits unique interpretation only in the very simple case where two molecules are formed from one as a result of reaction. The other possible approaches will be either to study the species by mass spectrographic technique or to study the optical absorption of the molecules. In the present investigation the latter method has been used to study the germanium chlorine system at various temperatures under equilibrium conditions, and significant conclusions with regard to vapor phase species have been drawn. The optical study of this system is considered particularly important since there is no report in the literature of such a study for the wavelength region 2300 to 20,000Å.

Experimental Arrangement

The experimental arrangement is shown in Fig. 1. A chopped monochromatic beam of light emerging from the exit slit of a Perkin Elmer double pass monochromator fell first on a plane mirror M_1, then on concave mirrors M_2 and M_3 and finally on the photomultiplier. An RCA 1P28 photomultiplier tube was used as a detector. The sample cell was placed in the central part of the furnace, located in the path of the monochromatic beam of light between the concave mirrors M_2 and M_3. The furnace consisted of three coils, a central coil and a back up coil on each end, both of which could be controlled independently from the central coil. Thus, in the investigation of the $GeCl_4$ + Ge system the windows could be maintained at a slightly higher temperature than the experimental chamber in order to prevent deposition of germanium on the windows of the cell. A quartz window was placed at each end of the furnace to minimize chimney effects.

[1] Present address: IBM Laboratory, Boeblingen, Germany.

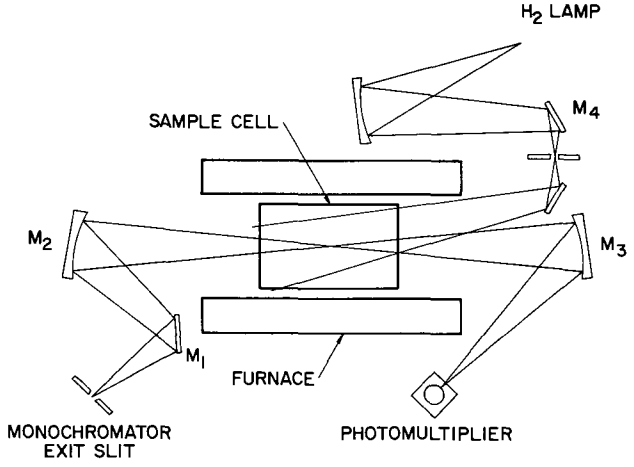

Fig. 1. Optical arrangement for transmittance measurement

The sample cell consisted of a cylindrical quartz tube 120 mm long and 35 mm in diameter with a quartz window at each end. Introduction of $GeCl_4$ into the sample cell was accomplished in the following manner: The $GeCl_4$ liquid was distilled *in vacuo* (after breaking the tip of the supply) into small calibrated Pyrex or quartz ampoules in a sealed system. The ampoules provided with a breaking tip, were sealed and removed from the system while the $GeCl_4$ was kept at liquid nitrogen temperature. An ampoule was then placed (with or without a weighed amount of additional solid Ge) in the sample cell, which was pumped to a pressure of 5×10^{-6} mm Hg and sealed. The purpose of sealing the tube at high vacuum was to eliminate the possibility of contaminating the sample with water vapor or other gases. The sample cell had a built-in thermocouple well which permitted accurate measurement of the temperature of the gas. In most of the experiments, the amount of $GeCl_4$ introduced into the cell produced a pressure of approximately ½ atm at 100°C.

By means of an additional mirror, M_4, continuous light from a strong uv source could be shined on the sample to perform the optical dissociation experiments described in a subsequent section.

Result

The absorption studies were conducted for the wavelength region 2300 to 20,000Å. Since no significant absorption was observed at wavelengths beyond 5000Å, the data for that region are not shown in the graphs.

The transmittance of pure $GeCl_4$ gas as a function of wavelength is shown in Fig. 2. At 150°C an absorption edge beginning at 2300Å and extending into the shorter wavelength regions was observed. As the temperature of the sample was raised, the absorption increased and the absorption edge shifted to longer wavelengths. However, in the temperature range (150°C $T \leq$ 800°C), in which the investigation was made, no absorption band due to pure $GeCl_4$ at wavelengths exceeding 3000Å was observed. The nature of the absorption in the short wavelengths region was investigated in more detail and is described in a subsequent paragraph.

Figure 3 shows the transmittance of $GeCl_4$ at various temperatures when solid germanium was present in the system. The amount of $GeCl_4$ introduced into the cell was approximately the same as that in the cases represented by Fig. 2. The molar quantity of Ge added was less than that of $GeCl_4$. The solid germanium was first etched with White etch and then thoroughly washed with DI water and alcohol before being introduced into the cell, in order to prevent contamination of the sample by the surface oxide layer.

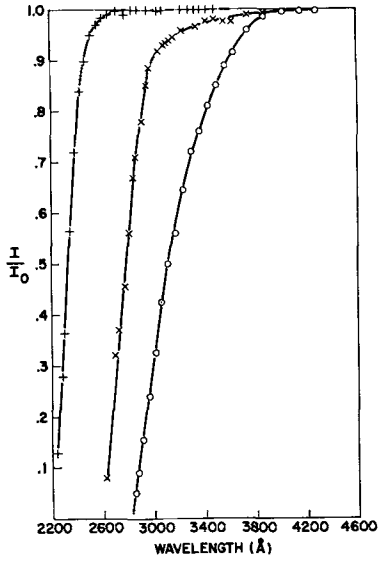

Fig. 2. Transmittance of pure $GeCl_4$. +, 150°C; ×, 500°C; ○, 800°C; $GeCl_4$ pressure at 100°C, 380 mm Hg.

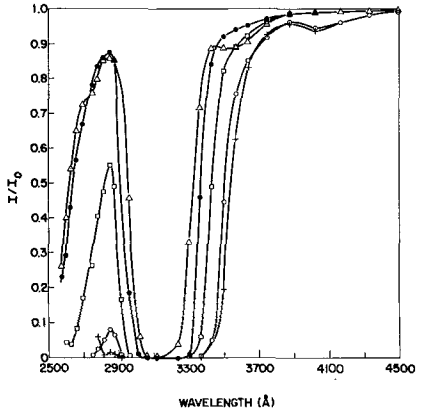

Fig. 3. Transmittance of germanium deficient system. △, 200°C; •, 250°C; □, 300°C; ○, 400°C; +, 500°C. $GeCl_4$ + 12 mg Ge.

The results in Fig. 3 show that $GeCl_4$ and germanium reacted to give rise to a species which has an absorption band with a peak at 3150Å. As the temperature of the system was raised, this absorption increased rapidly.

In addition, at higher temperatures there is an indication of increased absorption at wavelengths below 2800Å. This is apart from the increase of $GeCl_4$ absorption effected by temperature rise shown in Fig. 2. The following experiment demonstrates this: Two ampules, one containing pure $GeCl_4$ and the other containing solid germanium, were introduced into the cell. First the ampule with $GeCl_4$ was broken, and the absorption of pure $GeCl_4$, both at room temperature and at 500°C, was measured. Similar measurements were then made after breaking the ampule containing solid germanium. The results exhibited in Fig. 3a show that at wavelengths shorter than 2800Å, there was a rise in absorption after the introduction of solid germanium. The absorption of $GeCl_4$ was expected to go down, due to decrease in its concentration as a result of reaction with solid germanium. Contrary to expectation. it increased. This result has been further confirmed by measurements on a flow system in which $GeCl_4$ carried by He was passed through a germanium bed.[2] If the amount of free Ge added exceeded that required to complete the assumed reaction

[2] This result will appear in a subsequent article. Extended Abstract, Electronics Division, Electrochemical Society Meeting, Oct. 11-15, 1964, 13, [2], Abstract No. 141.

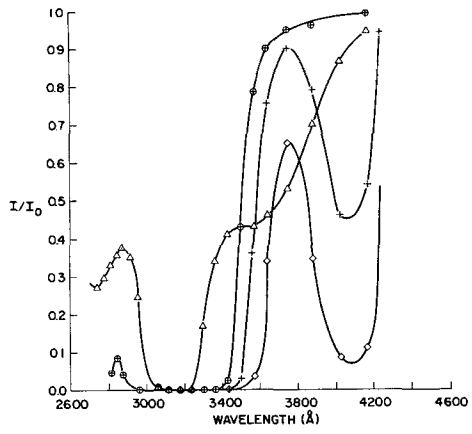

Fig. 4. Transmittance of germanium excess system. △, 180°C; ⊕, 380°C; +, 500°C; ◇, 600°C. Cell 4, $GeCl_4$ + Excess Ge, 101 cm^3, $GeCl_4$, 15 mm.

$$GeCl_4(g) + Ge(s) \rightleftarrows 2GeCl_2(g)$$

an additional band with a peak at 4120Å appeared at 500°C. As the temperature was raised, this absorption also increased (Fig. 4).

In order to understand the absorption due to pure $GeCl_4$ at the short wavelength end of the spectrum, the following experiment was performed: From a hydrogen lamp, a beam of light which could be turned on or off by means of a shutter, was impinged on the sample cell, while the species were monitored by means of a chopped monochromatic beam as before. Precautions were taken to prevent the light from the hydrogen lamp from falling on the photomultiplier. When the beam of light from the hydrogen lamp was turned on by removing the shutter, approximately a 4% decrease in transmission was observed for wavelengths 3300Å and longer.

To determine if any error was introduced in the measurements by possible deposition of germanium on the cell windows, the following experiment was conducted:

A cell containing $GeCl_4$ and solid germanium was heated and cooled several times, while the intensity of the transmitted beam at 3150Å was observed. The intensity (of the transmitted beam) always returned to the initial value when the sample cooled to room temperature, indicating that there was no effect due to deposition of germanium film on the window. Further, when the cell was taken out of the furnace, there was no indication of any germanium film on the window of the cell.

Discussion

For proper understanding of the results, the following cases should be distinguished: (*a*) pure $GeCl_4$ system; (*b*) the $GeCl_4$ and germanium deficient system; (*c*) the $GeCl_4$ and Ge excess system.

A germanium deficient system is one in which the molar quantity of free germanium added is less than the molar quantity of $GeCl_4$. A germanium excess system is one in which the molar quantity of free germanium added is greater than the molar quantity of tetrahalide. The three systems are now discussed individually.

The $GeCl_4$ *system.*—As seen in Fig. 2, pure $GeCl_4$ exhibited only an absorption edge, which, with an increase in temperature, extended into longer wavelength regions. Since no absorption band with a peak at 3300Å (the peak of Cl_2 absorption band) was observed, there was no indication of thermally induced decomposition of $GeCl_4$ within the temperature range of the present investigation. The nature of the long wavelength absorption edge due to pure $GeCl_4$ was investigated by monitoring the species while the sample was irradiated with uv light from a hydrogen lamp

source described earlier. The result of this experiment indicated the formation of new species due to uv irradiation. Thus it was concluded that the absorption edge was the beginning of a dissociation continuum. This result, along with those shown in Fig. 2 (*i.e.*, the extension of the absorption edge to longer wavelengths with rise in temperature of the sample) can be understood in the following way: As the temperature of the sample is raised, higher vibrational levels in the electronic ground state become occupied, and as a result, lower energy photons induce the electron to make transitions to unstable excited states, causing dissociation of $GeCl_4$ molecule. It would appear logical to conclude that one of the dissociation products was chlorine for the following reasons: (*A*) the dissociated species showed absorption at 3300Å; (*B*) the $GeCl_4$ molecules can break up only by releasing free chlorine.

The $GeCl_4$ and germanium deficient system.—With the addition of solid germanium to $GeCl_4$ in molar quantity less than that of the tetrahalide, an additional structure developed upon heating. Most significantly, as seen by comparing Fig. 2 and 3, an absorption band at 3150Å appeared. Less obvious, however, was an enhanced absorption at wavelengths below 2800Å. These two phenomena may be indicative of the formation of either one or two new species as a consequence of the reaction between germanium and $GeCl_4$. However, optical study alone cannot resolve this question.

Based on the results of a recent Bourdon gauge investigation[3] of the $GeCl_4$ and $GeCl_4$-Ge system, it would seem reasonable to attribute the 3150Å absorption band to $GeCl_2$. From the same result one might infer that the enhanced absorption at wavelengths below 2800Å was also due to $GeCl_2$. As will be discussed below, this inference is somewhat tenuous.

The $GeCl_4$ and germanium excess system.—When the molar quantity of Ge exceeded that of $GeCl_4$, an additional band at 4120Å was generated (Fig. 4), implying either the formation of an additional species or an enhanced absorption at a weak absorption band due to increased concentration of $GeCl_2$. However, the latter possibility has been discarded on the basis of the following two experiments: (*i*) with a $GeCl_4$ and germanium deficient system, and (*ii*) with a $GeCl_4$ and germanium excess system. The amount of $GeCl_4$ and free germanium introduced into the cells in the two cases were such that the amount of $GeCl_2$ formed in case (*i*) was far in excess of that formed in case (*ii*). Measurements showed no absorption at 4120Å in the case of the deficient system, while significant absorption was observed in the case of the excess system. This would indicate that a second species was formed if the molar quantity of free germanium added was greater than that of $GeCl_4$. This is indicative of an apparent inconsistency between the results of optical and Bourdon gauge measurements. One possible explanation for the differences observed in the two approaches is that the absorption band with a peak at 4120Å may have been due to a species whose concentration was too small to perturb the pressure data, and yet whose extremely high absorption coefficient made it observable in optical measurement.

In an effort to find possible structure in the 3150Å absorption band, an experiment was performed with much reduced $GeCl_4$ pressure, approximately 1.5 mm Hg, compared to ½ atm in other cases. Results are shown in Fig. 5. Apart from reduced absorption due to corresponding reduction in density of material, no significant difference in absorption characteristics was noticed.

[3] Paper presented by T. Sedgwick at the Toronto Meeting of the Society, May 1964.

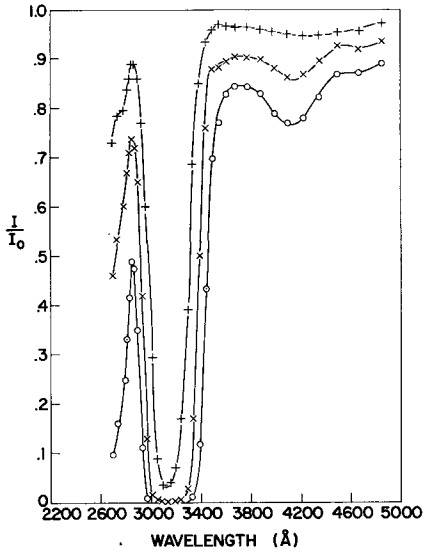

Fig. 5. Transmittance of germanium excess system with low $GeCl_4$ pressure. + 350°C; ×, 400°C; ○, 500°C $GeCl_4$ + Ge. $GeCl_4$ pressure at 100°C = 15 mm Hg.

Conclusions

From the above experiments the following tentative conclusions have been drawn.

1. Up to 800°C there was no thermally induced reaction in the $GeCl_4$ system.
2. When $GeCl_4$ was irradiated with uv light at suitable temperatures, it decomposed into chlorine and some subchloride other than $GeCl_2$.
3. At 300°C, $GeCl_4$ reacted with Ge to give rise to $GeCl_2$ which absorbed at 3150Å.
4. The species formed as a result of reaction between $GeCl_4$ and Ge also absorbed at wavelengths shorter than 2800Å as well as in the region of 3150Å.
5. When the amount of free Ge added was greater than what would be required to complete the assumed reaction

$$GeCl_4 + Ge = 2GeCl_2$$

a second absorption band at 4120Å appeared at 500°C. This absorption was due to some subchloride, presumably GeCl or some other germanium chlorine complex.

Polarization Phenomena and Other Properties of Phosphosilicate Glass Films on Silicon

E. H. Snow and B. E. Deal

Research and Development Laboratory, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

A study has been made of phosphosilicate glass films prepared by predepositing P_2O_5 on thermally oxidized silicon. Many of the properties of these films including composition, density, etch rate, conductivity, dielectric constant, and dielectric strength have been measured and are compared with the corresponding properties of thermally produced silicon dioxide layers. A polarization effect is discussed which gives rise to an increase of about 20% in the dielectric constant of the glass at high temperatures and low frequencies ($\sim$ 250°C at 50 cps). Under d-c bias at lower temperatures this polarization causes a slow drift in the capacitance-voltage characteristic of metal-oxide-semiconductor (MOS) capacitors which use the glass as a dielectric. The MOS capacitance-voltage method is used to study the time, temperature, and voltage dependence of the polarization, and mechanisms are discussed which can account for the observed results.

Modern silicon planar technology (1) involves the use of silicon dioxide films to mask certain areas of the underlying silicon against the diffusion of n- and p-type dopants. The thickness of SiO_2 required to mask against various phosphorus diffusion conditions has been investigated by Sah, Sello, and Tremere (2) and by Allen, Bernstein, and Kurtz (3). Sah *et al.* concluded that P_2O_5 vapor reacts with SiO_2 to form a layer of P_2O_5-SiO_2 glass of an unknown composition over the remaining pure SiO_2. The thickness of the glass layer increases at the expense of the SiO_2 as phosphorus diffuses through the glass and reacts at the interface. A cross section of such an oxidized silicon surface subsequently predeposited with P_2O_5 is sketched in Fig. 1. The existence of the sharp interface has been verified by Pliskin and Gnall (4) who developed a selective etch which removes the phosphorus containing glass much faster than the SiO_2 underneath.

The phase diagram of the SiO_2-P_2O_5 system has been determined by Tien and Hummel (5), and Kooi (6) has recently studied the composition of glass layers obtained by depositing P_2O_5 on silicon and diffusing in nitrogen or oxygen at 920°-1310°C. In general, Kooi found that after a sufficiently long diffusion time the composition of the glass approached that corresponding to the limiting solubility of SiO_2 in the liquid phase.

In device manufacture, the glass layer which remains on the passivating oxide after phosphorus diffusion may or may not be removed by etching, but it has recently been reported by Kerr, Logan, Burkhardt, and Pliskin (7) that the presence of a phosphorus glass layer greatly increases the stability of planar transistors and MOS devices under temperature and voltage stressing.

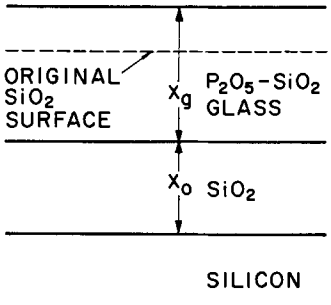

Fig. 1. Cross section of a phosphosilicate glass-silicon dioxide double layer on a silicon substrate. The double layer is prepared by predepositing P_2O_5 on a thermally oxidized silicon slice.

Because of its importance in silicon technology and particularly in view of the results of Kerr *et al.* there is need for a more thorough knowledge of the properties of the SiO_2-P_2O_5 system. The present paper surveys some of these properties and describes an electrical polarization effect which limits the stability of MOS devices utilizing phosphorus glass.

Experimental

Preparation of oxide layers.—The silicon used in these studies was single crystal, Czochralski pulled, (111) surface oriented with an initial dislocation count of less than 100 cm^{-2}. It was obtained in the form of circular slices, lapped both sides to 250μ thickness from the Kollstan Semiconductor Elements Company, Westbury, New York. Both n-type (phosphorus) and p-type (boron) silicon with dopant concentrations in the 10^{15} to 10^{16} cm^{-3} range were included in these studies. Slices used for thickness or weight measurements were mechanically polished, with 25μ removed per side. To assure clean, noncontaminated surfaces, these slices were then cleaned in both organic and inorganic solvents. Silicon slices used for electrical measurements were cleaned and then chemically polished in a HF:HNO_3 solution and quenched in acetic acid. At least 50μ per side was removed by this procedure.

All slices were oxidized in dry oxygen at 1200°C. Oxide thicknesses varied, depending on the particular measurement being conducted, but generally were between 0.10 and 0.50μ (1000-5000Å). Following oxidation, some of the samples were placed in a P_2O_5 predeposition[1] furnace for various times. For the most part the substrate temperature was 1020° $\pm$ 1°C with the P_2O_5 source at 230° $\pm$ 2°C. Dry nitrogen was the carrier gas. In some cases subsequent diffusions were carried out at temperatures ranging from 1020° to 1200°C in nitrogen or oxygen.

For those experiments in which electrical measurements were made, such as dielectric breakdown, conductivity, etc., field plates were prepared by evaporating 3000Å of aluminum over the oxide and preparing circular dots 250-1400μ in diameter by photoresist techniques. The oxide was then stripped from the back of the slice, aluminum was evaporated on the bare silicon, and alloyed at 550°C for several minutes to assure good ohmic contact.

Thickness measurements.—In the next section, several properties of the predeposited P_2O_5-SiO_2 system are reported. The experimental procedures involved

[1] The term predeposition, as used in semiconductor technology, is that step preceding diffusion in which the semiconductor slice is given a relatively short thermal treatment in the presence of an ambient containing a doping impurity (1).

in each particular measurement are described as that property is discussed. However, since the measurement of the oxide and glass layer thicknesses was required for all determinations, the general method will be discussed here.

Multiple beam interferometry was used for the film thickness measurements. The principle of this technique, which involves the measurement of an interference fringe displacement across a metallized step etched in the oxide, has already been adequately described (8, 9). For this particular work, a silver film was evaporated over a step etched in the oxide layer with 49% HF. The reference surface was a glass slide evaporated with a 97% reflecting multilayer dielectric film prepared by Optics Technology, Palo Alto, California.

Initial examination of fringe displacements across steps etched in phosphorus glass indicated a much more abrupt step than was obtained on regular thermal oxides. This was true whether the oxides were etched separately, or as a double layer, as pictured in Fig. 1. Photographs of the actual fringes obtained are shown in Fig. 2. In (a) and (b) the difference in step profile can be readily observed between the P_2O_5-SiO_2 glass and the conventional thermal SiO_2. The taper of the SiO_2 step depicted by the fringes in Fig. 2(b) was reported by Booker and Benjamin (9) to be due to undercutting of the oxide by the HF. Figure 2(c) shows fringes produced due to a step etched (with HF) across a mixed glass-thermal oxide layer. This system was produced by predepositing P_2O_5 over an existing SiO_2 film. Again the difference in etching characteristics can be seen, with the abrupt fringe change due to the P_2O_5-SiO_2 glass and the tapered change due to the underlying SiO_2.

It appeared that the difference in etching characteristics across a double layer oxide as indicated in Fig. 2(c) might provide a rapid means of determining thicknesses of the two layers. To check this possibility, special measurements were conducted. These involved

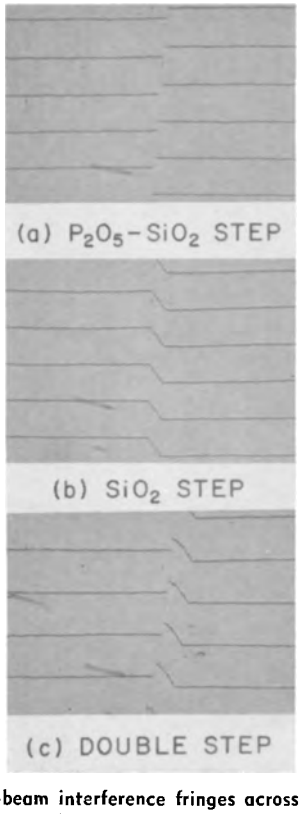

Fig. 2. Multiple-beam interference fringes across metallized steps etched in three types of oxides. Phosphosilicate glass is shown in (a), (b) is standard thermal silicon dioxide, while (c) shows double step in phosphosilicate glass over standard thermal oxide. Area to left of steps represents top surface of oxides.

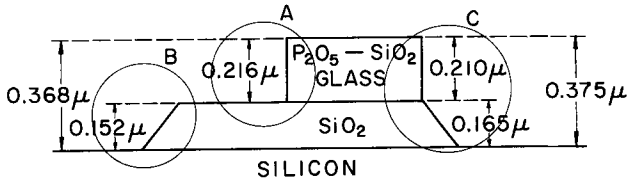

Fig. 3. Cross section of phosphosilicate glass over silicon dioxide, showing thickness values obtained for single step measurements (regions A and B), as compared with double step measurement (region C). Corresponding fringes for regions A, B, and C are shown in Fig. 2.

preparing a double layer oxide (P_2O_5-SiO_2 over SiO_2), selectively etching a portion of the glass from the SiO_2 (see next section), etching a second step in the exposed SiO_2, and measuring the fringe displacements across the resulting steps. Results were compared with fringes crossing a step made by etching through the entire double layer. The photographs in Fig. 2 are typical of these measurements and the measured thicknesses are indicated in Fig. 3. The circled areas labeled A, B and C in Fig. 3 represent the corresponding regions pictured in Fig. 2 with A and B being the single steps and C the double step. It can be readily observed that the thickness values obtained from the double step are within 100Å of the single step determinations. The ultimate accuracy of the method would be determined by the selectivity of the etch used to remove the glass layer and the sharpness of the interface between the two layers.

The above method has been used successfully on various glass-silica systems and becomes even more useful when the etch rates of the two oxides approach each other and a selective etch cannot be used rapidly for single step measurements. In the above case the phosphorus glass etched 100 times faster than the SiO_2. Instead of causing more undercutting and thus a more tapered step in the glass, the conditions of etching evidently are such that a more vertical etch profile is obtained.

Properties of SiO_2-P_2O_5 Layers

Composition.—The ratio of P_2O_5 to SiO_2 in a predeposited phosphosilicate layer over oxidized silicon was determined as follows. Weights of a silicon slice were determined using a Mettler Model M-5-S/A Microbalance at the following processing steps.

Wt 1. Original cleaned, chemically polished silicon.
Wt 2. After oxidizing in dry O_2 to desired oxide thickness, *i.e.*, 3000Å.
Wt 3. After predepositing P_2O_5 in N_2 onto oxidized silicon.
Wt 4. (Optional) After diffusing predeposited, oxidized silicon in N_2 or O_2.
Wt 5. After selectively etching P_2O_5-SiO_2 glass from SiO_2 using Pliskin's "P-etch" (15 parts conc. HF, 10 parts conc. HNO_3, and 300 parts H_2O) (4).
Wt 6. After stripping remaining SiO_2 in conc. HF.

The accuracy of the weight measurements was ± 2 μg, with a typical 3000Å oxide weighing 680 μg or 70 $\mu g/cm^2$.

From the gain in weight due to predeposition (Wt 3-Wt 2) and the weight of the glass layer (Wt 3-Wt 5), the ratio of P_2O_5 to SiO_2 in the glass could be determined.[2] Also by comparing total thermal oxide weight (Wt 2-Wt 6) with total silicon consumed (Wt 1-Wt 6) a measure of the oxidation efficiency may be determined (10). In these experiments, it was shown that no additional SiO_2 was formed during predeposition, and thus all weight gain during this step was P_2O_5. This is due mainly to the N_2 ambient used during predeposition.

The over-all results indicated that at a predeposition temperature of 1020°C, 5-6 moles of SiO_2 were present

[2] For the purpose of this analysis, all silicon oxide was assumed to be SiO_2 and all phosphorus oxide P_2O_5.

in the glass layer to 1 mole of P_2O_5. In terms of atoms, one out of four silicon atoms are replaced by a phosphorus atom during the predeposition, with an extra oxygen atom being associated with every two phosphorus atoms. The above ratio corresponds to about 14.5 to 16.5 mole % of P_2O_5, which agrees with the findings of Kooi (6) in related work involving the SiO_2-P_2O_5 system. This composition was constant over predeposition times of 10-60 min.

If the predeposited structure was subjected to additional thermal treatment (diffusion) in oxygen or nitrogen for 30 min, either at 1020°C or higher temperatures, a ratio of SiO_2 to P_2O_5 was obtained representative of the diffusion temperature. These compositions corresponded to those given in ref. (6); the value at 1020° remaining at about 15 mole % while at 1200° the P_2O_5 concentration dropped to 7 mole %. Additional diffusion time decreased the P_2O_5 percentage only very slowly.

It should be noted that thickness measurements indicated that the movement of the glass "front" into the SiO_2 during predeposition obeyed a diffusion-controlled relationship, *i.e.*, $y = kt^{1/2}$, where y is the distance of the front from the original outer surface of the SiO_2 and t is the predeposition time. At 1020°C, $k \approx 0.18\ \mu/\sqrt{\text{hr}}$ in agreement with data first reported by Sah, Sello, and Tremere (2). The total volume increase of the oxide due to phosphorus was about 40% at 1020°C, agreeing with the composition and density (see next paragraph) results.

Density.—Apparent densities of the P_2O_5-SiO_2 glass layers were obtained using the weight and thickness results. In general the density values were between 2.35 and 2.40 g/cm^3. This compares with 2.24-2.27 g/cm^3 for the underlying SiO_2 layer, the latter agreeing quite well with earlier results (11). The density of amorphous P_2O_5 is reported to be 2.39 g/cm^3 (12), and so the values for the P_2O_5-SiO_2 glass mixture determined in this work are reasonable when the results of the previous section are considered.

Etch rate.—The etch rate of the phosphosilicate glass in Pliskin's p-etch (4) appeared to be a function of P_2O_5 content. For the higher phosphorus concentration (16 mole % P_2O_5 obtained at a 1020°C predeposition temperature) the rate was 500 Å/sec. However, as the P_2O_5 concentration decreased to 7% at 1200°C, the etch rate also decreased (logarithmically) to 15 Å/sec. The corresponding value for SiO_2 in this etch is about 2 Å/sec. As discussed in the section above describing thickness measurements, the phosphosilicate glass also etches much more rapidly than SiO_2 in HF solutions, but both etch so rapidly it is not known if the same dependence on P_2O_5 concentration exists.

Sodium masking.—It has been reported (7) that a thin layer of P_2O_5-SiO_2 glass over SiO_2 on MOS-type devices will greatly reduce drift in the capacitance-voltage characteristic under bias at elevated temperatures (~200°C). Special experiments were conducted to test this possibility. MOS structures, prepared both with a 0.20μ thermal SiO_2 layer and with a double-layer consisting of 0.15μ of SiO_2 plus 0.07μ of P_2O_5-SiO_2 glass, were contaminated with sodium ions prior to metallization (13). Noncontaminated controls were also included. Under 10v bias at 300°C for 5 min, the standard, noncontaminated SiO_2 samples did not drift in voltage by more than 0.5v with bias of either polarity. The contaminated SiO_2 samples drifted more than —60v under the positive field plate bias, with no drift under negative bias. Both the noncontaminated and the contaminated P_2O_5 glass structures drifted about 1v under both positive and negative bias. This drift was undoubtedly due to a polarization phenomenon to be discussed later. It was clear, however, that the P_2O_5 layer prevented the large drift due to sodium ion migration which was observed in the contaminated silicon dioxide sample.

Electrical conductivity.—For determining electrical properties of the P_2O_5-SiO_2 glass layers, special structures were prepared. This was done by predepositing the P_2O_5 at 1020°C over a 0.20μ thermal oxide so that the glass front extended to within 100Å of the silicon surface. The total glass thickness was 0.275μ. A thermal oxide of the same thickness but without phosphorus was used as a control. MOS structures were prepared as described in the Experimental Section, with aluminum dot diameters of 250, 440, 800, and 1400μ.

Using these samples, the electrical conductivity of the phosphosilicate glass was compared with that of pure SiO_2. Currents corresponding to an approximate steady state were measured after a bias of ±10v had been applied for 10 min at 200°C. In the case of the silicon dioxide samples, the currents under either polarity were too small to measure and corresponded to less than 10^{-11} amp/cm^2. In the case of the phosphosilicate glass the currents were easily measureable and gave current densities in the range 2 to 3 x 10^{-10} amp/cm^2. If bulk resistivities at 200°C are calculated from these data, the values obtained are 2 x 10^{15} ohm-cm for the phosphosilicate glass and greater than 5 x 10^{16} ohm-cm for the SiO_2.

Dielectric breakdown.—Dielectric breakdown values were obtained using an Anodicator (manufactured by the R. O. Hull Company, Rocky River, Ohio). The applied voltage (60 cps a.c.) was increased at the rate of 32 v/sec until breakdown occurred. Values of the peak field at breakdown were 1200 -1450 v/μ (848-1025 v/μ rms) for the phosphosilicate glass samples compared to 810-870 v/μ (572-615 v/μ rms) for the SiO_2. Even though leakage currents are larger, the phosphosilicate glass shows a marked increase in dielectric strength. This has also been found to be the case with other glasses formed by predeposition over thermal oxides on silicon.

Dielectric constant.—Small-signal capacitance measurements were made in the frequency range 50 cps to 100 kc/sec using Boonton model 74C and Wayne-Kerr type B221 bridges. During the measurements a large negative d-c bias was applied to the field plate so that the p-type silicon surface was strongly accumulated and the true oxide capacitance was obtained. From the measured capacitance, the field plate area, and the oxide thickness, dielectric constants were calculated and were found to be independent of frequency at room temperature. The values obtained were in the range 4.0 to 4.1 for the phosphosilicate glass. Slightly lower values of 3.75 to 3.9 were obtained for the thermal oxides in agreement with previously published values (14, 15).

The temperature dependence of the dielectric constant was also investigated, and in the case of the phosphosilicate glass it was found to increase markedly at high temperatures and low frequencies. Figure 4 shows the dielectric constant *vs.* temperature at 50 cps for both the glass and the SiO_2 samples. For the glass, the dispersion is about 20% while for the SiO_2 it is less than 1%. At higher frequencies, the dispersion shifts to higher temperatures and vice-versa. Under a d-c bias, the polarization effect responsible for the dispersion manifests itself as a drift in the ca-

pacitance-voltage characteristic of the MOS structure. This drift was observed in the sodium masking experiment above and was the subject of an extensive investigation to be described in the next section.

A summary of the properties reported above for the silicon-dioxide and the phosphosilicate glass layers on silicon is shown in Table I. In the case of the phosphosilicate layers, only the properties of the glass formed by predeposition at 1020°C are included.

Polarization Effects

The phosphosilicate glass films[3] were examined for polarization effects using the MOS capacitance-voltage method (15). In applying this method to study polarization, one first measures the initial capacitance-voltage characteristic of the device. A polarizing voltage V_P is then applied to the field plate for a given length of time at an elevated temperature. After quenching to room temperature, the C-V characteristic is remeasured and any shift ΔV along the voltage axis is related to charge displacement or polarization in the glass. The details of the technique are described in ref. (13) and (16). In addition to being a measure of the polarization, the shift ΔV has a very practical significance since it corresponds directly to the change in turn-on voltage which would be observed in an MOS transistor using the glass for gate insulation.

In these films, two distinct and easily separable polarization effects were observed. The first of these was relatively small and saturated rapidly at low temperature (a few minutes at ~100°C). The second effect was much larger, but required over 100 hr at 300°C to reach saturation. We shall discuss the smaller low temperature effect first.

Low-temperature polarization.—The time dependence of the shift in the C-V characteristic of a typical sample at 60°C and —50v bias is shown in Fig. 5. The

[3] All phosphosilicate films used for the following polarization studies were prepared by depositing P_2O_5 at 1020°C for various times onto thermally formed SiO_2.

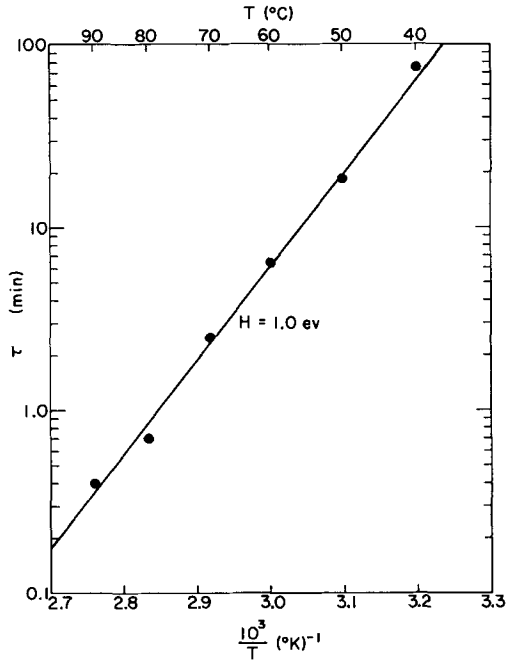

Fig. 6. Temperature dependence of the time constant for polarization of the phosphosilicate glass layer. The polarization process is characterized by an activation energy of about 1 ev.

approach to saturation is not exponential and a detailed description would require a broad distribution of time constants. Nevertheless, we define an effective time constant τ as that time required for ΔV to come within $1/e$ of its saturation value. This is about 6 min in the example of Fig. 5. The effective time constant τ was evaluated at several other temperatures between 40° and 100°C, and its dependence on temperature is shown in Fig. 6. This temperature dependence can be described by an activation energy of 1.0 ev (23 kcal/mole).

The time constant was not very sensitive to the magnitude or sign of the applied polarizing voltage V_P, but the saturation drift ΔV_{SAT} was almost precisely proportional to V_P and was opposite in sign. In Fig. 7, a number of capacitance-voltage curves are shown which were obtained from the same device after biasing at various voltages at 120°C for 5 min (more than sufficient to reach saturation). These curves were reproducible and did not depend on past history. They could be obtained in any order by simply biasing at the desired voltage for a time long enough to achieve saturation. Upon heating under short circuit the characteristic always returned to the zero bias case. The

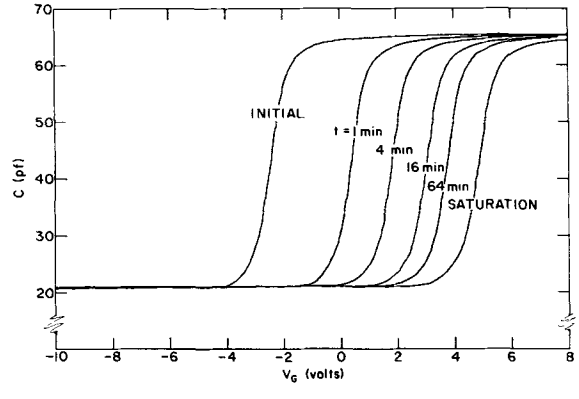

Fig. 5. Capacitance-voltage curves obtained on a double-layer capacitor after application of —50v to the field plate at 60°C for various lengths of time. The shift of the C-V characteristic is due to the build-up of a polarization in the phosphosilicate layer.

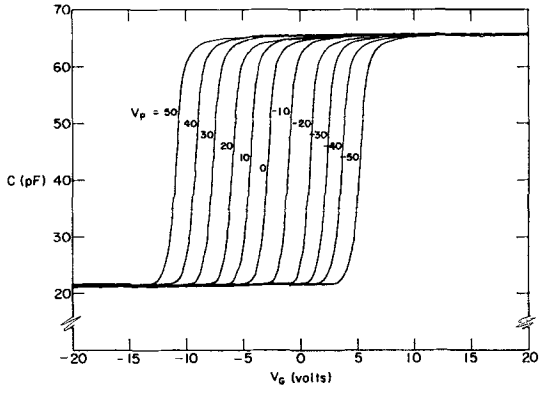

Fig. 7. Capacitance-voltage curves obtained on a double layer capacitor after biasing until saturation at various applied voltages. The shift of the C-V curve ΔV_{SAT} is proportional to the applied voltage. $x_g = 0.24\mu$; $x_o = 0.04\mu$.

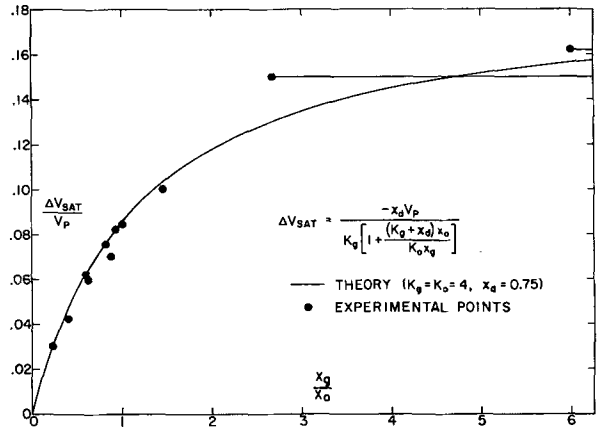

Fig. 8. Dependence of the saturation shift of the C-V curve per unit applied voltage $\Delta V_{SAT}/V_P$ on the phosphosilicate glass to silicon dioxide thickness ratio x_g/x_o. Each point corresponds to a different sample. The theoretical curve is calculated from Eq. [9]. ——, Theory ($K_g = K_o = 4$; $x_d = 0.75$).

saturation drift per unit applied voltage $\Delta V_{SAT}/V_P$ was found to be larger for larger values of the glass-to-oxide thickness ratio x_g/x_o. This dependence was investigated on a large number of samples with a wide range of x_g/x_o ratios and the results are shown in Fig. 8. The points corresponding to very large x_g/x_o ratios are rather uncertain because of difficulty in measuring the thinnest oxide layers. The curve through the data points is a theoretical one, and its basis will be discussed later. These data show that $\Delta V_{SAT}/V_P$ is a saturating function of x_g/x_o and that even when the insulating layer is essentially all phosphorus glass ΔV_{SAT} is only about 18% of the applied polarizing voltage.

Similar drift effects in a lead borosilicate glass have been explained by the migration of mobile cations in the glass (16). These ions drift under an applied polarizing voltage until space charges have been built up at the metal-glass and glass-oxide interfaces which completely cancel the electric field in the glass layer. This model predicts a saturation drift in the C-V characteristic which is given by

$$\Delta V_{SAT} = -\frac{K_o x_g}{K_g x_o} V_P \qquad [1]$$

where K_o and K_g are the relative dielectric constants of the oxide and glass, respectively. Hence for large x_g/x_o, ΔV_{SAT} can be many times the polarizing voltage. In the present experiments, on the other hand, ΔV_{SAT} was not proportional to x_g/x_o and was always much less than V_P. This shows that the polarization is not due to the unlimited migration of ions within the glass layer which would correspond to an infinite polarizability but must be described by a finite polarizability χ_p. Under an applied voltage, such a polarizability will give rise to the slow build-up of a uniform volume polarization $P = \epsilon_o \chi_p E_g$ where ϵ_o is the permittivity of free space and E_g is the field in the glass layer.[4] This slow polarization is in addition to the instantaneous polarization which is related to the high-frequency dielectric constant K_g. Such a volume polarization is equivalent to a surface charge on the glass-oxide interface of density

$$Q_p = P = \epsilon_o \chi_p E_g \qquad [2]$$

and a surface charge on the glass-metal interface of equal magnitude but opposite sign.

After equilibrium is reached, we can relate Q_p to the applied polarizing voltage as follows. The applied voltage must be the sum of the voltage drops across the oxide and glass layers

$$-V_P = E_g x_g + E_o x_o \qquad [3]$$

Also, the fields in the glass and oxide are related by

$$K_o E_o = (K_g + \chi_p) E_g \qquad [4]$$

since the electric displacement must be continuous across a dielectric interface. Eliminating E_o between [3] and [4] we obtain

$$E_g = \frac{-K_o V_P}{(K_g + \chi_p) x_o + K_o x_g} \qquad [5]$$

and substituting this into [2] we have

$$Q_p = \frac{-K_o \epsilon_o \chi_p V_P}{(K_g + \chi_p) x_o + K_o x_g} \qquad [6]$$

If C_g and C_o are the capacitances of the glass and oxide layers, respectively, then the charge induced in the silicon by Q_p is

$$Q_s' = \frac{C_o Q_p}{C_o + C_g} \qquad [7]$$

and the shift in the C-V characteristic caused by this excess charge is

$$\Delta V_{SAT} = \frac{(C_o + C_g)}{C_o C_g} Q_s' = \frac{Q_p}{C_g} = \frac{x_g Q_p}{\epsilon_o K_g} \qquad [8]$$

Finally, substituting [6] into [8] we obtain for the saturation drift as a function of applied voltage

$$\Delta V_{SAT} = \frac{-K_o x_g \chi_p V_P}{K_g[(K_g + \chi_p) x_o + K_o x_g]} \qquad [9]$$

Note that if we let $\chi_p \to \infty$, this reduces to Eq. [1] for a completely polarizable glass layer.

Equation [9] gives a linear dependence of ΔV_{SAT} on V_P and predicts that $\Delta V_{SAT}/V_P$ is a saturating function of x_g/x_o as was observed experimentally. The theoretical curve in Fig. 8 was plotted from Eq. [9] using the approximate values $K_o = K_g = 4$ and choosing for the polarizability $\chi_p = 0.75$. It will be seen from the figure that this single value of the polarizability is in reasonable agreement with the data on all of the samples which have been measured. Since these samples were prepared in several different furnaces and on some of them $POCl_3$ was substituted for P_2O_5 as a source of phosphorus, it seems unlikely that this polarizability results from an unintentional trace contamination. It is more likely that it is an intrinsic property of the phosphosilicate glass itself.

It has been assumed throughout the preceding discussion that the polarization was uniform throughout the glass layer and was zero in the oxide layer. This fact was demonstrated by an etching experiment using two identical samples. One was polarized at —60v while the other remained unpolarized. The aluminum electrodes were then etched off both samples and the glass layers were etched away in small steps. After each step C-V curves were made using a gold ball pressed against the glass surface as the metal electrode. The displacement between the C-V curves made on the polarized and unpolarized samples was then plotted as a function of the remaining glass thickness and the result is shown in Fig. 9. The straight line thus obtained verifies the linear dependence of ΔV on x_g (for a given Q_p) which is predicted by Eq. [8]. Since this equation was derived on the basis of a uniform polarization in the glass, that assumption is justified. The fact that ΔV goes to zero when all of the glass is removed proves that there is no polarization in the SiO_2 layer.

The mechanism responsible for the polarizability χ_p has not been established, but two possibilities will be considered. These are illustrated schematically in Fig. 10 (a) and (b). The first is the orientation of permanent dipoles uniformly distributed in the glass. This mechanism results (17) in a polarizability given by

[4] Rationalized MKS units are used throughout this section.

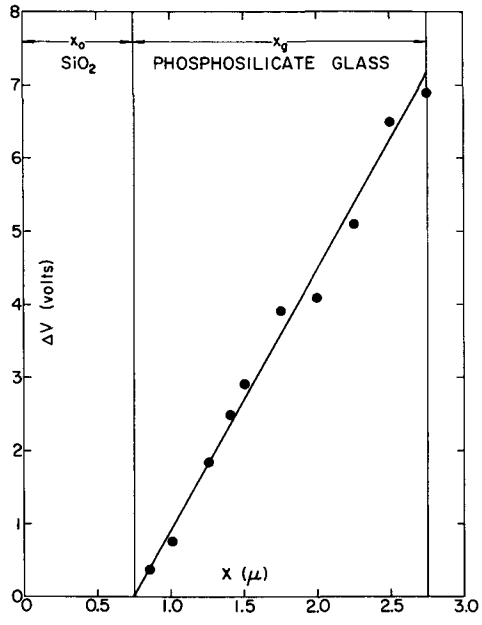

Fig. 9. Displacement ΔV between C-V curves made on polarized and unpolarized devices as a function of glass removed by etching. The straight line intersecting the x-axis at the glass oxide interface implies a uniform polarization in the glass and zero polarization in the SiO_2.

$$\chi_p \text{ (dipolar)} = \frac{Nq^2a^2}{2\epsilon_o kT} \qquad [10]$$

where N is the concentration of dipoles, qa is their dipole moment, k is Boltzmann's constant, and T is the absolute temperature. Assuming a dipole length $a = 5$Å, this model would require a concentration of dipoles of the order of $10^{19}/cm^3$. One difficulty with this model is that the predicted temperature dependence of χ_p was not observed experimentally.

A second, and more likely, possibility is that the glass is not homogeneous, but that it contains a small amount of a conductive phase (perhaps a crystalline precipitate) uniformly dispersed in the glass layer. The apparent polarizability that is observed would then be due to interfacial polarization between the conductive inclusions and the bulk of the glass. The resulting expression for the polarizability depends somewhat on the shape of the small conductive regions, but if it be assumed they are spheres, one gets (18, 19)

$$\chi_p \text{ (interfacial)} = \frac{9K_{g1}^2 v_2/v_1}{2K_{g1} + K_{g2}} \qquad [11]$$

where K_{g1} and K_{g2} are the dielectric constants of the bulk glass and the conductive phase and v_2/v_1 is the fractional volume of the conductive phase. Assuming $K_{g1} \simeq K_{g2}$ and using $\chi_p = 0.75$ we obtain from [11] $v_2/v_1 = 0.06$ or the conducting phase must occupy about 6% of the total volume of the glass. If, instead of being spherical, the inclusions were needle-shaped with the axis perpendicular to the surface, then a much smaller volume of conductive material could account for the observed polarizability (19). The time constant for the build-up of this interfacial polarization is (18, 19), again assuming spherical conducting regions

$$\tau = (2K_{g1} + K_{g2})\ \epsilon_o/\sigma_2 \qquad [12]$$

where σ_2 is the conductivity of the conducting phase. From this equation and the measured time constants of Fig. 6 we get a conductivity which increases exponentially with temperature with an activation energy of 1 ev and which has a value of 2×10^{-15} mho/cm at 60°C. As was noted earlier, the τ used here is an effective value representing an average of a distribution of relaxation times. This distribution could be explained either by variations in the shapes of the conducting regions or by variations in the conductivity itself.

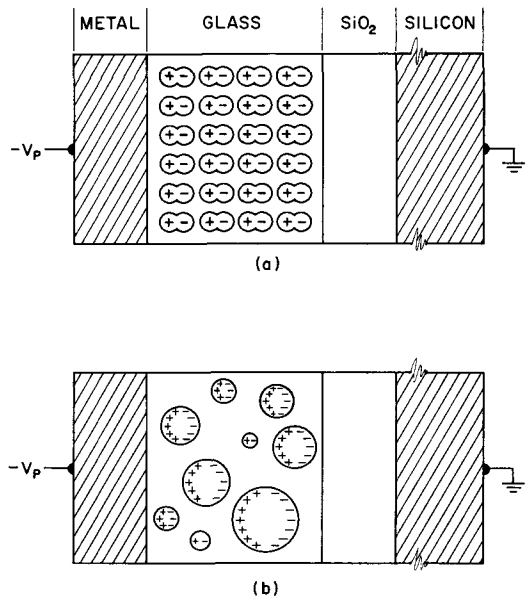

Fig. 10. Schematic illustration of two models which could account for the observed polarization of the phosphosilicate glass layers: (a) the orientation of permanent dipoles; if the dipole length were 5Å, a concentration of the order of $10^{19}/cm^3$ would be required; (b) interfacial polarization due to conducting inclusions in the glass layer. If the conducting regions were spherical they would have to occupy about 6% of the glass volume.

High-temperature polarization.—It was possible to obtain much larger polarization effects than those just described by biasing for very long periods of time at higher temperatures. This high temperature polarization was also proportional to the applied voltage and was approximately symmetrical under positive and negative bias. Figure 11 shows ΔV *vs.* time at three different temperatures for a set of identical samples. The dotted line indicates the saturation value of the low-temperature drift. At 125°C about 10 hr are required before any additional drift can even be observed. At 200°C the drift is much faster, but it has still not saturated after 3000 hr. At 300°C the drift is still faster, and it finally saturates at slightly over 100

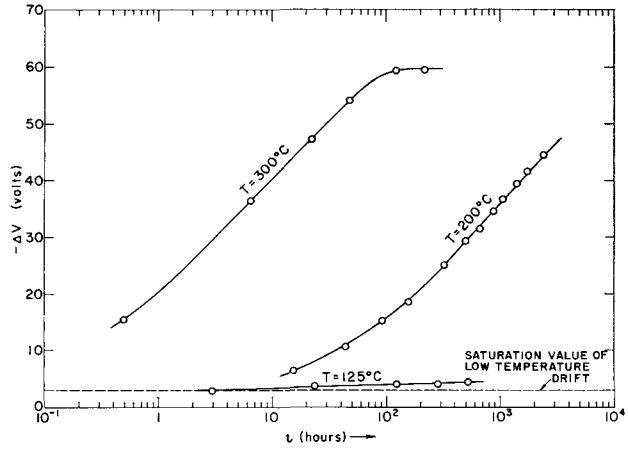

Fig. 11. Long-term, high-temperature drift in the C-V characteristic of phosphosilicate glass-silicon dioxide double-layer capacitors. This effect can be explained by ion migration through the bulk of the glass layer causing interfacial polarization on the glass-oxide interface. $x_g = 0.20\mu$; $x_o = 0.075\mu$; $v_p = +22.5$v.

hr. In this case the ΔV at saturation is 20 times larger than that corresponding to the low-temperature drift.

This long-term drift can be explained in terms of ion migration in the bulk of the glass film. The migrating ions build up a space-charge on the glass-oxide interface which eventually cancels the applied field in the glass layer and leads to saturation. This type of polarization has been discussed at length in ref. (16) and leads to a shift ΔV_{SAT} given by Eq. [1]. For the sample dimensions and the applied voltage indicated in Fig. 11, this equation predicts a ΔV_{SAT} of 60v which is in excellent agreement with the observed value. The 200° and 300° curves in Fig. 11 are nearly parallel, being displaced from each other along the time axis by a factor of about 160. This shift corresponds to an activation energy of 1.15 ev, a value only slightly higher than that for the low-temperature effect.

This long-term drift effect is definitely associated with the phosphosilicate glass layer since it was not observed with uncontaminated silicon dioxide films under similar test conditions (13, 15).

Summary and Conclusions

A survey has been made of the properties of the phosphosilicate glass which is obtained when P_2O_5 is predeposited on thermally oxidized silicon. Such properties as the composition, density, etch rate, resistivity, dielectric constant and dielectric strength have been determined and compared with the corresponding properties of silicon dioxide films.

It has also been found that a phosphosilicate glass layer over silicon dioxide is an effective barrier to sodium ion migration, and this fact may account for the reported increase in stability of planar transistors and MOS devices which include such a glass layer (7). On the other hand, reproducible polarization effects have been discovered in the phosphosilicate glass which appear to be unrelated to contamination. Thus, while the glass layer eliminates the gross instabilities which result from alkali contamination, these polarization effects lead to MOS devices less stable than those which can be made using pure uncontaminated SiO_2. The polarization of the phosphosilicate glass has been studied in detail using the MOS capacitance-voltage method, and a model has been presented for interpretation of the results.

Acknowledgments

The authors wish to thank Mrs. D. S. Sklar, L. D. Allasia, and P. J. Fleming for assistance with the experimental portion of this work. Thanks are also due to A. S. Grove, C. A. Bittmann, and G. E. Moore for many stimulating discussions.

Manuscript received Nov. 5, 1965; revised manuscript received Dec. 16, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

High-Temperature Immiscibility of Uranium Mono- and Dicarbides[1]

Mildred Bradley Sears, Leslie M. Ferris, and Robert J. Gray

Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The high-temperature, uranium monocarbide-dicarbide immiscibility region was determined by examining the microstructures of specimens with compositions from $UC_{1.1}$ to $UC_{1.8}$, which had been prepared by decomposing mixtures containing the sesquicarbide at 1820°-2130°C. The low carbon miscibility boundary, which occurs between $UC_{1.1}$ and $UC_{1.2}$ (5.2 and 5.7% carbon), is nearly composition invariant between 1820° and 2070°C. The high carbon miscibility boundary occurs at about $UC_{1.65}$ (7.7% carbon) at 1820°C and the solubility of the monocarbide in the dicarbide phase increases linearly with increasing temperature. The peak of the immiscible region occurs at about $UC_{1.2}$ (5.7% carbon) and a temperature above 2070°C.

There is general agreement that cubic uranium monocarbide (UC) and cubic uranium dicarbide [usually designated as UC_2 although, in fact, it is always substoichiometric, the most common composition being $UC_{1.8}$ (1)] form a complete series of solid solutions near the melting point (1-8). A region of immiscibility has been observed at temperatures between about 1800° and 2100°C, but has not been clearly defined. Mallett *et al.* (2) placed the upper limit of the immiscible region at about 2025°C and 6.2% carbon based on microstructure studies, while Witteman and Bowman (9) determined the critical temperature as 2050° ±50°C at a composition of $UC_{1.35\pm0.05}$ (6.4±0.2% carbon) from thermal arrest data. At one time Chubb and Phillips (10) felt that the region of immiscibility extended to the melting point, but soon afterward revised their constitutional diagram when they found evidence of a single-phase region at 2300°C (3). Mal-

[1] Research sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

lett *et al.* (2) found little or no solubility of UC_2 in UC at 1800°C based on microstructure studies. From the change in the UC lattice parameter at high temperatures, Wilson (4) concluded that a UC-UC_2 solid solution containing up to 5.2% carbon exists at 1820°C, and that UC may also dissolve a small amount of excess carbon at lower temperatures. Unfortunately at high temperatures the surface composition, which determines the x-ray diffraction pattern, differed from the bulk composition of the specimens so that Wilson had to estimate the carbon compositions from the lattice parameters by assuming that the lattice parameter varied linearly with composition from cubic UC to cubic UC_2 (Vegard's law). A number of phase diagrams appear to be based on Wilson's solubility data (1, 3, 5, 6, 8, 10). From thermal arrest data, Witteman and Bowman (9) established that one boundary of the immiscible region intersects the UC_2 cubic-to-tetragonal transition isotherm at a composition between $UC_{1.0}$ and $UC_{1.065}$ (4.8-5.07% carbon). While they did not give a temperature for the UC_2 phase transition, co-workers of theirs have reported a value of 1785° ±20°C (11). Magnier and Accary (7) found practically no solubility of UC_2 in UC at 1800°C, and Chubb (6) in his most recent diagram lowered the miscibility boundary to about 5% carbon; no data were given. The boundary at the high-carbon end of the system at about 1800°C has been placed at 8.2% carbon by Mallett *et al.* (2), about $UC_{1.6}$ (7.5% carbon) by Witteman and Bowman (9), 8.5% carbon by Wilson (4), 8.8% by Magnier and Accary (7), and 7.8% by Chubb (6). Takahashi *et al.* (12) believe that a UC_{2-y} phase containing 7.8% carbon or more is stable at the transition temperature.

Examination of the microstructures of diffusion couples which had been annealed at 1800°C and higher led Chubb and Phillips (10) to postulate a eutectoid at 7-7.5% carbon and just below 1800°C. They revised Wilson's constitutional diagram (4), and this revision has been incorporated into several other diagrams (1, 3, 5, 8). Chubb deleted the eutectoid from his 1964 diagram (6). Takahashi *et al.* (12) found no evidence of a eutectoid in the microstructure of a specimen containing 6% carbon, and Magnier and Accary (7) did not include it in their diagram.

This paper presents the results of a microstructure study of uranium carbide specimens with compositions from $UC_{1.1}$ to $UC_{1.8}$ (5.3-8.3% carbon) which had been prepared by decomposing mixtures containing uranium sesquicarbide at temperatures from 1820° to 2130°C.

Experimental

Preparation of the carbides.—Specimens were prepared by first arc-melting high-purity uranium metal (<400 ppm total impurities) and spectroscopic grade carbon, using nonconsumable tungsten electrodes, and quenching the melts on a water-cooled button mold as described previously (13-16). The resulting buttons were then heat-treated for 65 hr at 1600°C in a Brew High Vacuum Furnace, No. 424 B, to form monocarbide-sesquicarbide and sesquicarbide-dicarbide mixtures (15). Finally, the mixtures were heat-treated in the Brew furnace at temperatures between 1820° and 2130°C to decompose the sesquicarbide and reform monocarbide-dicarbide mixtures. Temperatures were measured with an accuracy of ±20°C with a Leeds and Northrup optical pyrometer. Although samples were not quenched after the heat-treatments, they were furnace-cooled to 1000°C in less than 5 min and to 500°C within 10 min. Graphite crucibles were used to contain the specimens. Most of the specimens with compositions from $UC_{1.1}$ to $UC_{1.3}$ were set on small disks of uranium monocarbide to prevent reaction with the crucible. Under these conditions there was no visible reaction of the specimens with the crucibles, and only specimen 8G ($UC_{1.3}$ heat-treated at 2130°C directly on graphite) showed any noticeable increase in the carbon concentration as a result of the heat-treatments.

[c] Average composition of the specimen after it reacted with the graphite crucible.

Characterization of the carbides.—Chemical analyses of the specimens, after the final heat-treatment, for uranium, total carbon, and free carbon are given in Table I. Tungsten contamination from the electrodes averaged 0.05% w/o (weight per cent). Specimens were also analyzed for oxygen (0.01% or less) and nitrogen (avg. 30 ppm). The x-ray diffraction powder patterns of the specimens after cooling to room temperature were those of uranium monocarbide-dicarbide mixtures; no residual sesquicarbide from the 1600°C heat-treatments was detected. There was no shift in either the monocarbide or dicarbide lines in the x-ray powder patterns as a function of the total carbon content between $UC_{0.8}$ and $UC_{2.4}$, or as a function of the heat-treatment indicating that at room temperature there is very little if any solubility of monocarbide in dicarbide and *vice versa*. The hydrolysis properties of many of these specimens have been reported elsewhere (16).

Procedures.—All chemical analyses were conducted by procedures developed in the study of the hydrolysis of the as-cast uranium carbides (14). X-ray powder patterns were determined with a Debye-Scherrer 114.59-mm-diameter powder camera using CuK-α radiation. Specimens were mounted for metallographic examination in a room-temperature setting epoxy resin[2] 1.25-in. mount, rough ground through 320, 400, and 600 grit silicon carbide papers using a water-free silicone fluid[3] as a lubricant, and vibratorily polished 6-12 hr on a nylon cloth using a silicone fluid-Linde A-graphite slurry (17). The carbides were etched with equal parts of glacial acetic acid, 15.8*M* (70%) nitric acid and water for 10 to 15 sec for uranium monocarbide, 15 to 30 sec for uranium dicarbide, and 10 to 30 sec for uranium sesquicarbide. The variation for each of the three carbides was due to the relative amount of the other carbide(s) present in the microstructure. Etching formed an interference film on the surface of the sample which varied in color with the orientation and composition of the substrate. Black and white photomicrographs were made under bright field illumination with Royal Pan film, using Polydel developer.

Results

Two different types of microstructures were observed when mixtures containing sesquicarbide were decomposed by heat-treating in the range of 1820°-2130°C: (*i*) orientated platelets of monocarbide (dark) or dicarbide (light) were observed as a homogeneous dispersion throughout the entire specimen if the sesquicarbide decomposition had occurred in a region where

the monocarbide and dicarbide formed a solid solution (Fig. 1, 3a, 4a, 5a, 6a, 7, and 8), and (*ii*) large, irregularly shaped areas of monocarbide-rich and dicarbide-rich phases were observed if the decomposition had occurred within the monocarbide-dicarbide immiscibility region (Fig. 2, 3b, 4b, 5b, and 6b).

The first type of microstructure was similar to those observed by Takahashi *et al.* (12) for slow-cooled specimens and, in general, the postulates of these authors concerning the morphologies of the precipitates are applicable here. The microstructure of specimen 8G, which reacted with the graphite crucible at 2130°C, varied from Fig. 3a which was typical of the low carbon part of the specimen ($UC_{1.3}$) to a microstructure resembling Fig. 7 ($UC_{1.7}$) in the part of the specimen in contact with the crucible. Across this range of composition, only the first type of microstructure indicating solid solution was observed.

The second type of microstructure (Fig. 2, 3b, 4b, 5b, and 6b) was distinctly different from the first type.

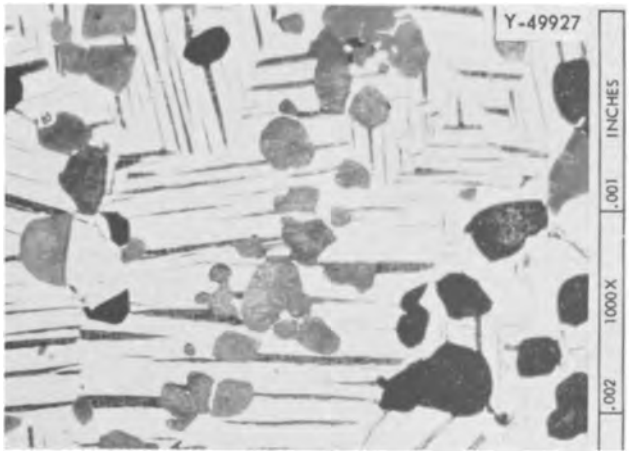

Fig. 5b. $UC_{1.49}$ heat-treated at 1900°C (specimen U_2C_3-3H). The specimen appears to have been heated in a two-phase region. Nitric-acetic etch.

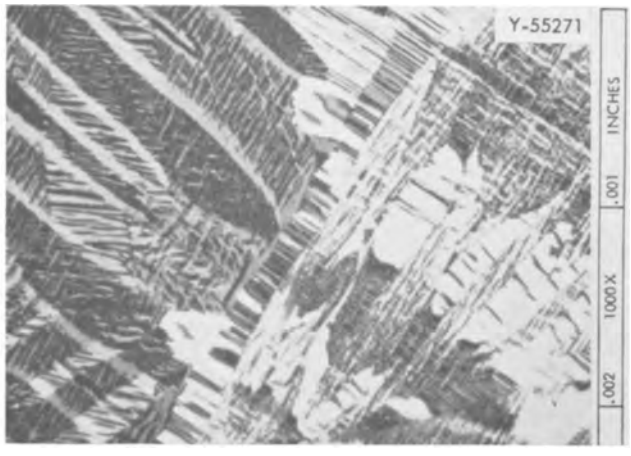

Fig. 6b. $UC_{1.62}$ heat-treated at 1820°C (specimen 12I). The specimen appears to have been heated in a single-phase region. Nitric-acetic etch.

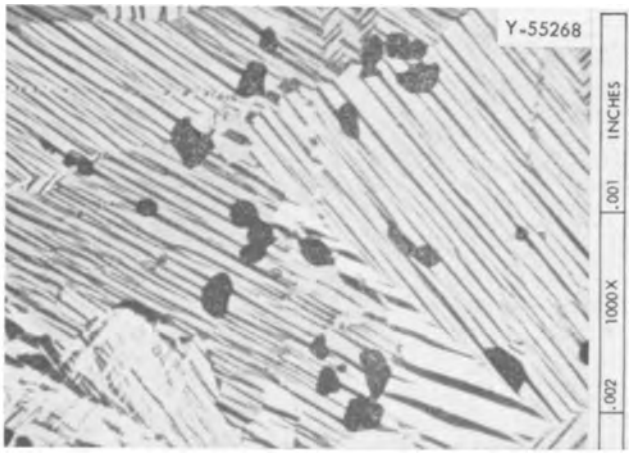

Fig. 6b. $UC_{1.62}$ heat-treated at 1820°C (specimen 12I). The specimen appears to have been heated in a two-phase region. Nitric-acetic etch.

While the second type contained some orientated platelets indicating partial solid solution formation, there were also relatively large, irregularly shaped areas of monocarbide-rich and dicarbide-rich phases indicative of immiscible phases at the heat-treating temperature. The dicarbide-rich areas were similar in appearance to the $UC_{1.7}$ specimen which had been heated in the single-phase region (Fig. 7) and always contained parallel platelets of monocarbide which did not cross the twin boundaries. Because of a fine substructure (observed at 2000X), the relative areas of UC and UC_2 in the dicarbide-rich phase could not be estimated by point counting on a grid. The monocarbide-rich sections of the $UC_{1.2}$ and $UC_{1.3}$ specimens (Fig. 2 and 3b) resembled the $UC_{1.1}$ specimen which had been heated in the single-phase region (Fig. 1) and contained parallel sets of dicarbide lamellae having up to three different orientations. Specimens with a composition of $UC_{1.20}$ which had been heated at 1820°, 1900°, and 2000°C had similar microstructures to specimen 17M, which was heated at 2070°C (Fig. 2). The composition of the monocarbide phase in equilibrium with excess dicarbide at 1820°, 1900°, 2000°, and 2070°C was estimated as being very close to $UC_{1.1}$ by point counting on a 0.25 in., 187 point-grid the relative areas of the dicarbide platelets and monocarbide matrix in the monocarbide-rich portions of these $UC_{1.2}$ specimens, and correcting for the densities of UC and UC_2.

Partial Constitutional Diagram

The high-temperature, uranium monocarbide-dicarbide immiscibility region as determined by examining the microstructures of specimens with compositions from $UC_{1.1}$ to $UC_{1.8}$, which had been prepared by decomposing mixtures containing the sesquicarbide at 1820°-2130°C, is illustrated in Fig. 9. The low carbon immiscibility boundary is nearly composition invariant between 1820° and 2070°C. This is in marked contrast to current phase diagrams (1-8) which show increasing solubility of the dicarbide in the monocarbide with increasing temperature in this range. At 1765°C only a trace of dicarbide dissolved in the monocarbide

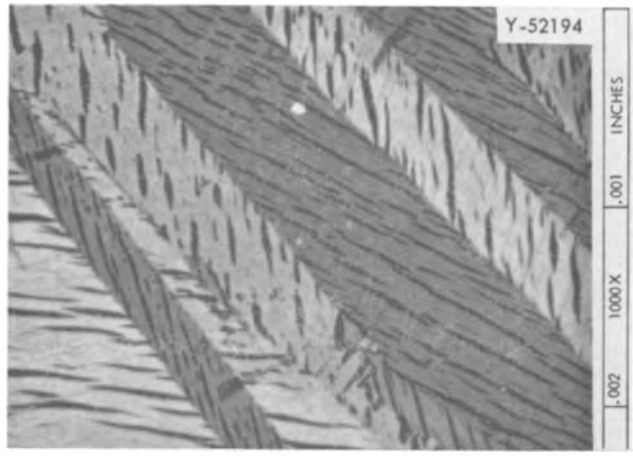

Fig. 7. $UC_{1.73}$ heat-treated at 1820°C (specimen 10I). The specimen appears to have been heated in a single-phase region. Nitric-acetic etch.

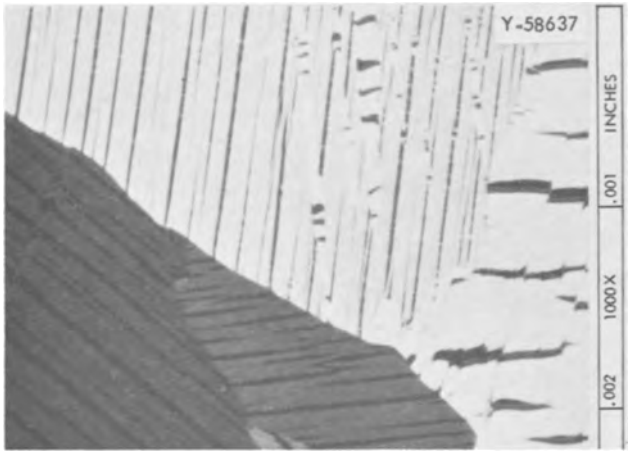

Fig. 8. $UC_{1.80}$ heat-treated at 1820°C (specimen UC_2-211). The specimen appears to have been heated in a single-phase region. Nitric-acetic etch.

phase (18) indicating that the miscibility boundary must change rapidly with temperature between 1820° and 1765°C. This proposal is consistent with the Los Alamos work placing the miscibility boundary somewhere between $UC_{1.0}$ and $UC_{1.065}$ (9) at 1785° ± 20°C (11). On the high carbon side of the immiscible region, our work shows a much wider range of solid solution formation than was reported by Mallett *et al.* (2), Wilson (4), Chubb (6), and Magnier and Accary (7). Although our high carbon boundary is about the same as that given by Frost (1), Rough and Chubb (3), Imoto *et al.* (5), and the IAEA Panel (8), we found no indication of the eutectoid shown in their diagrams. Our results are consistent with those of Takahashi *et al.* (12) who first observed that alloys containing 7.8% carbon or more were stable solid solutions above the dicarbide transition temperature. The peak of the immiscible region occurs at about $UC_{1.2}$ (5.7% carbon) and a temperature above 2070°C. Unfortunately 2100°C was about the maximum temperature attainable in the Brew furnace, so we were unable to define the exact peak temperature. The estimate of 2100°C in Fig. 1 was based on the results of

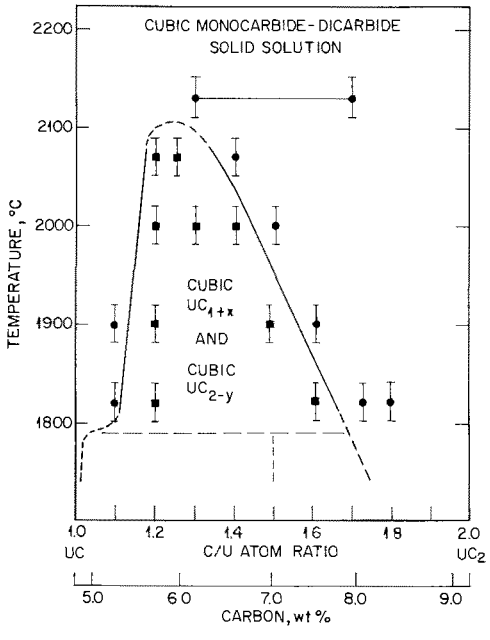

Fig. 9. High-temperature uranium monocarbide-dicarbide immiscibility region. Square dots represent specimens heat-treated in a two-phase region and round dots specimens heated in a single-phase region.

Witteman and Bowman (9) and Mallett *et al.* (2), who found the peak at 2050° ± 50° and 2025°C, respectively. In fact, the miscibility boundary lines of Fig. 9 can be extrapolated to a peak as high as 2200°C.

The microstructures of specimens prepared by decomposing mixtures containing the sesquicarbide show the high temperature monocarbide-dicarbide immiscibility region much more clearly than do the microstructures of as-cast specimens which had been annealed at 1800° to 2100°C such as were used by Mallett *et al.* (2) and Rough and Chubb (3) in determining their constitutional diagrams. Although we cannot prove in this study that the phases reached equilibrium during heat-treating, the heat-treating times were long enough to produce marked changes in the microstructures compared with most of the original sesquicarbide mixtures, and were probably much longer than those used in the previous studies: Mallett *et al.* (2) heat-treated for "nominal periods of time" and Rough and Chubb (3) for 2 to 20 min, compared with 2 to 6 hr in this study. While caution must always be exercised in determining high-temperature phenomena by metallographic examination at room temperature, our procedure has included chemical analyses of the specimens both before and after heat-treating so that the chemical compositions are known precisely, which was not the case in Wilson's (4) high-temperature x-ray studies.

Acknowledgments

The authors wish to thank the following members of the ORNL Metals and Ceramics Division for their aid in this study: R. E. McDonald and L. Queener for arc-melting the carbides; J. P. Hammond and C. Hamby for heat-treating the specimens; and B. C. Leslie for the photomicrographs. The ORNL Analytical Chemistry Division provided analyses: x-ray analyses by R. L. Sherman and chemical analyses by the group of W. R. Laing.

Manuscript received July 22, 1965; revised manuscript received Oct. 25, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Electrolytic Reduction of Diisopropyl Ketone in Acid Solution

Sherlock Swann, Jr., D. K. Eads,[1] and L. H. Krone, Jr.[2]

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

The electrolytic reduction of diisopropyl ketone has been studied in acid solution at cathodes of zinc, cadmium, mercury, and lead. The main products are the saturated hydrocarbon and secondary alcohol with pinacol and olefin in smaller amounts. The temperature at which the solid electrodes were cast had a marked effect on the course of the reduction.

This paper is a continuation of a study of the electrolytic reduction of aliphatic ketones, in which it was shown that methyl propyl ketone was reduced to pentane at cathodes of zinc, cadmium, mercury, and lead in yields varying from 23 to 75% (1). Since it might be expected that steric hindrance would influence the course of the reduction of an aliphatic ketone (12), it seemed desirable to investigate the effect of branched chains adjacent to the carbonyl group. A study of the electrolytic reduction of diisopropyl ketone was therefore undertaken. Only one previous example of the electrolytic reduction of a branched chain aliphatic ketone has been reported in the literature. Wibaut, Hoog, Langedijk, Overhoff, and Smittenberg (2) found that the main product of the reduction of 3.3-dimethylbutanone at a cadmium cathode was the saturated hydrocarbon. The olefin and alcohol were also present in small amounts.

Apparatus and Procedure

The apparatus has been described previously (3, 4). In the early part of the investigation the calcium chloride tube was omitted.

First procedure.—After much experimentation the following procedure for the recovery of products was adopted. The catholyte and washings of the porous cup and cathodes were poured into a separatory funnel where they divided into two layers. The lower, aqueous, layer was removed and the remaining liquid transferred to a small flask. The aqueous part was subjected to simple distillation and the fraction boiling up to 88°C collected. This fraction was diluted with water and the oily layer which formed added to the rest of the organic material in the flask. The residual aqueous layer was again redistilled and the fraction taken off and treated as before. This procedure was repeated four times.

The oil was fractionated in a small column. The first fraction 62°-64°C, was a constant boiling mixture of hydrocarbons and ethyl alcohol. The next fraction was evidently all ethyl alcohol. The second cut was, therefore, made at 85°C.

The distillation was then continued under 14 mm pressure and the next fraction cut at 60°C. This consisted of diisopropyl carbinol and ketone. A residue, very probably of dehydration products of the pinacol, was left.

The hydrocarbon-ethyl alcohol fraction was diluted with water and the hydrocarbon which separated, dried with anhydrous magnesium sulfate and weighed. A portion of it was analyzed for unsaturation by bromine titration.

[1] Present address: Rohm and Haas Co., Bristol, Pa.

[2] Present address: Monsanto Chemical Company St. Louis, Missouri. National Science Foundation Fellow, 1952-53.

The carbinol-ketone fraction was weighed, dried over anhydrous magnesium sulfate, and analyzed for ketone by refractive index.

To establish the identity of the saturated hydrocarbon, the mixed hydrocarbons were shaken in a separatory funnel with concentrated sulfuric acid and syrupy phosphoric acid to remove the olefin. The acids were removed with sodium carbonate solution and water after which the residual hydrocarbon was dried over anhydrous magnesium sulfate and distilled. The bulk of the material boiled at 80°-81° and upon redistillation at 80.5°C. The refractive index was $N_D^{20} = 1.3806$. These constants correspond closely with those reported in the literature for 2,4-dimethylpentane, bp 80.5°C and $N_D^{20} = 1.38145$. The unsaturated heptene was determined in representative samples of hydrocarbons by titration with bromine in the first part of the investigation and with iodine in the latter part.

The presence of diisopropyl carbinol in the ketone-carbinol fraction was established by making its phenylurethane, mp 93°-94°C. The melting point reported in the literature is 94°-95°C (7). To identify the ketone an attempt was made to prepare the 2,4-dinitrophenylhydrazone. This was unsuccessful, but it was found possible to prepare the semicarbazone, mp 156°-157°C. The melting point reported in the literature is 160°C (8).

Second procedure.—In the latter part of the investigation the catholyte and washings were neutralized with sodium carbonate before separation of the oily layer. The aqueous layer was distilled and the fraction boiling up to 85°C collected and diluted with water as before to recover hydrocarbons. Since the amount of oil obtained in this way was very small, only one distillation was usually carried out. The rest of the procedure was the same as that previously described except that the residue was dissolved in low boiling petroleum ether causing the crystallization of 2,5-dimethyl-3,4-diisopropyl-3,4-hexanediol, mp 89°-90°C. After recrystallization the melting point was 90.5°-91°C. The pinacol has been prepared previously by Young and Roberts (5) and by Nazarov (6). The melting point reported was 91°-92°C.

All temperatures reported in this paper are uncorrected.

Preparation of cathodes.—Solid cathodes were cast in a cold mold and in a mold 50°C under the melting point of the metal. For other experiments they were electropolished. Zinc was electropolished in phosphoric acid-ethyl alcohol (9), cadmium in phosphoric acid-butyl alcohol (10), and lead in perchloric acid acetic anhydride (11). The solid cathodes were always anodized in 20% sulfuric acid before use except when electropolished.

The number following the metal is the casting temperature. RT means at room temperature. No metallo-organic compounds were found.

Results and Conclusions

The results of the investigation are shown in Tables I and II and in the discussion, which follows.

The products of the runs in which yields of pinacol are reported were recovered by the second of the procedures previously described.

It will be noted in Table I that under strictly comparable conditions the yields of hydrocarbon and alcohol do not vary much with the temperature at cathodes of zinc, cadmium, and lead, but the yield of pinacol increases markedly at the lower temperature. The yield of hydrocarbon at mercury is, however, decidedly poorer at the lower temperature. It is interesting to note that in the one example of the relation of the effect of temperature with the physical structure of the cathode material, cadmium, and temperature seems to be the deciding factor in the formation of pinacol.

In the runs reported in all tables where no attempt was made to isolate the pinacol the temperatures were taken in the anolyte. In all others the temperature was that of the catholyte. Under the conditions of the experiments, there was little difference.

It may be seen in Table II and also with cadmium cathodes in Table I that the temperature at which the metal is cast had a marked effect on the yield, higher yields of hydrocarbon being obtained at metals cast in a cold mold and higher yields of alcohol at those cast 50°C under their melting points. The physical structure of the cathode had little effect on the yield of pinacol as previously indicated (temperature 25°-30°C, other conditions as in Table I).

Effect of electropolishing.—The most important effect of electropolishing the solid cathodes was the lowering of the yields of hydrocarbons about 8-10%. The yield of alcohol was unchanged at cadmium and

zinc, but was raised about 4% at lead. The yields of pinacol were lowered at the zinc and cadmium, but were unchanged at lead.

The high yields of hydrocarbons at cathodes cast in a cold mold and low yields at electropolished cathodes would indicate that the reduction to the hydrocarbon was favored by the presence of grain boundary material (temperature 25°-30°C, other conditions as in Table I).

Effect of acid concentration.—The effect of reducing the acid concentration from 30 to 10% was of significance only at a zinc cathode, the yield of hydrocarbon decreasing about 5% while the yield of the alcohol increased about 3% (temperature 55°-60°C, other conditions as in Table I).

Effect of current density.—Reductions were carried out at all cathodes at current densities of 0.02 and 0.05 amp cm^2; cadmium and zinc cathodes also at 0.1 amp/cm^2. The theoretical amount of current was allowed to flow. The effect of the current density varied considerably with the cathode material. Hydrocarbon formation was favored by current densities greater than 0.02 amp/cm^2 at all cathodes except lead at which the reverse was true. It is interesting to note that the formation of hydrocarbon from methyl propyl ketone at a lead cathode was also favored by low current densities (1). The yield of the alcohol was unaffected except at lead where a high current density was favorable. The effect of the current density on the yield of pinacol was important only at zinc, the best results being obtained at a low current density.

Formation of olefin.—The amount of olefin, presumably, 2,4-dimethyl-2-pentene, found as an impurity in the saturated hydrocarbon, was related to the cathode material. The average with zinc was 4, with cadmium 5, with mercury 10, and with lead 8 per cent by weight.

General Conclusions

The products of the electrolytic reduction of diisopropyl ketone were found to be 2,4-dimethylpentane, diisopropyl carbinol, 2,5-dimethyl-3,4-diisopropyl-3,4-hexanediol, and an olefin. The highest yield of hydrocarbon, 44.5%, was obtained at a cadmium cathode which had been cast in a mold at room temperature. The highest yields of the alcohol, 49.3%, and pinacol, 11.4%, were obtained at zinc cathodes cast in a mold 50°C below the melting point of the metal. The least active of the four cathodes was mercury, at which only a fair yield of hydrocarbon, a very small amount of the alcohol, and a trace of pinacol were obtained.

Decreasing the temperature of the catholyte caused a lowering of the activity of a mercury cathode but had little effect on the yields of hydrocarbon and the alcohol at the solid cathodes; higher yields of pinacol were obtained at the lower temperature.

The effect of acid concentration was appreciable only at a zinc cathode where the yield of hydrocarbon was greater at the higher concentration the reverse being true for the alcohol.

The effect of the current density was dependent on the cathode material. At cathodes of zinc, cadmium, and mercury, higher yields of hydrocarbon were obtained at higher current densities, the reverse being true at lead. The yield of alcohol was affected only at a lead cathode where it was favored by a high current density. Again, the yield of pinacol was affected only at zinc, with best results at a low current density.

The change in the physical structures of the solid cathodes due to casting in a cold mold or in a mold held 50°C under the melting point of the metal had an important effect on the course of the reduction. In all cases higher yields of hydrocarbon were obtained at cathodes cast in a cold mold while the reverse was true of the alcohol. The yields of pinacol were little affected by the change in physical structure. Electropolishing on the other hand brought about certain changes, the most important of which was the lowering of the yields of hydrocarbon.

The yields of products obtained in the electrolytic reduction of diisopropyl ketone were quite different from those with a typical straight chain ketone such as methyl propyl (1, 13). At cathodes of zinc and cadmium diisopropyl ketone was reduced to the hydrocarbon and to the alcohol in considerable amounts while the main product of the reduction of the straight chain ketone was predominantly the hydrocarbon. At cathodes of lead and mercury diisopropyl ketone was not reduced to the metallo-organic compounds which were found in the products of the reduction of the straight chain ketone.

Acknowledgments

Acknowledgments of gifts of metals for electrodes and for their casting have been made in previous papers. The authors are indebted to Dr. H. M. Kvalnes and Dr. K. B. Walker of the Experimental Station of the E. I. DuPont de Nemours Company for much of the diisopropyl ketone. The analysis of the pinacol was carried out by Mr. Jozsef Nemeth.

Manuscript received Feb. 15, 1963. This paper was presented at the New York Meeting, April 12-16, 1953.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

An Ellipsometric Study of Steady-State High Field Ionic Conduction in Anodic Oxide Films on Tantalum, Niobium, and Silicon

L. Young and F. G. R. Zobel[1]

Electrical Engineering Department, University of British Columbia, Vancouver, British Columbia, Canada

ABSTRACT

The classical theory of ionic conduction in solids at high field strengths (10^6 to 10^7 v cm^{-1}) predicts that the relation between the ionic current density I and the field strength E should be $I = I_o \exp(-W(E)/kT)$ where the activation energy $W(E) = W_o - qaE$, q is the magnitude of the charge on the ions, a is half the distance between successive sites occupied by the ions, and I_o is a constant. Deviations from this supposed law have been reported in various forms. New experimental results for steady-state conditions are reported which were obtained by *in situ* ellipsometry. These confirm for tantalum and establish for the first time for niobium that the deviations may be simply and accurately described by taking the activation energy to be nonlinear in E in a way which may be represented over the experimental range of E by $W_o - q(\alpha - \beta E)E$. Data were also obtained for silicon, but were not sufficiently accurate to detect nonlinearity. Models are discussed which might give this effect. A model in which ions move fairly freely in channels with infrequent trapping by a coulombic potential leads to a law of the form $I = I_o \exp(-(W_o - \gamma E^{1/2})/kT)$, analogous to the Schottky and Poole-Frenkel laws for electronic currents. Such a law fits the data well enough for the model to be considered as realistic.

Anodic oxide films grow by a process of ionic conduction in the oxide at high field strengths (1, 2). The ionic current density defines the rate of increase of the thickness of the film. The purpose of the present experiments was to re-investigate the relation between the ionic current density, the field strength, and the temperature for films on tantalum and niobium, and to obtain such data for the first time for silicon, only the order of magnitude of the fields necessary to produce appreciable ionic current having been determined previously (3). The method used was to determine the thickness as a function of time by ellipsometry during anodization at constant potential. The field was then obtained from the potential with respect to the reversible oxide potential by dividing by the thickness of oxide. The ionic current density was obtained by calculating the rate of increase of thickness. With tantalum and niobium the optical measurements were made with the specimens still immersed in the solution (that is by *in situ* ellipsometry), but this could not be done with silicon because the refractive index of the oxide was too close to that of the solution.

It is difficult to give a brief account of the theory [which we have reviewed elsewhere (1, 2)] because no general agreement exists on a model which reproduces the complicated behavior of the ionic current under steady-state and transient conditions. It is usually considered that the problem is basically one of field assisted thermal activation of ions over potential energy barriers. The mobile ions are supposed to be deactivated after each jump. Consideration of the rate at which energy is supplied by the field to moving ions suggests that ions once mobile may traverse several minima and maxima of potential energy before being halted. The behavior of the current when a large field is suddenly applied suggests that some form of ionic avalanche multiplication process may occur under these circumstances (3).

In order to explain the transients, it appears to be necessary to construct a model in which the concentration of mobile ions is field dependent but responds slowly to a change in field. The model of Bean, Fisher, and Vermilyea (4) satisfies this requirement by postulating that two processes of ionic movement are involved. These are (*a*) the production of Frenkel defects by the movement of ions from lattice (or glass network) sites into interstitial sites, and (*b*) the mobility process of ions in interstitial sites. The transients may then be partially explained as due to a variation of the concentration of mobile ions. However the build-up of current when a large field is suddenly applied is definitely inconsistent with the treatment of this model according to the classical idea of field assisted thermal activation of ions over potential energy barriers.

The classical theory of ionic conduction at high field strengths [*cf.* Frenkel (5)] predicts a law of the form $I = I_o \exp(-W(E)/kT)$ where the activation energy $W(E) = W_o - qaE$ and where q is the magnitude of the charge on the ions, a is the average distance from minimum to maximum potential energy along the path of the ions (resolved along the field direction), I_o is a constant, k is Boltzmann's constant, and T is the absolute temperature. Thus qaE is the work done on the ion by the field as it travels from a minimum to the following maximum potential energy. The quantity a is sometimes called the activation distance and may include factors allowing for the effective field being different from the applied field (6) and for the effective charge being different from the valence charge or even varying with distance (7).

If both types of process postulated by Bean *et al.* obey this type of law, with destruction of Frenkel defects by a capture cross-section process of vacancies for interstitial ions, the steady-state kinetics are controlled by an expression of the same form as the classical expression but with the parameters representing averages of the values for the two processes.

The use of thin films allows an accurate test to be made of theories of conduction at high field strengths. This is hardly possible with bulk specimens. Deviations from the form of law predicted by Frenkel have been observed, starting with the work of Vermilyea [for references see (1), (2)]. These deviations were difficult to explain in the form which they were first thought to have, that is that $\partial E/\partial \log I$ was (as expected) independent of E at constant T but was almost independent of T under steady-state conditions (and even as was found later, decreased with increasing T under transient conditions) instead of being proportional to T as expected. Dewald proposed a theory to explain the steady-state kinetics in which a transition was supposed to occur (as space charge became effective in modifying the field) from control by the metal/

[1] Present address: Unilever Research Laboratory Port Sunlight, Cheshire, England.

oxide interface (Mott and Cabrera's model) to control by the bulk oxide [Verwey's model, if a modification of Dewald's postulates is made (1)]. This theory could not explain the transients, and it is now usually supposed that the process is one of conduction in the electrically neutral oxide. Bean, Fisher, and Vermilyea proposed a model for the high field production of Frenkel defects with a parabolic potential superimposed on a periodic potential energy *vs.* distance curve. This gave an activation distance for the production of Frenkel defects which was stepwise dependent on the field. Experimental results for the steady state required a field dependent pre-exponential factor to fit this model (8). Later, Vermilyea (9) was driven by consideration of the transient behavior to conclude that the oxide was modified structurally by the passage of current, a model which was not amenable to calculation. Winkel, Pistorius, and van Geel (10) considered that the existence in the amorphous oxide of a range of site parameters would explain the kinetics, but it was later shown that this idea was not sufficient (11).

On the basis of further experimental work, using an optical technique for the determination of the thickness, Young (11, 12) proposed that the best form of description of the experimental results both for steady-state and transient conditions ($\partial E/\partial \log I$ data) was obtained by writing $W(E) = W_o - q(\alpha E - \beta E^2)$, that is that the activation energy need not be linear in E (as has usually been taken to be the case in processes of this nature). Various physical processes could be considered *a priori* as possible causes of such an effect. This substitution gave an adequate phenomenological description of the steady-state $\log I$ *vs.* E data and of the transient data for $\partial E/\partial \log I$ for tantalum. It reduced the anomalies to a form which suggests an explanation not dependent on a transition between mechanisms. Dignam (13) observed similar effects with aluminum. His theory of the effect is discussed later. Dreiner (14), however, has recently obtained further experimental results for tantalum which confirm the original Frenkel law, in the sense that $\log I$ *vs.* E plots were linear. It was later realized that his values of $\partial \log I/\partial E$, although linearly dependent on $1/T$, do not extrapolate to zero at zero $1/T$, so that the Frenkel law was not observed accurately. (We thank Dr. Dreiner for a private communication on this point which we had missed.) In any case a further experimental test on tantalum was evidently required. The present experiments were extended to niobium since if the nonlinearity were established for three metals (tantalum, niobium, and aluminum) it could safely be concluded that it is basic and not due to fortuitous relations between parameters leading to some transition of mechanism or the like. Actually a transition between two mechanisms can hardly explain the results even for tantalum since there is no indication of two linear portions in the plots of $\log I$ *vs.* E but rather a smooth change of slope over the whole range of field. Measurements were also made on silicon, since according to Schmidt and Michel (3) the field strengths with this material are extremely high (10^7 v cm^{-1}) so that nonlinear effects should be increased. However, the scatter was too large to detect nonlinearity with silicon.

Experimental Procedure

The tantalum and niobium specimens were Fansteel material. They were 1.5 x 2.5 cm and 2 x 2.5 cm, respectively, with a tab, and were about 0.02 cm thick. They were prepared by abrasion on metallurgical papers followed by electropolishing as previously described (15). Anodization was carried out in 0.2N H_2SO_4. The experiments on silicon were carried out on p-type (111) oriented single crystal slices. Mostly the specimens had a resistivity of 0.094 ohm-cm, but some measurements were made on 0.006 ohm-cm material. The specimens were mechanically polished and then etched for 2 to 3 min in CP4A solution (5 parts concentrated HNO_3, 3 parts glacial acetic acid, and 3 parts of 49% HF, by volume). The etchant was quenched with 5% HF solution. Electrical contact was made to the silicon by means of a 0.005 in. diameter, chemically polished tantalum wire welded on the slice with an electron beam in vacuum. The silicon was then immersed briefly in CP4A, the weld and tantalum wire being kept from contact with the etchant, rinsed in 49% HF, washed well, and boiled for 30 min in deionized water to remove any adsorbed fluoride.

Anodization was carried out in a solution of N-methylacetamide saturated with KNO_3 at 32°C (about 0.05N). The N-methylacetamide was used as-received and appeared to be practically anhydrous (M.P. > 30°C). No special precautions were taken to prevent the absorption of water by the solution, but the anodizing cell was kept closed off from the air. The specimen was measured dry on the ellipsometer, since the similar refractive indices of N-methylacetamide (1.43) and anodic silicon dioxide (1.47) make *in situ* ellipsometry impractical. For similar refractive indices of oxide and immersion medium, a very small ψ, Δ loop is obtained which makes thickness determination inaccurate. The same difficulty applies to some of the other nonaqueous solvents in which silicon may be anodized, *e.g.*, ethylene glycol and tetrahydrofurfuryl alcohol. For dry examination the niobium and tantalum were anodized in a cell similar to that described previously (15). For *in situ* examination they were mounted in a specially constructed glass cell as shown in Fig. 1a, which was attached to the specimen platform of the Gaertner L119 ellipsometer. The light beam entered and left through windows made by sealing optical flats on the side arms. A constant temperature was maintained by circulating water from a thermostatted bath through the double wall of the cell. The specimen was held between stubs of tantalum wire inserted into two pieces of Teflon which were held together by a screw at their upper ends as shown in Fig. 1b. Electrical contact to the specimen was made through one of the tantalum wire stubs.

The calibration of the ellipsometer (16) and its application to anodic oxide films on tantalum (17) have been described in detail previously. The incident light is considered to be resolved into two components, p-light with the electric vector in the plane of incidence, and s-light with the electric vector perpendicular to the plane of incidence. If R_p and R_s are the complex reflectivities for p- and s-light, respectively, the quantities ψ and Δ are defined by $|R_p/R_s| = \tan \psi$ and $\arg R_p/R_s = \Delta$.

The analyzer and polarizer Glan-Thompson prisms were set for extinction, a quarter wave plate being

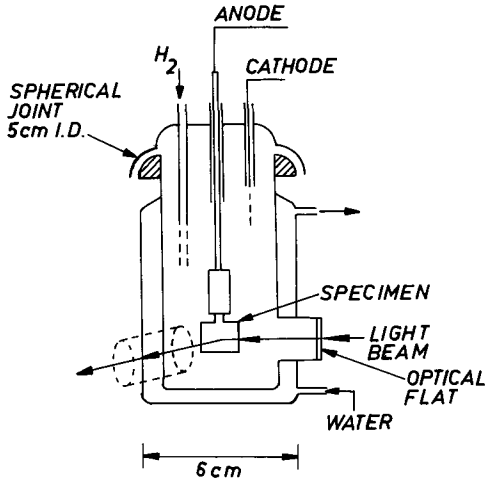

Fig. 1a. Water-jacketted cell for *in situ* ellipsometry

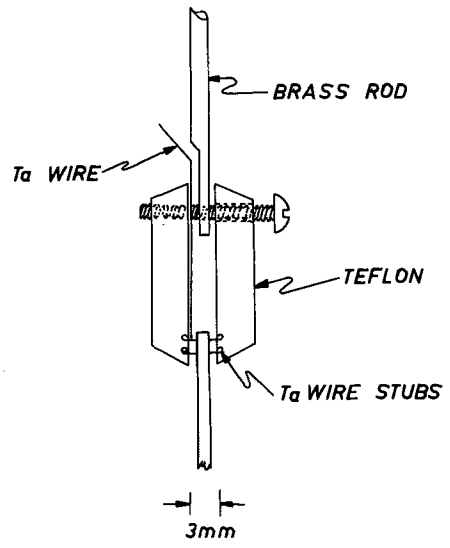

Fig. 1b. Device for supporting specimens

set at ± 45° azimuth. The detector was a photomultiplier (RCA 931A) coupled to an amplifier tuned to the frequency of the chopped light. The ellipsometer was enclosed in a box to minimize stray light. The quantities ψ and Δ are derived directly from the settings of the analyzer and polarizer prisms. Several sets of readings may be obtained, which may be classified into zones according to the scheme given by McCrackin, Passaglia, Steinberg, and Stromberg (16). The calibration appears to be a more critical matter than is sometimes made clear. The scheme of McCrackin *et al.* was followed. Specimens were exchanged with other workers in this field, and it was found that the agreement was not as good as would be expected from the precision with which readings may be taken, being only to about 0.2° in ψ and 1.2° in Δ.

For measurements *in situ* it was found advisable to make measurements in all four zones. This was found to minimize the small errors due to the polarization of the light by the cell windows. The windows are, of course, the same throughout, but the state of polarization of the light incident on them is changed with the zone. Measurements on the same specimen (dry) inside and outside the cell gave adequately concordant results.

For a discussion of the question of variation of optical constants with angle of incidence reference is made to a paper by Hall (18).

Results for Tantalum

Determination of the optical constants.—Data on ψ and Δ *vs.* the angle of incidence are not included here but are available for comparison by anyone wishing to reproduce these experiments.

The optical constants were obtained by trial and error fitting of the experimental and calculated curves. Figure 2 shows ψ *vs.* Δ for tantalum anodized at 8 ma cm^{-2} in 0.2*N* H_2SO_4 at 25°C and examined dry. Measurements were made at 5461Å and at an angle of incidence of 67.5° using a quarter wave plate as compensator. (A Soleil-Babinet compensator set as a quarter wave plate gave indistinguishable results.) The calculated curve was fitted to the experimental points using the constants $n_2 = 3.30 \pm 0.02$, $k_2 = 2.30 \pm 0.05$ for the metal ($\bar{n} = n - ik$) and $n_1 = 2.22 \pm 0.02$ for the oxide. The uncertainties are obtained by comparison of the experimental points with curves calculated from slightly different optical constants.

The Hartmann equation reported by Young (19) for films formed at 25°C and 10 ma cm^{-2} was $n_1 = 2.14 + 0.292/(\lambda/10^3\text{Å} - 2.305)^{1.2}$. This gives 2.21 for

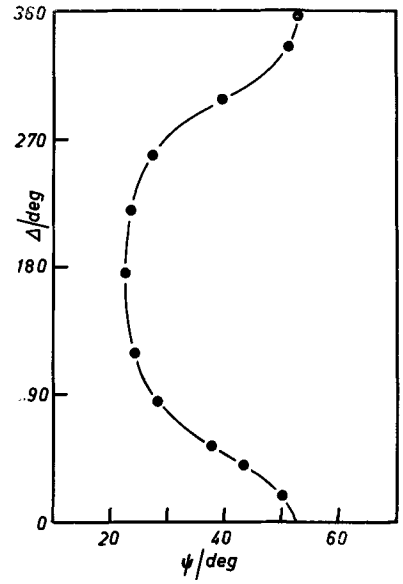

Fig. 2. Ellipsometry data for tantalum at 5461Å, angle of incidence 67.5° for specimen measured dry. The curve is calculated with $n_1 = 2.22$, $n_2 = 3.30$, and $k_2 = 2.30$.

the oxide refractive index at 5461Å in good agreement with the present estimate. Young's values were based on a value of n_1 in sodium light determined by the Becke method using S/Se mixtures plus dispersion data from interferometric measurements. Masing, Orme, and Young (15) found that the refractive index determined by a modification of a method due to Abelès was just detectably dependent on the current density and temperature at which the oxide was made. A direct comparison with their values is not possible because their work was at 4358Å, but using the dispersion relation given by Young to convert to 5461Å the agreement is satisfactory. Kumagai and Young (17) fitted their ellipsometric data for tantalum anodized in 0.2*N* H_2SO_4 at 25°C and 1 ma cm^{-2} using $n_2 = 3.5$, $k_2 = 2.4$, and $n_1 = 2.26$ at 5461Å.

The deviations of the experimental points from the calculated curve are shown in Fig. 3, which was plotted assuming that the errors occur entirely in Δ or entirely in ψ. The shape of the curve causes the deviations in Δ to appear rather large, but probably

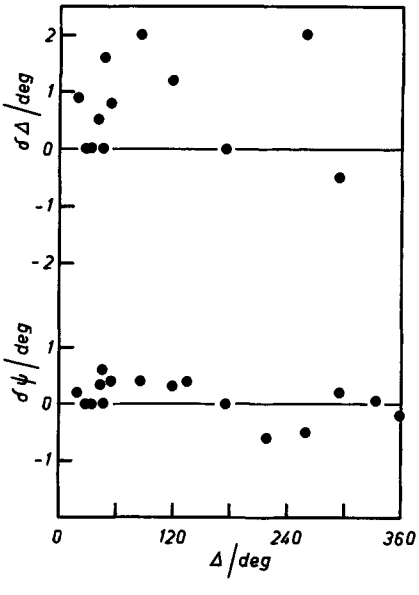

Fig. 3. Deviations of the experimental points in Fig. 2 from the fitted curve, assuming error lies entirely in Δ or in ψ respectively.

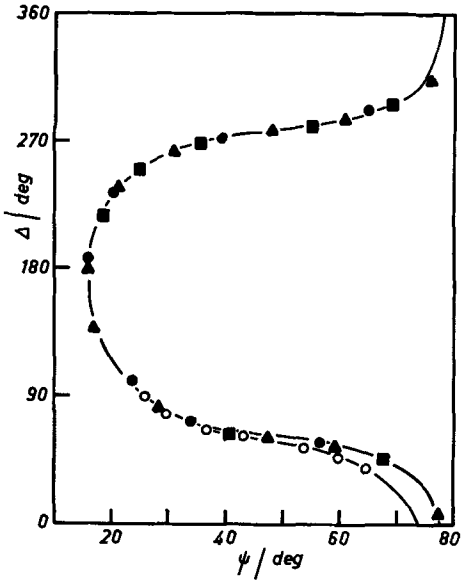

Fig. 4. Ellipsometry data (*in situ*) for tantalum at 5461Å, angle of incidence 67.5°. •, ■, ▲, first, second, and third cycles of curves at 25°C for which $n_0 = 1.334$ and the other constants as in Fig. 2. O data at 60°C, $n_0 = 1.329$, $n_1 = 2.27$.

the deviations in ψ are more meaningful. The mean deviation in ψ is 0.27°.

ψ, Δ curves measured during the anodization of tantalum specimens *in situ* at 25° and 60°C are shown in Fig. 4. The same angle of incidence and wavelength were used as for the dry measurements. The refractive index of the solution was taken as $n_0 = 1.334$ at 25°C and 1.329 at 60°C. The curve at 25°C was fitted using the same optical constants for the metal and oxide as the "dry" curve, but at 60°C, an oxide refractive index of 2.27 was used (with the same constants for the metal). The experimental points are shown for 3 cycles of the 25°C curve lie on a single curve. This demonstrates that within the thickness range studied (about 3700Å) the optical constants do not alter appreciably. The deviations of the experimental points from the calculated curve are shown in Fig. 5.

Steady-state formation kinetics (tantalum).—In order to obtain the kinetics of the oxide growth, specimens were first anodized to at least 90v at a constant

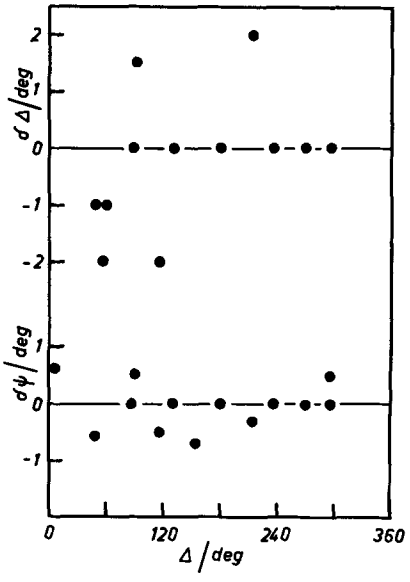

Fig. 5. Deviations of the experimental points from the fitted curves at 25°C for Fig. 4.

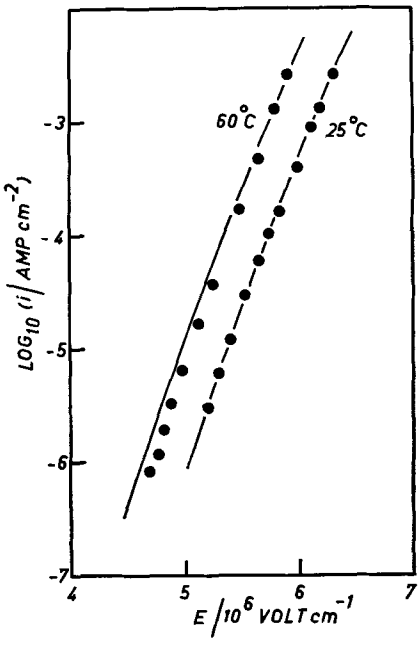

Fig. 6. Tafel plot for tantalum. Points, this paper; lines, calculated from constants given by Young (11) corrected to n_1 (5461Å) = 2.22.

current of about 10 ma cm^{-2} and then held at constant voltage with respect to a small platinum wire (0.7 x 0.05 cm diameter) cathode, the current being allowed to decay as the thickness increased. A small cathode gives a more constant potential than a large cathode. All measurements were carried out with the specimen *in situ*. The applied voltage was measured with a digital voltmeter. The solution was kept saturated with hydrogen. Measurements were made at 25° and 60°C. At suitable intervals the current was interrupted and the thickness measured. A sufficiently long time was allowed between interruptions so that approximately steady-state conditions were observed. Switching at the shorter intervals of time (less than 1 min) was accomplished by means of an electronic timer. The longer times were measured with a stopwatch, and the circuit was then broken manually.

The resulting values of thickness *vs.* $\log_{10}$ (time) were fitted by a smooth curve and differentiated using an IBM 7040 computer. The approximation made by Dreiner is not necessary. Results were checked by graphical differentiation. The ionic current is obtained from the rate of increase of thickness by applying Faraday's law: $I = (10\ F\rho/M)\partial D/\partial t$ where I is the ionic current per unit area, t is the time, F is Faraday's constant, ρ is the density, M the molecular weight, and D the thickness of the oxide.

The potential of the cathode was measured relative to a Pt/H_2 electrode in the same solution for currents over the range used. The ohmic potential drop across the solution was also determined over this current range. The electric field in the oxide was taken as $E = V/D$, where V is the potential of the tantalum in excess of the reversible potential for oxide formation (1).

The so-called Tafel plots of log I *vs.* E are shown in Fig. 6. The smooth curves were calculated from the constants used by Young (*11*) to fit his experimental results. The agreement is mostly within 1% in the field when both sets of data are brought to the same refractive index basis.

Figure 7 shows $T\Delta\log_{10}I/\Delta E$ (where $\Delta\log_{10}I = 1$) *vs.* mean field. This plot emphasizes the nonlinearity of the log I *vs.* E relation and shows that, although the curvature of plots of log I *vs.* E may appear small to the eye, it is large compared to experimental uncertainties.

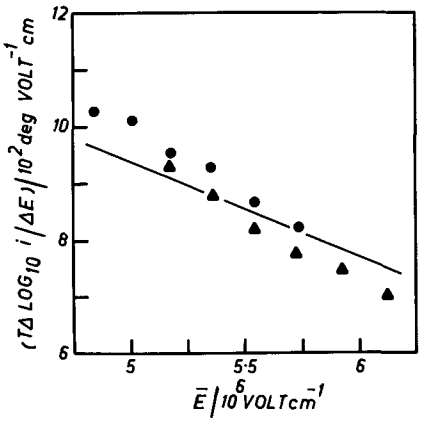

Fig. 7. $T\ \Delta \log_{10} I/\Delta E$ for $\Delta \log_{10} I \simeq 1$ for data of Fig. 6. The line corresponds to the equation fitted by Young to his data. ▲, 25°C; ●, 60°C.

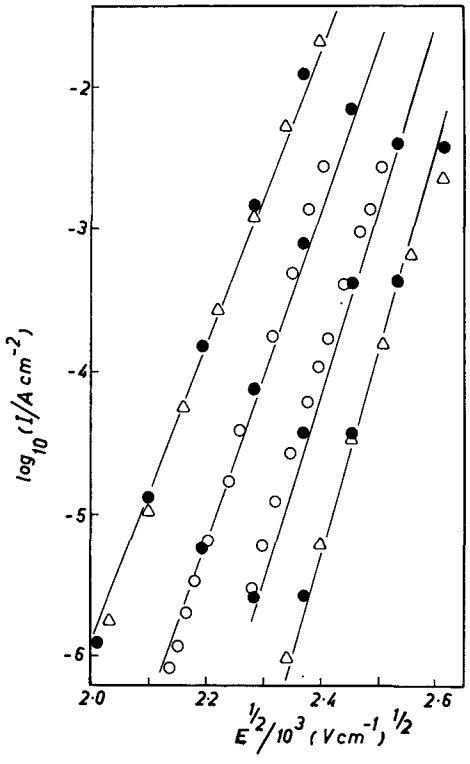

Fig. 8. Schottky-type plot: (*i*) O data from Fig. 6 converted to refractive index used by Young (19, 11); (*ii*) ●, points calculated from equation with $W(E) = W_0 - q\alpha E + q\beta E^2$ fitted by Young; and (*iii*) Δ experimental data of Vermilyea [(8) plus private communication of tabular data] converted by factor 7.93 x 0.99/8.74 to allow for assumed density. The straight lines are calculated from $I = I_0 \exp((-W + \gamma E^{1/2})/kT)$ with $I_0 = 10^{8.05}$ Acm^{-2}, $W = 2.56$ ev, and $\gamma = 7.65 \times 10^{-4}$ ev/(v cm^{-1})$^{1/2}$.

It is of interest (see Discussion) to test the equation $I = I_o \exp[-(W_o - \gamma E^{1/2})/kT]$. Figure 8 shows that this expression represents the data quite well, certainly better than the Frenkel law. This "Schottky" expression contains one less adjustable parameter than the expression with $W = W_o - q\alpha E + q\beta E^2$, and it cannot, therefore, be expected to give so good a fit as this expression.

Figure 8 also serves to compare the data of Vermilyea (8), Young (11), and the present paper. All have been brought to the same basis of thickness determination. (Vermilyea's data were based on an assumed value of the density which later work has shown to be about 10% too high). Evidently the agreement is excellent.

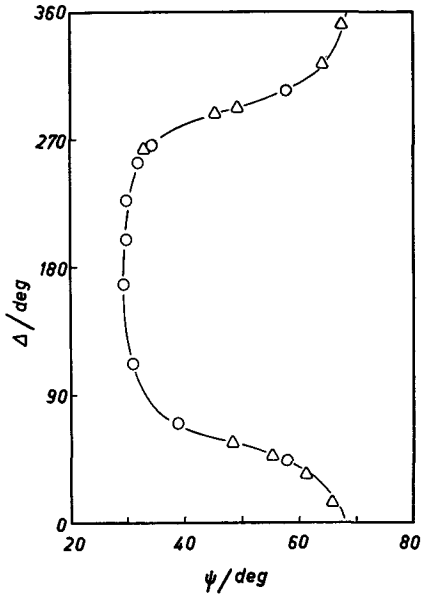

Fig. 9. Ellipsometry data at 5461Å and 67.5° angle of incidence for niobium measured dry. The curve is calculated from $n_1 = 2.37$, $n_2 = 3.60$, and $k_2 = 3.60$. 0, first cycle; Δ, second cycle.

Results for Niobium

The procedures and the general nature of the results were very similar to those for tantalum. The formation voltage was, however, 60v at 25°C and 40v at 75°C since niobium does not behave so ideally as tantalum at higher voltages.

The optical constants of the metal were determined by fitting curves for specimens measured dry. They were $n_2 = 3.60 \pm 0.05$ and $k_2 = 3.60 \pm 0.05$ for the metal and $n_1 = 2.37 \pm 0.02$ for the oxide. The oxide index agreed within experimental error with that calculated for this wavelength 5461Å from the dispersion curves given by Young (20), obtained by a spectrophotometric method with scaling using an absolute value determined using a modification of a method due to Abelès by Masing, Orme, and Young (15).

Figure 9 shows ellipsometric data for immersed specimens anodized and measured at 25°C. The data

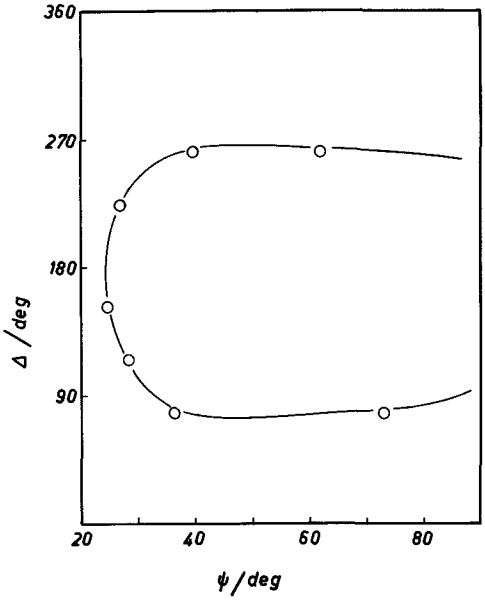

Fig. 10. Ellipsometry data *in situ* for niobium. The curve is calculated with $n_0 = 1.334$ and the other constants as in Fig. 9.

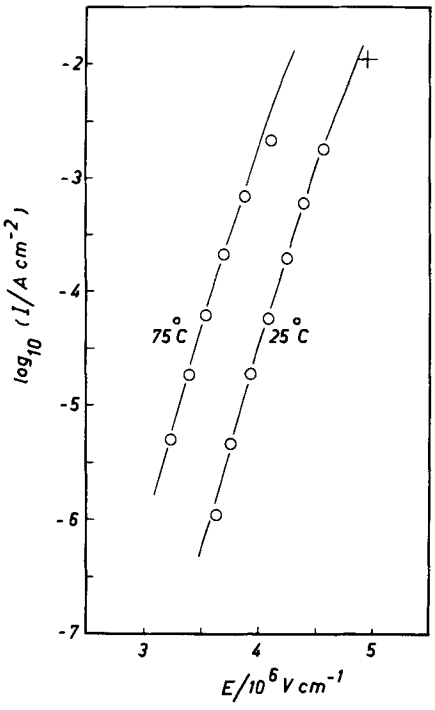

Fig. 11. $\log_{10} I$ vs. E for niobium. The curves are the fitted equation (see text).

at 75°C were of equivalently good fit to the curves using the optical constants determined from measurements on dry specimens. The index of the solution was taken as 1.334 at 25°C and 1.320 at 75°C.

Figure 11 shows plots of $\log_{10} I$ vs. E. The values of the current density were obtained from $\partial D/\partial t$ using density 4.74g cm^{-3} (21). Figure 12 shows $T\Delta \log_{10} I/\Delta E$ vs. mean field. The line in Fig. 12 and the curves in Fig. 11 correspond to the fitting equation

$$I = 10^{7.24} \exp\left(-\frac{2.168ev}{kT}\right) \exp\left(\frac{e(10.74 \times 10^{-8}cm - 8.36 \times 10^{-15}volt^{-1}cm^2 E)E}{kT}\right) Acm^{-2}$$

The constants in this equation are quoted with sufficient accuracy to reproduce the data. If they are given some physical interpretation, they cannot be regarded as determined to the number of decimals quoted since they are not independent. Figure 11 also contains a single point determined by the spectrophotometric method for the thickness (20). This is in good agreement. An earlier investigation of the anodic oxide films on niobium (22) gave a nonlinear relation which was interpreted in terms of Dewald's theory, and the present simpler description was not tested. It is hardly necessary to demonstrate that the Schottky law fits quite adequately. Plots of log I vs. $E^{1/2}$ are again certainly more linear than the Frenkel type of plot, log I vs. E. The above equation again gives a better description, but this is because it contains an extra adjustable parameter.

Results for Silicon

The ellipsometric method is particularly useful for silicon because with this material the ionic current is only a very small fraction of the total current as contrasted with tantalum and niobium with which the ionic current constitutes nearly all the current, despite the high field strengths.

The experimental ellipsometry data were fitted by curves calculated using Archer's values (23) for the optical constants of silicon $n_2 = 4.05$ and $k_2 = 0.028$ with the oxide refractive index taken as $n_1 = 1.475 \pm 0.005$. Claussen and Flower (24) found $n_1 = 1.468 \pm 0.003$ for silicon anodized in 0.0025N KNO_3 in anhydrous N-methylacetamide.

Log I vs. E for a number of experiments is shown in Fig. 13. The line is $I = 10^{-14} \exp(10^{-6}\ cm\ v^{-1}\ E)\ Acm^{-2}$. The activation distance is only very roughly determined by the data, and there is no question of deciding whether or not curvature is present. The data suggest an activation distance of 0.6 to 1.5Å.

Discussion

The form $W = W_o - q\alpha E + q\beta E^2$ was first proposed (11, 12) as an empirical equation but with the basic assumption in mind [ref. (12), p. 406] that some form of nonlinearity in $W(E)$ was to be expected at high field strengths and that no transition with increasing field between two mechanisms was required to give a nonlinear relation between log I and E. If the free energy of activation is expanded in powers of E, one should expect that sufficiently accurate measurements will require the inclusion of terms of higher order than the first power. Various sources of such an effect were discussed, including the nature of the potential energy vs. distance relation. (The model with high curvature at the minimum and a sinusoidal maximum was correctly shown to give too small an

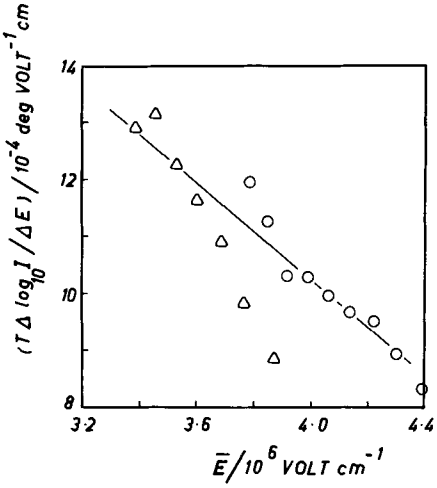

Fig. 12. $T\Delta \log_{10}/\Delta E$ vs. mean E for $\Delta \log_{10} I = 1$ for data of Fig. 11. The line corresponds to the fitted equation. 0, 25°C; Δ, 75°C.

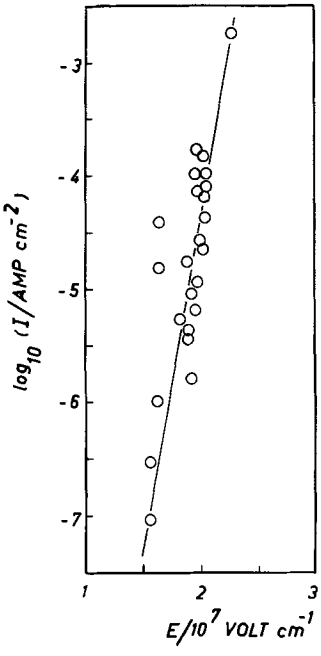

Fig. 13. $\log_{10} I$ vs. E for silicon

effect, but the statement about mirror symmetry was an error.) A physical mechanism was later proposed (25) which gives the observed type of effect and which has the decided advantage that it must occur to some extent. This is that the activation energy will increase due to the compression of the lattice which must occur on application of an electric field. The compression will be proportional to the square of the field. Dignam (7) has criticized this theory on the grounds that the data of Jost [cf. (26)] for halide crystals which were quoted as indicating the correct order of magnitude give only 1/20 of the required effect (which would still seem to satisfy the "order of magnitude" description). However, the present materials are open glassy structures of low density which may reasonably be expected to give larger effects than halide crystals. A direct test of the theory by applying pressure was unsuccessful due to experimental difficulties.

Dignam proposed instead that the effects were due to the form of the potential energy *vs.* distance relation, seen by the mobile ion in moving from one site to the next. Dignam expanded $W(E)$ in powers of E for three P.E. curves: a clipped parabolic function, a sinusoidal function, and a Morse function: P.E. $= W_o[1 - \exp(x/L)]^2$ in our notation, where x is distance, and L a constant. He found that the first two functions gave an inadequate effect, but that the Morse function fitted data for tantalum, niobium, and aluminum very well. His conclusion was that the curvature "arises quite naturally from a more detailed analysis of the ion transfer process at high fields." This would seem to be misleading. We suggest that what Dignam has done is to show that, if the observed curvature is to be explained entirely in terms of the P.E. *vs.* distance relation function, this function must approximate to the shape of a Morse function. Such a function does not seem to be applicable quite as generally as Dignam suggests. In effect, it suppresses any periodic nature of the material. The position of maximum energy at zero field is at infinity. In a crystalline material one would surely expect that the peaks in the potential energy curve would be relatively sharp so that an applied field would not move them very far. A model to which the Morse function is more appropriate is as follows. We suppose that ions move fairly freely in channels through the labyrinthine open structure of these films, but may become trapped by coulombic attraction at pockets of excess negative charge which will be present, due to the random nature of the glassy structure, at infrequent places along the channels.

With this model the transients might arise from a variation of the proportion of trapped ions and from the building of queues at blocks in the channels. The accelerating build-up of current when a large field is suddenly applied could be due to the clearing of jams by rapidly moving ions. The ions would acquire greater velocity and hence be more effective as the process continued. The obvious and simplest way to treat the above model is in fact not to assume a Morse function but to assume that except very near to the traps the attraction between the mobile ions and the trapping centers in coulombic. With an applied field E we have P.E. $= -A/x - qEx$ (where A is a constant and x is the distance along the path of the ion). A derivation analogous to that of the Schottky law for high field emission of electrons from metals or to that of the Poole-Frenkel law for high field liberation of electrons from traps leads to $I = I_o \exp(-W_o/kT) \exp(\gamma E^{1/2}/kT)$ where γ is a constant. We should perhaps not expect γ to have the value $q_2 q_1^{1/2}/(\epsilon\epsilon_o\pi)^{1/2}$ (M.K.S.) predicted by the above treatment (where $q_1 = z_1 e$ = charge on trap, $q_2 = z_2 e$ = charge on mobile ion, and ϵ = dielectric constant) since, as in the model of Bean, Fisher, and Vermilyea, the steady-state parameters will include an allowance for the change in concentration of mobile ions with field. However, we have shown elsewhere (2) that the transient $\partial \log I/\partial E$ data for tantalum also fit a Schottky law and that the slope is consistent with $z_1 = z_2 = 1.4$. It should perhaps be mentioned that the Schottky form of law was tested as an empirical law by Güntherschulze and Betz (27) and again by Charlesby (28).

A later paper by Dignam (29) presents a radically new approach in which the amorphous nature of the oxide is brought fully into play. However, it need not be discussed in relation to the present results since the feature which reproduces the nonlinearity of $W(E)$ is again the use of a Morse function potential energy.

A further difficulty is presented by the tracer experiments of Davies, Pringle, and their collaborators [*e.g.*, (30), reviewed in (2)]. These experiments appear to show that both metal and oxygen ions move to about equal extents in the oxide films on tantalum, niobium, and aluminum. As has been noted before by various authors in connection with various theories which required similar coincidences, it is unlikely that both ions should move to similar extents if their motions are independent, since even a slight difference of activation energy or activation distance should prevent this. Dignam (29) explained this result in terms of a reorganization which he supposed will occur in the individual mosaic blocks (which he postulated are present in the structure of the oxide) each time they receive an extra ion, because of the disturbance of the dipole moment of the mosaic blocks and because of the comparatively large amount of energy which the mobile ions will pick up from the field and hand over to the mosaic block on arrival. Vermilyea (in a private communication) suggested that when a metal ion breaks loose from the network the neighboring oxygen ions will also tend to be freed. Some such *ad hoc* assumption seems the only way at present to fit the mobility of both ions, if it is accepted, into the theory.

The Characterization of Anodic Aluminas

III. Barrier Layer Composition and Structure

G. A. Dorsey, Jr.

Department of Metallurgical Research, Kaiser Aluminum & Chemical Corporation, Spokane, Washington

ABSTRACT

High-purity aluminum sheets were anodized in both sulfuric and deuterosulfuric acid electrolytes. The anodic coatings from each electrolyte were analyzed by infrared to determine the composition and nature of the anodic barrier layer. We found that deuteration of the alumina lowered the absorption frequency of the 900-1000 wavenumber barrier layer band and also reduced the amount of both the porous layer Al = O and barrier layer. We conclude, from these data, that the barrier layer is a trihydrate. The primary phase of the barrier layer, as obtained initially or by boric acid anodizing, may be a cyclic aluminic acid trihydrate. A secondary barrier phase may be a decyclized form of the primary, having more terminal groupings and a lower polymer weight.

Previous studies have shown that the infrared absorption of the barrier layer distinguishes it from the porous layer even when the two layers are present together within the same film (1). The following correlation chart was derived from this preliminary work; the absorption band belonging to the barrier layer is included.

Alumina bond type	Infrared absorption frequency range, wavenumbers
AlO↔H stretch	3660-2940
Al<=>O stretch	1696-1345
Al↔OH bend	1162- 900
(Monohydrates near 1070 cm^{-1}, while trihydrates below 1025 cm^{-1})	
(Barrier layer	1000- 900)
Al↔OAl stretch	Below 900

Barrier layers, then, always exhibit an absorption band within only a narrow region of the infrared spectrum, a region normally ascribed to alumina trihydrates. A barrier layer formed by boric acid anodizing has only one absorption band within the 4000 to 33 cm^{-1} range (1), a band near 950 cm^{-1}. Further, the barrier layer was found to change during the course of anodizing, as the growth of the porous layer was first initiated and then accelerated (2). Quantitative infrared analyses revealed that the absorption band defining the barrier layer tended to shift toward higher frequencies as the amount of porous layer increased. A frequency shift in this direction normally corresponds to a conversion from a high polymer weight to a series of lesser polymers.

The primary objective of the present study was to establish whether or not the anodic barrier layer is truly hydrated. The barrier layer infrared absorption band is within the alumina trihydrate region; however, alumina hydrates also normally have a second series of bands located in the higher frequency region near 3400 cm^{-1}. Barrier layers do not have infrared bands in this region or at least not until the barrier layer 1000-900 cm^{-1} band has shifted, indicating an alteration in the structure of the barrier layer. This presents an anomaly. If the barrier layer is truly an alumina hydrate, then some irregularity of structure has caused the AlO ↔ H stretch band to disappear, or, as with hydrogen bonding, the band could be broadened to such an extent that it cannot be located.

Frequently, structures involving hydrogen can be elucidated by replacing the abundant hydrogen with one of its isotopes: here, deuterium was substituted for protium. The mass of the deuterium ion is twice that of protium, and the increase in the reduced mass of a deuterated system causes a reduction in the wavenumber of absorption bands involving hydrogen. A comparison of the infrared spectrum of the protonated material with that of the deuterated compound reveals those bands that involve structural hydrogen; these bands will have shifted to lower frequencies as a result of the isotopic mass effect.

Accordingly, we attempted to determine the composition of the barrier layer by anodizing in deuterium oxide (heavy water) solutions of deuterosulfuric acid. Parallel anodizing studies were also made in protonated systems of sulfuric acid.

Experimental

Anodic aluminas.—Cleaned 99.99% aluminum sheets were used as the substrate material for the samples prepared. The two electrolyte systems were prepared as described below and were verified by titration before proceeding further.

1. Deuterated system: 1.0*N* deuterosulfuric acid in heavy water. Both reagents were obtained from Diaprep, Inc. of Atlanta and were reported to be more than 99% deuterated.

2. Protonated system: 1.0N sulfuric acid in distilled water.

Both electrolytes were used with a 1.08 amp/dm^2 current density for 5.0 min. Anodizing temperatures were varied to cover the region between 10° to 45°C. The samples were not sealed after anodizing.

Infrared analysis.—The samples were examined, as before (1), over the 4000-600 cm^{-1} range of the Beckman IR-7. The flat anodized sheets were mounted in the sample stage of a C.I.C. ATR-1 reflectance attachment at a 45° angle of incidence. Double beam spectra were obtained *vs.* a front-surfaced aluminized mirror, which was mounted the same as the sample.

Quantitative determinations were made using a weight method of graphical integration. Checks showed that precision, using this method, was within ± 1.3%. The IR-7 was operated with a slit program and gain settling yielding an unloaded SB/DB ratio of 1.5; speed and period were adjusted for each sample so that the instrument response was adequate.

Results and Discussion

As was done earlier (2), we chose to identify the porous component of the sulfuric acid anodic coating with an Al=O band occurring at 1325 wavenumbers. Sulfuric-anodized films also show a probable sulfate band near 1150, but the absorbance of this band could be altered by both anodically incorporated and free residual sulfate. Changes in the absorbance of the Al=O band should be caused only by changes in the amount of porous coating. We recognize that a one-to-one correlation has not been established between the Al=O absorbance and the "amount" of porous layer (2). Further, the concentration of this bond group may vary with the thickness of a porous layer. Pending further work, we will refer only to the amount of porous layer Al=O, or to the apparent amount of porous layer, and not to the "amount" of porous layer itself.

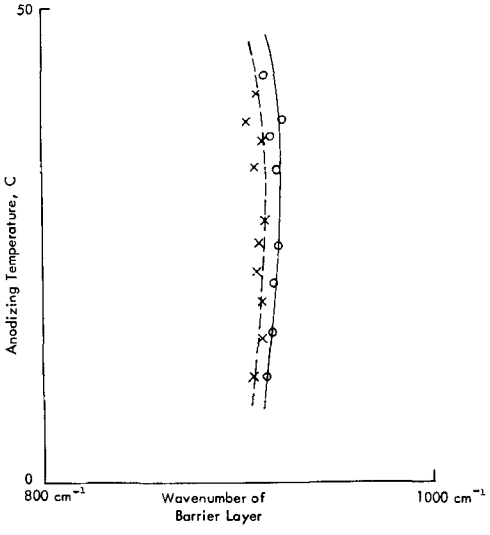

Fig. 1. Anodizing temperature *vs.* wavenumber of barrier layer. ○, 1.0*N* H_2SO_4, 1.08 amp/dm^2, 5 min; X, 1.0*N* D_2SO_4, 1.08 amp/dm^2, 5 min.

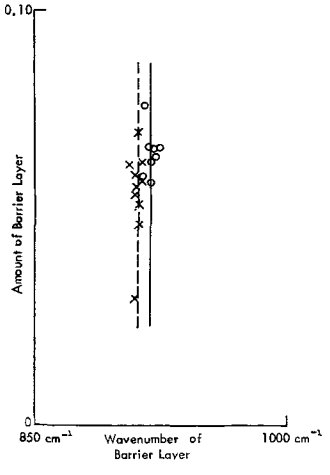

Fig. 2. Amount of barrier layer *vs.* wavenumber of barrier layer. ○, 1.0*N* H_2SO_4, 1.08 amp/dm^2, 5 min; X, 1.0*N* D_2SO_4, 1.08 amp/dm^2, 5 min.

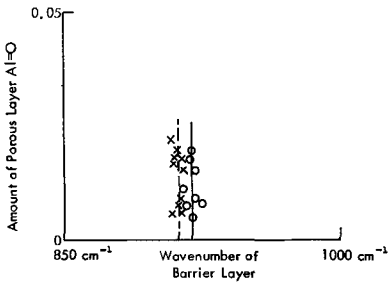

Fig. 3. Amount of porous layer Al=O *vs.* wavenumber of barrier layer. ○, 1.0*N* H_2SO_4, 1.08 amp/dm^2, 5 min; X, 1.0*N* D_2SO_4, 1.08 amp/dm^2, 5 min.

The amount of barrier layer was determined from the absorbance of the band lying within the region of from 900 to 1000 cm^{-1}.

Figures 1, 2, and 3 clearly show the effects of deuteration on the barrier layer. The infrared absorption band of the barrier layer was at a lower frequency when the barrier layer was prepared in a deuterated system than it was when prepared in a protonated system. The difference between protonated and deuterated systems is apparent regardless of the anodizing temperature (Fig. 1), the amount of barrier layer (Fig. 2), or the apparent amount of porous overlayer (Fig. 3). When prepared under the same conditions, the barrier layer absorption was at 920 cm^{-1} for the protonated system and 912 cm^{-1} for the deuterated system.

We also found that deuteration changed the apparent amount of porous coating obtained at different anodizing temperatures. The deuterated system required a higher anodizing temperature to produce the same apparent amount of porous coating as that produced in the protonated system (Fig. 4). Deuteration produced a similar change in the relation between the barrier layer and the electrolyte temperature (Fig. 5).

Reactions involving deuterium generally proceed at slower rates than those involving hydrogen, and the extent of chemical reactions is generally less complete (3). Therefore, higher temperatures or longer reaction times are usually required to make the same amount of product (here, anodic alumina) when deuterium is substituted for protium. These differences were

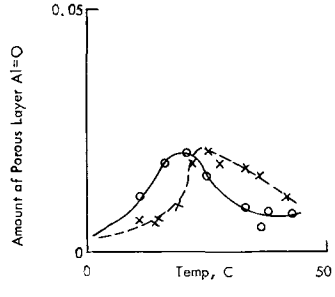

Fig. 4. Amount of porous layer Al=O *vs.* anodizing temperature. ○, 1.0*N* H_2SO_4, 1.08 amp/dm^2, 5 min; X, 1.0*N* D_2SO_4, 1.08 amp/dm^2, 5 min.

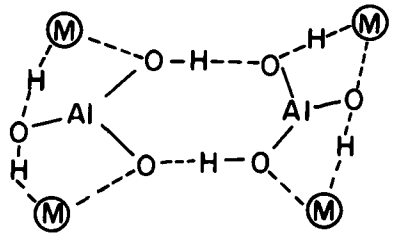
noted in our observations regarding the relative amounts of porous and barrier layers obtained in deuterated and protonated systems, respectively.

Conclusions

The data show that hydrogen is an integral component of the anodic alumina barrier layer; if this were not so, deuteration would have had no effect.

It was previously shown that the barrier layer infrared band was in the alumina hydrate region (2), but anomalies were found: (*i*) barrier layers showed no absorption in the 3400 AlO-H stretch region, and (*ii*) barrier layers showed no Al-OAl absorption bands even when examined down to 33 cm^{-1}.

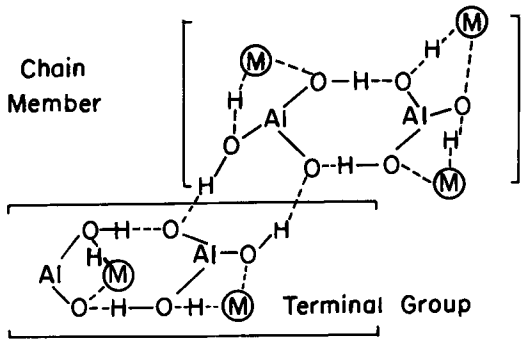
It is well established that hydrogen bonding shifts the frequency of the oxygen-hydrogen stretch vibration and reduces the intensity of the band by broadening it (4). Strong hydrogen bonding may entirely remove the band from the 3400 region. Hydroxyl vibrations are also shifted by hydrogen bonding, but band intensities are not similarly affected. We propose that the absence of a 3400 region infrared band indicates that strong hydrogen bonding is present within the barrier layer. Further, since no Al-OAl linkages were detected in barrier layer infrared spectra, and since the barrier layer infrared band is in the alumina trihydrate region, the barrier layer must have a trihydrate composition. The simplest structure for a strongly hydrogen-bonded trihydrate is:



when this represents a unit section of a long polymer chain and M designates an identical unit within the same chain.

However, the barrier layer structure must have terminal groups, and to fit the existing data, the linkages within the terminal groups must be identical with those in the chain. If more than one fundamental type of linkage were present, then the barrier layer spectrum would have more than one absorption band: weak Al=O or weak Al=O-plus-monohydrate absorptions. The spectrum has only one band, however, and that lies in the lower frequency region for trihydrates, between 900 and 1000 cm^{-1}. We must attempt to account for chain-terminating groups using only AlOH---OAl linkages. The simplest structure here would require that aluminum have a subvalent oxidation state within the terminal groups.

Our proposed structure for the anodic barrier layer is then as follows, where aluminum is present in both divalent and trivalent oxidation states.



We propose to call this structure the primary barrier layer phase and refer to it as a cyclic aluminic acid trihydrate. The oxygen deficiency of the anodic barrier layer has long been established (5-8), and our divalent aluminum-containing barrier layer is consistent with this deficiency. The divalent aluminum content of the barrier layer would produce a greater aluminum/oxygen ratio than that corresponding to the solely trivalent aluminum in Al_2O_3. Although Al (I) is a more common subvalent oxidation state for species such as gaseous aluminas, Al (II) has also been suggested (9).

We have found that a second type of bonding, the Al=O bond, forms as anodizing progresses further to produce the porous layer (2). It was also noted that the frequency of the barrier layer band increased as this occurred. This was taken to mean that the barrier layer underwent a change from high to low polymer weights as anodizing progressed through to the porous layer stage; the altered form of the barrier layer was termed the "parent layer" since the conversion appeared to be a requirement for porous layer formation.

We now propose that the parent layer represents a secondary phase of the barrier layer which has undergone a conversion from the cyclic to a decyclic form. The oxygen-deficient terminal groups of the cyclic primary phase would be a logical site for further oxidation leading to depolymerization with the formation of Al=O linkages. The introduction of these chain-terminating groups would also give rise to a series of lower polymer weights; this would result in a wavenumber shift of the barrier layer infrared band, as has been reported earlier (2).

Reflectivity Studies of Epitaxial $Ga_xIn_{1-x}As$

R. W. Conrad, C. E. Jones, and E. W. Williams

Texas Instruments Incorporated, Dallas, Texas

The reflectivity spectra in the uv-visible range of various $Ga_xIn_{1-x}As$ alloys, prepared by a gradient-freeze method, have been reported by Woolley and Blazey (1). A linear variation of the energy of the E_1 (low energy) reflectivity peak with alloy composition was observed. The E_1 transition has been ascribed by Cardona (2) to an L (Brillouin zone edge) transition, but later work by Brust *et al.* (3), with germanium indicates a Λ (within the Brillouin zone) transition, perhaps at about the point (1/6, 1/6, 1/6) in k space. We wish to report the results of our reflectivity measurements on single-crystal, epitaxial $Ga_xIn_{1-x}As$ alloys deposited on GaAs substrates, in particular the anomalous results obtained on as-grown and mechanically polished deposit surfaces.

Experimental

Epitaxial $Ga_xIn_{1-x}As$ alloys were prepared from the vapor phase in an open-tube reactor system[1] using undoped GaAs and InAs source materials[2] and $AsCl_3$-saturated hydrogen as transport agent. Substrates were Cr-doped, semi-insulating (4) and Te-doped (5×10^{18} cc^{-1} GaAs,[2] cut 3° off the (111) toward the (100). These were chemically polished, using a technique similar to that described by Reisman and Rohr (5) for the room-temperature polishing of GaAs. All substrates were chemically etched in hot aqueous NaOCl solution immediately prior to deposition. Deposits were obtained on both sides of the substrates, but in general, only one side of the substrate had been chemically polished beforehand. In several deposition experiments, two substrates were used, one with a chemically polished A (111) surface, the other with a chemically polished B (111) surface. Deposit thicknesses were from 2-15μ on B (111) substrates and 10-50μ on A (111) substrates. Deposition rates tended to decrease when depositing higher indium-content alloys.

[1] Details of the reactor system will appear in a later publication.

[2] From Texas Instruments Incorporated, Dallas, Texas.

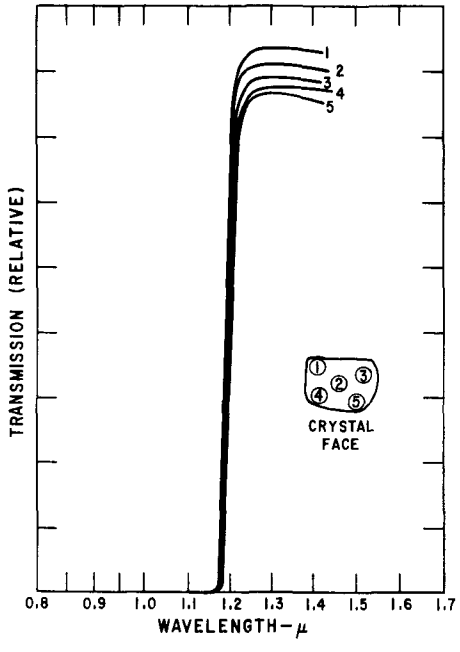

Fig. 1. Infrared transmission of epitaxial $Ga_xIn_{1-x}As$ illustrating lateral composition homogeneity.

Deposits were evaluated for single-crystallinity by microscopic examination of surface and cleaved edge, and by "light-figure" patterns of the surfaces (6). Several representative samples were also examined for single-crystallinity and epitaxial orientation by electron diffraction reflection scans of the as-grown surfaces. To determine composition homogeneity, infrared transmission spectra were measured at several different locations on the sample surfaces. Figure 1 shows the results of such measurements for a typical sample and indicates very good composition homogeneity both in the plane of and perpendicular to the deposit surface.

The reflectivity spectra in the range 0.35-0.75μ were measured with a Perkin-Elmer Model 350 recording spectrophotometer. Alloy compositions were calculated from the E_1 peaks for a series of as-grown samples, with the reactor conditions varied to obtain various alloy compositions. In every case, the apparent compositions of the as-grown layers were higher in GaAs on the A (111) side. This apparent composition difference was independent of whether the particular substrate surface had been chemically polished or not, prior to deposition. Examination of several of these samples by infrared transmission and x-ray diffraction methods, however, showed no difference in composition between the A and B side deposits. Further, the reflectivity compositions of the A (111) samples were in good agreement with values determined from x-ray and infrared transmission measurements, the B (111) samples being anomalous. To determine if the apparent composition difference was peculiar to polar substrates, several depositions were made on (100) GaAs substrates. In each case, the compositions of the as-grown deposits as determined from reflectivity were identical on the two sides of the substrates and in good agreement with x-ray and transmission measurements. These results are summarized in Table I.

Several B (111) samples which exhibited anomalous reflectivity compositions were re-examined by reflectivity after successive removal of thin layers of deposit (0.5-2.0μ) by hand-lapping with 0.3μ alumina abrasive. The E_1 peaks were appreciably broadened and compositions determined after each lapping varied erratically and were unreproducible. In the case of one sample whose actual composition (from infrared transmission and x-ray diffraction) was $Ga_{0.5}In_{0.5}As$, composition determined by reflectivity after successive lappings varied randomly from $Ga_{0.2}In_{0.8}As$ to $Ga_{0.8}In_{0.2}As$. This effect was also observed for A (111) and (100) surfaces of epitaxial alloys, whereas epi-

* From A side reflectivity confirmed by x-ray diffraction and infrared transmission.

taxial and bulk GaAs and InAs showed only peak broadening but no shift in energy.

To determine if the anomalous reflectivity results after mechanical polishing could be caused by surface melting (7) and subsequent regrowth of a thin surface layer of different composition from the rest of the deposit, several InAs (111) substrates were mechanically polished with a 0.3μ alumina-liquid gallium slurry (at *ca.* 35°C). Were surface melting to occur, alloying with the gallium should take place, forming a thin surface layer of $Ga_xIn_{1-x}As$. Reflectivity spectra of the surface of these substrates after such a treatment showed no shift in the E_1 peak.

Light chemical etching of the alloy deposit surface was found to yield very reproducible reflectivity spectra. A short treatment of either as-grown or mechanically polished deposit surfaces with dilute bromine-methanol solution, sufficient to remove 1-2μ of deposit, gave reproducible reflectivity spectra in every sample examined. Further, the compositions of the A and B side deposits after etching were found to be identical, the apparent fraction of GaAs in the B side deposit having increased to that of the as-grown A side deposit, with the A side composition remaining unchanged. These results are illustrated in Fig. 2 which shows the shift in reflectivity peaks for as-grown A and B side deposits, and in Fig. 3 which shows the coincidence of the reflectivity peaks for the same sample after chemical etching.

To determine if a difference in mechanism of thermal dissociation of the A and B side deposits, such as reported by Miller *et al.* (8) for GaAs, could be a factor in producing the anomalous reflectivity results on as-grown B (111) surfaces, we heat-treated a chemically etched sample for a short time at 720°C in flowing hydrogen. These conditions are similar to those in the vapor deposition reactor during the shutdown procedure. Reflectivity measurements on this sample, however, showed no apparent change in composition.

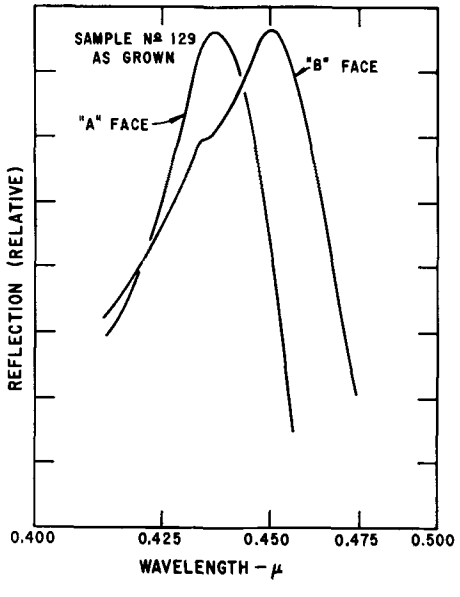

Fig. 2. Reflectivity spectrum of a sample of as-grown epitaxial $Ga_xIn_{1-x}As$.

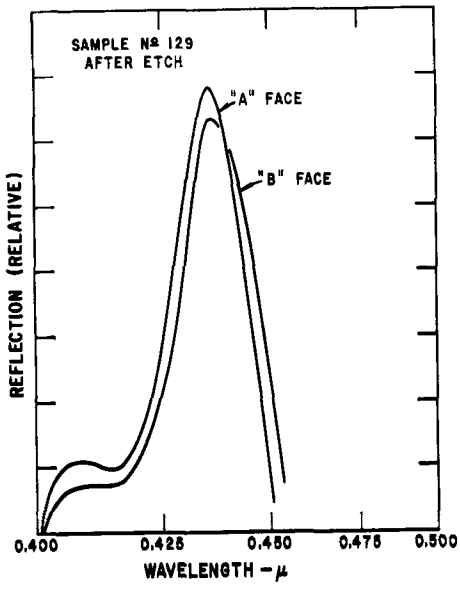

Fig. 3. Reflectivity spectrum of a sample of epitaxial $Ga_xIn_{1-x}As$ after etching.

Discussion

The anomalous compositions as determined by reflectivity for the B (111) side $Ga_xIn_{1-x}As$ alloy deposits appear to be connected in some fashion to the fundamental differences between the A (111) and B (111) sides, and not to some peculiarity of the vapor deposition system, since deposits on nonpolar (100) GaAs substrates do not exhibit this effect. A difference in mechanism of thermal dissociation of A (111) and B (111) $Ga_xIn_{1-x}As$ surfaces, although probably present, does not seem to be a factor in producing anomalous reflectivities. Whatever the reason for this phenomenon, light chemical etching apparently eliminates it.

A satisfactory explanation for the anomalous composition values obtained by reflectivity on mechanically polished $Ga_xIn_{1-x}As$ alloy surfaces is still lacking. Surface melting probably can be eliminated as a factor, but oxide formation has yet to be investigated.

Cardona (9) has listed semiconductor surface preparation techniques in order of decreasing quality as: cleaved > vapor grown > liquid grown > electropolished > chemically etched > mechanically polished. Our results for epitaxial $Ga_xIn_{1-x}As$ indicate: chemically etched > as-grown > mechanically polished.

Phase Diagram for the Pseudobinary System InSb-InSe

D. F. O'Kane and N. R. Stemple

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

This note describes the results of an investigation of the InSb-InSe pseudobinary phase diagram using differential thermal analysis (DTA) and x-ray methods.

InSb has a zinc blende structure with a lattice parameter a = 6.4782Å (1). InSe has been reported to have a rhombohedral structure (2) with a = 4.02Å and c = 25.05Å and a hexagonal structure with a = 19.2Å, c = 4.00Å (3) and a = 4.05Å, c = 16.93Å (4). There is no known investigation of the pseudobinary system composed of InSb-InSe.

Our samples were prepared from the pure elements (99.999%)In, Sb, and Se. Fifteen grams of the elements were reacted in evacuated, fused silica tubes and water quenched from the liquid state. The samples were ground to a fine powder and annealed near 440°C for 6 to 57 days before making the x-ray powder patterns and the DTA measurements. The exact annealing conditions for each sample are described in Table I. The DTA sample tubes were made of fused silica with a thermocouple well in the bottom. The DTA heating and cooling rate was 2°C/min.

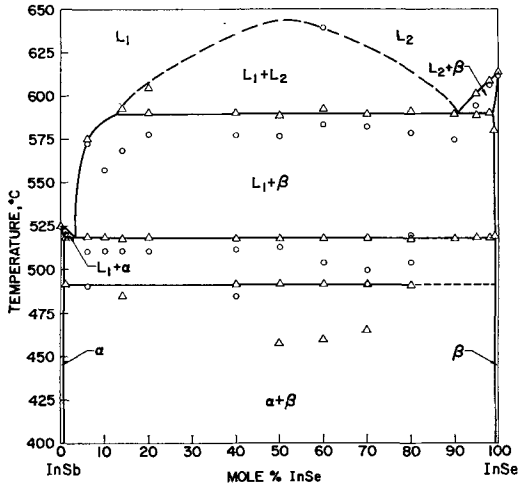

Fig. 1. Phase diagram for the pseudobinary system InSb-InSe. △, from DTA heating curves; ⊙ from DTA cooling curves.

Results

The phase diagram for the InSb-InSe pseudobinary system is shown in Fig. 1. InSb and InSe are not miscible in all proportions. A monotectic occurs at 591°C and 91 mole % InSe, and the composition of the InSb rich melt at the monotectic temperature is 13 mole % InSe. The extent of the miscibility gap in the liquid state above 591°C was difficult to estimate from differential thermal analysis, and this boundary is shown as a dashed line to indicate this uncertainty.

A eutectic exists near 3 mole % InSe and 519°C. This eutectic transformation appeared as a thermal arrest on all the heating curves for the annealed compositions between 1 and 98 mole % InSe. The DTA samples at 1 and 95 mole % InSe were annealed 57 days at 450°C in order to determine if a solid solution was formed at each of these compositions. The occurrence of the 519°C eutectic transformations in the DTA heating curve of each sample indicates a lack of complete solid solution. Zone refining of the composition $(InSb)_{30}(InSe)_{70}$ resulted in the separation of a crystal containing 0.60 w/o (weight per cent) Sb, which is equivalent to $(InSb)_{0.96}(InSe)_{99.04}$, in the first section to freeze. DTA measurements on the latter composition showed the 519° and 591°C eutectic and monotectic transformations during the heating cycle. The data on the annealed and zone refined samples indicated that the solubility of InSe in InSb

is less than 1%, and the solubility of InSb in InSe is also less than 1%.

The phase diagram characteristics associated with two phase transitions could not be determined. One transition occurred sharply at 492°C between 1 and 80 mole % InSe, and it is assumed to be a high-temperature solid-solid phase transition. The heat necessary for this transformation is only 1/10 of the quantity required for the eutectic transformation at 519°C. A smaller transition near 460°C in the 50, 60, and 70 mole % InSe samples occurs gradually over a range of 10°C and may be an order-disorder type of reaction.

The x-ray powder patterns on annealed samples of 10, 50, 80, 90, and 95 mole % InSe showed both InSb and InSe phases present. In an x-ray sample of 6 mole % InSe, which was annealed at 450° ± 5°C for 26 days, the principal phase had a lattice parameter of $a = 6.4765$Å. This is not significantly different from the reported values of $a = 6.4782$Å (1) and 6.4760Å (5) for InSb. A significant decrease in lattice parameter to $a = 6.4721$Å was noted on the annealed 50 mole % InSe; this may be connected with the transformations near 492° and 460°C.

Initially, there was a question about the powder pattern diffraction lines associated with InSe in the InSb-InSe samples. Several lines reported for InSe (3) did not show up in the InSb-InSe patterns. However, examination of InSe which was quenched from the liquid state, annealed InSe, and zone refined InSe showed a difference in diffraction lines as illustrated in Table II. After annealing the quenched InSe, the diffraction pattern was identical to that of the zone refined InSe. The change in InSe diffraction patterns may be explained by the phase diagram characteristics of the InSe binary system in the vicinity of InSe. The limits of solid solubility of InSe are unknown. Fast quenching from the liquid state could result in a two phase mixture if the maximum melting point is not exactly at InSe, and annealing could produce a single phase material.

The different lattice parameters (2-4) reported for InSe may be partially explained by the methods of preparation. Sugaike (3) used a single crystal grown by the Stockbarger method for his lattice parameter determination, Schubert (2) does not describe his method of sample preparation, and Semiletov (4) used an evaporation procedure.

Summary

Differential thermal analysis and x-ray methods have been used to characterize the InSb-InSe pseudobinary phase diagram. A monotectic exists at 591°C and 91 mole % InSe, and the composition of the InSb rich melt at the monotectic temperature is 13 mole % InSe. A eutectic occurs at 519°C and 3 mole % InSe and two other phase transitions at 492° and 460°C were present in the system. The solubility of InSe in InSb is less than 1% and less than 1% of InSb is soluble in InSe.

Acknowledgments

The authors wish to express their appreciation to J. Angilello for his assistance with the x-ray work and to B. L. Gilbert for the chemical analysis work. The zone refined InSe was obtained from Dr. D. R. Mason. Thanks are due to Drs. L. M. Foster and A. H. Nethercot for reviewing the manuscript.

Manuscript received Sept. 13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Phase Diagram for the Pseudobinary System of Sb-SnTe and Some Electrical Properties of the Ternary Alloys

D. F. O'Kane and N. R. Stemple

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

The purpose of this work was to determine the phase diagram characteristics of the pseudobinary system of Sb-SnTe, and to examine the electrical properties of some of the alloys in the system. Investigation of the Sb-SnTe system was motivated by a separate investigation in these Laboratories of the band structure of the compounds of average valence V.

The elements Sb, Sn, and Te are in the same row of the periodic table and would be expected to show substantial mutual solubilities. Sb has a rhombohedral structure with $a = 4.307$Å and $c = 11.273$Å (1). SnTe has the sodium chloride structure with $a = 6.314$Å at the composition 50.4 a/o (atomic per cent) Te-49.6 a/o Sn (2). This is the maximum melting (806°C) point composition in the Sn-Te system. Krebs *et al.* (3) have investigated the solubility of SnTe in Sb and report the limit of solubility as $Sb_{87.0}(SnTe)_{13.0}$.

Experimental Procedure

Differential thermal analysis (DTA), x-ray methods, microstructure examination, and zone refining were used to establish the phase diagram for the Sb-SnTe system. The DTA samples were made in two ways. For those samples for which only DTA cooling data

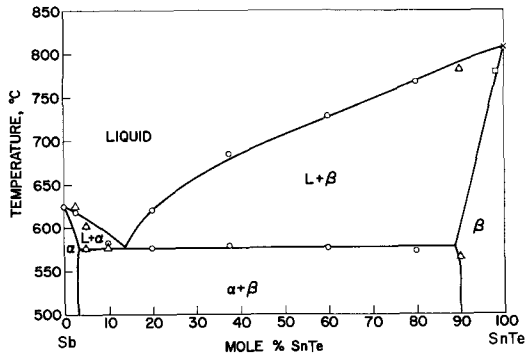

Fig. 1. Phase diagram for the Sb-SnTe pseudobinary system. △, from DTA heating curves; ⊙, from DTA cooling curves; square with a dot, from crystal No. 38; X from Brebrick (2).

were to be obtained, the elements (99.999% purity) were reacted in the DTA furnace and cooled at 2.0°C/min. The remaining samples at 5, 10, and 90 mole % SnTe were prepared by reacting the elements and water quenching them from the liquid state. They were then ground to a powder, sealed in evacuated, fused silica tubes, and annealed at 525°C for 51 days. The DTA heating and cooling rate on the annealed samples was 2.0°C/min. The x-ray powder pattern samples of 5, 10, 85, 87, and 90 mole % SnTe were annealed at 525°C for 31 to 51 days.

Zone refining for 4 to 9 passes at 0.5-0.8 in./hr. was used to separate the eutectic composition in the Sb-SnTe system for chemical analysis, and to establish the solubility of SnTe in Sb. The use of zone refining to separate the eutectic composition in a binary system has been previously demonstrated by Yue (4). Sn and Te were analyzed in the Sb-rich samples, and Sb was analyzed in the SnTe-rich samples.

Single crystals for electrical measurements were pulled at 4 mm/hr from melts of $Sb_{15}(SnTe)_{85}$ and $Sb_{95}(SnTe)_5$ in a Czochralski-type crystal puller. Electrical resistivity and Hall effect were measured by the direct current method on samples approximately 0.25 x 1 x 7 mm^3 with a magnetic field of 4,000 gauss for determination of the Hall coefficient.

Results

The phase diagram for the Sb-SnTe pseudobinary system is shown in Fig. 1. A eutectic exists at the composition $Sb_{85.8}(SnTe)_{14.2}$ and 576° ± 2° C. The limits of solid solubility are $Sb_{97}(SnTe)_3$ and $Sb_{10}(SnTe)_{90}$.

The solid solubilities and the eutectic composition were established by zone refining, microstructure examination, x-ray powder patterns on annealed samples, x-ray diffractometry on single crystal cleaved surfaces, and chemical analyses.

The results of chemical analyses on zone refined samples and Czochralski pulled crystals are summarized in Table I. X-ray analyses are summarized in Table II. The number in brackets with each sample number in Table I indicates the section number of the material analyzed. Section 3 was near the first to freeze section of the zone refined ingot, section 5 was at the center of the ingot, and section 7 was the last section to freeze. The first section, 3, to freeze in zone refined ingot No. 082 was single crystalline with the approximate composition of $Sb_{97.1}(SnTe)_{2.9}$. This should represent essentially the limit of solubility of SnTe in Sb, since section 5, which contained $Sb_{94.7}(SnTe)_{5.3}$, showed free SnTe in the powder pattern. This latter section was similar to an annealed sample of $Sb_{95}(SnTe)_5$ which also contained some second phase. The powder pattern for a mechanical mixture of 10 mole % SnTe-90 mole % Sb showed the same diffraction lines as those obtained on the annealed $Sb_{90}(SnTe)_{10}$ sample. The addition of SnTe to the Sb lattice caused an increase in volume of 0.06% at the maximum solubility of $Sb_{97}(SnTe)_3$.

Table II. Summary of x-ray analyses

Sample No.	Composition	Heat-treatment Time, days	Heat-treatment Temp, °C	Lattice parameters a, Å	Lattice parameters c, Å
	Sb			4.307*	11.273**
082(3)	$Sb_{97.1}(SnTe)_{2.9}$			4.303*	11.308
078	$Sb_{95}(SnTe)_5$	51	525	4.306*	11.283
094	$Sb_{15}(SnTe)_{85}$	31	525	6.322†	
088	$Sb_{13}(SnTe)_{87}$	23	525	6.321†	
		49	525	6.321†

		51	525	6.323†	

* Rhombohedral structure.
† Sodium chloride structure.
** From ref. (1).

Equilibrium conditions for the solution of SnTe in Sb were more closely approached in the zone refiner than in the crystal puller, as shown in Table I. This is seen by the difference in composition between the zone refined sample 082 at position 3, which was near the leading end, and the Czochralski crystals 26 and 36, which also represented the first to freeze.

The eutectic phase was observed by microstructure examination of the DTA samples of $Sb_{95}(SnTe)_5$ and $Sb_{90}(SnTe)_{10}$. The results of chemical analysis (Table I) on the end sections, 082(7), 083(7), and 090(7), of zone refined samples of $Sb_{95}(SnTe)_5$ and $Sb_{85}(SnTe)_{15}$ indicate a eutectic composition of $Sb_{85.8}(SnTe)_{14.2}$.

The limit of solubility of Sb in SnTe at 525°C is $Sb_{10\pm2}(SnTe)_{90\pm2}$. The single phase $Sb_{10}(SnTe)_{90}$ had lattice parameters of a = 6.321Å and a = 6.323Å after 33 and 51 days, respectively, at 525°C. $Sb_{13}(SnTe)_{87}$ was two phase after 49 days at 525°C; the lattice parameter of the principal phase was a = 6.321Å. These lattice parameters are comparable to the values of a = 6.318Å (2) and a = 6.322Å (5) obtained for the composition 50.1 a/o Te-49.9 a/o Sn in the Sn-Te binary system. At 777°C, the solubility of Sb in SnTe is $Sb_{1.8}(SnTe)_{98.2}$ from the chemical analysis of a single crystal pulled from a melt of $Sb_{15}(SnTe)_{85}$.

A small heat effect that occurred at 551°C during the cooling of the DTA samples containing 5, 10, and 20 mole % SnTe apparently is not representative of the equilibrium phase diagram. This transition does not appear in annealed samples during the heating cycle and may be related to the 540°C eutectic between Sb and Sb_2Te_3, which extends into the ternary

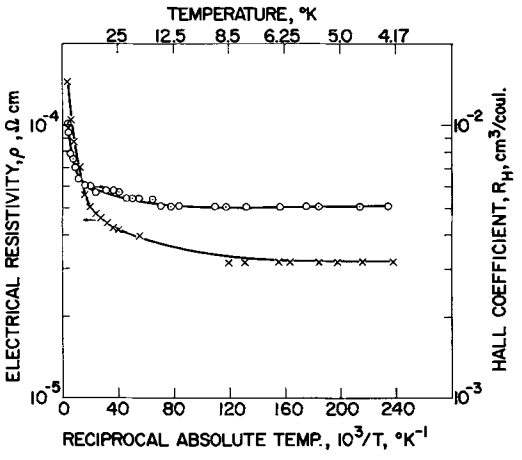

Fig. 2. Electrical resistivity and Hall coefficient vs. reciprocal absolute temperature for single crystalline $Sb_{1.8}(SnTe)_{98.2}$, sample No. 38.

field. These experimental points have been omitted from the phase diagram of Fig. 1.

The electrical resistivity and Hall coefficient data below 300°K for the single crystal $Sb_{1.8}(SnTe)_{98.2}$ are shown in Fig. 2. The concentration of Sb is 2 x 10^{20} at./cm³ from chemical analysis. The apparent hole concentration is 6 x 10^{20}/cm³ at 300°K (from $p = 1/eR_H$, where e is the electron charge and R_H is the Hall coefficient). The hole mobilities are 74 and 110 cm²/volt-sec at 300° and 77°K, respectively. These mobilities are identical to the results obtained by Brebrick (2) on doped and undoped SnTe. The $Sb_{1.8}(SnTe)_{98.2}$ crystal was grown from a melt at 777°C. SnTe grown from a Sn-rich melt at the same temperature has a carrier concentration of 3.5 x 10^{20}/cm³ at 300°K. The hole conduction in this compound is attributed to doubly ionized tin vacancies. This one experiment suggests that possibly the Sb is going on tellurium sites and increasing the tin vacancies.

At the opposite end of the phase diagram, a single crystal of $Sb_{97.6}Sn_{2.2}Te_{0.2}$ was pulled from a melt of $Sb_{95}(SnTe)_5$. The electrical resistivity, ρ, was 6 x 10^{-5} and 3 x 10^{-5} ohm-cm at 300° and 77°K, respectively. Electrical measurements were made with the current flow along the binary direction. Electrical measurements on pure Sb single crystals by Tanaka (6) resulted in $\rho_{297°K}$ = 1.28 x 10^{-4} ohm-cm and $\rho_{20.4°K}/\rho_{297°K}$ = 4.6 x 10^{-3} for current flow in the binary direction.

Summary

The Sb-SnTe pseudobinary phase diagram is a simple eutectic system with the eutectic point at 576°C and $Sb_{85.8}(SnTe)_{14.2}$. The limits of solubility are $Sb_{10}(SnTe)_{90}$ and $Sb_{97}(SnTe)_3$ at 525°C. The latter result does not agree with Krebs (3) who obtained a solubility limit of $Sb_{87.0}(SnTe)_{13.0}$ for samples annealed 24 hr near 470°C. The increase in crystal volume of Sb with the addition of 3 mole % SnTe is 0.06%. The addition of 10 mole % Sb to SnTe causes no significant change in lattice parameter from SnTe. The electrical properties of $Sb_{1.8}(SnTe)_{98.2}$ are similar to those of SnTe.

Acknowledgments

The authors would like to thank Dr. J. F. Woods for obtaining the electrical measurements and J. Angilello for assisting with the x-ray work. The chemical analyses were performed by B. L. Gilbert and B. L. Olson. Thanks are due to Dr. L. M. Foster and Dr. A. H. Nethercot for reviewing the manuscript.

Manuscript received Sept. 13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Annular Facets and Impurity Striations in Tellurium-Doped Gallium Arsenide

G. R. Cronin, G. B. Larrabee, and J. F. Osborne

Texas Instruments Incorporated, Dallas, Texas

The preparation of uniformly doped GaAs single crystals is important for use as substrates for epitaxial deposition and for the fabrication of devices from bulk material. The growth of uniformly doped material from the melt is not as simple as it would appear to be.

Work by LeMay (1) on tellurium-doped GaAs described the effects of constitutional supercooling and facet formation on crystals whose growth axis was 15° off the <111>. Striations believed to be caused by impurity segregation have been revealed by a variety of techniques including anodic etching (2), chemical etching (3), infrared transmission (4), and electron microscopy (5). This work describes several GaAs crystals pulled from a melt doped with radioactive tellurium. The radiotracer technique has the advantage of permitting a direct correlation between the impurity distribution as revealed by autoradiograms and the etching characteristics of the material.

Experimental

Three crystals were grown doped with radioactive tellurium in concentrations ranging from about 5 x 10^{16}/cm³ to 1 x 10^{19}/cm³. The crystals were grown on the <111> orientation from x-ray oriented seeds in a vertical pulling apparatus described previously (6). The GaAs melt was compounded *in situ* and Te-127m-127[1] was added in elemental form to the gallium which was contained in an alumina crucible. The crystals, grown from the <$\bar{1}\bar{1}\bar{1}$> or arsenic end of the seed, were entirely single, and weighed approximately 50g each. They were then cut into wafers 30 mil thick from which the autoradiograms were made and the tellurium concentration measured. Dislocation density measurements by etch pit counting were made follow-

[1] Te-127m-127 was produced by the neutron irradiation of tellurium metal isotopically (91.6%) enriched in tellurium^{126} obtained from Oak Ridge National Laboratories.

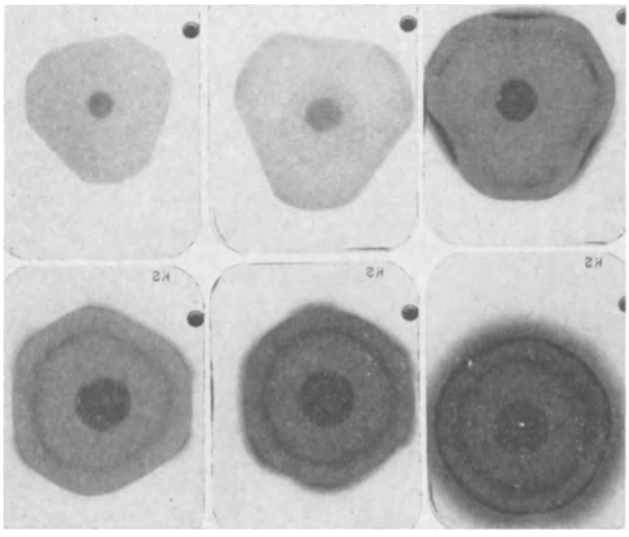

Fig. 1. A "top to bottom" series of autoradiograms from tellurium-doped GaAs crystal 218. Note appearance of annular facet on third and fourth autoradiogram.

ing a method described by Richards *et al.* (7). The radio purity of the tellurium was checked by gamma ray spectroscopy in each crystal, and only tellurium-127m-127 activity was found. The activity of each slice was measured by conventional gamma counting techniques. Autoradiograms were also made on each slice to determine doping uniformity.

Results and Discussion

Six autoradiograms taken from the first crystal (218) are shown in Fig. 1 The tellurium concentration in this crystal ranged from about 5 x 10^{16}/cm^3 to 1 x 10^{17}/cm^3. The appearance of the sharply outlined central facet in the upper portion of the crystal is similar to those reported by Allred and Bate for tellurium in InSb (8). The most striking feature of this crystal, however, is the appearance of a second well-defined area of high tellurium concentration which appeared about midway through the growth of the crystal. This concentric or annular facet then persists throughout the remaining lower half of the crystal. The origin of this type of annular facet, we believe, is related to the shape of the growth interface. We have observed, by withdrawal from the melt, that as the crystal first begins to grow, the interface tends to have a maximum concave curvature and hence a relatively small area which approximates a (111) plane. The result is a small central facet at the top of the crystal as shown in Fig. 2 and the autoradiograms of Fig. 1.

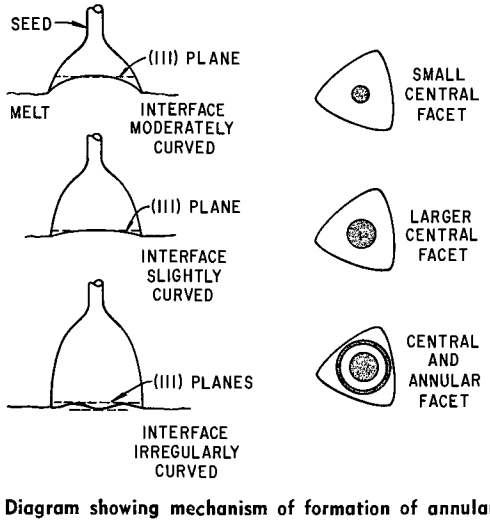

Fig. 2. Diagram showing mechanism of formation of annular facets

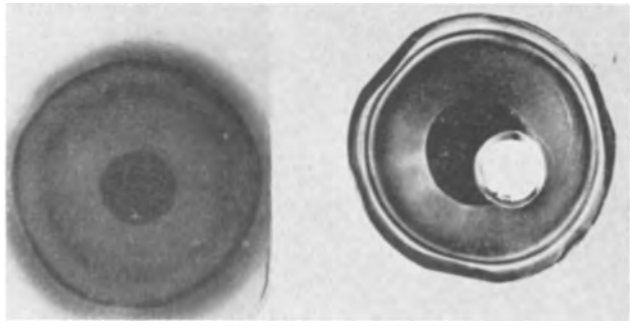

Fig. 3. Photograph and autoradiogram of the bottom of crystal 218. The white area is the portion of the last drop to freeze as the crystal was withdrawn from the melt.

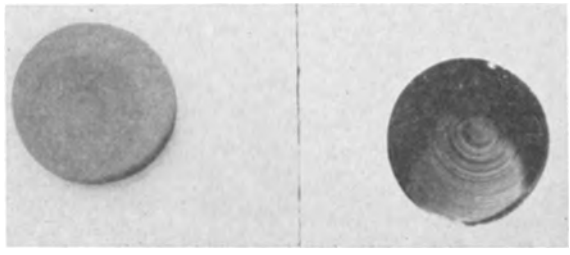

Fig. 4. (Left) autoradiogram of 10^{19}/cm^3 tellurium-doped GaAs showing portions of impurity striations; (right) same slice after etching in 15 H_2SO_4-3 H_2O_2-3 H_2O mixture.

As the crystal continues growing, the interface becomes more planar and the central facet grows larger. The sudden appearance of the annular facet shown in Fig. 1 suggests that at some point during the growth of this crystal a second distinct area of the interface surrounding the central facet also approximated a (111) plane. This, of course, implies an irregularly shaped interface such as depicted in Fig. 2. The irregular shape of the bottom of this crystal (218) as it was withdrawn from the melt (Fig. 3) is good evidence for this explanation.

Some of the autoradiograms shown in Fig. 1 also show edge facets which we have often seen on crystals grown on the ($\bar{1}\bar{1}\bar{1}$) orientation.

The tellurium concentrations on and off facet were determined by analyzing cavitroned specimens from these areas. Data shown in Table I are from upper and lower portions of the crystal. The on/off facet ratios agree fairly well with LeMay's reported figure of 2.6 (1).

Crystal 205 was doped with tellurium at about 1 x 10^{19} at./cm^3. Autoradiograms taken from several slices show no evidence of tellurium precipitation at this concentration but do exhibit nonuniform distribution of dopant again resulting from faceting. These facets were primarily limited to the outer edges of the crystal indicating some misorientation of the seed. Several autoradiograms, however, showed the striated pattern of concentric circles similar to those which LeMay (1) has attributed to constitutional supercooling.

These slices were then subjected to the chemical polishing procedure undergone by GaAs substrates prior to epitaxial deposition. The pattern produced by

22	$3 \times 10^3/cm^2$	

the final etch, a mixture of sulfuric acid and hydrogen peroxide, coincided with the tellurium distribution revealed by the autoradiograms as shown in Fig. 4. We have observed similar patterns on material doped as low as 10^{17} at./cm^3. No correlation could be drawn between the spacing of the striation and the rotation and withdrawal rates.

The etch pit density of this crystal was relatively low even at this high tellurium concentration. Counts of 3-6 x $10^3/cm^2$ were made in the approximate center of several slices.

Hall data taken from this crystal show excess carrier concentration lower than the tellurium concentration in every measurement (Table II) with a maximum electrical activity at 8 x 10^{18} excess carriers/cm^3. Black and Lublin (9) have reported that in tellurium-doped GaAs at concentrations of 3 x 10^{19} at./cm^3 (by chemical analysis) the free carrier concentration was only 8.5 x 10^{18}/cm^3 indicating that part of the tellurium is either un-ionized or electrically compensated at this concentration. We feel, however, that the presence of these impurity striations in our crystal casts some doubt upon the validity of our Hall measurements.

The third crystal (223) was grown on the <115> orientation with a tellurium concentration in the low 10^{16} at./cm^3 range. Slices were cut both on the (111) and (115) orientation. Autoradiograms of both orientations show entirely uniform distribution of tellurium with neither rings, nor central facets, nor striations. The dislocation density aparently shows no appreciable increase by pulling crystals on this orientation. Etch pit densities on the (111) slices were nominally in the high 10^3-low $10^4/cm^2$ range.

Growth on this <115> orientation appears to be uniform at this doping level and may offer a solution to the problem of obtaining uniformly doped material. Previous experience in this laboratory has shown that crystals of other materials such as indium antimonide are much more uniform when grown on the <115> orientation. We plan to investigate more heavily doped gallium arsenide crystals grown on this orientation.

Cristobalite Formation on Vitreous Silica Boats and the Relation to the GaAs Crystal Growing

M. Yamaguchi, Y. Mizushima, S. Hirota, and H. Noake

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

In the course of making single crystals of GaAs by means of the horizontal zone-leveling method, we have found spherulitic cristobalite formation on the sand-blasted surface of a vitreous silica boat which greatly facilitates single-crystal growth.

It is customary to use a sand-blasted vitreous silica boat for single crystal preparation (1). A graphite boat can be used for synthesis, but for single crystal zoning it is inferior to a vitreous silica boat. But even if the vitreous silica boat itself was sand-blasted, GaAs frequently stuck to the boat so that it cracked and the crystals failed to be single.

As the contact points between the molten semiconductor and the boat may promote the nucleation, it would be advantageous if the solidifying interface of the molten zone bends forward in the direction of zone-travel, as (solid/liquid) $\rightarrow$, so that the solidification proceeds downward from the free surface. The lower zone heater carried more current than the upper, to make the vertical temperature difference about 20°C in the furnace tube (25 mm in diameter). Zone-traverse-velocity was 15 mm/hr.

Otherwise successively appearing nuclei may grow up and interfere with the single-crystal formation. By using a boat of high purity (Al_2O_3 50 ppm, Fe_2O_3 10 ppm, CuO 0.1 ppm, MgO tr) and sand-blasted with 600-mesh carborundum we have experimentally verified that the bending interface method is effective for single-crystal preparation[1] and for avoiding sticking of the GaAs to the boat. In this case the whole GaAs surface is as smooth and shiny as that of a free surface.

After the above procedure we always found a layer of white powder on the inner surface of the boat, but only on the area in contact with the liquid phase of GaAs. Electron diffraction analysis showed the powder to be coarsely grained α-cristobalite (Fig. 1). Electronmicrographs of the surface before and after the treatment are shown in Fig. 2 and 3. The crystal has spherulite-like appearance and is fixed with stems to a pit of the vitreous silica surface. The shape of the crystals becomes dendritic at the area where the GaAs solidification proceeds upward from the base surface and the GaAs crystal partly sticks (Fig. 4), so that the cristobalite would have not enough space to grow up.

As a reaction product between the GaAs and silica one may suppose $GaAsO_4$ which is isostructural to SiO_2 (2). They have almost the same crystal parameters. Although $GaAsO_4$ is not known to exhibit α-cristo-

[1] The bending-interface appeared in Pfann's (3) and Chalmers' (4) works to improve the crystallinity so that it tilted backward as (solid/liquid) $\rightarrow$

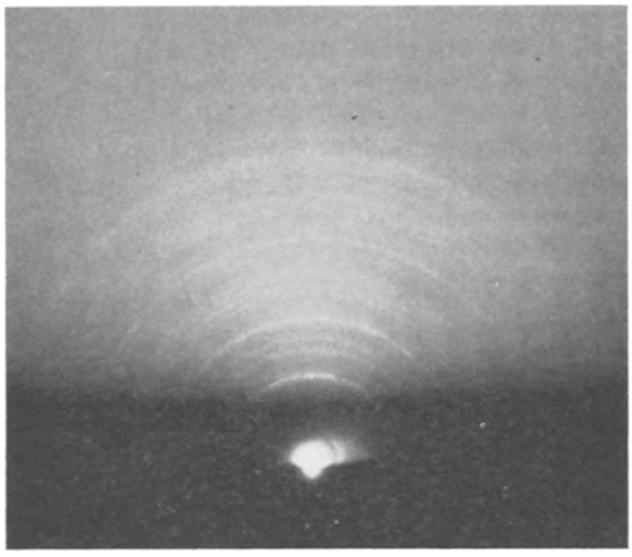

Fig. 1. Electron diffraction pattern of the white powder on the quartz boat showing α-cristobalite. The lattice parameters coincide with the value in ASTM cards.

Fig. 2. Electron micrograph of the sand-blasted quartz boat surface.

Fig. 3. Spherulite-like crystals of α-cristobalite found on the quartz boat after downward solidification of GaAs.

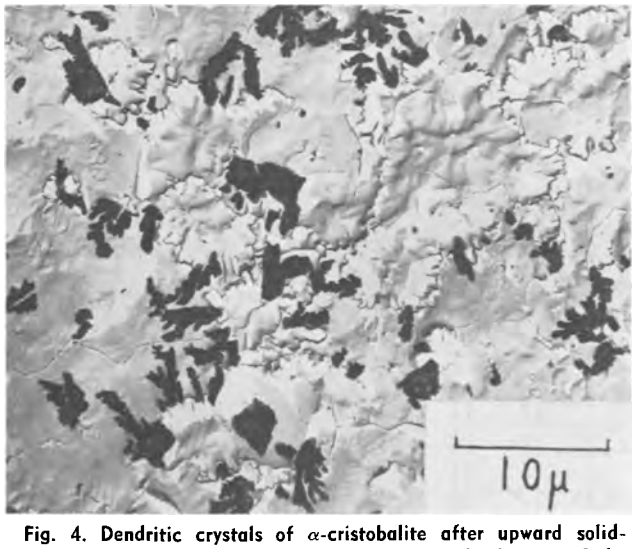

Fig. 4. Dendritic crystals of α-cristobalite after upward solidification of GaAs. There are sticking traces at the bottom of the dendritic crystals.

balite structure (2), we have tested the existence of Ga and As in the powder of α-cristobalite under the x-ray microanalyzer, but neither of them were detected as a major constituent. The probability of this reaction product is therefore excluded.

The melting point of the cristobalite (1713°C) is very much higher than the softening point of the vitreous silica (about 1300°C). In fact, the sand-blasted vitreous silica surface evidently shows softened traces after the crystal-growing (Fig. 3). But the surface retains its roughness even after zone-leveling unless it has contact with the melt of GaAs. Therefore the change of the surface into α-cristobalite is induced not by heat softening, but by the existence of the liquid phase of GaAs.

At the melting point of GaAs (1238°C) the cristobalite crystals prevent the melt from coming in direct contact with the vitreous silica, and the melt is supported by its surface tension on the spherulites so that relatively little stress is introduced into the crystal.

The minimum contact area also ensures minimum contamination from the boat material. Two pieces of GaAs polycrystal cut from the same part of a rod ($n = 10^6$ cm^{-3}) were placed in the same vitreous silica boat, the one (A) was on the white layer of α-cristobalite and the other (B) on the part of the boat which had been only sand-blasted. After melting for the same length of time, both samples were analyzed by means of emission spectroscopy. Table I shows that the amount of detected impurities differs considerably between the two samples. Thus, the cristobalite layer is evidently effective in preventing contamination during the heat-treatment once the cristobalite is formed, since cristobalite is more stable than the vitreous form. The solubility of the more stable cristobalite in the liquid GaAs would be less than that of the metastable vitreous silica.

Table I. Emission spectroscopic result of impurities in GaAs crystal: (A) was molten on the layer of α-cristobalite and (B) on the sand-blasted surface of the quartz boat for about 2 hr

$+ > (+) > \pm >$ tr $>$ $\overline{\text{tr}}$ (doubtful) $>$ — (not detected)

Impurity elements	Wavelength	Before heat-treatment	(A)	(B)
Si	2881.568	$\overline{\text{tr}}$	$\overline{\text{tr}}$	(+)
	2516.123	—	—	tr
Mg	2852.129	+	±	+
	2795.53	±	tr	±
Cu	3247.540	—	—	$\overline{\text{tr}}$
	3273.962	—	—	—

It is peculiar that cristobalite spherulite crystallizes at a temperature never above 1250°C. Also, the thermodynamic stability of cristobalite below 1470°C is questionable, although minute substitution of Ga or As in SiO_2 may stabilize this structure. To identify this stabilizing, impurity experiments were performed in which Ga was heated for 2 hr at 1300°C in a sand-blasted vitreous silica boat in an evacuated ampule. In the area in contact with Ga the same α-cristobalite spherulitic crystals were found. Therefore it is possible that Ga acts as a stabilizing agent.

The mechanism of crystallization is not clear at this time. Consider the following points: SiO_2 [or Si produced by the reaction of SiO_2 in the GaAs melt (5, 6)] dissolves in the melt and segregates at the solidifying interface as SiO_2. With sand-blasting the stressed rough surface may act as the active point for the solution and/or the nucleation, or the transformation, from vitreous silica to the cristobalite structure since this structure does not occur without sand-blasting.

The Preparation of Epitaxial Semi-Insulating Gallium Arsenide by Iron Doping

P. L. Hoyt and R. W. Haisty

Texas Instruments Incorporated, Dallas, Texas

The preparation of semi-insulating GaAs by iron doping melt-grown crystals has been reported previously (1). This material has been shown to have a deep acceptor with an energy level of about 0.5 ev and typical resistivities of 10^4-10^5 ohm-cm at room temperature.

This note describes the preparation of epitaxial iron-doped gallium arsenide by an open tube halide transport technique employing GaAs and $AsCl_3$, similar to the method used for Ga(As, P) by Finch and Mehal (2).

Figure 1 shows the experimental apparatus. Hydrogen, purified by Pd diffusion, was bubbled through distilled $AsCl_3$, carrying the vapor into the feed holder in the reactor (R_3). For convenient control of the $AsCl_3$ concentration in the feed region, additional hydrogen was metered in (R_2), and the reaction products from the feed zone were swept toward the seed by a steady flow of hydrogen (R_1). Typical operating conditions were: R_1, 25.0 cm³/min; R_2, 15.0 cm³/min; R_3, 75.0 cm³/min; seed temperature 750°C; GaAs source temperature 950°C.

The GaAs used for feed material and substrates was cut from undoped pulled crystals grown in this laboratory and especially selected for high purity since care must be taken to keep the donor concentration such as Si very low. The substrates were polished to a mirror finish with *ca.* 2.5% NaOCl solution on a polishing wheel (3). Deposits were made on (100), (111), and (115) oriented GaAs seeds. The (115) and (100) orientations were preferred because of faster deposition rate and because better surfaces were obtained on these seeds.

High-purity iron (99.999%) used as the dopant, was placed in the feed holder, typically in four pieces weighing about 50 mg each with 15g of GaAs feed. The iron was cleaned 4-5 min in dilute hydrochloric acid and rinsed in distilled water followed by methanol. Wet chemical and x-ray analysis confirmed the formation of FeAs in the feed holder which appears to be necessary before transport of the iron occurs. The first run after the addition of the iron invariably produces a low resistivity n-type deposit. However, it is convenient to add elemental iron, which can be obtained in a high degree of purity, and form the arsenide in the reactor.

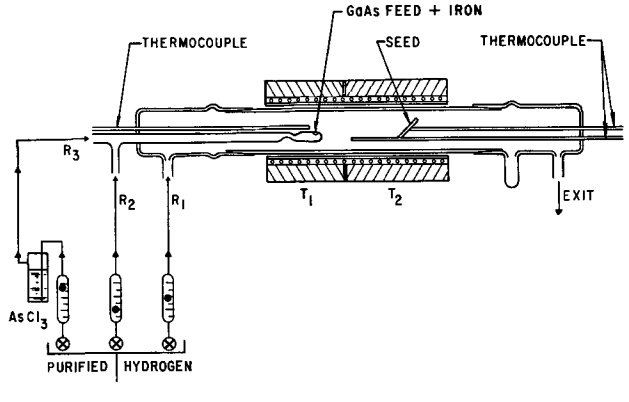

Fig. 1. Vapor deposition system. $R_1 = H_2$ dilution flow; $R_2 = H_2$ feed dilution flow; $R_3 = AsCl_3 + H_2$ flow.

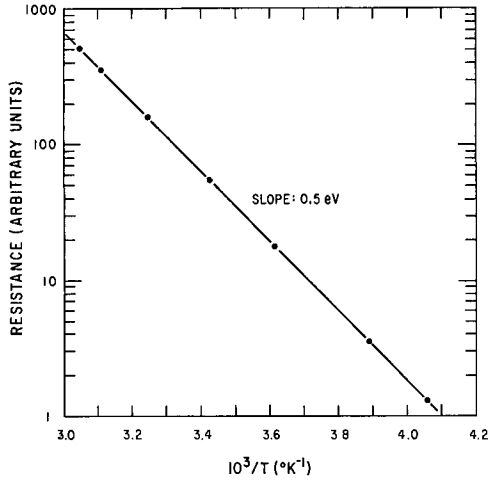

Fig. 2. Temperature dependence of resistance for epitaxial Fe-doped gallium arsenide.

Table I. Electrical properties of epitaxial and melt-grown Fe-doped GaAs at 300°K

Crystal No.	ρ, ohm-cm	μ, cm²/v-sec	p, cm⁻³
Epitaxial GaAs			
145	9.0×10^4	230	3.1×10^{11}
146	6.9×10^4	330	2.7×10^{11}
147	2.7×10^4	370	6.3×10^{11}
Melt-grown GaAs			
3-33	2.7×10^4	208	1.1×10^{12}
3-34	9.6×10^4	206	3.2×10^{11}
3-36	7.2×10^4	243	3.6×10^{11}

To determine the thickness of the deposits, the samples were angle-lapped and either gold plated (4) or stained with a HNO_3 + Fe stain developed by Mehal of this laboratory.[1] The energy level of the deep acceptor in the deposits was determined in the following manner:

1. Samples were cleaved to obtain clean edges.
2. Alloyed Au-5% Zn contacts were applied to the surface of the deposits. (The contacts were shown to be ohmic by measuring current *vs.* voltage at a fixed temperature.)
3. Resistance was measured as a function of temperature. A plot of log resistance *vs.* 1/T (Fig. 2) gave a slope of 0.51 ev which corresponds to the iron level in bulk GaAs. The deposits checked p-type by thermoelectric probe, using an electrometer indicator.

Hall effect measurements made on several Fe-doped deposits for comparison with melt-grown iron-doped GaAs showed that about the same doping levels were achieved in both cases. The epitaxial GaAs used for the measurements was deposited on Cr-doped semi-insulating substrates with resistivities about 10^8 ohm-cm at room temperature, three to four orders of magnitude higher than the deposit to be measured. The deposits were typically about 30μ thick as determined by angle-lapping and staining techniques. Cavitroned samples with side arms were used for the Hall measurements. Ohmic contacts were made using indium contacts. Table I shows a comparison of the electrical measurements of the epitaxial deposits with typical melt-grown, Fe-doped crystals.

It is interesting to note that, while the properties are quite similar, the mobilities are somewhat higher in epitaxial GaAs (5, 6).

To show the possibility of using iron doped semi-insulating epitaxial GaAs in discrete devices or to provide electrical isolation in integrated circuits, such as three-dimensional electronic blocks (7), a sample n-SI-n sandwich structure was prepared. This structure was made using the apparatus described above in the following manner:

1. A 15μ n-type GaAs layer was deposited by the usual technique on a high-resistivity (115) oriented substrate, using undoped feed material.
2. This substrate and deposit were then removed from the reactor, and several runs were made with iron added to the feed material to insure that semi-insulating deposits were being obtained consistently.
3. The original substrate with n-type deposit was cleaned in hot methanol and placed in the reactor.
4. An 8μ semi-insulating layer was deposited on the n-type deposit with no appreciable change in the latter.
5. The reactor was cleaned and new undoped feed material was placed in the feed holder.
6. The sample was again cleaned and returned to the reactor for the final n-type deposition. An n-type deposit (7μ) was produced on the semi-insulating layer.

The sequence of angle-lapped, stained sections made during the entire process showed no appreciable movement of the boundaries during deposition steps, which indicated that diffusion of the dopants is not a problem in this case.

[1] The NHO_3-Fe staining solution is made by dissolving about 1g of iron in 100 cc of 1.0*N* HNO_3.

The Epitaxial Growth of Ge on Si by Solution Growth Techniques

J. P. Donnelly and A. G. Milnes

Carnegie Institute of Technology, Pittsburgh, Pennsylvania

Solution growth techniques have a long history in the field of crystal growth. The solution growth process reported in this work is based on the work of Nelson (1, 2) for fabricating tunnel and laser diodes. This same method has also been used to fabricate p Ge-n GaAs heterojunctions (3-5).

The stable oxide layer of silicon, however, presented many problems in trying to fabricate Ge-Si heterojunctions by similar solution growth techniques. To overcome these problems, it was decided to use in-growth cleaving techniques to achieve oxide free surfaces. Silicon L-bars with their major axis in the <111> direction, as first described by Gobeli and Allen (6), were used as seeds. An all-graphite boat, with a clamping arrangement at one end to hold these L-bars securely, was constructed. Provisions were made for a quartz cleaving rod to facilitate in-growth cleaving of the L-bars. During the growth cycle the graphite boat is locked in position at the center of a long constant temperature zone of a quartz tube furnace which is free to rotate about its center. Solutions consisting of 20g Sn, 2.5g Ge and 0-100 mg of

either Ga for p-type material or As for n-type material are free to run from one end of the graphite boat to the other depending on the tilt of the furnace. Forming gas (95% nitrogen, 5% hydrogen) or hydrogen is passed through the furnace during the growth cycle to prevent oxidation.

With the solution at the end of the boat opposite the clamped silicon L-bar, power is applied to the furnace heating winding, and the temperature of the graphite boat is raised from room temperature to 625°C in approximately 1 hr. At this temperature, the power is turned off and the furnace tipped so the solution completely covers the L-bar. When the temperature cools to 600°C, the silicon L-bar is cleaved using the quartz cleaving rod. This creates the oxide free silicon surface on which the germanium depositing from the cooling solution grows epitaxially. At 400°C, the furnace is tipped back so the solution runs off the seed stopping the growth. During the growth period, the cooling rate used is between 10° and 15°C/min.

Using this method single crystal germanium layers up to 5 mils thick were grown on the cleaved silicon seeds. The growth rates were approximately 0.35 mils/min. Although the surfaces were often very rough due to the solidification of some of the solution which tended to cling to the sharp edges of the cleaved seed and clamping arrangement, the junctions were consistently very flat as shown in Fig. 1. Laue back reflection x-ray photographs indicated good single crystal germanium overgrowth in the 111 direction. However, there was slight elongation and splitting of some of the Laue spots. It is believed that the elongation and splitting are due to thermal strain and cracking, respectively, which occur because of the large thermal mismatch between Ge and Si. The cracks become evident on etching with any standard Ge etch. Figure 2 shows a typical photograph of these cracks after a 30-sec etch with etching solution composed of (5 vol HNO_3, and 1 vol HF). Beside the cracking difficulty in these layers, the stacking fault density was found to be high as shown in Fig. 3. The stacking faults were brought out by polishing the grown layer with alumina abrasive powder (0.05μ) and then etching in a solution (0.2g $AgNO_3$, 25 ml H_2O, 10 ml HF, 15 ml HNO_3) which plates the imperfections with silver. Although most of these faults are probably due to lattice mismatch and strain effects, similar measurements on Ge layers grown on Ge and GaAs from both indium and tin solutions (3, 5) indicate that better crystallographic material might be obtained by using a lower melting point solvent such as indium or a lead-tin alloy instead of tin. Impurity concentrations as low as approximately 10^{17} cm^{-3} could be obtained by varying the amount of As and Ga in the solution.

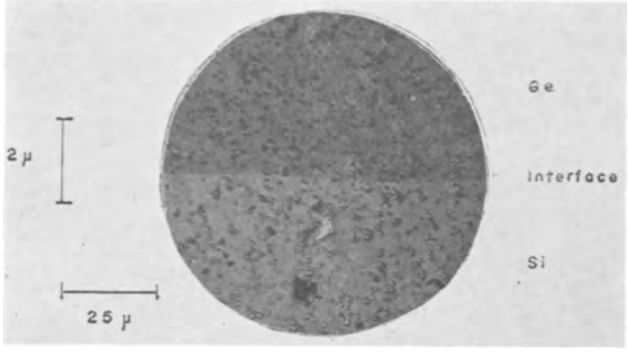

Fig. 1. View of 6° angle-lapped section of a germanium layer grown on a cleaved Si seed from a tin solution.

Fig. 2. Cracks in germanium grown on silicon from a tin solution after 30-sec white etch.

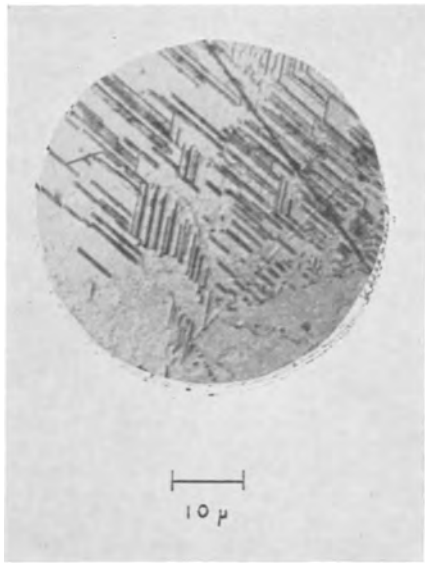

Fig. 3. Stacking faults in germanium grown on silicon from a tin solution.

In conclusion, a rapid reliable method of obtaining abrupt Ge-Si heterojunctions has been developed. Although the Ge overgrowths were cracked due to thermal effects, large enough uncracked areas were obtainable to fabricate diodes. The characteristics of these diodes are reported elsewhere (5, 7) and are comparable with those obtained on diodes fabricated by the germanium diiodide disproportionation reaction (8).

On the Removal of Dislocations in Crystals Grown by Travelling Solvent Method

G. A. Wolff and B. N. Das

Tyco Laboratories, Inc., Waltham, Massachusetts

X-ray diffraction contrast methods provide an efficient means for observing dislocations in crystals. The phenomenon of anomalous transmission of x-rays is observed in nearly perfect crystals and results in enhanced transmission when the crystal is set for Laue diffraction. The effect was first observed by Borrmann (1); its theory was described in detail by Batterman and Cole (2) with reference to previous work.

In previous experiments on the TSM growth of GaAs (3) and $SrTiO_3$ (4), it has been shown by etching techniques that the etch pit concentration decreases fairly abruptly to values which are lower by at least an order of magnitude for the regrown material compared to the original seed material. Since a one-to-one relationship between etch pits and dislocations in crystals is not expected to exist in all cases, an anomalous x-ray transmission technique was used to determine dislocations and dislocation density. Preliminary anomalous transmission tests on GaAs (5) and GaSb (6) have largely confirmed the findings of etching investigations. In the following, specific evidence is presented for such a dislocation decrease in GaSb and for anomalous transmission in transmission Laue micrographs for this material. The propagation of dislocations in TSM crystal growth and the method of evaluation of Burgers vectors in single crystals are also discussed.

High-purity GaSb of 1 x 10^{17} (electronic) hole carrier concentration, 650 cm^2/volt-sec Hall mobility, and 0.1 ohm-cm resistivity, was used in this study. The TSM grown GaSb crystal of 0.7 mm thickness and 1 mm height was mounted on a goniometer head after being etched in 1 part HF: 4 parts HNO_3: 5 parts distilled water for 1 min and accurately set in front of a 40 cm collimator. Preliminary x-ray photographs were taken on Ilford industrial x-ray film (type G), and the final exposures were made on single coated, Kodak industrial x-ray film (type M). The time of exposures varied from 2 hr to 8 days. Dislocations were studied on TSM grown GaSb crystals using white radiation (schematic in Fig. 1 and Fig. 2) and characteristic radiation ($CuK\alpha$) at operating voltage of 25-40 kv and 15-20 ma current.

Figures 3 a, b, and c, show, respectively, the $(31\bar{1})$, $(24\bar{2})$, and $(51\bar{1})$ reflection micrographs of the GaSb crystal obtained by Laue transmission. All three micrographs show an increase of x-ray transmission in the upper regrown section of the crystal over the transmission in the lower seed crystal section. When the product μt (with μ being the linear absorption coefficient and t the thickness of the crystal) is large ($\mu t >> 1$), the conditions for observing anomalous transmission are satisfied. This is observed, since, for the shortest wavelength (which satisfies the Laue condition) of these reflections, $\mu t \simeq 6.4 >> 1$. The elimination of dislocations during crystal growth apparently increases the anomalous transmission through the (upper part of the) crystal. This produces the photographic contrast between the two sections of the photographs, which correspond to the regrown region and the seed region of the crystal. The dark striations

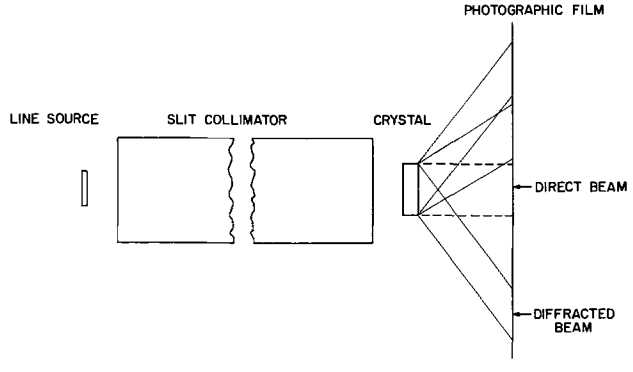

Fig. 1. Schematic of experimental arrangement for anomalous transmission study by Laue transmission.

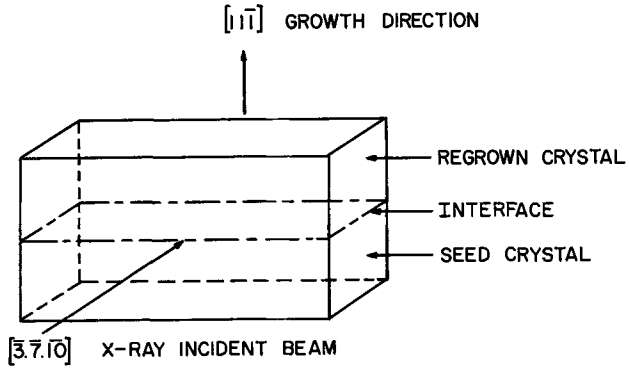

Fig. 2. Schematic view of the GaSb crystal investigated

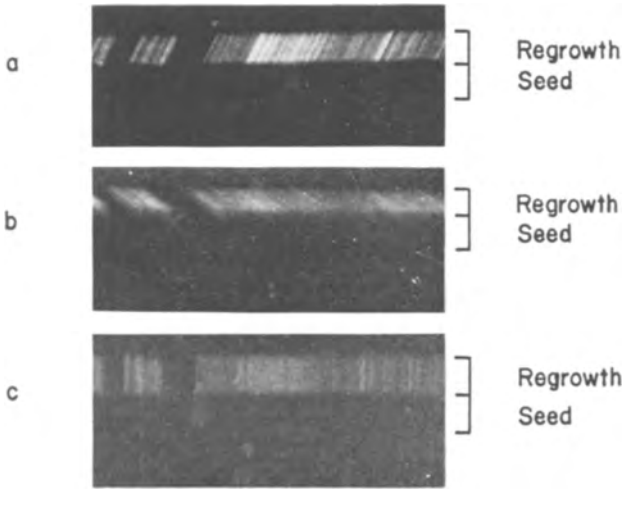

Fig. 3. (a) (top), (b) (middle), and (c) (bottom) show, respectively, the $(31\bar{1})$, $(24\bar{2})$ and $(51\bar{1})$ reflection micrographs of the GaSb crystal obtained by Laue transmission. The upper regrown section is largely made up of light areas of low dislocation content. Striation indicates direction of dislocation lines. The two dark patches in the upper section represent nonreflecting crystals of slightly different orientations which have been nucleated by poor solvent wetting.

in the photograph positive, then, indicate the trace of dislocation lines (in the regrown section) projected onto the plate in a direction which is parallel to the forward reflected x-ray beam. They do not indicate oriented impurity segregation or strain fields not associated with dislocations or simple surface scratches, as one could perhaps assume, since, upon comparison of such a micrograph with others from different reflections in this case, the actual striations in the crystal due to impurity or strain should not differ in orientation, which is contrary to the findings. This is particularly apparent when x-ray micrographs of neighboring reflections are compared, where orientation differences of more than 30° [*e.g.*, $(31\bar{1})$ *vs.* $(51\bar{1})$] are observed. An anomalous x-ray transmission photograph obtained with CuKα radiation from $(11\bar{1})$ of the GaSb crystal also showed two sections, with the brighter section corresponding to the regrown part and the darker section corresponding to the seed part. This result thus supports the first finding. Due to the relatively long transmission paths of transmitted and reflected beams, the resolution was not high enough to show individual dislocations; in addition $\mu t \simeq 80$ in this case was too high for anomalous transmission analysis. In silicon single crystals dislocations have also been observed using white x-ray radiation (extinction contrast) (7, 8).

The contrast of individual dislocation lines in the micrograph is determined by the dislocation density and the orientation of the dislocation lines relative to the reflecting plane. The dislocation density must be low enough for these lines to be individually distinguishable. The maximum value of dislocation concentrations for which single dislocation lines can still be recognized in the Laue transmisison micrographs is approximately 10^4 lines/cm^2. For the 0.7 mm thick sample, about 200 lines/cm corresponding to 3×10^3 lines/cm^2 are counted, which is roughly of the same order of magnitude as the etch pit count of 10^3 etch pits/cm^2 found in our crystals.

Since the condition for dislocation contrast is $\vec{g} \cdot \vec{b} \neq 0$ (with $\vec{g}$ being the diffraction vector and $\vec{b}$ the Burgers vector), the observed orientation of dislocation lines in each photograph permits the determination of the respective Burgers vector and the type of dislocation as shown in Table I. In this table the Burgers vectors and the type of dislocations observed were correlated with the dislocation models derived by Hornstra (9). The corrections due to perspective and geometrical conditions were taken into account. It has been found that glide planes for most of the grown-in dislocations and their deduced Burgers vectors lie in octahedral planes.

Table I. Dislocations in GaSb as evaluated by x-ray diffraction microscopy

Further identification of the multiple choices of Burgers vectors would be possible by taking photographs from other directions of incident beam. The (022) reflection micrograph shows three different types of dislocation lines as indicated by the three different sets of striations. Reflections from $(31\bar{1})$, $(24\bar{2})$ and (511) are presented in Figs. 3, (a), (b), and (c), respectively.

* Although dislocations of type VII are possible, they are not included in this table.

** These dislocation types are possible one at a time or in combination.

The mechanism of dislocation removal can be explained by either a closed loop formation, or by degeneration through transformation to other types of dislocations which then propagate sideways and normal to the crystal growth direction until they intersect with the surface (5, 6). Specifically, it is possible that during crystal growth, pairs of screw dislocations of opposite sign will terminate in closed half-loops, and single screw dislocations transform to dislocations with edge-components, which propagate sideways to the crystal surface (Fig. 4). The latter dislocation system may conveniently be called "partial loops." The formation of both half-loops and partial loops is a result of climb and is confined to the very first stages of solvent growth. This is indicated by the abrupt change of dislocation density at the crystal interface where regrowth started, and by the uniform dislocation density of the regrown crystal (Fig. 3). This process represents a dislocation climbing mechanism directly associated with crystal growth, since the dislocation half loops and partial loops propagate as each layer deposits. The half loop and partial loop formation and associated elimination of dislocations are limited to the first 100μ, or less, of solvent growth as estimated from Fig. 3. This is in fair agreement with the value of 150μ given for GaAs (5). In a somewhat related way the elimination of edge and edge-type dislocation observed can be explained. It appears, therefore, that dislocations are not required and do not participate critically in the mechanism of travelling solvent growth of GaSb and GaAs from the metal solution. It must be concluded that the catalytic (equilibrating) influence of the (liquid metal) solvent becomes greater than the catalytic influence of dislocations in crystal growth.

Since each specific anomalous transmission reflection records only dislocations with their Burgers vectors not parallel to the reflecting planes, the evaluation of such reflections allows the analysis of the mechanism of crystal growth and dislocation removal, using separately white and characteristic x-ray radiation. This work will be reported in a later publication. Decoration and (Berg-Barrett) x-ray techniques also indicate a similar elimination of dislocations in SiC by TSM regrowth (10).

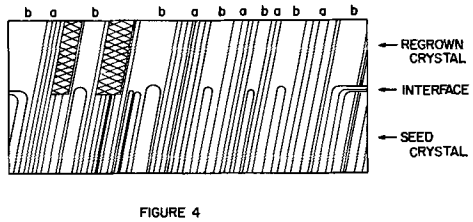

FIGURE 4

Fig. 4. Two-dimensional schematic illustrating dislocation removal observed in travelling solvent single crystal growth, as related to Fig. 2. Idealized dislocations of one type are shown as a system of parallel lines. The two-cross-hatched areas represent slightly disoriented regrown single crystal sections, where Bragg reflection does not occur (see also Fig. 3). Dislocations are eliminated from propagation in the regrown crystal by half-loop formation (regions b), or else by the formation of screw or edge type (60°) dislocations (here called "partial loops") parallel to the crystal growth front, both of which are the result of climb. All dislocations eliminated in this way terminate at the plane of solvent growth commencement. Anomalous x-ray transmission is low in sections a, and enhanced in sections b.

Acknowledgments

The authors wish to thank Doctors A. I. Mlavsky and M. Weinstein for helpful discussions, Miss A. D. Sarney for aid in the calculations, and Mr. E. J. Alexander for crystal growing and experimentation. A Method of Casting Sound Ingots of Thermoelectric Materials

W. N. Borle and B. L. Sharma

Solid State Physics Laboratory, Delhi, India

In general, ingots of semiconducting materials are prepared by melting the charge and casting it into fused silica tubes, Vycor tubes, or graphite molds (1, 2). Cast polycrystalline ingots are often used for thermoelectric device work, zone refining, etc. Especially for thermoelectric generators and coolers in which the authors are interested (3, 4), the ingots should, apart from having uniform thermoelectric properties, contain no mechanical defects like shrinkage cavities and blow holes.

Ingots of PbTe, for example, are prepared by first mixing and melting thoroughly stoichiometric amounts of the constituent elements in a quartz tube or graphite mold and then freezing the melt to form an ingot within the tube. Usually, as shown in Fig. 1, a long shrinkage piping occurs along the vertical axis of the ingot. This piping can be reduced by slow directional freezing, but then the segregation during solidification increases. In order to overcome these difficulties a simple method of casting sound ingots having uniform composition and thermoelectric properties has been devised and is discussed below.

In this method, as mentioned above, the compound is prepared by melting Pb and Te under inert atmosphere (hydrogen, argon, or nitrogen) in a quartz container. The furnace is rocked mechanically to ensure complete homogenization of the molten charge. PbTe is then remelted in a graphite mold having required

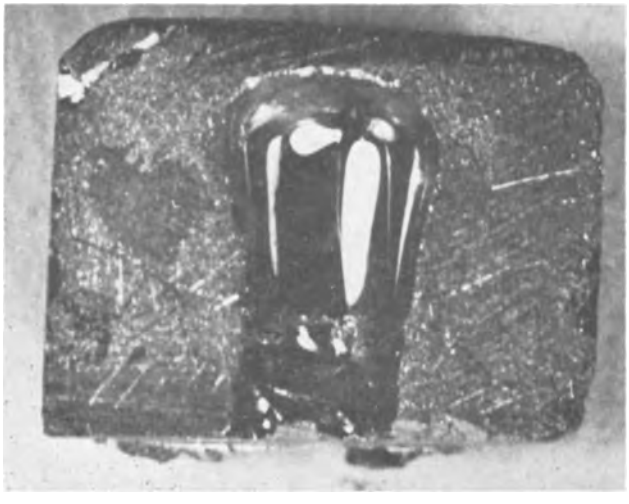

Fig. 1. Cross-sectional photograph of the top end of a PbTe ingot obtained by the ordinary casting method.

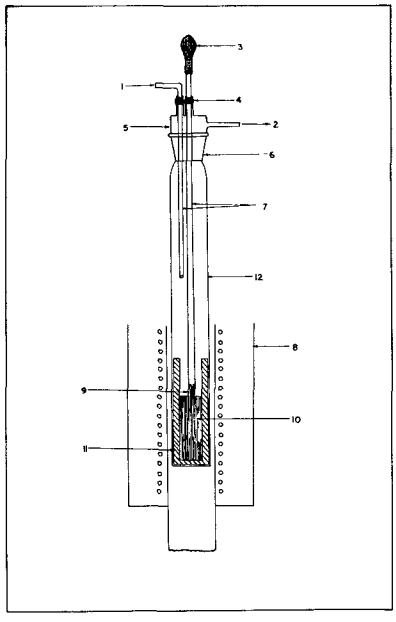

Fig. 2. Apparatus for casting sound ingots: 1, inlet; 2, outlet; 3, rubber bulb; 4, rubber tube; 5, Pyrex glass; 6, ground joint; 7, quartz tubes; 8, furnace; 9, arrested cavity; 10, molten material; 11, graphite mold; 12, quartz jacket.

dimensions. As shown in Fig. 2, a quartz tube, having a sliding arrangement at the top of the ground joint of the atmosphere enclosure, is used as a shrinkage cavity arrestor. By vertical displacement with the slider, this tube is inserted in the melt to approximately 1 cm depth. Then with the help of the rubber bulb fixed at the top of the quartz tube a small quantity of the molten material is sucked into the tube. In this process one must ensure that the immersed portion of the quartz tube attains the same temperature as that of the molten material in the graphite mold. This can be achieved by heating the complete assembly for a long time inside the furnace.

After this, the complete assembly is lowered vertically through the furnace so that it is rapidly air quenched and the molten material solidifies directionally from the bottom. As the rate of cooling of the material inside the graphite mold is faster than that of the material in the quartz tube due to the differences in the thermal conductivities of the two, the material inside the quartz tube will be the last to

Table I. Comparison of the electrical resistivity along the length of PbTe samples before annealing

Distance from the bottom end in mm	By above technique ρ in ohm-cm	By slow directional freezing method ρ in ohm-cm
0-5	2×10^{-3}	2.1×10^{-3}
5-10	1.6×10^{-3}	3.7×10^{-3}
10-15	2.5×10^{-2}	3.9×10^{-3}
15-20	2.3×10^{-3}	5.6×10^{-3}

freeze. We speak only in relative terms since, although the rate of lowering in the furnace and actual process of quenching are important factors, they depend entirely on experimental parameters, such as the geometry of the furnace, the assembly, etc. In the above experiments rapid air quenching was used to minimize the segregation problem, as this is a comparatively faster method of solidification than the slow directional freezing method (modified Bridgman technique). By minimizing segregation in the cast ingot, subsequent annealing periods can be reduced considerably. The electrical resistivity before annealing treatment, of two typical samples of PbTe, prepared by the above and by the usual slow directional freezing technique are compared in Table I.

Very sound ingots of doped lead-telluride without shrinkage cavity or blow holes were cast by this technique. Figures 1 and 3 show the vertical cross sections of the upper portion of samples prepared by the ordinary casting method and by this method, respectively. It is clear from the photographs that the shrinkage cavity is localized and completely arrested in the quartz tube and from Table I that the segregation is minimum.

Measurement of the Reflectance of an Electrode Surface

D. F. A. Koch and D. E. Scaife

Division of Mineral Chemistry, Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia

The measurement of the adsorption of ions or molecules on an electrode surface is of major importance in studies of electrochemical energy conversion, corrosion, and electropolishing. The surface coverage can be determined electrochemically by pulse and rapid potential sweep methods, by chemical analysis, or by radio tracer techniques. Recently it has been shown (1) that, for a strongly adsorbed species such as oxygen on platinum, the changes in light reflectance can be directly related to the amount of oxygen adsorbed on the surface. This technique could offer advantages in systems where competing reactions not involving a strongly adsorbed species occur. For example, we have found (2) that the adsorption of formaldehyde on platinum has no significant effect on the reflectance spectra, and, consequently, the oxygen coverage can be determined by the reflectance method in the presence of this reacting species. In cases where the metal dissolves, large changes in reflectance are caused by etching or polishing of the surface; a recent study of such a system (3) demonstrated this behavior clearly and also showed that the passivation of a gold surface in cyanide solution could be attributed to the effect of adsorbed films on the dissolution mechanism.

In this paper, we shall describe in greater detail the experimental techniques used and some of the results obtained for oxygen adsorption on platinum and gold dissolution in cyanide.

Experimental

The electrolysis cell is shown in Fig. 1. The electrode was in the form of a metal disk suspended from a platinum hook sealed into a glass tube, which fitted through a cone and socket joint and could be rotated into position once placed in the cell. The distance of the electrode from the optically flat silica window was 2-3 mm, and the metal disk was sufficiently rigid on its suspension to avoid disturbance from bubbling. The cell was equipped with gas inlets and outlets, to provide a controlled atmosphere and agitation, and with a Luggin capillary connected to a saturated calomel reference electrode. Potentials were controlled by an electronic potentiostat (4).

In the systems studied here, uneven current distribution between front and back faces of the electrode is not a serious problem. In the case of platinum, very little current was passed; in the case of gold dissolution in cyanide, currents of the order of 1 ma/cm^2 were passed, and the changes in reflectance still coincided with the passivation potentials measured in a conventional cell.

The front face of the cell was held against the sample port of a Beckman DK2A Spectroreflectometer, the

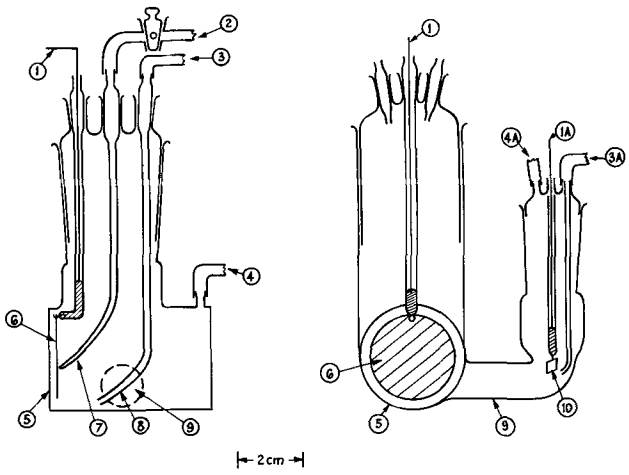

Fig. 1. Electrochemical cell for reflectance measurements: 1,1A, leads to potentiostat. 2, H_2SO_4-filled bridge to saturated calomel reference electrode; 3,3A, gas inlets; 4,4A, gas outlets; 5, silica window; 6, working electrode; 7, Luggin capillary; 8, gas bubbler; 9, side arm connecting to compartment with counter electrode, gas inlet and outlet; 10, counter electrode.

metal sample being just a little larger than the sample port. In this system, light from the sample is reflected back into the MgO-coated integrating sphere of the reflectometer, and measured by a detector at the top of the sphere in comparison with the light reflected from a standard sample in the reference beam. In this work MgO plates, or flat disks of the metal under examination, were used as standards.

To enable the cell to be fitted against the sample port, the door of the reflectometer was replaced by a large aluminum box 25 x 25 x 30 cm high made completely light-tight, and painted matte black inside. This box contained various built-in clamp supports and holes for gas and electrical leads, and had a removable lid. The front section of the box was swung on the hinges provided for the standard door which it replaced.

The exact positioning of the electrode relative to the light beam was found to depend on the nature of the surface; in the case of samples which were completely flat and of mirror-finish, it was necessary to determine whether diffuse or total reflectance measurements were appropriate. In the former case, the light reflected specularly (*i.e.*, at the angle of incidence) must be reflected back out through the beam entrance ports of the sphere, only diffusely reflected light being collected by the sphere for measurement. In the latter case, the specularly reflected beam is reflected back onto the walls of the sphere and measured. In fact, none of the samples used in this work were sufficiently flat or polished to present this problem, random scratches in particular causing the specularly reflected beam to lose coherence almost completely. A very small amount of light was diffusely reflected from the silica window and liquid medium, and a slightly larger specular component of reflected light occurred at the air-silica and silica-liquid interfaces. Both of these components were negligible for the purpose of this study, being in any case constant during a set of measurements. Light losses in the gap between sample and window were similarly negligible.

The platinum electrodes used in this work were of cold-rolled sheet, flame annealed, and anodized and cathodized several times before use. Temperatures in the cell were 27°-30°C.

Results and Discussion

The performance of the system may be judged from data obtained for a platinum electrode in *N* H_2SO_4 solution. The relationship between reflectance (relative to MgO), measured when it showed no further

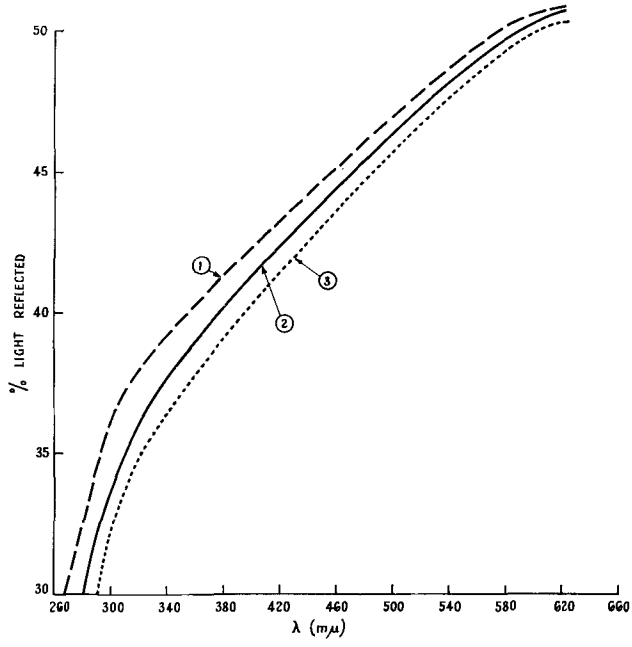

Fig. 2. Reflectance (MgO reference) *vs.* wavelength for Pt in *N* H_2SO_4, at various potentials: 1, 0.3v (*vs.* N.H.E.); 2, 1.2v; 3, 1.6v.

change, and wavelength, at three potentials is shown in Fig. 2. It can be seen that the absorption edge of the platinum is shifted in the direction of longer wavelength as the potential is increased in the anodic direction. From the curves of Fig. 2 values can be calculated for the change in reflectance, ΔR, with potential, which is plotted against wavelength in Fig. 3. There is a continuous increase in ΔR with decreasing wavelength, the sharpest rise occurring below 420 mμ. Previous results against MgO suggested a maximum in these curves (1), but the more sensitive differential method against platinum (see below) confirmed the results shown in Fig. 3. The small inflections indicated by the points off the curves are probably within experimental error, and no discrete absorption band structure is clearly shown.

The changes in reflectance with time, as a function of electrode potential, were recorded at a constant wavelength of 350 mμ, and are shown in Fig. 4. Before the application of the required potential, the electrode surface was stripped of oxygen by maintaining it at 0.3v (*vs.* N.H.E.) (5) for about 3 min. This provided a reproducible initial surface which served as a base line for changes in reflectance. In this case, the reflectance of the sample was compared with that of a

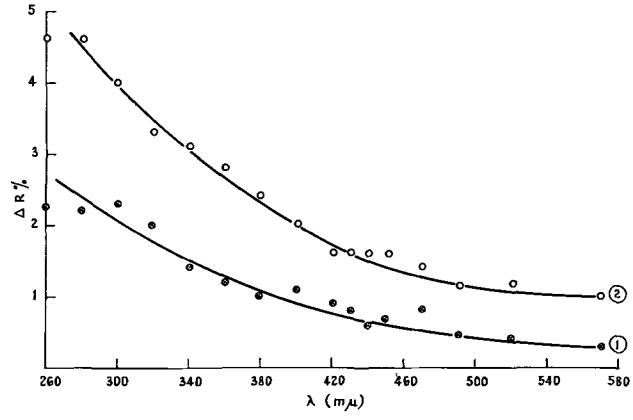

Fig. 3. Change in reflectance (ΔR) vs. wavelength for Pt in *N* H_2SO_4 at various potentials (v *vs.* N.H.E.): 1, $R_{(0.3v)} - R_{(1.2v)}$; 2, $R_{(0.3v)} - R_{(1.6v)}$.

platinum metal disk as reference instead of MgO. This provided closer matching (within 1-2%) of the sample and reference reflectance over the whole wavelength range, and allowed the use of the 0-10% reflectance differential setting on the instrument to amplify tenfold the small changes in reflectance of the sample on application of anodizing potentials. The changes of reflectance shown in Fig. 4 are, therefore, ten times the absolute changes relative to MgO. For a pen circuit time constant of 0.6 sec, the peak-to-peak noise in the traces was approximately 10% of the maximum change in reflectance measured. The rates of change of reflectance on changing the potential indicated (see Fig. 4) an initial fast reaction, with time constant of about 5 sec, followed by a slower reaction. (Surfaces previously saturated with hydrogen, which diffuses into the metal, showed considerably slower reactions.) The changes in reflectance measured when the reflectance became steady, were found to be related to the electrode potential, and a curve was obtained (1) which followed closely the plot of oxygen surface coverage (in coulombs) against potential. Similar curves for the changes in reflectance with potential were found at other wavelengths.

It is probable that this experimental method could be applied to other systems in which corrosion by material transport of metal from the surface does not occur. Similar results have, in fact, been obtained for gold in dilute sulfuric acid.

The reflectance changes with electrodes which dissolved under the experimental conditions (Au in KCN or Ni in H_2SO_4) were basically different to those obtained with insoluble electrodes (Pt and Au in H_2SO_4). In the former case, large changes (up to 50%) in reflectance were observed which were often only slowly reversible and which continued for 15 min or more without reaching steady values, while in the latter case, reproducible and constant reflectance values were obtained in a few minutes, and the changes in reflectance were always rapidly reversible.

This behavior of the dissolving electrodes, together with the visual observation that the electrode surface was roughened after a treatment which produced a decrease in reflectance, suggests that the changes in reflectance in these systems are caused by etching and polishing of the surface. The change in reflectance with time of a gold surface in cyanide solution, shown in Fig. 5, is a clear example of this behavior, the changes in this case being very much slower than those observed with platinum (Fig. 4).

By starting with an electrode fully roughened by etching, and using carefully standardized procedures,

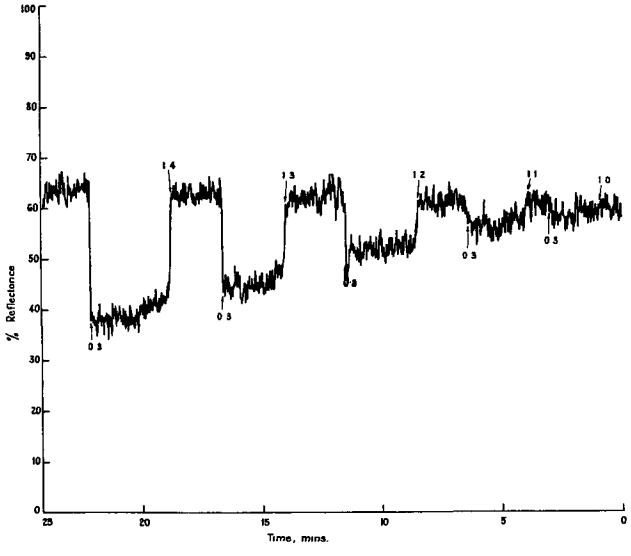

Fig. 4. Reflectance (Pt reference) vs. time for Pt in N H_2SO_4 for a series of potentials (volts vs. N.H.E.). Scale expanded approximately 10 x scale of Fig. 2 and 3.

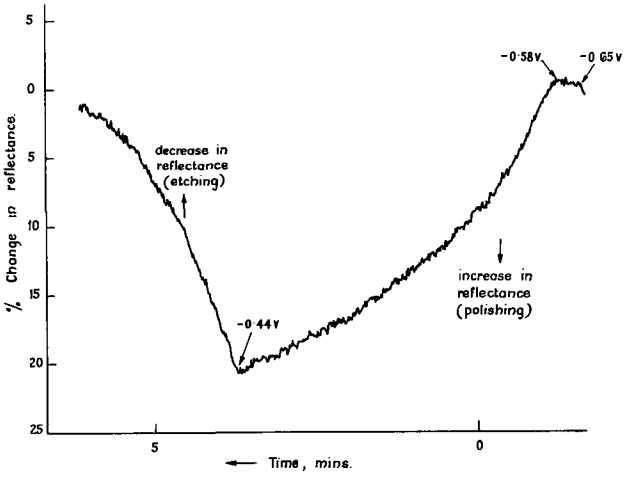

Fig. 5. Change in reflectance (Au reference) vs. time for Au in 0.25% KCN (pH 12) for a series of potentials (volts vs. S.C.E.).

the method may be used to follow such etching and polishing changes (2). In the absence of gas evolution, which causes large variable changes in reflectance, the method may provide a rapid means of determining the optimum potential for electropolishing in a particular system.

For the change of reflectance of a platinum surface in H_2SO_4, an explanation of the observed effects is possible in terms of light absorption by an oxide layer on the surface of the metal. In what follows, the scattering factor of the metal covered with oxide is assumed to be the same as that of the metal alone.

In Fig. 6, I_0 = light intensity incident on the liquid-oxide interface; I_1 = light incident on the oxide-metal interface, after absorption in the oxide layer; I_2 = light leaving the metal-oxide interface after absorption by the metal; and I_3 = light leaving the oxide-liquid interface after absorption in the oxide layer. Then $I_3/I_0 = R_{(\text{metal oxide})} = R_0$ where R = per cent reflectance/100

$$I_2/I_1 = R_{(\text{metal})} = R_M$$

$$I_1/I_0 = 10^{-\epsilon ct}$$

where ϵ = molar extinction coefficient of the oxide layer, c = concentration of the absorbing species in this layer, moles/1; and t = thickness of oxide layer in cm.

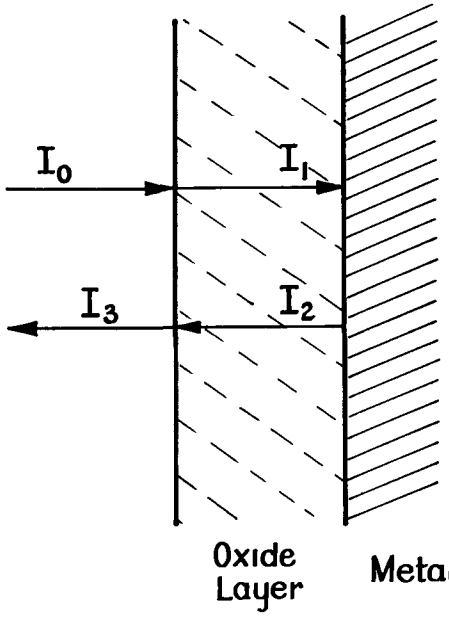

Fig. 6. Light absorption in an oxide layer on Pt metal

Then

$$I_3/I_0 = I_3/I_2 \times I_2/I_1 \times I_1/I_0$$

$$R_M 10^{-2\epsilon ct}$$

$$\Delta R = R_M - R_O = R_M(1 - 10^{-2\epsilon ct}) \quad [1]$$

At 350 mμ, $R_M \simeq 0.40$, $R \simeq 0.03$ (maximum effect)
Then $\epsilon ct \simeq 0.0164$
Thus, $\epsilon ct << 1$, and Eq. [1] can be reduced to

$$\Delta R = 4.606\ R_M\ \epsilon ct \quad [2]$$

Laitinen and Enke (6) have obtained coulometric data for the formation of oxide films on Pt, in 1*N* perchloric acid solution, using anodizing times and other conditions comparable to those in our experiments, and if, as seems probable, the behavior of Pt in the anodic region is the same in sulfuric acid and perchloric acid solutions, it is possible to use their data to obtain an estimate of ϵ as follows:

$$Q_{total} = \frac{A \times t \times nF \times \rho}{\text{Mol. wt.}}$$

where Q_{total} = charge in coulombs; A = electrode area in cm²; t = thickness; F = the Faraday; n = the number of electrons involved in the reduction of one molecule; and ρ = the density.

$$\therefore\ Q = \frac{t\,n\,F\,\rho}{\text{Mol. wt.}} \quad [3]$$

where Q is in coulombs/cm².

The concentration of the absorbing species in the layer is given by

$$c = \frac{\rho \times 10^3}{\text{Mol. wt.}} \text{ moles/l} \quad [4]$$

Substituting [4] in [3]

$$Q = t\,n\,FC \times 10^{-3}$$

$$i.e.,\ t = \frac{Q \times 10^3}{nFC} \quad [5]$$

Substituting [5] in [1]

$$\Delta R = R_M \frac{4.606\ Q \times 10^3 \epsilon}{n\,F}$$

If ϵ/nF is constant over the range of oxide coverage, a plot of ΔR against Q would give a straight line through the origin.

Figure 7 shows our experimental values of ΔR at various potentials plotted with Laitinen and Enke's values of Q. The straight line passes through the origin and has a slope from which can be calculated

$$\epsilon = \frac{n\,F}{4.606 \times 10^3 \times R_M} \frac{\partial(\Delta R)}{\partial Q}$$

$$= 2.62 \times 10^3\ n \text{ for } R_M = 0.40$$

For the reduction of PtO or PtO_2, n = 2 or 4, so ϵ is in the range 5000-10000.

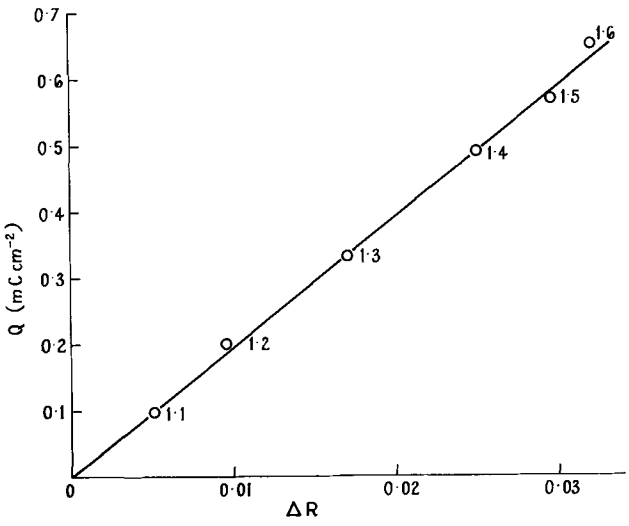

Fig. 7. Relationship between ΔR and Q for Pt in N H_2SO_4 at various potentials (v *vs.* N.H.E.).

The large values of ϵ required to account for the results by the above mechanism and the increase in the effect at shorter wavelengths suggest that the electronic transition responsible is of the charge transfer type. The much less intense ligand-field transitions between d-orbitals on the Pt atoms in the oxide ($\epsilon \sim 100$) would be beyond the limit of detection. Three different types of charge transfer process could occur in a metal-oxygen system: (*a*) transitions of an allowed nature between metal orbitals in the oxide and oxygen orbitals; (*b*) transitions between metal levels and levels of the oxide, across the metal-oxide interface; (*c*) transition between levels in the oxide itself.

The absorption occurs at wavelengths near the absorption edge for a "clean" platinum surface which suggests that the transition involves the metal itself, as in mechanism (*b*).

Brief Communications

An Electroless Method for Deposition of Lead on Copper

B. G. Slay and B. G. Carbajal

Texas Instruments Incorporated, Dallas, Texas

Occasionally it is desirable to plate lead on copper where it is either impossible or impracticable to do so electrolytically. This would be the case with incoherent copper patterns.

Several preparations were tried using water as the solvent, lead nitrate, $PbNO_3$, as the lead containing compound, and thiourea, CN_2SH_4, as a complexing and reducing agent. Results were generally poor, as the lead plate obtained was either very granular or would not adhere to the copper.

A successful answer to the problem was found when dimethyl sulfoxide was tried as the solvent. A typical plating solution was 35g each of $PbNO_3$ and thiourea in 175 ml of dimethyl sulfoxide heated to 45°C. The solution is not critical to either the amount of reagents used or to the temperature. The copper surface was prepared by cleaning with a bright dip solution.

The lead plate obtained using this technique adhered well to the copper and was shiny in appearance. For the intended applications, it was necessary that the coating be superconducting. This coating was found to be superconducting at some temperature greater than 4.2°K.

This is an "electroless" process catalyzed by copper and lead surfaces. The glass beaker or plastic stirring rods were not coated. After several days or weeks some chemical reduction takes place in the solution. Metals other than copper and lead were not investigated as catalytic surfaces.

It should be pointed out that dimethyl sulfoxide penetrates the skin very readily and that care should be taken in working with this solution to avoid possible lead poisoning; also, dimethyl sulfoxide has been removed from the list of chemicals permitted for therapeutic tests on humans.

Manuscript received Nov. 15, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Growth of Pink Magnesium Aluminate ($MgAl_2O_4$) Single Crystals

Cortland O. Dugger

Air Force Cambridge Research Laboratories, Office of Aerospace Research, Bedford, Massachusetts

Transparent magnesium aluminate (1 mole MgO/1.04 mole Al_2O_3) single crystals, doped with 1.2 ppm chromium sesquioxide (Cr_2O_3) have been grown six times from molten salt solution following the hydrolysis of some of the MgF_2 to MgO and the chemical formation and dissolution of the magnesium aluminate phase. The starting composition of the mixture was 38.1 mole % BaF_2, 38.1 mole % MgF_2. xH_2O weighed as MgF_2, 23.8 mole % Al_2O_3, and 200 ppm Cr_2O_3. The largest octahedral crystals measure 4 mm from apex to apex and 3 mm across. Polarizing microscopy, Laue, and Debye-Scherrer x-ray analyses confirm the isotropic character, monocrystallinity, and spinel structure of the crystals, respectively.

An extensive literature search in the Chemical Abstracts from 1907 to 1965 and the Defense Documentation Center files has not revealed the previous growth of spinel crystals by the hydrolysis technique. Kubo (1) recently used this method to grow needle-like crystals of zinc oxide from zinc fluoride. Although many sintering reactions of magnesium aluminate have been reported, to this author's knowledge, only Linares (2), has reported the growth of chromium-doped spinel crystals from a molten salt solution.

The thermal hydrolytic reactions of some of the MgF_2 to MgO, the chemical formation of spinel ($MgAl_2O_4$), and the dissolution of spinel in the molten salts, plotted by differential thermal analysis (3), occurred within the temperature range of 155°C to approximately 1642°C.[1] Upon programmed cooling, at 1642°C recrystallization of the spinel phase was initiated. A mechanism of the hydrolysis of MgF_2 to MgO has been proposed by Buckner (4) and most recently by Messier (5).

[1] "Approximate" because the known accurate maximum temperature limit of our differential thermal analysis apparatus is 1620°C.

The crystals were grown in an open molybdenum crucible, which contained the noncalcined and unreacted starting chemicals. The crucible was heated under a vacuum to 900°C in a carbon furnace. At 900°C, a helium atmosphere was introduced and the temperature raised to 1650°C. This temperature was maintained for 3 hr and then lowered at approximately 5°C/hr to 1510°C. The furnace was then rapidly cooled (500°C/hr) to room temperature. The temperatures were measured by an optical pyrometer, uncorrected for emissivity. The crystals were removed by destroying the crucible and gently tapping the matrix with a hammer. The crystals easily separated from the crystallized fluoride solvent. The x-ray density, lattice parameter, and the refractive index of the crystals are 3.577 g/cm^3, 8.0835Å, and 1.710, respectively. Navias (6) reported for 1MgO/1Al_2O_3, a specific gravity and lattice parameter of 3.578 g/cm^3 and 8.0832Å, respectively. Wickersheim and Lefever (7) published an index of refraction of 1.708 for the stoichiometric spinel.

If the solution is cooled from 1650° to 1510°C at approximately 15°C/hr, the crystals are smaller (2 mm) but are more heavily doped (15 ppm) with chromium oxide (8.0846Å) than those crystals grown by cooling at 5°C/hr. Semiquantitative emission spectrochemical analysis detected 50 ppm barium.

If the starting composition is placed in a platinum crucible, covered, heated in air to 1470°C, and then slowly cooled at approximately 1°C/hr to 1200°C, a new compound is formed in which barium is included in the lattice (Fig. 1). Single crystals of this new compound demonstrate a hexagonal habit and the largest crystal measures 5 x 5 x 3 mm.

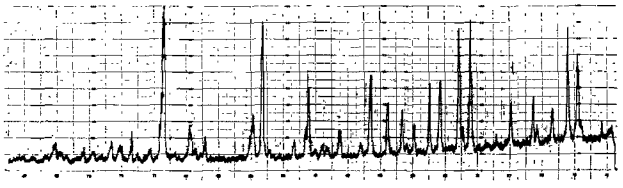

Fig. 1. X-ray diffraction pattern (in degrees) of chromium doped barium magnesium aluminate.

These crystals are uniaxial optically positive crystals whose indices of refraction are 1.700 and 1.716 for the ordinary ray and the extraordinary ray, respectively. X-ray analysis has identified the compound as hexagonal with a c axis equal to 22.56Å and an a axis equal to 5.63Å. Neglecting the chromium ion content, its formula from wet chemical analysis is $BaMgAl_{10}O_{17}$, which is isostructural with $NaAl_{11}O_{17}$ (8), whose unit cell dimensions are: c equal to 22.48Å and a equal to 5.58Å.

Fluorescence spectra were obtained for both the spinel crystals of greater chromium ion concentration (15 ppm) and chromium oxide doped barium magnesium aluminate ($BaMgAl_{10}O_{17}$) crystals at liquid nitrogen temperature (77°K) and room temperature (300°K). The fluorescence wavelength, which is the same at both temperatures, is 6880Å and 6950Å for $(MgAl_2O_4)Cr$ and $(BaMgAl_{10}O_{17})Cr$, respectively.

Absorption spectra demonstrate that $(BaMgAl_{10}O_{17})Cr$ has two absorption bands, one at 3900Å and the other at 5600Å. Liquid nitrogen and room temperature measurements were made at 5600Å. The absorption lines are broad and do not change appreciably with temperature.

The hydrolysis of a fluoride to an oxide, which might be considered a new technique for growing single crystals of some refractory oxides, has been extended to the growth of other crystals. Using different soak temperatures, crystals of yttrium iron garnet (12.377Å), yttrium aluminum garnet (12.015Å), barium zirconate, magnesium oxide, zinc oxide, and a double salt of magnesium orthosilicate (forsterite) and magnesium fluoride have been grown and verified by x-ray analyses.

Acknowledgments

The author wishes to express his appreciation to Jane Bruce, Anahid Thomasian, and John Fitzgerald of the Properties and Analysis Branch at AFCRL. He also wishes to acknowledge the spectra measurements made by the Sperry Rand Research Center and the index of refraction measurements made by Manlabs, Inc.

A Long-Life Thermal Cell

Lawrence H. Thaller

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

ABSTRACT

Cells consisting of magnesium anodes, mixed copper oxide cathodes, and an electrolyte of the eutectic mixture of lithium chloride and potassium chloride, had service lives measured in days. Seven cells were discharged at temperatures of 425°-535°C. Electrode efficiencies varied from 73% for a cell that was discharged over a period of six days to 93% for a cell that was discharged over a period of one day. For these nonoptimized research cells, energy densities of 28 whr/lb of total battery were shown.

Thermal cells, which usually have solid electrolytes, become activated when these solids are melted. Such cells have been described by several authors including Vinal (1), Goodrich and Evans (2), and McKee (3). These cells are generally employed when very high currents are desired for very short periods of time. Once activated, a lifetime measured in minutes is the rule. In general, the anode reacts with the electrolyte, and the soluble cathode material reacts with the anode. These undesirable side reactions are only of minor significance during the short-term operation of these short-life thermal cells.

A program was initiated to investigate electrochemical systems which might prove suitable for making a battery that would have an operating temperature of about 425°C and a service of several days. The potential application of this type of battery would be on missions where the environment itself would supply the heat to activate and maintain the battery at its operating temperature. The more usual thermal cell employs a pyrotechnic device to supply a short-term high-temperature environment for the battery. The high self-discharge characteristics of this class of cells renders them unsuitable for long-term applications.

Research was begun on a new class of cells which, for the present, contain no added mechanical separators or diffusional hindrances. The general criteria established for these long-life thermal cells were the following:

1. All components should possess interface compatibility. Since it is questionable whether metastable equilibrium will exist at these temperatures, thermodynamic data and criteria should be used to determine compatibility.
2. The electrodes should be very insoluble in the electrolyte. Solubility of the electrode materials would lead to self-discharge of the cell.
3. The products of reaction should be only sparingly soluble in the electrolyte. Excess solubility of the discharge products might adversely affect the physical properties of the electrolyte such as the melting point, conductivity, etc.

The eutectic mixture of lithium chloride (LiCl) and potassium chloride (KCl) (59 mole % LiCl) was chosen for the molten salt electrolyte. This mixture has a rather low melting point (363°C), a high conductivity, and the individual compounds have large free energies of formation ΔF_f^o. Magnesium was chosen for the anode material. It is lightweight, has a rather high melting point (651°C), will not replace lithium (Li) or potassium (K) from the molten salt (as does calcium), and is relatively insoluble in the molten salt. Any number of likely cathode materials could have been tested. In general, the halides could be ruled out because of their solubility in the halide electrolyte (4). The oxides would not as a rule be very soluble in the electrolyte, and thus they represent a source of potential cathode materials (5). Calculation of free energy changes of some metal oxides makes it possible to find a number of oxides that might form cells with high energy densities. From this latter group, mixed copper oxides (Cu_2O, CuO) were chosen for investigation because this system possesses good electronic conductivity and thus could serve as the current collector.

Experiment

Cells.—Figure 1 shows the general construction of the cells used in these studies. The can was constructed of commercially pure copper (99.9% Cu with some P and S) or nickel (99.4% Ni, 0.1% Cu, 0.15% Fe, and 0.25% Mn). The lid assembly had three small tubes used for adding electrolyte, venting the cell during the addition of electrolyte, and affixing the positive lead to the cell. An electrical feedthrough, consisting of a ceramic insulator brazed between two metal tubes, was also affixed to the top of the can. A stainless-steel rod, which was screwed into the shank end of the anode and was silver soldered to the upper part of the ceramic feedthrough, served as the negative terminal of the cell. The cathode of copper oxides rested on a small piece of coiled copper tubing, which, in turn, rested on the bottom of the can. The cathode of copper oxides was raised above the floor of the cell to prevent the possibility of solid products of reaction from clogging the passages of the checker-work cathode. Another stainless steel rod was silver soldered into one of the small tubes. This rod was the positive lead of the cell. The lid assembly was by heliarc

welded to the can. This welding was performed in a dry box filled with argon.

The cells were then filled as needed by the addition of the electrolyte. The small tubes were then pinched off and silver soldered. The weights of the individual components are given in Table I. When the copper can cells were discharged, the entire cell was enclosed in an evacuated glass envelope to prevent the oxidation of the copper cans. One cell was constructed using only an anode, a cathode, and a glass envelope to permit visual observation of the discharging cell. Copper wires were used to connect the electrodes to the tungsten feedthroughs. This cell will be referred to as the glass cell.

The anodes were of primary magnesium (99.8% Mg, 0.15% Mn, 0.02% Cu), while the cathodes were a mixture of Cu_2O and CuO. The anodes were made in the form of thick round disks with a shank on one end. The cathodes were made by oxidizing a checkerwork of oxygen-free high conductivity (OFHC) copper plates, which had been slotted and fitted together. This checkerwork was placed in a furnace and oxidized in air for 6 hr at 1000°C followed by a 1-day oxidation at 600°C. The cathodes were analyzed to be nominally 16 mole % CuO and the remainder Cu_2O.

Although some effort was made to have an anhydrous melt, there were always some hydrolysis products in the melt. The salts were dried in an oven for several days at about 150°C, weighed in the proper proportion, and melted. To the melt were added some magnesium chips to react with water; when reaction was no longer apparent the melt was filtered through quartz wool. The electrolyte in effect was the eutectic of LiCl and KCl with some dissolved MgO plus some unwanted hydrolysis products.

A U-shaped cell (Fig. 2) was discharged at 425°C. Folded magnesium ribbon served as the anode, while oxidized copper wires were used at the cathode. The cell was constructed of heat-resistant glass, which permitted visual observation of the cathode and anode regions separately. The ampere-hours withdrawn were noted and then the cell was broken into two portions. These sections were then analyzed for total magnesium.

Experimental setup.—Most of the experiments were carried out at 425°C (Table II) using a setup shown in Fig. 3. The cell undergoing discharge was wired to a load resistor and the switching relay. The value of load resistance (1, 5, 10, and 20 ohms) depended on the duration the cell was expected to last. The voltage across this load resistor was fed into a high impedance voltmeter. A recording potentiometer was connected to the output of the voltmeter. A cycle timer was employed during several runs. It would alternately place the cell under load for 15 min, followed by 2 min in the no-load condition. The system was connected so

the voltmeter would read the voltage across the load resistor during one portion of the cycle and the no-load voltage during the other. The ampere-hours delivered during discharge were calculated from the recorded voltage across the load resistor.

Analysis techniques.—The discharged cells were analyzed in an attempt to follow the course and extent of the chemical and electrochemical reactions that took place within the cells. After discharge the nickel cells were analyzed quantitatively for reaction products and unused electrode components. The copper cells and the glass cell were analyzed qualitatively.

The magnesium and copper oxides were expected to react to form magnesium oxide and metallic copper. Selis *et al.* (6), however, found in the analysis of the molten salt cell, Mg/KCl-LiCl/Fe_2O_3, Ni, that the oxidized magnesium in the spent cells was water soluble magnesium chloride ($MgCl_2$). The oxide ion from the discharging iron oxide cathode was taken up in the form of nonsoluble $Li_2O \cdot (FeO)_x$.

An analysis routine (Fig. 4) was made up, which tried to take into account all possible courses of reaction. The resultant routine allowed for analyses of the following constituents as they would appear after a spent cell had been opened and the contents dissolved if possible in water: magnesium metal, water soluble magnesium compounds, magnesium oxide, cop-

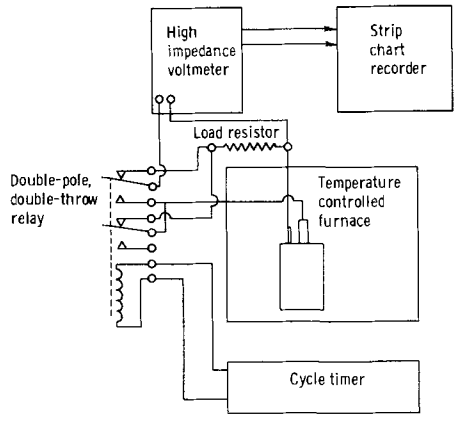

Fig. 3. Schematic diagram of apparatus

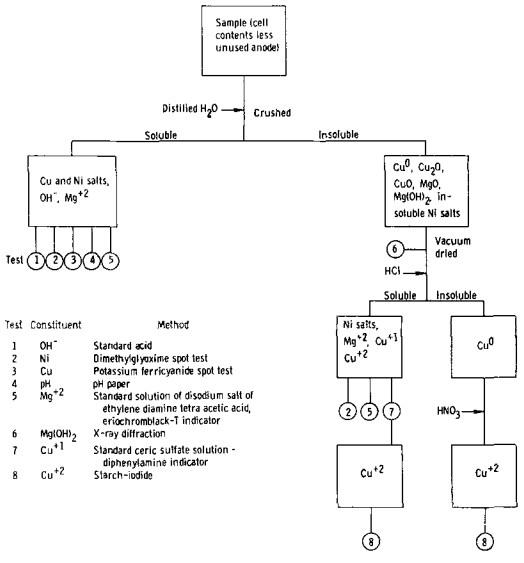

Fig. 4. Flow sheet of analysis

per metal, acid or water soluble compounds of copper and nickel, and finally any alkali metal hydroxides. The pH of the initial wash solution was also measured. If any $MgCl_2$ was present in the spent cells formed during these studies, it would react with the corresponding amount of alkali metal oxide to form, in the presence of water, $Mg(OH)_2$, but this was absent. Analyses of the spent cells for unused reactants would permit calculation of the electrode efficiencies, while analyses for products of reaction would allow some conclusions to be made concerning the course of the reaction. Figure 4 gives details of the analytical routine.

Results and Discussion

General observations.—Figure 5 is a plot of the open-circuit voltage and load voltage against time for the intermittently operated glass cell. This cell was used so that the condition of the cell materials could be observed as a function of depth of discharge. It was noted that a white flocculent material and also small particles of copper were formed and held in suspension. The copper particles ranged in size from less than 1μ to more than 50μ. Most of the copper formed remained on the cathode.

The U-shaped cell experiment (Fig. 2) was performed to gather more information than available from chemical analysis and the glass cell concerning the physical state and region of origin of the MgO. It was already suspected from the discharge curves of the copper and nickel cells that a tightly bound, electrochemically formed layer of MgO was not present at either electrode. Such an insulating layer would greatly inhibit further electrochemical action. A white flocculent cloud of material was formed at both the

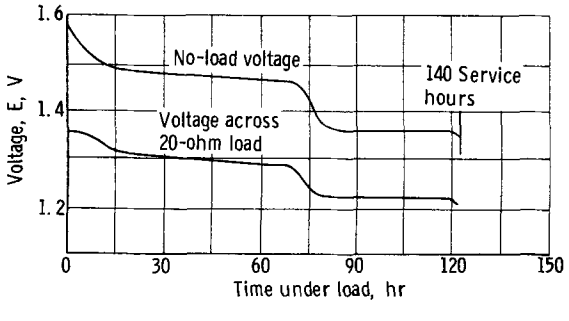

Fig. 5. Discharge characteristics of glass cell. Duty cycle: 15-min load, 2-min open circuit.

anode and cathode regions and these grew toward the center of the cell. Before the clouds overlapped, the reaction was stopped, the cell frozen and broken into two portions as indicated. Each of these portions was analyzed for Mg^{+2}. The presence of Mg^{+2} (MgO) was found in both compartments; about 60% was in the anode half and 40% in the cathode portion.

After the nickel cells had been discharged the ampere-hours withdrawn were determined and the cells were opened and analyzed. Table II (a) shows a set of typical results. The weights of the magnesium and copper compounds are reported not only in grams but also in terms of milliequivalents and ampere-hour equivalents.

Electrochemical and chemical cell reactions.—The chemical analyses showed that the oxidized magnesium in the spent cells was present as solid MgO dispersed throughout the electrolyte. The U-shaped cell experiment showed that MgO was formed in both the anolyte and catholyte, evidently by the reaction of magnesium ions and oxide ions in the electrolyte. It was concluded that the anode reaction in the cell is $Mg \rightarrow Mg^{++} + 2e$.

The chemical analyses also showed that copper oxide cathodes were reduced to metallic copper. This was also evident visually from observation of the glass cell. The probable cause of this reaction can be determined from consideration of the free energy changes of various possible reactions. Working from Laitinen and Liu's (4) list of standard electrode potentials in this electrolyte at about the same temperature, it may be seen that the couple Cu^o/Cu^{+2} would not be expected to exist under the conditions present in the cell, since

$$Cu^{+2} + Cu^o \rightarrow 2Cu^{+1} \quad E^o = +0.509v; \ \Delta F = -46 \text{ kcal}$$

where E^o = standard electrode potential against Pt^o/Pt^{+2} and ΔF = change in free energy. This means that as soon as any Cu^{+2} is reduced electrochemically to metallic copper, chemical reaction will occur to yield Cu^{+1}. Thus, after the cell has been operated for a short time, the principal oxidized form of copper on the cathode will be Cu^{+1}. The cathode reaction is then

$$Cu^{+1} + e \rightarrow Cu^o$$

The over-all cell reaction is

$$2Cu^{+1} + Mg^o \rightarrow Mg^{+2} + Cu^o$$

The voltage of the cell is given by

$$E_{cell} = E^o_{Mg/Mg+2} - E^o_{Cu/Cu+1} - \frac{RT}{nF} \ln \frac{A_{Mg+2}}{(A_{Cu+1})^2}$$

Using Laitinen and Liu's values for the standard electrode potentials, Laitinen and Bhatia's (5) values for the solubility of Cu_2O, and our value for the solubility of MgO (6.52×10^{-2} mole liter^{-1}), the value of E_{cell} is found to be between 1.50 and 1.54v, depending on which value for the solubility of Cu_2O is used. The value of 1.48v was found for these cells after there had been enough electrochemical action to saturate the cell with reactants and products of reaction (Fig. 5). Considering the uncertainty associated with certain of the values used in the cell voltage calculation, this is very good agreement.

Electrode efficiency.—Table III shows the results of life testing of these cells. After an encouraging life test on the glass cell, the three nickel cells were discharged over a rather short period of time and then analyzed thoroughly for products of reaction and unused reactants. The output of the cells varied considerably, but failure was in no case due to depletion of electrode materials by either chemical or electrochemical reaction. The cells were cathode limited, containing 6.9 amp-hr of copper oxides. The best performance gave 5.29 amp-hr (75% of theoretical) and the poorest only 2.48 amp-hr. This latter cell devel-

Table III. Determination of cell life, output, and efficiency for cells of different can material

Cell Can material	No.	Temperature, °C	Life, hr	Cell output, amp-hr	Anode efficiency, %	Cause of failure
Copper	1	425	46	1.04	—	Cell leaked
	2	425	28	2.55	—	Disconnection of anode
	3	425	52	1.73	64.3	Cell leaked
Glass		425	140	5.82	73.4	Disconnection of anode
Nickel	1	425	35	2.48	92.5	Internal short
	2	425	22	5.29	97.8	Disconnection of anode
	3	425-535	5	3.04	90.5	Disconnection of anode

oped an internal short believed to be caused by a bridge of copper metal particles bridging between the electrodes. This has been observed by McKee (3) in other cells containing copper with the lithium chloride, potassium chloride electrolyte. The cell giving 75% of theoretical life failed because the anode lead became disconnected. Considering this, the cell showed a very fine efficiency of the cathode. This was also indicated by cell No. 7 where the efficiency of the cathode, calculated on the amount of copper ions reduced, was slightly over 100% (Table II-b). A figure of over 100% is probably due to a slight oxidation of the finely divided copper formed during cell discharge. Both massive bright shiny copper and micron-size dull red copper were formed. The very fine particles most likely underwent some oxidation during the handling procedure, even though precautions were taken to prevent this.

The anode efficiency calculated for the nickel cells varied from 90.5 to 97.8% (Table III). These efficiencies are the average of the efficiencies based on magnesium lost by the anode and magnesium gained in the electrolyte. On the basis of these calculations, it appears that the anode would be the limiting material if equal equivalents were used for the anode and cathode.

The over-all cell, assuming no other cause of failure, should have an efficiency better than 90%. One possible reason for some loss of efficiency is the slight solubility of the copper oxides. Once this material is in solution, it can migrate to the magnesium and react chemically. This would affect both electrodes. Another possible factor reducing anode efficiency could be the amount of water or KOH in the electrolyte by the reaction $Mg + H_2O \rightarrow MgO + H_2$. By proper preparation of the electrolyte, this loss should be negligible.

Conclusions

A long-life thermal cell was built and was discharged over a period of six days at 425°C, with an anode efficiency of 73%. Other cells that were discharged over shorter periods of time had anode efficiencies greater than 90%.

It was concluded that the following reactions took place at the electrodes. At the cathode, the slightly soluble cuprous oxide was reduced to metallic copper. At the anode, the magnesium was oxidized to soluble magnesium ion. Insoluble magnesium oxide was found to form in the region of both the cathode and anode. The value of the cell voltage, 1.48, was in agreement with that calculated assuming the cell reaction responsible for the emf to be

$$2Cu^{+1} + Mg \rightarrow 2Cu^{o} + Mg^{+2}$$

The Morphology of Magnetite Growth on Mild Steel in Alkaline Solutions at 316°C

T. F. Marsh

Central Electricity Research Laboratories, Leatherhead, Surrey, England

ABSTRACT

In previous work on the oxidation of mild steel to magnetite in high-temperature alkaline solutions different workers have obtained markedly differing types of oxide under apparently similar conditions. The types of oxide obtained, the conditions under which they were grown, and possible reasons for the difference in oxide morphology are discussed. Experiments are described which support the idea that the type of magnetite growth obtained upon an area of mild steel depends upon the presence or otherwise of a suitable cathodic surface in contact with it. For example, the oxidation of a mild steel specimen in a new pressure vessel will take place in a different manner to that of a specimen in a vessel with a pre-formed protective magnetite film coating its sides, since the magnetite film in the latter case probably acts as a cathode for the oxidation of the specimen. The properties of the types of growth, and in particular their healing properties, are discussed with particular reference to the practical problem of pitting growth in steam generator tubes.

Under the conditions existing in modern power stations, the mild steel comprising the boiler tubes is thermodynamically unstable in the presence of the high-temperature feed water and reacts to form magnetite with liberation of hydrogen. Fortunately, operating experience has indicated that the magnetite produced in slightly alkaline feed waters forms a protective film which, if maintained, ensures that thinning of the tube walls is negligible under normal conditions of operation.

In recent years (1-6), studies have been made of the growth of protective magnetite films on mild steel in alkaline solutions at typical operating temperatures in order to establish their properties and to throw some light upon the occasional circumstances in which they lose their protective character and produce a rapid pitting attack.

The investigations which concern the morphology of these films have been complicated by the fact that the protective magnetite films obtained by different investigators at the same temperatures and solution pH's have had markedly different morphologies. In general, two different types of film growth have been observed under apparently similar conditions and the experiments described subsequently were performed in order to resolve the differences observed and to determine which of the two growth mechanisms would be likely to predominate on a boiler tube wall in operation.

Previous work.—Experiments have been performed involving the oxidation of mild steel in sodium hydroxide solutions of up to 40% by weight in the expectation that oxide films of a similar character to those produced in the just-alkaline feed water would be obtained, but of a thickness large enough for their morphology to be studied.

Studies were made by Potter and Mann (1) and later by Adams, Field, Holmes, and Stanley (2) which involved the oxidation of small mild steel specimens (ground on 600 grade silicon carbide paper and degreased in acetone) in partly filled mild steel pressure vessels sealed with Ermeto caps.[1] The former used solutions ranging from distilled water to 20% sodium hydroxide solution at temperatures from 250° to 355°C, whereas the latter used 15% NaOH at 316°C. In both cases "conditioned" pressure vessels were used, that is, with a magnetite film grown in NaOH solution on the internal walls.

[1] Manufactured by British Ermeto Corporation Ltd., Maidenhead, Berkshire, England.

Under these conditions oxide films consisting of two layers were observed (Fig. 1). The films adjacent to the metal ("inner-layer") were regular, compact, and adherent and were found to be protective in most cases despite a porosity of 8-15% (2, 7).

In contrast, the "outer-layer" consisted of a loose array of tetrahedral crystals and, when the original metal surface was ground, apparently afforded no protection to the metal.

Bloom and Krulfeld (3) studied the alkaline corrosion of mild steel by continuous measurement of the hydrogen released in the oxidation reaction. This was achieved by taking a length of annealed mild steel tubing, flattening to an oval cross-section and sealing solutions inside by squeezing the ends in a hydraulic press and spot-welding. On raising to temperature the capsules remain completely filled with liquid since the hydrostatic pressure generated inside is greater than the vapor pressure of the solution and the hydrogen produced by the corrosion reaction diffuses through the capsule wall.

The growth obtained by Bloom on mild steel in 40% NaOH and 15% NaOH, although still protective, was quite dissimilar to that shown in Fig. 1 (4, 5). Figure 2 shows a section of magnetite growth on annealed mild steel in 15% sodium hydroxide solution typical of that obtained by Bloom. The growth is irregular at both the oxide/metal and oxide/solution interfaces, and there is no division into two layers. Direct examination of the oxidized metal surface by reflected light reveals a mass of magnetite tetrahedra similar to the surface of "outer-layer" described above.

These irregular films appear to be considerably more protective than the regular films obtained by Potter

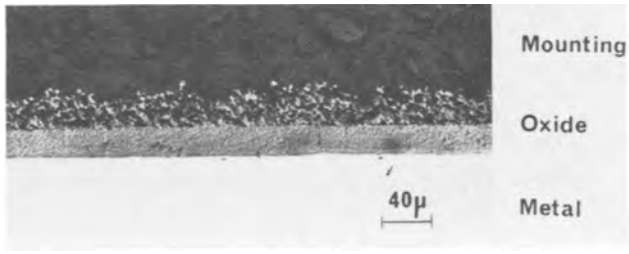

Fig. 1. Normal section of Fe_3O_4 growth on mild steel specimen contained in conditioned pressure vessel. Oxidized for 250 hr in 15% NaOH.

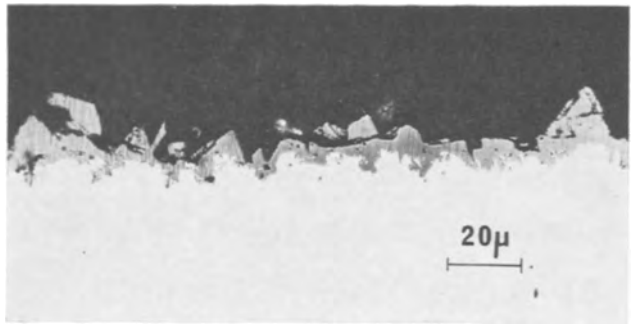

Fig. 2. Normal section of Fe_3O_4 growth on the inner surface of a mild steel capsule. Oxidized for 72¼ hr in 15% NaOH.

and Mann. For example, in 15% NaOH solution the thicknesses of Bloom films appear to differ only marginally after oxidation periods of 3.7 and 42 days (6). For Potter and Mann growth, calculations based on the growth curves shown in Fig. 4 of ref. (1) indicate that in 13% NaOH the thickness of metal oxidized (*i.e.*, the thickness of the inner-layer) increases from 11-12 μm to 35-36 μm in the same time period. These results are in accord with surface area measurements involving the adsorption of radioactive krypton (8) which indicate that the Bloom films do not have the porosity possessed by the Potter and Mann films.

In addition to the protective film, there is a tendency for hemispherical pits to form in the later stages of growth (4, 5). No such type of pitting growth was observed on the block specimens used by Potter and Mann.

Comparison of Experimental Conditions

It seemed necessary first of all to eliminate the possibility that the different growth mechanisms were a result of differences in the composition of the mild steels used, or in the purities of the NaOH solutions. The former was disposed of by the oxidation in a conditioned pressure vessel of small sections of tubing,[2] of the same mild steel as that used in Bloom's capsule experiments. This resulted in two-layer Mann and Potter type films on the samples used.

Differences in surface treatment also were found to have no radical effect on the morphology of oxide grown on specimens in conditioned pressure vessels: a blue air-formed interference color film (grown at 316°C) did not affect the form of the film grown subsequently in NaOH solution, and the change in oxide morphology produced by the oxidation of annealed specimens was inadequate to explain the growth differences previously described. Two distinct oxide layers are still formed on annealed specimens, but with a much increased size of "outer layer" crystal which acts as an additional local protection to the underlying metal. This effect is described in more detail by Field and Holmes (7).

The effect of the stress existing in the walls of Bloom's capsules was considered also. However, elastic and plastic straining were found to have no effect on the morphologies of two-layer films. A piece of steel was bent into an arc corresponding to a maximum strain of 1.06%, held in a jig of the same material and oxidized for 51¼ hr in 15% NaOH and 316°C in a conditioned pressure vessel. A two-layer Potter and Mann film was observed on the strained specimen.

Similarly a mild steel specimen in the form of a test piece for a Hounsfield Tensometer was strained until near to fracture and then oxidized in a conditioned pressure vessel in 17% NaOH. The unstrained ends of the test piece grew between 9 and 13 μm of inner layer; in the region where necking had occurred and the plastic strain was as high as 15% the growth of inner layer had increased to 24-28 μm. The morphology of both types of growth was nevertheless found to be the same (9).

It will be seen below that it is possible to obtain Bloom-type films on specimens oxidized in nonconditioned pressure vessels. This supports the conclusion reached above that surface treatment, steel compositions, and presence of stress are not the factors determining whether Bloom growth or Potter and Mann growth is obtained, and also eliminates factors such as the effect of dissolved oxygen or of minute amounts of other impurities in solution.

Effects of Hydrogen

In Bloom's experiments with mild steel capsules it is believed that all the hydrogen produced in the corrosion reaction diffuses directly away from the site of the reaction through the thin (0.05 cm) mild steel tubing. The excellent agreement obtained between the corrosion rates, as estimated by hydrogen effusion and those obtained on other specimens by Blaser and Owens (10) as estimated by measurements of the weight loss of descaled specimens supports this. On the other hand, a residual pressure is almost invariably observed after cooling in thick-walled conditioned pressure vessels used for the oxidation of block specimens. This suggests that some of the hydrogen generated in the iron/water reaction has been liberated as hydrogen gas into the solution instead of diffusing away in monatomic (or ionic) form through the steel.

If hydrogen produced near the metal were unable to escape directly through the steel, as it appears to do in Bloom's experiments, then the evolution of molecular hydrogen into the solution might alter the morphology of the oxide film. If this were so, then the differences between the two types of growth might be caused by the different conditions in which hydrogen is evolved; the continual interference of hydrogen evolved at or near the metal with the oxide growth producing the porous Potter and Mann growth, the escape of hydrogen through the metal with little or no interference with the growing oxide film producing the more compact and protective Bloom growth.

On this picture, the pits obtained in Bloom growth would arise from local hydrogen evolution from parts of the steel surface.

Galvanic Effects

Another possible difference between the conditions of oxidation used by Bloom and by Potter and Mann lies in the electrochemistries of the systems involved: in particular, the possibility of galvanic coupling existing when Potter and Mann growth is obtained.

An unoxidized mild steel specimen placed in a conditioned mild steel vessel is in contact, both electrically and via the solution, with a comparatively large surface area of magnetite. It is known that a magnetite surface can act as an efficient cathode, for example a magnetite electrode can serve as a passivator for stainless steels and titanium (11). When magnetite grows inside a capsule, no such cathodic surface is present at the start of the oxidation and during oxidation the cathode reaction will presumably be confined to the vicinity of the corroding metal.

It is therefore possible that the presence of a cathodic surface external to the oxidizing steel gives rise to the conditions necessary for the growth observed by Potter and Mann, whereas oxidation with no such external cathode produces Bloom growth.

Bloom (12) has suggested that galvanic effects may accelerate corrosion in the early stages and that hydrogen generation can subsequently render the oxide film less protective, but has not described any experiments in support of this.

Further Experiments

In order to determine more precisely the conditions in which the two categories of growth are obtained, with a view to deciding the relative importances of the

[2] Kindly supplied by Dr. Bloom.

factors described above, the types of magnetite formed on mild steel in several different systems are described below. In all experiments the oxide was grown in 15% sodium hydroxide solution at 316°C.

Except for the mild steel tubing and capsules supplied by Dr. Bloom, the four mild steels used in the experiments had the following compositional ranges: C, 0.05-0.23; Mn, 0.37-0.71; S, 0.01-0.02; Si, < 0.08; Ni, 0.10-0.20; Cr, 0.05-0.11; Cu, 0.04-0.16; P, 0.014-0.017; Mo, 0.05-0.07; V, <0.05.

Composition differences in the mild steels of both pressure vessels and specimens within the ranges above were found to have no effect on the oxide morphologies obtained in the experiments described below.

Growth on pressure-vessel walls.—The magnetite growth on the walls of pressure vessels of the type used by Potter and Mann was studied and in the early stages was found to be Bloom-type, but with a greater proliferation of pits than is seen inside a capsule. The wall thickness was 0.4 cm; local reduction to thicknesses of 0.2 cm, 0.1 cm, 0.05 cm appeared to have no effect.

Specimens in unconditioned pressure vessels.—In these experiments, which were referred to above, specimens were oxidized in pressure vessels under the same conditions as those known to promote the formation of two-layer films, except that the conditioning film of magnetite was no longer present on the interior walls at the start of the oxidation. On removal and examination under the microscope the specimens were found to have oxidized to give Bloom-type magnetite films. Hemispherical and saucer-shaped pits, which often tended to occur at or near the corners of the rectangular mild steel blocks, were also observed many times. The oxide inside the pit was normally very similar to that constituting the inner layer of Potter and Mann growth (Fig. 3).

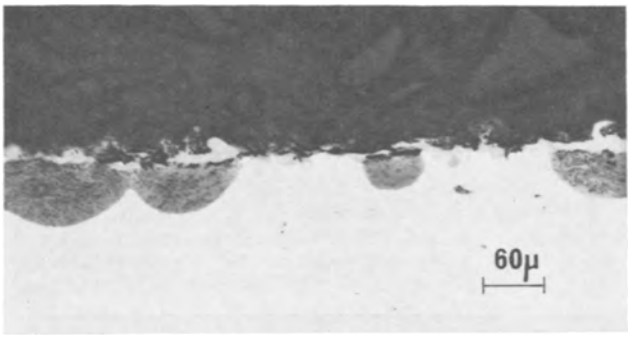

Fig. 3. Normal section of specimen oxidized in a nonconditioned pressure-vessel showing pitting growth. Oxidized for 185 hr in 15% NaOH.

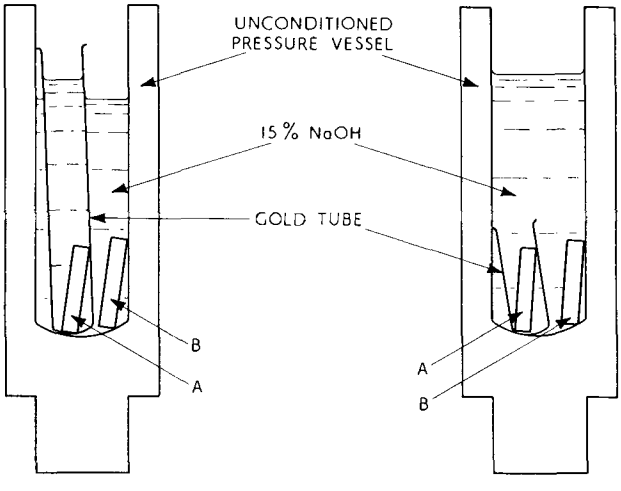

Fig. 4. and Fig. 5. Arrangements for experiments

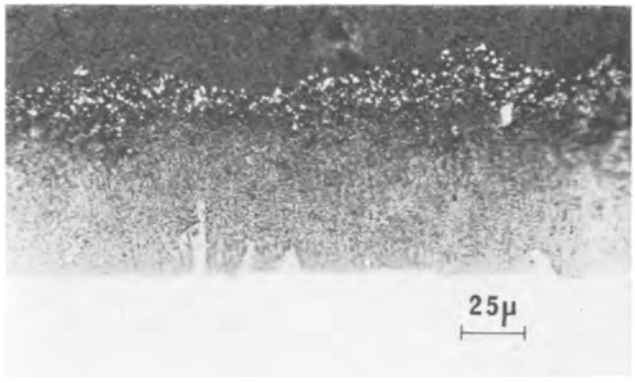

Fig. 6. Oxidation of specimen A (Fig. 4) to give relatively thick porous Fe_3O_4 film. Oxidized for 65 hr in 15% NaOH.

Use of gold tubes.—It has been suggested (13) that in some circumstances it might be possible for hydrogen to effuse directly from a corroding specimen to a tube wall and thereby escape. In view of the possible relevance of hydrogen escape in determining the oxide morphology, experiments were performed with the arrangements described in Fig. 4 and 5. Since hydrogen is insoluble in gold (14) no direct escape of atomic hydrogen could occur away from specimens A in either Fig. 4 or Fig. 5, whereas it could conceivably escape from B.

In order to take account of possible galvanic effects between the specimen and the gold care was taken to distinguish between the arrangements described in Fig. 4 where no intermixing of the liquids inside and outside the tube could take place, and those in Fig. 5 where contact between wall and both specimens existed through the solution. The results obtained are summarized below: A represents the specimen inside the tube, B, that in direct contact with the wall.

(*a*) *Unconditioned pressure vessels, no liquid contact between specimens*[3].—Specimens A were found to give more oxide growth than B. In a typical experiment a uniform 63 μm Mann and Potter film was observed on A after 65 hr with an appearance suggesting a greater porosity than is usual (Fig. 6). On B, a Bloom film was observed in a few places with coalescing saucer-shaped pits extending over the greater part of the specimen. Figure 7 is a normal section of the oxide occurring in the coalescing pits. From the smoother textured appearance and lesser depth of the oxide (16 μm) in comparison to that in Fig. 6 it appeared to be less porous.

(*b*) *Unconditioned pressure vessels, liquid contact between specimens.*—The two experiments performed gave completely different results: in one instance both A and B were coated with a thick growth similar to

[3] In fact at temperature it is possible that contact will exist between specimens via a thin film of liquid covering the tube above the level of the meniscus. However the results of the experiment indicate that the resistance of such a film is high enough for this contact to be ignored.

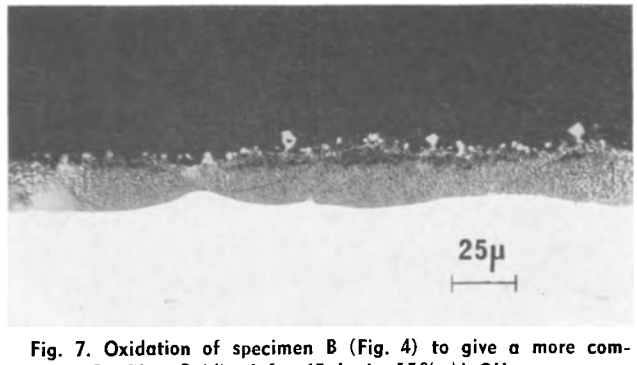

Fig. 7. Oxidation of specimen B (Fig. 4) to give a more compact Fe_3O_4 film. Oxidized for 65 hr in 15% NaOH.

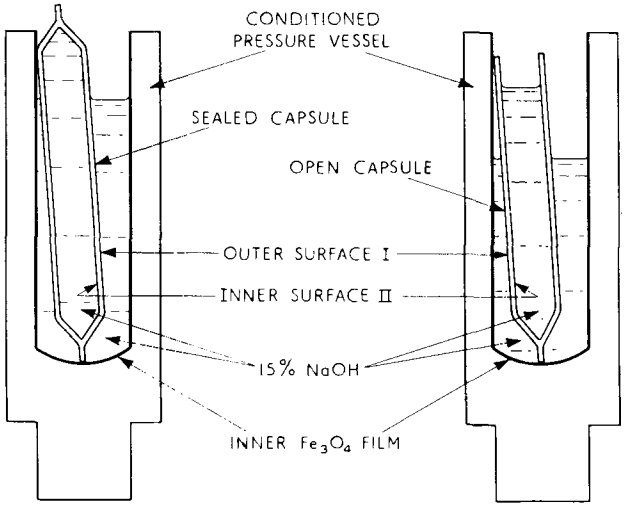

Fig. 8. and Fig. 9. Arrangements for experiments

Fig. 6; the other time the greatest part of the oxide in both cases was the nonporous Bloom film.

The most significant feature of (a) and (b) seems to be the fact that almost identical oxide growths on specimens A and B were obtained when the liquids were in contact, whereas A and B oxidized in different manners when no liquid contact existed. This implied that galvanic coupling was a more relevant factor in determining the type of growth than was the possibility of direct escape of atomic hydrogen from the specimen.

Capsules within conditioned pressure vessels.—(a) Through the kind cooperation of Dr. Bloom who provided sealed capsules containing 15% NaOH of the type used in his effusion experiments, these were oxidized in the experimental arrangement shown in Fig. 8, in order to observe the effect of a reaction on outer surface I upon that on internal surface II. I oxidized as expected to give Mann and Potter growth, but this had no effect upon the oxidation of the interior, on which Bloom growth was observed. (b) Capsules sealed at one end only were oxidized as shown in Fig. 9 care being taken that no contact existed between the liquid outside and inside.[4] Regular Mann and Potter films were always observed on surfaces I, Bloom films (plus pits) on II.

A blank experiment was performed in which a short length of a similar half-sealed capsule was oxidized while totally immersed in a conditioned pressure vessel. A regular Mann and Potter film of constant thickness was produced on all the capsule surface, except where the capsule was sealed.

[4] In fact at temperature it is possible that contact will exist between specimens via a thin film of liquid covering the tube above the level of the meniscus. However the results of the experiment indicate that the resistance of such a film is high enough for this contact to be ignored.

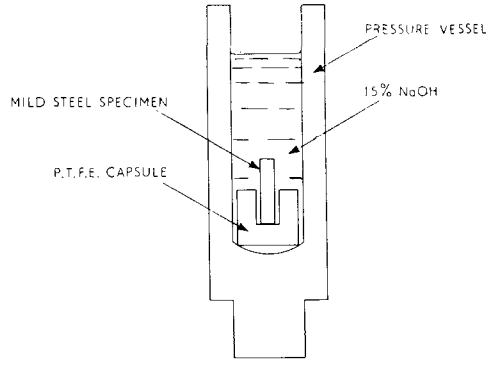

Fig. 10 Treatment of specimen

Use of P.T.F.E. capsules.—Specimens were electrically insulated from the pressure vessels by being contained in small capsules of polytetrafluoroethylene (P.T.F.E.) as in Fig. 10. In 11 of the 13 experiments performed involving both conditioned and nonconditioned pressure vessels Bloom growth was observed on the specimen, although a fairly large incidence of pitting was observed on several specimens.

One of the other two experiments produced a thick porous film, similar to Fig. 6, on the specimen; the other produced a film very similar to normal Potter and Mann growth except for a more irregular metal/oxide interface.

The action of the 15% NaOH solution at 316°C was found to have darkened the P.T.F.E. surface, and to ensure that the oxidation of the specimen was not influenced by contamination of the solution by an oxidation product of P.T.F.E. blank experiments were performed in which specimens were oxidized along with P.T.F.E. chips. Similarly, experiments were performed in which oxidation took place in the solutions previously used for the oxidation of the specimens in P.T.F.E. capsules. None of these experiments showed any change in the expected growth morphology.

Additional Experiments

Some further experiments were performed in order to check the effect of an external magnetite surface upon the oxidation of mild steel. A specimen was oxidized in an unconditioned pressure vessel for 3 days, thereby building up a Bloom-type magnetite film on the specimen and wall. On the third day a second specimen was placed in the pressure vessel and after a further day of oxidation the two specimens were removed, mounted, and examined under a microscope. The specimen which had had 4 days' oxidation was covered by a continuous Bloom film thickness *ca.* 1 μm; that which had only one day's oxidation but which was in contact with a magnetite surface (that formed on the other specimen and the pressure vessel) during this period had grown 11 μm of Mann and Potter-type growth. It was thus apparent that completely different types of oxide had grown on the two specimens on the fourth day.

Similarly, when a specimen oxidized in a new pressure vessel to give Bloom growth had one face ground to remove the film and was then reoxidized in the same pressure vessel, the exposed face was found to have given Potter and Mann growth while the other faces continued to give Bloom growth (Fig. 11). By exposing small areas of metal under a Bloom film and reoxidizing it was found possible to produce hemispherical pits similar to those observed by Bloom (Fig. 12).

Fig. 11. Section perpendicular to specimen showing Potter and Mann growth on vertical face, Bloom growth on horizontal face. The specimen was oxidized in 15% NaOH in a nonconditioned pressure vessel for 63¾ hr to give a Bloom film on all faces; the Bloom film was removed from the vertical face and the specimen re-oxidized for 70¼ hr in the same pressure vessel.

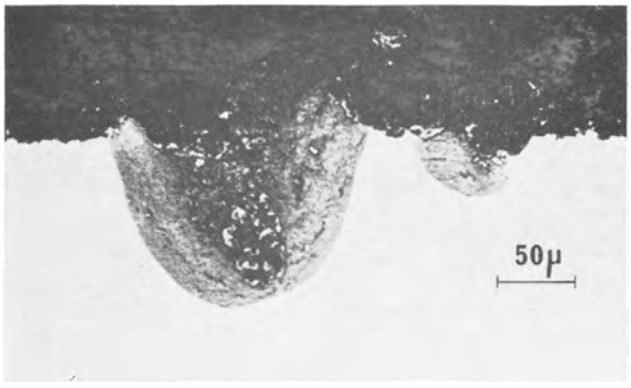

Fig. 12. Normal section of pits produced after removing small areas of a Bloom film and re-oxidizing in 15% NaOH for 328 hr.

Interpretation of Results

Galvanic effects.—A surface able to act as an efficient cathode for an anodic reaction taking place external to it must have the following characteristics: (a) Good electronic conduction. (b) The cathodic reaction on the surface must occur with ease, *i.e.*, with a low overvoltage. (c) Contact must take place with the anode both via an electronic conductor and via a solution of good conductivity. (d) The surface must not itself be supporting an anodic reaction taking place at a comparable rate. For example, when a specimen is placed in NaOH solution in an unoxidized pressure vessel the specimen and pressure vessel wall will oxidize to magnetite at very similar rates and there is no reason why the magnetite surface produced on the wall [a potential cathode with respect to (a), (b), and (c)] should act as a cathode for the corrosion of the specimen or vice versa. On the other hand, if a film of (protective) magnetite is already present on the wall, the initial corrosion rate of the wall will be less than that of the specimen and hence the magnetite on the wall is able to support the cathode reaction associated with the corrosion of the specimen.

The oxidations of the mild steel surfaces present in the systems described above are classified in Table I in terms of the presence or absence of a suitable external cathode fulfilling the requirements (a) to (d).

Table I shows a correlation between Mann and Potter growth and the presence of an external cathode, and between Bloom growth and the absence of one, but with the following discrepancies.

In Table I [5] the surface of B gave a mixture of Bloom films in a few places together with Mann and Potter films despite the presence of the gold tube exterior as a possible cathode. Here, however, as Fig. 4 indicates, the exterior of the gold tube was "shared" by both B and the pressure-vessel wall and hence it is possible that the differences in the oxidation behaviors of A and B are indicative of the relative areas of anode and cathode. During the oxidation of A a larger ratio of cathode surface/anode surface might promote thick porous Mann and Potter films; for B the smaller ratio might be related to the more protective Mann and Potter films together with the Bloom growth observed.

In Table I [6], although A and B oxidized in the same manner, the fluctuation in the oxidation behavior of the few specimens used so far is difficult to explain. It is hoped to do further experiments of this kind.

In Table I [8] an unexpectedly high incidence of pitting was observed on the specimens and, on 2 out of 13, Mann and Potter-type films were obtained. This may be associated with a high rate of oxidation of the pressure-vessel wall, with the subsequent possibility of electronically conducting magnetite "bridges" between specimen and wall. In one of these experiments the pressure vessel was known to have oxidized at an abnormally high rate.

Effects of hydrogen.—The provision of an external cathode has been shown to have a pronounced effect upon the growth of magnetite in 15% sodium hydroxide solution. Since there is such a distinct change in the morphology of the oxide this effect is not simply an acceleration of the growth rate resulting from galvanic coupling and so, for a fuller understanding of both types of growth, it is necessary to know the mechanism by which the morphology is changed.

It was described above how the evolution of hydrogen and its interference with the growing oxide film might change the type of oxide obtained. For this mechanism to be relevant one can assume that hydrogen is produced at the anode and that the growth acceleration produced by coupling the oxidizing mild steel to magnetite (or gold) increases the rate of the anode reaction sufficiently for the hydrogen evolved from the metal surface to produce a porous oxide.

On this view, proposed by Bloom (12), a strong correlation between the morphology and the rate of growth would be expected and the provision of ex-

Table I. Oxidation of mild steel surfaces

Conditions	Oxidizing surface	Possible external cathode	Type of growth [M = Mann & Potter, B = Bloom]

ternal cathodes would serve to increase the rates of growth of magnetite to values at which porous magnetite films are formed.

Both the Bloom growth obtained in capsules and the Potter and Mann growth in conditioned pressure vessels have been obtained with growth rates varying over a wide range, depending on the temperatures and alkalinities used, and consequently the author feels that the function of the cathodic surface in changing the growth is not simply the indirect result of its increasing the growth rate. However, further experimental evidence is necessary before a definite mechanism can be established.

Discussion and Conclusions

A satisfactory explanation of the discrepancies between the results of the experiments performed previously in growing protective magnetite now seems to be available and it is possible to describe the conditions under which the known types of protective growth are obtained, although the reasons why these conditions should give rise to the particular types of growth obtained are not yet fully understood.

A mild steel specimen oxidizing in high temperature alkaline solution and in electrical contact with a suitable area of magnetite (or gold) in the same solution will, in general, subject to the limitations mentioned above, produce a fine-grained porous film together with an array of tetrahedral crystals usually located at the outer surface of the film. The function of this external magnetite (or gold) surface is presumably as a cathode, the cathodic reaction probably being

$$2e + 2H_2O \rightarrow 2OH^- + H_2$$

(In the initial stages, when some dissolved oxygen is present in solution, the reaction

$$4e + 2H_2O + O_2 \rightarrow 4OH^-$$

may occur.)

Magnetite films produced in the presence of an external cathode have been observed with what appears to be varying degrees of porosity: this may be related to the relative sizes of the anodic and cathodic areas. Investigations into this are proceeding.

On the other hand, if a mild steel specimen has no contact with a suitable cathodic surface an irregular, nonporous film is obtained which displays greater protectiveness and a strong similarity to the "outer-layer" tetrahedra observed in the other type of growth.

Pits are eventually formed in this type of growth: as suggested by Bloom (5) these probably occur after the rupture of the protective film. The intact film can then act as a cathode for the high rate of corrosion at the point of breakage, condition (d) mentioned above is now fulfilled. Since the corrosion at the point of pitting is taking place in the presence of an external cathode, it is not surprising that the oxide formed in pits often bears a strong resemblance to that observed in Potter and Mann films. Figure 11 shows the hemispherical pits observed after oxidation of a specimen in a nonconditioned pressure vessel for 185 hr.

The oxidation of the internal surfaces of boiler feedwater tubes will take place initially under conditions similar to the oxidation of the inside of capsules, *i.e.*, in the absence of an external cathode. Consequently, it appears that the growth mechanism and properties of Bloom films might be of most relevance to a study of the protective oxide growth on boiler tubes.

Perhaps one of the most important properties of Bloom films to be considered in this respect is the way in which a broken film is repaired. In 15% sodium hydroxide the rupture of a Bloom film produces a site anodic to the rest of the metal upon which a porous oxide grows. If films with the properties of the Bloom films investigated are also grown in the very dilute alkaline solutions in boiler tubes then, should any breakage occur, oxide with the properties of Potter and Mann growth will be formed at the break. Although at places such as these the oxide will be protective under normal conditions, by virtue of their anodic nature they are likely to be the sites of more severe attack should abnormal conditions arise.

For example, it has been suggested (15) that if Cl^- ions are present in the feed water then ferrous chloride, known to promote a nonprotective growth on mild steel (16), might be formed by anodic action at the steel surface. It is possible that the fracture of a Bloom film might produce such a relatively anodic site. Any Potter and Mann growth (assumed to be porous) formed prior to the ingress of chloride ions would no longer be protective after ferrous chloride had been formed: indeed, it has been suggested that such a growth might aggravate the corrosion by assisting the accumulation of anodic products near the metal (15).

Acknowledgments

The author would like to thank Dr. M. C. Bloom for supplying some of the mild steel capsules used in the experiments, his colleagues at C.E.R.L. and Dr. J.S.Ll. Leach for many interesting discussions, and Miss M. J. Rowbotham and Mr. P. D. Cooper for assistance with the experimental work.

The work was carried out at the Central Electricity Research Laboratories, and this paper is published by permission of the Central Electricity Generating Board.

Manuscript received Aug. 25, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

Characteristic Scales on Pure Nickel-Chromium Alloys at 800°-1200°C

G. C. Wood and T. Hodgkiess

Corrosion Science Division, Department of Chemical Engineering, Faculty of Technology, University of Manchester, Manchester, England

ABSTRACT

Thermogravimetric measurements, metallography, and electron-probe microanalysis have revealed the nature of characteristic scales produced on pure Ni-14.6, 27.4, and 40.2 w/o (weight per cent) Cr in oxygen at 800°-1200°C. The growth kinetics are relatively independent of the surface preparation but are critically affected by the method of heating the specimen to temperature. Preferentially oxidized specimens usually produce only Cr_2O_3 scales, but samples immediately located in the hot zone possess an outer layer which is largely NiO. For high chromium contents and low temperatures the inner layer is Cr_2O_3, but under the opposite conditions it is multiphase. Cr_2O_3, subscale formation is extensive and can stop rapid development of stratified scale by joining up to give a complete layer. Cr_2O_3 is definitely the oxide which renders scales on these alloys protective. Extensive chromium depletion in the underlying alloy has serious consequences if protective scale fails. The mechanism of oxidation of Ni-Cr alloys is discussed and briefly compared with that of Fe-Cr alloys, from which there are distinct differences.

A surprising feature of the alloy oxidation field is the extensive disagreement about the nature of protective scale on Ni-Cr alloys rich in chromium when they are oxidized in air or oxygen (1-15). It is also curious that this system has been neglected during the recent trend to study the behavior of pure materials by topographical and microanalytical methods, which can scarcely fail to resolve such problems.

Except for quite low-chromium alloys (15-16), scarcely any optical micrographs of scales on reasonably pure materials have been published. In addition, no detailed electron-probe microanalyses have appeared yet. Use of these techniques, in conjunction with kinetic measurements, provides a close characterization of the scaling behavior, with precise details of scale topography and analysis, and data regarding the location and time of appearance of the various oxides, information lacking in previous studies. This paper presents such data for Ni-Cr alloys containing respectively 14.6, 27.4, and 40.2% chromium over a wide range of exposure times at 800°-1200°C. This allows a more precise description of the mechanism of scaling than given previously (9), without arbitrary divisions according to composition.

Experimental Procedure

The Ni- 14.6, 27.4, and 40.2 w/o (weight per cent) Cr alloys were made from nickel of 99.97% purity (C 0.008, Fe < 0.03, S < 0.002, Pb < 0.002, B < 0.001, Cr, Co, Mo, Ti, Al, Si, Mn, Zr, Mg, and Cu < 0.01%) and from pure chromium (C < 0.005, O 0.035, H 0.01%; N 7, Pb 3, Sn 4, Al 4, Fe 2, Na 4, Mg, Cu, Ni, Ag, Sb and B < 1 ppm) by rapid vacuum melting and were rolled to strip 0.06 cm thick. They were then given a preliminary annealing treatment in an inert gas at 1000°-1100°C which produced a coarse, heavily twinned, equiaxed grain structure with few Cr_2O_3 inclusions and a homogeneous bulk composition.

Specimens 2.0 x 0.5 x 0.06 cm were annealed "in vacuo" (10^{-5} mm Hg) for 8 hr at 1050°C in a further effort to obtain complete homogeneity and a large grain size; this led to mild preferential oxidation of the surface but no subscale. The final treatment was usually an adaptation of one previously used satisfactorily in studies of the oxidation of Fe-Cr alloys (17-18) and chromium (17). The specimens were electropolished for about 5 min at 0.1 amp/cm² (15v) in a freshly prepared solution containing 450 ml glacial acetic acid, 40 ml perchloric acid (sp. gr. 1.61) and 15 ml water below 20°C. Since there was a chromium-depleted surface layer at least 20μ thick, developed during fabrication and not easily removed by annealing, it was thought essential to use this long polishing time to remove about 40μ from each side. Microanalysis then indicated uniform composition throughout the specimen similar to that of the original alloy. Specimens were usually given a final dip or a minimum cathodic etch at 10 μamp/cm² for 60 sec in 5% HF, although a few were used in the electropolished condition or after abrasion on dry silicon carbide papers to grade 600. Potential/time curves recorded during etching were similar but not identical to those previously reported for Fe-Cr alloys (17). Unlike the Fe-Cr case, no attack was visible on the alloy after etching.

Samples were generally located immediately in the hot-zone of a previously heated silica-spring thermobalance (sensitivity ± 0.1 mg/cm²), containing slowly flowing pure dry oxygen and a crucible containing Cr_2O_3 near the specimen. The Cr_2O_3 was present to minimize losses from the specimen of a volatile species [probably CrO_3 (17)] which would invalidate the kinetic measurements. Weight gains were measured within 5 min of exposure and were continued for periods up to 100 hr. In several experiments the specimen was brought to temperature over 2-3 hr in an oxygen pressure lower than 5 x 10^{-5} min Hg, after which oxygen at atmospheric pressure was admitted. Scale structures were unaffected by the method or rate of cooling.

Metallography was more difficult than with scales on Fe-Cr alloys which may partly explain the absence of previously published micrographs. Many methods were tried but none proved better than conventional polishing.

Certain specimens, made conducting by a thin carbon film, were studied in a Cambridge Mk II "Microscan" electron-probe microanalyzer at 29 kv, the x-ray source size producing 95% of the characteristic radiation in the oxide being 1.7-2.5μ. The results are presented as scanning x-ray images or as ultra-slow-scanning line concentration profiles. The individual points on these traverses indicate where absorption and fluorescence corrections have been made and the whole curve adjusted accordingly, rather than the location of static probe measurements. The latter were occasionally used to check results.

Electron-probe microanalysis and optical examination are entirely adequate for identification of single-phase regions which are nearly pure Cr_2O_3 or NiO, and of larger subscale particles and loops which are always Cr_2O_3. The terms Cr_2O_3 and NiO are used for single phases of such oxides containing about 1% Ni and 1% Cr, respectively. In multiphase regions, it is only possible to give mean compositions and rely on the extensive literature on diffraction data for likely structural identification.

Results and Interpretation

General considerations.—The general pattern of behavior of the alloys, prepared and exposed in the usual manner described earlier, will be given before specific modes of scaling are introduced.

1. Ni-40.2% Cr always produces a NiO-rich outer layer a few microns thick, formed in the early stages, above a further uniform layer of Cr_2O_3 which thickens during the remainder of the run, at a faster rate the higher the temperature.

2. Ni-27.4% Cr behaves as above at 800°C and generally at 1000°C, although sometimes at 1000°C the Cr_2O_3-rich layer eventually fails and complex stratified scale grows. At 1200°C, however, nodular scale, with an outer NiO layer and an inner multiphase layer [probably NiO, $NiCr_2O_4$, and Cr_2O_3 in varying proportions (7, 8, 16)] grows. Cr_2O_3 subscale joins up to form a complete Cr_2O_3 layer at the main scale base and this alone thickens quite rapidly subsequently.

3. At all temperatures, Ni-14.6% Cr displays similar nodular stratified scale which develops faster at high temperatures. Completion of the "healing" Cr_2O_3 layer takes many hours at 800°C but is rapid at 1000° and 1200°C, although at 1200°C the outer scale is very thick. The subsequent Cr_2O_3 growth at 1000°C is much slower than with Ni-27.4% Cr at 1200°C.

4. Chromium depletion and nickel enrichment in the underlying alloy is extensive and persistent. Cr_2O_3 subscale is formed even behind protective Cr_2O_3 scale.

Thus, in general Ni-27.4% Cr at 800° and 1000°C behaves like Ni-40.2% Cr at 800°-1200°C and Ni-27.4% Cr at 1200°C acts like Ni-14.6% Cr at 800°-1200°C. This gradation of behavior demonstrates that arbitrary subdivision of alloys at compositions of ~10% (9, 19), 20%, or any other figure in this vicinity (30, 31) is fundamentally meaningless and practically misleading. The actual behavior depends on factors such as temperature, environment, and surface finish which in turn determine the contribution of thermodynamic, kinetic, nucleation, and mechanical factors to the final scale product.

Influence of surface preparation.—Typical growth curves at 1000° and 1200°C for the oxidation of Ni-40.2% Cr specimens, prepared by the three techniques described earlier, and allowed to enter the hot zone of oxygen immediately, are shown in Fig. 1. The reproducibility was good, particularly for specimens given an electropolish followed by a minimum etch which were studied in most detail. Clearly, ignoring small deviations due to balance errors, there is little influence of surface finish, although the abraded specimen at 1000°C oxidizes somewhat slower than the others, after the first few minutes. This is also true for the other alloys whether they produce protective or stratified scale.

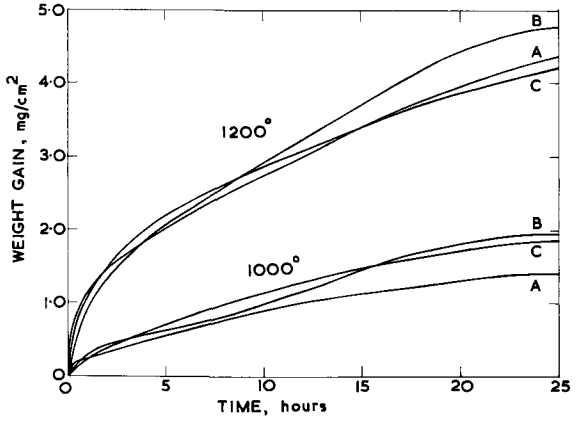

Fig. 1. Influence of surface pretreatment on the oxidation rate of Ni-40.2% Cr at 1000° and 1200°C. A, abraded; B, electropolished; C, electropolished and etched.

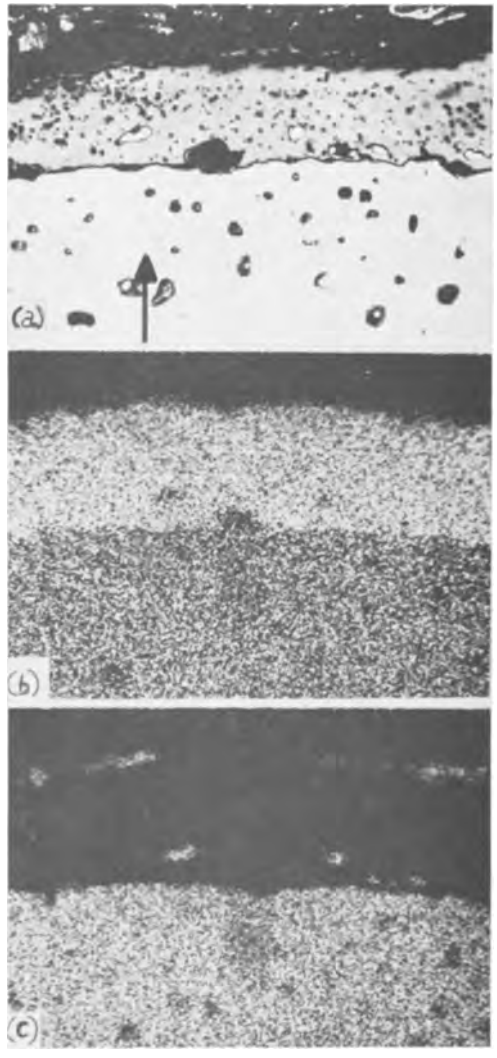

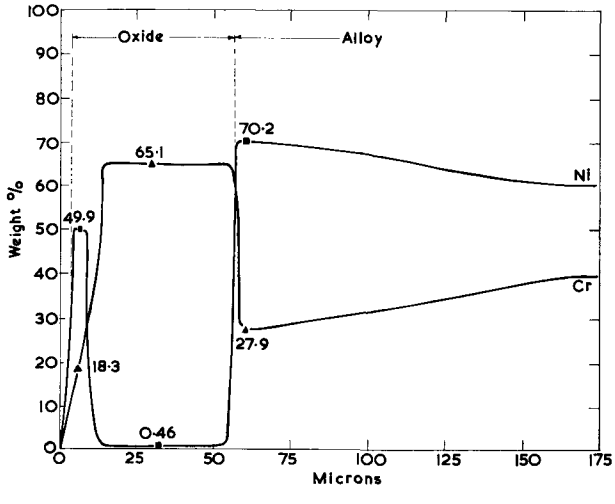

Fig. 2. Electropolished Ni-40.2% Cr oxidized for 25 hr at 1200°C. a, Optical image in cross section, magnification *ca.* 500X. b, Cr Kα x-ray image. c, Ni Kα x-ray image. d, Concentration profiles along line of traverse on Fig. 2a.

After the first 40-60 min at 1200°C the abraded and electropolished and etched specimens show good agreement with the parabolic growth relationship (rate constant = 1.62×10^{-10} g^2 cm^{-4} sec^{-1}). It will become apparent that this stage is associated with the formation of a thick, uniform Cr_2O_3-type scale. The earlier deviations from the above rate can be represented by a faster parabolic rate constant (6.34×10^{-10} g^2 cm^{-4} sec^{-1}), but this is probably fundamentally meaningless because it represents a stage where nickel and chromium are both entering the scale and the Cr_2O_3 layer is becoming developed.

On cooling, the scale on electropolished specimens sometimes tended to lift in flakes, and that on abraded specimens to fail explosively in some places, but elsewhere adhesion was good. The scale generally adhered to specimens which had been lightly etched after electropolishing. Despite these gross differences, microtopography and composition were largely independent of surface finish, except for a few areas on long-term electropolished specimens, a conclusion which is predictable from the growth curves. The results presented here for an electropolished specimen are also characteristic of the other two preparations.

The scale on an electropolished specimen oxidized for 25 hr at 1200°C (Fig. 2 a-c) consists mainly of a thick, uniform, compact chromium-rich oxide, containing a few metallic particles and occasionally keyed to the alloy by tongues of similar oxide. There is also an internally oxidized layer 50-60μ deep and outside the main scale there is a thin friable layer of nickel-rich oxide. Such layers could not be improved in appearance except when formed on other specimens at 800°C (see later). The concentration profiles (Fig. 2d) confirm that the outer layer is largely NiO. It is not clear whether the chromium measured in this layer is genuine, indicating the presence of some Cr_2O_3 or $NiCr_2O_4$, or whether the x-ray source is overlapping the two layers. The inner layer is Cr_2O_3 containing 0.46% nickel. Chromium is depleted to 27.9% at the alloy/oxide interface over a distance of about 110μ, there being a corresponding nickel enrichment. Except where otherwise stated, the alloy compositions at the alloy/oxide interface are genuine, care having been taken to avoid subscale particles and overlap with the main scale.

Over $<$ 10% of electropolished specimen surfaces only, complex ballooned oxide above more compact layers was observed, particularly at 1000°C. This agrees with the observation (Fig. 1) that electropolished specimens oxidized slightly faster in the later stages than the other samples at both temperatures. The outer scale along the line of traverse in Fig. 3 contained 68.9% chromium and 0.47% nickel, whereas the inner scale had an outer layer analyzing as 33.4% chromium and 19.0% nickel and an inner one as 61.0% chromium and 1.56% nickel. The chromium content at the alloy/oxide interface was depleted to 17.6% over a distance of about 40μ. Although the outer ballooned layer appeared to be Cr_2O_3 alone, it probably had a thin NiO-rich layer outside it which spalled off during ballooning at temperature. The inner scale which formed after the initial scale failure was similar to that previously described. The high apparent chromium content and low total weight per cent metal of its outer layer were again mainly due to its thinness.

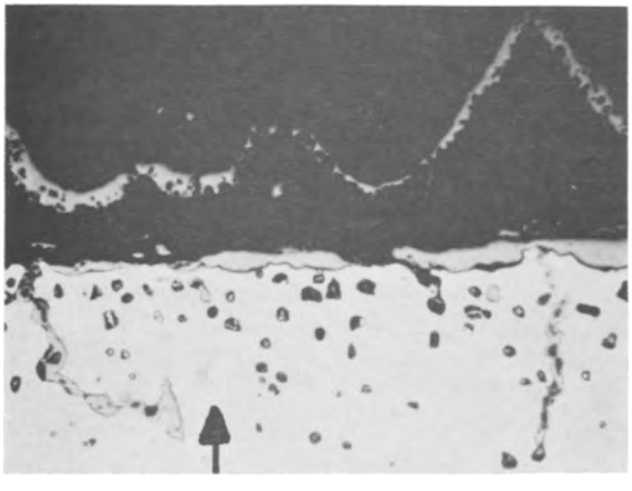

Fig. 3. Cross section of electropolished Ni-40.2% Cr oxidized for 25 hr at 1000°C, showing ballooned scale and subscale particles. Magnification 500X.

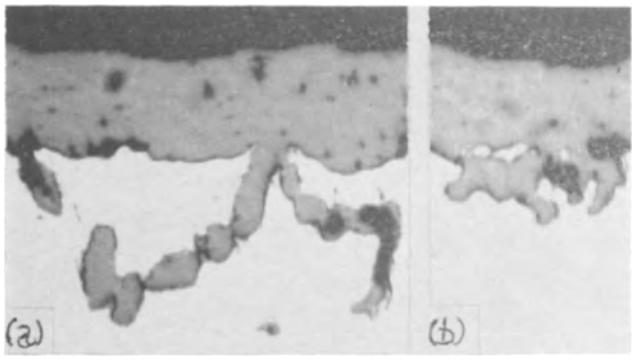

Fig. 4a and b. Cross sections of electropolished and etched Ni-40.2% Cr oxidized for 5 hr at 1200°C, showing development of subscale loop and alloy incorporation into the scale. Magnification 1000X.

An interesting feature of this study, which partly explains the general good adhesion of the Cr_2O_3 scales for all surface finishes, is the Cr_2O_3 loop development, probably along grain boundaries, behind the main scale. Such loops, and also the smaller internal oxide particles of the same oxide, are particularly prevalent for all alloys at high temperature and after long oxidation times. Figure 4a shows an almost complete loop on an electropolished and etched specimen subsequently oxidized for 5 hr at 1200°C. It also shows how the metallic particles become incorporated in the scale, although the much smaller particles shown previously in Fig. 2a were probably formed as in Fig. 4b.

Influence of pre-oxidation.—When specimens with any of the three surface finishes were preheated to temperature "in vacuo" (oxygen pressure less than 5×10^{-5} mm Hg) for 3 hr at 1000°C, prior to admitting oxygen at atmospheric pressure (a technique used by some investigators) quite different scale structure resulted. Ni-40.2% Cr and Ni-27.4% Cr produced nearly pure Cr_2O_3 with no outer NiO-rich layer. Ni-14.6% Cr also generally gave only Cr_2O_3 but stratified scale sometimes appeared in places, probably after the breakdown of the initial Cr_2O_3 layer. Reproducible growth of Cr_2O_3, largely independent of surface finish, usually occurred for at least 25 hr.

One specimen of Ni-14.6% Cr gave only Cr_2O_3, 6-10μ thick, over its entire surface with a few massive complete subscale loops, when oxidized for 285 hr at 1000°C (Fig. 5a). Figure 5b, which avoided the loops, indicates a single Cr_2O_3 layer containing 1.8% nickel with no outer NiO and static probe analysis of the subscale gave a similar composition. A significant observation with all specimens is the extensive and persistent chromium depletion beneath the scale, indicating the slow interdiffusion in the alloy.

Typical growth relationships.—Growth curves for the remaining specimens to be described, all of which were given the minimum etched finish after electropolishing before direct exposure at temperature, are shown in Fig. 6a and b. Figure 6b continues the curves for the long-term runs and includes a curve for a Ni-27% Cr alloy at 1000°C which displayed limited break-through. Reproducibility with other runs not

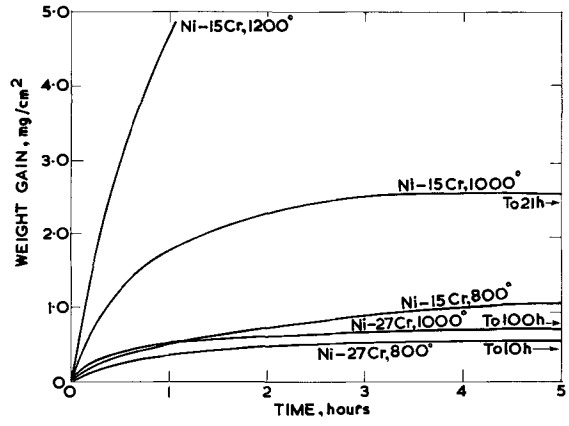

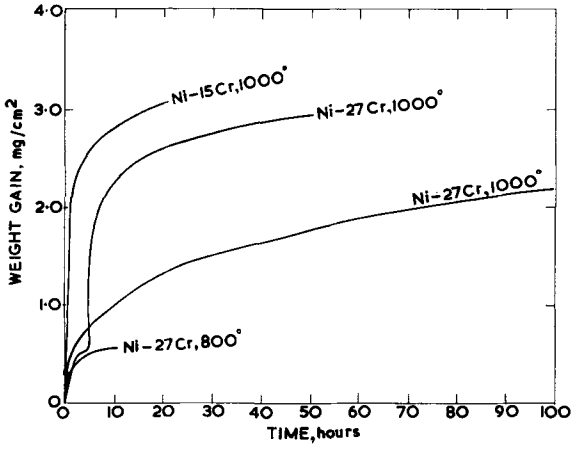

Fig. 6. Rates of formation of scales on electropolished and etched Ni-14.6% Cr (at 800°, 1000°, and 1200°C) and Ni-27.4% Cr (at 800° and 1000°C). a (top), 0-5 hr. b (bottom), 0-100 hr. Curves for Ni-14.6% Cr at 800° and 1200°C are omitted from Fig. 6b and that for Ni-27.4% Cr showing breakthrough at 1000°C from Fig. 6a in the interests of clarity.

reported was generally remarkably good, even in some cases when scale nodules formed, rendering the kinetics fundamentally meaningless. The only exceptions were the occasional failure of Ni-27.4% Cr at 1000°C after the early stages, which could be expected to be irreproducible, since it depended on irregular lifting and failure of Cr_2O_3-rich scale, and the nodular growth of scale on Ni-14.6% Cr at 1200°C.

The oxidation of Ni-40.2% Cr and Ni-27.4% Cr at 800° and 1000°C suggested the same two-stage parabolic behavior as Ni-40.2% Cr at 1200°C, but the scatter in the very low weight gains in the early stages made this difficult to prove absolutely. Quantitative treatment of other growth curves was unwarranted due to complex scale formation.

Protective scale.—Despite careful precautions the thin scales on samples of Ni-40.2 and Ni-27.4% Cr oxidized for short times (5-30 min at 800°-1200°C) invariably exhibited severe spalling on cooling. Such specimens in section showed a thin uniform oxide 1-2μ thick which had lifted almost entirely from the alloy surface on cooling. This process probably led to spalling of any outer NiO-rich layer but in any case it may not have emerged sufficiently in this short time to be detected by the microanalyzer. Indeed, line traverses merely revealed a chromium-enriched oxide, containing some nickel, and slight chromium depletion in the alloy. After 1-2 hr at these temperatures the layered structure described below was fully developed.

The scale on Ni-27.4% Cr after 10 hr at 800°C is interesting because the uniform outer NiO-rich layer remained adherent (Fig. 7). Concentration profiles indicated a 5μ outer layer of NiO containing about 1.5% Cr and a 1-2μ inner layer (appearing black in the micrograph due to relief polishing) of nearly pure Cr_2O_3. The presence of NiO at this low temperature is evidence for its genuine direct formation and suggests that its appearance at 1000° and 1200°C could not possibly be related to volatilization of chromium oxides or similar material from the outer layer. Depletion of chromium to 13.9% at the interface occurred over only 3-4μ of alloy. Exposure for 100 hr at 800°C failed to thicken the NiO layer, only the Cr_2O_3 inner layer growing during this period.

After 100 hr at 1000°C the thickness is still remarkably uniform over the entire surface and the inner layer is considerably thicker than at shorter times and lower temperatures (Fig. 8a). The x-ray images (Fig. 8b and c) confirm the existence of the outer layer and show that this and part of the inner layer

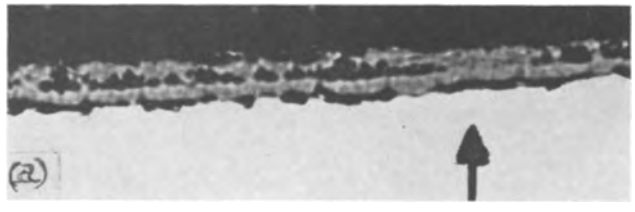

Fig. 7. Cross section of electropolished and etched Ni-27.4% Cr oxidized for 10 hr at 800°C, showing distinct outer NiO-rich layer, magnification 1000X.

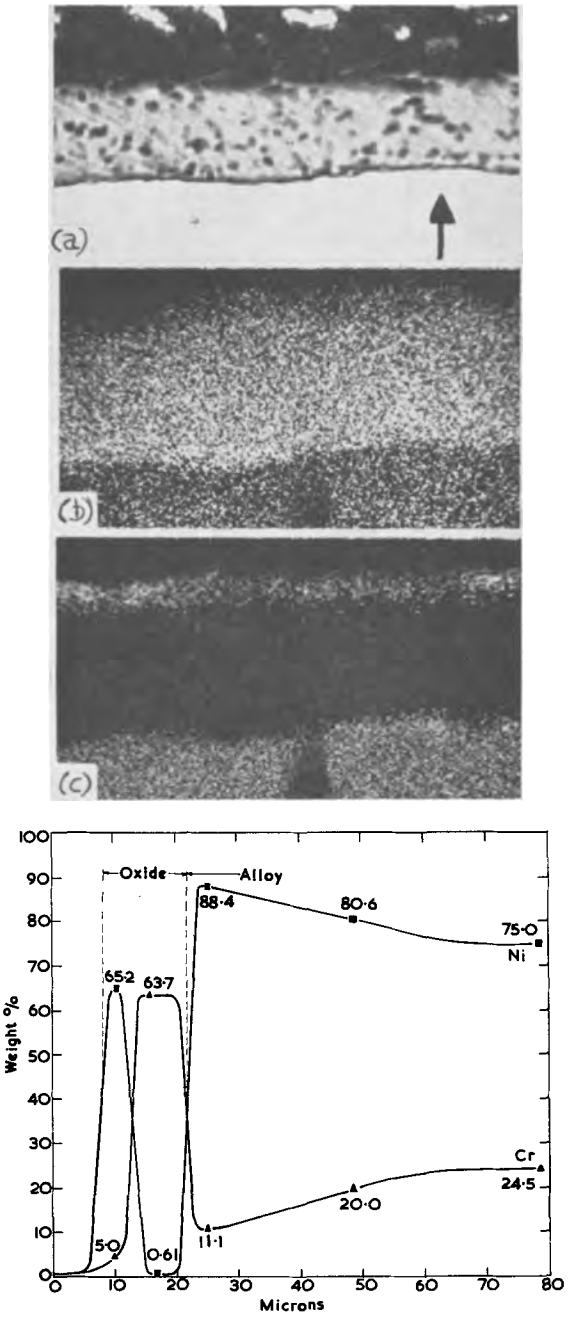

Fig. 8. Electropolished and etched Ni-27.4% Cr oxidized for 100 hr at 1000°C, showing protective scale. a, Optical image, magnification *ca.* 1500X. b, Chromium Kα x-ray image. c, Nickel Kα x-ray image. d (bottom), Concentration profiles along line of traverse on Fig. 8a.

are invisible in the optical image due to polishing problems. Figure 8d shows the outer 3μ-layer apparently containing 65.2% nickel and 5.0% chromium (some of the chromium could be due to x-ray source overlap) and the inner 10μ-layer 63.7% chromium and 0.61% nickel. Chromium depletion to 11.1% occurs over a distance of 48μ from the bulk alloy.

In summary, the early relatively rapid stages of oxidation are associated with the appearance of an outer NiO-rich layer of constant thickness and the establishment of a Cr_2O_3-rich layer at its base. The final slower oxidation is connected entirely with the growth of the Cr_2O_3.

Complex scale formation after protective scale failure.—For certain specimens of Ni-27.4% Cr at 1000°C (Fig. 6, 50 hr specimen) the oxidation rate increased suddenly after an initial protective period, and then declined again. Such specimens are too complex to be detailed here but a relatively simple area with several scale layers is shown in Fig. 9a-c, with corresponding concentration profiles in Fig. 9d. Almost certainly the initial protective Cr_2O_3 scale, covered by a thin NiO-rich layer, was lost from a few regions of the surface by lifting and cracking after about 6 hr (20). The chromium-depleted underlying alloy then behaved like a lower chromium alloy, producing a thick outer NiO layer and multiphase oxides in the inner layer. Eventually, however, the higher bulk chromium concentration re-asserted itself and a new Cr_2O_3 scale developed at its base, so healing the main scale. The thickening of this Cr_2O_3, and of that where failure had not occurred, occupied the final 40 hr of the run.

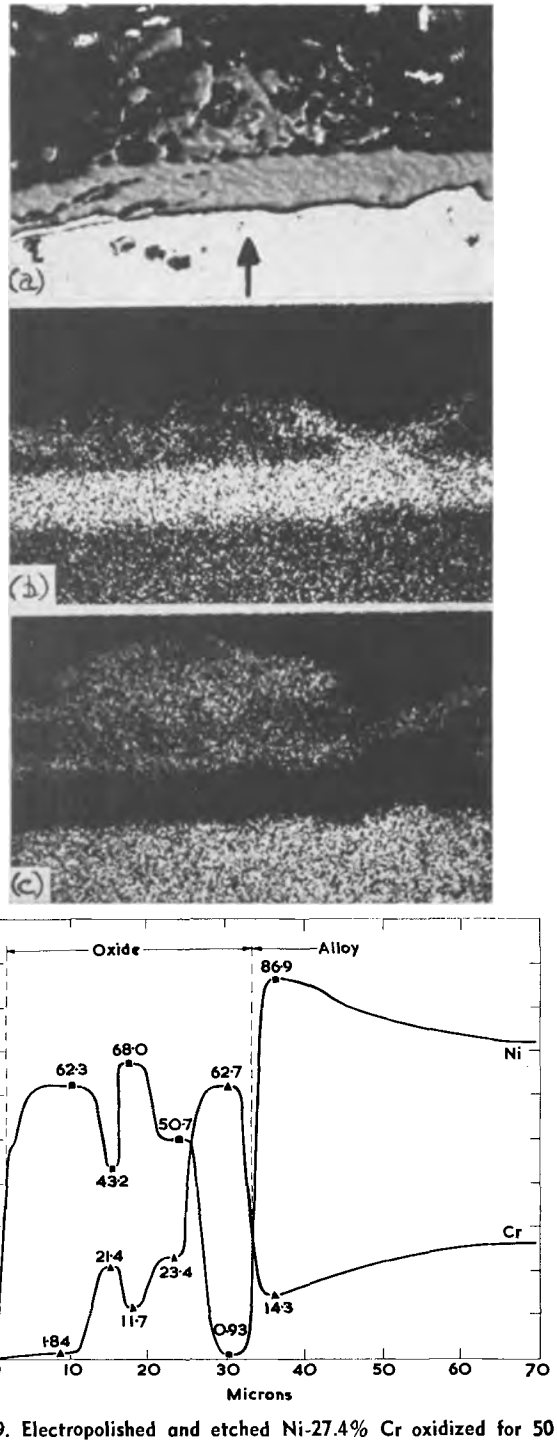

Fig. 9. Electropolished and etched Ni-27.4% Cr oxidized for 50 hr at 1000°C, showing complex scale. a, Optical image, magnification *ca.* 800X. b, Chromium Kα x-ray image. c, Nickel Kα x-ray image. d (bottom), Concentration profiles along line of traverse on Fig. 9a.

Stratified scale.—Uniform stratified scale formed on Ni-14.6% Cr at 800°C in 5 hr possesses a compact outer layer and a friable inner layer (Fig. 10a). A dense layer of subscale particles beyond resolution also appears over the entire surface and this persisted in other samples for at least 25 hr. Figure 10b reveals an outer layer containing 74.1% nickel and 1.2% chromium, an inner layer with 44.1% nickel and 24.4% chromium, a step representing the mean composition of the internal oxide and alloy matrix containing it, and no depleted alloy layer. The same is true in the very early stages at 1000°C, but the subscale soon joins up to give a complete Cr_2O_3 layer.

Healed stratified scale.—Figure 11 a-c shows a Cr_2O_3 layer which grew at the base of the nodular stratified scale initially developed on Ni-14.6% Cr at 1000°C. This Cr_2O_3 layer controls the asymptotic growth observed during the final 19 hr of exposure at this temperature (21 hr specimen in Fig. 6). An outer, single-phase, nickel-rich layer covers a region of at least two phases containing nickel and chromium which is in turn insulated from the alloy by the Cr_2O_3. In the thicker scale the outer and intermediate layers are of approximately equal thickness, with their interface located at the original alloy surface, but at the thin end of the wedge the intermediate layer eventually disappears. The chromium-rich loop in the inner layer of the thick scale, similar to others occasionally found, is difficult to explain but presumably represents some transitional form of scale which did not maintain protection. The underlying alloy is depleted in chromium but shows no subscale.

Concentration profiles were made along the three lines of traverse in Fig. 11a. In the thin region, the scale is like protective oxide on alloys richer in chromium with outer and inner layers of nearly pure NiO and Cr_2O_3, respectively. The middle region (Fig. 11d) possesses outer NiO containing 0.45% chromium, an intermediate layer with a uniform composition of 49.3% nickel and 22.7% chromium, and inner oxide rich in Cr_2O_3. Five layers, with the two outermost zones having analyses similar to those in the previous traverses, appear in the thickest region [traverse (iii)]. The thick intermediate layer is again remarkably uniform at 49.2% nickel and 21.7% chromium, a composition found for many specimens studied under these conditions. In the present case a chromium-rich region and a further NiO-rich layer are sandwiched between this oxide and the inner Cr_2O_3-rich layer.

The extent and depth of chromium depletion in the alloy (chromium reduced to 6.7-9.1% at the interface over 26-28μ) is independent of the type of superficial scale. Thus, the boundary of the region of chromium-depleted alloy follows a similar contour to the alloy/oxide interface because the depletion was

achieved during the final 19 hr of the run, in which only the Cr_2O_3 was thickening at a slow rate.

Partly healed stratified scale.—When Ni-14.6% Cr is oxidized at 1200°C, thick stratified scale grows very rapidly, but the formation of a Cr_2O_3 layer at its base is accomplished much sooner than at lower temperatures. Figure 12 shows a typical stratified nodule almost insulated from the alloy by a Cr_2O_3 layer after 1 hr. Healing was achieved earlier to the left of the image than to the right and the process was not complete in the center, where a small cluster of Cr_2O_3 subscale particles is still visible. Line traverses along (i) and (ii) proved that the intermediate layer is of variable composition, showing some chromium-rich regions, including a small loop like that in the previous specimen, and a thin chromium-rich band between the two main layers. Furthermore, there does not seem to be a complete network of macropores in the multiphase region, although this appeared to be so in other specimens. The outer layer is nearly uniform NiO containing 0.9-1.5%Cr and the inner layer is nearly pure Cr_2O_3. Even where only subscale Cr_2O_3 particles exist there is a severe depletion in chromium to 6.3% immediately below in the alloy. This indicates that although alloy interdiffusion was very rapid at 1200°C, so was Cr_2O_3 formation.

Discussion

Mechanism of oxidation of Ni-Cr alloys.—Before discussing the nature of oxidation of Ni-14.6% Cr at 800°-1200°C and of Ni-27.4% Cr at 1200°C it is appropriate to summarize certain of the new quantitative facts. The outer NiO layer on Ni-14.6% Cr contains 0.25-1.5% chromium (depending on the temperature and time of oxidation) which presumably thus increases the cation vacancy concentration in this layer. On Ni-27.4% Cr, which acts in the same way at 1200°C, 3.5-6% Cr is measured in this layer, but some of this may conceivably be $NiCr_2O_4$ or Cr_2O_3. Once the Cr_2O_3 healing layer is complete, the composition of the intermediate layer on Ni-14.6% Cr is remarkably uniform at about 50% nickel and 20% chromium through its entire thickness at 1000°C and through certain regions of the more undulating profiles at 1200°C. It was not possible to resolve the small particles in the layer, which could contain NiO and $NiCr_2O_4$ in the weight ratio 1:1, or NiO and Cr_2O_3 in the ratio 2:1, or a mixture of all three phases. This layer is porous but this could have been produced on cooling and possibly accentuated on metallographic preparation. It was impossible to measure the alloy composition between the subscale particles because they were densely populated, but there was little chromium depletion behind them in the bulk alloy, particularly at 1000°C.

The nucleation and growth of these scales are explicable by extending a theory proposed for low-chromium alloys (16, 21). It states that when the alloy is exposed, NiO and Cr_2O_3 both form initially but rapidly combine and coalesce to give $NiCr_2O_4$ granules in a matrix of excess NiO, so effectively forming the inner layer. Partial dissociation of NiO occurs at the alloy/oxide interface and oxygen diffuses into the alloy, provoking the precipitation, by preferential oxidation, of Cr_2O_3 in a matrix of what becomes essentially pure nickel. As the external scale develops the Cr_2O_3 granules become incorporated into the inner layer where they are rapidly converted to $NiCr_2O_4$. Only Ni^{2+} ions can diffuse through the inner layer to extend the outer layer since Cr^{3+} ions are localized in the Cr_2O_3 or $NiCr_2O_4$ particles and Cr^{3+} ions are relatively insoluble in NiO.

A second theory (9) requires oxygen to diffuse into the bulk alloy, preferentially oxidizing chromium to Cr_2O_3, the matrix then oxidizing like almost pure nickel to give double-layer scales. The outer layer grows by the outward diffusion of electrons and Ni^{2+} ions and the porous inner layer by the inward diffusion of oxygen gas, produced by dissociation of NiO in voids at the interface between the two layers. There is also some Ni^{2+} diffusion out through bridges of scale in the porous inner layer.

There are still certain doubts about both theories. The dissociation mechanism has not been proved, so both layers may in fact grow by cation movement outwards, as suggested in the first theory. It has not been experimentally demonstrated that the metal between the subscale particles is nearly pure nickel and also mechanical factors in the scale have been neglected. It is not clear how Cr_2O_3 subscale particles are transformed to $NiCr_2O_4$ particles of similar appearance on entering the oxide and, in any case, Cr_2O_3 has also been reported in such scales (7).

Despite these doubts it is reasonable that the NiO outer layer, the intermediate layer, and the Cr_2O_3 subscale develop in general as suggested for the lower-chromium alloys. Scale thickening is then uniform over the surface at 800°C but nodules appear at 1000° and 1200°C. The chromium content of the complex inner layer increases with time before the healing Cr_2O_3 layer is complete when it becomes constant. This increase tends to reduce the over-all oxidation rate and favor complete subscale coalescence before it is absorbed by the encroaching scale. Thus the subscale population now becomes sufficiently dense to link up and produce a complete "healing" Cr_2O_3 layer at the base of the stratified scale, this process taking longer at lower temperatures. Variations in the time to establish it lead to permanent differences in local total scale thicknesses. The layer is completed when the rate of oxygen arrival into the subscale/alloy interface region is of the same order as chromium arrival there, with consequent continued precipitation. Subsequently, slow growth of the Cr_2O_3 alone occurs, with no other noticeable processes other than the development of extensive chromium depletion and nickel enrichment in the alloy. It is just possible that a chromium-rich layer is simultaneously developing independently in the base of the scale, by chromium reducing NiO here (22) or by oxygen gas at low partial pressure diffusing through pores in the inner layer and preferentially oxidizing chromium in the depleted alloy in contact with the scale. Neither theory could, of course, hold if the metal between the subscale particles is pure nickel. If the Cr_2O_3 really is a p-type metal deficit semiconductor, the nickel would tend to block cation vacancies and reduce its formation rate.

The Cr_2O_3 subscale coalescence to give a complete layer is an example of the theory that below a critical base metal concentration internal oxidation occurs, whereas above it only external scale is obtained, except that here the situation is being decided behind a pre-existing nonprotective surface scale. Where a complete layer of base metal oxide is formed, oxygen entry into the alloy is inhibited or prevented. The simplest situation has been discussed theoretically (23) and tested in the case of Ag-In alloys (24). In the present system it has been suggested (15, 19) that internal oxidation is possible only for alloys containing less than 9% chromium. This paper shows such an arbitrary division to be false because the mode of scaling depends on the oxidizing variables.

Ni-27.4% Cr at 800°-1000°C and Ni-40.2% Cr at 800°-1200°C start to oxidize in the same way as Ni-14.6% Cr but the Cr_2O_3 layer develops rapidly and there is little time for an extensive intermediate layer or for dense Cr_2O_3 subscale to grow. It can be stated categorically that the protective part of the scale is Cr_2O_3 (generally containing less than 1% nickel) and not $NiCr_2O_4$. Previous reports of spinel being the protective oxide are inexplicable but it should be noted that trace elements such as manganese in impure materials may promote its formation. It is not true to say (9), however, that the sole oxide is Cr_2O_3, at least when the alloy is immediately exposed to the hot atmosphere, although this is true for specimens brought to temperature in a so-called vacuum. There is always an outer NiO-rich layer a few microns thick, (containing a little chromium which in few extreme cases might exist as $NiCr_2O_4$ or Cr_2O_3). Incidentally, there is little evidence of the NiO-rich and Cr_2O_3-rich layers combining to give an extensive $NiCr_2O_4$ layer, although it is likely that a thin layer does exist.

The mode of scaling is similar to that described in theoretical papers (25). Probably NiO and Cr_2O_3 nucleate separately on the bare surface but the more rapidly growing NiO rapidly overgrows the Cr_2O_3 to form an outer layer. The Cr_2O_3 then spreads laterally until a complete layer is developed, whereupon this is the only oxide to continue growing. The time required to do this depends partly on the initial spatial distribution of nuclei in the scale, but also on the alloy chromium content, the atmosphere, and the temperature. It takes longer than with corresponding Fe-Cr alloys because metallic interdiffusion in the alloy is slower and oxygen solubility is apparently greater. It is sufficiently rapid for Ni-40.2% Cr and for Ni-27.4% Cr at 800° and 1000°C for any intermediate layer to be unnoticed with the microanalyzer, but for Ni-27.4% Cr at 1200°C and Ni-14.6% Cr it only occurs after both layers are well developed and internal oxidation has been extensive. Possibly some of the NiO-rich material in the initial inner layer is also reduced to metal by chromium, again promoting the Cr_2O_3 layer formation. The two-stage parabolic plot for Ni-40.2% Cr at 1200°C indicated a slower oxidation rate after 40-60 min, when the mean scale thickness was 6-8μ. This agrees well with the observation that the outer NiO-rich layer was always 4-9μ thick for oxidation times longer than 1 hr. Under preferential oxidation conditions no NiO is formed because Cr_2O_3 is thermodynamically favored and oxygen solubility in the alloy is drastically reduced while alloy interdiffusion is unaffected. If cation movement is postulated in both Cr_2O_3 and NiO, Cr_2O_3 could grow at their interface by the reaction

$$2Cr^{3+} + 6\epsilon + 3NiO = 3Ni^{2+} + 6\epsilon + Cr_2O_3$$

Consequently in these later stages only the thermodynamically stable Cr_2O_3 grows and the NiO, which owes its presence merely to a nucleation effect, continually reforms. An alternative mechanism, involving the inward diffusion of oxygen ions through the Cr_2O_3, obtained directly from NiO at the Cr_2O_3/NiO interface or after gaseous oxygen diffusion through a porous outer NiO layer, would have to be invoked if Cr_2O_3 is an n-type semiconductor, which is the minority view. Recently, mechanisms involving cation and anion movement have been published (1, 17). One of these (17), however, appears to rely heavily on the idea that stresses cannot be developed in oxides growing by cation movement (26) in its prediction of anion movement. Work on copper (27) seems to challenge this concept and indicates that the original theory (26) is oversimplified.

Volatilization losses from Cr_2O_3-rich scale in pure oxygen would be low due to the outer NiO-rich layer, which is an important practical point when considering commercial heat-resistant nickel-base alloys. There are also theories current (28) referring to chromium vapor effects, but there is no adequate mechanism for its movement through compact oxide. There are objections to its movement through grain boundaries, so it can only be concluded that the oxide is not compact where chromium vapor does make a contribution to scale growth.

Once the protective Cr_2O_3-rich scale is established it usually adheres well to the alloy at temperature and often on cooling, even on electropolished specimens. Any influence of the outer NiO layer in restraining the Cr_2O_3 is doubtful and obscure but the Cr_2O_3 subscale must play an important keying-on role. Occasionally the double layer of NiO above Cr_2O_3 did fail after a few hours on Ni-27.4% Cr at 1000°C, presumably by the mechanism of lifting and cracking reported for Fe-23% Cr (20), because there is no evidence of nickel in the alloy tending to transform the surface Cr_2O_3 to $NiCr_2O_4$, giving complex layered structures with alternate nickel-rich and chromium-rich oxides. No transformation of Cr_2O_3 to $NiCr_2O_4$ would be expected on thermodynamic grounds (9) because the alloy chromium content measured at the interface (shown by consideration of the interdiffusion equations to be close to the actual value) was still relatively high. Layered structures were also sometimes noted on electropolished specimens of Ni-27.4% Cr and Ni-40.2% Cr. They contrast with multilayered Cr_2O_3 found on pure chromium and on iron-chromium alloys (17, 18).

The extensive chromium depletion existing behind protective scales for long periods and to great depths, due to the slowness of metallic interdiffusion in the Ni-Cr system, would considerably assist stratified scale growth, so it is fortunate that scale failure at temperature does not occur more frequently. The chromium depletion, together with the likely higher solubility of oxygen in Ni-Cr alloys than in Fe-Cr alloys, explains the Cr_2O_3 internal oxide and subscale loops linking alloy to complete Cr_2O_3 inner layers. Cr_2O_3 at the alloy/oxide interface tends to dissociate, the resulting oxygen diffusing slowly into the alloy to permit the internal oxidation. As expected from the lower dissociation pressure of Cr_2O_3, this is a much slower process (occurring mainly at higher temperatures and after long times) than the formation of such oxide behind stratified scale where NiO is the dissociating oxide and can give a more plentiful oxygen supply. Also the alloy composition between widely spaced internal oxide particles, as well as behind a complete Cr_2O_3 layer, is far from being nearly pure nickel which may be the case between densely packed particles. There is some similarity between these thick scale protrusions into the alloy, before they link up to give loops, and the irregular interfaces suggested in theoretical papers (25). There must be some lateral diffusion of chromium to continue the subscale loop growth. It is again arguable that the subscale is evidence in favor of oxygen ion movement in the Cr_2O_3 scale, since it is supposed not to be formed behind scale growing by cation movement. The authors do not think this is strong evidence because heavy intergranular oxidation is also observed behind compact NiO on pure nickel at 1000°-1300°C

and feel that the whole subject of internal oxidation on pure metals requires further study.

In summary, most of the somewhat vague statements in the literature, regarding deviations from parabolic growth (1, 8) and the presence of NiO in late and early stages of oxidation (1, 2, 11-14, 16, 31-33), appear to fit in with the theories developed above but this is not true of protection by $NiCr_2O_4$ (1-6) which seems something of a myth. Protection is by Cr_2O_3, as has been previously suggested (7-14). Where NiO has not been observed outside, this may have been due to spalling, preferential oxidation effects, or to it forming a small percentage of the scale after long runs, particularly with Ni-60% Cr and Ni-80% Cr (9). Observations and detailed theories given elsewhere (2) appear at variance with the present work.

The results make interesting comparison with corresponding studies of Fe-Cr alloys (17, 18, 20). In general, initial protective Cr_2O_3-rich scale is less easily established but more readily retained on Ni-Cr alloys. The better adhesion is related to subscale keying on of Cr_2O_3 (absent for Fe-Cr alloys), which means that surface finish is also less important. Scale lifting and cracking are much less prevalent which is fortunate because chromium depletion in the underlying alloy is greater and longer-lived than for Fe-Cr alloys. Stratified scale development is thus potentially more likely but in practice less frequently found. These differences are largely due to the undoubted slower rate of intermetallic diffusion and the probable greater oxygen solubility in the Ni-Cr system. Stratified scale grows less rapidly because Ni-rich oxides are more protective than Fe-rich oxides, and are more readily healed by linking up of the denser population of Cr_2O_3 subscale particles to give a complete protective layer at the scale base. Few data are available on Co-Cr alloys (29) but they appear to behave more like Ni-Cr than Fe-Cr alloys.

Conclusions

1. The growth kinetics (approximately parabolic after an initial deviation) are relatively independent of the surface preparation but are critically affected by the method of heating the specimens to temperature.

2. Scales owe their protective properties to Cr_2O_3 generally containing less than 1% nickel.

3. Specimens preferentially oxidized by elevation to temperature "in vacuo" produce Cr_2O_3 alone but samples immediately located in the hot zone possess an outer nearly pure NiO layer. With high alloy chromium contents and low temperatures the inner layer is Cr_2O_3 but for the reverse conditions it is multiphase.

4. Cr_2O_3 subscale formation is moderate behind Cr_2O_3 and extensive behind stratified scale. Its coalescence to give a complete Cr_2O_3 layer at the scale base invariably halts stratification.

5. Chromium depletion in the alloy is extensive and long-lasting. If the protective scale fails, stratified nonprotective scale can appear on relatively chromium-rich alloys. In practice this is rare, because Cr_2O_3 subscale loops key the initial scale to the alloy.

Acknowledgments

Our thanks are due to Professor T. K. Ross for providing facilities and for his interest and to the Science Research Council for a maintenance allowance to one of us (T.H.). We are indebted to Mr. R. M. Cook of the International Nickel Company (Mond.) Ltd. for making the alloys.

Manuscript received Aug. 13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Passivation of Iron in the Presence of Pertechnetate and Chromate Ions[1]

G. H. Cartledge

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Experiments were carried out to determine whether reducible inorganic inhibitors passivate iron solely by their own cathodic reduction or have some additional role in the passivation process. Passivation was effected potentiostatically in pertechnetate and chromate solutions at potentials noble to the calculated reversible potential of the inhibitor couple under the conditions prevailing. It was found that the inhibitors reduce greatly both the critical current density and charge required for anodic passivation when they are not themselves reduced. It was shown also that neither of the inhibitors is capable of supplying more than a very small fraction of the current density required for passivation in the absence of the additional effect which arises, presumably, through adsorption of the inhibiting anions. The results show the inadequacy of the hypothesis that the oxidation-reduction properties of the inhibitor alone are sufficient to account for its passivating action.

The most widely used inorganic inhibitors of the corrosion of iron and steel have one or more of the following properties: (*a*) they are derived from weak acids and consequently their salts have buffering action at the corrosion interface; (*b*) their anions form sparingly soluble products with the escaping cations and thus provide a more or less protective film; (c) they have oxidizing properties which have been presumed to be sufficient to produce passivation by a pure oxidation-reduction reaction; or (*d*) they are adsorbed at the interface in such a way as to alter the mechanism or rate constants of one or more of the corrosion partial processes. Theories of their inhibiting action have been variously derived from these characteristics (1).

In the purely electrochemical mechanism [(c), above] (2), no specific action is ascribed to the inhibitor other than its ability to provide a mixed potential with the corroding metal in the region of passive potentials.[2] On the contrary, there are reasons for assuming that adsorbed inhibitor anions produce specific electrostatic or other kinetic effects over and above any results of their oxidizing action alone. An example of such specific effects may be seen in the destruction of passivation by added electrolytes which do not alter the oxidation-reduction properties of the inhibitor. Such effects have been demonstrated in this laboratory for iron in the use of several inhibitors (3, 4). A competitive adsorption has been assumed to be in operation, and this has been measured in the case of iodide ion (5). Hackerman and Powers have shown the competitive action of sulfate and chromate ions at a surface of chromium (6), and the ion exchange of unreduced chromate ions by hydroxide or sulfate ions on stainless steel has also been studied quantitatively (7). Posey and Sympson (8) found that their study of the effect of anions upon certain cathodic processes on stainless steel could be interpreted mathematically in terms of a dynamic adsorption equilibrium at the electrode.

It is, of course, true that if a metal is capable of being passivated by anodic polarization, and if a reducible inhibitor has a sufficiently noble electrode potential and a cathodic polarization curve that passes to the high-current side of the critical passivation current density of the metal, then no further participation of the inhibitor is required beyond its cathodic polarization. Even so, it remains to be considered whether, in the case of a metal capable of passivation, the inhibitor may not also act specifically and noncathodically on some step of the mechanism which leads to passivation. In view of the highly irreversible character of both the Cr(III-VI) and Tc(IV-VII) couples in acidic media, it is indeed most unlikely that the cathodic polarization of these inhibitors could possibly supply the large current densities necessary for passivation of iron in sulfate or perchlorate systems.

The present work was undertaken to provide a more detailed study of passivation and activation of iron in the presence of a reducible inhibitor, in the hope that effects specifically related to adsorption of unreduced inhibitor might be differentiated from simple anodic passivation by reduction of the inhibitor. The method followed was to determine what effects, if any, the inhibitor produces in the polarization of the metal in acidic media at potentials noble to the oxidation-reduction potential of the inhibitor so that its reduction is ruled out. The pertechnetate ion is admirably suited for such a study. Its reduction forms a film of $Tc(OH)_4$, with the normal potential of 0.738v (9)

$$Tc(OH)_{4(s)} \rightleftharpoons TcO_4^- + 4H^+ + 3e^-;\ V_h^\circ = 0.738v$$

It is therefore convenient to carry out potentiostatic polarizations under conditions which either produce $Tc(OH)_4$ or keep it oxidized to TcO_4^-. It is possible also to examine the effects of $Tc(OH)_4$ on the surface, as well as effects arising from addition of a foreign ion, such as the sulfate ion. By utilizing the beta activity of ^{99}Tc, it is possible also to determine the amount of technetium on an electrode.

The experiments demonstrated that the presence of either pertechnetate or chromate ions greatly reduces both the current density and charge required for passivation of iron at potentials noble to the respective couple potentials under the prevailing conditions. Beta counting confirmed the absence of reduction of the inhibitor during passivation in the pertechnetate solutions. Cathodic polarizations showed both pertechnetate and dichromate ions to be capable of supplying much lower current densities than are required for passivation of iron in uninhibited solutions.

Experimental

The electrode material was Armco iron; it was machined into a cylinder 1.25 cm long and 0.625 cm in diameter. The upper end was threaded to fit a stainless steel rod by which it could be drawn tightly against a Teflon sleeve. Before use, the electrode was electrolytically cleaned in a mixture of H_3PO_4(100),

[1] Research sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

[2] Stern (2) recognized the possibility that an inhibitor might reduce the critical current density required for passivation.

HNO_3(20), and excess CrO_3. It was then treated alternately with HNO_3 and HCl several times, the final treatment being activation in HCl immediately before use. Solutions were made from NH_4TcO_4 or $KTcO_4$ and were acidified to the desired *p*H value by addition of Dowex-50 resin in the hydrogen-ion form. The volume of solution used (125 ml in each side of an H-cell) was sufficiently large to prevent significant change in *p*H during polarization, as shown by repeated measurement during the experiments. To produce heavy deposits of $Tc(OH)_4$ on the electrode, when desired, it was polarized cathodically in a separate cell containing a slightly acidic solution of a pertechnetate.

Anodic polarization was effected by a FairPort Potentiostat-Galvanostat, Model 610. The potentiostat was preset to the desired potential, and the circuit was closed by inserting the electrode. A rapid stream of helium kept the oxygen concentration at a harmless level during the operation. The polarizing potentials in different experiments varied between +350 and +850 mv, referred to the saturated calomel electrode. The theoretical reversible potential of the Tc(IV-VII) couple in the most concentrated and most acidic solution used was +326 mv (SCE). Polarizations were continued until the current density for electrodes that were initially free of $Tc(OH)_4$ fell to an approximately steady value. This required from 20 to 40 min in the different experiments. The current densities on filmed electrodes were not quite limiting values, owing to continuous oxidation of $Tc(OH)_4$ from the film. From the recorder trace of the current flowing during the polarization stage, the charge accumulated during passivation was computed graphically. Upon completion of the polarization, the electrode and reference cell were quickly detached from the potentiostat circuit and connected to a vibrating reed electrometer with a Brown recorder for following the open-circuit potential.

To confirm the assumption that passivation was effected without reduction of pertechnetate ions, an electrode was carefully decontaminated from ^{99}Tc and polarized at +400 mv (SCE) in 10^{-2} *f* TcO_4^-, *p*H 2.80, under helium for 43 min, at which time the current density had fallen to 3.0×10^{-6} amp/cm^2. The electrode was quickly withdrawn from the cell, washed in five beakers of distilled water, and held under running distilled water for 30 sec. The specimen was again counted for beta activity. Since the cylindrical form of the electrode made its exact counting geometry indeterminate, it was placed on the fourth (lowest) shelf of the counter to minimize the uncertainty. As will be detailed in the section on Results, the experiment succeeded in confirming the absence of $Tc(OH)_4$.

In a few passivations, the early stages of current flow were examined by use of an oscilloscope (Tetronix, Model 536),[3] the very brief initial surge of current decaying too fast to be followed with the Brown recorder. Here again, the circuit was closed by insertion of the freshly activated electrode into the pertechnetate solution.

Possible effects of $Tc(OH)_4$ in the surface film were examined by comparing polarization curves of filmed and bare electrodes in sulfate media. Both potentiostatic and galvanostatic procedures were used. The effect of $Tc(OH)_4$ was apparent also in the activation experiments, some of which were conducted with a preformed film of $Tc(OH)_4$ in too great an amount to be oxidized completely during passivation at the elevated potential. In other experiments, the antagonistic action of sulfate and pertechnetate ions was shown by anodic polarization in simple and mixed electrolytes.

To evaluate practically the current density obtainable in reduction of the inhibitor, both pertechnetate and dichromate solutions were polarized with platinum electrodes containing the respective reduction products.

[3] The author is indebted to his colleague, Dr. Franz A. Posey, for assistance in these observations.

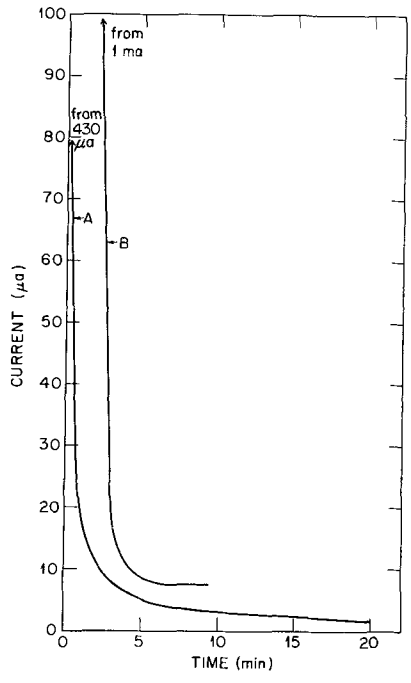

Fig. 1. Anodic charging curve in pertechnetate solutions: A, 10^{-2} *f*, *p*H 3.00; area 2.77 cm^2; without $Tc(OH)_4$ in film. B, 10^{-3} *f*, *p*H 3.92; area 2.61 cm^2; lightly filmed with $Tc(OH)_4$.

Results

Passive-active transitions.—In repeated tests, it was found that the full anodic output of the potentiostat (*ca.* 40 ma) was insufficient to lead to passivation of either the Armco or electrolytically deposited iron electrodes in sulfate solutions of 0.1-0.5 *f* concentration at *p*H values between 1 and 4.18 when the potentiostat was set at +400 mv (SCE). On the contrary, in pertechnetate solutions of comparable concentrations and acidities, after an initial surge, the anodic current rapidly fell to values characteristic for passivation. Figure 1 shows the observed charging current for two typical electrodes. In one, curve A, the surface was free of any film when introduced into the electrolyte at +400 mv (SCE); in the other, the sur-

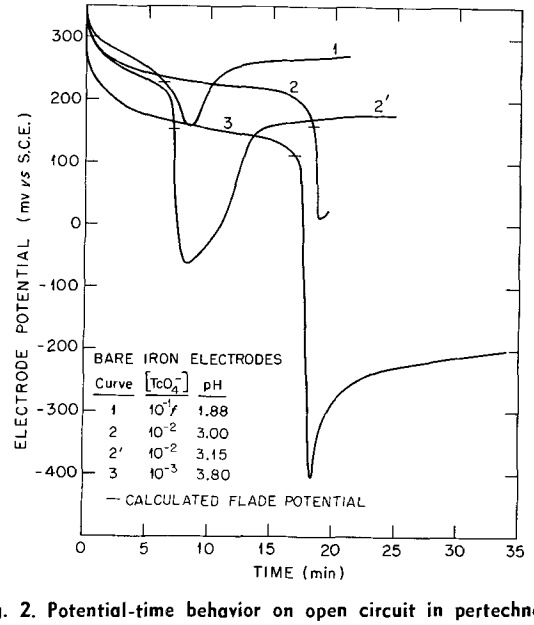

Fig. 2. Potential-time behavior on open circuit in pertechnetate solutions; electrodes free of $Tc(OH)_4$.

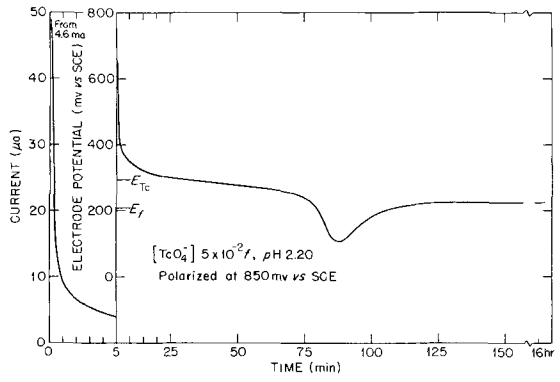

Fig. 4. Polarization of iron in 5.0×10^{-2} f $KTcO_4$, pH 2.20 for 5 min at 850 mv (SCE); area 2.25 cm^2.

face had a light brown film containing $Tc(OH)_4$, but was activated in HCl just before use. The polarization of the unfilmed electrode was discontinued when the current density became almost steady at 0.54 $\mu a/cm^2$; graphical integration of the recorder chart gave 2.1×10^{-3} coulomb/cm^2 as the charge passed up to this point. Similar results were repeatedly obtained with initially bare electrodes.

When the electrode was previously coated with $Tc(OH)_4$, somewhat higher current densities and charges were found because of oxidation of the $Tc(OH)_4$ which occurs slowly at +400 mv (SCE). The current density again fell rapidly, however, as the anodic process of passive film formation was completed. Use of the oscilloscope in certain of these experiments merely confirmed the observation of a surge of current which fell sharply within 0.5 sec to values picked up by the Brown recorder.

Figures 2 and 3 show the change of potential with time when the potentiostatic circuit was quickly replaced by a vibrating reed electrometer and recorder, with the electrode on open circuit. Table I gives the experimental conditions for the different curves in these figures, together with calculated values of the reversible potential of the Tc(IV-VII) couple and Flade potential for the same conditions (E_f = 0.338 −0.59 pH, SCE). The prior potentiostatic polarizations had been conducted at potentials that were well above the theoretical value for the Tc(IV-VII) couple.

In Fig. 1, curve B is for an electrode that was polarized until the visible film of $Tc(OH)_4$ had been so largely oxidized back to TcO_4^- that the potential fell to −270 mv (SCE) before beginning to re-ennoble. Its behavior in this respect resembled closely that shown by an unfilmed electrode, such as shown by curve 3 of Fig. 2 for the same concentration and pH value. The anodic charge was 30 mc/cm^2, whereas the smaller charge of 15 mc/cm^2 was found for the electrode represented by curve 3f in Fig. 3. In this case, the electrode retained a dark film of $Tc(OH)_4$. Both electrodes, however, were fully passive when put on open circuit.

Figure 4 gives both the current-time and potential-time curves for an electrode that was held for only 5 min at 850 mv (SCE) immediately after having fallen to a minimum open-circuit potential of 59 mv (SCE) following polarization at 400 mv (SCE). The polarization was stopped somewhat before the current density reached its limiting value, the charge passed amounting to 1.3 mc/cm^2 at this point. It is seen that the potential on open circuit fell rapidly by about 500 mv to the vicinity of the Tc(IV-VII) couple potential (E_{Tc} in Fig. 4) and then leveled off before debasing again as the Flade potential was approached. The 16-hr recording of the open-circuit potential shows that even though passivation was effected approximately at the reversible potential for evolution of oxygen [calc. 857 mv (SCE)], the surface state became stable in the electrolyte only after incipient activation and consequent deposition of some $Tc(OH)_4$ at the lower potential.

Table I. Passive-active transition experiments

Figure and Curve	$[TcO_4^-]$, M	pH	Final c. d. $\mu a/cm^2$	M-coulomb/ cm^2 passed	Calculated potentials mv (SCE) $E_{Tc(IV-VII)}$	E(Flade)
2-1	10^{-1}	1.88	1.8	14.0	326	227
2-2	10^{-2}	3.00	0.19	0.9	219	161
2-2′	10^{-2}	3.15	0.50	—	205	152
2-3	10^{-2}	3.80	0.22	2.1	136	114
3-1f	10^{-1}	1.88	1.6	8.8	326	227
3-2f	10^{-2}	3.00	5.3	—	219	161
3-3f	10^{-3}	3.80	5.5	15	136	114

The results shown in Fig. 2, 3, and 4 are typical of many experiments which differ somewhat in detail but agree in exhibiting the following uniform behavior. Consider, first, the results for electrodes having no film of $Tc(OH)_4$, Fig. 2, 4. (*A*) When the circuit was opened, the potential first fell rapidly; the rate of change soon decreased, however, and the inflection came at potentials that are clearly related to the reversible potential of the inhibitor couple in the different media. (*B*) The slow debasing was succeeded by a rapid fall in potential, and this change occurred close to the calculated Flade potential for the pH value involved. In these two respects the behavior resembles closely that observed in noninhibiting solutions. (*C*) The debasing of the potential was arrested before full activation occurred, however, and the minimum value of the potential and rate of re-ennobling were highly dependent on the concentration and acidity of the inhibiting solution. (Some of the observations were continued until the potential of the iron electrode approximated that of a platinum wire coated with $Tc(OH)_4$ in the same solution, although this required several hours).

Figure 3 refers to electrodes which were given a visible film of $Tc(OH)_4$ by a cathodic prepolarization. It is seen that the initial debasing on open circuit soon became very slow and that it halted without the electrodes becoming active. Again, the level of the approximately stable potentials parallels the shift in the Tc couple potential in the different media.

Although the properties of the Tc(IV-VII) couple make it convenient to carry out the potentiostatic passivations at potentials that are too noble for reduction of the inhibitor to occur, nevertheless the possibility remains that small active sites on the electrode might react with the inhibitor and cause deposition of radioactive $Tc(OH)_4$ locally. To test this possibility, an experiment was done at +400 mv (SCE) with an electrode that was first decontaminated of ^{99}Tc, counted, passivated, rinsed, and counted again. Current passed for 42 min, at which time the current density had fallen to 3.0 $\mu a/cm^2$ and the total charge passed was 27 mc/cm^2. The specimen gave 22 cpm (counts/minute) before passivation and 29 cpm afterward. At the 95% confidence level the two counts are the same. It may be calculated that if the charge of

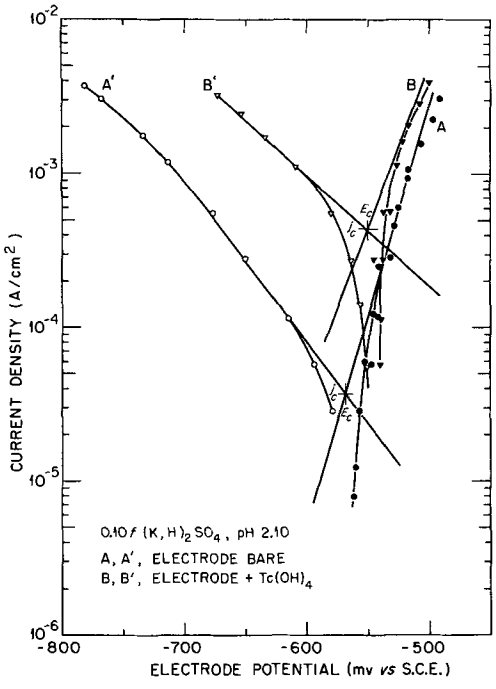

Fig. 5. Polarization of iron in 0.10 *f* $(K,H)_2SO_4$, *p*H 2.1, with and without a film of $Tc(OH)_4$. A, A' unfilmed, B, B' filmed.

27 mc/cm² had been augmented to the extent of even 1% by deposition of $Tc(OH)_4$, the specimen should have acquired 4500 cpm. (This result is based on a determination that the cylindrical surface of the electrode reduced the counting efficiency by a factor of 2).[4]

Influence of $Tc(OH)_4$ *on polarizations in absence of pertechnetate ions.*—Since the activation experiments disclosed a considerable effect of $Tc(OH)_4$ on the re-ennobling process, further polarizations were done in a sulfate medium to determine whether the film affects the anodic corrosion process at active potentials as well as the cathodic process. An acceleration of cathodic processes by deposited $Tc(OH)_4$ on passive iron was reported previously (12). It was difficult to obtain a high degree of reproducibility on filmed specimens, but a characteristic set of polarization curves is shown in Fig. 5, which was derived from both potentiostatic and galvanostatic measurements in 0.10 *f* $(K,H)_2SO_4$ at *p*H 2.10 under helium. The acceleration of the cathodic process is clearly seen in curves A' and B'. There is probably no appreciable effect on the anodic side, the observed displacement being no greater than the scatter of different polarizations of bare electrodes. For these reasons, the film makes the open-circuit potential in the sulfate solution somewhat less active than that of a bare electrode, but the corrosion rate on open circuit is considerably increased.

Polarization in a sulfate medium with and without pertechnetate.—The antagonistic effects of sulfate and pertechnetate ions were demonstrated by subjecting an electrolytically deposited iron electrode of 0.110 cm² surface to anodic polarization with the potentiostat set at +400 mv (SCE), first in 0.10 *f* $(K,H)_2SO_4$ at *p*H 1.85 and then in a mixed solution which was 3.9×10^{-2} *f* in sulfate and 6.1×10^{-3} *f* in pertechnetate at *p*H 2.15, in both cases under helium. In the pure sulfate solution, the electrode drew the limit of the anodic output in the potentiostat (*ca.* 360 ma/cm²) without passivation, that is, the instrument was incapable of bringing the potential to +400 mv. In the mixed solution, an initial current of 160 ma/cm² flowed. This fell to 20 ma/cm² in 5 min and to a nearly steady 5 ma/cm² in an additional 10 min. On opening the circuit, the potential fell rapidly to −550 mv (SCE) and became steady at −581 mv. This is about 10 mv noble to the potential to be expected in a simple sulfate solution (0.5 *f*), according to the results of Kelly (13). Hence, although a current density of 360 ma/cm² failed to induce passivation in the sulfate solution, a maximum initial current density of 160 ma/cm² sufficed in the presence of the pertechnetate ions, although the mixed solution was incapable of maintaining passivity.

Polarization of the Tc(IV-VII) *couple.*—Most discussions of the electrochemical action of reducible inhibitors have been based on schematic polarization diagrams, rather than on numbers obtained experimentally. The technetium and chromium couples are very sluggish, and few reversible values have been determined for them. Nevertheless, polarization data which are empirically useful for present purposes were obtained by polarizing a platinum electrode which had been cathodically coated heavily (black) with $Tc(OH)_4$.[5,6] The electrolyte was 0.10 f NH_4TcO_4 at *p*H 2.15 under helium. The potential of a freshly coated electrode is considerably negative to the reversible value, which it approaches very slowly. After some anodic pre-polarization, however, the equilibration is more rapid. The polarization of the electrode from its reversible potential soon runs into complications that lead to limiting currents of small magnitude. Thus, on the cathodic side, a 17-hr galvanostatic polarization at 54 μa/cm² led to a potential of −122 mv (SCE), or 430 mv negative to the reversible value. On the anodic side, a limiting value below 30 μa/cm² was reached. These results make it evident that, even at a concentration much higher than that necessary for effective inhibition, the available cathodic current density is very small in comparison with current densities required for passivation of iron in the absence of an inhibitor. For the conditions of this measurement, the exchange current density was of the order of 10^{-6} amp/cm².

Passivation and polarization in chromate solutions.—The action of the dichromate ion was examined briefly in passivation experiments similar to those done with the pertechnetate ion. The electrolytes were $K_2Cr_2O_7$, 0.20 *f*, *p*H 3.68 and 0.020 *f*, *p*H 4.10. The Cr(III-VI) couple gives such irreproducible values in acidic media that a potential calculated from free energies is not very meaningful. The values computed for the process

$$2Cr(OH)_3(\text{hydrous}) + H_2O \rightleftharpoons Cr_2O_7^{=} + 8H^+ + 6e^-$$

for the two solutions indicated above are +570 mv and +530 mv (SCE), respectively. When the iron electrode was passivated with the potentiostat at +400 or +600 mv (SCE), it was found that the charging curve resembled Fig. 1, but the charge passed for a steady current density was 60-100 mc/cm², or very considerably more than that required in the pertechnetate solutions.

After passivation at +600 mv in the 0.20 *f* solution, the iron electrode fell quickly to the same potential as that of a bare platinum wire, but there was a slow debasing to a somewhat lower value, without intervening activation. Without prior anodic passivation, an active iron electrode was inserted into the 0.20 *f* dichromate solution in helium. Its potential rose only to −100 mv SCE in 15 hr and was almost stationary at

[4] These experiments give direct support to the prior claim that no unreduced pertechnetate ions can be found on rinsed specimens (10, 11).

[5] The identity of such cathodic deposits with $Tc(OH)_4$ precipitated by chemical reduction of pertechnetates was established by transmission electron diffraction. The author is indebted to T. E. Willmarth of the Analytical Chemistry Division for this service.

[6] One would naturally wish to know the cathodic current density for reduction of the pertechnetate ion on an active iron surface. Such a measurement is impossible, however, since the metal immediately acquires a film of the reduction products at the active potential. Hence the measurement on a filmed surface is entirely realistic for a discussion of the extent of the cathodic action of the inhibitor. A platinum support for the film was preferred in order to eliminate direct action between the support and reducible anions.

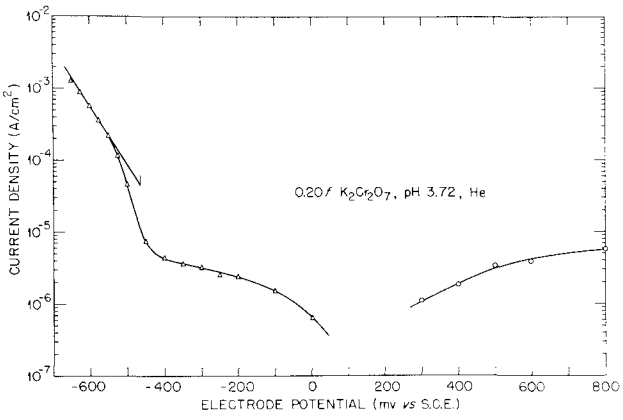

Fig. 6. Polarization of the Cr(III-VI) couple on a platinum electrode: 0.20 $K_2Cr_2O_7$, pH 3.72. Calculated potential for discharge of hydrogen —463 mv (SCE).

that point, the Flade potential for this pH value being +120 mv (SCE). The slowness and incompleteness of the debasing after anodic polarization are perhaps related to the fact (7) that the passive film binds some unreduced Cr(VI) species in an exchangeable form, whereas the Tc(VII) species is not so held. These observations agree with the previous study of the action of the chromate ion in the absence of oxygen (3, 10).

Since it is evident that reduction of chromate species in absence of oxygen does not produce complete passivation but does retard the corrosion process greatly, it seemed desirable to determine experimentally the magnitude of the current available for anodic polarization of the iron. Potentiostatic polarizations were therefore carried out, using the platinum electrode which had served as cathode in the previous passivation polarizations. The electrolyte was 0.20 *f* $K_2Cr_2O_7$ at pH 3.72, and helium was passed through the solution. Results are shown in Fig. 6, which is of no quantitative theoretical significance, except insofar as it accounts for the inefficiency of the Cr(III-VI) couple as a source of cathodic current. The large values of $dE/d \log j$ are also typical of similar values frequently observed on electrodes with poorly conducting films of reaction products. It is seen that the hydrogen-discharge reaction is superimposed on the reduction of Cr(VI) at potentials below —450 mv (SCE). A normal Tafel slope of —120 mv/decade is observed, with an exchange current density at the calculated reversible potential in close agreement with the values shown by Vetter (15). The presence of the dichromate ions is therefore without significant influence on the discharge of hydrogen.

Discussion

That a normal state of passivation resulted from the potentiostatic polarizations is shown by the clearly recognizable relation between the calculated Flade potential and the potential at which rapid activation set in with electrodes having no $Tc(OH)_4$ in the film. Both the noble potential at which the potentiostat was set and the absence of beta activity on the electrode passivated in the pertechnetate solution confirm the conclusion that reduction of the inhibitor was not involved in the passivation process in these experiments.

The passivation experiments of both Franck (16) and Olivier (17) showed that the time required for passivation of iron by galvanostatic polarization is related to the applied current density by the expression $(j - j_0)t_p = \text{const.}$, in which j_0 is a current density below which no passivation is attained. The constant then represents the charge presumably consumed in the passivation process alone. For iron in 1 to 2*N* H_2SO_4 the experimental arrangements of Franck and Olivier agreed in giving a value of around 1.7 coulombs/cm² for the constant. More recently, Froment, Keddam, and Morel (18) have conducted the passivation in 1*N* H_2SO_4 by raising the potential potentiostatically at different rates and recording the current. The lowest effective current density was about 154 ma/cm² for their conditions, this value being obtained when the potential was raised 16 mv/min. In a phthalate-sulfate buffer at pH 3, Weil and Bonhoeffer (19) found the requisite charge to be 1 c/cm², and this quantity fell only to 130 mc/cm² at pH values of 4-6. Even for an Fe-18% Cr, alloy, Olivier found the constant to be 8 mc/cm² and j_o = 11 ma/cm². Values of similar magnitude for stainless steels were found by Edeleanu (20).

The effective charges and current densities vary somewhat with the experimental conditions, hence it was necessary, in the present work, to ascertain definitely that no passivation resulted when a sulfate medium was used under the same conditions as were found to induce passivation in the inhibiting solutions. The negative result found in sulfate media at pH's as high as 4.18 could have been anticipated, in view of the limiting anodic output of the potentiostat employed. The measurements show, therefore, that the low values obtained for both the total charges and current densities in the presence of the inhibitors must be ascribed to an effect of their anions that does not depend upon their reduction. In all experiments, the potential-time behavior on open circuit showed that passivity had been attained, even when the total charge was as low as 1-2 mc/cm² on unfilmed specimens. The evidence indicates, therefore, that a film of no more than 10-15Å in thickness (calculated for the magnetite crystal structure) suffices to exhibit the low corrosion rate and Flade potential characterizing the passive state, although the film is not stable even in the pertechnetate solutions here used until some $Tc(OH)_4$ had been deposited at the lower potentials during incipient activation.

It is therefore necessary to conclude, for both pertechnetate and chromate systems, that the presence of the unreduced inhibitor tremendously favors the processes leading to passivation. From the references cited in the early part of the text, it is well established that anions are adsorbed, and it is only reasonable to assume that this adsorption is the origin of the great retardation of the anodic dissolution process in the presence of the inhibitors.

The experiments in which a visible film of $Tc(OH)_4$ was present demonstrated again some acceleration of cathodic processes in a sulfate environment, with little, if any, displacement of the anodic polarization curve. To the extent that reduction of the inhibitor is accelerated by $Tc(OH)_4$, however, by so much is maintenance or restoration of passivity favored in the open-circuit experiments in the presence of the pertechnetate.

It is possible that the $Tc(OH)_4$ which deposits in the interface normally may favor maintenance of passivity in two ways. The observed acceleration of cathodic processes would be one factor. Another may well be the sealing of pores or weak places in the normal film by the presumably low solubility of $Tc(OH)_4$, since, in general, the solubility of hydroxides decreases as the cation increases in valence, up to a point. This second possibility is rendered plausible by the earlier observation (14) that, if a little H_2O_2 is added to the inhibiting pertechnetate solution, stable passivation may be achieved at pH *ca.* 6 with deposition of no more $Tc(OH)_4$ than would suffice to cover a few tenths of a per cent of the surface. A thirteen-year observation shows that after stabilization is once established, no continuing consumption of the inhibitor is detectable (closed bottle occasionally opened for weighing and counting the specimen). In further support of this solubility effect, it was found also (14) that $Tc(OH)_4$ deposited on carbon steel cathodes is quickly oxidized to TcO_4^- by H_2O_2 with >90% decontamination, whereas if the hydroxide is formed together with the

anodic corrosion product, the decontamination efficiency in similar treatment is generally between 30 and 40%.

In the experiments with dichromate as inhibitor, the charge passed during passivation was up to 60-100 mc/cm^2 in different experiments. The thicker film so formed and its ability to bind exchangeable Cr(VI) ions are most probably the reason why complete activation did not occur on open circuit. In the absence of oxygen or external anodic polarization, however, even 0.20 *f* $K_2Cr_2O_7$ at *p*H 2.7 only slowly ennobled the iron potential, and an exposure of 16 hr left the electrode very considerably below the Flade potential. Unlike the pertechnetate ion and osmium (VIII) oxide (21), therefore, the chromates cannot be considered to be vigorous as passivating inhibitors under de-aerated conditions, though their own slow reducibility distinguishes them sharply from molybdates and tungstates, which are quite ineffective without a supplementary oxidizing agent.

Kolotyrkin and Bune (22) and Makrides and Stern (23) have presented data on electrode potentials and corrosion rates in solutions containing strong oxidizing agents which they used as evidence for the conclusion that passivating inhibitor anions function only by their cathodic action. It is to be noted, however, that both sets of experiments were done under conditions which make passivation easier than it is with iron, and at the same time both enhance the oxidizing power of the additive and destroy its possible inhibitory action. The experiments of Kolotyrkin and Bune were done with nickel, while Makrides and Stern used stainless steel; both metals are passivated at relatively low current densities. Both sets of experiments were done in 1*N* H_2SO_4, which differs in two essential respects from electrolytes in which the anions may actually produce inhibition, namely, the high acidity accentuates oxidizing power both thermodynamically and kinetically, and the high concentration of sulfate ions and low pH value completely suppress the inhibition observed under suitable conditions. Neither set of experiments can be used, therefore, as valid arguments against specific, noncathodic action by inhibiting anions when proper conditions for inhibition are used (24).

It was proposed earlier that the basic kinetic effect of adsorbed ions of the type of the Cr(VI) and Tc(VII) species comes from the space charge or potential gradient induced close to the site of adsorption (14, 25, 26). Such effects were shown to be of opposite sign for adsorbed sulfate and chromate ions, and the hypothesis led to the natural prediction that the pertechnetate ion should be inhibiting. This was at once found to be the case. Whether this particular mechanism is correct or not, the present experiments make it entirely clear that the action of the passivating inhibitors involves at least two very distinct functions. The noncathodic effects of such inhibitors will be discussed in another place.

Acknowledgment

The author is indebted to his colleague, Dr. E. J. Kelly, for helpful discussions.

Manuscript received Oct. 4, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1966 JOURNAL.

The Anodic Behavior of Iron-Carbon Alloys in Moving Acid Media

T. K. Ross, G. C. Wood, and I. Mahmud

Corrosion Science Division, Department of Chemical Engineering, Faculty of Technology, University of Manchester, Manchester, England

ABSTRACT

The anodic behavior of pure iron, mild steel (0.055% C) and iron-1.3% C was studied in flowing oxygenated and deaerated solutions of sulfuric and hydrochloric acids, the results being presented mainly as apparent anodic polarization curves at low current densities and as plots of potential against Reynolds number for a fixed current density at high current densities. The data were obtained largely by conventional galvanostatic methods for plate electrodes situated in a cell of square cross section, designed to allow the complete development of the hydrodynamic and mass transfer boundary layers. In solutions containing oxygen, the rest potentials and apparent polarization curves were shifted in the positive direction on increasing the flow rate, the effect being greater the lower the carbon content of the alloy. In deaerated acid the curves were insensitive to flow changes up to a critical current density, which was lower for more dilute acids and higher carbon contents, since the reactions involved are entirely activation controlled. Influences of carbon content, heat-treatment, and acid and cation concentrations on the position and length of the Tafel region of the anodic polarization curve are considered. At high current densities (*e.g.*, 100 ma/cm^2) the behavior of all three alloys departed from Tafel behavior, and potentiostatic and galvanostatic results were observed to be sensitive to the liquid flow rate in both hydrochloric acid and sulfuric acid solutions. From galvanostatic results obtained at a current density of 440 ma/cm^2 it was deduced that a film was formed at the anode surface. The presence of this film was shown to present an additional impediment to convective mass transfer of anolyte, thus occasioning a redistribution of the potential difference between metal surface and bulk electrolyte. While changes in liquid flow rate could be expected to control the rate of mass transfer in the liquid boundary layer, their effect on the thickness and nature of the porous surface layer was complex.

Over forty years ago Friend and Dennett (1) reported that the corrosion rate of rotating iron disks in aerated 0.01-0.2*N* H_2SO_4 increased linearly with rotational speed up to 4000 rpm. However, Whitman *et al.* (2, 3) found for aerated and oxygenated acid (0.33-5*N*), and to a lesser extent for nitrogen-saturated solution, that the corrosion rate of 0.12% C steel cylinders first decreased, passed through a minimum, and finally increased linearly with rotation rate. The speed corresponding to the minimum increased with acid concentration while the corrosion rate was independent of acid concentration at high flow rates, a result confirmed recently by other workers (4).

It is now generally accepted that the final rise in corrosion rate with flow velocity is due to an increase in the cathodic reduction current of oxygen. It was demonstrated further (5) that hydrogen surface films (or carbon or cementite films in the case of high-carbon alloys) interfere with this reaction. However, in all cases, electrolyte flow reduces the thickness of the boundary layer, thus allowing faster transport of oxygen to the metal surface.

The initial fall and minimum in corrosion rate has caused some controversy. It was originally suggested that (2, 3) the energy required to produce small hydrogen bubbles during rotation was greater than for the large bubbles produced in stagnant solutions, and presumably the bubbles interfered differently with oxygen arrival. Russian workers (4) refuted the latter idea, claiming that the phenomenon occurred in deaerated solutions but, as pointed out by Makrides (6), such solutions may contain traces of residual oxygen. This point was pursued by Foroulis and Uhlig (5) who provided strong evidence, using a variety of rotating iron-carbon alloy cylinders in 0.33*N* H_2SO_4, that very low concentrations of O_2 (and Fe^{3+} ions produced incidentally) act as anodic inhibitors rather than as depolarizers in this region, thus accounting for the initial fall and minimum. This effect of oxygen was evident in static solutions for low-carbon steels, but the minimum corrosion rate occurred at higher velocities for higher carbon steels, due to the need to remove hydrogen or cementite screens.

Other workers (6-8) applied quantitative treatments to the rate of arrival of depolarizers other than oxygen at a corroding iron surface. It was shown incidentally that the potential and dissolution rate of rotating specimens increased with velocity in air-saturated 2*N* HCl, but there was no effect in deaerated acid (7). This was confirmed subsequently in hydrogen-saturated 0.52*N* H_2SO_4 (6) and in nitrogen-saturated 0.33*N* H_2SO_4 (5). These results indicate that the anodic dissolution of iron and the cathodic evolution of hydrogen are not mass-transfer-controlled at these current densities. Surface roughening may affect corrosion rates at high velocities, and this phenomenon must clearly be considered in flow studies because of possible influences on boundary layers (8).

Corrosion of iron and steel tubes by flowing acid has been less extensively and less quantitatively studied. It was reported (4) that in concentrated H_2SO_4 $Y = 0.0026\ Re^{0.8}$, where Y is the corrosion rate at Reynolds number (Re) and in more dilute acid $Y = a + bV^{0.8}$, where V is the velocity and a and b are constants. The latter result agrees with corresponding work for rotated specimens (9), but it was also shown (4) that the corrosion rate was independent of flow rate above a certain velocity (presumably in aerated solutions). Ross and Jones (10) emphasized the importance of mass transfer considerations and showed that the dissolution rate of mild steel in *N* H_2SO_4 varied as $\sqrt{Re}$ and directly as Re for laminar flow (Re <2000) and turbulent flow, respectively.

There has been surprisingly little study of the influence of flow at high current densities where concentration polarization and consequent filming occur in what may be termed the prepassive region. It was suggested (11) that for concentrated acid velocity is not important below that critical value required to erode the protective $FeSO_4$ film. Hines and Williamson (12, 13) also commented briefly on the flow sensitivity of mild steel in very concentrated H_2SO_4. Apparently a thin compact ferrous sulfate layer beneath the porous visible layer controls the current density at constant potential, but diffusion from a layer of saturated solution outside the film may also be important. Hoar and Rothwell (14) studied the electropolishing of copper in orthophosphoric acid in a flow system of square section under potentiostatic control, but their results refer only to $Re < 1000$.

All of the previous work is open to criticism. Dissolution in pipes has often been studied in the presence of oxygen and under not clearly specified flow conditions. For the experimentally simpler system of a rotating cylinder or a revolving disk in deaerated acid, it is not always possible to establish the precise hydrodynamic and mass transfer conditions necessary for quantitative treatment. For example, segregation of the corrosion products according to mass by the centrifugal forces may play an important part in the relative extent of depolarization of anodic and cathodic processes. The edges of revolving disks also dissolve faster than the inner regions due to the thinner diffusion layer at the edges.

In the flow cell used in the present study, the hydrodynamic and mass transfer boundary layers were fully developed on the corroding anodic surface. Dissolution of pure iron, mild steel and iron-1.3% carbon were studied galvanostatically over a wide range of current densities in aerated, oxygenated and deaerated sulfuric and hydrochloric acids. This study is the first quantitative consideration of mass transfer at a rapidly dissolving anode surface where concentration polarization and consequent filming prevail.

This part of the paper deals with mass transfer at a dissolving unfilmed anode at relatively low current densities. In the second part the influence of flow on dissolution through an anodic film is discussed with special reference being made to mass transfer considerations.

Mass Transfer Relationships for an Unfilmed Anode Dissolving under Transport Control

It may be assumed that changes in velocity and concentration of an electrolyte flowing past a dissolving plate occur within thin boundary layers. Although velocity boundary relationships can be derived in terms of fluid properties, the definition of the concentration boundary terms is only possible when a further simplifying assumption is made. This requires either that the interfacial concentration of the transferred substance is constant over the entire anode surface or, alternatively, that the diffusive flux (current density) is constant. It is not possible to state in advance which of these conditions applies during anodic dissolution, although experimental observations reported later suggest that an equipotential surface is attained.

When the flow over the anode plate is laminar, Eckert's (15) cubic velocity profile leads to the following expression

$$\frac{V}{V_b} = \frac{3}{2}\frac{y}{\delta_l} - \frac{1}{2}\frac{y^3}{\delta_l} \qquad [1]$$

from which the hydrodynamic boundary layer has the dimension

$$\delta_l = 4.64\ (Re_x)^{-0.5}$$

and the relevant integrated boundary layer mass transfer equation is of the form

$$\frac{d}{dx}\int_o^{\delta_d} (C_i - C)\,V \cdot dy = -D \left|\frac{dC}{dy}\right|_{y=\delta_l} \qquad [2]$$

Wranglen and Nilsson (16) applied Eckert's procedure to the case of a flat cathode and, if their derivation is followed for a dissolving anode, similar expressions result. However, because the concentration gradient is reversed during dissolution, the numerical constants are slightly different and the concentration boundary layer at an anode is generally thinner than at a cathode. It is also noteworthy that the diffusion boundary layer thickness δ_d depends not only on the Reynolds (Re) and Schmidt (Sc) groups, but also on the electrode length (x).

Expressions for the thickness of the concentration boundary layer under either assumption, and in both flow regimes, are given below

Equipotential surface

Laminar flow

$$\delta_d = B_l x\, Sc^{-0.33}\, Re_x^{-0.5}\left[1 - \left(\frac{x_o}{x}\right)^{0.75}\right]^{0.33} \qquad [3]$$

Turbulent flow

$$\delta_d = B_t x\, Sc^{-0.33}\, Re_x^{-0.6}\left[1 - \left(\frac{x_o}{x}\right)^{0.90}\right]^{0.33} \qquad [4]$$

Values of the constants B_l,B_t

cathodic deposition	*anodic dissolution*
$B_l = 4.53$	$B_l = 2.86$
$B_t = 6.97$	$B_t = 5.40$

Constant current density

Laminar flow

$$\delta_d = B_l x\, Sc^{-0.33}\, Re_x^{-0.50}\left[1 - \frac{x_o}{x}\right]^{0.33}$$

Turbulent flow

$$\delta_d = B_t x\, Sc^{-0.33}\, Re_x^{-0.60}\left[1 - \frac{x_o}{x}\right]^{0.33}$$

cathodic deposition	*anodic dissolution*
$B_l = 3.59$	$B_l = 2.26$
$B_t = 5.88$	$B_t = 4.87$

Equations [3] and [4] with the appropriate values of B_l and B_t show that the thickness of the mass transfer boundary layer is much less at the leading edge of a dissolving specimen; although at high flow rates a nearly constant value is rapidly attained, there is always a tendency for excessive dissolution at edges, as was indeed found in practice.

Experimental Procedure

Three materials, designated here as "pure iron," "mild steel," and "iron-1.3% C," were employed. The analysis of the pure iron was C 0.0059, Si 0.0070, Mn 0.0020, S 0.0080, P 0.0010, Ni 0.0044, Cr 0.0014, Co 0.0032, Cu 0.0028, Al 0.002, O 0.014%, and of the mild steel C 0.055, Si trace, Mn 0.360, S 0.020, P 0.016, Ni 0.020, Sn 0.007, Al trace, Cd 0.030%. The iron-1.3% C alloy was made by adding graphite to the vacuum-melted pure iron.

The pure iron and iron-1.3% C were in strip form, used mainly in a cold-worked condition, obtained by cold rolling from 0.254 to 0.163 and from 0.279 to 0.198 cm, respectively, after annealing for two hours at 650°C. For a few runs in the annealed condition, final vacuum annealing was carried out at 650°C for two hours. The commercial mild steel had been cold rolled from 0.274 to 0.170 cm and was annealed at 650°C.

Metallographic examination of the pure iron showed a single phase ferritic structure of massive grain size. The grains of the mild steel were smaller and contained a trace of pearlite. The iron-1.3% C contained large spheroidized cementite particles in a ferritic matrix.

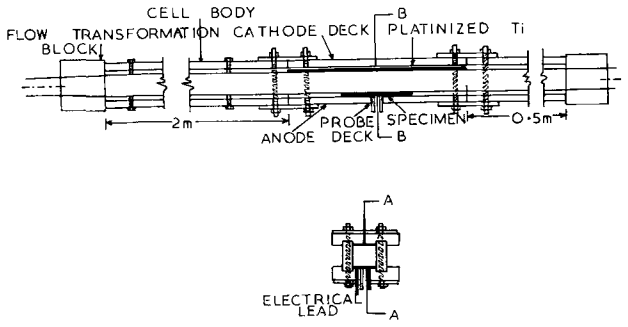

Fig. 1. Flow cell in section

Unless otherwise stated the solutions were always made from Analar grade reagents and distilled water. Solution concentrations were normally 0.5% or 5.0% w/w with respect to H_2SO_4 or HCl.

A flow cell of square cross section was used because mass transfer relationships have recently been published for a flat plate cathode in such a cell (16).

The flow cell, shown schematically in Fig. 1, was made of 0.95 cm thick Perspex and had an internal cross section of 1.90 x 1.90 cm. The sides were joined by bolts, and it was made leak-proof by applying a thin layer of polystyrene in the grooves. The cell sides were continuous except for the short lengths left vacant for insertion of the cathode and anode decks. The total length of the flow cell was 3m of which 2m (about 96 equivalent pipe diameters) preceded the length containing the specimen, so permitting the full development of the hydrodynamic boundary layer. About 25 equivalent diameters of cell length were provided at the end of the test section to avoid sudden changes in the direction of flow. Gradual conversion of flow, from a circular duct to a square one of somewhat larger cross section, was successfully provided at the two ends of the cell by means of Perspex blocks in which the shape of the cross section was changed gradually.

The cathode and anode decks were bolted into the main body of the cell and any minor joints made leak-proof. The specimen width was the same as that of the internal surfaces of the flow cell, and its length was generally greater than twice the distance required to develop the full mass transfer boundary layer but not as long as the cathode. Metal specimens were glued into shallow depressions in specimen decks, care being taken on mounting to ensure that they were flush with the deck and subsequently that the decks were flush with the sides of the flow cell. Platinized titanium cathodes, generally 15.24 x 1.90 cm, were attached to Perspex decks.

A plastic centrifugal pump was used to circulate the electrolyte at a controlled rate (measured by rotameters) through 1.59 cm bore glass tubing to the flow cell, the total volume of the system including the tanks being 30-40 liters. The solution was saturated with pure oxygen or pure nitrogen and was kept under a positive head of pressure. The temperature, measured well upstream from the flow cell, varied from 23° to 26°C.

Potentials were measured with a saturated calomel electrode through a backside Piontelli probe, thus avoiding IR_o drops and providing a minimum disturbance of the hydrodynamic boundary layer. The fine capillary Teflon probe fitted tightly into a hole in the center of the specimen and was held in position by screwing the thicker end into the Perspex back of the deck. The capillary was trimmed exactly flush to the surface of the specimen before use. All potential values are quoted on the standard hydrogen scale; they were obtained by adding 240 mv to the calomel values, liquid junction potentials being neglected.

Galvanostatic polarization curves were obtained as described later using conventional circuitry. Corresponding potentiostatic curves were sometimes obtained using a Wenking Potentiostat (standard 61/TR).

Due to the well-known hysteresis effects in the systems investigated, it was necessary to adopt standard procedure for all experimental runs. The mounted specimen was etched in 1:3 HNO_3 for 15 sec (or longer when it was felt that decarburized layers might exist on the specimen), washed, dried and inserted in the cell. Pure nitrogen was passed through the circulating electrolyte by-passing the flow cell for 2 hr before the cell was connected, deaeration then being continued for about 30 min until the specimen potential became constant. Current was next passed through the cell for 15 min with maximum circulation speed of the electrolyte until a new steady value was achieved. Readings of potential were then made at successively lower flow rates to the minimum, then rising again to the maximum, the velocity being changed every 2 min. Mean values are plotted on the various curves. With oxygenated and naturally aerated solutions a steady potential was obtained within 5 min of imposing the external current; readings were taken after a further 5 min during these runs. For low current density runs a single specimen could be used for several current densities, but at high current densities it was employed only once because of the change in geometry resulting from rapid dissolution.

Anodic Dissolution at Low Current Densities

Preliminary Considerations

Hysteresis and reproducibility.—It was early established that a polarization curve obtained by gradually raising the current density stepwise lay no more than 20 mv above the corresponding curve obtained subsequently by reducing the current (at Re 17,000). Similarly, on applying any current the potential of the anode rose sharply to a more positive value and then gradually dropped to a final value. The reverse phenomenon occurred when the current was switched off. Such general behavior can be related to potential-dependent specific surface activities of the specimen which cannot be discussed in detail here.

When specimens were used at several current densities, values were obtained with both progressively increasing and decreasing current density, mean figures being plotted on the characteristic curves. Experimental runs were all duplicated and were often triplicated. The reproducibility of potential readings was $\pm$ 2 mv below 10 ma/cm^2 and $\pm$ 5 mv at higher current densities. At very high current densities ($>$ 400 ma/cm^2) and low Re ($<$ 1000) it deteriorated to $\pm$ 20 mv, but such results are rarely quoted.

Potentiostatic and galvanostatic curves.—At relatively low current densities virtually identical results were obtained; however, at very high current densities and low flow rates a film of hydrogen accumulated on the cathode and affected the functioning of the potentiostat. Consequently galvanostatic control was adopted for most runs.

HCl or H_2SO_4.—Work at very high current densities was conducted mainly in hydrochloric acid because of the greater solubility of the iron salts and the smaller tendency to passivate in HCl. Polarization curves in H_2SO_4 and HCl at concentrations of 0.5% and 5% w/w showed relatively little difference.

Cell and specimen geometry.—The anode dissolved uniformly in static environments and in flowing solutions provided the current density was low. At high current densities, the leading and trailing edges dissolved faster than the rest of the surface. This suggests that the diffusion boundary layer was not fully established at the edges.

The higher dissolution rate of the edges was unaffected by the position of the cathode; placing the cathode well downstream failed to prevent preferential attack of the leading edge. The higher rate was not caused by the narrow crevices between deck and anode since masking of these crevices led to the de-

velopment of "lips" immediately adjacent to the covered areas.

Results were independent of anode size, provided it was smaller than the cathode. For the reverse case, there was excessive dissolution over an area roughly equal to the cathode area.

The anode was equipotential over its main surface: two probes placed 2.54 cm from each end showed the same potential. Also, a small (1.9 x 0.5 cm) anode, insulated from the main deck but kept at the same current density, showed the same potential as the rest of the deck provided it was not placed at an edge. The sides of the specimen corroded at the same rate as the center, even at high current densities (400 ma/cm^2). Therefore, the specimen behaved hydrodynamically as a flat plate.

Influence of Oxygen at Low Current Densities

In Fig. 2, the rest potentials are plotted against Re for all three materials in deaerated, oxygenated, and naturally aerated conditions. Corresponding apparent polarization curves are depicted in Fig. 3 to 5. The latter results are presented at all Re for the mild steel which shows behavior intermediate between that of the pure iron and the iron-1.3% C alloy. Results for these last materials have been condensed in Fig. 4 and 5.

For each material it was found that the rest potential changed very little (2-7 mv) on raising Re

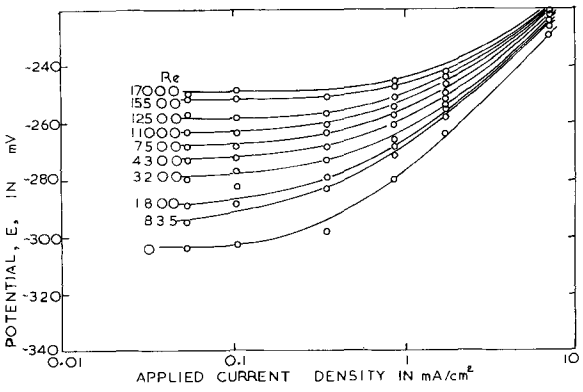

Fig. 3 (b). Naturally aerated

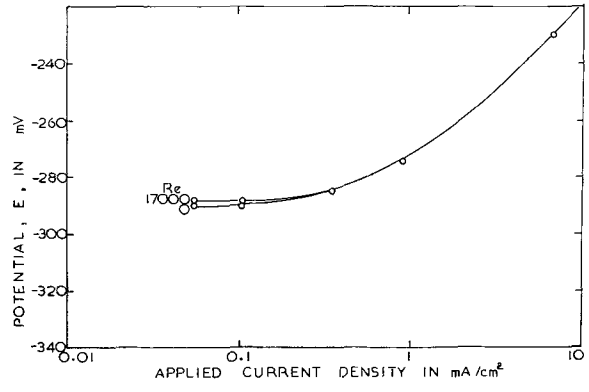

Fig. 3 (c). Deaerated

from 0 to 13,000-17,000 in deaerated solution. These small changes are undoubtedly due to minor traces of oxygen remaining in solution. On the other hand, for aerated and oxygenated solutions the rest potential increased with flow velocity, the effect being greater in the oxygenated solutions. The same general picture holds for the polarization curves; their position is independent of Re in deaerated solution, but they rise with Re in the presence of oxygen. The influence of oxygen on the rest potential and on the position of the apparent anodic polarization curve is increasingly important the lower the carbon content of the alloy.

It can be concluded that in a deaerated solution the rest potential and anodic polarization curve, and consequently the corrosion rate, are independent of flow rate in a duct of square cross section, thus confirming the corresponding results of Makrides (6) and Foroulis and Uhlig (5) with rotating electrodes. This result implies that iron dissolution and hydrogen evolution are not mass-transfer controlled under these conditions.

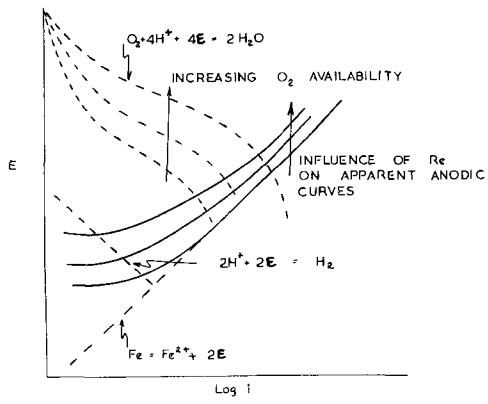

Fig. 6. Schematic representation of relationship between apparent anodic curves and true anodic and cathodic curves in solutions containing oxygen.

The reduction of oxygen raises the rest potential and the polarization curves by contributing to the cathodic reaction and increasing the dissolution rate. The effect is more pronounced the lower the carbon content (lower corrosion rate) for several possible reasons. First, the effect will be smaller at higher natural corrosion rates because the contribution of oxygen will be relatively less important than the very large hydrogen-evolution contribution to the cathodic current. Second, the presence of a hydrogen film on the surface interfering with the access of oxygen to the surface will become increasingly important the higher the corrosion rate, as has been pointed out by Foroulis and Uhlig (5). It is possible in the present flow cell for hydrogen to adhere to the surface even at high Re which apparently is not the case with rotating specimens. An additional obstacle to oxygen arrival exists in the case of the iron-1.3% carbon alloy because a carbon and cementite film accumulates on the anode surface.

Examination of all curves for aerated and oxygenated solutions shows that at high Re the rest potential is reaching a limiting value, also implying that the corrosion rate is becoming constant. This rate is determined by the arrival-rate of oxygen through the diffusion boundary layer which is reaching a limiting thickness at high Re.

An interesting, and apparently anomalous, effect for the pure iron and mild steel at Re $<$ 3000-4000, corresponding approximately to the region of laminar flow, is that the rest potentials (and polarization curves) are lower the greater the degree of oxygenation. Actually it was shown by allowing 15 min instead of the usual 2 min between readings that the differences between aerated and oxygenated solutions (always $<$ 5 mv) could have been due to hysteresis effects. In this region the resistance to diffusion of oxygen through the thick boundary layer must have been more important than the bulk oxygen content. The result for nominally deaerated solution, some 20 mv higher, could not be explained in this way and was quantitatively reproducible. The most likely explanation is that small quantities of residual oxygen (or Fe^{3+}) were adsorbed on active anodic sites, inhibiting iron dissolution and raising the slope of the true anodic curve (5). Once flow enters the turbulent region, oxygen readily arrives at the interface in oxygenated and aerated solutions and obscures this effect. Apparent confirmation of these ideas is obtained by scrutinizing the results for iron-1.3% C; no effect (other than the bogus displacement of oxygenated and aerated specimens due to hysteresis) is observed. This is because the hydrogen and cementite films would prevent oxygen adsorption and because the very rough surface might restrain the formation of laminar flow.

The apparent anodic polarization curve is initially almost flat and its slope rises with current density until it approaches the Tafel value. At low current densities, this curve is the algebraic sum of the anodic reaction current and of the two cathodic reaction currents, as shown schematically in Fig. 6. In the case of the pure iron in oxygenated solution the cathodic curves may be so dominant at high Re that a negative slope is observed, although this is almost within the limits of experimental error. As the oxygen content of the solution is raised, the apparent curve rises in the manner shown. On increasing the current density the proportion of cathodic areas and consequently of the cathodic reaction on the anode surface decreases and the shift with flow becomes proportionately less. In deaerated solutions no anodic shift was observed, and the slope of the curve was steeper. It is noticeable that for pure iron and mild steel in aerated and oxygenated solutions the slope at the highest current densities reported increased as Re decreased. This is in harmony with the theory given above. Further confirmation is afforded by the slopes of the curves for iron-1.3% C which are independent of Re because oxygen is relatively unimportant. Finally, most of the curves in aerated and deaerated solution do not exactly conform to true Tafel behavior (the slopes being too low) because the cathodic reaction on the anode surface is still significant. Results approximating more closely to Tafel behavior are discussed below.

Apparent Anodic Polarization Curves

The typical curve for mild steel in 0.5% w/w HCl, depicted in Fig. 7, shows three distinct regions. At low applied current densities (up to about 1 ma/cm²) the curve AB is relatively flat. At slightly higher current densities and potentials, where hydrogen evolution on the anode surface is much less, the apparent Tafel region BC is reached, with a slope of 65 mv. This region has been extrapolated above the current density of 12 ma/cm² where it ceases to hold true in practice. There is no sensitivity to flow in the first two regions because the reactions involved are activation controlled.

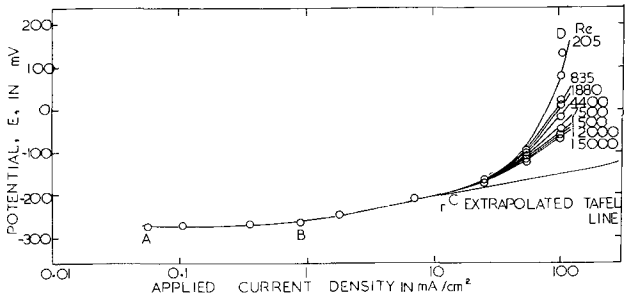

Fig. 7. Complete apparent anodic polarization curves for mild steel in deaerated 0.5% w/w HCl at various Re.

Nevertheless, above 12 ma/cm² the polarization curves (which should be largely "true" curves) rise sharply, the rise being greater the lower the Re. It is important to observe that once the current density corresponding to C is exceeded very rapid flow is incapable of depressing the polarization curve to the extrapolated Tafel line. Evidence will be presented in the second part to show that, once concentration polarization is established, filming of the anode surface occurs, and this is not readily removed. It is just possible that part of this residual overpotential is due to an IR_o drop in the electrolyte, even though a backside probe was adopted, but this possibility will be neglected here.

Corresponding curves for the three materials in deaerated 0.5% and 5% w/w HCl are given in Fig. 8, the two branches at high current densities represent-

ing values for Re 205 and 15,000, respectively. Included in the diagrams for pure iron are the results for annealed specimens. Some of the more important quantities are tabulated in Table I.

Influence of carbon content.—If the polarization curves for pure iron, mild steel, and iron-1.3% C taken from Fig. 8 are superimposed for each acid concentration several interesting conclusions may be drawn. First, allowing for slight variations in Tafel slope, which are probably related to changes in specific surface activity determined by the polarizing cycle imposed, the apparent polarization curves in the Tafel region are relatively close. There is some evidence that curves for the iron-1.3% C alloy lie to the right of those for the pure iron but the effect is not very pronounced. These curves clearly do not show up the massive differences in natural cell corrosion. Thus, Wood and Roberts (17) showed that true curves for iron-1.3% C obtained by weight loss measurements lie well to the right of those for pure iron corresponding to a tenfold increase in dissolution rate. In the present case at low current densities before Tafel behavior is observed the curves are higher and flatter for the higher carbon materials, due to the greater contribution of the cathodic reaction to the apparent anodic curve, and Tafel behavior does not start until the current density is higher (Fig. 9).

The second important point is that Tafel behavior ceases at a lower applied current density the higher the carbon content. This could be due to the contribution made by local cell corrosion in providing a sufficient concentration of Fe^{2+} ions for concentration polarization and film formation to occur at an earlier stage. An alternative explanation, which would be more likely in potential ranges where local cell corrosion is negligible, is that cementite and carbon corrosion products block the surface, so increasing the actual anodic current density in regions of free surface thus permitting an earlier onset of filming.

Table I. Important values for materials in deaerated solutions

Material	Rest potential, mv, E_H				Tafel slope, $\frac{dE}{d \log i}$, mv				Range of Tafel behavior current densities, ma/cm²			
	0.5% HCl		5% HCl		0.5% HCl		5% HCl		0.5% HCl		5% HCl	
	Annealed	Cold worked	Annealed	Cold worked	Annealed	Cold worked	Annealed	Cold worked	Annealed	Cold worked	Annealed	Cold worked
Pure iron	−280	−322	−242	−263	65	65	54	54	−23	0.9-55	0.45-155	0.45-155
Mild steel	−290	—	−245	—	65	—	42	—	1-12	—	0.11-110	—
Iron-1.3% C	−288	−291	−238	−248	57	57	50	50	1.8-8	1.8-8	0.7 -30	0.7 -30

Influence of annealing.—A few results were obtained on annealed specimens of pure iron and iron-1.3% C to compare with the cold-worked specimens normally used. Examination of the rest potentials in Table I shows that annealing raised the value for pure iron by 42 mv in 0.5% w/w acid and by only 21 mv in 5% w/w acid. The very small shifts for iron-1.3% C specimens are almost within the experimental error. The only apparent polarization curves which show any difference in the Tafel region are those for the pure iron in 0.5% w/w acid, where the curve for the annealed specimen lies 28 mv above that for the cold-worked specimen.

In view of the conflicting evidence and opinion on the importance of cold work on dissolution behavior (17-19), deductions must be made with reservation. At the outset it is important to emphasize the differences which occur when comparing the behavior of: (*a*) cold-worked specimens with specimens obtained from them by subsequent annealing, and (*b*) annealed specimens with specimens obtained from them by cold working. The comparison made here lies in the first category. The higher rest potentials of pure iron after annealing can be explained readily by the possible removal of many active anodic sites by annealing, and probably much more important, the reprecipitation of cementite at appropriate sites to form an increased number of cathodic areas. Hydrogen evolution will be simpler, cathodic polarization will be less, so the rest potential will be higher, in agreement with the findings of Foroulis and Uhlig for 0.002% C iron (18). The effect is less pronounced in the 5% w/w acid because the much greater H^+ concentration in the electrolyte makes hydrogen evolution easier, and it is less important to have specific cathodic sites. It is difficult to draw conclusions from the apparent anodic curves particularly if, as appears the case, some local cell action is still occurring in this region. However, the effect of annealing is less pronounced than for the rest potentials and is nonexistent in the case of the 5% w/w acid. The latter findings agree with those of Wood and Roberts (17) who demonstrated a shift between annealed and cold-worked specimens, using method (*b*) above, for 0.5% acid but not for 5% acid, but are not apparently supported by the theories of Foroulis and Uhlig. (18).

The insignificant changes in rest potential and the position of the polarization curves for the iron-1.3% carbon alloy are not surprising since subcritical annealing will not greatly affect the redistribution of massive cementite. However, a difference is observed in rest potentials and true anodic curves using scheme (*b*) above (17).

In agreement with the observations at low current densities, only the annealed pure iron in 0.5% w/w acid filmed more readily than the cold-worked material. This occurred at 23 ma/cm^2 instead of 55 ma/cm^2 due presumably to the greater inherent dissolution rate of annealed iron. It is not particularly clear why this should be so because local cell corrosion should be very small at this potential. The alternative explanation of partial surface blocking by cementite products does not look very likely either for such a relatively pure metal.

Influence of acid concentration.—Consideration of the apparent Tafel slopes shows them to lie within the range 42-65 mv which is in reasonable agreement with the literature. Not too great credence should be given to the present values since they were obtained from apparent curves obtained in a stepwise fashion. It does appear that the values are relatively independent of carbon content and are lower the higher the concentration of the acid, a trend also found by other workers (17).

For all alloys the onset of concentration polarization and consequent filming was delayed in the higher concentration of acid until a higher applied current density was attained. This could be ascribed possibly to the greater diffusivity of ferrous ions in the more concentrated acid, so restricting their accumulation in the boundary layers. Alternatively the film could be more soluble in the 5% acid, where the lower *p*H might be significant, but this is definitely not the case with yet higher concentrations (12, 13).

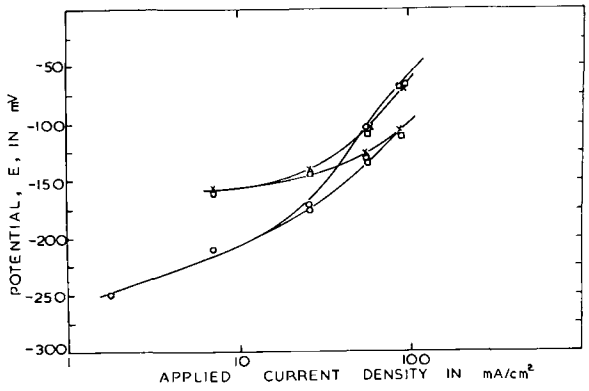

Fig. 10. Influence of adding $FeCl_2$ on anodic curves for mild steel in deaerated 0.5% w/w HCl: ○ no Fe^{2+} added; □ 0.57 g ions Fe^{2+}/liter; X 1.73 g ions Fe^{2+}/liter.

Influence of initially dissolved ferrous ions.—Anodic polarization curves were obtained for additions of 0.57 and 1.73 g ions Fe^{2+}/liter to solutions of HCl in the form of $FeCl_2 \cdot H_2O$. These additions raised the rest potentials to —190 and —188 mv, respectively, values partly determined by the increase in Fe^{2+} concentration but mainly by impurity filming of the anode as commercial grade $FeCl_2 \cdot H_2O$ had to be used.

The apparent polarization curves always remained higher for the $FeCl_2$-containing solutions, but the current density at which departure from Tafel behavior occurred was independent of $FeCl_2$ concentration (Fig. 10). This proved that the concentration of Fe^{2+} ions obtained at the interface just prior to filming must be much greater than those resulting from the relatively small additions of $FeCl_2$ solution.

Anodic Dissolution at High Current Densities

The results presented in the first part of this paper show that at low and medium current densities there is little dependence of either potential or current density upon the flow rate (Fig. 7). This is not to say of course that there is no mass transport, but rather that its contribution is negligible save in those instances where dissolved oxygen is present. When the dissolution rate is increased to a level where the specimen surface adopts an entirely anodic role and solute is generated at a rate approaching that at which it

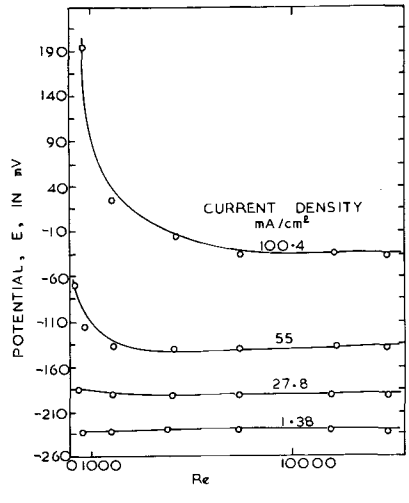

Fig. 11. Potentials of mild steel specimen in flowing deaerated 0.5% w/w H_2SO_4 at various current densities.

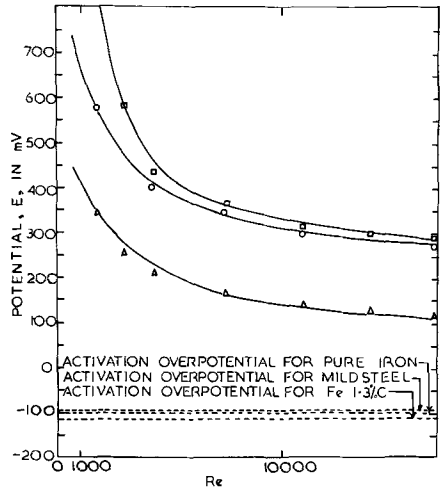

Fig. 13. Potentials of specimens in flowing 0.5% w/w HCl at current density of 440 ma/cm²: △ pure iron; ○ mild steel; □ iron-1.3% C.

is dispersed by diffusion and convection, a more marked response to flow rate should result. Figure 11 presents results typical of those obtained with all three metals in both hydrochloric and sulfuric acid; it shows that at 100 ma/cm² the potential responded to flow variations over a wide range of Reynolds number. Similarly, Fig. 12 is typical of potentiostatic data which show that at a sufficiently anodic potential there is a wide range of response to flow. The maximum current density employed was 440 ma/cm², and at this value there was a marked decrease in flow sensitivity even at high Reynolds numbers.

Reference to Fig. 7 and 8(a) suggests that at dissolution rates corresponding to a current density of 12 ma/cm² (in the case of mild steel exposed to 0.5% w/w HCl) the true Tafel behavior of the anodic reaction is disturbed by an increasing degree of concentration polarization and consequent filming. Above this value, therefore, the observed electrode potential includes activation overpotential, the concentration overpotential in the film and between the film and the bulk electrolyte, ohmic overpotential in the film, and any ohmic term in the probe. This last term is considered to be negligible in a back probe of the Piontelli type; the activation potential may be obtained by extrapolation of the Tafel region of the curve. A comparison of such values with those observed for all three metals in 0.5% HCl at maximum dissolution rate (Fig. 13) indicates how the apparent concentration overpotential and the ohmic overpotential in the film responded to flow rate. It is recognized that both of these factors will be operative, but since it is difficult to separate them in a quantitative manner, each will be dealt with as alternative explanations, as though the other were negligible.

When a solute is transported by means of diffusion and convection through a boundary layer under the influence of a concentration driving force, the simplified equation for the flux j_D, assuming no participation by the solvent or other species, is

$$j_D = K(C_i - C_b)$$

The concentration driving force is the difference between the interfacial concentration and the bulk concentration, and K is referred to as the mass transfer coefficient. Wranglen and Nilsson's treatment of the cathodic (16) process allows us, with an appropriate change of constant, to calculate K for an equipotential anodic process and compare theoretical mass transfer coefficients with those encountered at high current densities. The interfacial concentration C_i may be calculated from the apparent concentration overpotential (E_c) previously described by introducing the concentration of ferrous ions (C_r) corresponding to the reversible potential of the metal concerned.

Thus if

$$E_c = \frac{RT}{zF} \operatorname{lon} \left[\frac{C_i}{C_r} \right]$$

$$C_i = C_r \cdot \exp \left[E_c \frac{zF}{RT} \right] \qquad [5]$$

Now E_c may be read off from results such as those portrayed in Fig. 13, and C_r may be calculated from the reversible potential (E_{rm}) for each metal, as calculated by the method of Bockris (20)

$$E_{rm} = E^\circ + \frac{RT}{zF} \operatorname{lon} C_r$$

or

$$C_r = \exp \left[(E_{rm} - E^\circ) \frac{zF}{RT} \right] \qquad [6]$$

Concentration terms were used throughout because of the paucity of activity coefficient data.

The results of such calculations in the case of mild steel sustaining a current density of 440 ma/cm² in flowing deaerated 0.5% HCl are displayed in Table II, from which two facts are immediately apparent. First, the observed mass transfer coefficient (U) is many orders of magnitude less than the calculated value (K), and second, the interfacial concentration (C_i) is much higher than that expected from the solubility of the salts concerned in the medium employed (*e.g.*, 4.16 x 10^{-3} moles/ml for $FeCl_2$). Table III presents similar data obtained from mild steel in 5% HCl, where there is good agreement between U and K at high Reynolds numbers. The agreement between the predicted and observed mass transfer de-

pendence is thus clearly dependent on the metal and electrolyte and both matters are commented on later.

Supersaturation of the metal-electrolyte interface with metallic ions and nucleation and growth of soluble films have been observed by several workers in different systems. Although in this work conditions for passivity were not attained, the formation of crystalline layers due to supersaturation alone have been noted previously (21-23). The interfacial concentration C_i is the concentration prevailing at the metal surface where the anion concentration is low, while C_i' is that value at which the film substance is just soluble. It should be noted that a constant mass transfer rate requires that $(C_i' - C_b)$ remains constant also. Thus, if the transport properties of the film are represented by means of a film coefficient (h), the steady-state flux through both film and boundary layer in series may be written as

$$j_D = h(C_i - C_i') = K(C_i' - C_b) = U(C_i - C_b) \quad [7]$$

whence

$$\frac{1}{U} = \frac{1}{h} + \frac{1}{K}$$

and so

$$h = \frac{UK}{K - U}$$

This expression enables us to extract the film coefficient from the observed coefficient by means of the theoretical mass transfer coefficient.

The dimensions of the film are related to the solubility of the substance, as follows. Consider that a metal M of valency m reacts with an anion X of valency n thus, (again employing concentrations rather than activities)

$$\mathrm{M} \rightarrow \mathrm{M}^{m+} + m\epsilon$$

$$\frac{m}{n}\mathrm{X} + m\epsilon \rightarrow \frac{m}{n}X^{n-}$$

and

$$\mathrm{M}^{m+} + \frac{m}{n}\mathrm{X}^{n-1} \rightleftharpoons \mathrm{MX}_{m/n}$$

If the concentration of X ions is C_x, and the solubility product of $\mathrm{MX}_{m/n} = S$, solid exists at a cation concentration C_i,

when

$$S = [C_i][C_x]^{m/n}$$

or

$$C_i = \frac{S}{[C_x]^{m/n}}$$

now let

$$j_D = \frac{I}{AnF} = \frac{\partial c}{\partial y}(D + \epsilon) \quad [8]$$

where ϵ is the contribution to transport derived from turbulent eddies, and integrating between the limits

$$C = C_i \text{ when } y = 0$$

$$C = C_i' \text{ when } y = y_f$$

$$\left[C_i - \frac{S}{(C_x)^{m/n}}\right] = \frac{I}{AnF}\frac{y_f}{(D + \epsilon)} \quad [9]$$

or

$$y_f = (D + \epsilon)\frac{AnF}{I}\left[C_i - \frac{S}{(C_x)^{m/n}}\right] \quad [10]$$

This result may appear to suggest that increased turbulence at a fixed current density would result in a thicker film. However, increased turbulence would also reduce the interfacial concentration for it is the outer value C_i' which is controlled only by considerations of solubility.

Thus at any given flux (or current density) the film thickness decreases as the turbulent contribution to mass transport increases. Unfortunately lack of precise solubility data for iron salts in solutions of acids prevents an assessment of the absolute value of C_i but, as has been shown already in many instances, the film constituted the dominant resistance to the diffusion of ferrous ions.

The formation of a porous film on the anode increases the electrical resistance and introduces an IR_o drop. Employing this alternative approach, it is possible to calculate the resistance from the potential in excess of the appropriate activation potential. The results (Fig. 14) suggest that at current densities of less than 80 ma/cm^2 the film was not fully formed, and also that the fully developed resistance was dependent on flow rate.

If the limiting resistance values (R_o) from this graph are used in conjunction with experimental E *vs.* Re data, it is possible to compare the calculated overpotential (or IR_o drop) with the observed value, as in Fig. 15. It will be seen that close agreement be-

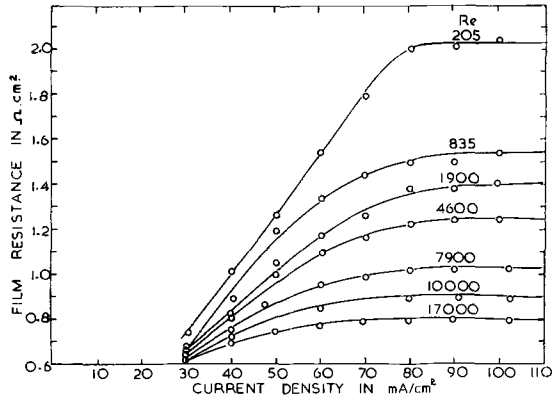

Fig. 14. Film resistance at various flow rates, for mild steel and 0.5% w/w HCl.

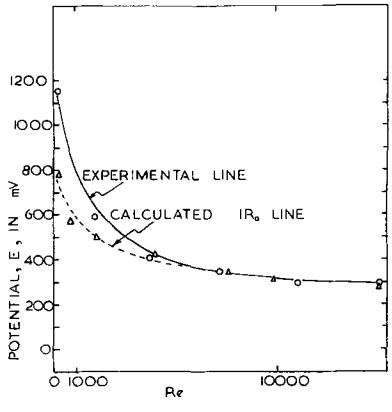

Fig. 15. Comparison of observed overpotential and that calculated from IR_o for mild steel in 0.5% w/w HCl at 440 ma/cm^2.

tween these two values exists at Reynolds numbers in excess of 5000, but that at lower flow rates a discrepancy becomes apparent. This could be due either to different film properties at low Re, or to a more substantial contribution from concentration polarization in the pores of the film at low current densities.

Effect of Variations in C content, Annealing, Acid Concentration, and Dissolved Fe(II) *Ions*

The results so far discussed, although illustrative of the behavior of all the systems examined at high current densities, were mainly drawn from experiences with mild steel in deaerated 0.5% w/w solution of hydrochloric acid. As in the current density regimes reviewed earlier, it is to be expected that changes in carbon content, heat-treatment, acid concentration, or in the initial presence of ferrous ions would result in changes in the effect of flow rate.

Carbon content.—As has been remarked, the current density at which departure from Tafel behavior and hence flow sensitivity is observed varies with carbon content. These figures were 55 ma/cm^2 for pure iron, 12 ma/cm^2 for mild steel, and 8 ma/cm^2 for 1.3% C alloy. The increased carbon content increased the natural dissolution rate so that the concentration overpotential and filming effects became more noticeable. Similar behavior is observed at high current densities (Fig. 13).

Annealing.—In only one instance, namely of pure iron in 0.5% w/w HCl solution, did annealing result in a changed behavior at high current densities. Figure 16 shows how the observed potential of the specimens differed from each other at various flow rates. It would seem that in this case the annealing amounted to a differential heat-treatment resulting in more numerous cathodic sites (18). This effect was not noticeable either in increased acid concentrations or when the carbon content was higher, because of the greatly increased natural dissolution rates.

Acid concentration.—The results obtained from specimens of all three metals exposed to 0.5 and 5.0% w/w HCl are shown in Fig. 17. It is clear that in both carbon-containing alloys the increased acid concentration reduced the degree of concentration polarization and the resulting filming process, thereby diminishing the sensitivity to flow rate. The potential of pure iron indeed ceased to be flow sensitive when immersed in the stronger acid.

Now a re-arrangement of Eq. [7] results in an expression for the film factor h

$$h = \frac{1}{1/U - 1/K} \qquad [11]$$

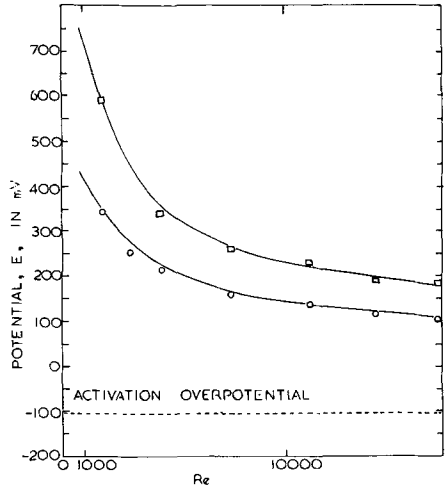

Fig. 16. Variation of potential of annealed (open box with dot) and cold worked (open circle) pure iron in flowing 0.5% w/w HCl (current density 440 ma/cm^2).

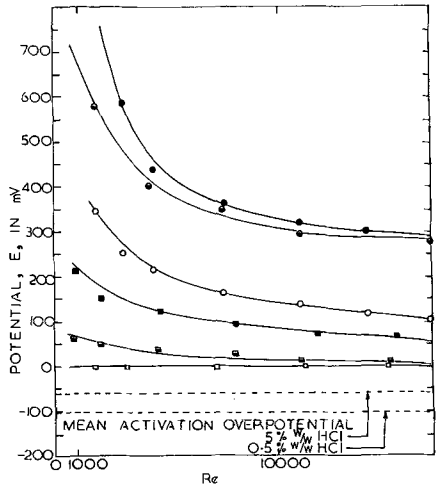

Fig. 17. Variation of potential of specimens in flowing HCl (current density 440 ma/cm^2). Circle, Pure iron in 0.5% w/w HCl; box, pure iron in 5.0% w/w HCl; half dark circle, mild steel in 0.5% w/w HCl; half dark box, mild steel in 5.0% w/w HCl; • iron-1.3% C in 0.5% w/w HCl; ■ iron-1.3% C in 5.0% w/w HCl.

and as at any fixed current density I/A

$$h(C_i - C_i') = K(C_i' - C_b)$$

$$C_i' = (hC_i + KC_b)/(K + h) \qquad [12]$$

substituting for $C' = S/(C_x)^{m/n}$

$$h = \frac{K\left[\dfrac{S}{(C_x)^{m/n}} - C_b\right]}{C_i - S/(C_x)^{m/n}} \qquad [13]$$

Thus an increase in C_x, the anion concentration, would reduce h, the film factor, in any flow state where K is constant.

$$C_i = C_i'\frac{(K+h)}{h} - C_b\left(\frac{K}{h}\right)$$

$$= \frac{S}{(C_x)^{m/n}}\left[\frac{K}{h} + 1\right] - C_b\left(\frac{K}{h}\right) \qquad [14]$$

now re-arranging [11] as

$$\frac{K}{h} = \frac{U}{h} - 1$$

and substituting

$$C_i = \frac{U}{h}\left[\frac{S}{(C_x)^{m/n}} - C_b\right] + 1 \qquad [15]$$

which also predicts that an increase in anion concentration (*i.e.*, acid strength) would result in a reduction of C_i, and hence the probability of the necessary concentration of cations to result in filming. For example, in the case of iron in HCl, where $m/n = 2$, a tenfold change in anion concentration results in almost a 100-fold change in C_i. Adopting the film resistance approach, apparent film resistances are given in Table IV. Films formed in concentrated acid may be thicker than the resistance indicates because entrapped acid is more conductive.

Ferrous ion concentration.—Equation [15] is also of interest inasmuch as it predicts that, once filming is complete, the presence of ferrous ions in solution (C_b) should have little effect on the interfacial concentration (C_i). Experiments were carried out in which 0.57 g ion Fe^{2+}/liter were added to 0.5% HCl solution, and 1.73 g ion Fe^{2+}/liter added to 5.0% HCl solution, in the form of $FeCl_2 \cdot H_2O$ crystals. At high dissolution rates the readings were rather unsteady, but in gen-

Table IV. Apparent film resistances for Re = 10,000 at c.d. of 440 ma/cm^2

Alloy	Electrolyte HCl	Physical state	Apparent film resistance, ohm · cm^2
Pure Iron	0.5%	Cold worked	0.53
Mild steel	0.5%	Annealed	0.90
Fe-1.3% C	0.5%	Cold worked	1.00
Mild steel	5.0%	Annealed	0.18
Fe-1.3% C	5.0%	Cold worked	0.32
Pure iron	0.5%	Annealed	0.75

eral there was little departure of behavior of all three alloys from that experienced in plain acid. It is of interest to note that this is not expected if diffusional control is entirely by mass transport in the boundary layer, but is predicted from Eq. [15] which includes the film factor.

Conclusions

1. The rest potentials and apparent anodic polarization curves for all materials in H_2SO_4 containing oxygen shift in the positive direction with increase in flow rate, due to oxygen reduction adding to the cathodic current. The shift is less at higher carbon contents due to the smaller relative contribution of oxygen to the total cathodic current and also to blocking the specimen surface by hydrogen, carbon and cementite films. Anomalous effects at low Re for pure iron and mild steel may be due to inhibition by oxygen or Fe^{3+} ions.

2. In deoxygenated HCl the apparent anodic polarization curve is composed of three distinct regions. The first is relatively flat, representing the net result of the true anodic and cathodic processes on the specimen; the second is a Tafel region where anodic dissolution is activation controlled; in the final region there is a sharp rise in potential due to concentration polarization which immediately produces filming. The overpotential in excess of the activation value may be accounted for either in terms of cation concentration gradients within the film and between the film and bulk solution or as an IR_o drop in pores in the film.

3. In the first two regions, the potential is not sensitive to flow during a galvanostatic run. Flow sensitivity apparent in the third region is attributed either to reduction in concentration overpotential in the film or to film thinning.

4. Increase in carbon content and decrease in acid concentration reduces the apparent range of current densities over which Tafel behavior is detected. The apparent Tafel slope is lower in more concentrated acid. The current density at which Tafel behavior ceases is independent of large concentrations of Fe^{2+} ion added to the acid.

5. Annealing a cold-worked specimen has no effect on any region in the case of Fe-1.3% C in 0.5% or 5% w/w HCl or of pure iron in 5% w/w HCl. However, pure iron in 0.5% w/w acid dissolves more rapidly in the annealed condition probably due to the production of favorable cathodic sites.

6. In the flow-sensitive region the leading edge dissolves preferentially in close accordance with theory.

7. Filming is caused by supersaturation of the boundary layer with Fe^{2+} ions and once the film is formed its stability is determined by its solubility product. The film is thicker for higher carbon contents and at low acid concentrations but is independent of the bulk Fe^{2+} concentration. Increase in flow rate reduces the film thickness or the concentration polarization associated with it to a limiting value. Although it has proved possible to treat the data quantitatively in terms of either phenomenon exclusively, it is not possible to separate their individual contributions to the measured overpotential.

A Redox Printing Technique for the Study of the Electronic Conductivity of Anodic Oxide Films on Valve Metals

Gerhart P. Klein

Laboratory for Physical Science, P. R. Mallory & Co. Inc., Northwest Industrial Park, Burlington, Massachusetts

ABSTRACT

A printing method using iodide-starch as the redox indicator in a solidified electrolyte was developed for applications to various valve metals and their anodic oxide films. It was used to study the electronic conductivity of anodic oxide films on tantalum and niobium and to detect defective sites in oxide films on aluminum. Applied to titanium, zirconium, and silicon, as well as the other valve metals, the technique was used for an evaluation of the surface condition of the metal substrates. The technique also was useful in cases where the oxide films corroded under the influence of the printing electrolyte.

Some of the valve metals are noted for high resistivity oxide films (1) that can be produced by anodic oxidation. However, the high resistivity can be realized only when materials of extreme purity are being used. In most practical cases, heterogeneities which disrupt the uniformity of the dielectric were found to be present in the oxide film giving inferior over-all properties. Impurities and several other conditions have been identified as sources for excessive electronic conductivity of anodic oxide films leading to "gassing," *i.e.*, oxygen evolution during formation in aqueous electrolytes in the absence of redox systems other than H_2O/O_2-system and to excessive leakage currents.

The distribution of the electronic current will depend on the distribution of the heterogeneities and impurities. It can vary from complete uniformity, both microscopically and macroscopically, to distinct singularity in cases of random contamination.

Measurements in electrolytes do not permit the determination of the distribution of the electronic currents unless the reaction products are immobilized at the site of their creation. These must be detectable by their color or other distinguishing characteristics.

The quantitative evaluation of electronic currents is possible, at least in principle, by measuring the reaction products of redox reactions by standard analytical or electroanalytical methods. However, the quantities of materials to be evaluated are usually so small, except in cases of large electronic currents and small volumes, that the sensitivity of most analytical methods is inadequate.

This situation led to our development of a thin layer printing-out technique which uses a redox indicator printing electrolyte in gelled form supported by a porous back-up material for the determination of the distribution and density of the electronic current passing through anodic oxide films in the formation direction. The electronic current is utilized to oxidize the reduced species of the redox indicator, the oxidized form of which must show a color distinctly different from the reduced form which ideally should be colorless. The oxidized form being fixed by the gel can then be evaluated optically.

Experimental Procedures

From the large number of redox indicators available only few qualify for use in the printing technique as applied to anodic oxide films. The main criteria for their selection were: sensitivity, redox potential, distinctness of color change, diffusion of the oxidized form in the printing electrolyte, chemical stability and stability towards light, compatibility with the anodic oxide films and substrate metals to be tested. One of the systems found to be most satisfactory from the point of view of these criteria was the iodide/iodine-starch redox system for reasons that will become evident in the following.

The printing electrolyte consisted of an agar-agar gel 0.01-0.1 molar in potassium iodide, 0.05 molar in borax, and containing varying amounts of soluble starch. The mixture was kept liquid in a water bath. On cooling it solidified to a rigid, non-tacky gel. The borax served as both a buffer and a means to make the solidified gel more rigid.

To perform a printing test liquid gel was spread on a specimen in the form of sheet or foil. The specimen then was sandwiched between two sheets of a suitable back-up material, such as MILLIPORE filter paper, and compressed in the printing press (Fig. 1).

The press was made from a clamp to the jaws of which electrode plates had been attached. Excess elec-

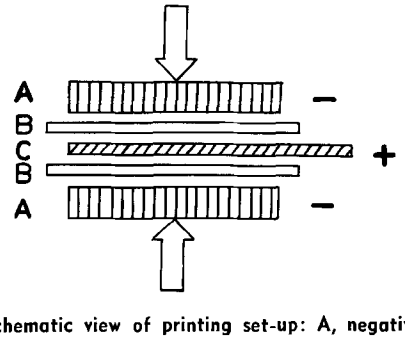

Fig. 1. Schematic view of printing set-up: A, negative electrode plates; B, printing medium consisting of back-up material and electrolyte; C, specimen.

trolyte gel was squeezed out assuring a thin smooth layer of printing electrolyte in intimate contact with the specimen surface and well bonded to the back-up material which, at the same time, became soaked with electrolyte. Electrical connections were made to a constant current or constant voltage power supply, depending on the test to be performed. The specimen was connected to the positive, and the press with the electrode plates to the negative output of the power supply.

Electronic current oxidized iodide to iodine which, upon reacting with starch, led to the formation of a blue to black coloration on a clear white background. The prints were preserved by bonding them to glass slides with the gel side down followed by drying in an air stream. The color changed to brown after drying. They could be stored for several months without noticeable deterioration.

Two printing-out modes were used. In the dynamic mode, the printing was done at constant currents, *i.e.*, while formation of the oxide film was taking place. In this case we obtained the integral electronic charge that passed while the film was formed to a certain voltage. Printing was usually done in voltage intervals with a new layer of printing medium used in every printing interval. This resulted in a series of prints which covered the whole range of anodic oxidation of a specimen up to the scintillation voltage and which reflected the electronic conductivity and its variation while the oxide film was being grown. In the static mode, the printing was done at constant voltage on a specimen that had been oxidized previously. The test was performed at the formation voltage of the film or a fraction thereof. This test was used to test the electronic conductivity of specimens that had been anodized previously under any experimental condition and could be used to evaluate the effect of formation conditions on the electronic conductivity and to detect defects in the oxide film.

The minimum sensitivity of the printing technique to detect electronic charges was found to be 1 millicoulomb/cm^2, approximately, for the iodide/iodine-starch redox system. Since the electronic current is integrated while a print is being taken even small currents could be detected if the printing time was extended. However, this was practical only within certain limits because the printing medium tended to dry out and because of slight fading and diffusion. Best results were obtained when the printing time was kept below about 15 min. This corresponded to minimum current densities which could just be detected of approximately 1 μa/cm^2. Point defects could be detected if their current was of the order of 1 nanoamp and higher.

Two factors contribute to the distinctness of the printing marks:

1. The iodine forms an adsorption complex with starch in which the iodine vapor pressure is reduced greatly.

2. The starch, being a high polymer, is immobilized in the matrix of the agar gel. The same is true for the adsorption complex with iodine.

The second factor, on the other hand, is also responsible for the spreading of the printing marks while they are being produced. The iodine has to diffuse to regions around the current source that have free starch still available. This explains the increase in the size of the marks with increasing printing time without further increase after the power has been shut off. Only if a large excess of iodine has been formed will there be additional spreading by diffusion. The greater the starch concentration the sharper the prints. The high sensitivity, the color change from colorless to blue-black, the distinctness of the printing marks, and their stability are the main advantages of the iodide/iodine-starch redox indicator system over most of the other redox systems which, in most cases, gave very diffuse patterns only.

Nothing has been said so far about the compatibility of this redox system with the anodic oxidation of the common valve metals. Most oxide forming metals exhibit a particular sensitivity toward halide ions which are responsible for corrosion effects which prevent the formation of protective and insulating oxide films. This effect is very noticeable with aluminum where even traces of chloride can be harmful when insulating anodic oxide films are to be formed. The only metals where such effects have been found to be absent are tantalum and niobium. The printing technique with iodide can be applied to these metals without limitations. In the case of most other valve metals, iodide-iodine containing electrolytes lead to specific corrosion, a fact that limits the use of the printing method. However, it is still a useful tool for the detection of imperfections in oxide films on these metals, as will be shown in the next paragraphs.

The concentration of iodide in the printing electrolyte has to be chosen such that the scintillation potential of the electrolyte is sufficiently high; this requires low concentrations. On the other hand, high concentrations are required to suppress oxygen evolution at sites of high local current density. If the concentration of iodide is too low, depletion in the layers adjacent to the substrate surface will lower the iodine solubility and thus lead to the formation of free iodine which cannot reach unreacted starch. Obviously, the most suitable iodide concentration has to be determined empirically for each application.

Applications of the Printing Technique

Tantalum and niobium.—Anodic oxide films on tantalum and niobium can be formed in electrolytes containing iodide as readily as in more conventional formation electrolytes. The linearity of the voltage increase during constant current formation of very clean specimens and the well-defined sparking voltages observed as a function of the concentration of potassium iodide were considered to be sufficient criteria for a "normal" formation behavior. The iodide printing-out technique could, therefore, be applied to tantalum and niobium in the dynamic and static modes. For example, a vacuum annealed tantalum foil specimen could be oxidized anodically while prints were taken in the arrangement described above without any trace of general darkening and only a few spots due to the oxidation of iodide to iodine and its reaction with starch (Fig. 2a). The voltage increased linearly to the scintillation point which was found to be near 200v for the particular electrolyte used in this experiment.

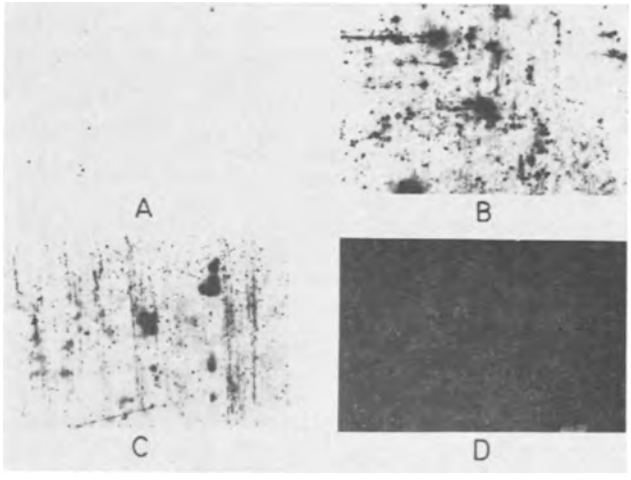

Fig. 2. Anodic prints obtained with tantalum and niobium foil. a. Vacuum annealed tantalum foil; dynamic print at 1 ma/cm^2, 0-150v formation. b. "As received" tantalum foil; dynamic print at 1 ma/cm^2, 0-50v formation. c. "As received" niobium foil; dynamic print at 1 ma/cm^2, 50-100v formation. d. Same foil as c., reverse side. Area of each print approximately 2 cm^2.

Specimens of foil in the "as received" condition by contrast produced prints which revealed a large number of localized electronically conducting centers, or even uniform electronic conductivity (Fig. 2b-d). Figure 2c and d, obtained from "as received" niobium sheet, show how the electronic conductivity patterns may differ on the two sides of a specimen.

Anodic oxide films on tantalum and niobium formed in the electrolytes containing iodide may not show satisfactory properties for use as thin film dielectrics, *e.g.*, in capacitors, but this is not due to any damage done by the printing process. The printing process itself is neutral as was shown by a comparison of prints obtained with clean and contaminated specimens. In addition, the properties of the electronically conducting sites in anodic oxide films were found to be unaffected by the printing process. No corrosion phenomena, such as have been observed with aluminum and the other valve metals, have been observed with tantalum and niobium.

Aluminum.—Aluminum behaves quite differently from tantalum and niobium which were inert toward iodide and iodine, respectively. Aluminum cannot be oxidized anodically in halide containing electrolytes, such that insulating films are formed with a voltage increase typical for constant current formations. The presence of even small amounts of halide ions leads to the corrosion of anodic oxide films formed in halide-free electrolytes. By applying the printing-out technique with iodide-starch to aluminum that had been anodized previously in electrolytes containing ammonium borate, we found that violent breakdown reactions took place if we applied the full previous formation voltage of the film. However, by applying a fraction of the formation voltage, typically between 20 and 50%, the current was found to be stable in the low milliampere per square centimeter range with only a slight tendency to increase with time. Only if one print after the other was taken at the same voltage did the current increase to higher values. It was still limited by the oxide film itself, however. The prints revealed a pattern of specks on the white background of the printing medium. The oxide film had clearly been corroded at sites of current flow, but the surprising result was that the corrosion at these sites had been accompanied by electronic current which led to the marks on the prints. By comparison, prints taken at constant current with bare aluminum did not show any blackening. Also, large areas of the oxides were free of corrosion sites if the aluminum was of high purity and, in addition, was cleaned properly. The prints obtained from various specimens are shown in Fig. 3. They were all oxidized in ammonium borate solution to 100v and aged for 1 hr. The prints were taken at 40v for 30 sec each. The first print of the series was obtained with 99.999% aluminum foil after electrochemical polishing, the second print with the same foil in the "as received" condition, the third with 99.99% foil in the "as received" condition, and the fourth print with commercial aluminum wrap, also in the "as received" condition. It is easily seen that characteristic differences were observed with these specimens and that the printing-out method clearly revealed defective areas in the anodic oxide film. The importance of the surface condition as an electronic current determinant is indicated by the differences between the prints obtained with chemically polished and "as received" 99.999% foil on the one hand and "as received" 99.99% foil on the other. It indicates that the stated purity is meaningful only if it specifically includes the surface purity.

The printing-out technique, as applied to aluminum with iodide-starch as the redox indicator, can be considered as a corrosion test which uncovers inhomogeneities in the oxide films by virtue of the electronic current that accompanies the corrosion reaction. A correlation between the electrical properties of the anodic oxide films and the number of corrosion sites has been found to exist.

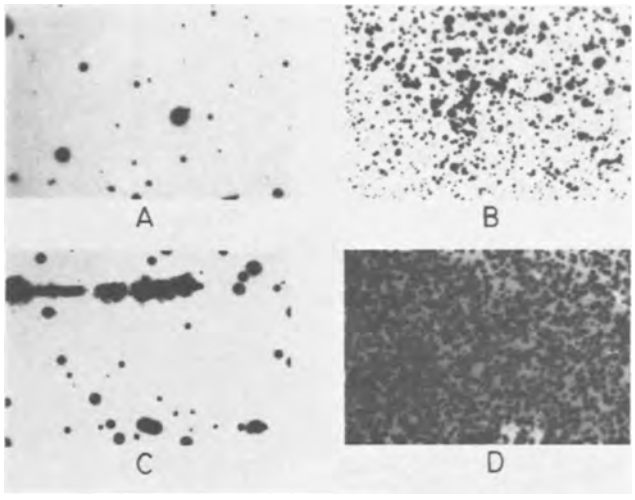

Fig. 3. Anodic prints obtained with aluminum foil. a. 99.999% pure foil, electropolished and oxidized to 100v in aqueous ammonium borate solution. Static print taken at 40v with 30 sec printing time. b. Same foil, in "as received" condition. Test as in (a). c. 99.99% pure foil in the "as received" condition. Test as in (a). d. Household aluminum wrap, as received. Test as in (a). Area of each print approximately 2 cm^2.

Titanium, zirconium, silicon.—Anodic oxide films were produced on these metals but the films were usually of lower quality than those on tantalum and aluminum. The oxide films on these materials are all quite sensitive to halides so that formation in halide containing electrolytes is either impossible or proceeds only to a few volts. The behavior of the oxide free and oxide covered metals is intermediate to that of tantalum and aluminum, even though closer to the latter. The anodic oxidation of titanium did not proceed beyond 4-5v under the conditions of the printing test at constant current. Figure. 4a and b give the result of tests performed with 99.9+% titanium sheet. Figure 4b was obtained with the sheet in the "as received" condition, Fig. 4a shows the result obtained with chemically polished material. A print similar to Fig. 4a was obtained when a chemically polished specimen was oxidized to 100v in ammonium borate and tested at 10v. Again, the various prints reflect characteristic differences in the distribution and density of the electronic conductivity which show that the printing-out technique, even when the system is not inert, can still give information helpful for the evaluation of surface treatments and specimen quality.

In Fig. 4c and d two examples of prints with zirconium are given. Zirconium behaved similarly to titanium, except in the case when a chemically polished specimen was tested. A more or less uniform distribution of the electronic conductivity was found with titanium compared to a distribution showing a few very active areas in the case of zirconium.

Silicon could be oxidized to about 25v under the printing condition. A comparison of prints obtained with specimens with different surface treatments and doping again revealed characteristic differences which could be utilized for an evaluation of the quality and surface condition of silicon specimens.

Conclusions

1. The electronic conductivity of anodic oxide films on tantalum and niobium could be studied during the growth of the oxide. The behavior of electronically conducting sites could, therefore, be studied dynamically and statically with respect to the growth of the oxide film.

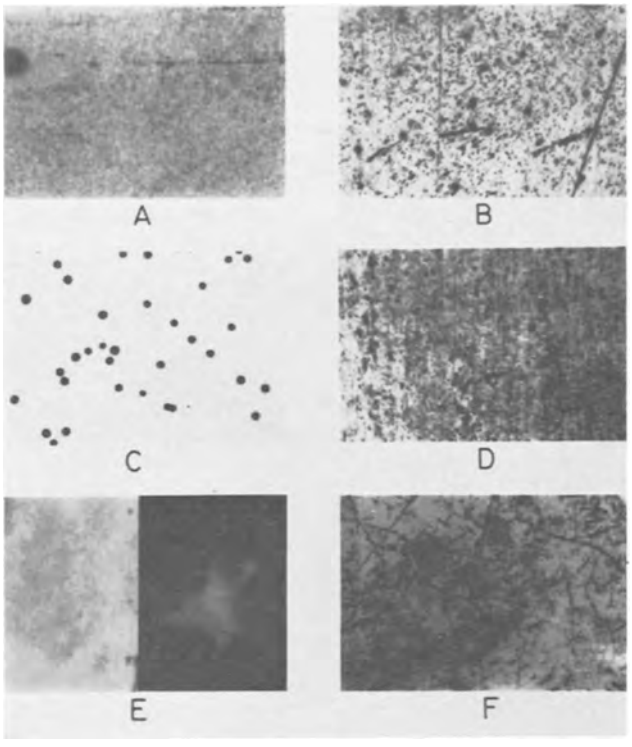

Fig. 4. Anodic prints obtained with titanium, zirconium, and silicon. a, Chemically polished titanium sheet 99.9+% purity. Dynamic print at 1 ma/cm^2 for 60 sec reached 4v, approximately. b. Same foil as above in "as received" condition. Test as in (a). c. Chemically polished zirconium sheet 99.9+% purity. Test as in (a). d. Same foil as in (c), in "as received" condition. Test as in (a). e. Two sides of silicon slice, (left) polished, (right) "rough." Dynamic print at 1 ma/cm^2 reached 25v in about 2 min. f. Mechanically polished and etched silicon slice. Test as in (e). Area of each print approximately 2 cm^2.

Surface contamination of random distribution was found to be the main reason for the high electronic conductivity of "as received" foil. Chemical polishing and vacuum annealing produced specimens essentially free of gross defects.

2. The printing-out technique could be used for the detection of defects in anodic oxide films on aluminum at potentials well below the formation voltage. The corrosion of the oxide film at defective sites was found to be accompanied by electronic currents. No electronic currents were observed with bare aluminum.

3. In the case of titanium, zirconium, and silicon, the printing-out technique could be used for an evaluation of the surface condition even though the anodic oxidation proceeded only to a few volts. A behavior similar to that of aluminum was found for anodic or thermally grown oxide films when tested at a fraction of the formation voltage or its equivalent.

4. The detection sensitivity of the printing medium for uniform electronic currents approached the low microampere/square centimeter range in the case of tantalum and niobium. Point defects could be detected if their current was in the nanoampere range.

In the case of aluminum and the other metals the sensitivity could not be evaluated quantitatively. It was found, however, that in the case of aluminum very small defects could be activated, allowing enough time and a sufficiently large fraction of the formation voltage, such that the electronic current accompanying the corrosion reaction would lead to their detection.

The situation may be similar with some of the other metals and their oxide films, even though this was not studied in any detail.

5. The printing-out method is a quick and reliable method to evaluate the quality of oxide film dielectrics and the surface condition of substrate materials. It is particularly useful in the case of tantalum and niobium where the test is nondestructive. One of the main advantages of the test is that prints can be obtained which record directly the electronic current distribution.

The Electronic Conductivity of Defective Anodic Tantalum Oxide Films

Gerhart P. Klein

Laboratory for Physical Science, P. R. Mallory & Co. Inc., Northwest Industrial Park, Burlington, Massachusetts

ABSTRACT

The conditions under which anodic oxide films on tantalum showed electronic conductivity were studied using an electrochemical printing-out technique with starch-iodide as the redox indicator. The sensitivity for the detection of electronic charge was approximately 1 millicoulomb/cm^2. The effect of alloying (contamination), thermal oxidation, plastic deformation, and surface topography were investigated with regard to their contribution to the electronic conductivity of anodic oxide films on mechanically treated ("rough") tantalum surfaces. It was concluded that impurities alone were responsible for the electronic conductivity even in cases where supposedly clean tantalum had been abraded with tantalum. Roughness by itself was not a sufficient condition for electronic conductivity.

The electronic conductivity (e.c.) of anodic oxide films on substrate metals such as tantalum, niobium, aluminum, and other "valve" metals in electrolytic systems and with solid counter electrodes may be made up of two parts: A uniformly distributed part which is due to the electronic conductivity of the bulk oxide, and a nonuniformly distributed one which is localized in heterogeneities in the oxide film. By

heterogeneities we mean deviations in the structure and composition in the widest sense, *i.e.*, factors which disrupt the uniformity of the dielectric. A separation of the two parts of the electronic conductivity (e.c.) is required before an analysis of either part can be attempted successfully.

Heterogeneities in anodic oxide films were considered by several authors to explain abnormal formation behavior, excessive leakage currents, abnormal a-c properties (1, 2), electrolytic rectification (2-4), and luminescence (5). Pores, cracks, microfissures, with or without direct electrolyte contact to the substrate, or highly conducting areas of unspecified nature were discussed to explain these phenomena. A blocking mechanism had to be assumed in order to explain why the active sites could withstand the high field strength present across the film. Oxygen bubbles formed at the base of pores and cracks were discussed by Vermilyea (6) and Young (1), who also suggested the condenser pressure as a possible means of closing microfissures.

Vermilyea (7) published electronmicroscopic studies of flaws which he found to have been caused by a variety of different treatments and conditions.

In a previous paper (8) we described a printing-out technique and showed how it could be applied to the study of the gross electronic conductivity of anodic oxide films on tantalum and niobium. In this paper, we describe its use in the investigation of the conditions under which anodic oxide films on these metals became electronically conducting and its use to study the dynamic changes of the electronic conductivity (e.c.) during film formation and the external factors affecting it.

Previous studies (1, 2, 6) have shown that the electrical properties, especially the e.c. of anodic oxide films formed on "rough" (mechanically treated) surfaces differed greatly from those of films formed on "smooth" (chemically polished) surfaces. Rough surfaces, in general, were produced by abrasion or by rolling as in the case of sheet material in the "as received" condition. Obviously, mechanical surface treatments can have many more effects than just the production of a rough topography of the surface. They can be grouped into four categories: effects of (*i*) contamination; (*ii*) local heating of the surface; (*iii*) plastic deformation of the surface layers; (*iv*) surface topography, that is, roughness in the true sense.

We shall consider each of these factors separately and then apply these results to the problem of the e.c. found with oxide films on mechanically treated surfaces in general.

Experimental Procedures

The anodic printing technique described in an earlier paper (8) was used to study the electronic currents in the oxide films; we refer to that paper for experimental details.

Specimens were cut from Kawecki tantalum sheet 0.01 and 0.002 in. thick which was designated as high reliability, capacitor grade, annealed material of 99.9+% purity. The chemical polishing followed standard procedures, *i.e.*, the specimens were dipped in a mixture of 5 parts H_2SO_4, 2 parts HNO_3, 1.5-2 parts HF (parts per volume of concentrated commercial acids) for 10-20 sec at 40°-50°C, and was followed by a 10-sec dip in concentrated HF to remove the film left from the polishing treatment. Vacuum annealing and alloying of the tantalum sheet was done in a Varian high vacuum resistance heated furnace under pressures of 10^{-6} mm Hg and lower.

Experimental

Contamination: Electronic conductivity of anodic oxide films on alloys of tantalum with iron, nickel, and carbon.—Bulk contamination.—Contamination is known to be responsible for excessive electronic conductivity of anodic oxide films (9, 10). From the large number of possible contaminants, we chose three in order to demonstrate the specific effects of alloying constituents in Ta on the e.c. of anodic oxide films as detectable with the printing technique.

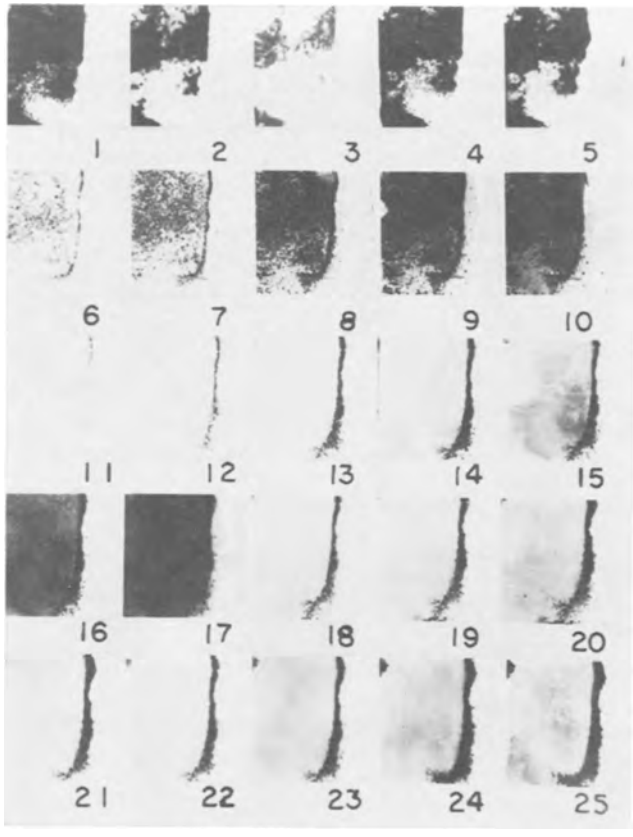

Fig. 1. Anodic prints of Ta alloyed with Fe by heating Ta sheet with Fe powder under the following conditions: Pressure less than 10^{-6} mm Hg, temperature 1400°C, time 2 hr. See Table I.

Table I

Print No.	Current density $\mu a/cm^2$	Time sec	Formation voltage range	Remarks
1	625	70	to 10	
2	250	60	to 13.5	
3	62.5	60	to 10.5	
4	625	70	15 to 20	
5	625	70	20 to 23	After No. 5-1 min dip in conc. HF
6	625	35	to 10	
7	625	50	10 to 20	
8	625	65	20 to 30	
9	625	75	30 to 40	
10	625	85	40 to 50	After No. 10-1 min dip in conc. HF
11	625	40	to 10	
12	625	55	10 to 20	
13	625	55	20 to 30	
14	625	50	30 to 40	
15	625	55	40 to 50	
16	625	60	50 to 60	
17	625	55	60 to 70	After No. 17-1 min dip in conc. HCl
18	625	55	70 to 80	
19	625	55	80 to 90	
20	625	55	90 to 100	
21	625	55	100 to 110	
22	625	55	110 to 120	
23	625	55	120 to 130	
24	625	55	130 to 140	
25	625	60	150 to 160	

The alloys were prepared by heating chemically polished tantalum sheet with thin layers of iron, nickel, and carbon powder at 10^{-6} mm Hg pressure and 1400°C for 2 hr. Powder was used because it proved the simplest way of producing alloys with a composition gradient at the surface, a condition that gave a qualitative picture of the effects of composition on the e.c.

Tantalum alloyed with iron.—Three series of prints are shown in Fig. 1 obtained from the Ta-Fe alloy speci-

men. The first group of prints was taken without further pretreatment of the specimen, the second and third groups were taken after removal with HF of the oxide films formed in series one and two, respectively. The anodic oxidation to 10v (Print 1.1) was accompanied by high electronic current. Prints 1.2 and 1.3 were taken at one fifth and one tenth of the initial current density and give more details of the conducting area due to the lower intensity of the prints. Prints 1.4 and 1.5, again taken with full current density, show that the rate of voltage increase at constant current slowed down progressively and approached almost zero above 20v. Treatments in conc. HCl, dilute HNO_3, and aqua regia either prior to taking the first print or between prints did not affect the electronic conductivity as reflected in the following prints. The initial oxide film was removed with conc. HF before the second series of prints was taken. This treatment also dissolved some of the Ta-Fe alloy as could be seen from the gas evolution and the formation of pits at sites where the Fe powder particles had alloyed with the Ta. Prints 1.6 through 1.10 show the electronic conductivity of the film formed after the HF treatment. The formation proceeded rapidly at first but again slowed down after the e.c. developed with increasing film thickness. The formation time through 10v increased from 50 sec in the first interval to 85 sec in the fifth interval. At the end of the first series formation through 3v had required 70 sec.

The HF treatment was repeated as before and another series of 10v interval prints was taken. Again, the e.c. built up gradually, even though much slower than before (except for a narrow area at the right-hand side which gave prints rather like those in the second series). Even print 1.17 with the strongest blackening required only 55 sec for a formation through 10v. The specimen was dipped in conc. HCl after print 1.17 and then printing was continued. Print 1.18 no longer showed the blackening of the background while the marks at the right-hand side were not affected by HCl.

Tantalum alloyed with nickel.—The prints taken of a Ta-Ni alloy specimen are shown in Fig. 2. In contrast to the Ta-Fe alloys, the e.c. was low initially so that film formation proceeded smoothly to 30v with only little increase in the formation time for a 10v interval. Upon further oxidation, the e.c. increased rapidly which is reflected both in the more intense blackening of the prints and the increase in time to cover a 10v formation interval. Dipping the specimen in aqua regia for 1 min after print 2.5 strongly reduced the e.c. in the following formation interval. The e.c. increased rapidly after the aqua regia dip which was repeated after print 2.7 with the same result: The first print after the dip showed very little blackening while the following one was again extremely dark, it required 100 sec for the 10v interval formation. A static print at 45v was clear.

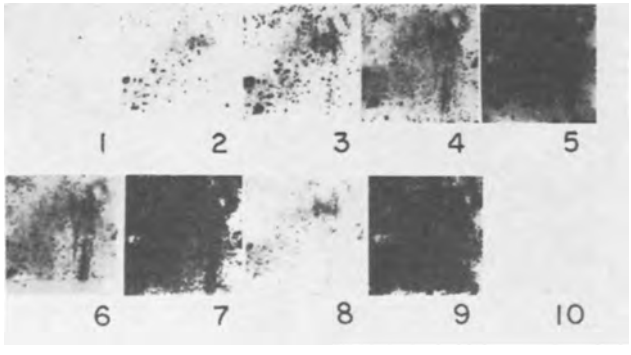

Fig. 2. Anodic prints of Ta alloyed with Ni by heating Ta sheet with Ni powder under the following conditions: Pressure lower than 10^{-6} mm Hg, temperature 1400°C, time 2 hr. See Table II.

Table II

Print No.	Current density, $\mu a/cm^2$	Time, sec	Formation voltage range	Remarks
1	625	45	to 10	
2	625	55	10 to 20	
3	625	60	20 to 30	
4	625	55	30 to 40	
5	625	75	40 to 50	After No. 5-1 min dip in aqua regia
6	625	75	50 to 60	
7	625	90	60 to 70	After No. 7-1 min dip in aqua regia
8	625	50	70 to 80	
9	625	100	80 to 90	
10	—	60	45	Constant voltage

Tantalum alloyed with carbon.—The prints obtained from tantalum foil containing tantalum carbide are shown in Fig. 3. Prints 3.1-3.10 were obtained with a specimen containing an area of low and uniform concentration while the concentration in the following specimen, prints 3.11-3.20, was high and nonuniform. The behavior of the e.c. with film formation differed greatly from that observed with alloys of tantalum with iron and nickel. The initial one or two 10v inter-

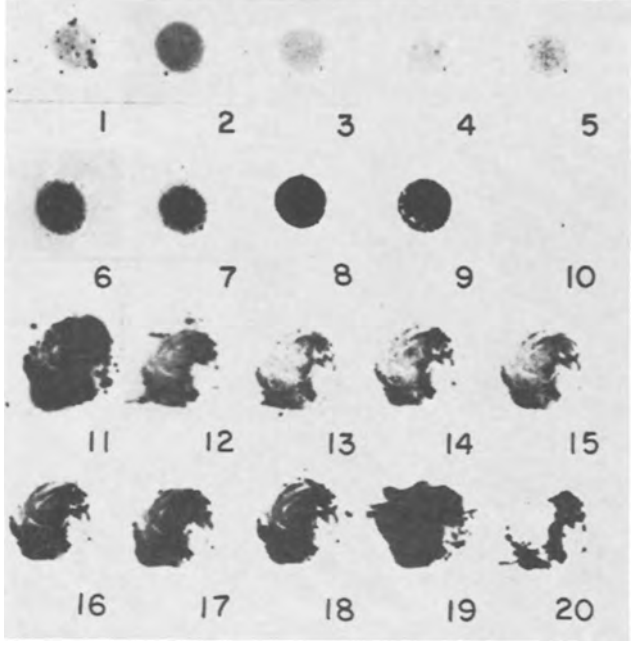

Fig. 3. Anodic prints of Ta alloyed with C by heating Ta sheet with thin layer of graphite under the following conditions: Pressure lower than 10^{-6} mm Hg. temperature 1400°C, time 2 hr. Series A (No. 1-10): low concentration of Ta_2C; Series B (No. 11-20): higher concentration of Ta_2C. See Table III.

Table III

Print No.	Current density, $\mu a/cm^2$	Time, sec	Formation voltage range	Remarks
1	625	50	to 10	Series A—low conc. of Ta_2C
2	625	75	10 to 20	
3	625	75	20 to 30	
4	625	70	30 to 40	
5	625	72	40 to 50	
6	625	80	70 to 80	
7	625	80	90 to 100	
8	625	80	100 to 110	
9	625	75	120 to 130	
10	—	60	50	Const. voltage
11	625	55	to 10	Series B—higher conc. of Ta_2C
12	625	55	10 to 20	
13	625	53	20 to 30	
14	625	55	30 to 40	
15	625	55	40 to 50	
16	625	60	70 to 80	
17	625	45	90 to 100

20	—	60	20	Const. voltage

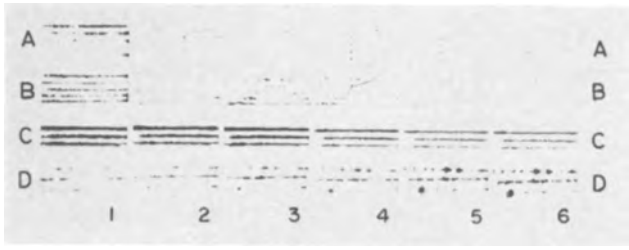

Fig. 4. Anodic prints of Ta sheet scratched with: a. Ta; b. Ni; c. C; d. Fe. See Table IV.

Table IV

Print No.	Current density, $\mu a/cm^2$	Time, sec	Formation voltage range	Remarks
1	125	30	to 2.6	a. Ta
2	625	60	20 to 30	b. Ni
3	625	65	40 to 50	c. C
4	625	70	70 to 80	d. Fe
5	625	65	110 to 120	
6	625	65	130 to 140	

val prints revealed higher e.c. compared with the following ones obtained during formation from 20 through 80v. Above 80v the e.c. started to increase and became extremely high above 120v. Constant voltage prints taken at fractions of the formation voltage after this activation had taken place showed different results for the two specimens with low and high carbide content. The specimen with the lower concentration still exhibited the rapid decrease in the e.c. with field observed previously with Fe and Ni alloys of Ta. The areas with high concentration of carbide were active regardless of the voltage applied. The resistance in these areas was rather low and apparently ohmic.

Surface contamination.—Electronic conductivity in scratches can be seen in Fig. 4 which gives prints taken of a specimen of chemically polished Ta sheet that was scratched with Ta, Ni, Fe, and C. The Ta scratches were taken as the basis for comparison. The first print, taken at low current density with a formation voltage still below 2v gives the initial distribution of the e.c. along the scratches. Subsequent prints were taken in 10v intervals at the higher current density of 625, $\mu a/cm^2$. Very high current density was required to overcome the initial range of high e.c. always observed with mechanically treated specimens. The Ta scratch gave only a few distinct sites of e.c., while the other scratches were highly conducting with C scratches being dominant. The e.c. of the C and Ni scratches decreased with increasing formation voltage while the e.c. in the Fe scratch area increased strongly. The Ta line, after being almost invisible in intermediate voltage ranges, became more uniform and more pronounced toward higher formation voltages.

Tantalum scratches on Ta sheet that was annealed for 8 hr at 2100°C gave very low nonuniform e.c. on the first 10v print, no e.c. between 10 and 120v, and very faint uniform e.c. above 120v. Less pure material showed more of the discontinuous e.c. along the scratches.

Thermal oxidation of tantalum.—Mechanical surface treatments may lead to local temperature increases and the formation of additional thermal oxide beyond that always present on Ta. By studying specimens of Ta foil which were heated in air we attempted to evaluate the effect of pre-existing thermal oxide in the e.c. of subsequently formed anodic oxide films.

The heating of tantalum in air leads to the formation of amorphous and crystalline oxides. Amorphous oxide is formed initially at temperatures below 350°C, longer times and higher temperatures favor the formation of crystalline oxide (11).

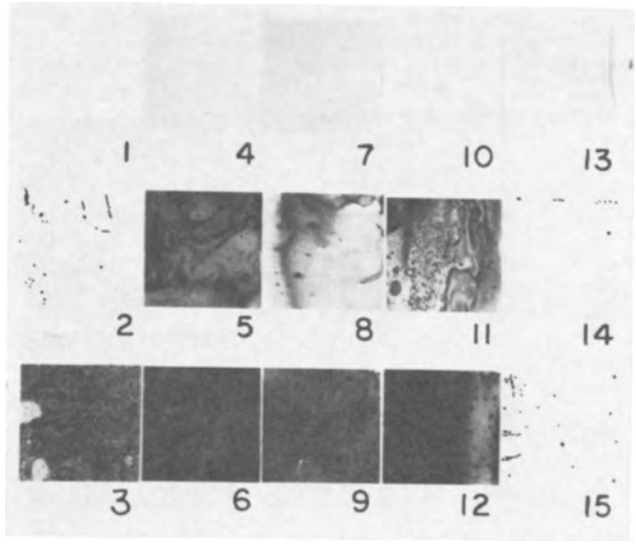

Fig. 5. Anodic prints of Ta sheet given various pretreatments and oxidized thermally in air. See Table V.

Table V

Print No.	Pretreatment	Thermal oxidation	Printing conditions
1	v.a	none	60 sec; 1 ma/cm^2
2	v.a.	500°C; 5 min	60 sec; 1 ma/cm^2
